ABOUT COVER		Ji RL, Xia SH, Di Y, Xu W. Mechanism and dose-effect of Ginkgolide B on severe acute pancreatitis of rats. World J Gastroenterol 2011; 17(17): 2241-2247 http://www.wjgnet.com/1007-9327/full/v17/i17/.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

The intestinal epithelial cells (IECs) form a selective permeability barrier separating luminal content from underlying tissues. Upon injury, the intestinal epithelium undergoes a wound healing process. Intestinal wound healing is dependent on the balance of three cellular events; restitution, proliferation, and differentiation of epithelial cells adjacent to the wounded area. Previous studies have shown that various regulatory peptides, including growth factors and cytokines, modulate intestinal epithelial wound healing. Recent studies have revealed that novel factors, which include toll-like receptors (TLRs), regulatory peptides, particular dietary factors, and some gastroprotective agents, also modulate intestinal epithelial wound repair. Among these factors, the activation of TLRs by commensal bacteria is suggested to play an essential role in the maintenance of gut homeostasis. Recent studies suggest that mutations and dysregulation of TLRs could be major contributing factors in the predisposition and perpetuation of inflammatory bowel disease. Additionally, studies have shown that specific signaling pathways are involved in IEC wound repair. In this review, we summarize the function of IECs, the process of intestinal epithelial wound healing, and the functions and mechanisms of the various factors that contribute to gut homeostasis and intestinal epithelial wound healing.

INTRODUCTION

The surface of the gastrointestinal tract is covered with epithelial cells that function under physiological conditions as a barrier preventing undesirable luminal antigens from entering the body[1]. Upon injury, the intestinal epithelium undergoes a wound healing process. Intestinal wound healing is dependent on the precise balance of migration, proliferation, and differentiation of the epithelial cells adjacent to the wounded area[2]. Previous studies have shown that various regulatory peptides, including growth factors and cytokines, modulate intestinal epithelial wound healing[3]. Recent studies have revealed that novel factors, which include toll-like receptors (TLRs)[4], regulatory peptides[5], particular dietary factors[6,7], and some gastroprotective agents[8-10], also modulate intestinal epithelial wound repair. In addition, it has been shown that the activation of specific signaling pathways is involved in intestinal epithelial wound healing[11,12].

Ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory intestinal disorders and known as

inflammatory bowel disease (IBD). Although an etiology of both diseases remains unknown, it is suggested that disruption of the intestinal barrier function and repeated intestinal epithelial damage are key features of IBD, as well as other intestinal disorders[1,3]. In this context, it is suggested that the identification of the specific factors that improve wound healing of the intestinal epithelium might contribute to therapeutic strategies in IBD, and many studies using animal colitis models and intestinal epithelial cell (IEC) lines have been conducted.

We summarize the function of intestinal epithelium, the process of intestinal epithelial wound healing, and the functions and mechanisms of the various factors that contribute to intestinal epithelial wound healing and gut homeostasis. We also discuss the association of some of these factors with IBD.

BARRIER FUNCTION OF INTESTINAL EPITHELIAL CELLS

The intestinal epithelial cells (IECs) form a selective permeability barrier separating luminal content from underlying tissues[1,13]. The gastrointestinal epithelial lining consists of a monolayer of columnar cells[13]. This monolayer of IECs is constantly moving at a speed of 5-10 μm/h[14] and is renewed every 2-5 d. The maintenance of this barrier is critical for normal growth, development, and disease prevention[15]. Normally, IECs function as a barrier that prevents undesirable solutes, microorganisms, viruses, and luminal antigens from entering the body[1,16]. Several elements that participate in the barrier function include the epithelial cells themselves along with tight junctions, adherens junctions, and luminal secretions such as mucus or unstirred layers on the apical aspects of the epithelium[1].

Tight junctions function as semi-permeable gates that regulate the passive movement of luminal fluid and solutes through the paracellular pathway, and limit passive diffusion of proteins and lipids between the outer leaflet of the apical and basolateral plasma membrane domains[1,17]. Subjacent to tight junctions, adherens junctions are important in regulating intercellular adhesion[1]. Both tight junctions and adherens junctions are positioned in the apical end of the lateral plasma membrane, and are intimately linked in their regulation and function. Thus, the tight junctions and adherens junctions are collectively referred to as the apical junctional complex (AJC)[1,13,17]. Major transmembrane proteins in the AJC include occludin, claudins, junctional adhesion molecules (JAMs), coxsackie adenovirus receptor (CAR), and E-cadherin[1]. Subjacent to the AJC are spot-like intercellular junctions referred to as desmosomes; the function of which in IECs is poorly understood[13].

Despite the barrier function of IECs, this barrier has to allow some non-pathological gut-derived bacteria access to the immune system, thereby promoting maturation of the immune system and evolution of immune tolerance[1]. As is described later, recent studies have demonstrated that the activation of TLRs by commensal bacteria plays an essential role in inhibiting inflammatory responses and maintaining colonic homeostasis[18].

PROCESS OF WOUND HEALING OF INTESTINAL EPITHELIAL CELLS

The intestinal epithelium can be injured by toxic luminal substances, normal digestion, inflammation, interactions with microbes, oxidative stress, and pharmaceuticals, despite its barrier function[19,20]. After injury, the intestinal epithelium undergoes a wound healing process. Intestinal wound healing is dependent on the precise balance of migration, proliferation, and differentiation of the epithelial cells adjacent to the wounded area[2]. First, epithelial cells surrounding the wound lose their columnar polarity, take on a flattened morphology, and rapidly migrate into the denuded area to restore barrier integrity. This process has been termed "epithelial restitution"[3,15,21]. Restitution starts within minutes to hours of injury and is independent of proliferation[3,21]. Then, proliferation of the mucosal epithelium to increase the pool of enterocytes available to resurface the defect generally begins hours or days after the injury[21]. Finally, maturation and differentiation of epithelial cells is needed to maintain the mucosal barrier function[3]. Rat IECs (IEC-6) at 24 h after wound formation are shown in Figure 1A. Most of the epithelial cells found in the wounded area across the wound border are thought to have migrated in the process of restitution. The process of repair of IEC-6 cells wounded by mechanical cell denudation is shown in Figure 1B. These wound assays were performed in our laboratory.

During the restitution of IECs, extensive reorganization of the actin cytoskeleton is necessary[22]. The organization and remodeling of the actin cytoskeleton is suggested to be controlled by the Rho family of small GTPases, which includes Rho, Rac and Cdc42[23]. These proteins have been implicated in the formation of stress fibers, lamellipodia (cytoskeletal protein actin projection on the mobile edge of the cell), and filopodia (slender cytoplasmic projections, similar to lamellipodia, which extend from the leading edge of migrating cells)[23]. In detail, Rho regulates stress fibers and focal adhesion assembly; Rac regulates the formation of lamellipodia protrusions and membrane ruffles; and Cdc42 triggers filopodial extensions at the cell periphery[24,25]. The wound margin of IEC-6 cells is shown in Figure 1C. Lamellipodia- and filopodia-like epithelial cells are found at the leading edge of the wounded IEC-6 cells (Figure 1C). Other investigations regarding the mechanism of cell migration have also been reported[26-28].

Chemokines can be subdivided into distinct inflammatory or homeostatic subsets, with the latter being minimally regulated by pro-inflammatory cytokine stimulation[29]. It has been shown in leukocytes that Rho-GTPase regulates homeostatic chemokine receptor CXCR4-mediated chemotaxis or metastasis to the sites of cognate

Figure 1 Wounded rat intestinal epithelial cell-6 cells. A: Confluent monolayers of intestinal epithelial cell (IEC)-6 cells were wounded with a razor blade. ligand CXCL12 production[30]. Moyer *et al*[2] have demonstrated that CXCL12 increases Rho-GTP and F-actin localization to the leading edge of wounded IEC-6 and T84 monolayers. Since Rho-GTP is known to be required for membrane protrusions in intestinal cell lines[28], it has been postulated that CXCR4-mediated activation and localization of Rho at the leading edge of restitutive epithelial cells may facilitate the formation of lamellae that are required for wound healing[2]. It has also been suggested that CXCR4 and CXCL12 function as an autocrine and paracrine mucosal signaling network that regulates the competency of the epithelial barrier to withstand injury and mediate repair following damage[2].

Defensins are highly conserved key molecules that participate in host defense through the direct killing of microbes[31]. Like the homeostatic chemokine receptor CXCR4, the chemokine receptor CCR6 is expressed by immature dendritic cells and circulating T cells, which directs their trafficking to sites of inflammation following binding by the chemokine ligand CCL20[19,32]. Vongsa *et al*[19] have demonstrated that human β-defensins and CCL20 stimulated accumulation of F-actin, phosphorylation of the myosin light chain and RhoA, and restitutive migration of IEC-6 cells. These findings suggest that chemokines and β-defensins are protective host defense molecules that function not only to recruit immune cells and kill microbes, but also to increase the efficiency of wound healing in the gut. Annexin 2 is a calcium-dependent phospholipid-binding protein that also plays a role in regulating the actin cytoskeleton, and has been implicated in cell migration[33,34]. It has been shown that annexin 2 regulates IEC migration and wound closure through Rho-dependent signaling pathways and related actin cytoskeletal remodeling[33]. We have summarized various

Table 1 Various factors promoting or inhibiting wound healing of intestinal epithelium and mucosa

Categories	Factors	Promoting effect	Inhibitory effect	No effect	Models

COX: Cyclooxygenase; TGF: Transforming growth factor; EGF: Epidermal growth factor; HB-EGF: Heparin-binding epidermal growth factor; HGF: Hepatocyte growth factor; FGF: Fibroblast growth factor; KGF: Keratinocyte growth factor; IGF: Insulin-like growth factor; IL: Interleukin; IFN: Interferon; PDGF: Platelet-derived growth factor; TLR: Toll-like receptor; HIF: Hypoxia-inducible factor; GM-CSF: Granulocyte-macrophage colony stimulating factor; TNF: Tumor necrosis factor.

factors that can have specific effects on IEC or intestinal mucosal wound healing in Table 1.

REGULATORY PEPTIDES AND SIGNALING PATHWAYS IN INTESTINAL WOUND HEALING

Previous studies have shown that various growth factors [including transforming growth factor (TGF)-α and TGF-β, epidermal growth factor (EGF), hepatocyte growth factor (HGF), fibroblast growth factor (FGF), keratinocyte growth factor (KGF), insulin-like growth factor (IGF)-Ⅰ and IGF-Ⅱ], the cytokine interleukin (IL)-1β and IL-2, and trefoil peptides enhance restitution or proliferation of IECs[3,21,35-42]. In contrast, platelet-derived growth factor (PDGF), IL-6, and tumor necrosis factor (TNF)-α have no effect on cell migration[21]. With regard to interferon (IFN)-γ, a previous study has shown that IFN-γ enhanced epithelial cell restitution by 3.8-fold[21]. However, a recent study has shown that IFN-γ inhibits enterocyte migration by preventing inter-enterocyte gap junction communication[5]. Among the regulatory peptides, TGF-β is known to be a central factor that intrinsically contributes to the restitution of wounded

IECs, although it inhibits IEC proliferation[21]. It is noteworthy that cytokines (IL-1β, IL-2), EGF, FGF, HGF and TGF-α promote epithelial cell restitution through enhanced production of bioactive TGF-β, namely, the TGF-β-dependent pathway[21,35,36,41]. On the other hand, it has been shown that both trefoil peptides, which are secreted onto the surface of the gastrointestinal tract, and galectin-2 and -4, which ameliorate colitis in several models of intestinal inflammation, promote IEC restitution through a TGF-β independent pathway[42,43]. In contrast, TGF-α mediates its stimulatory effects on the proliferation and restitution of IECs through different mechanisms; as described above, it enhances IEC restitution through a TGF-β-dependent pathway but promotes IEC proliferation through the activation of extracellular signal-regulated kinase (ERK)1/ERK2 mitogen-activated protein kinase (MAPK)[44].

It has been shown that the activation of specific signaling pathways is involved in intestinal epithelial wound repair. El-Assal *et al*[11] have demonstrated that heparin-binding epidermal growth factor-like growth factor (HB-EGF) enhances restitution of the intestine *in vivo* and *in vitro* in a phosphatidylinositol 3-kinase (PI3K)/Akt- and MAPK/ERK kinase (MEK)/ERK1/2-dependent fashion. Using mouse epithelial cell lines, Dise *et al*[15] have

shown that the PI3K and Src signaling cascades cooperate with Rac and promote IEC migration in response to EGF. Other studies have shown that the activation of the ERK1/2 MAPK or PI3/Akt pathway plays an important role in the regulation of intestinal epithelial proliferation, survival, and wound healing[12,45-47]. Recent studies have suggested that nuclear factor (NF)-κB has not only proinflammatory but also has a tissue-protective function in IECs[48]. In addition, Pickert *et al*[49] have reported using conditional knockout mice with an IEC-specific deletion of signal transducer and activator of transcription (STAT) 3 activity that intestinal epithelial STAT3 activation regulates immune homeostasis in the gut by promoting IL-22 dependent mucosal wound healing. Trem2 is a cell surface receptor that is specifically induced in macrophages by IL-4/IL-13. Seno *et al*[50] have shown that Trem2 signaling promotes efficient wound healing of colonic mucosal injuries by inhibiting cytokines that can enhance M1 macrophage activation, and by promoting cytokines that can promote M2 macrophage activation.

Previous studies have shown that prostaglandin (PG) E2 plays a major role in the regeneration of the epithelial crypts and in the prevention of decreased epithelial cells proliferation after radiation- or dextran sodium sulfate (DSS)-induced intestinal injury[51,52]. Mucosal PGs are synthesized from arachidonate by cyclooxygenase (COX)-1 or COX-2[52]. Thus, it has also been shown that COX-1 and COX-2 share a crucial role in the defense of the intestinal mucosa[53,54]. In this context, Brun *et al*[55] have shown that the neuropeptide neurotensin (NT) significantly increases COX-2 mRNA levels and stimulates PGE2 release in the colonic cell line HT29. They also have shown that NT significantly enhances the migration of HT-29 cells into the denuded area of a wound model. It has also been shown that PGE2 reduces radiation-induced apoptosis in the intestine through transactivation of the EGFR, enhanced activation of Akt, and reduced Bax translocation from the cytoplasm to the mitochondria[56].

Epithelial-mesenchymal interactions are necessary for proper gut morphogenesis[57]. These interactions also play important roles in intestinal epithelial wound healing. Epimorphin is expressed on the surface of mesenchymal cells in various organs, including intestinal mucosa, and is suggested to play a key role in the morphogenesis of epithelial cells[58,59]. We found that epimorphin also has a novel function to promote restitution of IECs under oxidative stress conditions through the activation of the EGF receptor and MEK/ERK, PI3K/Akt signals[60]. HGF, FGF and KGF are also secreted by mesenchymal cells[57]. Göke *et al*[61] have shown that fibroblasts, which are derived from primitive mesenchyme, promote intestinal cell proliferation in addition to affecting secretory responses, differentiation, and morphogenesis, and that this function is predominantly mediated by the paracrine action of HGF.

Recent studies using experimental colitis models have shown that the Muc3 mucin cysteine-rich domain[62], hypoxia-inducible factor (HIF)[63], and granulocyte-macrophage colony stimulating factor (GM-CSF)[64] improve wound healing of the colonic mucosa. We summarize the various factors and signaling pathways that contribute to intestinal epithelial and mucosal wound healing in Figure 2.

DIETARY FACTORS AND INTESTINAL WOUND HEALING

Several studies have shown that enteral nutrition with an elemental diet is efficacious in the treatment of CD, especially for maintaining clinical remission or reducing clinical and endoscopic recurrence after resection[65-67]. Although some of this effectiveness may be due to the low antigenic load, low fat content, and modulation of the commensal bacterial flow, the precise mechanisms remain unclear. In this context, the effectiveness of the constituent amino acids of the elemental diet for intestinal epithelial and mucosal wound healing has been reported.

Glutamine, the most abundant free amino acid in the bloodstream, is a non-essential amino acid that is essential for gut homeostasis and is an essential respiratory substrate for cells in the small intestinal mucosa[68,69]. Enteral glutamine is thought to stimulate intestinal mucosal protein synthesis and protect against apoptosis[68]. Larson *et al*[68] have shown that glutamine supplementation stimulates IEC growth and prevents apoptosis, and that activation of ERK is an important contributor to glutamine-mediated intestinal cell survival. Sukhotnik *et al*[6] have evaluated the preventive effects of oral glutamine supplementation in an intestinal ischemia-reperfusion injury in a rat. It was found that pretreatment with oral glutamine prevents mucosal injury and improves intestinal recovery following ischemia-reperfusion injury through the stimulation of cell proliferation rather than the inhibition of cell apoptosis.

On the other hand, Andou *et al*[7] have assessed the role of histidine, an essential amino acid, in controlling colitis by using an IL-10-deficient cell transfer model. In this study, it was shown that dietary histidine reduced histological damage of the colon and TNF-α mRNA expression by inhibiting NF-κB activation, following the downregulation of pro-inflammatory cytokine production by macrophages. Son *et al*[70] also have reported that histidine significantly inhibits both hydrogen peroxide- and TNF-α-induced IL-8 secretion and mRNA expression in intestinal epithelial-like cell lines. This study has also shown that histidine abolishes the NF-κB-dependent activation of the IL-8 promoter induced by TNF-α, suggesting that histidine has the potential to attenuate intestinal inflammation. These reports investigating the function of glutamine and histidine have suggested the efficacy of an elemental diet for improvement of intestinal mucosal wound healing in patients with CD.

Previous studies have suggested a link between vitamin D deficiency and IBD risk[71]. Kong *et al*[72] have investigated the role of the vitamin D receptor (VDR) in mucosal barrier homeostasis by using the DSS-induced colitis model. In this study VDR$^{+/+}$ mice were mostly resistant

Figure 2 Various factors and signaling pathways contributing to the process of wound healing of intestinal epithelial cells and intestinal mucosa. IEC: Intestinal epithelial cell; TGF: Transforming growth factor; EGF: Epidermal growth factor; HGF: Hepatocyte growth factor; FGF: Fibroblast growth factor; KGF: Keratinocyte growth factor; IGF: Insulin-like growth factor; HB-EGF: Heparin-binding epidermal growth factor; IL: Interleukin; COX: Cyclooxygenase; TLR: Toll-like receptor; HIF: Hypoxia-inducible factor; GM-CSF: Granulocyte-macrophage colony stimulating factor; ERK: Extracellular signal-regulated kinase; MAPK: Mitogen-activated protein kinase; PI3K: Phosphatidylinositol 3-kinase; NF: Nuclear factor; STAT: Signal transducer and activator of transcription.

to 2.5% DSS, but VDR$^{-/-}$ mice developed severe colitis, leading to death. They also found severe disruption in the epithelial junctions in VDR$^{-/-}$ mice after DSS treatment. In cell cultures, 1,25-dihydroxy-vitamin D$_3$ [1,25(OH)$_2$D$_3$] markedly enhanced tight junctions and stimulated epithelial cell migration *in vitro*. These observations suggest that VDR plays a critical role in mucosal barrier homeostasis by preserving the integrity of junction complexes and the healing capacity of the colonic epithelium.

GASTROPROTECTIVE AGENTS IN INTESTINAL EPITHELIAL WOUND HEALING

Recent studies have shown that some gastroprotective agents, including ecabet sodium (ES), rebamipid, and sucralfate, have therapeutic effects on IBD and other types of colitis[73-76]. Previous studies have shown that rebamipide enema is effective for treatment of experimental DSS-induced colitis in rats[8,77]. Okayama et al[77] have suggested that the protective effect of rebamipide may be attributable to both the radical scavenging action and the increase in the production of mucus in the colon. Watanabe et al[78] have performed wound assays using gastric epithelial cells and have shown that rebamipide

prevents delay of wound repair induced by hydrogen peroxide. On the other hand, Sasaki et al[9] have investigated the therapeutic mechanism of ES for intestinal mucosal injury by using the rat IEC-6 cell line. The investigation clarified that ES prevents the delay of wound repair in IEC-6 cells induced by hydrogen peroxide, probably through the activation of ERK 1/2 MAPK and the induction of COX-2. Takagi et al[79] have shown that intracolonic administration of ES accelerates TNBS-induced ulcer healing *in vivo*. Shindo et al[10] have investigated the therapeutic mechanism of sucralfate for intestinal mucosal injury. It has been demonstrated that sucralfate also prevents the delay of wound repair in IEC-6 cells induced by hydrogen peroxide through the induction of COX-2 and an anti-apoptotic mechanism. The effects of sucralfate may be initiated by the activation of the NF-κB pathway. These studies have suggested the possibility that some gastroprotective agents could be used for the treatment of IBD.

ROLE OF THE INNATE IMMUNE SYSTEM IN COLONIC HOMEOSTASIS AND INTESTINAL WOUND HEALING

The commensal bacteria population is comprised of at

least 400 species, with a load of as many as 10^{12} bacteria per gram of intestinal content[80]. As described previously, IECs are the first line of defense against commensal or pathogenic luminal microflora. Recognition of enteric bacteria is mediated by several mechanisms, the most important of which rely on host receptors specific for conserved bacterial structures not found in the host[81]. The two major host receptors currently recognized in humans are TLRs and the nucleotide-binding oligomerization domain (NOD)-containing proteins[81]. In this context, it is notable that mutations in NOD2, a cytoplasmic innate immune-recognition receptor, are associated with susceptibility to CD[82,83]. TLRs are innate immune-recognition receptors that bind a spectrum of pathogen-associated molecular patterns (PAMPs) present in pathogenic and commensal bacteria and viruses, as well as some endogenous proteins[84-86]. TLR family members were first noted to be expressed by immune cells such as monocytes and dendritic cells[84-86], then, it was shown that IECs also express TLRs[4]. With regard to the association of TLRs with IBD, several studies have shown the alteration of TLR expression and the specific antibody to the TLR ligand in patients with IBD. First, Cario *et al*[87] reported the upregulation of TLR4 in IECs in UC and CD, and the downregulation of TLR3 in CD. A recent study has shown the association between the TLR2 polymorphism R753Q and the severe UC phenotype[88]. Such associations have also been found between the TLR4 polymorphism at Asp299Gly and the development of CD and UC, and the TLR4 polymorphism at Thr399Ile and UC[89,90]. On the other hand, the presence of high titers of flagellin-specific antibodies in the serum of CD patients has been reported[91].

The following *in vivo* and *in vitro* studies have provided evidence that each TLR contributes to intestinal homeostasis and intestinal mucosal repair. TLR2 recognizes lipoproteins derived from a variety of bacteria, peptidoglycan, lipoteichoic acid from many Gram-positive bacteria, and lipopolysaccharide (LPS) from *Leptospira* and *Porphyromonas gingivalis*[4]. Cario *et al*[92] have shown that TLR2 stimulation effectively preserves the tight junction-associated barrier assembly in IECs against stress-induced damage, and suppresses mucosal inflammation and apoptosis of IECs *in vivo*. The same group has shown that TLR2 controls gap junction intercellular communication and commensal-mediated intestinal epithelial wound repair by modulating intestinal epithelial connexin-43[93]. Furthermore, they have shown that TLR2 controls terminal goblet cell differentiation by selectively regulating trefoil factor 3 expression in the intestine and confers anti-apoptotic protection to the intestinal mucosa[94].

TLR3 recognizes double-stranded RNA, which is a molecular pattern associated with viral infection[86]. A recent study has shown that administration of TLR3 ligand polyinosinic acid: cytidylic acid protects against DSS-induced colitis[95]. In contrast, Sato *et al*[96] have performed

wound assays using IEC-6 cells and have shown that TLR3 ligand rotavirus double-stranded RNA induces apoptosis and diminishes wound repair of IECs *in vitro*.

TLR4 recognizes LPS that is an integral component of the outer membranes of Gram-negative bacteria[4]. Using DSS-induced colitis mice, Rakoff-Nahoum *et al*[97] have demonstrated that commensal bacteria are recognized by TLRs (TLR2 and TLR4) under normal steady-state conditions, and that this interaction plays a crucial role in the maintenance of intestinal epithelial homeostasis. They have shown that activation of TLRs by either the TLR2 or TLR4 ligand is critical for the protection against gut injury and associated mortality. This group has also shown that TLR-mediated signaling plays a critical role in intestinal inflammation in the context of deficiency in the anti-inflammatory cytokine IL-10, but not in the context of insufficient activity of regulatory T cells[98]. Another study using a murine colitis model also has shown that TLR4 is important in intestinal response to injury and in limiting bacterial translocation[99]. On the other hand, Cetin *et al*[100] have reported that LPS inhibits IEC-6 cell migration through a RhoA-dependent increase in focal adhesions and enhanced cell adhesiveness.

Flagellin, the primary structural component of bacterial flagella, is recognized by TLR5 present on the basolateral surface of IECs[101]. A recent study has shown that, in salmonella infections, flagellin plays a dominant role in the activation of not only innate immunity but also anti-apoptotic processes in epithelial cells[102]. The same group also has shown that pretreatment of epithelial cells with flagellin can protect cells from a subsequent bacterium-mediated apoptotic challenge through the activation of NF-κB and PI3K/Akt signaling[101]. These studies suggest that the TLR5 ligand flagellin has a fundamental cytoprotective effect in inflammatory stress.

TLR9, an intracellular protein in immune cells, is expressed on the surfaces of IECs, both on the apical and basolateral membrane[18]. TLR9 recognizes CpG motifs, derived from bacterial DNA[4]. Recent studies have demonstrated that TLR-9 signaling in IECs contributes to colonic homeostasis[18,103-105]. Katakura *et al*[103] have shown that TLR9 agonist suppresses the severity of experimental colitis by inducing type I IFN (IFN-α/β). The same group also has shown that administration of probiotics (non-viable irradiated or viable probiotics) ameliorates the severity of DSS-induced colitis[105]. They have suggested that TLR9 signaling is essential in mediating the anti-inflammatory effect of probiotics, and that live microorganisms are not required to attenuate experimental colitis. They have shown that while basolateral TLR9 signaling is fully capable of inducing an NF-κB-mediated pro-inflammatory response, apical TLR9 signaling does not induce an inflammatory response due to a defect in NF-κB activation[18,104]. They have suggested that stimulation of apical TLR9 compromises the inflammatory cascade induced basolaterally by several other TLR ligands, and thus, apical exposure to luminal microbial DNA restrains

intestinal inflammation and supports colonic homeostasis *via* the activation of TLR9.

In conclusion, most of these studies investigating the function of TLRs strongly suggest the possibility that the activation of TLRs by commensal bacteria plays an essential role in maintaining colonic homeostasis and protection of IECs from gut injury. These studies also support the therapeutic efficacy of some antibiotics[106-108] or probiotics[109] in IBD patients. Thus, modulations of host-commensal interactions *via* TLRs might be targeted for optimal therapeutic strategies in IBD.

Abstract

Mallory-Denk Bodies (MDB) are important as investigators, suggesting MDB as an indicator of the histologic severity of chronic hepatitis, causes of which include hepatitis C, primary biliary cirrhosis (PBC), and nonalcoholic fatty liver disease (NAFLD). Matteoni *et al* scored MDB in patients with NAFLD as none, rare and many, and reported that MDB plays a prominent role in this classification scheme in an earlier classification system. In this study, we evaluated 258 patients with chronic hepatitis due to metabolic, autoimmune and viral etiologies. Liver biopsy samples were evaluated with hematoxylin and eosin, periodic acid-Schiff-diastase, Gordon and Sweet's reticulin, Masson's trichrome, and iron stains. Both staging and grading were performed. Additionally, MDB were evaluated and discussed for each disease. We examined patients with nonalcoholic steatohepatitis (NASH; 50 patients), alcoholic hepatitis (10 patients), PBC (50 patients), Wilson disease (WD; 20 patients), hepatitis B (50 patients), hepatitis C (50 patients) and hepatocellular carcinoma (HCC; 30 patients). Frequency of MDB was as follows; NASH: 10 patients with mild in 60% and moderate in 40% and observed in every stage of the disease and frequently seen in zone 3. PBC: 11 patients with mild in 10%, moderate in 70%, and cirrhosis in 20%, and frequently seen in zone 1. WD: 16 patients with moderate and severe in 60% and cirrhosis in 40% and frequently seen in zone 1. Hep B: 3 patients with mild in 66% and severe in 34%. Hep C: 7 patients with mild in 40% and moderate in 60% and observed in every stage. HCC: 3 patients with hep B in 2 patients. We found that there is no relationship between MDB and any form of chronic hepatitis regarding histologic severity such as alcoholic steatohepatitis and NAFLD and variable zone distribution by etiology.

HISTORICAL BACKGROUND OF MALLORY-DENK BODIES IN HEPATOLOGY

Frank Burr Mallory first reported Mallory-Denk Bodies (MDB) in patients with alcoholic cirrhosis in 1911[1]. Then, this pearl of pathology was reported in various hepatic diseases such as the hepatitis B and C virus, Wilson's

disease, chronic cholestatic injuries, nonalcoholic fatty liver disease (NAFLD), drug injuries, focal nodular hyperplasia, and hepatocellular carcinoma (HCC).

THE PATHOGENESIS OF MDB FORMATION IN CHRONIC HEPATITIS: WHAT WE KNOW

MDB are an intracellular deposition of misfolded protein aggregated into ubiquitin (Ub)-rich cytoplasmic inclusions in ballooned hepatocytes[2]. MDB formation, which consists of abnormally phosphorylated, ubiquitinated, and cross-linked keratins and non-keratin components, are not entirely interchangeable since not all ballooned hepatocytes contain MDB. Both ballooning of hepatocytes and MDB are the two hallmarks of ongoing inflammation (Figure 1). To understand the pathogenesis of MDB, we first have to know the development of ballooning of hepatocytes.

Ballooning or swelling of hepatocytes is induced by oxidative stress and its products such as oxyradicals. The swelling of hepatocytes could be explained by water accumulation in the cytoplasm as a response to accumulated stress proteins such as heat shock proteins (HSPs) or fat. HSPs are the precursor of MDB and indicate hepatocytes injury[2,3]. Currently, we do not know exactly whether ballooning are adaptive (physiological, reversible) or degenerative changes (pathological, most likely irreversible) of hepatocytes against the changed environment.

Swelling of hepatocytes represents volume increase (hydration) of the hepatocytes. It occurs against different stressors, particularly oxidative stress. It is reported that mild volume changes (up to 10% increase on the volume of the hepatocytes) without the biochemical evidence of free radicals are physiologic and adaptive. Hepatocyte damage may not be observed. However, high grade swelling (such as at least 30% increase on the volume of the hepatocytes) could be degenerative and can cause hepatocyte apoptosis, necrosis, and even death.

Most of the previous studies came from animal models. A hepatocyte includes two big compartments, namely wet (water) and cellular dry solids (fat, protein, nucleic acids, anions and cations and other solutes) which are in balance. Any intracellular solute (such as fat or abnormal proteins) accumulation into the cytoplasm may cause water movement, and water volume increase within the hepatocyte. This may change hepatocyte membrane transport system activation (such as ion channels) and may increase intracellular metabolism (increase both protein and glycogen synthesis and inhibit both proteolysis and glycogenolysis). The only purpose of these mechanisms is to maintain the functioning of both hepatocytes, and the liver as an organ. The volume ratio between these two compartments should be maintained at the same level under normal conditions and also against stressors.

It is experimentally shown in rats that the initial response of hepatocytes against iron, which is a well-known strong oxidative agent, was the accumulation of increased

Figure 1 Zone 1 distribution of Mallory-Denk Bodies in primary biliary cirrhosis (× 400). This distribution was observed in both early and later stages of primary biliary cirrhosis, such as cirrhosis.

stress proteins, such as HSPs, within the cytoplasm. Increased stress proteins, along with the other elements of the increased metabolic process, cause macromolecular crowding and activate volume regulator mechanisms. To maintain the ratio between wet (water) and increased dry compartments (such as HSPs), volume regulator mechanisms increase the hepatocyte hydration with increasing water content of the cytoplasm (cloudy swelling). The real mission of this regulatory system is to preserve the intracellular environment and hepatocyte functioning. This is an adaptation mechanism of hepatocytes against oxidative stress (up to 10% increase on the volume of the hepatocytes). However, too much increased water within the cytoplasm of hepatocytes may cause degenerative changes and disturbances in both normal hepatocyte morphology and functioning. Then, hepatocyte apoptosis, necrosis and death may occur.

Additionally, we can discuss the toxic fatty liver animal model. Investigators used rats treated with CCl-4, which is a well-known steatogenic oxidant agent. CCl-4 is a cause of high grade hepatocyte swelling. This chemical poison was injected into the rats daily (one injection per day). Then the livers of the rats were examined for three compartments (water, fat, and fat-free dry solids) at the entry, after 1 injection, and after 6 injections. Investigators observed that both fat and water were increased significantly while fat-free dry solids were not changed or only slightly changed. The highest grade increase of water was seen after the sixth injection (25% water increase after 1 injection, and 48% water increase after 6 injections) which was related to the increased hepatocyte hydration. This means that there were many well-established ballooned hepatocytes in the liver of CCl-4 injected rats.

However, these protection mechanisms are not infinite. A strong oxidative stress may cause high amplitude ballooning of hepatocyte due to both increased hydration and dry solids. One of the increased cellular dry solids is stress protein, such as HSPs. HSPs, as examples of misfolded proteins, are the indicators of cellular dysfunction. Under normal conditions, these potentially harmful proteins are targeted by covalent attachment of multi-Ub

Table 1 Analysis of our 258 patients for Mallory-Denk Bodies and staging of the disease *n* (%)

	No. of pts	MDB (+) pts	Staging[1] in pts with MDB	Comment
NASH	50	10 (20)	Mild in 60% and moderate in 40%	MDB observed in every stage of NASH, predominantly in zone 3
Alcoholic (ASH)	10	5 (50)	Mild in 40% and moderate in 60%	MDB observed in every stage, predominantly in zone 3
PBC	50	11 (22)	Mild in 10%, moderate in 70%, and cirrhosis in 20%	Frequently seen in later stages with predominantly in zone 1
WD	20	16 (80)	Moderate and severe in 60% and cirrhosis in 40%	Frequently seen in later stages with predominantly in zone 1
Hep B	48	3 (6)	Mild in 66% and severe in 34%	Mild case with steatosis
Hep C	50	7 (14)	Mild in 40% and moderate in 60%	MDB observed in every stage
HCC	30	3 (10)		Two cases with Hep B
Total	258	55 (21)		

[1]Mild: Stage 1; Moderate: Stage 2-3; Severe: Stage 4, and cirrhosis. MDB: Mallory-Denk Bodies; ASH: Alcoholic steatohepatitis; NASH: Nonalcoholic steatohepatitis; PBC: Primary biliary cirrhosis; WD: Wilson disease; HCC: Hepatocellular carcinoma; pts: Patients.

chains. Then, a protective mechanism, the Ub-proteasome pathway eliminates these products. When this control system fails, under the strong oxidative stress, abnormal cytokeratins (CKs) may become accumulated along with HSPs (70, 90, and 25), Ub, tissue transglutaminase, proteasome subunits, tubulin, and p62. Young, tiny and then well-formed MDB were well established in ballooned hepatocytes. This mechanism has not been fully understood yet. There are two possible ways for this pathway to fail: (1) production of these misfolded proteins exceeding the capacity of this protective system or (2) inhibition of the pathway. Well-established MDB might be a degenerative rather than adaptive response of hepatocytes against stronger stressors. Then, satellite cell activation occurs. Sustained liver injury leads to fibrosis and cirrhosis.

In conclusion, there is no contrast of MDB pathogenesis in hep B, hep C, PBC, NAFLD and the others.

DIFFERENCES IN THE FREQUENCY AND ZONAL DISTRIBUTION OF MDB IN PATIENTS WITH CHRONIC HEPATITIS

MDB are typical features of alcoholic steatohepatitis (ASH) and NAFLD. NAFLD exhibits slightly less prominent MDB than ASH[4]. MDBs can also be detected after intestinal bypass surgery for morbid obesity, in chronic cholestasis, PBS, Wilson disease (WD) and other types of copper toxicosis, various metabolic disturbances, and hepatocellular neoplasms. In idiopathic copper toxicosis and HCC, MDBs may coincide with another type of cytoplasmic inclusions.

MDB is not present in the majority of individuals with hep C, or even in hep C patients with NAFLD (the presence of MDB in patients with hep C is 7.1%). However, hepatocyte ballooning with MDB is much more likely to lead to advanced fibrosis in these patients.

MDB in periportal liver cells have been reported in patients with Wilson's disease. MDBs are found in mice by feeding them the hepatotoxic substances griseofulvin and 3,5-diethoxycarbonyl- 1,4-dihydrocollidine.

Figure 2 Mallory-Denk Bodies, located perinuclear, has been shown as a larger picture in a patient with primary biliary cirrhosis (× 1000).

MDBs have not been observed in acute cholestasis, acute viral hepatitis, acute toxic or drug-induced liver diseases.

OUR RESULTS: FREQUENCY OF MDB IN DIFFERENT FORMS OF CHRONIC HEPATITIC DISEASES

Two hundred and fifty-eight patients with hepatitis have been examined at our pathology department. Outpatient percutaneous percussion guided needle liver biopsies were performed using Menghini soft tissue biopsy needles (1.4 or 1.6 mm, adult size, Hepafix, Braun, Melsungen, Germany). Liver biopsy samples were evaluated with hematoxylin and eosin, periodic acid-Schiff-diastase, Gordon and Sweet's reticulin, Masson's trichrome, and iron stains by a single pathologist, unaware of the clinical and biochemical data. We examined patients with nonalcoholic steatohepatitis (NASH; 50 patients), alcoholic hepatitis (10 patients), primary biliary cirrhosis (PBC; 50 patients), WD (20 patients), hepatitis B (50 patients) and hepatitis C (50 patients), and HCC (30 patients) for grading and staging and MDB. Results were shown at Table 1. Furthermore, the characteristics of MDB in each disease have been

Figure 3 Mallory-Denk Bodies, located both perinuclear and intracytoplasmic, was observed in zone 1 in early stages of Wilson disease, but in every zone at the later stages, such as cirrhosis (× 400, 1000, respectively). Hydrophobic degeneration was more exaggerated. The diameter of Mallory-Denk Bodies was not homogenous in patients with Wilson disease.

Figure 4 Perinuclear location of Mallory-Denk Bodies in patients with hepatocellular carcinoma depends on the cause (× 1000). In this case, hepatitis B is responsible from Mallory-Denk Bodies.

Figure 5 Tiny and uniform Mallory-Denk Bodies was seen in patients with nonalcoholic steatohepatitis (× 1000).

shown in Figures 1-5. MDB showed zone 1 distribution in PBC and its distribution, located perinuclear, observed in both early and later stages, such as cirrhosis. MDB, located both perinuclear and intracytoplasmic, was observed in zone 1 in early stages of WD, but in every zone at the later stages, such as cirrhosis. Hydrophobic degeneration was more exaggerated in WD and the diameter of MDB was not homogenous in patients with WD. Perinuclear localized MDB in patients with HCC depends on hepatitis B, which is responsible for MDB. Lastly, tiny and uniform distribution of MDB was seen in patients with NASH. Although patients with PBC and WD showed MDB frequently in later stages, we found that there is no relationship between MDB and any form of chronic hepatitis regarding histologic severity, such as in ASH and NAFLD. Moreover, zone distribution of MDB is very variable by etiology, such as zone 1 in PBC and WD as zone 3 in ASH and NAFLD. Of the 3 hepatitis B patients with MDB, 2 showed steatosis with mild fibrosis. Most probably, MDB in these cases was caused by steatosis due to metabolic reasons.

MDB IN NAFLD

In an earlier classification system, Matteoni *et al*[5] scored MDB in patients with NAFLD as none, rare and many. MDB plays a prominent role in this classification scheme as well as follows; Type 1: Fatty liver alone, Type 2: Fat and inflammation, Type 3: Fat and ballooned hepatocytes, and Type 4: Fat and ballooned hepatocytes and either MDB or fibrosis.

The Kleiner system is widely accepted and, as such, has superseded the previous classification system (Matteoni *et al*'s system)[6]. Although this system includes several parameters, there are four main histologic features as steatosis, inflammatory infiltration, ballooning degeneration of hepatocytes, and fibrosis are more important than others. Also, significantly, presence or otherwise of MDB is of much less consequence in the Kleiner system.

Frequency of MDB is very variable, reported from 7% to 90% in adult patients with NAFLD[7-18]. Furthermore, it was not demonstrated or uncommon in pediatric patients with NAFLD[17,18].

DIAGNOSTIC CRITERIA OF MDB

Technical difficulties on the showing of MDB may be the most important reason for the differences. To better understand this issue and its contradictions, we must be aware of some basic knowledge about MDB. MDB are intracellular depositions in ballooned hepatocytes which reflects a peculiar morphological manifestation of liver cell injury[19,20].

Figure 6 Shows development of Mallory-Denk Bodies in ballooned hepatocytes. MDB: Mallory-Denk Bodies; HSPs: Heat shock proteins; HCC: Hepatocellular carcinoma.

Three stages are demonstrated according to the development rank of MDB in ballooned hepatocytes: (1) misfolded proteins such as CKs, Ub, protein p62, and high and low molecular weight HSPs; (2) pre-MDB (young/tiny form) positive ballooned hepatocytes; and (3) mature or well-established MDB positive ballooned hepatocytes.

Misfolded proteins present the earliest stage of MDB and induced in response to a variety of cellular injuries. They are indicators of cellular dysfunction. Normally, these potentially harmful proteins are targeted by covalent attachment of multi-Ub chains. Then, a protective mechanism, which is the Ub-proteasome pathway, eliminates these products. When this control system fails, the CKs become accumulated in MDB along with HSPs, Ub, tissue transglutaminase, and p62. Then, mature MDB in ballooned hepatocytes is well established. There are two possible ways for this pathway to fail: (1) production of these misfolded proteins exceeding the capacity of this protective system (overexpression); and (2) inhibition of this pathway.

Pathogenesis of MDB is thought to include lipid peroxidation, oxidative stress, free radicals, bile retention, defective protein synthesis and copper accumulation (Figure 6). There are many modalities to detect MDB such as immunostaining using cytokeratin and Ub, and special staining methods for other misfolded proteins. The other one, the historically important hematoxylin and eosin, is not suitable for detecting misfolded proteins or small/tiny MDB. Almost all previous studies interested in NAFLD used hematoxylin and eosin staining for showing both mature and young forms of MDB. This is a cost effective and an easily available method. Furthermore, there is more evidence and experience about its safety in the medical literature. On the other hand, the immunostaining method is relatively new and expensive. Immunostaining demonstrates not only mature form of MDB but also both its young forms and misfolded proteins such as CKs, Ub, p62 protein and HSPs in ballooned hepatocytes. The question is which one is the best to use in general practice and clinical trials? We have to look at the current medical literature to give the correct answer for this question. However, there is no growing body of evidence on this issue. A study from Denmark used immunostaining for the cell stress protein Ub in 148 fine needle liver biopsies, which included 88 biopsies from patients with clinically diagnosed or suspected alcoholic liver disease and 60 selected biopsies from non-alcoholics[20]. They showed that MDB in ballooned hepatocytes by both hematoxylin and eosin and immunostaining (Ub) in all of 33 biopsies with alcoholic hepatitis. Of the 55 biopsies from alcoholic patients without alcoholic hepatitis (without MDB or pre-MDB in hematoxylin and eosin stained sections), Ub (+) cells were found in eight (14.5%) by immunostaining. Finally, they studied 60 selected biopsies from non-alcoholic patients, and demonstrated a few Ub (+) cells in two out of ten patients with PBC, but none in biopsies with hepatitis. According to the study results, as Ub/immunostaining is a highly sensitive and specific tool in the detection of MDB and MDB precursors in alcohol-using patients, its use in other forms of hepatitis is limited.

p62 is another misfolded protein and encoded by an immediate-early response gene that rapidly responds to a variety of extracellular signals, particularly oxidative stress. Then, protein p26 binds non-covalently to Ub.

These results may also represent a sampling error of liver biopsy. The method of liver biopsy we chose (such as percutaneous or ultrasound guided or CT guided or laparoscopic), the type of biopsy needle, the average length of the biopsies performed, and how many samples are obtained or number of biopsies performed would be important.

POSSIBILITIES IN THESE DIFFERENCES AND MANAGEMENT

Both environmental factors and genetic differences between the study groups may play a role in these differences[21]. These remarkable differences may be induced by different levels of alcohol consumption and an incomplete patient history of alcohol consumption in these studies. Ignored alcoholic liver disease is a significant cause of MDB in some. Incomplete examination of Wilson's disease, such as just measuring serum ceruloplasmin levels or with no examination of hepatitis C virus infection, may play a role. This is especially relevant with Wilson's disease and hepatitis C because both microvesicular and macrovesicular fatty changes and glycogen nuclei are shown in both diseases.

ALCOHOLIC LIVER DISEASE

MDB is found in 70% to 75% of patients with alcoholic liver disease[22,23]. Men and women who drink more than 80 g and 40 g of ethanol/d, respectively were accepted at substantial risk for the development of liver disease in the previous studies. Recent studies showed that the risk of liver disease begins at 30 g of ethanol/d[24]. This finding has led to a general recommendation that the maximal safe level of ethanol consumption is 20 g/d or two "drinks" per day for men and 10 g/d for women. However, it should be kept in mind that disease severity does not correspond to classic dose dependency.

Although one of the major criteria for the diagnosis of NAFLD is no excessive alcohol consumption in all previous case series, there has been no certain agreement on this issue, and a wide range of alcohol consumption was generally allowed. Thus, these remarkable differences on the frequency of MDB might be explained with the generously allowed alcohol consumption in previous series. It must also be considered that patients sometimes underreport ethanol intake.

CONCLUSION

Frequency (MDB) is reported as very variable. Both environmental factors and genetic differences between the study groups, and technical difficulties for showing of MDB and its early stage components may play a role in these remarkable differences.

Abstract

Nitric oxide (NO), a multifunctional endogenous gas molecule, is metabolized from L-arginine by enzymatic reaction in the presence of nitric oxide synthase. NO, an important gas signaling molecule, is a gastric mucosa protective factor that contributes significantly to maintain normal gastric mucosa integrity. NO increases gastric mucosa blood flow, regulates the secretion of mucus and bicarbonate, and inhibits the secretion of gastric juice. Asymmetric dimethylarginine (ADMA) has been identified as the major endogenous inhibitor of nitric oxide synthase. The function of ADMA is to decrease NO production *via* inhibiting nitric oxide synthase activity. Besides inhibiting NO synthesis, ADMA also directly induces oxidative stress and cell apoptosis, and participates in inflammation reaction. Its systemic accumulation was observed in conjunction with several cardiovascular and metabolic diseases. ADMA also mediates gastric ulcer injury induced by ethanol, stress, *helicobacter pylori* and indomethacin. The mechanism of ADMA directly producing adverse effect in gastric mucosa is incompletely understood. It is widely accepted that NO bioavailability decrease is the majority reason. Promotion of apoptosis and aggravation of inflammation may be other important mechanisms of ADMA-induced gastric injury. ADMA might be a novel clinical and experimental biomarker related to gastric mucosa disorder. Although therapeutic tool targeting to ADMA is available in multiple cardiovascular diseases, it is unknown in gastrointestinal disease. The strategy to inhibit ADMA is beneficial to gastric ulcer induced by ethanol in rats. Thus, ADMA might be a candidate of therapeutic target in gastric mucosa damage.

INTRODUCTION

Nitric oxide (NO), a multifunctional endogenous gas molecule, is metabolized from L-arginine by enzymatic reaction in the presence of NO synthase (NOS)[1]. It is accepted as the most critical messenger and functional executant in a variety of biologic activities. Numerous researches have reported the beneficial effects of NO, including endothelium protection, inhibition of local inflammation and cell pathoproliferation[2]. NO bioavailability is most directly regulated by the abundance and/or activity of NOS. NOS can be competed by substrates, endogenous L-arginine and asymmetric dimethylarginine (ADMA)[1]. The function of ADMA is to decrease NO production *via* inhibiting the NOS activity. ADMA is derived from the catabolism of

proteins containing methylated arginine residues[3]. Arginine methylation of cellular proteins is catalyzed by protein arginine methyltransferases[3]. ADMA is hydrolyzed by dimethylarginine dimethylaminohydrolase (DDAH)[3].

Growing evidence has shown that excessive accumulation of ADMA can decrease NO bioavailability in cells/tissues, induce domain dysfunctions or produce detrimental effects in multiple systems[4]. Besides inhibiting NO synthesis, ADMA can directly induce oxidative stress and cell apoptosis, and participate in the inflammation reactions[5,6]. It is well documented that ADMA is involved in a wide range of cardiovascular disorders. ADMA impairs endothelial functions, thus leading to hypertension, atherosclerosis, coronary heart disease, diabetes mellitus, pulmonary hypertension and renal failure[7,8]. Although it is well established that ADMA is an independent risk factor of cardiovascular diseases, the pathological role of ADMA in other diseases is still unknown, including gastric diseases.

NO AND GASTRIC MUCOSAL PROTECTION

Gastric mucosal diseases, including gastric ulcers, affect 25%-30% of the world's population. The mechanism of gastric mucosal damage and protection is yet unclear. NO, an important gas signaling molecule, is a gastric mucosal protective factor that contributes significantly to maintaining normal gastric mucosal integrity[9]. Gastric mucosa is composed of gastric epithelial cells and glands. Gastric epithelial cells can secrete multiple active substances, including NO. There is substantial evidence that NO may be an important defendant factor of gastric mucosa[10]. In the animal models of gastric mucosal injury induced by ethanol, endothelin, ischemia/reperfusion, cold-stress, water immersion restraint, indomethacin and aspirin, NO exerts protective effects on gastric mucosal integrity[11-13]. The mechanisms underlying the protective effects of NO could be explained as follows: (1) NO increases gastric mucosal blood flow; (2) NO regulates the secretion of mucus and bicarbonate, which compose the first level of gastric tissue defense; and (3) NO inhibits the secretion of gastric juice[14,15].

ADMA AND GASTRIC MUCOSAL DAMAGE

Helicobacter pylori (*H. pylori*) infection is a definitive cause of gastroduodenal ulcer. Epidemiological analysis has shown that 70%-80% gastric ulcers and 95%-100% duodenal ulcers are attributed to *H. pylori* infection. In a clinical investigation of *H. pylori*-positive and -negative volunteers, *H. pylori* infection was found to increase the tissue contents of ADMA[16]. More importantly, a laboratory research has shown that proteolysis of *H. pylori* extract also results in a substantial accumulation of ADMA, indicating that *H. pylori* infection must be taken into account as a cause of increased ADMA levels[17]. Strong associations have also been found between ADMA and gastric mucosal dysfunction. Exogenous administration with ADMA inhibits the

Figure 1 The hypothesized role of asymmetric dimethylarginine in gastric mucosal injury and the underlying mechanisms. ADMA: Asymmetric dimethylarginine; NO: Nitric oxide.

mucosal alkaline response to acid exposure, which is regarded as one of the important beneficial factors of gastric mucosa complaint. And an increase in ADMA mediates the water extract of *H. pylori*-induced acid-base imbalance in duodenal tissues[17]. In our *in vitro* experiment, we found that intervention of *H. pylori* stimulated ADMA release from cultured gastric epithelial cells[18]. We also observed that *H. pylori* infection markedly exacerbated ADMA-produced gastric tissue injury in rats[19].

Besides *H. pylori* invasion, gastric mucosal function is also disturbed by other factors, such as ethanol, indomethacin and cold-stress. Our recent studies have explored the role of ADMA in gastric mucosal injury induced by other causes in addition to *H. pylori* infection. The results have shown that ADMA levels are increased in gastric juice in three separate gastric mucosal models, including ethanol, indomethacin and cold-stress initiated mucosal injury, accompanied with a decrease in NO level and DDAH activity[19]. Pretreatment with L-arginine, an antagonist of ADMA, markedly reduces the degree of gastric injury and elevates NO bioavailability. Administration of exogenous ADMA significantly exacerbates gastric injury, concomitantly with a decrease in plasma level of NO. These findings indicate that ADMA may participate in the gastric mucosal injury process induced by various deleterious factors. Multiple exogenous NOS inhibitors, such as L-NMA, L-NAME and L-NMMA intensify gastric mucosal injury by decreasing gastric mucosal blood flow, while NO donor (nitroprusside sodium) or substrate (L-arginine) reverses such effects[13,20].

Cigarette smoking is one of the risk factors provoking gastroduodenal ulceration[21]. It increases both the incidence and relapse rate of peptic ulcer diseases and delays ulcer healing. Besides reducing bioavailability of NO, nicotine, a major component of tobacco, aggravates gastric mucosal injury due to some factors such as ethanol or stress[22]. Recently, we have found that in the rats treated with ethanol, the ulcer index and ADMA level were increased and the NO level was decreased, and these effects of ethanol were augmented by pre-treatment with nicotine[23]. Nicotine alone did not show significant impact on ulcer index, ADMA level and NO level. *In vitro* incubation of epithelial cells with ethanol induced cell injury and increased ADMA level in the cultural medium, an effect that was amplified in the presence of nicotine. Therefore, the

accelerated effect of nicotine on gastric mucosal dysfunction is associated with endogenous ADMA.

The mechanism of ADMA directly producing adverse effect in gastric mucosa is incompletely understood. It is widely accepted that NO bioavailability decrease is the major reason. Apoptosis reaction produced by ADMA has been observed in different types of cells, such as endothelial cell and smooth muscle cell[6,24]. Cell apoptosis has also been observed in cultured gastric epithelial cells when exposed to an exorbitant concentration of ADMA[23]. ADMA could directly induce the production of inflammatory cytokines tumor necrosis factor (TNF)-α and soluble intercellular adhesion molecule-1 *via* activation of p38 MAPK and ERK1/2 pathways in cultured endothelial cells[25]. We deduce that inflammatory reaction may be another important factor for ADMA-induced gastric injury because TNF-α level, the marker of inflammation, is significantly elevated when cells are damaged by ADMA in gastric mucosal epithelial cells. The hypothesized role of ADMA in gastric mucosal injury and the underlying mechanisms are summarized in Figure 1.

PERSPECTIVES AND CLINICAL IMPLICATIONS

ADMA might be a novel clinical and experimental biomarker related to gastric mucosal disorder. The mechanisms of impairment involve NO generation inhibition, inflammatory reaction and apoptosis promotion. Although the therapeutic tool targeting ADMA is available in multiple cardiovascular diseases, it is unknown in gastrointestinal diseases. The strategy to inhibit ADMA is beneficial to the treatment of gastric ulcer induced by ethanol in rats[26]. Thus, ADMA might be a candidate of therapeutic target in gastric mucosal damage.

Abstract

AIM: To correlate circulating soluble ST2 (sST2) levels with the severity of ulcerative colitis (UC) and serum levels of pro-inflammatory cytokines, and to demonstrate the predictive power of sST2 levels for differentiation between active and inactive UC.

METHODS: We recruited 153 patients: 82 with UC, 26 with Crohn's disease (CD) and 43 disease controls [non-inflammatory bowel disease (IBD)]. Subjects were excluded if they had diagnosis of asthma, autoimmune diseases or hypertension. The serum levels of sST2 and pro-inflammatory cytokines [pg/mL; median (25th-75th)] as well as clinical features, endoscopic and histological features, were subjected to analyses. The sST2 performance for discrimination between active and inactive UC, non-IBD and healthy controls (HC) was determined with regard to sensitivity and specificity, and Spearman's rank correlation coefficient (r). To validate the method, the area under the curve (AUC) of receiver-operator characteristic (ROC) was determined (AUC, 95% CI) and the total ST2 content of the colonic mucosa in UC patients was correlated with circulating levels of sST2.

RESULTS: The serum sST2 value was significantly higher in patients with active [235.80 (90.65-367.90) pg/mL] rather than inactive UC [33.19 (20.04-65.32) pg/mL], based on clinical, endoscopic and histopathological characteristics, as well as compared with non-IBD and HC ($P < 0.001$). The median level of sST2 in CD patients was 54.17 (35.02-122.0) pg/mL, significantly higher than that of the HC group only ($P < 0.01$). The cutoff was set at 74.87 pg/mL to compare active with inactive UC in a multicenter cohort of patients. Values of sensitivity, specificity, and ability to correctly classify UC, according to activity, were 83.33%, 83.33% and 83.33%, respectively. The AUC of the ROC curve to assess the ability of this molecule to discriminate between active *vs* inactive UC was 0.92 (0.86-0.97, $P < 0.0001$). The serum levels of sST2 in patients with UC significantly correlated with endoscopic and histo-

pathological scores ($r = 0.76$ and $r = 0.67$, $P < 0.0001$, respectively), and with the pro-inflammatory cytokine, tumor necrosis factor-α ($r = 0.69$ and $r = 0.61$, respectively, $P < 0.0001$). Interestingly, we found a direct correlation between total intestinal ST2 content and serum levels of sST2, adjusted to endoscopic activity score in patients with mild ($r = 0.44$, $P = 0.004$), moderate ($r = 0.59$, $P = 0.002$) and severe disease ($r = 0.82$, $P = 0.002$). Only patients with inactive UC showed no significant correlation ($r = 0.45$, $P = 0.267$).

CONCLUSION: sST2 levels correlated with disease severity and inflammatory cytokines, are able to differentiate active from inactive UC and might have a role as a biomarker.

INTRODUCTION

Inflammatory bowel diseases (IBDs) belong to the group of chronic diseases that cause intestinal inflammation. Ulcerative colitis (UC) and Crohn's disease (CD) are the two most important diseases in this group. Their characteristics are mainly episodes of active inflammation or remission. In order to provide a differential diagnosis of these diseases, it is necessary to know the clinical, endoscopic, histological, radiologic and serologic characteristics, as well as their course throughout time[1].

Currently, classifications of IBD are based on epidemiologic (age, gender, race), clinical (activity rate, localization and phenotype) and genetic [single nucleotide polymorphism (SNP)][2,3] parameters, and the presence of biological markers[4,5]. However, due to the high percentage of non-classifiable IBD (10%-15%) and the difficulty of a differential diagnosis, it has become necessary to search for new markers for these diseases.

One ideal characteristic of an IBD biomarker is the specificity; however, it also has to be easy to detect, tests must be minimally invasive, low-cost, quick to perform and replicable across laboratories[6,7]. In addition, the biomarker should be able to identify individuals at risk of developing the disease, detect the activity, monitor the effect of the treatment and, finally, have a prognostic value for the reactivation of the disease[7,8]. Current biomarkers for IBD include serological levels of specific antibodies (ASCA, ANCA, anti-OmpC, anti-Cbir, anti-glycans)[9-12], serum (CRP and cytokines)[13-15] and fecal proteins (calprotectin and lactoferrin)[5,7,16-20]. Nevertheless, the majority of these markers show a low sensitivity and/or specificity, and they cannot reflect the real intestinal damage.

In this context, sST2 protein has recently been identified as a new and reliable biomarker of heart failure[21-26]. High serum levels of sST2 have been described in patients with chronic inflammatory diseases, such as autoimmune diseases[27,28] and asthma[29].

ST2 belongs to the interleukin (IL)-1R super-family, is coded in human chromosome 2 and is expressed as two splice variants: one membrane bound, ST2L, which is a receptor of IL-33; and a soluble protein, sST2[30-32].

Recently, in our laboratory, we have described for the first time increased levels of sST2 in serum and total ST2 in the colonic mucosa in IBD patients, and also its distribution in epithelial and infiltrating cells from colonic mucosa. In addition, we showed that serum sST2 levels significantly correlate with total ST2 levels in colonic mucosa[33]. Supporting our results, other groups also have shown evidence that the ST2/IL-33 system could be participating in the development of IBD[34-36].

To date, there are no studies that correlate levels of sST2 with severity of the UC.

The aims of the present study were to determine in another cohort of UC patients whether serum sST2 and intestinal total ST2 levels correlate with the severity of the disease, based on endoscopic and histological activity rates, and with serum levels of pro-inflammatory cytokines.

MATERIALS AND METHODS

Participants were recruited from the Gastroenterology Departments at "*Clínica Las Condes*", "*Hospital Clínico de la Universidad de Chile*" and "*Hospital Clínico de la Pontificia Universidad Católica de Chile*", respectively. Patients were diagnosed based on standard clinical, endoscopic and histological criteria. The study was approved by the Ethics Committee/Ethics Review Board of each participating center, and all patients signed an informed consent prior to their participation in this study.

During the study process, between January 2008 and December 2009, 153 patients were subjected to colonoscopy. Procedures were carried out by gastroenterologists with more than 5 years of experience in colonoscopy (co-authors RQ, MA-L), and findings were classified according to the clinical criteria of the Montreal Classification. Inclusion criteria for the study were: IBD diagnosed patients, > 18 years, blood specimens collected just before colonoscopy, biopsies taken and informed consent.

Exclusion criteria were: non-classifiable inflammatory disease, indeterminate colitis, infectious ileocolitis, asthma, history of autoimmune diseases, celiac disease and hypertension.

Patients were grouped based on endoscopic and histological criteria: Group UC (n = 84) and CD (n = 26), and non-IBD controls (irritable bowel syndrome, colorectal cancer, family history of colorectal cancer, diverticular disease and chronic diarrhea; n = 43). In addition, a group of healthy subjects (n = 40, between 18 and 45 years old) were included to determine reference levels of sST2.

A 5 mL blood specimen was obtained from each patient, and 3 to 4 biopsies were immediately frozen in liquid nitrogen and stored at -80℃ until analysis. From the healthy subjects, only a blood sample was obtained for analysis.

In the case of UC, endoscopic activity was determined in the most swollen area using the endoscopic Mayo Score[37]. In the case of CD, clinical activity was determined according to the Harvey-Bradshaw Index (HBI)[38], and for endoscopic activity, we used the Simple Endoscopic Score for Crohn's Disease (SES-CD)[39]. Histopathological score was used for the evaluation of intestinal inflammation in both diseases. Each biopsy was graded on a scale of 0-3 (0 = normal; 1 = mild; 2 = moderate; 3 = severe and included those patients with active ulceration) according to Gomes *et al*[40].

Quantification of serum sST2 and total intestinal ST2 levels

Levels of sST2 and total intestinal ST2, in serum and protein extract of colonic mucosa, respectively, were determined using a commercial enzyme-linked inmunosorbent assay (ELISA) kit for human ST2 (DuoSet, R&D Systems, Minneapolis, MN, USA) according to the manufacturer's instructions. Serum samples obtained from 5 mL of blood were subjected to a treatment with protein A/G PLUS-Agarose (Santa Cruz Biotechnology, Santa Cruz, CA, USA). Protein extracts were obtained from each sample by homogenization using a lysis buffer supplemented with a protease inhibitor cocktail (Complete Mini, Roche Diagnostics, Basel, Switzerland) and subsequent disruption by sonication. Levels of total intestinal ST2 were adjusted to the total protein concentration determined by Bradford protein assay. All samples were analyzed in duplicate and each determination was expressed in pg/mL. The detection limit of the technique, provided by the kit's manufacturer, is 20 pg/mL.

Measurement of serum inflammatory cytokines

Serum levels of IL-33 (Apotech, Geneva, Switzerland), IL-6 (Human IL-6 ELISA Ready-Set-Go, eBioscience, San Diego, CA, USA), and tumor necrosis factor (TNF)-α (Human TNF-α ELISA Ready-Set-Go, eBioscience) were measured using an ELISA kit, according to the manufacturer's instructions. The detection limits provided by the kit manufacturers are 5 pg/mL, 2 pg/mL and 4 pg/mL

for IL-33, IL-6 and TNF-α, respectively. Samples were prepared as previously described for ST2 determination.

Statistical analysis

Data were analyzed using the statistical software GraphPad Prism4 (La Jolla, CA) and are presented as average ± SD for variables with a normal distribution, and as a median (25th-75th) in the case of non-parametric distributions. Differences and significances among analyzed groups were established by multiple comparisons using the non-parametric Kruskal-Wallis tests. Further comparisons of individual groups *vs* control were performed by using Bonferroni-Dunn statistics and a 5% significance level. Sensitivity and specificity for levels of sST2, and their respective confidence intervals of 95%, were calculated according to endoscopic activity and compared to a non-inflammatory condition. The best cut-off value for sST2 that discriminated between inactive UC and active UC patients and the different levels of endoscopic activity was determined by area under the curve (AUC). Uni and bivariate analyses were carried out to determine the risk factors associated with each one of the following demographic and clinical parameters: gender, age, extent of the disease and medication at endoscopy. The associations between serum levels of sST2 and total intestinal ST2, and serum cytokines, were analyzed using Spearman's rank correlation coefficient (r). For each statistical test that was used, values of $P \leqslant 0.05$ were considered significant.

RESULTS

Main characteristics of IBD patients

During the study period, a total of 153 patients were recruited. Of these, 84 (54.9%) corresponded to UC, 26 (16.9%) to CD and the other 43 (28.1%) to non-IBD controls. Table 1 summarizes the main characteristics of IBD patients following the Montreal classification and also indicates gender and age distribution among groups, as well as medication at endoscopy. At the time of the procedure, 40 UC (47.6%) and 12 CD patients (46.1%) were active according to endoscopic Mayo and SES-CD criteria, respectively.

Determination of reference levels and cut-off value for sST2 in patients with IBD

The reference level of sST2 in serum, determined in the healthy subject group (HC), was 32.40 (19.00-49.00) pg/mL; in the case of the non-IBD, CD and UC groups, levels were 46.33 (26.00-74.66) pg/mL, 54.17 (35.02-122.0) pg/mL and 67.59 (30.78-199.1) pg/mL, respectively, with significant differences (P < 0.001) between UC *vs* HC and CD *vs* HC (Figure 1A). Due to the low number of patients with each of the CD phenotypes, such as inflammatory, penetrating and stenosing, we decided to focus on the analysis of sST2 levels restricted to the group of UC patients. Analysis of the levels of sST2 in the serum of the UC group, according to the Mayo Score of endoscopic activity (active $\geqslant$ 2) resulted in concentrations of

33.19 (20.04-65.32) pg/mL for inactive UC and 235.8 (90.65-367.9) pg/mL for active UC, with significant differences between active UC *vs* HC, non-IBD and inactive UC ($P < 0.0001$) (Figure 1B).

Figure 1C shows the ROC curve for sST2 levels in the active UC group in relation to the inactive UC group of patients. The optimal cut-off value estimated for sST2 that allows for the discrimination of active UC compared to inactive UC was 74.87 pg/mL. The AUC of the ROC values, cut-off, sensitivity and specificity are summarized in Table 2.

Levels of sST2, IL-33, TNF-α and IL-6 in serum and their correlation with disease activity

The range of serum sST2 concentrations for the different UC sub-groups, according to endoscopic Mayo score,

is shown in Figure 2 and Table 3. Significant differences were observed among groups with moderate (Score 2) and severe activity (Score 3) comparing to inactive (Score 0) and mild activity (Score 1) sub-groups ($P < 0.001$) (Figure 2A). Regarding the histopathological compromise of the mucosa, the serum sST2 levels were significantly higher in the severe (Score 3) and moderate (Score 2) inflammation groups compared to both normal (Score 0) and mild (Score 1) sub-groups ($P < 0.001$ and $P < 0.01$, respectively) (Figure 2B). Endoscopic and histopathological scores directly correlated with serum sST2, with $r = 0.76$ and $r = 0.67$, respectively (Table 3).

Levels of serum TNF-α in the different UC sub-groups were directly proportional to endoscopic and histopathological scores. When comparing serum sST2 and cytokine levels, only TNF-α significantly correlated, both

Figure 1 Distribution of serum levels of sST2 in the groups of studied patients. Box-plot showing the distribution of serum sST2 levels in healthy patients (HC) compared to non-inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC) patients (A) and comparison of HC with non-IBD and inactive and active UC patients (B). Data are represented as median and percentiles (25th-75th) and significant differences in serum sST2 levels are shown between UC and CD patients *vs* HC (A) and between active UC and other groups (B). Receiver operating characteristics (ROC) curves for sST2 cut-off point determination (C). ROC curves illustrate the specificity and sensitivity in serum sST2 level determination to differentiate active from inactive UC. tion (*P* = 0.0061) and medication (*P* = 0.0067) of the UC group (Table 4). These results show the same trend observed in Figure 2A and B, based on endoscopic and histopathological scores, regarding gender (*P* < 0.0001), localization (*P* < 0.0001) and medication with 5-aminosalicylic acid (5-ASA) (*P* = 0.0005) (data not shown). These findings demonstrate that sST2 values exclusively depend on the severity of the disease.

Levels of total intestinal ST2 correlate with disease activity scores and serum levels of sST2 in UC patients

In order to determine if the findings observed at the systemic level reflect the local damage, total intestinal ST2 was measured in colonic mucosa. Similarly to the serum sST2 levels, total intestinal ST2 levels in UC are closely distributed to activity endoscopic (*P* < 0.0001) (Figure 2C) and histopathological score (*P* < 0.0001) (Figure 2D). Significant differences were observed between moderate and severe activity sub-groups compared to inactive and mild (Figure 2C and D). Similarly, total intestinal ST2 levels significantly correlated with endoscopic (*r* = 0.62, *P* < 0.0001) and histopathological scores (*r* = 0.60, *P* < 0.0001) (Table 3), as seen for serum sST2 levels (Figure 2A and B).

Furthermore, serum sST2 levels and total intestinal ST2 directly correlate, according to endoscopic Mayo activity score, in the severe (*r* = 0.82, *P* = 0.0027), moderate (*r* = 0.59, *P* = 0.0020) and mild (*r* = 0.44, *P* = 0.0045) sub-groups (Figure 3).

DISCUSSION

Our group first reported that the ST2/IL-33 system, described in other inflammatory diseases, could be involved in the pathogenesis of IBD, because levels of ST2 and IL-33 in IBD patients were higher than in healthy sub-

with endoscopic (*r* = 0.69, *P* < 0.0001) and histopathological scores (*r* = 0.61, *P* < 0.0001) (Table 3).

Uni and bivariate analyses of serum levels of sST2, with reference to demographic and clinical parameters such as age, gender, localization of the disease and medication at the endoscopy for each one of the analyzed groups, are shown in Table 4. In addition to the activity score, significant differences were observed for localiza-

Activity: 0 = inactive; 1 = mild; 2 = moderate; 3 = severe. The trend lines for each analyzed group are shown. *r*: Spearman's rank correlation coefficient.

jects[33]. Recently, Pastorelli *et al*[34] also reported an increase in ST2/IL-33 system components in patients with IBD, both in the colonic mucosa as well as in serum. However, they reported that the circulating IL-33 levels in IBD patients were higher than our results and than in other diseases, even higher that those shown in sepsis[34]. Another two articles in the field[35,36] also confirmed elevated IL-33 expression in the mucosa of active IBD patients, with the limitation that these observations were conducted mainly at mRNA level, but ST2 levels were not studied.

The present study demonstrates, for the first time, a direct association between serum levels of sST2 protein and the degree of endoscopic and histopathological activity in UC.

Currently, a large number of serological, fecal or miscellaneous molecules have been proposed as indirect markers of IBD severity: C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and even antineutrophil cytoplasmic antibodies (ANCA) and anti-*Saccaromyces cerevisiae* antibodies (ASCA). However, lately they have become less useful for the diagnosis and prognosis of the diseases. This is mainly due to a low sensitivity and specificity to intestinal inflammation[41] and these markers do not allow accurate differentiation between IBD and other intestinal diseases, nor do they discriminate activity status. Some molecules detected in serum are rather systemic markers that in general do not show inflammatory bowel processes[12,42]. The use of a serum inflammation marker that reflects the intestinal damage would be helpful for the management and prognosis of IBD patients. Fecal molecules, such as calprotectin and lactoferrin, represent an inflammatory neutrophilic process of the intestinal mucosa[16]. However, these are also non-specific markers of inflammation, which are increased in organic intestinal diseases such as diverticular disease[43,44] polyposis[45] and colorectal cancer[46,47].

Serum levels of sST2 allow for a highly valuable discrimination between UC patients and healthy subjects; however, this efficacy is reduced when trying to differentiate UC from organic intestinal diseases presenting any

degree of inflammation. Alternatively, sST2 would allow, as happens with fecal calprotectin, the differentiation between UC and functional diseases, such as irritable bowel syndrome, chronic diarrhea and abdominal pain[5,19,48]. Many studies have shown that calprotectin significantly correlates with endoscopic and histological activity scores in CD and UC patients[49-51]. Calprotectin level decreases during clinical remission, which could be related to endoscopic mucosal healing[42,49,52], and consequently is considered a predictor of IBD reactivation. Serum sST2 levels allow for the differentiation between active and inactive UC with a high sensitivity and specificity. The cut-off value determined (74.87 pg/mL) permits the differentiation between active and inactive UC patients, as well as healthy subjects.

Similarly to fecal calprotectin, serum sST2 levels from UC patients significantly correlated with endoscopic (*r* = 0.76), as well as histopathological score (*r* = 0.67). Serum IL-33 level, another of the cytokines evaluated, did not show a direct relationship with disease activity; this might be due to the low levels detected compared to sST2, despite being the specific ligand of ST2. Serum sST2 levels in UC patients correlate with activity scores comparable with TNF-α, a commonly used serum inflammation marker. These characteristics result in the proposition of sST2 as an appropriate marker of inflammatory activity degree in UC. However, correlation of serum sST2 levels has to be achieved with other activity biomarkers previously associated with IBD, such as CRP or calprotectin.

In the case of CD patients, the analysis of serum sST2 values showed similar tendencies to those in UC, in relation to control patients (Figure 1A). The low incidence of CD in Chile[53], in addition to the exclusion criteria used in our study, account for the low number of CD patients included. Future studies will allow us to determine the association of sST2 with the inflammatory, stenosing and penetrating phenotypes of CD so as to support the concept that sST2 may also be applicable as a biomarker in CD.

Recently, ST2 has been described as a biomarker for heart failure, as serum levels correlate with hemodynamic variables, cardiac damage (BNP and pro-BNP) and inflammatory markers (CRP)[22,23,54,55]. In those studies, serum sST2 levels increase after myocardial infarction[21,56]; hence patients with a history of cardiopathies and hypertension were excluded.

In addition, some biochemical properties of sST2 support its characteristic as a reliable biomarker in UC, mainly based on its stability[57] and limited dependence on epidemiological and clinical factors, such as age, gender and diet[58].

In our study, serum sST2 levels in healthy subjects were similar to those described previously [32.4 (19-49) pg/mL *vs* 49 (4-89) pg/mL][54]. In addition, serum sST2 levels were higher in males than in females, and slightly increased between 18 and 24 years in age, as previously described[58]. However, when considering serum sST2 levels together with endoscopic activity, adjusted by gender, the distribution remained the same; therefore, we conclude that sST2

levels do not depend on these factors.

Therapeutic strategies for IBD patients are determined according to severity and localization of the affected area. UC patients with pancolitis presented higher serum sST2 levels in relation to proctitis or left-sided colitis. UC patients receiving systemic corticoids showed an increased sST2 level when compared to other treatments. Due to the low number of patients, we were not able to determine whether corticoids affect the sST2 concentration and its correlation with activity scores. However, in UC patients, ST2 levels did not show an association with mesalazine (5-ASA) treatment and in those patients sST2 levels follow activity degree of the disease. One of the most important qualities of a biomarker is that it has to be used in clinical practice and not be affected by drug therapy[12]. One of the main limitations of calprotectin as an IBD marker is the influence of non-steroidal anti-inflammatory drugs on its level, as previously shown[59-61]. In our study, 66.3% of IBD patients were receiving 5-ASA treatment, so measurement of calprotectin in those patients may be inconclusive.

Total ST2 levels in the colonic mucosa of UC patients significantly correlated with endoscopic and histopathological activity scores. In addition to the fact that total intestinal ST2 levels are directly associated with serum sST2 levels, these findings verify it as a new and promising UC activity biomarker. The relation between serum sST2 and inflammatory bowel activity would allow, in the future, the avoidance of a colonoscopic procedure in patients that do not require it. Association studies between ST2 and other biomarkers, such as calprotectin, may confirm its use.

It is possible that sST2 not only acts as a marker of UC activity; functions attributed to sST2 account for a role as an immunomodulator in inflammatory processes. At the cellular level, sST2 has been described as an inhibitor of IL-33/ST2L signaling[62], which causes polarization of naive T cells into Th2, and further, the production of IL-5 and IL-13 that are associated with UC[63,64]. On the other hand, ST2L activation with IL-33 stimulates TNF-α, IL-6 and IL-8 secretion in mast cells[65,66] and, together with IgE, stimulates degranulation[67]. The increase of sST2 during periods of inflammation may be involved in the control of the immune response associated with IBDs such as UC.

In summary, we demonstrated that serum sST2 levels allow for the effective differentiation between the endoscopic activity degrees of UC. Determining whether serum sST2 levels could have any prognostic value for UC (and possibly for CD), whether sST2 levels could monitor the treatment impact on endoscopic mucosal healing, and whether they could predict the risk of complications in IBD course or need of surgery, are some of the questions that should be answered by further studies.

ACKNOWLEDGMENTS

COMMENTS

Background
Inflammatory bowel diseases (IBDs) belong to the group of chronic diseases that cause intestinal inflammation. Ulcerative colitis (UC) and Crohn's disease are the two most important diseases in this group. Their characteristics are mainly episodes of active inflammation or remission. Currently, classifications of UC are based on epidemiologic, clinical and genetic parameters, and the presence of biological markers. Therapeutic strategies for UC patients are determined according to severity and localization of the affected area.

Research frontiers
To date, there are no studies that correlate levels of soluble ST2 (sST2) with severity of UC. It is possible that sST2 not only acts as a marker of UC activity; functions attributed to sST2 account for a role as immunomodulator in inflammatory processes. At the cellular level, sST2 has been described as an inhibitor of interleukin (IL-33/ST2L) signaling. The increase of sST2 during periods of inflammation may be involved in the control of the immune response associated with IBD.

Innovations and breakthroughs
Soluble ST2 protein has been identified as a new and reliable biomarker of heart failure. High serum levels of sST2 have been described in patients with chronic inflammatory diseases, such as autoimmune diseases and asthma. Recently, in their laboratory, the authors have described for the first time increased levels of sST2 in the serum and total ST2 in the colonic mucosa of UC patients. In this study, we show that serum sST2 levels significantly correlate with total ST2 levels in the colonic mucosa. Supporting our results, other groups also have shown evidence that the ST2/IL-33 system participates in the development of IBD.

Applications
The relation between serum sST2 and inflammatory bowel activity would allow, in the future, avoidance of colonoscopy procedures in patients that do not require them. In addition, some biochemical properties of sST2, such as its stability, support its characteristic as a reliable biomarker in UC. If sST2 levels decreased during clinical remission, these could be related to endoscopic mucosal healing, and therefore be considered a predictor of UC reactivation.

Terminology
ST2 belongs to the IL-1R super-family, is coded in human chromosome 2 and is expressed as two splice variants: one membrane bound, ST2L, which is a receptor of IL-33; and a soluble protein, sST2.

Peer review
The authors examined the expression of components of the ST2/IL-33 system in serum and colonic mucosa in UC patients and correlated levels of sST2 with severity of the disease. The study revealed that sST2 levels are able to differentiate active from inactive UC and correlate with endoscopic and histopathological activity scores. In addition to the fact that total intestinal ST2 levels are directly associated with serum sST2 levels, these findings verify that circulating sST2 levels may play an important role as a new and promising biological marker in UC.

Abstract

AIM: To assess the peripheral T lymphocyte subsets in chronic hepatitis B virus (HBV) infection, and their dynamics in response to adefovir dipivoxil monotherapy.

METHODS: Proportions and absolute counts of peripheral natural killer cells, B cells, CD8+, CD4+, CD8+CD38+, CD8+CD28+ and CD4+CD28+ T cells were determined using three-color flow cytometry in chronic hepatitis B patients (n = 35), HBV carriers (n = 25) and healthy controls (n = 35). Adefovir dipivoxil was initiated in 17 chronic hepatitis B patients who were regularly followed for 72 wk, during which period the T cell subsets and serum viral load were measured at each follow-up point.

RESULTS: The peripheral CD4+ T cell counts and CD8+ T cell counts decreased in chronic HBV infection. In chronic hepatitis B patients, proportions of CD8+CD38+ T cells were 62.0% ± 14.7%, much higher than those of HBV carriers and healthy controls. In the 13 hepatitis B patients who were treated and responded to adefovir dipivoxil, proportions of CD8+CD38+ T cells decreased from 53.9% ± 18.4% pre-therapy to 20.1% ± 11.3% by week 72 (P < 0.001), concomitant with viral load decline (HBV DNA fell from 7.31 to 3 log copies/mL). CD8+ T cell counts also underwent an average increase of 218 cells/μL by the end of 72-wk treatment. In those who failed the therapy, the CD8+CD38+ T cell population had more fluctuations.

CONCLUSION: CD8+ T cells abnormally activated in chronic HBV infection can be partially reversed by antiviral therapy. HBV-associated immune activation may be a crucial part of the pathogenesis and a promising target of treatment.

INTRODUCTION

Hepatitis B virus (HBV) infection is a global public health concern. Despite the availability of effective vaccines since the 1980s, approximately one third of the world's population has serological evidence of past or present infection with HBV[1]. In China, over 8% of the

Table 2 Counts and proportions of patient peripheral lymphocyte subsets

T subsets	CHB patients (n = 35)	HBV carriers (n = 25)	Healthy controls (n = 35)
White blood cells × 10^9/L	4.96 ± 1.18^b	5.60 ± 0.96^b	6.53 ± 1.42
Lymphocytes × 10^9/L (%)	1.60 ± 0.51^b (32.7 ± 8.7)	1.72 ± 0.44^b (31.2 ± 8.8)	2.13 ± 0.49 (33.1 ± 6.6)
Natural killer cells /μL (%)	197 ± 102^a (12.2 ± 5.1)	272 ± 189 (15.1 ± 8.4)	310 ± 181 (14.6 ± 7.8)
B cells/μL (%)	228 ± 148 (14.3 ± 6.3)	220 ± 113 (12.6 ± 4.6)	242 ± 95 (11.4 ± 3.8)
CD3+ T cells/μL (%)	1145 ± 380^b (71.5 ± 7.1)	1190 ± 278^b (70.4 ± 9.6)	1516 ± 382 (71.4 ± 7.6)
CD3+CD4+ T cells/μL (%)	573 ± 194^b (36.3 ± 6.9)	673 ± 148^b (40.1 ± 6.9)	816 ± 259 (38.2 ± 7.0)
CD3+CD8+ T cells/μL (%)	489 ± 213^a (30.1 ± 8.0)	445 ± 157^b (25.9 ± 6.1)	609 ± 177 (28.9 ± 5.7)

CD8+CD38+ T cells/μL (%)	301 ± 152 ($62.0 \pm 14.7^{b,d}$)	285 ± 121 (51.8 ± 18.5)	274 ± 81 (46.3 ± 11.9)
CD4+CD28+ T cells/μL (%[1])	532 ± 191^b (96.0)	622 ± 149^a (95.7)	744 ± 221 (94.7)
CD8+CD28+ T cells/μL (%)	235 ± 125^a (51.1 ± 15.5)	245 ± 100^a (55.7 ± 16.0)	306 ± 94 (51.3 ± 11.7)

[1]Medians were used as the CD4+CD28+ T cell proportions were non-normal variables according to Kolmogorov-Smirnov Normality Test. $^aP < 0.05$, $^bP < 0.01$ *vs* normal healthy controls; $^dP < 0.01$ *vs* hepatitis B virus (HBV) carriers. CHB: Chronic hepatitis B.

Peripheral blood T lymphocyte subset measurement

Peripheral blood T cell subset measurements were routinely performed during each follow-up review. Percentages of T cell subsets were determined on 100 μL ethylenediamine tetra-acetic acid (EDTA) blood sample, using a three-color direct immunofluorescence method (Beckman-Coulter, USA, EPICS2XL). In sample Tube 1, CD3+ T cells were autogated and analyzed for CD4 and CD8 cell expression using CD4/CD8/CD3 cell triple staining. In Tube 2, CD16/CD19/CD3 cell triple staining was used to identify B cells and natural killer (NK) cells. In Tubes 3, 4 and 5, CD38/CD8/CD3, CD28/CD8/CD3 and CD28/CD4/CD3 cell triple antibody cocktails were used, respectively, for analysis of CD38 and CD28 expression. Absolute counts of lymphocyte subpopulations were calculated according to complete blood cell counts on the same day.

Statistical analysis

SPSS version 11.0 was used. Baseline variables were assessed for all 95 subjects. For those who were included in the adefovir dipivoxil treatment and follow-up, virological and immunological parameters till the end of 72 wk were collected. Normal variables were summarized as means and standard deviations, and non-normal variables as medians and interquartile range (IQR) according to Kolmogorov-Smirnov Normality Test. Normal data were compared by Student t test or one-way ANOVA adjusted for multiple comparison, as appropriate. Multiple comparison of non-normal data was carried out by Kruskal Wallis test. All tests were two-sided, and a P-value $\leqslant 0.05$ was considered significant. Associations between variables were assessed using Spearman's rank correlations. Tested results of serum HBV DNA which were below the lower limit of detection (less than 1000 copies per milliliter) were all analyzed as being 1000 copies per milliliter for the ease of analysis.

RESULTS

T lymphocyte subsets in chronic HBV infection

As shown in Table 2, the T lymphocyte counts in chronic

Figure 1 CD8+CD38+ T cell proportions in hepatitis B patients, hepatitis B virus carriers and healthy controls. Levels of CD8+CD38+ T cells in chronic hepatitis B patients were markedly higher than those of the other two groups. HBV: Hepatitis B virus.

hepatitis B patients and HBV carriers were 1145 ± 380 and 1190 ± 278 cells/μL, respectively, both significantly lower than those of the healthy controls ($P < 0.01$). The absolute counts of CD4+ T cells and CD8+ T cells in chronic hepatitis B patients and HBV carriers were also lower than those of the controls. Yet the proportions thereof showed no significant differences between these three groups. The average counts of NK cells in chronic hepatitis B patients showed a moderate decrease compared to those of the carriers and controls. There were no significant differences in B cell counts between the different groups.

Levels of CD8+CD38+ T cells were also examined for each group of patients. We noticed a marked increase of CD8+CD38+ T cell proportions in chronic hepatitis B patients (62.0% ± 14.7%), compared to those of the HBV carriers (51.8% ± 18.5%) and healthy controls (46.3% ± 11.9%) ($P < 0.01$) (Figure 1). No such differences were observed in absolute CD8+CD38+ T counts between these patients. The CD8+CD38+ T cell levels of the HBV carriers and healthy controls showed no differences.

The counts of functional subsets CD4+CD28+ and CD8+CD28+ T cells were both markedly decreased in

Figure 2 Hepatitis B viral load changes of the 13 patients who responded well to adefovir dipivoxil, by week of treatment. HBV: Hepatitis B virus.

Figure 3 Changes of CD3+CD8+ and CD3+CD4+ T cell counts and median hepatitis B virus DNA in good responders, by week of adefovir dipivoxil treatment. [a]$P < 0.05$, [b]$P < 0.01$ *vs* baseline T cell counts before adefovir dipivoxil treatment. HBV: Hepatitis B virus.

chronic hepatitis B patients and HBV carriers. However, again, no significant differences were observed as to the proportions thereof compared with the normal controls.

Virological responses

Median change in serum HBV DNA load is presented as $\log_{10}$ copies/mL. Among all the 17 patients receiving adefovir dipivoxil, 13 have achieved significant viral suppression, with their median HBV DNA decreased to undetectable levels ($< 10^3$ copies/mL) since 24 wk of treatment (Figure 2). However, the other 4 failed to respond to the therapy, either with no virological improvement or with a later rebound. As will be discussed later, changes in T lymphocyte subsets were analyzed based on patients' virological responses.

Changes in T lymphocyte subsets

CD3+CD8+ and CD3+CD4+ T lymphocyte subsets: As is shown in Figure 3, in those who responded well to adefovir dipivoxil, we observed a marked increase of 34.5% in absolute CD8+ T cell mean counts, from 505 ± 144 to 723 ± 324 cells/μL ($P < 0.01$) at the end of 72 wk of treatment. This increase began in the first

12 wk of treatment ($P < 0.05$), concomitant with the reduction of HBV DNA loads. Meanwhile, percentage of CD8+ T cells was also elevated at the end of 72 wk, from 30.7% to 33.2% ($P < 0.05$). In contrast, patients with poor response to adefovir dipivoxil showed no increase of CD8+ T cells.

Fluctuations of CD3+CD4+ T cell counts and proportions were also examined throughout the treatment. No significant changes were observed in either population. Absolute counts of CD4+ T cells at each time point are also shown in Figure 3.

As regards NK cells and B lymphocytes, neither the absolute numbers nor the proportions thereof showed any significant changes after the treatment.

CD8+CD38+ T cell subsets: In those who achieved good control of HBV viremia with adefovir dipivoxil, both the proportions and absolute counts of CD8+CD38+ T cells declined dramatically in peripheral blood (Figure 4A). From the first 12 wk after starting therapy, levels of CD8+CD38+ T cells began to decrease sharply. By week 24, the proportions of CD8+CD38+ T cells fell significantly from $53.9\% \pm 18.4\%$ to $36.8\% \pm 14.8\%$, while the absolute counts fell from 271 to 215 cells/μL ($P < 0.01$), and the same trends were sustained afterwards. By week 72, proportion of CD8+CD38+ T cell count had decreased as much as 62.8% from baseline to 20.1%. Absolute counts thereof showed a similar pattern of change. In contrast, the other 4 patients who did not achieve successful responses, though initially having some reduction of CD8+CD38+ T cell levels, showed CD8+CD38+ T cell fluctuations as their HBV load became unstable. CD8+CD38+ T cell changes of those who failed the therapy are depicted in Figure 4B.

As is apparent from Figure 4A, the drop in CD8+CD38+ T cell levels during the first 24 wk of treatment coincided with a marked change in serum HBV DNA load, with a median reduction from 7.30 log copies/mL to undetectable level. Regardless of virological responses to adefovir dipivoxil, in both patient groups the shape of the CD8+CD38+ T cell fluctuation curve followed that of the HBV DNA level. Also, there was a close relationship between changes in viral load and changes in CD8+CD38+ T cell levels. Further analysis from all available data paired for viral loads and T cell subsets indicated that CD8+CD38+ T cell subpopulations in chronic hepatitis B patients are significantly and positively related to serum HBV DNA log values (Figure 5, $r = 0.438$, $P = 0.001$).

Moreover, changes in CD8+CD38+ T cells were examined in 11 individuals who had achieved and maintained a viral load below 10^3 copies/mL, including at least two assessments of CD8+CD38+ T cells during the period of virological suppression. Of these 11 patients, 9 (82.2%) experienced a further fall in CD38+ T cell counts and proportions, whereas changes in HBV DNA were undetectable, all below 10^3 copies/mL. The mean change in CD8+CD38+/CD8+ percentage from

[b]*P* < 0.01; B: Changes of CD8+CD38+ T cell subsets in 4 non-responding patients 008, 014, 015, and 018. Among them, Patient 008 and 015 only finished 60 and 48 wk of treatment, respectively. Patient 014 and 018 completed 72 wk of treatment. HBV: Hepatitis B virus.

Figure 5 Correlations between CD8+CD38+ T cell levels and median hepatitis B virus DNA. HBV: Hepatitis B virus. *r* = 0.438, *P* = 0.001.

the first available count to the last was -10.6% (*P* < 0.01), indicating that reductions in CD8+CD38+ T cell proportions had continued even after serum HBV DNA become undetectable.

CD4+CD28+ and CD8+CD28+ T cell subsets: We also examined changes of CD28+ subpopulations both in CD8+ and CD4+ T lymphocytes before and after adefovir dipivoxil treatment. No statistically significant changes took place during the treatment (Data not shown).

DISCUSSION

In addition to HBV DNA level and liver function, chronic hepatitis B is further characterized by marked changes

in lymphocyte subpopulations and their activation status, which has only been poorly described in the literature. In the present study, we have identified discoordinate T cell profiles in chronic hepatitis B patients, with decreased counts of CD8+ T cells and robust CD8+ T activation, determined by an increase in the proportions of CD8+CD38+ T cells.

CD8+ and CD4+ T cells are two major components of the cellular immune system. As mentioned above, multiple studies have revealed that CD8+ T cells play an important role in clearance of the virus and progression of the disease. However, reports of CD8+ T cell subset changes in chronic hepatitis B patients have been rather conflicting. In the present study, we examined lymphocyte absolute counts as well as relative proportions in all 55 HBV infected patients and 35 healthy controls. We observed reductions of both CD8+ and CD4+ T cell levels in chronic hepatitis B patients and HBV carriers, which might reflect the T cell disturbance and suppression. Furthermore, in conjunction with the adefovir dipivoxil monotherapy, a marked elevation of CD8+ T cell levels took place, which demonstrated a partial restoration of T cell subsets and T cell immunity after the treatment. Prior studies have suggested that antiviral therapy can also overcome CD8+ T cell hypo-responsiveness in chronic HBV infection[14,15]. We believed that there could be some improvement of T cell functions with adefovir dipivoxil treatment. However, right at this point, more functional studies are needed in order to make a conclusion. On the other hand, neither counts nor proportions of CD4+ T cells demonstrated any significant changes throughout the therapy in our study, despite the initial reduction of CD4+ T cells in chronically infected patients. However, some have suggested that functions of HBV specific CD4+ T cells would be improved in response to antiviral treatment[19]. The peripheral CD4+/CD8+ ratios were much the same level in these three groups, perhaps because of the relatively localized infection and immunity that takes place in subjects with HBV infection. In addition, some prior studies have indicated that CD4+/CD8+ ratio of liver-derived lymphocytes, instead of peripheral lymphocytes, appeared to be more related to the level of HBV replication[20]. In this sense, our analysis of the peripheral T cell composition had its limitations in directly evaluating the local immune functions. However, it is still a much easier way for evaluating the immune status in a more general clinical practice.

The further evaluation of each functional and activated T cell subset in chronic HBV infection highlighted the group of CD8+CD38+ activated T cell subsets. We have found much higher proportions of circulating CD8+CD38+ T cells in chronic hepatitis B patients. CD38 is a surface glycoprotein existing on many immune cells. As a marker of cell activation, it is associated with many infectious diseases such as HIV, EBV or other infections. In certain infections, CD8+CD38+ T cells undergo a rapid up-and-down pattern after the infection once the immune control of acute phase is achieved[21].

However, persistency of immune activation and CD38+ expression throughout the acute and chronic phase is also possible, which may reflect the failure of the host's immune system to fully suppress viral replication. According to our observation of the peripheral CD8+CD38+ T cells in chronic hepatitis B patients, chronic HBV infection showed a mode of persistent T cell activation, just like that of HIV infection. However, elevations of CD8+CD38+ T cells in chronic hepatitis B patients were not so high as those of HIV-, EBV- or cytomegalovirus-infected patients[5,6,13,22], perhaps due to the relatively localized infection of HBV in liver tissue in contrast to other systemic infections. On the other hand, HBV carriers, though also chronically infected, had similar levels of CD8+CD38+ T cells as healthy controls. This difference of CD8+ T activation may help to explain the relative immune quiescence of HBV carriers.

In further assessment of the 17 patients receiving adefovir dipivoxil monotherapy, we found that not only did the treatment effectively inhibit HBV replication, but it also resulted in a concomitant, profound and rapid decline in the CD8+CD38+ T cell levels. This reduction in CD8+CD38+ T cells began to take place after the first 12 weeks of treatment, and in the majority of treated patients, CD8+CD38+ T cell levels finally became fully normalized. This recovery of CD8+CD38+ T cell proportions confirmed the abnormal T cell activation as a result of the virological failure in active HBV infection. A further correlation analysis showed a positive and significant relationship between the CD8+CD38+ T cell proportions and serum HBV DNA, which indicated a T phenotype drift with viral stimulation. However, at this stage, it remains unclear whether the immune activation we observed was only a secondary change of viral insults, or part of HBV pathogenesis. Based on the variance of T cell activation between hepatitis B patients and HBV carriers with similar levels of viremia, CD8+CD38+ activated T cells most probably represent multiple interactions between viral and host factors. Studies of immune activation in HIV have suggested that CD8 T cell activation levels can predict the rate of disease progression independent of viral load, though the causes of this immune activation are likely multifactorial[23,24]. Furthermore, some have tried to target HIV-associated immune activation by using immunomodulatory agents in addition to antiretroviral therapy[25-27]. The role of immune activation in chronic HBV infection has been poorly described. Here, our study of CD8+CD38+ activated T cells raises the possibility that T immune activation helps to shape the fate of chronic HBV infection and, therefore, use of immunomodulatory agents may help with the control of hepatitis B virus. However, a larger sample size and more specific and functional studies are needed to establish this conclusion.

Moreover, a continued decline in CD8+CD38+ T cell levels was observed even after HBV DNA became undetectable and CD8+CD38+ T cells became normalized in successfully treated patients. This finding is interesting,

because we have also observed similar phenomena in other treated viral infections. It could be an indication of presentations of the residual virus below the lower limit of viremia detection. Another possible explanation is that the CD8+CD38+ T cell levels under normal conditions may actually present an overall balance between the human immune system and occasional environmental insults, and that non-specific antiviral medications such as adefovir dipivoxil may also have an effect on these other pathogens, thus reducing the chances of immune activation in these patients. A longer follow-up of these patients during and after treatment may help to better explain the dynamics of the CD8+CD38+ T cell subsets.

The functional subsets of CD8+CD28+ and CD4+CD28+ T cells were also examined in our study. CD28+ acts as a co-stimulating molecule on the surface of T cells. However, according to a few currently available evaluations[12,28], unlike HIV infection which leads to the down-regulation of CD28 on the surface of T cells[29,30], HBV infection seems to have no significant impact on CD28 expression. In our study, the proportions of CD8+CD28+ and CD4+CD28+ T cells in the three groups were similar to each other. The absolute counts, though lower in chronic hepatitis patients and HBV carriers, were actually reflections of the decreased CD8+ and CD4+ T cell levels. Further treatment, which resulted in good control of the virus, did not change CD28 expression on the CD4+ or CD8+ T cells either, which further confirmed our observations before the treatment.

COMMENTS

Background

Chronic Hepatitis B virus (HBV) infection is a global health concern. Studies have identified that T cellular immune responses are essential for disease control. However, profiles of T cell subsets in chronic HBV infection, especially those of activated T cell subsets, have not been fully revealed. The authors studied the peripheral T cell subsets in chronic HBV infection, and their dynamics in response to adefovir dipivoxil monotherapy.

Research frontiers

T cellular immune responses are essential for pathogenesis of chronic HBV infection; impaired balance of peripheral T subpopulations has been reported at various stages of chronic HBV infections, and can be partially restored after antiviral therapy.

Innovations and breakthroughs

The study systemically assessed the peripheral T lymphocyte subsets in different types of chronic HBV infection. For the first time, the authors highlighted the group of CD8+CD38+ activated T cells, and their dynamics before and after treatment. The authors found T cell activation was linked with active HBV infection, and declined with successful antiviral treatment, which suggested the crucial role of immune activation in HBV pathogenesis.

Applications

The authors clarified differences of peripheral T cell subsets between different clinical types of chronic HBV infection, and changes thereof in response to treatment. HBV-associated immune activation may be crucial for the pathogenesis of HBV infection. This adds to current knowledge of T immune functions in chronic HBV infection, and helps with a better understanding of HBV pathogenesis. The abnormal T immune activation status in chronic hepatitis B suggests the possible use of immunomodulatory agents as further treatment.

Peer review

This is an interesting and well-written manuscript that clearly shows the link between CD8+38+ T-cells and HBV DNA levels. The authors described a decrease in total CD4 and CD8 T cell counts in chronic hepatitis B along with a higher proportion of CD8/CD38 cells after treatment. The amount of activated cells decreased in patients responding to an antiviral therapy while the amount of CD8 cells rose. The authors suggest HBV-associated immune activation may be a crucial part of the pathogenesis and a promising target of treatment.

Abstract

AIM: To investigate effects of hepatotropic growth factors on radical production in rat hepatocytes during sepsis.

METHODS: Rat hepatocytes, isolated by collagenase perfusion, were incubated with a lipopolysaccharide (LPS)-containing cytokine mixture of interleukin-1β, tumor necrosis factor-α and interferon-γ to simulate sepsis and either co-incubated or pre-incubated with hepatotropic growth factors, e.g. hepatocyte growth factor, epidermal growth factor and/or transforming growth factor-α. Cells were analyzed for glutathione levels. Culture supernatants were assayed for produc-tion of reactive oxygen intermediates (ROIs) as well as NO_2^-, NO_3^- and S-nitrosothiols. To determine cellular damage, release of aspartate aminotransferase (AST) into the culture medium was analyzed. Activation of nuclear factor (NF)-κB was measured by electropho-retic mobility shift assay.

RESULTS: Rat hepatocytes treated with the LPS-con-taining cytokine mixture showed a significant increase in ROI and nitrogen oxide intermediate formation. AST leakage was not significantly increased in cells treated with the LPS-containing cytokine mixture, independent of growth-factor co-stimulation. However, pretreatment with growth factors significantly reduced AST leakage and ROI formation while increasing cellular glutathi-one. Application of growth factors did not result in increased NF-κB activation. Pretreatment with growth factors further increased formation of NO_2^-, NO_3^- and S-nitrosothiols in hepatocytes stimulated with LPS-con-taining cytokine mixture. Thus, we propose that, to-gether with an increase in glutathione increased NO_2^-, NO_3^- formation might shift their metabolism towards non-toxic products.

CONCLUSION: Our data suggest that hepatotropic growth factors positively influence sepsis-induced he-patocellular injury by reducing cytotoxic ROI formation *via* induction of the cellular protective antioxidative systems.

INTRODUCTION

After partial hepatectomy, the remaining liver tissue undergoes rapid regeneration of its lost mass. Although it has been studied for many years, the exact mechanisms and interactions of this regenerative process are still the focus of many investigations[1-4]. Despite advances in surgical techniques and perioperative management, liver failure occasionally occurs after extended hepatectomy often being associated with postoperative infections that lead to multiple organ failure and death[5,6].

Although a two-thirds resection of the liver is not fatal, there is increased sensitivity to endotoxin, caused by up-regulation of the toll-like receptor 4, in the period following experimental hepatectomy[7]. Thus, intravenous injection of a sub-lethal dose of lipopolysaccharide (LPS) 48 h after surgery results in a high mortality in rats[8]. LPS directly activates Kupffer cells (the hepatic macrophages) to produce the tumor necrosis factor (TNF)-α and other inflammatory cytokines[9] through activation of the transcription factor, nuclear factor (NF)-κB. During liver regeneration, however, cytokines as well as hepatotropic growth factors have been well demonstrated to be involved in the process of tissue regeneration[10].

Numerous publications suggest a direct link between nitric oxide (NO) production, cellular loss of glutathione (GSH) and reduction of glutathione reductase activity. Thus, depletion of GSH reduces cellular NO levels while increasing superoxide formation, because GSH is an important cofactor for NO synthase[11-16]. Togo *et al*[17] suggest that NF-κB is the major transcription factor regulating the initial steps of liver regeneration. Growth factors, by different mechanisms, play an essential role in cell growth, proliferation, differentiation and DNA synthesis[18-21]. Certain interplays between cytokines and growth factors indeed seem to exist. Inflammatory cytokines increase the intracellular radical formation if not being blocked by intracellular antioxidative systems, e.g. GSH[22]. Therefore, it might be possible that adequate proliferation and regeneration occurs after partial hepatectomy, and the interplay of growth factors and cytokines could be shifted towards protective proliferation rather than hepatocellular injury.

Using an experimental model of sepsis/inflammation, we investigated the effects of hepatotropic growth factors, hepatocyte growth factor (HGF), epidermal growth factor (EGF) and/or transforming growth factor (TGF)-α on radical production and glutathione content in rat hepatocytes that were exposed to an inflammatory cytokine mixture of interferon (IFN)-γ, TNF-α and interleukin

(IL)-1β, including LPS.

MATERIALS AND METHODS

Isolation, culture and treatment of primary rat hepatocytes

Rat hepatocytes were isolated from healthy Sprague-Dawley rats with a body weight between 250 and 300 g (Fa. Harlan-Winkelmann, Borchen, Germany) in accordance with the institutional guidelines of the Charité (Berlin, Germany) by collagenase P (Boehringer, Mannheim, Germany) digestion as described previously[23]. Hepatocytes were separated from non-parenchymal cells by differential centrifugation at 50 *g*. Cells were further purified by density gradient centrifugation using 30% Percoll (Pharmacia, Piscataway, NJ, USA). Hepatocyte purity, assessed by microscopy, was > 95% and viability, examined by trypan blue exclusion method, was consistently > 90%. Immediately after isolation, hepatocytes were plated onto gelatin-coated culture dishes (5×10^4 cells/cm^2) in Williams medium E (0.5 mmol/L L-arginine, 1 μmol/L insulin, 15 mmol/L HEPES, 2 mmol/L L-glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin and 10% fetal calf serum). The next day, experiments were performed in serum-free medium. To imitate inflammation, cells were stimulated with a cytokine mixture (CM) consisting of 100 U/mL IFN-γ, 500 U/mL TNF-α, 10 U/mL IL-1β and 10 μg/mL LPS (*Escherichia coli* 111:B4) for 24 h. To investigate the effect of growth factors on inflammation, cells were either co-stimulated or pretreated (12 h) with 20 ng/mL HGF, 30 ng/mL EGF and/or 20 ng/mL TGF-α.

Measurement of NO_2^-, NO_3^- and S-nitrosothiols

Culture supernatants were assayed for the stable end products of NO oxidation (NO_2^- and NO_3^-) and S-nitrosothiols using modified procedures based on the Griess reaction as described previously[24].

Aspartate aminotransferase measurement

In order to evaluate cellular damage, culture supernatants were measured for aspartate aminotransferase (AST) leakage using commercially available reaction kits (Roche Diagnostics, Mannheim, Germany).

Determination of cellular GSH levels

To evaluate total cellular GSH levels [GSH + oxidized glutathione (GSSG)] cells were suspended in 1 mL metaphosphoric acid (3%) and centrifuged at 1000 *g* for 5 min. Supernatants were adjusted to pH 7.5-8.0 with K_2CO_3. Total cellular GSH was assayed, using an enzymatic recycling procedure, as described previously[22]. Reduced GSH was sequentially oxidized by 5,5'-dithiobis-(2-nitrobenzoic-acid) (DTNB) to GSSG. The rate of DTNB formation was monitored at 412 nm and glutathione content was determined from a standard curve. To determine GSSG, GSH was masked with 2-vinylpyridine. Then, GSSG was reduced by NADPH to GSH in the presence of glutathione reductase to react again with DTNB. Oxidized and

reduced GSH that may be released in the supernatant were measured in the same way. All data were normalized to total protein content determined from cell pellets.

Determination of superoxide (O$_2^-$)
Release of O$_2^-$ into culture supernatant was measured by monitoring the superoxide dismutase-dependent reduction of 160 μmol/L ferricytochrome c at 550 nm and 37℃, where 1 mol O$_2^-$ reduces 1 mol ferricytochrome c[14].

Measurement of NF-κB activation
The NF-κB binding activity was analyzed by electrophoretic mobility shift assay (EMSA). Nuclear extracts were prepared from cells that were homogenized in sucrose buffer (2.1 mol/L sucrose, 10 mmol/L HEPES, 1 mmol/L MgCl$_2$, 5 mmol/L NaF, 0.5 mmol/L Leupeptin, 0.5 mmol/L pepstatin, 5 mmol/L aprotinin, 1 mmol/L DTT, and 0.1 mmol/L PMSF). Nuclei were separated by centrifugation (35 000 *g*, 3 h, 4℃) and washed twice in sucrose washing buffer. Nuclei were resuspended in high-salt buffer (20 mmol/L HEPES at pH 7.9, 1.5 mmol/L MgCl$_2$, 440 mmol/L NaCl, 0.2 mmol/L EDTA, 25% glycerin, 5 mmol/L NaF, 0.1 mmol/L PMSF, 0.5 mmol/L leupeptin, 0.5 mmol/L pepstatin, 5 mmol/L aprotinin, and 1 mmol/L DTT). After incubation on ice for 50 min, nuclei were spun down (14 000 *g*, 15 min, 4℃). Following quantification, protein extracts were stored at -70℃. NF-κB binding activity was performed as described previously[25]. The DNA probe used for EMSA corresponded to the high-affinity kB sequence found in the mouse κ light chain enhancer. Two oligonucleotides (sense 5'-AGCTT-GGGGACTTTCCACTAGTACG-3', antisense 5'-AAT-TCGTACTAGTGGAAAGTCCCCA-3') were annealed to generate a double-stranded probe. Labeling was accomplished by the Klenow fragment of DNA polymerase I in the presence of dGTP, dCTP, dTTP and α[^{32}P] dATP. After labeling, the probe was added to 5 μg nuclear protein and 5 μg poly-dI-dC (Pharmacia Biotech Enzyme GmbH, Freiburg, Germany). Binding reactions were carried out in 10 mmol/L Tris-HCl (100 mmol/L NaCl, and 4% glycerol, pH 7.5) for 30 min on ice. DNA-protein complexes were resolved by electrophoresis in a 4% non-denaturing polyacrylamide gel. Monoclonal antibodies raised against various NF-κB subunits (p50, p52, rel A/p65, C rel, and rel B; Santa Cruz Biotechnology, Heidelberg, Germany) were used to confirm the nature of the DNA-protein complex. Competition assay was performed using unlabeled κB probe in 10- 50- and 100-fold concentrations[25].

Statistical analysis
Results are expressed as mean ± SE of at least five independent experiments (*N* = 5) measured in triplicates (*n* = 3). Data sets were compared by Kruskal-Wallis followed by Dunn's multiple comparison test (GraphPad Prism software; El Camino Real, Sunnyvale, CA USA). *P* < 0.05 was taken as minimum level of significance.

Figure 1 Pre-stimulation with growth factors significantly reduces cellular damage induced by lipopolysaccharide-containing cytokine mixture. Primary rat hepatocytes (*N* = 5, *n* = 3) treated with lipopolysaccharide (LPS)-containing cytokine mixture (CM) for 24 h showed a slight increase in aspartate aminotransferase (AST) leakage into the culture supernatant. Co-incubation with the hepatocyte growth factor (HGF), epidermal growth factor (EGF) and transforming growth factor (TGF)-α, individually or in combination, did not reduce AST leakage significantly (empty bars). However, preincubation with these hepatotropic growth factors resulted in a significant reduction in AST leakage (grey bars). [a]*P* < 0.05, [b]*P* < 0.005 *vs* corresponding rat hepatocytes treated with LPS-containing CM alone.

RESULTS

Measurement of AST leakage in rat hepatocytes pre- and co-treated with growth factors
Incubation of primary rat hepatocytes (*N* = 5, *n* = 3) with LPS-containing CM led to a slight increase in AST levels in the culture supernatant (30.0 ± 8.0 to 36.0 ± 5.6 U/L and 45.0 ± 6.0 to 50.0 ± 8.0 U/L). Co-incubation with growth factors (20 ng/mL HGF, 30 ng/mL EGF and/or 20 ng/mL TGF-α) individually or in combination did not reduce AST leakage (Figure 1, empty bars). However, preincubation with growth factors significantly reduced AST leakage in cells treated with LPS-containing CM (Figure 1, grey bars).

Determination of reactive oxygen intermediate levels in rat hepatocytes co-treated with growth factors
Incubation of primary rat hepatocytes (*N* = 5, *n* = 3) with the LPS-containing CM slightly increased reactive oxygen intermediate (ROI) production (63.0 ± 6.7 to 80.0 ± 9.0 pmol O$_2^-$/min every 10^5 cells), while the intracellular glutathione levels were not notably affected as compared to untreated controls. Co-incubation with all growth factors combined slightly reduced ROI levels (Figure 2A and B, empty bars).

Determination of cellular GSH from rat hepatocytes pretreated with growth factors
Rat hepatocytes (*N* = 5, *n* = 3) were pretreated with growth factors 12 h prior to incubation with LPS-containing CM. As observed before, LPS-containing CM

Figure 2 Increased oxidative stress in rat hepatocytes treated with lipopolysaccharide-containing cytokine mixture. A: Treatment of primary rat hepatocytes (N = 5, n = 3) with lipopolysaccharide (LPS)-containing cytokine mixture (CM) for 24 h caused a slight increase in O_2^- production. B: Cellular glutathione levels were not significantly affected by this treatment. Co-incubation with single hepatocyte growth factor (HGF), epidermal growth factor (EGF) or transforming growth factor (TGF)-α did not reduce reactive oxygen intermediate (ROI) production significantly. Co-incubation with the hepatotropic growth factor mixture alone was able to reduce ROI production significantly. Furthermore, co-incubation with the growth factors did not alter cellular glutathione levels (empty bars). On the other hand, preincubation with these growth factors, individually or in combination, significantly reduced ROI production (except for pretreatment with HGF alone). Preincubation with the different growth factors increased cellular glutathione significantly (grey bars). [a]P < 0.05, [b]P < 0.001 *vs* corresponding rat hepatocytes treated with LPS-containing CM alone.

Figure 3 Hepatotropic growth factors increase nitric oxide formation in primary rat hepatocytes. NO_2^- plus NO_3^- (empty bars) and RSNO (grey bars) levels demonstrated a significant increase after hepatocyte (N = 5, n = 3) pretreatment with growth factors and subsequent stimulation with lipopolysaccharide (LPS)-containing cytokine mixture (CM), if compared to treatment with LPS-containing CM alone [except for pretreatment with hepatocyte growth factor (HGF) alone]. [a]P < 0.05, [b]P < 0.005, [c]P < 0.001 *vs* corresponding untreated rat hepatocytes; [d]P < 0.05, [e]P < 0.005, [f]P < 0.001 *vs* corresponding rat hepatocytes treated with LPS-containing CM alone. NO: Nitric oxide; EGF: Epidermal growth factor; TGF: Transforming growth factor.

slightly increased ROI production (65.0 ± 6.7 to 70.0 ± 7.0 pmol O_2^-/min every 10^5 cells) without a notable effect on intracellular glutathione levels (Figure 2A and B, grey bars). However, pretreatment with growth factors, both individually or in combination, significantly reduced ROI production by subsequent stimulation with LPS-containing CM. At the same time, intracellular glutathione levels were significantly increased. This goes along with the reduction in AST leakage observed with growth-factor-pretreated cells (Figure 1, grey bars). Combination of all three growth factors did not further decrease ROI production or increase intracellular glutathione compared to

treatment with single growth factors. Pretreatment with HGF alone was not able to reduce ROI production by subsequent stimulation with LPS-containing CM.

Determination of NO_2^-, NO_3^- and S-nitrosothiol formation in rat hepatocytes pretreated with growth factors
Incubation of hepatocytes (N = 5, n = 3) with the LPS-containing CM led to a significant increase in NO production as compared to untreated controls. Formation of stable end products of NO oxidation (NO_2^- and NO_3^-) and S-nitrosothiols was even more increased in hepatocytes pretreated with growth factors when subsequently stimulated with LPS-containing CM. Pretreatment with HGF alone did not further increase NO_2^-, NO_3^- and S-nitrosothiols compared to stimulated cells without pretreatment (Figure 3). This was in accordance with the lack of reduction of ROIs under the same conditions.

Determination of NF-κB activation in rat hepatocytes stimulated with LPS-containing CM pretreated with or without growth factors
Rat hepatocytes, with and without pretreatment with growth factors, were stimulated with LPS-containing CM. NF-κB activation was measured at 0.5, 1, 2, 3 and 6 h after stimulation by EMSA. NF-κB was markedly increased 6 h after stimulation with LPS-containing CM (Figure 4A). Pretreatment with the combined or individual growth factors did not further increase NF-κB activation (Figure 4B). Moreover, growth factors alone (without LPS-containing CM) were not able to cause NF-κB expression (Figure 4B). The competition assay

using an excess of unlabeled κB probes demonstrated the specificity of the signal (Figure 4C).

DISCUSSION

Recovery after partial hepatectomy requires an adequate interplay between hepatotropic growth factors and cytokines, as both factors are markedly involved and obviously well-balanced in the process of residual liver tissue proliferation and regeneration[26,27]. In this context, it has been reported that IL-6 plays a crucial role for regeneration, because it is supposed to prime remnant hepatocytes, in a way that they can fully respond to growth factors and enter a pre-replicative phase (G1)[26-28]. However, in our earlier studies, we have found that addition of IL-6 to hepatocyte cultures does not alter ROI or nitrogen oxide intermediate production in the presence of other inflammatory cytokines. When using the mentioned growth factors, there was also a lack of significant alterations in ROIs, and intracellular glutathione was seen. This suggests that growth factors have no direct impact on radical formation, cellular injury and/or cellular antioxidative protection systems.

Under septic or inflammatory conditions, as in the case of any infectious post-operative complication, when both plasma HGF and inflammatory cytokine levels are increased[29-31], cytokine and growth factor compositions might be different. Indeed, increased cytokine levels and protein--protein interactions may have positive and negative effects on liver regeneration[32,33]. Thus, IL-1β is markedly expressed during inflammation, and acts as a very potent inhibitor of hepatocyte proliferation[34]. Clinically observed, severe infections may seriously affect the post-operative course after liver resection, which results in an increased incidence of liver insufficiency and patient loss[6,35,36].

Obviously, cytokines and growth factors act in a well-balanced process under normal regenerative conditions. To gain a better understanding of the avoidance of the deleterious effects of postoperative infectious complications following liver resection, the interplay of growth factors and cytokines was a focus or our attention.

As cytokine reduction is hard to achieve if inflammation has already occurred, we focused our analysis on the effects of hepatotropic growth factor (pre)treatment in hepatocytes exposed to an inflammatory LPS-containing CM.

In the present study, we could demonstrate that growth factors, namely HGF, EGF and/or TGF-α may positively influence influenced cytokine-induced hepatocellular injury. In pre-treated hepatocytes, we found increased NO levels, while the expression of NF-κB was comparable to untreated controls. Our results confirm the study of Kaido *et al*[37] who have reported on successful prevention of post-operative liver failure in cirrhotic rats by continuous HGF supply. They have shown that rats with HGF-secreting fibroblasts (genetically modified to secret rat HGF and implanted in syngeneic rat spleen 7 d prior to exposition exposure of to hepatotoxins)

Figure 4 No additional nuclear factor-κB activation by hepatotropic growth factors. Electrophoretic mobility shift assay for nuclear factor (NF)-κB after hepatocyte pretreatment with hepatotropic growth factors and subsequent stimulation with lipopolysaccharide (LPS)-containing cytokine mixture (CM) demonstrated that stimulation with growth factors combined (A) or individually (B) did not further increase NF-κB expression when compared to stimulation with LPS-containing CM alone. Super shift and competition analysis (C) of NF-κB. HGF: Hepatocyte growth factor; EGF: Epidermal growth factor; TGF: Transforming growth factor.

showed a dramatic resistance to carbon tetrachloride- and LPS-induced liver injury, which resulted in a significantly improved survival rate (80% *vs* 20%). In the same line of evidence, Kosai *et al*[38] have shown that HGF treatment 6 h and 30 min before and 3 h after intra-peritoneal LPS administration resulted in a significant increase of survival in mice (75% *vs* 0%). Although not focusing on patho-physiological interactions of HGF and cytokines, they clearly described HGF-related hepatic protection in case of severe endotoxemia[37,38].

Although several mechanisms may lead to hepatocyte injury, oxidative stress with increased radical formation as a consequence of inflammation, sepsis or ischemia-reperfusion, plays an important role. Intracellular antioxidative systems, e.g. p38-mitogen activated protein kinase or p21 may protect the cells, but they also decrease the hepatocyte proliferation rate by inhibiting hepatic DNA synthesis during the late G1 phase[39,40]. Other intracellular antioxidative systems include upregulation of enzymes e.g. heme oxygenase-1 by NF-κB[41]. We hypothesize that increased glutathione synthesis reduces the amount of cytotoxic radical formation. As further mechanisms improve oxygen supply, subsequent NO-dependent vasodilatation may contribute to the growth-factor-related protection of rat hepatocytes during sepsis. This could explain the results of Seto *et al*[42] who have observed that HGF pretreatment attenuates LPS-induced sinusoidal endothelial cell injury and intra-sinusoidal fibrin deposition.

However, further studies are required because this kind of cell protection was present only in hepatocyte pretreatment. Indeed, direct stimulation of rat hepatocytes with growth factors had no impact on intracellular ROI levels, glutathione content or AST levels under septic conditions.

Nevertheless, this aspect could provide new therapeutic options in case of partial hepatectomy. Pretreatment with hepatotropic growth factors may potentially decrease the incidence of postoperative liver insufficiency in patients undergoing extended liver resection, and subsequent infectious complications by shifting the postoperative course towards growth-factor-related liver tissue proliferation rather than cytokine-related cellular injury.

COMMENTS

Background
The exact mechanisms and interactions of the regenerative process in the liver after partial hepatectomy remain unclear. The well-balanced interplay of liver growth factors and cytokines is strongly interfered when any infectious post-operative complications occur. This effect leads to higher mortality *via* radical formation.

Research frontiers
The deleterious effects of postoperative infectious complications following liver resection have not been examined adequately. In particular, the interplay of pretreated growth factors and cytokines was studied.

Innovations and breakthroughs
The main reason for increased survival of growth-factor-pre-treated hepatocytes is the intracellular antioxidative system that prevents cell-damaging radical formation. Nitric oxide production during sepsis especially increases cell survival.

Applications
Pretreatment with hepatotropic growth factors can be a new therapeutic option

in case of patients undergoing extended liver resection and may potentially decrease the incidence of postoperative liver insufficiency.

Terminology
Partial hepatectomy describes the process by which tumors are surgically removed from the liver. Cytokines are regulatory proteins that are released by cells of the immune system and act as mediators in the generation of an immune response.

Peer review
This paper is interesting and reports a large number of experiments. The methodology is well described and the results are clearly shown.

Abstract

AIM: To determine if liver stiffness (LS) measurements by means of transient elastography (TE) correlate with the presence of significant esophageal varices (EV) and if they can predict the occurrence of variceal bleeding.

METHODS: We studied 1000 cases of liver cirrhosis divided into 2 groups: patients without EV or with grade 1 varices (647 cases) and patients with significant varices (grade 2 and 3 EV) (353 cases). We divided the group of 540 cases with EV into another 2 subgroups: without variceal hemorrhage (375 patients) and patients with a history of variceal bleeding (165 cases). We compared the LS values between the groups using the unpaired t-test and we established cut-off LS values for the presence of significant EV and for the risk of bleeding by using the ROC curve.

RESULTS: The mean LS values in the 647 patients without or with grade 1 EV was statistically significantly lower than in the 353 patients with significant EV (26.29 ± 0.60 kPa *vs* 45.21 ± 1.07 kPa, *P* < 0.0001). Using the ROC curve we established a cut-off value of 31 kPa for the presence of EV, with 83% sensitivity (95% CI: 79.73%-85.93%) and 62% specificity (95% CI: 57.15%-66.81%), with 76.2% positive predictive value (PPV) (95% CI: 72.72%-79.43%) and 71.3% negative predictive value (NPV) (95% CI: 66.37%-76.05%) (AUROC 0.7807, *P* < 0.0001). The mean LS values in the group with a history of variceal bleeding (165 patients) was statistically significantly higher than in the group with no bleeding history (375 patients): 51.92 ± 1.56 kPa *vs* 35.20 ± 0.91 kPa, *P* < 0.0001. For a cut-off value of 50.7 kPa, LS had 53.33% sensitivity (95% CI: 45.42%-61.13%) and 82.67% specificity (95% CI: 78.45%-86.36%), with 82.71% PPV (95% CI: 78.5%-86.4%) and 53.66% NPV (95% CI: 45.72%-61.47%) (AUROC 0.7300, *P* < 0.0001) for the prediction of esophageal bleeding.

CONCLUSION: LS measurement by means of TE is a reliable noninvasive method for the detection of EV and for the prediction of variceal bleeding.

INTRODUCTION

Transient elastography (TE) is a new promising noninva-

sive and rapid method for the diagnosis and quantification of liver fibrosis in patients with chronic liver disease. It was originally developed to detect solid malignancies in soft tissues such as breast cancer and prostate cancer[1]. Liver stiffness (LS) measurement using TE is reproducible and independent of the operator[2]. Some recent extensive studies have demonstrated that LS measurement with TE is a good alternative for liver biopsy. The amount of fibrosis can be quantified very easily and reliably and is feasible in more than 95% of the patients[3-5]. In cirrhotic patients, LS measurements range from 12.5 to 75.5 kPa. However, the clinical relevance of these values is unknown.

The risk of variceal hemorrhage is clearly related to the size of esophageal varices (EV). Therefore primary prevention of variceal bleeding applies in patients with previously diagnosed large EV (grade 2 or 3) detected by periodical upper digestive endoscopy [Baveno V and American Association for the Study of Liver Diseases (AASLD) Consensuses][6,7]. A generalized program of periodical upper tract endoscopy in these patients might result in a heavy economic burden even for developed countries. Furthermore, repeated examinations, when not performed under profound sedation, are often poorly accepted by patients who may refuse further follow up.

TE may be used to predict the presence of portal hypertension. LS measurement may allow prediction of the presence of large EV in patients with cirrhosis and may help to select patients for endoscopic screening[8-11].

The purpose of this study was to determine if TE can be used to predict indirectly the presence of portal hypertension and the risk of variceal bleeding. At present the Baveno V and AASLD Consensuses recommend screening all cirrhotic patients for EV. If LS measurement could predict the presence of large EV in patients with cirrhosis, we could select these patients for endoscopic screening.

MATERIALS AND METHODS

We studied 1000 consecutive patients with liver cirrhosis. Patients with hepatocellular carcinoma were excluded. In all patients, upper digestive endoscopy was performed by 10 experienced endoscopists (at least 300 upper digestive endoscopies performed). The time interval between endoscopy and TE evaluation was less than three months. EV were classified as: small (grade I) - small straight varices; medium (grade II) - enlarged tortuous varices occupying less than one third of the lumen; large (grade III) - large coil-shaped varices occupying more than one third of the lumen.

In accordance with EV diagnosed on endoscopy and the history of variceal bleeding we divided this batch into 2 groups: Group V0,1 - without EV and patients with grade 1 varices (647 cases); Group V2,3 - with significant portal hypertension (grade 2 and 3 EV) (353 cases).

We selected only those cases with EV and we divided them into 2 groups: Group no upper digestive bleeding (UDB) - without variceal hemorrhage (375 patients) and

Group UDB - (165 cases) with variceal bleeding.

In all patients we performed LS measurement by TE using a FibroScan device (Echosens, Paris). Measurements were performed in the right lobe of the liver through the intercostal spaces, on patients lying in the dorsal decubitus position with the right arm in maximal abduction. The tip of the transducer probe was covered with coupling gel and placed on the skin, between the rib bones at the level of the right lobe of the liver. The operator, assisted by an ultrasonic time-motion image, located a liver portion of at least 6 cm thick, free of large vascular structures. Once the measurement area had been located, the operator pressed the probe button to start an acquisition. Measurement depth was between 25 mm and 65 mm below the skin surface. Measurements which did not had a correct vibration shape or a correct follow up of the vibration propagation were automatically rejected by the software. Ten successful measurements were performed on each patient. The success rate (SR) was calculated as the ratio of the number of successful measurements over the total number of acquisitions. The results are expressed in kilopascal (kPa). The median value of the successful measurements was kept as representative of LS. Only LS measurements obtained with at least 10 successful measurements, with a SR of at least 60% and an IQR < 30% (IQR, the interquartile range interval, is the difference between the 75th and the 25th percentile, essentially the range of middle 50% of the data) were considered reliable.

Both the endoscopist and FibroScan operator were blinded to the result of TE evaluation and endoscopic evaluation of EV, respectively.

For a statistical study of quantitative variables, the mean and standard variation were calculated. T-tests were performed to compare mean values of LS in various subgroups. The diagnostic performance of LS measurements was assessed by using receiver operating characteristics (ROC) curves. ROC curves were thus built for the detection of various grades of EV and for predicting the risk of variceal bleeding. Optimal cut-off values for LS measurements were chosen to maximize the sum of sensitivity and specificity.

The statistical analysis was performed using Microsoft Excel (Microsoft Office 2007) and GraphPad Prism 5 programs.

RESULTS

The mean LS values in the 647 patients without or with grade 1 EV were statistically significantly lower than in the 353 patients with significant EV (26.29 ± 0.60 kPa *vs* 45.21 ± 1.07 kPa, $P < 0.0001$) (Figure 1).

Using the ROC curve we established a cut-off value of 31 kPa for the presence of significant EV, with 83% sensitivity (95% CI: 79.73%-85.93%) and 62% specificity (95% CI: 57.15%-66.81%), with 76.2% positive predictive value (PPV) (95% CI: 72.72%-79.43%) and 71.3% negative predictive value (NPV) (95% CI: 66.37%-76.05%)

Figure 1 Mean liver stiffness values in patients with no or grade 1 esophageal varices as compared to those with significant esophageal varices (grade 2 and 3). Whiskers = minimum and maximum. EV: Esophageal varices.

Figure 3 Mean liver stiffness values in patients with upper digestive bleeding due to variceal bleeding as compared to those without upper digestive bleeding. Whiskers = minimum and maximum. UDB: Upper digestive bleeding.

Figure 2 Predictive value of liver stiffness for the presence of at least grade 2 esophageal varices. ROC: Receiver operating characteristic.

Figure 4 Predictive value of liver stiffness for upper digestive bleeding due to variceal bleeding. UDB: Upper digestive bleeding.

(AUROC 0.7807, $P < 0.0001$) (Figure 2).

The mean LS values in the group with a history of variceal bleeding (165 patients) were statistically significantly higher than in the group with no bleeding history (375 patients): 51.92 ± 1.56 kPa *vs* 35.20 ± 0.91 kPa, $P < 0.0001$) (Figure 3).

For a cut-off value of 50.7 kPa, LS had 53.33% sensitivity (95% CI: 45.42%-61.13%) and 82.67% specificity (95% CI: 78.45%-86.36%), with 82.71% PPV (95% CI: 78.5%-86.4%) and 53.66% NPV (95% CI: 45.72%-61.47%) (AUROC 0.7300, $P < 0.0001$) (Figure 4).

DISCUSSION

In previous studies, LS values < 19 kPa were highly predictive of the absence of significant EV ($\geqslant$ grade 2), the cut off values for the presence of grade 2 and 3 EV ranging from 27.5 to 35 kPa, and the cut off value for esophageal bleeding being 62.7 kPa[12-14].

In other studies, LS measurement by TE was not accurate for the prediction of EV, with AUROC ranging from 0.76 to 0.84. Although sensitivity was good (71%-96%), specificity and PPV were low (60%-80% and 48%-54%, respectively) and overall accuracy was inferior as compared to simple tests like platelet count/spleen

diameter ratio[11]. Another problem arising from these studies is the wide range of proposed cut offs, varying from 13.9 to 21.3 kPa for all varices, from 19 to 30 kPa for grade 2 varices and from 55 to 63 kPa for bleeding varices. The optimal cut offs therefore are still to be defined[15,16].

Foucher *et al*[13] (2006) assessed the accuracy of TE for the detection of large EV and the risk of variceal bleeding in patients with chronic liver disease. For the presence of EV grade 2 and 3, and esophageal bleeding, the cut offs were 27.5 and 62.7 kPa, respectively. The authors concluded that TE use for the follow-up and management of these patients could be of great interest and should be evaluated further.

Rudler *et al*[17] reported their data on consecutive patients admitted to the intensive care unit with variceal hemorrhage who underwent hepatic venous pressure gradient (HVPG) measurement and TE. With an HVPG cut off > 20 mmHg (HVPG > 20 mmHg is an independent predictor of death in patients with cirrhosis and variceal bleeding), 8 patients were enrolled, but 4 could not undergo elastography because of severe ascites. Correlation between LS and HVPG was poor. The authors concluded that TE is unlikely to be of utility in this patient popula-

tion.

Klibansky *et al*[18] was more successful in describing a useful application of TE to predict clinical outcomes in cirrhosis. Clinical endpoints were defined as the development of ascites or encephalopathy, variceal bleeding, development of hepatocellular carcinoma, or liver transplantation. Multivariate analysis indicated that the only independent predictors of outcome were Child-Pugh score and LS.

In 2009, Castéra *et al*[19] showed that TE could be a valuable tool for the diagnosis of cirrhosis but cannot replace endoscopy for variceal screening.

Another study assessed the correlation between LS with FibroScan and HVPG in diagnosing significant portal hypertension in 150 patients who underwent a liver biopsy and hemodynamic measurements. In patients with significant portal hypertension (HVPG > 10 mmHg), AUROC for FibroScan was 0.945. The cut off value of 21 kPa accurately predicted significant portal hypertension in 92% of patients for whom measurements were successful[20].

Due to the controversial results of all the studies described above we wanted to evaluate the value of TE for the prediction of EV and for the risk of bleeding in our patients.

The results of our study showed that TE is a useful technique for evaluating the presence of EV and hemorrhage prediction in cirrhotic patients. For a cut off value of 31 kPa, negative and PPVs were 76.2% and 71.3%, respectively. For > 31 kPa criterion, the cut off value was chosen to maximize the sum of sensitivity and specificity, whereas for > 40 kPa criterion we chose a cut off value to have a PPV of more than 85% with 77.8% sensitivity (95% CI: 74.57%-80.79%), 68.3% specificity (95% CI: 62.55%-73.68%), 86% PPV (95% CI: 83.18%-88.66%) and 55% NPV (95% CI: 49.60%-60.23%). For a cut-off value of 17.1 kPa, chosen to have a NPV close to 90%, we found the NPV to be 89.3%, with 43.2% PPV, 92.6% sensitivity and 33.5% specificity.

In clinical practice, such results could be of major relevance for the follow up of patients with cirrhosis. Cirrhosis places the patient at risk of clinical complications, such as portal hypertension, and variceal rupture is the second cause of death in cirrhosis, justifying early screening for EV. The usual means of diagnosing EV is upper gastrointestinal endoscopy. However, endoscopy can be considered invasive due to the technique and level of discomfort and the last recent consensus did not recommend endoscopic screening for the evaluation of bleeding risk in patients with grade 2 or 3 EV[6,7]. Non-invasive methods for diagnosis need to be developed.

According to our data, in patients with TE values > 40 kPa at least 8/10 cases will have significant portal hypertension. Therefore it is reasonable to recommend prophylactic β-blocker therapy without endoscopy. On the other hand, in patients with TE values < 40 kPa, 5/10 cases will have significant EV (NPV 54.9%), thus we recommend endoscopic evaluation. Below the cut-off value of 17.1 kPa we do not recommend endoscopic evalua-

tion, since the chance of those patients having significant EV is only 1 in 10 (NPV 89.3%).

In our study we established an LS cut off value of 50.7 kPa for the risk of bleeding. A cut off value higher than 64 kPa correlates with a PPV > 90%, which means that those patients have a very high risk of bleeding despite primary prophylaxis with propranolol, with 77.75% sensitivity (95% CI: 73.64%-81.50%), 72.94% specificity (95% CI: 62.21%-82%), 93.88% PPV (95% CI: 90.96%-96.08%), 38.04% NPV (95% CI: 30.56%-45.96%). This data shows that 9 from 10 cases with TE values above 64 kPa will have variceal bleeding and we recommend prophylactic ligation in patients with LS values of more than 64 kPa.

In conclusion, LS measurement by means of TE is accurate for assessing the presence of large EV and the risk of variceal hemorrhage in cirrhotic patients.

COMMENTS

Background
The risk of variceal hemorrhage is related to the size of esophageal varices (EV). Therefore primary prevention of variceal bleeding applies in patients with previously diagnosed large EV (grade 2 or 3) detected by periodical upper digestive endoscopy. A generalized program of periodical upper tract endoscopy in these patients might result in a heavy economic burden even for developed countries. Furthermore, repeated examinations when not performed under profound sedation are often poorly accepted by patients who may refuse further follow up. Transient elastography (TE) may be used to predict the presence of portal hypertension. Liver stiffness (LS) measurement by means of TE may allow prediction of the presence of large EV in patients with cirrhosis and may help select patients for endoscopic screening

Research frontiers
TE may be used to predict the presence of portal hypertension. LS measurement may allow prediction of the presence of large EV in patients with cirrhosis and may help to select patients for endoscopic screening. The purpose of this study was to determine if TE can be used to predict indirectly the presence of portal hypertension and the risk of variceal bleeding. Currently, the Baveno V and AASLD Consensuses recommend screening all cirrhotic patients for EV. If LS measurement could predict the presence of large EV in patients with cirrhosis, we could select these patients for endoscopic screening.

Innovations and breakthroughs
The study showed that, in patients with TE values > 40 kPa at least 8/10 cases will have significant portal hypertension. Therefore it is reasonable to recommend prophylactic β-blocker therapy without endoscopy. In patients with TE values < 40 kPa, 5/10 cases will have significant EV [negative predictive value (NPV) 54.9%], thus endoscopic evaluation is mandatory. Below the cut-off value of 17.1 kPa endoscopic evaluation is not recommended, since the chance of those patients having significant EV is only 1 in 10 (NPV 89.3%). The research team established a LS cut off value of 50.7 kPa for the risk of bleeding. A cut off value higher than 64 kPa correlates with a positive predictive value > 90%, which means that those patients have a very high risk of bleeding despite primary prophylaxis with propranolol. The data shows that 9 from 10 cases with TE values above 64 kPa will have variceal bleeding and they recommend prophylactic ligation in patients with LS values of more than 64 kPa.

Applications
The authors recommend prophylactic β-blocker therapy without endoscopy in all patients with LS measurements > 40 kPa. In patients with LS measurements between 17.1 kPa and 40 kPa, considered to be "the grey zone", we recommend endoscopic evaluation of EV. Below the cut-off value of 17.1 kPa, endoscopic evaluation is not recommended since the chance of those patients to have significant EV is only 1 in 10 (NPV 89.3%). In patients with LS measurements higher than 64 kPa we recommend prophylactic band ligation of EV.

Terminology
TE is a new promising noninvasive and rapid method for the diagnosis and

quantification of liver fibrosis in patients with chronic liver disease. Some recent extensive studies have demonstrated that LS measurement by means of TE is a good alternative for liver biopsy. In cirrhotic patients, LS measurements range from 12.5 to 75.5 kPa.

Peer review

This is a nice study on the important topic of the non invasive diagnosis of large EV. Its strengths are in its size and what appears to be reliable data from TE.

Abstract

AIM: To study intestinal permeability (IP) and its relationship to the disease activity in patients with inflammatory bowel diseases (IBD) - Crohn's disease (CD) and ulcerative colitis (UC).

METHODS: Fifty-eight patients with active IBD (32 with CD and 26 with UC) and 25 healthy controls consented to participate in the study. The clinical activity of CD was estimated using the Crohn's Disease Activity Index (CDAI), and the endoscopic activity of UC using the Mayo scoring system. IP was assessed by the rise in levels of iohexol, which was administered orally (25 mL, 350 mg/mL) 2 h after breakfast. Three and six hours later serum (SIC mg/L) and urine (UIC g/mol) iohexol concentrations were determined by a validated HPLC-UV technique.

RESULTS: In the CD group, SIC values at 3 h (2.95 ± 2.11 mg/L) and at 6 h after ingestion (2.63 ± 2.18 mg/L) were significantly higher compared to those of healthy subjects (1.25 ± 1.40 mg/L and 1.11 ± 1.10 mg/L, respectively, $P < 0.05$). UIC (g/mol) values were also higher in patients, but the differences were significant only for UIC at 6 h. Significant positive correlation ($P < 0.05$) was found between the CDAI and IP, assessed by SIC at 3 h ($r = 0.60$) and 6 h ($r = 0.74$) after the ingestion. In comparison to controls, SIC and UIC of UC patients were higher in the two studied periods, but the differences were significant at 6 h only. Significantly higher values of SIC ($P < 0.05$) were found in patients with severe endoscopic activity of UC compared to those of patients with mild and moderate activity (3.68 ± 3.18 *vs* 0.92 ± 0.69 mg/L).

CONCLUSION: Serum levels of iohexol at 3 h and 6 h after its ingestion reflect increased IP, which is related to the disease activity in patients with IBD.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC), the two

principal forms of inflammatory bowel disease (IBD), are characterized by a chronic inflammation of the gastrointestinal tract. Over the past decade there has been increasing recognition of the importance of both epithelial barrier function and innate immunity in the genesis of intestinal inflammation[1-5].

Mucosal barrier function in IBD has been investigated in numerous studies and many of them, but not all[6], have demonstrated increased intestinal permeability (IP) in some of the patients[7-11]. Alterations of IP can be evaluated using several different probes such as disaccharides (lactulose, cellobiose), monosaccharides (mannitol), polyethylenglycols of different molecular mass and ^{51}Cr-ethylenediamine-tetraacetate (^{51}Cr-EDTA). Studies have utilized different methods for the assessment of permeability, both in regard to administration procedures of the different probes and to outcome measures[12,13].

So far, IP assessment in patients has been performed by measuring urine recovery of ingested permeability substrates. The urine test can be relatively uncomfortable and can lead to potential inaccuracy[14,15] due to incomplete urine collection, renal dysfunction and variable hydration status of the tested subjects. In addition, some analytical difficulties in quantifying carbohydrates in urine have limited the widespread use of those permeability markers. Furthermore, urinary tract infections may compromise the recovery of sugar permeability markers[16]. Measurement of the permeability substrates in plasma or serum could eventually reduce the problems with urine recovery and could potentially have a valuable role, particularly in pediatric patients.

The aim of the present study was to evaluate IP in patients with active IBD (CD and UC) by measuring serum and urine levels of water-soluble contrast medium iohexol, to assess the relationship of IP to the disease activity, and to compare the reliability of serum *vs* urine levels of iohexol as an IP disease marker.

MATERIALS AND METHODS

Patients and controls

The study included 58 patients with active IBD: 32 patients with CD (16 males, 16 females, mean age 38.9 years: range 18-70 years) and 26 patients with UC (11 males, 15 females, mean age 41.5 years: range 21-70 years), hospitalized in the Clinical Centre of Gastroenterology, University Hospital Queen Joanna, Sofia. Diagnosis was based on the commonly accepted clinical, endoscopic and histological criteria. Disease activity of CD patients was estimated using the Crohn's Disease Activity Index (CDAI); values greater than 150 were accepted as a marker for clinical activity[17]. The endoscopic activity (EA) of UC was assessed using the Mayo scoring system (findings on endoscopy): 0: normal or inactive disease; 1: mild disease (erythema, decreased vascular pattern, mild friability, erosions); 2: moderate disease (marked erythema, lack of vascular pattern, friability); 3: severe disease (spontaneous bleeding, ulceration) (Table 1). CD patients were divided in two subgroups with regard to the endoscopic activity score: "EA

Table 1 Characteristics of patients with Crohn's disease and ulcerative colitis

Variables	CD (n = 32)	UC (n = 26)
Males/females	16/16	11/15
Age (yr), mean (range)	38.9 (18-70)	41.5 (21-70)
Duration of the disease (yr), mean (range)	6 (1-31)	6 (1-26)

Severe (EA 3)		15

GI: Gastrointestinal; UGIT: Upper gastrointestinal tract; CDAI: Crohn's Disease Activity Index.

3" - severe and "EA 1+2" - mild and moderate endoscopic activity.

The location and behavior of CD, and extent and severity of UC, were classified using the modified Montreal classification[18]. According to CDAI, all CD patients had active disease (CDAI > 150). All patients with UC had endoscopic features of an active disease. Twenty-five healthy persons (18 males, 7 females, mean age 40.6 years: range 25-68 years) were recruited as a control group. None of them had signs or symptoms of gastrointestinal disorders or renal diseases. None of the investigated subjects took alcohol, non-steroidal anti-inflammatory drugs or any other medications (antidepressants, anticholinergics, metoclopramide, lactulose) that have the potential to affect gastrointestinal motility, for at least 2 wk before the test. Renal function, assessed by serum creatinine levels and calculated Glomerular Filtration Rate, was normal in all investigated subjects (Table 1).

The study was approved by the Ethics Committee of University Hospital Queen Joanna. Written informed consent was obtained from all patients and control subjects.

Assessment of the IP

Iohexol (Omnipaque™, Nycomed-General Electric) was administered orally (25 mL of 350 mg/mL injection solution) in the morning, 2 h after breakfast, immediately after voiding. Drinking was not allowed for the next 3 h. Food was permitted after 5 h. Blood and urine samples

were collected at 3 and 6 h after the iohexol ingestion. Serum was separated within 45 min after the blood withdrawal by centrifugation at 1 500 *g* for 10 min. Serum and urine were kept frozen at -20°C until analysis. Iohexol concentrations were determined by a validated high pressure liquid chromatography technique. Briefly, sample preparation consisted of protein precipitation; separation was performed on a C8 column with a mobile phase of 5% aqueous acetonitrile and detection at 240 nm. Selectivity was confirmed by comparing the signal in blank and spiked samples in 12 individual sources of human serum and urine. Accuracy and precision (within-run and between-runs) were within 12%; extraction recovery was over 90%; linearity range was 0.25-10.00 mg/L for serum samples and 2.50-700.00 mg/L for urine samples; $R^2 > 0.998$. Stability was also validated accordingly. Urine results were presented as iohexol/creatinine ratios (g/mol). Results of the control group (mean + 2SD) were used as a cut-off level for increased IP at 95% confidence interval, and values exceeding that cut-off were considered abnormal.

Statistical analysis

Statistical methods used: descriptive statistics, nonparametric ANOVA (Kruskal-Wallis test), nonparametric Mann-Whitney *U* test for overall testing the difference between subject groups, nonparametric Wilcoxon test for the difference between pairs of groups, Pearson's test (*r*) for correlation. Each hypothesis was tested at a level of significance of 0.05.

RESULTS

All permeability tests were well tolerated and no side effects were reported. Based on the results obtained from healthy subjects, values of SIC over 4.0 and 3.3 mg/L at 3 and 6 h respectively, as well as values of UIC over 35.5 and 31.4 g/mol at 3 and 6 h after ingestion, were accepted as abnormal (cut-offs). One control subject had slightly increased IP at 3 h, and two control subjects at 6 h, post-iohexol ingestion.

The results from applied Kruskal-Wallis test showed that the factor "group" is significant ($P < 0.05$). Mann-Whitney *U* test results indicated that in the group of CD patients the mean values of SIC at 3 h (2.95 ± 2.11 mg/L) and at 6 h (2.63 ± 2.18 mg/L) post-ingestion were significantly higher than those in the control group (1.25 ± 1.40 mg/L and 1.11 ± 1.10 mg/L, respectively). Abnormal IP was found in 10 patients at 3 h (31%) and in 16 patients at 6 h (50%) after iohexol intake. Urine recovery of iohexol was also higher in patients 3 h (18.09 ± 13.13 g/mol) and 6 h (36.92 ± 27.68 g/mol) post-ingestion compared to the control group (14.64 ± 10.44 g/mol and 14.18 ± 7.78 g/mol, respectively), but the difference was significant only for the mean UIC values at 6 h.

In the UC group, the mean serum levels (1.57 ± 1.55 mg/L and 2.49 ± 2.80 mg/L) and urine recovery of

Figure 1 Serum Iohexol concentrations (A) and urine Iohexol concentrations (B) (mean ± SE) at 6 h post-ingestion according to Endoscopic Activity Mayo score (EA) of patients with ulcerative colitis. EA3: Severe endoscopic activity; EA 1+2 : Mild and moderate endoscopic activity. [a]*P* < 0.05, SIC and UIC *vs* control group; [b]*P* < 0.05, EA 3 *vs* EA 1+2 group. SIC: Serum Iohexol concentrations; UIC: Urine Iohexol concentrations.

iohexol (9.86 ± 9.26 g/mol and 27.76 ± 25.18 g/mol) at 3 and 6 h after its ingestion, respectively, were higher than those for healthy controls, but the differences were significant only at 6 h for both parameters. IP was established as abnormal in 3 (11%) and 8 (31%) patients with UC at 3 and 6 h post-iohexol ingestion, respectively.

There was a significant positive correlation between the parameters SIC and CDAI in the group of CD patients at 3 h ($r = 0.60$) and at 6 h ($r = 0.74$) post-ingestion, while the correlation between CDAI and UIC was insignificant both at 3 h ($r = 0.48$) and at 6 h ($r = 0.32$) post-ingestion of iohexol.

In the subgroup "EA 3" of patients with severe endoscopic activity of UC ($n=15$), the mean values of SIC at 6 h were significantly higher (3.68 ± 3.18 mg/L), compared to those of the control group (1.11 ± 1.10 mg/L), while the values (0.92 ± 0.69 mg/L) for the patient subgroup "EA 1+2" ($n = 11$) with mild and moderate endoscopic activity did not differ from the controls (Figure 1A). The mean UIC values for patient subgroup "EA 3" at 6 h were also significantly higher (33.60 ± 28.42 g/mol) compared to those of the control group (14.18 ± 7.78 g/mol), and mean UIC values of the subgroup "EA 1+2" (19.78 ± 18.25 g/mol) were slightly but insignificantly higher from the control values (Figure 1B).

The permeability disturbances were five-fold more frequent in the subgroup of patients with severe activity (47%) in comparison to the subgroup of patients with

mild and moderate activity (9%).

DISCUSSION

Altered barrier function in IBD is documented in experimental and clinical studies, but it is difficult to compare the results of IP due to the existing variability in the chemical nature of the chosen candidate markers in the experimental design and methodology. It is considered that the larger molecular weight markers reflect the changes predominantly in paracellular permeability, while smaller ones register transcellular transfer changes. Paracellular permeability across the epithelial cell monolayers is regulated primarily by the tight junctions (TJs) that encircle the apical poles of the epithelial cells[1,7]. The epithelium in the inflamed intestinal segments of patients with CD is characterized by a reduction of the TJ strands, strand breaks, and alterations of the TJ proteins. In patients with UC the epithelial leaks appear early due to micro-erosions resulting from upregulated epithelial apoptosis and in addition to a prominent increase of claudin-2[3]. Immune regulation of the epithelial functions by cytokines may cause a barrier dysfunction not only by the TJ impairments but also by apoptotic leaks, transcytotic mechanisms and mucosal gross lesions[4].

In our study, IP in patients with IBD was examined by measuring of the serum levels and urine recovery of iohexol, following oral administration. Andersen *et al*[19] demonstrated that water-soluble radiographic contrast media could be of use for evaluation of the altered intestinal barrier function. The contrast agent iohexol is a moderately large molecule (molecular weight 821 Dalton) with a low absorption under normal conditions, and enhanced absorption through the inflamed intestinal mucosa. It does not bind to serum proteins and is filtered through the glomerulus without indications of tubular secretion or reabsorption. Until now, to the best of our knowledge, serum levels of iohexol have not been used for the assessment of IP. The results of this study demonstrate that iohexol permeation through the intestinal mucosa is significantly increased in both CD and UC patients. Using different probes, similar findings have also been reported in numerous studies both in adult and pediatric populations with IBD[7-11,20-24]. The findings of this study support the understanding that patients with active IBD (including both CD and UC) have a mucosal barrier dysfunction, which can be assessed by measurement of IP. The permeability alterations were more frequent in CD than in UC patients: increased iohexol absorption as a marker for the abnormal IP was established in 50% of CD and in 31% of UC patients, figures which were significantly more frequent in comparison to the healthy subjects. Taking into account the fact that 3 h after ingestion iohexol is located in the large intestine[7], the higher SIC and UIC at 6 h after ingestion in patients with UC in our research suggest that this test can be used for evaluation of the colon permeability also.

The relationship between increased IP and disease activity in IBD has been established in some studies[9,11,20,21]. IP in CD patients is increased proportionally to the disease activity; it can be used to predict the clinical relapse of the disease (due to subclinical mucosal inflammation) and to assess prognosis[25,26]. However, the data in the literature are contradictory, most probably due to the usage of different permeability probes as mentioned above. Our study demonstrates that the permeation of iohexol through the intestinal mucosa, evaluated by serum concentrations, correlates positively with the disease activity in CD patients. These results are in agreement with data reported by Halme *et al*[7,20] for increased IP of iohexol (measured by its urinary recovery) and its correlation with the clinical disease activity indices. Furthermore, Halme *et al*[27] concluded that the iohexol test is a superior activity marker compared to the lactulose-mannitol test in patients with IBD. We established a relationship between serum levels of iohexol and the endoscopic activity score for UC patients. Using different permeability markers, Miki *et al*[11], Arslan *et al*[23] and Casellas *et al*[24] found a relationship between IP and disease activity in IBD patients. However, other investigators did not establish such a correlation[8,28,29]. Our data for significant positive correlation between iohexol penetration through the intestinal mucosa and disease activity support the hypothesis of the important role of the impaired intestinal barrier in the pathogenesis of active IBD[2,3,5].

In conclusion, the water-soluble contrast medium iohexol is a suitable marker for assessing the gut barrier function as its penetration through the intestinal mucosa is increased in patients with active IBD (both CD and UC) and is related to the disease activity. In our study, serum iohexol concentration appears to be a superior marker of altered IP, compared to urinary iohexol level. Measurement of a single serum sample of iohexol 6 h following its oral administration makes the proposed permeability test more convenient and provides a possibility for the assessment of altered barrier function in both small and large intestine.

COMMENTS

Background

Increased intestinal permeability (IP) has been implicated in the pathogenesis of the inflammatory bowel diseases (IBD). Mucosal barrier function has been investigated by the measuring of urine recovery of ingested permeability substrates, which is relatively uncomfortable and could lead to potential inaccuracy. To clarify the role of barrier dysfunction and to introduce better diagnostic procedure, the authors decided to evaluate IP in patients with active IBD by measuring serum and urine levels of water-soluble contrast medium iohexol, to assess the relationship of IP to disease activity, and to compare the reliability of serum *vs* urine levels of iohexol as an IP disease marker.

Research frontiers

In the present study the relationship between IP and disease activity in patients with active IBD was investigated by using the iohexol test. The findings support the hypothesis that, by affecting the penetration of macromolecules and pathogens, the permeability disorders are linked to intestinal inflammation and play a role in mucosal damage in IBD.

Innovations and breakthroughs

Mucosal barrier function in IBD has been investigated in numerous studies which differ with respect to methods for the permeability assessment, both in

regard to administration procedures of the different probes and to outcome measures. Measurement of permeability substrates in plasma or serum may reduce the problems with urine recovery and might potentially have a valuable role.

Applications

The assessment of permeability alterations with the suitable, easy to perform, and convenient iohexol test provides a platform for therapeutic modulation of the gut barrier function for better control of IBD patients.

Terminology

IP reflects the integrity of the intestinal mucosa to prevent penetration of macromolecules and bacterial antigens from the gut lumen. Tight junctions are continuous, circumferential, belt-like structures that encircle the apical poles of the epithelial cells. They are a key regulator of paracellular permeability across the intestinal epithelium. Iohexol is a non-ionic, water-soluble contrast agent.

Peer review

The authors found that patients with active ulcerative colitis and Crohn's disease had increased serum and urinary concentration of iohexol, indicating disruptive IP. There was a correlation between severity of intestinal leakiness and disease activity. The authors concluded urinary and serum iohexol are acceptable methods of assessing IP. The authors concluded that IP disrupted in patients with active IBD. It is an interesting study and data appear to support the conclusion.

Abstract

AIM: To investigate the preoperative factors that can predict neoplastic polypoid lesions of the gallbladder (PLGs) as well as malignant PLGs.

METHODS: A retrospective analysis was conducted on the 210 consecutively enrolled patients who underwent cholecystectomy due to a PLG larger than 10 mm, as was determined by preoperative trans-abdominal ultrasonography or endoscopic ultrasonography. We analyzed the medical, laboratory, radiologic data and the pathologic results.

RESULTS: In 210 cases, 146 had non-neoplastic polyps (69.5%) and 64 cases were neoplastic polyps (30.5%). An older age ($\geq$ 65 years), the presence of diabetes mellitus (DM) and the size of polyp ($\geq$ 15 mm) were revealed to be independent predictive variables for neoplastic polyps with odd ratios (OR) of 2.27 (P = 0.044), 2.64 (P = 0.021) and 4.94 (P < 0.01), respectively. Among the neoplastic PLGs, an older age ($\geq$ 65 years), the presence of DM and polyp size ($\geq$ 15 mm) were associated with malignancy with ORs of 4.97 (P = 0.005), 6.13 (P = 0.001) and 20.55 (P < 0.001), respectively.

CONCLUSION: Among patients with PLGs larger than 10 mm in size, higher risk groups such as elderly patients more than 65 years old, those with DM or a large polyp size ($\geq$ 15 mm) should be managed by cholecystectomy.

INTRODUCTION

A polypoid lesions of the gallbladder (PLGs) is defined

as any elevated lesion of the mucosal surface of the gall-bladder wall. Sonographers have described PLGs as an image with similar echogenicity as that of the gallbladder wall; the lesion projects into the lumen and it is fixed, lacks displacement, it may or may not have a pedicle and it shows no acoustic shadow on ultrasonography[1-3]. The prevalence of PLGs varies from 0.3% to 12% in healthy adults who undergo abdominal ultrasonography (US)[4-11]. Although the exact prevalence of PLGs is not clear, the detection of PLGs has been increasing according to the more frequent use of abdominal imaging. Most of the PLGs that are without symptoms are non-neoplastic lesions, but a small portion of them are found to be malignant or premalignant neoplasms. The incidence of malignant polyps has varied from 1% to 20% of the resected PLGs among diverse study populations in previous reports[2,12-17]. The largest PLG series was a review of 172 surgically resected cases, and this showed that the most common type of PLG was the cholesterol polyp (62.8%). They also reported that 7% were inflammatory polyps, 7% were hyperplasia, 5.9%% were adenoma, 9.6% were miscellaneous and 7.7% were malignant polyps in the study population[18]. Due to the considerable incidence of malignant polyps among the PLGs, surgical resection, including laparoscopic cholecystectomy, is widely accepted as the treatment of choice for PLGs that are more than 10 mm in size[18]. This surgical treatment guideline has been supported by many previous published reports[14,15,19]. However, the number of non-neoplastic polyps that are unnecessarily resected exceeds more than 3 times the number of neoplastic polyps when the resected polyps are in accordance with the above mentioned guideline[20]. For this reason, some clinicians hesitate to recommend an operation based on this guideline.

Over the last 10 years, several interesting small trials have attempted to determine the endoscopic or transabdominal ultrasonographic features of neoplastic gallbladder polyps, as compared with those of nonneoplastic polyps[10,11,21-23]. However, these sonographic findings have several limitations such as a mixed component of a benign nature, the lack of standardization and interobserver discrepancy[20].

With this background, this study aimed to reveal the clinical and sonographic predictive findings of neoplastic PLGs, including malignant PLGs, in patients who have PLGs larger than 10 mm. We also tried to demonstrate the guidelines for the decision making for the surgical management of incidentally diagnosed gallbladder polyps.

MATERIALS AND METHODS

Patients
We performed a retrospective analysis of the consecutively enrolled patients who were diagnosed with a PLG larger than 10 mm by preoperative trans-abdominal ultrasonography or endoscopic ultrasonography (EUS) between March 1, 2003 and April 30, 2009 at Seoul National University Bundang Hospital. The study protocol

Figure 1 A diagram of the patients' enrollment. PLGs: Polypoid lesions of the gallbladder.

was approved by the Institutional Review Board of our hospital. According to our institution's policy, we recommended cholecystectomy to all patients who had a PLG that was more than 10 mm in size if they were in an operable condition. During the study period, a total of 2281 cases of PLG were diagnosed. Among them, 12 definite adenomyomatosis lesions with a sonographic "comet tail sign" and 20 lesions that were suspected of being gallbladder cancer that had invaded the liver or other adjacent organs were excluded. The 166 cases that did not have sonographic findings available or where polyps were measured by different sonographic equipment were excluded. Among the remaining cases, 1743 patients with small polyps (smaller than 10 mm) and 31 patients who did not undergo an operation were also excluded. Therefore, 210 patients who underwent cholecystectomy were ultimately analyzed in this study (Figure 1).

Based on the final diagnosis of the pathologic reports, all the polyps were divided into 2 groups: the non-neoplastic polyps (chronic cholecystitis, inflammatory polyps, adenomyomatosis, cholesterolosis or cholesterol polyps) and the neoplastic polyps (adenomatous polyps with low grade dysplasia, adenomatous polyps with high grade dysplasia, adenocarcinoma)[24].

The following parameters of all patients were recorded and analyzed: the demographic features, including age, gender, a smoking history, a history of drinking alcohol, the presence of diabetes mellitus (DM), the presence of hypertension, clinical symptoms, measurements of obesity, a complete blood count, a routine chemistry panel, the fasting glucose level and the lipid profiles. The body mass index (BMI) was calculated by dividing the weight in kilograms by the square of the height in meters. Obesity was defined as a BMI > 25 kg/m^2 according to the Asian-Pacific criteria for obesity[25]. Clinical symptoms were defined as abdominal pain that was compatible with biliary colic, such as right upper quadrant pain with or

without radiation pain that becomes aggravated with eating a fatty meal.

The radiologic reports were retrospectively reviewed by one experienced radiologist to describe and record the polyp size, the echogenicity, the echo pattern, the number of lesions, the location of lesion, lesion combined with gallbladder stones, the size change of the lesion and the duration of the size change. The histologic findings of all the resected specimens were retrospectively reviewed by one experienced pathologist.

Equipment and the definition of the sonographic findings

Abdominal sonography was performed by well trained sonographers who used 6-2 MHz cuvelinear transducers with IU 22 or HDI 5000 units (Phillips). An EUS (endoscopic ultrasonogram) was obtained with 7.5-MHz or 12-MHz radial sector scan transducers (EUS-2000, Olympus Optical Co.), and these procedures were performed by 2 well-trained endosonographers. The EUS probe was advanced to the second portion or bulb of the duodenum and the gallbladder was scanned *via* the water-filled balloon method. All the sonographic findings of the patients were reviewed by two experienced radiologists.

The size of the polypoid lesion was measured by assessing the long diameter of the largest polypoid lesion. The echogenicity was determined on the ultrasonogram by comparing it with the echogenicity of the adjacent liver. For some cases that had a severe fatty liver, the echogenicity of the lesion was compared with the echogenicity of the kidney in same ultrasonographic series of the case. We classified the echogenicity into 3 categories: "hypoechoic", "isoechoic" and "hyperechoic". The surface pattern of the polypoid lesions was divided into 2 groups: "smooth" and "nodular"[26]. The internal echo pattern of the polypoid lesions was divided into 2 categories: "homogeneous" and "inhomogeneous". The number of polyps was diveded into 2 categrories: "multiple" and "solitary". The patients with multiple polyps that consisted of both neoplastic and non-neoplastic polyps in one specimen were classified as having neoplastic polyps. The shape of the polypoid lesions was classified to 2 categories: "pedunculated" and "sessile". Hyperechoic spots were defined "a single 1-5 mm, highly echogenic dot", or "partial aggregates of 1-3 mm sized, multiple, highly echogenic spots"[26].

Statistical analysis

Continuous variables are presented as the mean ± SD, and categorical variables are summarized as frequencies and percents. The variables were compared assuming a 95% probability for rejection of the null hypotheses. Fisher's exact test, Pearson's χ^2 test and student's *t*-test were used, when appropriate, to calculate the statistical significance of the different demographic and clinical variables. Multivariate binary logistic regression analysis was performed to determine the significance of the various predictive variables that were found to be significant by univariate

analysis. P values of < 0.05 were deemed as significant. All the statistical analyses were carried out using SPSS 15.0 software (SPSS, Chicago, Illinois, USA).

RESULTS

Clinical and sonograhic characteristics of the patients

Of the 210 patients, 145 had non-neoplastic polyps (69.0%) and 65 had neoplastic polyps (31.0%). The histological diagnosis of the resected PLGs revealed that 54 cases (25.7%) were chronic cholecystitis, 3 cases (1.4%) were inflammatory polyps, 78 cases (37.1%) were cholesterol polyps, 10 cases (4.8%) were adenomayomatosis, 29 cases (13.8%) were adenoma with low grade dysplasia, 6 cases (2.9%) were adenoma with high grade dysplasia and 30 cases (14.3%) were adenocarcinoma.

We compared the clinical and laboratory features between the non-neoplastic polyps group and the neoplastic polyps group. The results are described in Table 1. The mean age, the proportion of DM patients and the mean serum alanine transferase (ALT) level were higher in the neoplastic polyp group than that in the non-neoplastic group ($P < 0.001$, $P < 0.001$, $P = 0.041$, respectively). Yet no significant difference was found for gender, medical history and the other laboratory findings between the two groups.

For the sonographic findings, the mean sonographic diameters of the polyps were 13.5 ± 4.5 mm and 22.1 ± 11.1 mm for the non-neoplastic group and the neoplastic group, respectively ($P < 0.001$). In addition, the inhomogeneous echo pattern ($P = 0.019$), a solitary lesion ($P = 0.002$) and a nodular surface pattern of the polyps ($P < 0.001$) revealed significant correlation with neoplastic polyps (Table 1).

For the detailed analysis, maximum diameter was divided to 2 categories by use of reciever-operator characteristic (ROC) curves. At a cutoff value of 15 mm diameter of PLGs' size, the area under the ROC curve (AUC) had the highest sensitivity and specificity. (70.8%, 75.9%, Figure 2).

Predictive variables for neopalastic PLGs

On the univariate analysis, we obtained several important predictive clinical and sonographic values such as an age > 65 years, the presence of DM, the ALT level, a larger sonographic size (≥ 15 mm), solitary lesions and a nodular sonographic surface pattern (Table 1). On multivariate analysis, an older age (≥ 65 years), the presence of DM and polyp size (≥ 15 mm) were found to be the independent predictive variables for neoplastic polyps [odd ratios (OR) = 2.27, $P = 0.044$, OR = 2.64, $P = 0.021$ and OR = 4.94, $P < 0.001$, respectively]. A nodular surface pattern was found to have an association with neoplastic polyps, with borderline significance (OR = 2.31, $P = 0.058$) (Table 2).

Predictive variables for malignant PLGs

In addition, we subdivided the neoplastic group into two

Table 1 Comparative data for the prevalence of the demographic, laboratory and sonographic findings between the non-neoplastic polyp group and the neoplastic polyp group (mean ± SD) *n* (%)

groups according their histologic results. The polyps that contained adenocarcinoma were classified as the malignant PLGs group and the other neoplastic polyps were classified as the benign PLGs group. We also compared the clinical and sonographic variables to discriminate the malignant PLGs group from the benign group. On univariate analysis, the important predictive clinical and sonographic values for malignant polyps were an older age (≥ 65 years, *P* = 0.02), the presence of DM (*P* < 0.001), the ALT level (*P* = 0.033), a larger sonographic size (≥ 15 mm, *P* < 0.001) and an inhomogeneous echo pattern (*P* = 0.016) (Table 3). But on multivariate analysis, it was observed that an older age (≥ 65 years), the presence of DM and polyp size (≥ 15 mm) had statistical significance

with the malignant PLGs group (OR = 4.97, *P* = 0.005, OR = 6.13, *P* = 0.001, OR = 20.55, *P* < 0.001, respectively) (Table 4).

For a more detailed analysis of the chronological change of the neoplastic polyps, we classified all the cases into three subgroups: the adenoma with low grade dysplasia group; the adenoma with high grade dysplasia group; and the adenocarcinoma group. After this subgroup analysis, we found a linear stepwise increase in the mean age of each groups; adenoma low grade dysplasia, high grade dysplasia and adenocarcinoma. The difference of the mean age was 18.9 years between the adenoma with low grade dysplasia group (46.4 ± 13.4 years) and the adenocarcinoma group (65.3 ± 18.0 years) (*P* < 0.001), and the difference of the mean age was 13.2 years between the high grade dysplasia group (52.1 ± 7.4 years) and the adenocarcinoma group (*P* = 0.004) (Figure 3).

DISCUSSION

GB polyps larger than 10 mm in size have generally been recommended for surgical resection despite of the large portion of non-neoplastic polyps among them. Because the current data for making the preoperative differentiation between neoplastic and non-neoplastic polyps is limited, a practical guideline was lacking to decide when to perform cholecystectomy. In this study, we tried to

determine the predictive values for neoplastic PLGs. We evaluated a total of 210 cases of resected GB polyps larger than 10 mm in size and we found that an older age (> 65 years), a history of DM and a large size were the significant predictive values for neoplastic PLGs. We also found that an older age(> 65 years), a history of DM and a large size were significant predictive values for malignant PLGs.

In our study, older patients more than 65 years showed a statistical relation with neoplastic or malignant PLGs, as compared to that of the younger patients (*P* = 0.021, *P* = 0.005, respectively). This result corresponds with previous studies about the correlation between age and neoplastic PLGs[12,13,18,27,28]. With this background, we tried to determine a more detailed correlation of age with the subdivided groups among the neoplastic PLGs. According to pathologic results, the neoplastic PLGs were sorted into three subgroups; adenomatous polyp with low grade dysplasia, adenomatous polyp with high grade dysplasia and adenocarcinomas. We then compared the mean ages of each subgroup. After this detailed analysis, we found out a trend for a stepwise increase of mean age in the different neoplastic groups.

A new finding we discovered in this study was the relationship between DM and neoplastic polyps. Our results showed that patients with DM have a strong probability of having neoplastic and malignant polyps, as compared to that of the patients without DM, on univariate (*P* < 0.001, *P* < 0.001, respectively) and multivariate analyses, which were adjusted by age and gender (OR = 2.64, *P* = 0.021, and OR = 6.13, *P* = 0.001, respectively). There has been one document which reported the relation between diabetes and gallbladder cancer[29]. But the exact mechanism or pathogenesis is not known. There have been a few reports that have found DM or hyperglycemia to be an independent risk factor for gastrointestinal or endocrine malignancies, such as colorectal[30] or pancreatic cancers[31]. Some recent researchers have proposed that the insulin resistance associated with hyperinsulinemia plays an important role as an oncogenic factor[32,33]. According to many etiologic studies, it has become evident that the insulin-like growth fac-

tor (IGF) system plays a permissive role in cancer development and tumor progression[34-38]. But, none of them mentioned any evidence of the IGF-I receptor pathway being involved in the development of gallbladder cancer. So we think that well designed trials are warranted in order to prove that this IGF signal pathway system plays a leading role in developing gallbladder cancer.

We found that the size of polyps ($\geq$ 15 mm) is a powerful predictor for neoplastic polyps (OR = 4.94, $P <$ 0.001). There was also a similar trend for malignant polyps (OR = 20.55, $P <$ 0.001). Many studies have reported on the size criteria of PLGs as one of the predictive values for neoplastic lesions. The majority of them insisted that a size of gallbladder polyps more than 10 mm may be the most reliable predictor of malignant neoplasm[12,13,18,27,28]. In a retrospective analysis of 354 subjects with resected PLGs, the authors suggested increasing the size criteria for cholecystectomy from 10 to 12 mm[39]. Our study result showed a larger size than the previous noted criteria because small polyps less than 10 mm were not included in the analysis.

For the sonographic findings, solitary polyps ($P =$ 0.001), an inhomogeneous echo pattern ($P =$ 0.019) and a nodular surface pattern ($P <$ 0.001) had a significant correlation with neoplastic PLGs on univariate analysis. However, only one variable, the nodular surface pattern, showed borderline statistical correlation with neoplastic polyps on the multivariate analysis. In addition, a nodular surface pattern did not show statistical significance with malignant polyps. The other sonographic parameters failed to show correlation with neoplastic or malignant PLGs. Many sonographers and endosonographers have recently tried to determine the sonographic characteristics that can reliably predict premalignant polypoid lesions in the gallbladder[20,21,23,40]. They have suggested various sonographic findings as having predictive value for neoplastic lesions; the echo pattern, marginal irregularity, the shape, solitary lesion and preservation or loss of the GB wall layer structure. In spite of vigorous efforts to standardize these ultrasonographic features, inter-observer discrepancy is still the main concern to utilize these values to differentiate malignant polyps from benign polyps.

On the contrary, among 110 cases, which were lower risk groups for neoplastic polyps, such as those younger than 65 years old, those without DM and those with polyps less than 15 mm in sonographic diameter, 15 cases (13.6%) were reported as neoplastic polyps and the remaining 95 cases (86.4%) were non-neoplastic polyps.

The major limitations of this study include the following; first, this is not prospective study, rather, it is a cross-sectional study. There was no additional follow up data about the unresected PLGs more than 10 mm in size. However, because this study included patients who were consecutively enrolled during the study period, we could rule out a common selection bias. To the best of our knowledge, this study is the largest study that has enrolled patients with pathologically comfirmed PLG larger than 10 mm in size. Thus, this data might be valuable when making decisions on how to manage such patients with PLGs.

In conclusion, among patients with PLGs more than 10 mm in size, the higher risk groups, such as elderly patients who are more than 65 years, those with DM and those with a large sized polyp ($\geq$ 15 mm) should be recommended cholecystectomy more seriously than other groups.

COMMENTS

Background
Some neoplastic polypoid lesions of the gallbladder (PLGs) including early cancer show similar appearances to the non-neoplastic PLGs. But there have been no definite guidelines except size criteria (more than 10 mm diameter) for the recommendation of surgical resection.

Research frontiers
Many studies have investigated the relationship between the neoplastic nature of PLGs and their morphological characteristics such as the number of polyps, the polyp shape, the diameter of the largest polyp, the echo level and internal echo pattern, and the polyp margin. But previously published documents showed a lack of case number, pathologic results, and long term follow up data. Also reports about the relationship between other clinical parameters and neoplastic PLGs were rare.

Innovations and breakthroughs
The authors performed the study using the consecutively enrolled pathologic data of patients with PLGs more than 10 mm in size to eliminate selection bias. This study demonstrated old age and diabetes history are added to the size criteria for predictive values of neoplastic PLGs for the decision about surgical resection.

Applications
Among patients with PLGs more than 10 mm in size considering surgical resection, the higher risk groups such as elderly patients who are more than 65 years, those with diabetes mellitus (DM) and those with a large sized polyp ($\geq$ 15 mm) should be recommended cholecystectomy more seriously than other groups.

Terminology
Neoplastic PLGs: PLGs which have the features of the neoplasm including adenoma and adenocarcinoma. Non-neoplastic PLGs: PLGs which do not have the features of the neoplasm including cholesterol polyps, adenomyomatosis and inflammatory polyps.

Peer review
The authors described that older age, DM and polyp size > 15 mm were independent predictors of neoplasia as well as malignancy. Over all, this paper is well written, concise and information.

Abstract

AIM: To examine the efficacy of glycyrrhizin preparation (GL-p) in the treatment of a rat model of ulcerative colitis (UC).

METHODS: Experimental colitis was induced by oral administration of dextran sodium sulfate. Rats with colitis were intrarectally administered GL-p or saline. The extent of colitis was evaluated based on body weight gain, colon wet weight, and macroscopic damage score. The expression levels of pro-inflammatory cytokines and chemokines in the inflamed mucosa were measured by cytokine antibody array analysis. The effect of GL-p on myeloperoxidase (MPO) activity in the inflamed mucosa and purified enzyme was assayed.

RESULTS: GL-p treatment significantly ameliorated the extent of colitis compared to sham treatment with saline. Cytokine antibody array analysis showed that GL-p treatment significantly decreased the expression levels of pro-inflammatory cytokines and chemokines, including interleukin (IL)-1β, IL-6, tumor necrosis factor-α, cytokine-induced neutrophil chemoattractant-2, and monocyte chemoattractant protein-1 in the inflamed mucosa. Furthermore, GL-p inhibited the oxidative activity of mucosal and purified MPO.

CONCLUSION: GL-p enema has a therapeutic effect on experimental colitis in rats and may be useful in the treatment of UC.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammation of the large intestine, which is characterized by pronounced infiltration of neutrophils into colonic lesions with hyperemia, hemorrhage, and ulcerations. Its etiology is not fully understood but immunological mechanisms seem to be involved[1,2]. Increased pro-inflammatory mediators, including cytokines and chemokines, are observed in patients with colitis[3]. An efficacious treatment strategy comprises controlling the expression and neutralizing the function of these mediators. Agents such as aminosalicylates, corticosteroids, and immunosuppressants inhibit the

production of these factors and are used in the treatment of UC; for example, antibodies that target tumor necrosis factor (TNF)-α are clinically efficacious to neutralize TNF-α actions[1,2]. However, these agents may cause serious adverse effects, such as agranulocytosis, severe infections, osteoporosis, and malignant lymphoid tumors.

Glycyrrhizin (GL), a natural compound extracted from the roots of the Chinese herb *Glycyrrhiza glabra*, has been used for several centuries in traditional Chinese medicine. Its preparation (GL-p) has been clinically used as an anti-allergic agent and also as treatment for chronic hepatitis for more than 30 years[4]. GL-p has useful pharmacological properties, such as anti-inflammatory, immunomodulatory, and cytoprotective effects[5]. Furthermore, treatment with GL-p is rarely accompanied by severe adverse effects, even during long-term use. However, the efficacy of GL-p in the treatment of other inflammatory conditions including UC is not well known.

Several models of experimentally induced colitis have been developed to investigate the mechanisms of inflammation and immunological disturbances[6]. Among them, an animal model with dextran sulfate sodium (DSS)-induced colitis exhibits several symptoms similar to those seen in human UC; therefore, they are considered reliable for studying the pathogenesis of UC[6,7].

To confirm the hypothesis that GL-p ameliorates colitis through its pharmacological effects, we have conducted experiments to investigate the therapeutic efficacy of GL-p for DSS-induced colitis in rats.

MATERIALS AND METHODS

Animals
Male Wistar rats (approximately 250 g, 8 wk old) were used for the experiments. All rats were housed in specific pathogen-free conditions in the animal facility of Gunma University and fed standard laboratory chow and tap water *ad libitum*. This study was approved by the Animal Care and Experimentation Committee at Gunma University.

Induction of experimental colitis
To induce colitis, rats were orally administered 3% solution of DSS (molecular weight, 5000; Wako Pure Chemical Industries, Ltd., Osaka, Japan) *via* drinking water for 7 d (from day 0 to day 6).

Treatment design
GL-p is commercially supplied by Minophagen Pharmaceutical (Tokyo, Japan) as a solution (Stronger Neo-Minophagen C®), which contains 2 mg GL monoammonium, 1 mg L-cysteine, and 20 mg glycine per mL in physiological saline solution. Rats in the GL-p and GL groups were respectively administered 1 mL GL-p or 0.2% GL solution transanally under diethyl ether anesthesia, once daily for four consecutive days (day 3 to day 6). Control rats were administered 1 mL saline. Body weight was measured throughout the experiments. All rats were killed on day 7 under excess diethyl ether anesthesia.

Assessment of mucosal damage
Body weight gain was calculated by subtracting the body weight at the beginning of the treatment from that at autopsy. An 8-cm long biopsy specimen of the distal colon was resected at autopsy and opened by longitudinal incision. The wet weight of this biopsy specimen was measured followed by observation of the gross appearance of the mucosa. Mucosal damage was measured and macroscopically scored on a scale of 0 to 10 according to the following criteria[8]: 0, no damage; 1, hyperemia without ulcers; 2, hyperemia and thickening of the bowel wall without ulcers; 3, one ulcer without thickening of the bowel wall; 4, two or more sites of ulceration and inflammation; 5, two or more major sites of ulceration and inflammation or one site of ulceration and inflammation extending > 1 cm along the length of the colon; 6-10, one point being added for each additional centimeter of involvement beyond an initial 2 cm. Tissue specimens were kept at -80℃ until cytokines were evaluated.

Measurement of myeloperoxidase activity
Myeloperoxidase (MPO) activity was measured according to the modified method of Bradley *et al*[9]. The mucosal scrapings were homogenized with a Diax 600 homogenizer (Heidolph, Germany) in 1 mL buffer that contained 0.5% hexadecyltrimethylammonium bromide and 50 mmol/L potassium phosphate (pH 6.0). The homogenates were sonicated for 10 s, freeze-thawed three times, and centrifuged at $40\,000 \times g$ for 15 min at 4℃. From each sample, 100 μL was added to 2.9 mL 50 mmol/L phosphate buffer (pH 6.0) that contained 0.167 mg/mL o-dianisidine hydrochloride and 0.0005% hydrogen peroxide. MPO activity was measured colorimetrically using a spectrometer with a change of absorbance of 460 nm during a 30-min interval at 25℃. One unit of MPO activity was defined as 1 mmol H_2O_2 broken down to H_2O and results were expressed as units per gram mucosal tissue. The MPO activities in the supernatant of mucosal homogenate and in the purified human MPO enzyme (Sigma-Aldrich Japan, Tokyo, Japan) were measured in the presence and absence of various amounts of GL-p.

Measurement of cytokines and chemokines using antibody array
The Cytokine Array (Raybiotech Inc., Norcross, GA, USA)[10] was used to detect 19 different cytokines and chemokines in the supernatant of homogenized colonic mucosal scrapings according to the manufacturer's recommended protocol. After the membranes were exposed to X-ray film (GE Healthcare Bioscience Co. Ltd.), the exposed films were digitized and the relative cytokine levels were compared by densitometrical analysis using ImageJ ver. 1.38x software (National Institute of Health, Rockville Pike, Bethesda, MD, USA). The relative cytokine levels were obtained by subtracting the background staining and normalizing from the positive controls on the same membrane.

Statistical analysis

All data are presented as mean ± SE. Student's *t* test was used for comparison between the data in the two groups. One-way ANOVA followed by Tukey's *post hoc* test was used to analyze the data for multiple groups. For evaluation of the damage score, the non-parametric Kruskal-Wallis test followed by the Steel-Dwass test was used. $P < 0.05$ was considered statistically significant. KyPlot 5.0 (KyensLab. Inc., Tokyo, Japan) was used for the statistical analyses.

RESULTS

Effects of GL-p enema on experimental colitis

After treatment with 3% DSS for 7 d, all the rats developed symptoms of colitis. Diarrhea was first observed on day 4 after the onset of treatment, followed by rectal bleeding and body weight loss. Compared to the control group, the GL-p and GL groups experienced significantly increased body weight gain ($P < 0.05$), decreased colon wet weight ($P < 0.05$), and reduced macroscopic damage score ($P < 0.05$) (Figure 1). Significant differences between GL-p and GL groups were not detected (Figure 1).

Effects of sodium carboxymethylcellulose accompanied with GL-p on experimental colitis

To determine whether the addition of carboxymethylcellulose (CMC) as a viscosity modifier augments the therapeutic effects of GL-p enema, we compared the group treated with GL-p alone to those treated with a combination of GL-p and CMC. The addition of 0.5% CMC seemed to increase body weight gain and significantly decrease the colon wet weight compared to GL-p alone ($P < 0.01$), whereas addition of CMC did not result in any changes in the macroscopic damage score (Figure 2).

Cytokine antibody array analysis

Using cytokine antibody array analysis, the 19 cytokine levels between the GL-p and control groups were compared (Figure 3). The levels of pro-inflammatory cytokines including interleukin (IL)-1β, IL-6 and TNF-α were significantly decreased in the GL-p group, and those of chemokines, such as cytokine-induced chemoattractant (CINC)-2 and -3, granulocyte-macrophage colony-stimulating factor (GM-CSF), monocyte chemoattractant protein (MCP)-1, and macrophage inflammatory protein (MIP)-3α, were also significantly inhibited in the GL-p group. Among Th1 cytokines, interferon (IFN)-γ was not significantly inhibited. Among Th2 cytokines, IL-4 and IL-6 decreased while IL-10 did not change. The levels of leptin, tissue inhibitor of metalloproteinase (TIMP)-1, fractalkine, and ciliary neurotrophic factor (CNTF) were decreased in the GL-p group.

Effects of GL-p on MPO activity

To evaluate the effect of GL-p on the number of neutrophils infiltrating the colon, levels of mucosal MPO activity were measured. Rats treated with GL-p showed a significantly low level of mucosal MPO activity compared to con-

Figure 1 Effects of glycyrrhizin preparation and glycyrrhizin treatments on body weight gain (A), colon wet weight (B), and macroscopic damage score (C) in rats with dextran sulfate sodium-induced colitis. trol rats ($P < 0.05$) (Figure 4A). We conducted *in vitro* experiments to assess the presence of an inhibitory effect of GL-p on MPO activity, and found that GL-p dose-dependently inhibited MPO activity in mucosal tissue (Figure 4B), as well as purified human enzyme (Figure 4C).

DISCUSSION

In the present study, we showed that GL-p ameliorated the extent of DSS-induced colitis in rats. We used cytokine antibody array analyses and revealed that GL-p reduced the level of pro-inflammatory cytokines and chemokines in the colonic mucosa. Furthermore, GL-p was shown to inhibit MPO activity.

We demonstrated that GL-p administration ameliorated the production of pro-inflammatory cytokines and chemokines, such as IL-1β, TNF-α, IL-6, CINC-2 and -3, MCP-1, MIP-3α, TIMP-1, fractalkine, CNTF, leptin, and GM-CSF. The relevance of pro-inflammatory cytokines and chemokines to the pathophysiology of chronic inflammation in inflammatory bowel disease (IBD) has recently been elucidated, and their manipulation has successfully reduced disease severity and maintained remission. IL-1β has been well characterized as a potent inflammatory cytokine that is produced by inflammatory and mucosal epithelial cells during colonic inflammation[11]. Its neutralization with antibodies suppresses the development

of DSS-induced colitis[12]. IL-6 is a pleiotropic cytokine that exerts its pro-inflammatory effects mainly by means of its soluble IL-6 receptor. The anti-IL-6 receptor monoclonal antibody abrogates murine colitis[13]. TNF-α is a key inflammatory cytokine produced mainly from macrophages and is a target of IBD treatment. Anti-TNF-α antibody and soluble TNF-α receptor are used clinically with significant benefits. Collectively, these findings suggest the efficacy of GL-p in the treatment of human UC.

GL-p used in this study was a combination of GL with 2% of glycine and 0.4% of L-cysteine. A diet that contains 5% glycine has recently been reported to prevent colitis in rats, which is chemically induced by DSS or 2,4,6-trinitrobenzene sulfonic acid (TNBS)[14]. Glycine inhibits the induction of pro-inflammatory cytokines and chemokines, such as IL-1β, TNF-α, CINC and MIP-2. On the contrary, dietary L-cysteine supplementation is also reported to have a therapeutic effect on DSS-induced porcine colitis[15]. However, no significant therapeutic differences were observed between GL alone and GL-p in the present study (Figure 1). Although the difference in the experimental settings, such as the route of administration, may be relevant to this contradiction, the precise reasons for this are unknown. One possibility is that the effect of amino acids in GL-p was masked by that of GL in our experimental settings. To evaluate this possibility, further experiments including a control group treated with amino acids alone is required.

Our study demonstrated that GL was beneficial in the treatment of rat colitis if administered intrarectally (Figure 1). However, GL was not proven to be efficacious in a previous study[16]. Although the beneficial effects of oral administration of Hange-shashin-to (HST), a combination of seven herbs[16], on DSS-induced colitis in rats

Figure 4 Glycyrrhizin preparation and myeloperoxidase activity. A: Effects of glycyrrhizin preparation (GL-p) treatment on myeloperoxidase (MPO) activity in the mucosa of rats with dextran sulfate sodium-induced colitis (n = 5 in each group); B: Effects of GL-p on MPO activity in the mucosal extract (n = 5 in each group); C: Effects of GL-p on MPO activity of purified human enzyme. [a]P < 0.05, [b]P < 0.01.

has been demonstrated, the previous study did not detect the effects of oral administration of a single constituent included in HST, such as GL. One possible explanation for the contradiction between their results and ours may be the difference in the type of experimental colitis used. They used a model of colitis induced by intracolonic instillation of TNBS, which is known as a model of Crohn's disease, and has distinct immunological features from those of the DSS-induced colitis that we used[6]. This seems to have caused conflicting responses to GL administration, which suggests that Crohn's disease and UC should be distinguished at the point of clinical application of GL treatment. Another possibility is the

differences in dose and route of administration. They administered an oral dose of 2.67 or 5.37 mg/kg GL. We administered a dose of 8 mg/kg (2 mg GL per rat weighing 250 g) intrarectally. We were subsequently able to deliver higher concentrations of GL to the inflamed colon compared to the previous study.

Regarding GL administration for colitis, Yuan *et al*[17] recently have reported the results of experiments using colitis induced by acetic acid installation, which is a model of acute colitis[6]. They found that GL reduced colonic injury with the suppression of nuclear factor-κB, TNF-α, and intercellular adhesion molecule-1 in the affected mucosa. They administered GL at a dose of 40 mg/kg, which was five times greater than that in our study. Furthermore, they chose the intraperitoneal route for administration. Use of this route may raise the systemic concentration of GL sufficiently high to cause adverse effects such as severe hypertension, hypokalemia, and other signs of mineralocorticoid excess, because the incidence of adverse effects is dose-dependent[4,5]. We administered GL and GL-p intrarectally to maintain low systemic concentrations of the agents despite high local concentrations[18]. For clinical application, rectal administration is preferable as it may maximize quality of life by reducing the necessity for frequent visits to outpatient clinics to receive parenteral administration of GL-p.

We demonstrated that GL-p treatment decreased MPO activity in the inflamed mucosa (Figure 4A), which indicates the inhibition of neutrophil accumulation at the site of injury through GL-p administration. MPO is mainly produced by neutrophils that infiltrate the inflammatory sites, therefore, MPO activity in specimens is believed to reflect the number of infiltrating neutrophils[9]. Furthermore, in this study, we demonstrated for the first time that GL-p suppressed MPO activity in a dose-dependent manner in experiments using the inflamed mucosa (Figure 4B), as well as purified human enzyme (Figure 4C). This appears to be a new mechanism in the therapeutic actions of this agent. Although the main function of MPO is to destroy phagocytosed microorganisms by strong oxidative species within the phagosome, the excessive amount and activation of MPO at inflamed sites may cause tissue injury by modification of lipids and proteins through reactive oxidative species[19]. Therefore, modulation of MPO oxidation activity by GL-p has a therapeutic potential for inflammation.

In the treatment of UC, development of colorectal carcinoma is a serious complication. It is noticeable that long-term use of GL-p is effective in preventing development of hepatocellular carcinoma in patients with chronic hepatitis C[20,21]. Amelioration of chronic inflammation is suggested to reduce the possibility of oncogenesis, therefore, GL-p enema may prevent the development of colon cancer.

In conclusion, our study suggests a therapeutic effect of GL-p enemas on experimental colitis in rats. Further studies are necessary to determine an effective administration strategy with higher efficacy and fewer adverse

effects in the treatment of patients with UC.

COMMENTS

Background
Ulcerative colitis (UC) affects many people worldwide. Its pathophysiology involves immunological mechanisms. Glycyrrhizin preparation (GL-p) may be useful in the treatment of UC because it has anti-inflammatory and immuno-modulatory effects.

Research frontiers
Although a previous study has demonstrated that oral administration of a combination of seven herbs is beneficial in the treatment of colitis in rats, the effect of GL, one of its constituents, was not detected.

Innovations and breakthroughs
The study demonstrated that GL-p was beneficial in the treatment of rat colitis if administered intrarectally. GL-p decreased the expression of pro-inflammatory cytokines and inhibited myeloperoxidase activity.

Applications
The results of this study suggest a therapeutic effect of GL-p enemas on experimental colitis in rats. Further studies are required to apply this treatment in patients with UC.

Terminology
GL is a natural compound extracted from the roots of the Chinese herb *Glycyrrhiza glabra* and GL-p has been clinically used as an anti-allergic agent and as a treatment for chronic hepatitis in Japan.

Peer review
GL, an active ingredient from licorice root, has long been used for traditional medicinal purposes. Very little work on this subject has been described in the mainstream literature, and this work is a welcome addition. The authors have done a commendable job of comparing their study with the only (to my knowledge) previously published work in the field, primarily that of Yuan *et al*.

Abstract

AIM: To investigate the effects of hyperbaric oxygenation (HBO) on regeneration of the biliary ductal system and postoperative cholestasis in hepatectomized rats.

METHODS: HBO was performed in Wistar rats daily starting 12 h after a 70% partial hepatectomy. Regenerated liver weight, serum parameters and the proliferating cell nuclear antigen labeling index of hepatocytes and biliary ductal cells were measured. Hepatocyte growth factor (HGF), c-Met and transforming growth factor (TGF) β-1 mRNA expression levels were analyzed by quantitative reverse transcription polymerase chain reaction.

RESULTS: HBO improved the postoperative serum levels of total bile acid but not transaminase levels. HBO promoted hepatocyte and biliary ductal cell proliferation. The hematoxylin and eosin-stained specimens revealed fewer ballooned hepatocytes and higher cell densities in the HBO group compared to the control group. HBO suppressed c-Met mRNA levels at 15 h but did not modulate HGF or TGF β-1 mRNA expression levels.

CONCLUSION: HBO promoted regeneration of biliary ductal cells and improved postoperative cholestasis after a partial hepatectomy.

INTRODUCTION

Extended hepatectomy and small graft liver transplantation can result in postoperative cholestasis and liver failure. Hepatectomized liver rapidly regenerates and its volume and function recover, but functional recovery lags behind quantitative recovery. Postoperative liver failure causes cholestasis; hence, it is important to improve cholestasis in order to reduce morbidity and mortality.

Hyperbaric oxygenation (HBO) has been used as a therapy in patients with carbon monoxide poisoning, decompression sickness and arterial gas embolism[1]. Effects of HBO that have been reported include upregulation of growth factors[2], down-regulation of inflammatory cytokines[3] and increased angiogenesis[4].

Studies have reported the effect of HBO on liver re-

generation after partial hepatectomy, but few studies have reported its effect on biliary ductal regeneration and cholestasis. In this study, we investigated the effects of HBO on the biliary system and postoperative cholestasis after a partial hepatectomy.

MATERIALS AND METHODS

Animals and surgery

All experiments were performed on 10-wk-old male Wistar rats ($n = 78$). Thirty-six rats were used in each group and preoperative data acquired from another 6 rats. Procedures were approved by the Review Committee on Animal Use of Gunma University, Maebashi, Japan. All the rats were housed under temperature- and light-controlled conditions with 12 h light and dark cycles. The rats were fed a standard rat diet and water as desired. Prior to the experiment, the rats were starved for 24 h with free access to water. Under ether anesthesia, a 70% partial hepatectomy was performed using the Higgins and Anderson technique[5]. After the transverse laparotomy, the median and left lobes were ligated and resected. All the rats were allowed free access to the standard diet and water after the surgery. The rats were sacrificed at various time points (12, 15, 24, 48, 72, and 96 h after the partial hepatectomy) by puncture of the inferior vena cava and exsanguination under ether anesthesia. The regenerated livers were removed and either fixed in 20% formalin or frozen and stored at -80℃.

HBO

The rats in the HBO group were placed in a hyperbaric chamber (Model KHO-200; Kawasaki Engineering Co., Ltd., Hyogo, Japan) pressurized to 2 ATA with 100% oxygen for 60 min. HBO was initiated 12 h after the end of surgery and performed once a day until postoperative day 4. HBO was not performed postoperatively in the control group.

Regenerated liver weight/% body weight

The regenerated liver weight/% body weight ratio was calculated using the following equation: $100 \times A/B$, where A is the weight of the regenerated liver at the time of sacrifice and B is the rat body weight at the time of sacrifice.

Serum parameters

The degree of hepatic injury and biliary function was assessed by determining the serum levels of alanine aminotransferase (ALT) and total bile acid (TBA) using standard laboratory methods.

Hematoxylin and eosin staining

Formalin-fixed liver specimens were embedded in paraffin, and 3-μm sections were prepared. Hematoxylin and eosin (HE) staining was performed according to standard procedures. Hepatocytes were counted in random high power fields (HPFs) without a visible Glisson's sheath or

central vein ($\times$ 400). The cell density was expressed as the mean number of hepatocytes per HPF.

Immunohistochemistry

Proliferating cell nuclear antigen (PCNA) expression was immunohistochemically detected using a monoclonal antibody against PCNA [dilution: 1:400, horseradish peroxidase-labeled, DAKO, PC10, (Code No. M0879)]. PCNA-positive cells were counted in random HPFs ($\times$ 400). The PCNA-labeling index was expressed as the percentage of PCNA-positive cells/total number of cells. Hepatocytes and biliary ductal cells were counted.

RNA isolation and cDNA synthesis

Total RNA was extracted from freshly frozen liver using the RNeasy Mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. The quantity of isolated RNA was measured using a ND-1000 spectrophotometer (NanoDrop Technologies, DE, USA). Template cDNA was synthesized from 13.5 μL of total RNA using an Omniscript reverse transcriptase kit (Qiagen), a random primer (hexadeoxyribonucleotide mixture) (TaKaRa, Shiga, Japan), and a ribonuclease inhibitor (porcine liver) (TaKaRa). Total RNA was reverse transcribed using 4 U of Omniscript reverse transcriptase in a reaction volume of 20 μL (60 min at 37℃, 5 min at 93℃, then placed on ice). The resultant cDNA samples were stored at -20℃ until analysis.

Quantitative reverse transcription polymerase chain reaction analysis of hepatocyte growth factor, c-Met, and transforming growth factor β-1 mRNA expression levels

Quantitative reverse transcription-polymerase chain reaction (PCR) analyses were performed using the ABI Prism 7000 Sequence detection system (Applied Biosystems, CA, USA). The standard reaction volume was 20 μL and contained 1 $\times$ SYBR Green PCR Master Mix (Applied Biosystems), 2.0 μL of cDNA template, and 0.5 μmol/L each of the forward and reverse primers. The initial PCR denaturation step was performed for 10 min at 95℃ followed by 45 cycles of 15 s at 95℃ (denaturation), 10 s at 60℃ (annealing), and 30 s at 72℃ (extension). All reactions were performed in duplicate. The data were adjusted using the mRNA level of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA and expressed as a ratio of the GAPDH levels. The primers for hepatocyte growth factor (HGF) and transforming growth factor (TGF) β-1 were used as described in previously published assays[6], and the primers for c-Met and GAPDH were designed using Primer 3 (primer3_www.results.cgi) with sequences from Ensembl Genome Browser (http://www.ensembl.org/index.html) (Table 1).

Statistical analysis

All values are expressed as mean $\pm$ SD. Statistical significance was determined using the post-hoc test of Bonferroni-Dunn. $P < 0.05$ was considered statistically significant.

Figure 1 Serum parameters after hepatectomy. No significant difference was observed in the postoperative serum alanine aminotransferase (ALT) levels between the 2 groups. Total bile acid levels at 48 and 72 h after hepatectomy were significantly lower in the hyperbaric oxygenation (HBO) group than in the control group. Results are expressed as mean ± SD of n = 6 for each period in each group. NS: No significant. [b]P < 0.01.

Figure 2 Regenerated liver weight /(% body weight). In both groups, the percentage weight of the regenerated liver increased daily after hepatectomy. At 96 h after hepatectomy, the percentage weight was higher in the hyperbaric oxygenation (HBO) group than in the control group. Results are expressed as mean ± SD of n = 6 for each period in each group. [a]P < 0.05.

RESULTS

Liver injury and biliary function after the partial hepatectomy

Blood parameters were measured at various time points. ALT levels peaked at 24 h after the partial hepatectomy in the control and HBO groups and then decreased rapidly (Figure 1). No significant differences were observed between the groups at any time point as the serum ALT level decreased. Serum TBA levels increased and peaked at 72 h (Figure 1); these were decreased by HBO. Signifi-cant differences were observed in TBA levels at 48 h and 72 h after the partial hepatectomy. These data indicate that HBO improved the postoperative biliary function.

Liver regeneration after the partial hepatectomy

Data in Figure 2 reveal that the regenerated liver weight/% body weight increased daily after the partial hepatectomy. At 96 h, the regenerated liver weight ratio was higher in the HBO group than in the control group. The PCNA labeling index of the hepatocytes was higher at 48 and 72 h and lower at 24 h in the HBO group than in the control group (Figure 3A). The PCNA labeling index of the biliary ductal cells peaked at 48 h in the HBO group and was significantly higher in the HBO group than in the control group (Figure 3B). Combined, these data indicate that biliary ductal cell proliferation was greater in the HBO group than in the control group.

HE staining after the partial hepatectomy

An edematous cytoplasm and ballooning hepatocytes were observed in the regenerated livers of the control group at 96 h after surgery; however, these findings were not observed in the HBO group (Figure 4). The cell density of the hepatocytes was higher in the HBO group at

Figure 3 Percentage of proliferating cell nuclear antigen-positive cells in both groups at 24, 48, 72 and 96 h after hepatectomy. A: The percentage of proliferating cell nuclear antigen (PCNA)-positive hepatocytes was higher at 48 and 72 h and lower at 24 h in the hyperbaric oxygenation (HBO) group than in the control group. The percentage of PCNA-positive biliary ductal cells in the HBO group was higher at 48 h compared with the control group; B: The proliferation of biliary ductal cells was increased in the HBO group, with an early peak at 48 h. Results are expressed as mean ± SD of $n = 6$ for each period in each group. [a]$P < 0.05$, [b]$P < 0.01$.

Figure 4 Hematoxylin and eosin staining of the liver slices at 96 h after hepatectomy. Control group (A: 100 × magnification, C: 400 ×). Hyperbaric oxygenation (HBO) group (B: 100 ×, D: 400 ×). In the control group, the regenerating livers were edematous and showed ballooned hepatocytes (C, arrow). In addition, the number of hepatocytes per high power field was lower in the control group than in the HBO group.

72 and 96 h (Figure 5). These findings suggest that HBO inhibited cell edema and protected the hepatocytes during liver regeneration.

Expression of HGF, c-Met and TGF β-1 mRNA

The expression of HGF and TGF β-1 mRNA peaked at 15 h in both groups and no significant differences in the mRNA levels of the HBO and control groups were observed. While the mRNA expression of c-Met increased and peaked at 15 h in both the groups, expression was significantly suppressed in the HBO group (Figure 6).

DISCUSSION

The goal of this study was to determine the effect of HBO on liver regeneration, particularly in biliary system restoration and improvement of postoperative cholestasis.

HBO involves the inspiration of a high concentration of oxygen in a pressure chamber at pressures higher than 1 ATA. During HBO, the partial pressure of oxygen increases, thereby increasing oxygen delivery throughout the body. The beneficial effects of HBO have been reported in ischemia-reperfusion injuries[6-8], acute liver fail-

Figure 5 Cell density calculated as the number of hepatocytes per high power field. ure after major hepatectomy[9], hepatic artery thrombosis after liver transplantation[10] and liver regeneration after portal vein embolization[11].

The hepatectomized liver enlarges to compensate for the mass of the resected lobes. In the early phase of liver regeneration, avascular clusters of hepatocytes are formed. Following hepatocyte proliferation, the vascular architecture and biliary ductal system are reconstructed in the regenerating liver. HBO promotes the proliferation of hepatocytes[11-13] and sinusoidal cells[14]. In the present study, data from the PCNA labeling index revealed that HBO promotes not only proliferation of hepatocytes but also biliary ductal cells. HBO probably improved bile drainage function during early phases of liver regeneration and decreased postoperative cholestasis.

During liver regeneration, hepatocytes exhibit morphologic changes such as cytoplasmic edema and ballooning. Ballooned hepatocytes are commonly observed in viral[15], drug-induced[16-18] and alcoholic[19,20] hepatic injuries and non-alcoholic steatohepatitis[21,22]. Hepatocytes are swollen in biopsies of orthotopic liver grafts after transplantation. Ballooning is associated with, but not directly caused by, bile retention. One of the pathogenetic factors of ballooned hepatocytes is ischemic damage. In a rat steatotic liver model, swollen hepatocytes caused abnormal microcirculation, manifested as reduced sinusoidal density[23]. The edematous state of hepatocytes can cause obstruction of the sinusoids and biliary ducts, secondary cholestasis and circulatory failure in the liver. HBO increases oxygen delivery and improves the ischemic state of the regenerated liver, breaking the cycle of hepatocyte ballooning and abnormal microcirculation. Our results suggest that HBO suppresses the edematous state of hepatocytes, accelerates bile drainage and improves postoperative cholestasis.

The present study revealed that HBO did not lower postoperative ALT levels. One study has suggested that HBO reduces serum ALT levels after a partial hepatectomy[14], while others have revealed no significant differences in ALT levels during liver regeneration[12,13,24]. The

Figure 6 Expressions of hepatocyte growth factor, c-Met and transforming growth factor β-1 mRNA in the liver tissues determined at various time points. Results are expressed as mean ± SD. Hepatocyte growth factor (HGF) and c-Met: $n = 6$ for each period in each group, transforming growth factor (TGF) β-1: $n = 5$ for each period in each group. [a]$P < 0.05$.

mechanisms of reduction of liver damage are mediated by various effects of HBO, which directly increases the oxygen concentration in the remnant liver and augments the expressions of HGF[11] and vascular endothelial growth factor (VEGF)[14].

HGF, known as the scatter factor, has mitogenic, motogenic, morpho-organogenic, angiogenic, and anti-apoptotic effects. HGF and its receptor c-Met are key factors for liver growth and function. TGF β-1 is an inhibitor of proliferation in hepatocyte cultures[25]. Data from the present study did not reveal significant differences in mRNA levels of HGF and TGF β-1 with HBO treatment after the partial hepatectomy. However, data did reveal that HBO suppressed c-Met mRNA expression at 15 h after the partial hepatectomy. HGF and c-Met promote liver

regeneration, while TGF β-1 inhibits it[25]. A balance of these promoter and inhibitor levels is important for liver regeneration[26]. HBO modulated the expression of c-Met mRNA and might cause an improvement in cholestasis and liver edema.

In conclusion, data from this study suggests that HBO has beneficial effects on the regeneration of biliary ductal cells and postoperative cholestasis after a partial hepatectomy. HBO also improved cell edema of hepatocytes in the regenerating liver. HBO might be useful for improving resectability and for decreasing the frequency of postoperative complications, such as liver failure, after a major hepatectomy.

ACKNOWLEDGMENTS

COMMENTS

Background

Extended hepatectomy and small graft liver transplantation can result in postoperative cholestasis and liver failure. Postoperative liver failure causes cholestasis; hence, it is important to improve cholestasis in order to reduce morbidity and mortality.

Research frontiers

Hyperbaric oxygenation (HBO) has been used as a therapy in patients with carbon monoxide poisoning, decompression sickness and arterial gas embolism. Effects of HBO which have been reported include upregulation of growth factors, down-regulation of inflammatory cytokines and increased angiogenesis.

Innovations and breakthroughs

The beneficial effects of HBO have been reported in ischemia-reperfusion injuries, acute liver failure after major hepatectomy, hepatic artery thrombosis after liver transplantation and liver regeneration after portal vein embolization. Further to this, the study would suggest that HBO promotes regeneration of biliary cells and improves cholestasis in rats after a partial hepatectomy.

Applications

The study would suggest that HBO has beneficial effects on the regeneration of biliary cells and postoperative cholestasis after a partial hepatectomy. HBO also improved cell edema of hepatocytes in the regenerating liver. HBO might be useful for improving resectability and for decreasing the frequency of postoperative complications, such as liver failure after a major hepatectomy.

Terminology

HBO involves the inspiration of a high concentration of oxygen in a pressure chamber at pressures higher than 1 ATA. During HBO, the partial pressure of oxygen increases, thereby increasing oxygen delivery throughout the body. In general, HBO has been used as a therapy in patients with carbon monoxide poisoning, decompression sickness and arterial gas embolism. Other beneficial effects of HBO in hepatic surgery and liver regeneration have been reported.

Peer review

The authors investigated the effect of HBO administration on bile duct cellular regeneration and cholestasis in a 70% model of hepatectomy. This is an area of high significance as findings may have a potential impact on therapeutic strategies in liver failure and regeneration following major hepatectomy. In limitation, the conclusions are based on results up to 96 h. The regeneration cycle is usually complete by day 8 and it may be appropriate to extend the time interval for the results to be obtained to this stage, before an appropriate conclusion may be reached. It may very well be the optimum results evident are a transient phenomena during the regenerative cycle.

Abstract

AIM: To investigate a limited water infusion method in colonoscopy.

METHODS: Consecutive patients undergoing minimally sedated colonoscopy were randomized to receive air insufflation (n = 89) or water infusion limited to the rectum, sigmoid colon and descending colon (n = 90). Completion rates, cecal intubation times, procedure times, need for abdominal compression, turning of patients and levels of discomfort were evaluated.

RESULTS: Completion rates, total procedure times, need for abdominal compression, and turning of patients were similar between groups. Less pain was experienced in the water group than in the air group (2.5 ± 2.5 *vs* 3.4 ± 2.8, mean ± SD, P = 0.021). The cecal intubation time was significantly longer in the water group than in the air group (6.4 ± 3.1 min *vs* 4.5 ± 2.4 min, P < 0.001). More water was infused in the water group (322 ± 80.9 mL *vs* 26.2 ± 39.4 mL, P < 0.001).

CONCLUSION: Limited airless water infusion in the distal colon reduces patients' pain during colonoscopy.

INTRODUCTION

Colonoscopy is currently the gold standard for the evaluation and treatment of colon disease[1,2]. The procedure can sometimes be quite painful and the success rate of intubation varies with the skills of the endoscopists[3]. Various methods have been used to reduce the pain of colonoscopy, including variable stiffness colonoscopy, magnetic endoscope imaging and oil lubrication[4-6]. Some of these measures require new instruments and their effects are controversial.

Pain during colonoscopy may originate from colon distension caused by air insufflation during the procedure. Adequate air insufflation opens the lumen of the

colon and improves the colonoscopic view. Overinflation, however, elongates the colon, accentuates the angles and results in difficult intubation. In addition, overinflation reduces mucosal blood flow in the laboratory setting and could possibly cause clinically significant ischemia[7].

Water instillation into the colon can facilitate intubation by straightening the sigmoid colon and decreasing the friction between the scope and the colonic mucosa during colonoscopy[6]. Recently, an airless water intubation method was proposed in which water, in lieu of air, was used to open the lumen of the colon[8]. In previous studies, this method was found to decrease the use of sedative medication during sedated colonoscopy and to increase patient willingness to receive unsedated colonoscopy[8-10]. However, a large amount of water was needed to inflate the colon adequately, and if water was infused manually with a syringe, the procedure time was prolonged[8]. Otherwise, an automatic infusion pump was needed[9-11].

In this randomized, controlled study, we simplified the water intubation method by limiting the infusion of water to the rectum and sigmoid colon. We aimed to investigate whether this limited water infusion method could reduce patient discomfort during minimally sedated colonoscopy.

MATERIALS AND METHODS

This prospective study was conducted between May and November 2009 at Buddhist Dalin Tzu Chi General Hospital. Patients undergoing minimally sedated colonoscopy performed by two endoscopists (Hsieh YH and Tseng KC) at our endoscopic suite were included. Patients with the following conditions were excluded: obstructive lesions of the colon, inadequate bowel preparation, allergy to meperidine, massive ascites, past history of partial colectomy, or refusal to provide written informed consent. The study was approved by the Institutional Review Board of the Buddhist Dalin Tzu Chi General Hospital.

Bowel cleansing was accomplished by asking the patients to ingest either 90 mL of sodium phosphate, or 4 bisacodyl tablets (4 × 5 mg) plus 250 mL of magnesium citrate (Purzer Pharmaceutical Co., Taipei, Taiwan) oral solution in two divided doses the night before the procedure.

Buscopan (hyoscine N-butylbromide, 20 mg), if not contraindicated, and 25 mg of meperidine were given intramuscularly immediately before the procedure to produce good colonic relaxation and reduce patient discomfort.

The colonoscopic examinations were performed by using a video colonoscope (CF 240AL, Olympus Optical Co. Ltd., Tokyo, Japan). All procedures were performed with the standard method, including starting with the patient in the left lateral decubitus position, avoiding and reducing loops as much as possible. The variable stiffness function was activated at the discretion of the endoscopist, usually after the sigmoid colon was passed and before manual abdominal pressure was applied. Intubation

of the cecum was defined as successful only if the base of the cecum could be touched with the tip of the colonoscope. Detailed examinations were undertaken during the withdrawal phase.

The patients were allocated into two groups randomly by means of a computer-generated list. In the air group, air insufflation was used throughout the procedure. In the water group, the air pump was turned off initially during the procedure. Instead, tap water in 50 mL syringes was instilled into the rectum and the sigmoid colon through the accessory channel to open the colon lumen. Water was not usually instilled into the descending colon because the infused water already accumulated in this dependent segment. If the tip of the scope came out of the water or could not find its way at the transverse colon, the air pump was then turned on. In addition, if the lumen could not be opened with water in the sigmoid colon after a 5-min attempt, the air pump was turned on.

Demographic data (age, gender, height, weight, and education level), indications for colonoscopy, history of abdominal surgery or hysterectomy, constipation and chronic use of laxatives were obtained before colonoscopy. At the end of the procedure, the following parameters were evaluated and recorded on the patient data sheet: quality of bowel preparation, cecal intubation time, total procedure time, activation of the variable stiffness function, use of abdominal pressure, use of changing position, presence of polyps and reasons for incomplete colonoscopy. Body mass index was calculated as body weight divided by body height squared (kg/m^2). The quality of bowel cleansing was classified by the endoscopist as: (1) good: dry colon or only a small amount of clear liquid; (2) fair: large amount of clear liquid fluid or minimal solid stools; (3) poor: significant amount of solid residue; and (4) inadequate: when stool residue precludes complete insertion.

A trained research assistant who was unaware of the randomization status administered a questionnaire to the subjects after the procedure. In the questionnaire, abdominal pain was graded according to 10 levels (VAS scale). The degree of satisfaction was also assessed by a similar scale.

Statistical analysis

A sample size of about 75 patients was chosen to detect a difference of 1 in the patient abdominal pain score during colonoscopy given a standard deviation of 2.2 with a two-tailed α of 0.05 and a β of 0.20. Statistical analysis was performed using SPSS version 12.0 software (SPSS Inc., Chicago, IL). All continuous variables were expressed as mean ± SD. The Student's *t*-test and an analysis of variance to compare the means of continuous variables were used where appropriate. The χ^2 test, with Yates' correction for continuity, was used for comparison of categorical data, while the Fisher exact test was used when numbers were small. Multivariate logistic regression was performed using the application of assistant-administered abdominal pressure as the end point. A *P*

value of less than 0.05 was considered to be statistically significant.

RESULTS

Between May 2009 and February 2010, 255 patients underwent colonoscopies performed by the two endoscopists at our hospital. Sixty-one patients wished to receive sedation, so they were not invited to participate in the study. Twelve patients were excluded because of prior hemicolectomy (*n* = 6), unwillingness to give written informed consent (*n* = 5), or massive ascites due to carcinomatosis (*n* = 1). The remaining 182 subjects were randomized to the air group (*n* = 90) or the water group (*n* = 92). Three patients were subsequently excluded because of inadequate preparation (one in each group) and severe colitis (one in the water group). The baseline characteristics of the remaining patients in both groups were similar (Table 1).

Incomplete colonoscopy occurred in 1 patient in the air group (1.1%) due to looping. Incomplete colonoscopy also occurred in 1 patient in the water group (1.1%) due to intolerance. However, air insufflation had to be used in 8 patients in the water group before reaching the transverse colon due to poor visibility in 2 patients, and an inability to open the lumen in 6 patients (4 at the sigmoid and 2 at the descending colon). These 8 patients were all subsequently intubated to the cecum.

Table 2 Outcomes of colonoscopy (mean ± SD) *n* (%)

	Air group (*n* = 89)	Water group (*n* = 90)	*P* value
No. of failed cecal intubations	1 (1.1)	1 (1.1)	1.000[4]
Cecal intubation time (min)	4.5 ± 2.4	6.4 ± 3.1	< 0.001[3]
Procedure time (min)	13.8 ± 5.6	14.5 ± 4.7	0.333[3]
Volume of water used (mL)	26.2 ± 39.4	322 ± 80.9	< 0.001[3]
Time of air insufflation during intubation (min)	4.5 ± 2.4	2.3 ± 2.6	< 0.001[3]
No. of cases requiring assistant-administered abdominal pressure	51 (57.3)	49 (54.4)	0.764[4]
No. of cases requiring change of position	24 (27.0)	17 (18.9)	0.217[4]
Patient pain score[1]	3.4 ± 2.8	2.5 ± 2.5	0.021[3]
No. of cases without pain	18 (20.2)	32 (35.6)	0.030[4]
Patient satisfaction score[2]	9.6 ± 0.8	9.6 ± 0.7	0.980[3]
No. of cases with polyps	52 (58.4)	44 (48.9)	0.232[4]
No. of cases with adenomas	31 (34.8)	32 (35.6)	1.000[4]

[1]0 = no pain, 10 = worst pain imaginable; [2]0 = not satisfied at all, 10 = completely satisfied; [3]Student's *t*-test; [4]χ^2 test.

The need for abdominal compression, need for changing position and total procedure time were similar between groups (Table 2). The cecal intubation time was shorter in the air group than in the water group (4.5 ± 2.4 min *vs* 6.4 ± 3.1 min, *P* < 0.001).

Significantly less water was infused in the air group than in the water group during the procedure (26.2 ± 39.4 mL *vs* 322 ± 80.9 mL, *P* < 0.001). The time of air insufflation during the insertion phase was less in the water group than in the air group (4.5 ± 2.4 min *vs* 2.3 ± 2.6 min, *P* < 0.001). The mean pain scores, as rated by the patients, were higher in the air group than in the water group (3.4 ± 2.8 *vs* 2.5 ± 2.5, *P* = 0.021). Also, more patients in the water group had no pain at all compared to patients in the air group (35.6% *vs* 20.2%, *P* = 0.030). Overall satisfaction with the procedure was similar between groups (9.6 ± 0.8 *vs* 9.6 ± 0.7, *P* > 0.05) (Table 2).

Polyps were detected in 52 (58.4%) patients in the air group. Thirty-one (34.8%) of these polyps were adenoma, 5 (5.6%) were tubulovillous adenoma and 3 (3.4%) were carcinoma. Polyps were detected in 44 (48.9%) patients in the water group. Thirty-two (35.6%) polyps were adenoma, 4 (4.4%) were tubulovillous adenoma and 1 (1.1%) was carcinoma (Table 2).

DISCUSSION

The results of this study show that water infusion rather than air insufflation at the rectum and sigmoid is associated with less pain during minimally sedated colonoscopy. In experienced hands, about 35.6% of the patients felt no pain at all. The water was infused manually with a syringe without additional instruments, making this method readily available. Although the limited water infusion group had a longer intubation time than the air insufflation group, the difference was small (less than 2 min). To the best of our knowledge, this is the first study to compare this new water infusion method with traditional air insufflation.

Water infusion to facilitate colonoscopy has been reported by several authors in the past; however it has not been applied frequently. Most authors used water infusion in conjunction with air insufflation. Falchuk *et al*[12] found it helpful to infuse up to 300 mL of water into the sigmoid colon while intubating patients with severe diverticulosis. Baumann compared water infusion (200 mL) with traditional air insufflation during colonoscopic examination[13]. He found that passing through the left colon was faster with the water method than with the air method. Brocchi *et al*[6] compared warm water (300 mL) infusion with seed oil and traditional air insufflation during colonoscopic examination. They found that water infusion was associated with a higher cecal intubation rate, shorter intubation time and less pain than in the control group.

Recently, Leung *et al*[9] employed a novel method with infusion of a large amount of water during the insertion phase. In their pilot study, airless water intubation permitted 52% of patients to complete the procedure without sedation. A mean volume of more than 1 L of water was infused in aliquots of 30 to 60 mL. The major drawback of this technique was the long intubation time of up to 22.6 min[9]. In a subsequent randomized, controlled study comparing water intubation with air insufflation, the water was infused intermittently with a peristaltic pump with a blunt needle adaptor through the biopsy channel[10]. The cecal intubation times were comparable between the two groups. The endoscopists found that the increments of medications and the maximum pain scores were significantly lower with the water method[10].

Our study showed that a lower mean pain score was experienced in the water group (2.5 ± 2.5) than in the air group (3.4 ± 2.8, $P = 0.021$). A previous study has shown that patient discomfort occurs when the colonoscope tip reaches the sigmoid colon[14]. Loop formation of the colonoscope occurring mostly in the sigmoid colon is the major cause of pain[15]. We infused water instead of air in the rectum and sigmoid colon in our study. By eliminating air in the sigmoid colon, we reduced the loop formation and caused less pain in these patients. The weight of the water might also be helpful in reducing looping over the sigmoid colon.

In the present study, we did not use air insufflation until the scope reached the transverse colon. The infused water accumulated at the descending colon due to gravity when patients were in the left lateral decubitus position. When the scope reached the transverse colon the air was switched on, otherwise much more water would have been needed to open the more proximal colon, which was at non-dependent areas. By limiting the use of water infusion to the distal colon, we could achieve intubation with little water (around 300 mL). This amount of water could easily be infused with a syringe instead of a peristaltic pump.

The intubation time was longer in the water group than in the air group (6.4 ± 3.1 min *vs* 4.5 ± 2.4 min). However, air had to be turned on prematurely in 8 (8.9%) patients in the water group. There are several reasons for the longer time in the water group. Firstly, it took time to infuse water into the biopsy channel repeatedly with a syringe. Secondly, it was difficult to open a collapsed segment or acute angle at a non-dependent portion without enough water. Thirdly, the view was less clear and the lumen was more difficult to find under water than with air insufflation, especially when the preparation was less than optimal. With a limited amount of water infused, our method had little cleansing effect on colon contents[8].

The polyp detection rates were similar in our study groups. After opening the lumen adequately with air insufflation and aspirating the residual stools and fluid, we inspected the mucosa closely when we withdrew the scope in both groups, so the infused water did not impair our ability to detect polyps. When the bowel preparation was adequate, we had no difficulty finding a polyp underwater during insertion.

In this study, we infused water at room temperature. Some previous studies used warm water[6,10,16], but others have used water at room temperature[13,17]. Church *et al*[16] showed that warm water minimized colon spasms and decreased patient discomfort. Most of our patients had received intravenous buscopan before colonoscopy, so we did not encounter any colon spasms in this study.

This study has several limitations. The procedures were performed by two experienced endoscopists, since the procedure conditions cannot appropriately be handled by less experienced doctors. The endoscopists were not blinded to the methods, but the patients were blinded. The use of the water method only reduced a small proportion (about 26%) of the pain scores; however the procedure was simple and cost-effective. We did not compare the syringe infusion method with a peristaltic pump method, although this does warrant further studies.

In conclusion, compared with traditional air insufflation, limited infusion of water at the distal colon resulted in less pain in patients undergoing minimally sedated colonoscopy, although a longer intubation time was required.

COMMENTS

Background

Colonoscopy can sometimes be quite painful. Pain during colonoscopy may originate from colon distension caused by air insufflation. Water instillation into the colon can facilitate intubation by straightening the sigmoid colon and decreasing the friction between the scope and the colonic mucosa. The weight of water also helps prevent loop formation.

Research frontiers

Recently, an airless water intubation method was proposed in which water, in lieu of air, was used to open the lumen of the colon. In previous studies, this method was found to decrease the use of sedative medication during sedated colonoscopy. However, a large amount of water was needed to inflate the colon adequately, which might increase procedure time or require an additional peristaltic pump. In this randomized, controlled study, the authors simplified the water intubation method by limiting the infusion of water to the rectum and sigmoid colon.

Innovations and breakthroughs

In the limited water group in the present study, the air pump was turned off initially during the procedure. Tap water in 50 mL syringes was instilled into the rectum and the sigmoid colon through the accessory channel to open the colon lumen. Water was not usually instilled in the descending colon because the

infused water already accumulated in this dependent segment. The air pump was opened when the colonoscope reached the transverse colon. No additional instrument was needed with this method and only about 300 mL of water was used to complete the colonoscopy.

Applications
This article shows that limited airless water infusion in the distal colon reduces patients' pain during colonoscopy. Further research should be done by less experienced endoscopists. In addition, head-to-head comparison of the limited water infusion method with total water infusion is needed.

Peer review
Hsieh *et al* present the results of the largest randomized trial yet performed to assess the value of water instillation to facilitate colonoscopy, here in minimally sedated patients. In general the paper is well written, the methodology is good and the results will generate widespread interest amongst endoscopists.

Abstract

AIM: To determine the optimal dosage and mechanism of Ginkgolide B (BN52021) on severe acute pancreatitis (SAP) of rats.

METHODS: Seventy male Wistar rats were randomly divided into seven groups (10 for each group). Sham-operation group (SO), SAP model group (SAP), dimethyl sulfoxide (DMSO) contrast group (DMSO), and groups treated with 2.5 mg/kg BN52021 (BN1), 5 mg/kg BN52021 (BN2), 10 mg/kg BN52021 (BN3), and 20 μg/kg Sandostatin (SS). The SAP model was established in Wistar rats by injecting 5% sodium taurocholate retrogradely into the common bilio-pancreatic duct. The rats of SO, DMSO and BN52021 were injected with 0.9% NaCl, 0.5% DMSO and BN52021 through femoral vein 15 min after the operation. The SS group was injected with Sandostatin subcutaneously. All rats were anaesthetized at 6 h after operation, and venous blood was collected to determine the levels of serum amylase and phospholipase A2 (PLA2), and pancreas tissue was harvested and stained.

RESULTS: There was no significant difference between the SAP and DMSO groups in serum amylase level, PLA2, ascites and pathologic score, but significant difference was found in SAP/DMSO groups compared with those in SO group ($P < 0.05$) and the levels of serum amylase, PLA2, ascites, and pathologic score were lower in the BN1, BN2, BN3 and SS groups than in the SAP and DMSO groups ($P < 0.05$). However, among BN1, BN2, BN3 and SS groups, BN2 had the best effect in decreasing the levels of serum amylase and PLA2 ($P < 0.05$). Expression of platelet activating factor (PAF) receptor (PAFR) mRNA and protein showed no significant difference between the SAP and DMSO groups, or among BN1, BN2, BN3 and SS groups, but there was remarkable difference between SAP/DMSO group and SO group ($P < 0.05$), and expression of PAFR mRNA and protein was higher in the BN1, BN2, BN3 and SS groups than in the SAP and DMSO groups ($P < 0.05$). PAFR expression was observed in the nucleus and cytoplasm of pancreatic islet cells in Wistar rats by immunohistochemistry.

CONCLUSION: By iv injection, 5 mg/kg of BN52021 is the optimal dosage for SAP rats. BN52021 may inhibit the interaction/binding of PAF with PAFR.

INTRODUCTION

Platelet activating factor (PAF) is a biologically active phospholipid mediator, playing its role by binding to PAF receptor (PAFR) which is a unique G-protein-coupled seven transmembrane receptor, and it activates multiple intracellular signaling pathways[1]. Flickinger *et al*[2] revealed specific localization of PAFR in the pancreatic vascular endothelium, but not in other pancreatic cell types. Recent studies demonstrated that PAF played an important role in the pathological progress of severe acute pancreatitis (SAP)[3].

Ginkgolide B (code: BN52021) is one of the four Ginkgolide constituents (Ginkgolide A, B, C and J), which are present in the whole extract of Ginkgo biloba leavies. It has been found that BN52021 possesses activity as antagonists of the action of PAF. It can inhibit PAF-induced cascade effect in inflammatory reactions. For example, it can reduce the portal vein pressure of liver cirrhosis, exhibit an anti-shock effect, and exert protective functions on experimental asthma[4,5].

SAP is dangerous to life. It can cause multiple organ system failure (MOSF) and if the patients do not receive effective treatment in time, they may die. But up till now, there has been no effective drug for this disease. Recent studies have shown that BN52021 has best effect on experimental SAP[6,7], but there is no report on its optimal dosage, and its mechanism has not been fully understood. Especially as an extract of Ginkgo biloba, it is hypotoxic, and can be used in clinical treatment of SAP. We investigated the optimal dosage of BN52021 and its mechanism on SAP.

MATERIALS AND METHODS

Main reagents and apparatus

BN52021 and sodium taurocholate were purchased from Sigma (St. Louis, MO, USA), amylase kit from Beijing Kemei Reagent Co. (Beijing, China), trizol and diethyl pyrocarbonate (DEPC) from Invitrogen (Carlsbad, CA, USA), RT kit from MBI Fermentas (Ontario, Canada), DNTPs and RNA enzyme inhibitor from TaKaRa Dalian Co., Ltd. (Dalian, China), DNA Tag enzyme from Promega (Madison, WI, USA), primary antibody of PAF-R rabbit-anti-rat serum and the enhanced chemiluminescence system from Santa Cruz Biotechnology (Santa Cruz, CA, USA), secondary antibody of sheep-anti-rabbit from Beijing Dingguo Biotechnology Co., Ltd. (Beijing, China), β-actin from Beijing Zhongshan Biotechnology Co., Ltd. (Beijing, China), DYY-12 electrophoresis system and electric trans-blot SD from Beijing Liuyi Instrument Factory (Beijing, China), Type-2720 polymerase chain reaction (PCR) apparatus from ABI (Foster, CA, USA), and gel scanning and imaging system and vertical electrophoresis system from Bio-Rad (Hercules, CA, USA).

Primer sequences

PAF-R and β-actin primer series are provided by Invitrogen (Carlsbad, CA, USA): PAF-R: forward primer (F): 5'-CCGCTGTGGATTGTCTATTA-3', reverse primer (R): 5'-AGGAGG TGATGAAGATGTGG-3' (377 bp)[8]; β-actin: F: 5'-TCC TAGCACCATGAAGATC-3', R: 5'-AAACGCAGCTCAGTAACAG-3' (190 bp)[9].

Experimental animal grouping and model preparation

Seventy Wistar male rats (Laboratory Animal Center of PLA, Academy of Military Medical Sciences, Beijing, China), aged 6-8 wk, and weighing 200-220 g (Grade Ⅱ, Certificate SCXK 2002-001) are used for this study. All rats were maintained in an environment of controlled temperature (22-25℃), humidity (55%-58%), and lighting (12 h light/12 h dark), with free access to tap water and regular chow diet. Rats were divided randomly into 7 groups: Sham-operation group (SO group, $n = 10$), SAP model group (SAP group, $n = 10$), DMSO contrast group (DMSO group, $n = 10$), and treatment groups of 2.5 mg/kg BN52021 (BN1 group, $n = 10$), 5.0 mg/kg BN52021 (BN2 group, $n = 10$), 10.0 mg/kg BN52021 (BN3 group, $n = 10$), and 20.0 μg/kg Sandostatin (SS group, $n = 10$)[10]. SAP model was established according to Aho *et al*[10]. All rats were weighed, marked and fasted for 24 h before operation. The rats were anesthetized by abdominal injection of 0.4% pentobarbital sodium (40 mg/kg), and fixed in dorsal decubitus. A 2-cm cut was made at the center of the upper belly, entering the abdominal cavity to look for rat's duodenum and pancreaticobiliary duct. The hepatic end of the pancreaticobiliary duct was clipped with a non-invasive vascular clip, and pancreaticobiliary duct retrograde centesis was performed with an obtuse needle through duodenum seromuscular layer. Then 5% sodium taurocholate (0.1 mL/100 g) was injected in the retrograde direction of pancreaticobiliary duct with a micro-syringe at an injection rate of 0.20 mL/min. After injection, the port of pancreaticobiliary duct entering duodenum was clipped with a non-invasive vascular clip and observed for 10 min. When no active bleeding was confirmed in the abdominal cavity, the abdomen was closed in two layers and the incision was covered with sterile gauze. Same treatment was given to the SO group but without injections into the duct. Fifteen min after the model was completed, the rats in SO and SAP groups were injected with physiological saline (0.9% NaCl) through femoral vein at a dose of 5ml/kg; the rats of DMSO group were injected with DMSO (0.5% DMSO) at a dose of 5ml/kg; the BN1, BN2, and BN3 groups were rapidly injected with BN52021 at doses of 2.5, 5.0 and 10.0 mg/kg, dissolved with 0.5% DMSO; and SS group was injected with Sandostatin subcutaneously at a dose of 20.0 μg/kg[11].

Collection and storage of samples

Rats in each group were anaesthetized at 6 h after first injection of Sodium taurocholate, because the $T_{1/2}$ of BN52021 is 5.23 h[12], venous blood was collected from right atrium and was centrifuged for 10 min at 3000 g/min after a 10-min water bath at 37℃. The supernatant was placed into a sterilized EP tube, and stored in refrigerator at -20℃ for serum amylase determination. Portions of pancreatic tissues were placed in liquid nitrogen overnight and frozen in refrigerator at -80℃, meanwhile, another portion of pancreatic tissues was fixed with 40 g/L neutral buffer formaldehyde, embedded in paraffin wax, cut into slices and stained with HE for pathological observation and scoring. Pneumonic tissues were fixed with 40 g/L neutral buffer formaldehyde, embedded in paraffin wax, and cut into slices for immunohistochemical studies.

Determination of serum amylase, PLA₂ and pathological observation, scoring of pancreatic tissues

Serum amylase and PLA₂ were detected with fully automatic biochemical apparatus, amylase and PLA₂ kits. Pancreatic tissue samples were observed pathologically and scored according to the reference[13].

Determination of PAFRmRNA expression by reverse transcription PCR

After total RNA from pancreatic tissue in each group was extracted, its integrality was checked with agarose electrophoresis, and its concentration and purity were determined with an UV spectrophotometer, and the concentration was calculated. RNA 5 μg and Oligo DT₁₅ 1.25 μg were placed into a water bath at 70℃ for 5 min, rapidly put into ice for 5 min, and centrifuged just for 15 s. 5 × M-MLV reverse transcription buffer 5 mL, DNTPS 0.05 μmol, RNA enzyme inhibitor 40 U, M-MLV and reverse transcriptase 1 μL were added, and diluted to 25 μL with deionized water treated by DEPC. The whole mixture was maintained at 42℃ for 60 min. Reverse transcription was conducted and reverse transcriptase was deactivated at 95℃ for 5 min. The mixture was maintained at 4℃ for 5 min and preserved at -20℃. Fifty microliters PCR reaction system consists of 3 μL reverse transcription product, 0.01 μmol DNTPS, 5 μL 10 × PCR buffer, 0.075 mol MgCl₂ (Magnesium Chloride), 50 pmol of each PAF-R specific sense strand and anti-sense strand, and 50 pmol of each β-actin sense strand and anti-sense strand. Reaction conditions were as follows: pre-denaturizing at 94℃ for 3 min, denaturizing at 94℃ for 45 s, annealing at 58℃ for 45 s, and extending at 72℃ for 45 s, 38 cycles in total; extending at 72℃ for 7 min, and preserving at 4℃. The PCR product was included in the PAF-R gene sequence of rat spleen (gi:470384), which was performed by Beijing Boya Biotechnology Co., Ltd. The PCR product was analyzed by 2% agarose gel electrophoresis, ethidium bromide staining, and a gel imaging system scanning. Gray level of PCR product was treated by PAF-R and β-actin was analyzed using the Quantity-One Software, and the change of PAF-R mRNA expression was evaluated semi-quantitatively.

Determination of PAFR protein expression by immunohistochemistry

Paraffin slices of pancreas (5 μm) were made, mounted on slides and treated with paraformaldehyde-lysine-periodate solution. The slides were immersed in 100% dimethylbenzene for 15 min, 100% ethanol for 10 min, 95% ethanol for 5 min, 80% ethanol for 5 min, 70% ethanol for 5min, and washed with phosphate-buffered saline (PBS). The slides were immersed in citrate solution for 15 min in microwave at high temperature, cooled at room temperature, washed for 3 times with PBS, incubated with the rabbit polyclonal antibody against a recombinant protein corresponding to amino acids at the amino terminus of PAFR (1:100) for 18 h at 4℃, then incubated with goat anti-rabbit IgG-HRP polymer (1:500) for 0.5 h at 4℃, washed with PBS after incubation, and then incubated with DABH₂O₂ solution for color development, and washed with lotic water. The slices were counterstained with hematoxylin and mounted with coverslips. The slices were observed and analyzed, and the quantity of PAFR protein expression was determined according to the density of positive cells. Some frozen slices of pancreatic tissues and paraffin slices of lung tissues were made to observe the location of PAFR in pancreatic and lung tissues by immunohistochemistry.

Statistical analysis

The experiments were repeated for 3 times and their average values served as the final values; all values were expressed as mean ± SD. Data were processed with SPSS 11.5 Statistical Software, and LSD and Dunnett's post-hoc method were used for comparison of ANOVA. Statistical significance was established at $P < 0.05$.

RESULTS

Serum level of amylase and PLA₂, quantity of ascites and pathological scores

There were no significant differences in the serum levels of amylase and PLA₂, quantity of ascites and pathological scores between SAP and DMSO groups. It was higher in SAP/DMSO group than in SO group ($P < 0.05$), and lower in BN1, BN2, BN3 and SS group than in SAP/DMSO group ($P < 0.05$). However, BN2 had the best effect in decreasing the serum level of amylase and PLA₂ among BN1, BN2, BN3 and SS groups ($P < 0.05$) (Table 1, Figure 1).

Expression of PAFR mRNA and its proteins in pancreatic tissues

There was no significant difference in expressions of PAFR mRNA and PAFR protein between SAP and DMSO groups, neither among BN1, BN2, BN3 and SS groups. Expression of PAFR mRNA and its proteins in pancreatic tissues was lower in SAP/DMSO group than in SO group ($P < 0.05$), and higher in BN1, BN2, BN3 and SS groups than in SAP/DMSO group ($P < 0.05$) (Table 2, Figures 2 and 3).

Location of PAFR in pancreatic and lung tissues

PAFR was located in pancreatic microvascular endothelial

Figure 1 Pathological change of pancreatic tissues (HE staining, × 200). A: Sham-operation group; B: Severe acute pancreatitis group; C: DMSO group; D: 2.5 mg/kg BN52021 group; E: 5.0 mg/kg BN52021 group; F: 10 mg/kg BN52021 group; G: 20 μg/kg Sandostatin group.

cells and bronchia epithelial cells. It was first found in the nuclei of pancreatic islet cells and cytoplasm of Wistar rats (Figure 4).

DISCUSSION

Amylase, PLA₂, score of pathologic changes of pancreas and quantity of ascites were reduced after administration of BN52021 at 2.510 mg/kg, and the pancreas PAFR mRNA or protein was protected. PAFR expression was found in the pancreas' islet, which has not been reported by others

up till now. The best effect was shown at 5 mg/kg among BN groups. BN52021 at 5 and 10 mg/kg showed equivalent effects on SAP, and 10 mg/kg was less effective such as in serum amylase. This may be caused by the dose range between 10 and 5 mg/kg.

PLA₂ is pivotal in the pathogenesis of SAP. There are two types of PLA₂: cytosolic phospholipase A₂ (cPLA₂) and secretory PLA₂ (sPLA₂).There is a cross-talk between

Figure 3 Expression of platelet activating factor receptor in pancreatic tissues by immunohistochemistry (HE staining, × 200). sPLA₂ and cPLA₂. sPLA₂ activates a signaling cascade, including activation of cPLA₂, arachidonic acid release, PAF production, and induction of COX-2[14]. PLA₂ can decompose the membrane to release PAF. It is known that PAF is an initiative factor in the pathogenesis of SAP, and the cascade exacerbates the course of pancreatitis by activating the PLA₂ in membrane. BN52021 antagonizes PAF by restraining the activation of PLA₂ and this is the first report about the relation between

BN52021 and PLA₂ in SAP.

Quantity of ascites showed the severity of pathological changes of pancreas. When pancreas is involved in inflammation, hemorrhage and putrescence, it would irritate peritoneum and peritoneal permeability was increased, resulting in the release of ascites. PLA₂ was closely correlated with the release of ascites[15]. The results indicated that BN52021 can reduce the PLA₂ in plasma and decrease the quantity of ascites, and that BN52021 may interact defi-

nitely on other inflammatory factors to reduce peritoneal permeability.

The level or regulation of PAFR mRNA and PAFR protein has not been clearly studied. In our experiments, expression of PAFR in pancreas was up-regulated in the initial 3 h in SAP, but down-regulated after 6 h[16]. The reason for this may be in the first 3 h, pancreas could release more inflammatory factors to induce the up-regulation of PAFR, such as tumor necrosis factor α[17] and interferon-β, but cellular membrane was destroyed completely along with severe damages occurring in the pancreas after 6 h. In addition, protein kinase C excess activation was reported to decrease expression of PAFR[18], followed by a down-regulation of mRNA. BN52021 protected the membrane so that it maintained the quantity of PAFR. There was significant difference between SAP and BN52021 groups. The ratio of IOD of PAFR to β-actin was gradually improved in 2.5 and 10 mg/kg BN52021 groups, although there was no significant difference among BN52021 groups, and remarkable difference was found among SO group, 5 mg/kg SAP group and 5 mg/kg BN group.

It was firstly reported that PAFR was located in pancreas' islet, and it is important to study the mechanism of pancreas inflammation. BN52021 exerted its protective effects in patients with diabetes and pancreatitis, but the active mechanism is not clear. When inflammation in pancreas happened, PAFR was up-regulated, and the cells released more PAF, which damaged the pancreas. As BN52021 competitively inhibited the combination of PAF and PAFR and released less PAF, the pancreas was protected. It meant that BN52021 achieved its effects on SAP not only by reducing the quantity of PAFR, but also by inhibiting the combination of PAF and PAFR and maintaining the integrity of the cells of pancreas.

In conclusion, 5 mg/kg BN52021 is the optimal dose in treating SAP rats, which can reduce the amylase and PLA₂ in serum and the quantity of ascites. It prevents the pancreas from severe damage induced by sodium taurocholate. Compared with Sandostatin, a classical drug for SAP, BN52021 exerts the best effects in treating SAP rats. This paper also showed that BN52021 achieves therapeutic effects in SAP rats not only by reducing the quantity of PAFR, but also by inhibiting the combination of PAF and PAFR and maintaining the integrity of the cells of pancreas. Because of its hypotoxicity as an extract of *Ginkgo bibola*, it will be of significance in clinical application. More experiments are needed for the extensive application of BN52021 in clinic.

COMMENTS

Background
Platelet activating factor (PAF) is a family of phosphorylcholine esters with diverse potent physiological effects. It is closely associated with the cell membrane and is found in a variety of cells. Numerous cell types and tissues have been shown to synthesize and release PAF upon stimulation and at the same time to exhibit biological responses to it. Flickinger *et al* found the specific localization of PAF receptor (PAFR) in the pancreatic vascular endothelium, but not in other pancreatic cell types.

Research frontiers
Recent studies demonstrated that PAF played an important role in the pathological progress of severe acute pancreatitis (SAP). It has been found that BN52021 possesses activity as antagonists of the action of PAF. However, there is no report on its optimal dosage. Although BN52021 has shown best effects on treating SAP, its mechanism has not been elucidated in details. This paper investigated the optimal dosage of BN52021 and its mechanism on SAP.

Innovations and breakthroughs
Recent reports have highlighted the importance of PAF in SAP and have shown that BN52021 has best effect on experimental SAP. This is the first study to report the optimal dosage of BN52021. The authors discovered that there is PAFR expression in the pancreas' islet, which has not been reported by others up to now. The *in vitro* studies suggest that this protein may be the cause of the repression in E-cadherin observed in this cancer.

Applications
By understanding how PAF is induced and by blocking its expression, this study may represent a future strategy for SAP treatment with BN52021.

Terminology
PAF is a biologically active phospholipid mediator, playing its role by binding to platelet activating factor receptor (PAFR) which is a unique G-protein-coupled seven transmembrane receptor, and it activates multiple intracellular signaling pathways, including the nucleal PAFR. Ginkgolide B (code:BN52021) is one of the four Ginkgolide constituents (Ginkgolide A, B, C and J), which are present in the whole extract of *Ginkgo biloba leavies*.

Peer review
The authors examined the level of serum amylase and PLA₂, quantity of ascites, and pathological scores, the expression of PAFR mRNA and its proteins in pancreatic tissues and location of PAFR in pancreatic and lung tissues. It revealed that PAFR expressed in the pancreas' islet and the best effect on SAP was shown in the 5 mg/kg group. This paper also showed that BN52021 achieves the therapeutic action on SAP rats not only by reducing the quantity of PAFR, but also by inhibiting the combination of PAF and PAFR and maintaining the integrity of the cells of pancreas. The results are interesting and may represent a molecular mechanism of BN52021 on SAP.

Abstract

AIM: To evaluate the association of human leukocyte antigen (HLA)-DQB1 alleles with hepatocellular carcinoma (HCC) through meta-analysis of published data.

METHODS: Case-control studies on HLA-DQB1 allele association with HCC published up to January 2010 were included in the analyses. The odds ratios (ORs) of HLA-DQB1 allele distributions in HCC patients were analyzed and compared with healthy controls. The meta-analysis software REVMAN 5.0 was applied for investigating heterogeneity among individual studies and for summarizing all the studies. A meta-analysis was performed using fixed-effect or random-effect methods, depending on the absence or presence of significant heterogeneity. Seven case-control studies containing 398 cases and 594 controls were included in the final analysis.

RESULTS: Among the five family alleles, two (DQB1*02 and DQB1*03) were found to be significantly associated with the risk of HCC. The combined OR for the association of DQB1*02 and DQB1*03 allele with the risk for HCC was 1.78 (95% CI: 1.05-3.03, P = 0.03) and 0.65 (95% CI: 0.48-0.89, P = 0.007), respectively. Among the 13 specific alleles, two (DQB1*0502 and DQB1*0602) were significantly associated with risk of HCC. The combined OR for the association of DQB1*0502 and DQB1*0602 allele with the risk for HCC was 1.82 (95% CI: 1.14-2.92, P = 0.01) and 0.58 (95% CI: 0.36-0.95, P = 0.03), respectively. No significant association was established for other HLA-DQB1 family alleles and specific alleles.

CONCLUSION: Our results support the hypothesis that specific HLA-DQB1 allele families and alleles might influence the susceptibility or resistance to HCC, although it needs further investigations.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third most com-

mon cause of cancer-related deaths worldwide and about 600 000 patients died from the disease annually[1]. Nearly 78% of the 600 000 cases are from Asian countries[2]. China alone accounts for more than 50% of the world's cases[3]. The development of HCC is linked to the interaction of the genetic, immunologic, environmental, dietary, and lifestyle factors. Its incidence and distribution vary widely among ethnic groups, sex, and geographic regions. HBV and HCV infection, liver cirrhosis, male gender, and old age are important risk factors of HCC. The clustering of HCC within families raises the possibility that genetic factors are also involved in the susceptibility to HCC.

The major histocompatibility complex (MHC) plays a key role in anti-virus and tumor defense. Human leukocyte antigens (HLA) function in the regulation of immune response to foreign antigens and discrimination of self from non-self antigens. They are encoded by a series of closely linked genetic loci found on chromosome 6[4,5]. HLA polymorphism is implicated in conferring genetic susceptibility to a large number of immune-mediated diseases, including some cancers. Given the pivotal role of HLA molecules in the immune system, several studies have investigated the association between specific HLA alleles and HCC. However, the association between HLA-DQB1 alleles and HCC in different ethnic populations is controversial. As many conflicting reports have been published to date, we conducted a systematic review of all the relevant studies published in the literature to evaluate the association between HLA-DQB1 alleles and HCC. Our principal objectives were to clarify the specific HLA-DQB1 allele families or alleles that are associated with the risk of HCC development.

MATERIALS AND METHODS

Literature search
Electronic databases (PubMed, EMBASE, Cochrane Library and China National Knowledge Infrastructure) were used to search for all genetic association studies evaluating the HLA-DQB1 polymorphism and HCC in humans in all languages up to January 2010. The search strategy was based on combinations of the key words, "HLA" or "human leukocyte antigen" and "hepatocellular carcinoma" or "HCC", and was not restricted by period. We also did a full manual search from the bibliographies of selected papers. In addition, we contacted the authors of studies containing relevant information, who did not report the results necessary for this analysis. Unpublished data were also accepted if an abstract was available and further information was obtained from the authors.

Inclusion and exclusion criteria
In the meta-analysis, the following inclusion criteria were set and reviewed by two independent investigators: (1) an independent case-control study; (2) studies with similar purpose and statistical methods; (3) studies providing enough information to calculate the odds ratio (OR); (4) HLA-DQB1 alleles were molecularly typed (high or low resolution level); and (5) the diagnosis of HCC was based on at least one of the following criteria: typical histological characteristics or serum α-fetoprotein (AFP) levels higher than 400 ng/mL together with radiological findings (ultrasound and CT) consistent with HCC.

The following exclusion criteria were set: (1) incomplete raw data; (2) repetitive reports (if more than one version of the same study was retrieved, only the most recent was used); and (3) materials and methods were not well-described and reliable.

Although assessment of study quality is considered important for systematic reviews and meta-analyses, scoring methods have been considered problematic[6] and may not accurately assess the quality measures of interest[7]. Therefore, we used reliability of patient selection, molecular typing method, and statistical analysis method as quality variables.

The frequency of HLA-DQB1 alleles varies according to ethnic and racial background, with some alleles being extremely rare. Therefore, articles were not required to identify all alleles for inclusion.

Data extraction
The studies were independently evaluated by two researchers (Xin YN and Lin ZH). Discrepancies in the evaluations of studies were resolved by discussion between the reviewers.

The following data were collected from each study: authors, publication year, journal, publication type and language, HLA genotyping method, allele genotype, number of cases and controls, definitions used for HCC, HCC sample description, control sample description (if there was more than one control group, we choose the healthy group as the control group in order to minimize the confounder). The main features of the trials included in the meta-analysis are shown in Table 1.

Statistical analysis
Homogeneity was calculated by Cochran's Q test (α = 0.05). If the results of the Q test had no significant heterogeneity, the Mantel-Haenszel fixed-effect model (Peto method) was used for the combined data. If the results of the Q test had significant heterogeneity, the Dersimonian-Laird random-effects model (DL method) was used for the combination of data[8]. A pooled OR was presented as a standard plot with 95% CIs. In the absence of heterogeneity, the two methods provided identical results. As a measure of association between HCC and HLA-DQB1 alleles, we combined ORs with 95% CIs stratified by gene subtype of patients and controls in a study. Funnel plots and the Egger's regression asymmetry test were used to evaluate publication bias[9]. We performed a sensitivity analysis to assess the stability of the results by sequential omission of individual studies. All P values presented are two-tailed. The analyses were performed using Revman 5.0 provided by the Cochrane Collaboration Internet.

Table 1 Characteristics of studies included in the meta-analysis

Study	Country/region	No. of HCC (M/F), age (yr)	No. of controls (M/F), age (yr)	No. of DQB1 alleles studied	Type of control	HLA genotyping method

RESULTS

Literature assessment

Figure 1 shows the flow diagram of publications identified by the literature search. The search strategy allowed us to identify 60 studies for potential inclusion in the meta-analysis. Only 7 case-control studies relating to HLA-DQB1 alleles polymorphism and susceptibility to HCC qualified on the basis of our selection criteria[10-16]. A total of 991 subjects were studied (398 patients and 593 controls) (Table 1). Two of these studies were conducted in mainland China, two in Hong Kong, and one each in Italy, Egypt, and Spain. The diagnosis of HCC was based on at least one of the following criteria: typical histological characteristics or serum AFP levels higher than 400 ng/mL together with radiological findings (ultrasound and/or CT) consistent with HCC. The control group of six studies consisted of healthy individuals, while only one study used HCV carriers as the control group[13]. Records of mean or median age and sex were incomplete in 4/7 reports. HIV status was determined in two reports[12,15].

HLA-DQB1 alleles were considered only when they were classified in at least two independent studies.

HLA-DQB1 alleles were molecularly typed (high or low resolution level). Six studies used high resolution molecular typing for HLA, while the Italian study used both high and low resolution molecular typing for HLA. Low resolution molecular typing methods for HLA could not identify the specific alleles. Accurate methods for HLA class II typing should involve the combination of polymerase chain reaction (PCR)-sequence-specific oligonucleotides probes, PCR-sequence specific primer and PCR-single strand conformation polymorphism[17].

Association between HLA-DQB1 alleles and HCC

A total of five HLA-DQB1 allele families and 13 specific alleles were extracted from the studies to investigate their association with HCC. Six specific alleles were excluded because each was identified in only one study.

Among the allele families, two (DQB1*02 and DQB 1*03) were significantly associated with risk of HCC. In the meta-analysis, the overall frequency of DQB1*02 was 32.9% (131/398) in HCC, and 24.5% (145/593) in controls. The heterogeneity test indicated that the variation of trial-specific ORs was statistically significant (χ^2 = 15.28, P = 0.02 and < 0.05); the random-effect method was used to combine the results. The combined OR was 1.78 (95% CI: 1.05-3.03) and was statistically significant (P = 0.03 and < 0.05). In sensitivity analysis, the exclusion of individual studies did not change this significant result, except for the studies by Li *et al*[10], López-Vázquez *et al*[13], Liu *et al*[14] and El-Chennawi *et al*[15], which produced a non-significant association. Overall, the frequency of DQB1*03 was 50.0% (199/398) in HCC and 62.7% (372/593) in controls. The heterogeneity test indicated that the variation of trial-specific ORs was not statistically significant (χ^2 = 11.53, P = 0.07 and > 0.05). The fixed-effect method was used to combine the results. The combined OR was 0.65 (95% CI: 0.48-0.89) and was statistically significant (P = 0.007 and < 0.05). In sensitivity analysis, the exclusion of individual studies did not change this significant result, except for the study by De Re *et al*[12], which produced a non-significant association. Statistics calculated for each study about DQB1*03 are shown in the forest plot (Figures 2 and 3). Meta-analysis for another 3 HLA-DQB1 allele

families (DQB1*04, DQB1*05 and DQB1*06) was carried out, but did not show any statistical effect.

Among the specific alleles, two (DQB1*0502 and DQB1*0602) were significantly associated with risk of HCC. In the meta-analysis, the overall frequency of HLA-DQB1*0502 allele was 18.3% (47/257) in HCC, and 12.3% (43/349) in the controls. The heterogeneity test indicated that the variation of trial-specific ORs was not statistically significant ($\chi^2 = 0.50$, $P = 0.92$ and > 0.05); the fixed-effect method was used to combine the results. The combined OR was 1.82 (95% CI: 1.14-2.92), and was statistically significant ($P = 0.01$ and < 0.05). In sensitivity analysis, the exclusion of individual studies did not change this significant result, except for the study by Donaldson et

al[11], which produced a non-significant association. Overall, the frequency of HLA- DQB1*0602 allele was 23.7% (41/173) in HCC and 31.4% (71/226) in controls. The heterogeneity test indicated that the variation of trial-specific ORs was not statistically significant ($\chi^2 = 1.26$, $P = 0.53$ and > 0.05); the fixed-effect method was used to combine the results. The combined OR was 0.58 (95% CI: 0.36-0.95) and was statistically significant ($P = 0.03$ and < 0.05). In sensitivity analysis, the exclusion of individual studies did not change this significant result, except for the study by Liu et al[14], which produced a non-significant association. Statistics calculated for each study of DQB1*0502 and DQB1*0602 are shown in the forest plot (Figures 4 and 5). Meta-analysis for another 11 HLA-DQB1 specific alleles

Study or subgroup	HCC		Control		Weight (%)	Odds ratio	Odds ratio

Test for overall effect: Z = 2.17 (P = 0.03)

Figure 5 Meta-analysis forest plot of included studies on the association between human leukocyte antigen-DQB1*0602 allele and hepatocellular carcinoma. HCC: Hepatocellular carcinoma.

Figure 6 The funnel plot to detect publication bias of each study for DQB1*02, DQB1*03, DQB1*0502 and DQB1*0602. Each point represents a separate study for the indicated association. A: Funnel plot analysis of human leukocyte antigen (HLA)-DQB1*02 allele and hepatocellular carcinoma (HCC) to detect publication bias ; B: Funnel plot analysis of HLA-DQB1*03 allele and HCC to detect publication bias; C: Funnel plot analysis of HLA-DQB1*0502 allele and HCC to detect publication bias; D: Funnel plot analysis of HLA-DQB1*0602 allele and HCC to detect publication bias.

(DQB1*0201, DQB1*0301, DQB1*0302, DQB1*0303, DQB1*0401, DQB1*0402, DQB1*0501, DQB1*0503, DQB1*0601, DQB1*0603 and DQB1*0604) was carried out, but did not show any statistical relationships.

Our meta-analysis of seven studies revealed that DQB1*02 and DQB1*0502 were risk factors for HCC, while DQB1*03 and DQB1*0602 were protective factors. These results suggest that patients with DQB1*02 and DQB1*0502 alleles were at a higher risk of developing HCC than those with DQB1*03 and DQB1*0602 alleles. These analyses were based on the data from seven studies irrespective of the ethnicity of the study populations. The shape of the funnel plot to detect publication bias of each study for DQB1*02, DQB1*03, DQB1*0502 and DQB1*0602 seemed to be asymmetrical (Figure 6), sug-

gesting that publication bias might affect the findings of our meta-analysis.

DISCUSSION

To our knowledge, this is the first published meta-analysis to comprehensively investigate the association between HLA-DQB1 alleles and HCC. Numerous studies have reported associations of HLA with malignant tumors, such as thyroid cancer, renal cell cancer, Burkett's lymphoma, Kaposi's sarcoma, Hodgkin's disease, nasopharyngeal carcinoma, cervical carcinoma, esophageal carcinoma, gastric cancer, and HCC. However, most of these studies focused on the association between HLA antigen and cancer based on HLA serotyping which has limited reso-

lution, and may be inaccurate for the assignment of many HLA antigens. With the development of DNA-based methods for HLA genotyping, HLA genotyping has become more accurate in the determination of the HLA-DQB1 alleles, and more precise than serotyping in the determination of the peptide-binding domain of MHC class II molecules. Hence, HLA genotyping is being used more frequently in the field of immunogenetics.

Recent studies on the association between HLA-DQB1 allele polymorphisms and HCC have been inconclusive. Pan[16] reported that some HLA-DQB1 alleles are significantly associated with HCC (DRB1*04 and DQB1*02), while others (DQB1*06) are not. Therefore, it is possible that the DRB1*04 and DQB1*02 alleles might be risk factors for the occurrence of HCC (OR = 4.373 and 3.807, respectively), and DQB1*06 may be a protective allele (OR = 0.259). Lopez-Vazquez *et al*[13] confirmed that HLA-DQB1*0301 carriers rarely develop end-stage liver disease (ESLD). This allele may, therefore, be considered to be a good prognostic factor. De Re *et al*[12] have shown that the DQB1*0301 allele played a major protective role in patients with HCV-associated HCC. Donaldson *et al*[11] observed that the alleles DRB1*1501, DQA1*0302 and to a lesser extent DQB1*0302 appeared to confer resistance to HCC.

The current meta-analysis indicates that specific HLA-DQB1 alleles are associated with HCC. Among the 5 family alleles, DQB1*02 and DQB1*03 were significantly associated with risk of HCC. The combined OR was 1.78 (95% CI: 1.05-3.03) and 0.65 (95% CI: 0.48-0.89), respectively. Among the 13 specific alleles, DQB1*0502 and DQB1*0602 were significantly associated with risk of HCC. The combined OR was 1.82 (95% CI: 1.14-2.92) and 0.58 (95% CI: 0.36-0.95), respectively. These results suggest that DQB1*02 and DQB1*0502 alleles may have a higher risk for HCC, while DQB1*03 and DQB1*0602 alleles may have a protective effect for HCC.

The DQB1*02 allele family is negatively associated with the incidence of breast cancer in the Tunisian population[18], while the DQB1*03 allele family is associated with susceptibility to cervical carcinoma in Europe (OR = 3.03)[19], cutaneous T-cell lymphoma in USA (OR = 2.7)[20], and HCV-related non-Hodgkin's lymphoma in Italy (OR = 0.23)[12]. The DQB1*0502 allele is also associated with the susceptibility to Sezary syndrome of cutaneous T-cell lymphoma in USA (OR = 7.75)[20], while the DQB1*0602 allele is associated with an increased gastric cancer risk in Taiwan (OR = 2.79)[21] and increased distal gastric cancer risk in southern European population (OR = 4.82)[22]. DQB1*0602 also appears to be a candidate protective allele for testicular germ cell carcinoma in the Japanese population (RR = 0.26, *P* = 0.02)[23]. The mechanisms for these effects are unknown, but larger-scale studies may confirm this observation.

Human tumor cells express diverse types of antigens, depending on the etiology and pathogenesis of the disease[24]. Because tumor development is preceded by chronic inflammation, immune responses, whether towards the infectious agent itself or against tumor antigens, may

be critical for development of tumor. Different types of HLA molecules have different capability of binding and presenting tumor antigens. The association of specific HLA alleles with susceptibility or resistance to malignant tumors is probably attributable to a direct involvement of the HLA molecules as an antigen presenter or possibly due to a neighboring linked gene[14].

Several other points should be considered when interpreting the results of our study. Most studies did not control for the matching variables in the analysis, and the risk for HCC was not controlled for possible confounders such as HBV or HCV. These observational studies are more prone to bias than randomized clinical trial (RCT) studies. The shape of the funnel plot seemed to be asymmetrical, suggesting that publication bias might affect the findings of our meta-analysis.

In conclusion, this meta-analysis reveals that DQB 1*02 and DQB1*0502 are risk factors for HCC, while DQB1*03 and DQB1*0602 are protective factors. These findings are consistent with the previous studies about the association of HLA alleles and other cancers. In the present study, no attempt has been made to account for the potential confounding influence of cirrhosis in the development of HCC, although future studies of HLA should take this into consideration.

COMMENTS

Background
Hepatocellular carcinoma (HCC) is the third most common cause of cancer-related deaths worldwide and about 600 000 patients died from the disease annually. Human leukocyte antigen (HLA) polymorphism is implicated in conferring genetic susceptibility to a large number of immune-mediated diseases, including some cancers.

Research frontiers
The clustering of HCC within families raises the possibility that genetic factors are involved in susceptibility to HCC. Much attention has been paid to the potential role of HLA in the pathogenesis of HCC in an attempt to uncover the underlying mechanisms. However, the relationship between HLA-DQB1 and HCC remains controversial and no meta-analysis has been conducted.

Innovations and breakthroughs
This is the first meta-analysis which systemically studied the relationship between HLA-DQB1 and HCC susceptibility, and suggested that specific HLA-DQB1 allele families and alleles might influence the susceptibility or resistance to HCC, which needs further investigations.

Applications
The study concludes that DQB1*02 and DQB1*0502 are risk factors for HCC, while DQB1*03 and DQB1*0602 are protective factors, which provides an insight into the role of HLA-DQB1 in the pathogenesis of HCC. Furthermore, these findings are meaningful to early diagnosis and provide a new strategic approach to the prevention of HCC.

Terminology
Meta-analysis is a means of increasing the effective sample size under investigation through the pooling of data from individual association studies, thus enhancing the statistical power of the analysis.

Peer review
This is a very interesting meta-analytic study dealing with an important topic in HCC. The described analysis has been performed with precision and accuracy.

Abstract

This paper reports the first case of a patient with hepatocellular carcinoma with lymph node metastasis treated by sorafenib combined with gemcitabine plus oxaliplatin, with a partial response and normalization of α fetoprotein, which allowed curative surgery. The potential synergy between these three drugs needs to be confirmed, and is currently being investigated in a randomized phase Ⅱ trial.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide and the third most common cause of cancer mortality[1]. Underlying cirrhosis is present in 90% of cases. Its prognosis remains poor with lots of advanced forms, and there is no curative therapeutic approach.

Since 2007, sorafenib has been the standard treatment for first-line therapy of advanced or metastatic disease that is not eligible for intra-arterial chemo-embolization. It has been shown to significantly improve progression-free and overall survival[2]. However, sorafenib is not able to induce any objective response and tumor shrinkage that allows secondary surgery. Its role in neoadjuvant therapy has not been established either.

Although HCC has been documented as a chemoresistant tumor, some chemotherapeutic regimens, such as gemcitabine plus oxaliplatin, have shown some interesting efficacy results, with objective response rates around 20% and disease control rates > 50% in phase Ⅱ trials[3-5]. Here, we report what is believed to be the first case of a patient with advanced HCC who received sorafenib together with gemcitabine plus oxaliplatin, which allowed secondary curative surgery.

CASE REPORT

A 61-year-old man, working as a radiologist, was admitted

Figure 1 Computed tomography scan. A: A 4.5-cm hypervascular hepatic tumor (arrow) that occupied the sixth hepatic segment, without signs of underlying cirrhosis; B: After eight cycles of gemcitabine and oxaliplatin combined with sorafenib, we observed tumor shrinkage of > 40% (arrow), as compared to baseline assessment; C: Secondary surgery was performed: hemostatic clips were still visible on this postoperative CT scan.

Figure 2 Computed tomography scan. A: Initially, there were two metastatic lymph nodes (MLNs): one celiac (thin arrow) measuring 4 cm and one measuring 3 cm located in the liver hilum (thick arrow); B: Computed tomography scan taken after the end of the eight cycles of gemcitabine plus oxaliplatin combined with sorafenib, showed that the MLNs (thin arrow for celiac node and thick arrow for hilar node) decreased in size dramatically with a more necrotic aspect, which allowed secondary surgery followed by radiotherapy.

for a liver mass that was detected by ultrasonography that was performed for abdominal pain, in December 2009. He had a history of cholecystectomy and post-transfusional hepatitis C, which was treated effectively by interferon and ribavirin therapy in 1998. Clinically, the ECOG performance status was 0, the patient weighed 94 kg, his height was 188 cm, and he had no symptoms except for moderate abdominal pain that was controlled with class II analgesics. In January 2010, Abdominal computed tomography (CT) showed a 4.5-cm hypervascular hepatic tumor that occupied the sixth hepatic segment, without signs of underlying cirrhosis (Figure 1A). There were also two metastatic lymph nodes (MLNs): one celiac measuring 4 cm, and one measuring 3 cm located in the liver hilum (Figure 2A). Laboratory data showed normal blood cell and platelet counts, liver enzymes, bilirubin and albumin levels. α-fetoprotein (AFP) was markedly increased at 2572 ng/mL (upper limit of normal = 8). Esophagogastroduodenoscopy did not show gastroesophageal varices or other upper gastrointestinal tract abnormalities.

Fine needle echoendoscopic aspiration from celiac lymph nodes was performed and showed a typical trabecular liver carcinoma. Evaluation by a multidisciplinary team concluded that the primary tumor was theoretically resectable in this patient, who had an excellent performance status, without underlying cirrhosis, and who wished an aggressive therapeutic approach. However, because there were MLNs, initial surgery was rejected and intensive systemic therapy with sorafenib combined with gemcitabine plus oxaliplatin was initiated. He received four cycles of the GEMOX regimen (gemcitabine 1 g/m^2 on day 1 and oxaliplatin 100 mg/m^2 on day 2), as previously described[3]. This treatment was repeated every 2 wk and sorafenib was taken every day (400 mg twice daily). No grade 3/4 toxicities were observed. Grade 1 diarrhea, thrombopenia and neurotoxicity were reported, together with grade 2 asthenia after the fourth cycle. Efficacy assessment showed a decrease of AFP from 2572 to 97 ng/mL. CT scan showed tumor shrinkage of 25% in the liver (Figure 1B), and a slight decrease in MLN size, which were more necrotic (Figure 2B). A new multidisciplinary

evaluation was performed and it was decided to continue the same therapeutic schedule for more cycles. Second efficacy evaluation showed normalization of AFP levels (2.7 ng/mL) and tumor volume reduction of around 40% (Figure 2A), as compared to baseline assessment.

Surgery was then decided upon, which consisted of removing the primary tumor, together with satellite adenopathies. The sites were marked by surgical clips (Figure 1C) to allow for postoperative radiotherapy (RT).

Pathological examination of the specimens showed a well-differentiated HCC that measured 2.5 cm, without underlying cirrhosis (METAVIR score A1F2). All resection margins were negative, and only one lymph node of five removed was metastatic, which was located in the liver hilum and measured 2 cm, with a necrotic center. There were no postoperative complications except for exacerbation of oxaliplatin-induced neurosensory toxicity, as previously described[6,7]. Global status of the patient improved and postoperative RT of MLNs was performed, by delivering 46 Gy over 5 wk, without any side effects. Complementary adjuvant chemotherapy, with combined sorafenib and gemcitabine for 3 wk in four, was started for 3 mo, and is currently ongoing. Oxaliplatin was not reintroduced because of persistent grade 2 neurosensory toxicity.

DISCUSSION

The role of chemotherapy in HCC patients is still a matter of debate. There is no clear evidence for efficacy of any tested schedule in the adjuvant (or neoadjuvant) setting, as reviewed by a recent Cochrane study[8]. However, many oncologists are using systemic chemotherapy for their HCC patients in a palliative setting. Doxorubicin, which was considered as potential standard chemotherapy 20 years ago, seems to be toxic and does not convincingly improve survival over that with supportive care[9]. Recent studies have suggested that oxaliplatin and gemcitabine could be interesting agents, alone or in combination, even if there has been no phase III trial to confirm their efficacy. The choice of gemcitabine-oxaliplatin combinations in this disease is based on: (1) synergy between the two drugs and their sequence dependency (gemcitabine followed by oxaliplatin is most active in preclinical models)[10]; (2) clinical activity of gemcitabine alone and of 5-fluorouracil/oxaliplatin combination in patients with HCC in phase II trials[11,12]; and (3) lack of renal and hepatic oxaliplatin toxicity in cirrhotic patients, unlike doxorubicin. The GEMOX combination has thus been evaluated in many phase II studies with promising results in term of response rate and survival[3-5,13]. Patients with complete response have been described by ourselves and others[14].

In the pivotal SHARP trial, response rate with sorafenib was particularly low (2.3%) and not significantly different from placebo[2]. To the best of our knowledge, only one patient receiving sorafenib and eligible for secondary surgery has been reported in the literature[15]. Sorafenib does not seem to be a candidate drug for tumor downstaging that allows secondary surgery. However, the antiangiogenic effect of sorafenib seems to modify HCC vascularization, by normalizing tumor vessels[16]. This vascular normalization has been described as potentially favoring chemotherapy efficacy through better delivery of the drugs to the tumor site[17]. Combination of sorafenib and GEMOX could thus lead to synergistic antitumor activity.

The toxicity of the GEMOX regimen has been well described over the past 10 years through 31 phase II and two phase III trials, mainly in pancreatic and biliary tract cancers. Grade 3 neutropenia, thrombocytopenia and neurotoxicity have been reported in 22%, 11% and 10%, respectively, and severe nausea has occurred in 16% of the cases[18]. These results are similar to those described in the phase II trials that have evaluated this combination in HCC patients with underlying cirrhosis. The elevated liver enzymes and anaphylactic reactions (due to gemcitabine and oxaliplatin, respectively) did not seem more frequent in this population.

In the SHARP trial, diarrhea (grade 2 in 50%, grade 3 in 10%), weight loss, fatigue, hand-foot skin reaction (grade 2 in 30%, grade 3 in 8%), and hypophosphatemia were the most frequent toxicities associated with sorafenib. To date, no trial has assessed GEMOX plus sorafenib combination therapy.

Adjuvant RT after resection of MLNs from HCC is not common. To the best of our knowledge, only two Asian cases have been described in the literature[19,20]. However, three retrospective studies have demonstrated its role in local control of MLNs from HCC that is not eligible for surgery, but is present in patients with good performance status. RT doses range from 40 to 60 Gy, and could prolong overall survival[21-23]. For example, in Zeng's retrospective study on 125 patients, partial and complete responses were observed in 37.1% and 59.7% of patients, respectively. The median survival was 9.4 mo[23]. However, these results need to be confirmed. To avoid unnecessary toxicity, the RT dose chosen in the present case did not exceed 50 Gy[21].

In conclusion, this case is an example of successful multimodal aggressive treatment for advanced HCC, which combined for the first time, GEMOX and sorafenib followed by surgery and adjuvant radiotherapy and chemotherapy. GEMOX + sorafenib combination therapy was well tolerated with only grade 1/2 toxicity that was easily manageable, and gave an objective response, together with a dramatic decrease in AFP levels. These promising results need to be confirmed and GEMOX/sorafenib combination therapy is currently being evaluated in an ongoing randomized phase II trial and compared to sorafenib alone.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifer, and Directory of Open Access Journals. ISI, Thomson Reuters, 2009 Impact Factor: 2.092 (33/65 Gastroenterology and Hepatology).

Published by
Baishideng Publishing Group Co., Limited

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office
World Journal of Gastroenterology

http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ABOUT COVER

Raithel M, Dormann H, Naegel A, Boxberger F, Hahn EG, Neurath MF, Maiss J. Double-balloon-enteroscopy-based endoscopic retrograde cholangiopancreaticography in post-surgical patients.
World J Gastroenterol 2011; 17(18): 2302-2314
http://www.wjgnet.com/1007-9327/full/v17/i18/2302.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Celiac disease now affects about one person in a hundred in Europe and North America. In this review, we consider a number of important and exciting recent developments, such as clinical associations, HLA-DQ2 and HLA-DQ8 predispositions, the concept of potential celiac disease, the use of new imaging/endoscopy techniques, and the development of refractory disease. This review will be of use to all internists, pediatricians and gastroenterologists.

INTRODUCTION

Celiac disease (CD) is an immune-mediated enteropathy characterized by intolerance to gluten. CD is usually characterized by various gastrointestinal (GI) symptoms (e.g. diarrhea, malabsorption, weight loss) associated with consumption of grains containing gluten (wheat, barley, rye). Although some CD patients may have primarily GI symptoms, CD may be detected due to associated extraintestinal disorders, even without GI symptoms, or due to screening for CD based on a positive family history. CD has a strong association with HLA-DQ2 and HLA-DQ8. Serological testing for antibodies to tissue transglutaminase (tTG) is usually positive (-95%) in the untreated patient. Endoscopic and histological damage seen in the proximal intestine is characteristic, but not diagnostic. As CD is defined to be a gluten-sensitive enteropathy, definitive diagnosis ultimately depends on a positive small bowel biopsy and demonstration of a response to a gluten-free diet (GFD)[1]. Common serological changes include the appearance of anti-tTG and other antibodies, e.g. endomysial antibodies (EMA). These antibodies have been reported in some, but not all studies, to decline or disappear in association with a clinical and/or histological response to a gluten-free diet.

The clinical spectrum of CD includes patients with classical gastrointestinal symptoms (e.g. diarrhea and weight loss), those who are detected on screening because of a family history of CD or having a CD-associated autoimmune condition, or those who have a predisposition for developing CD but at a particular time of testing, conceivably could have no symptoms, negative CD serology and a histologically normal small bowel biopsy. Now, a CD-specific quality of life instrument has also been developed and validated psychometrically[2], and may prove useful in everyday clinical practice.

EPIDEMIOLOGY

CD is highly prevalent in Caucasian populations and their descendants. The age of clinical onset (based on diagnosis) is often described by some experts as bimodal: the first peak is at 8 to 12 mo of age, and the second during the third to fourth decades of life[3]. Recent studies suggest, however, that CD should be considered as a disorder that has a risk of developing throughout life, even in the elderly. Overall, CD is twice as frequent among females as compared to males, possibly because the necessary HLA haplotypes, DQ2/DQ8, are more frequent in female than in male CD patients (i.e. 94% *vs* 85%)[4]. In addition, CD may be detected more frequently in females because females tend to seek medical care more often than males, usually at a younger age. With aging, however, this female predominant pattern disappears. In the elderly, the ratio of newly diagnosed males is equivalent to newly diagnosed females. In the few DQ2/DQ8 -negative CD patients, there is a male excess, and only inheritance of a paternal DQ2 haplotype leads to a daughter's predominance[4].

While it is estimated that CD affects up to 2% of Caucasians, the risk is higher in first-degree relatives of affected sibling pairs (17%), monozygotic twins (75%), and HLA-identical siblings (40%). Indeed, the single most important risk factor for celiac disease is having a first-degree relative with already-defined CD, particularly a sibling[5]. The estimated prevalence of CD in first-degree relatives living in Minneapolis, USA is 11% of all affected family members who carried at-risk genotypes (HLA-DQ2 in more than 90% of cases, and the remainder carrying HLA-DQ8). About half of these persons have clinically "silent disease", and yet, their small bowel biopsies may show severe architectural changes[6]. This apparent disconnection in some patients between severity of symptoms with CD and the severity of histological abnormalities (typically defined in the proximal small bowel) may reflect the variable extent of histological involvement further along the length of the small intestine.

The prevalence of CD appears to be increasing, particularly as the population ages[7]. CD in the elderly has been reviewed and also likely reflects increased recognition of undiagnosed CD in this age group[8-10]. The estimated prevalence of CD in individuals in the United Kingdom between 45 to 76 years of age is approximately 1.2%. About 20% of all newly diagnosed celiac cases are over 60 years of age. The clinical presentation in these older individuals is variable, ranging from "silent" disease, to vague abdominal complaints, to anemia. These limited symptoms could also lead to a delay in diagnosis.

Prolonged gluten exposure in undiagnosed CD is seen to increase the incidence of autoimmune diseases, such as diabetes and autoimmune thyroiditis. As far as gastrointestinal complications are concerned, it is important to rule out collagenous and lymphocytic colitis[11,12], which may be mistaken for non-compliance with a gluten-free diet (GFD). Eight percent of elderly persons in nursing homes or long-term care centers may have associated small bowel bacterial overgrowth, manifesting with malabsorption and diarrhea-like symptoms. Nutrient depletion in these individuals is common, and the incidence of osteopenic bone disease is increased. Finally, neurological disorders, such as dementia, are becoming increasingly recognized in elderly patients with CD[13].

Screening serological tests (IgA and IgG) appear to be age-independent in adults. However, the elderly seem to have an increased incidence of sero-negative CD. Interestingly, the fate of different celiac antibodies in genetically at-risk children on a normal diet has been assessed, and, remarkably, these appear to spontaneously disappear[14]. Specifically, antibodies to tTG and EMA were spontaneously lost in 49% and 45%, despite continuing gluten exposure. Although the procedural risk of endoscopy and biopsy may be marginally increased in the elderly, endoscopic biopsy remains crucial as the "gold standard" for diagnosis of CD in this age group as well as in all other age groups.

GENETICS

It is conceivable that CD could be a heterogeneous disorder, not only with differing clinical presentations, but also different degrees of pathological change in the small intestinal mucosa. Further morphometric and immunohistochemical studies from geographically and genetically diverse populations are needed to confirm observations on increased intraepithelial lymphocytes (IELs) in otherwise architecturally normal small intestine.

A small percentage of EMA-positive patients may have a small bowel biopsy in which the mucosa might be considered by some pathologists to be architecturally normal. From 409 children who were positive for celiac-related antibodies, 24 (5.9%) of the individuals were reported to have an architecturally normal small intestinal mucosa, 46% (11 of these 24 patients) had increased CD3+ intraepithelial lymphocytes, and 71% (17 of the 24) had an increased density of gamma-delta + cells[15]. In 17 of these 24 persons (70%), the number of lamina propria CD25+ cells was increased, and/or the expression of ICAM-1 and crypt HLA-DR was enhanced. Interestingly, in those persons with apparently normal jejunal histology, there appeared to be immunohistological evidence of immune activation in the epithelium, lamina propria and intestinal crypts. A GFD is usually not recommended in individuals with an architecturally-normal small bowel biopsy. Sophisticated immunohistochemical findings, such as these, raise the question as to whether definition of "normal" needs to be extended, and whether such subjects with abnormal antibodies in the intestinal biopsy may need further monitoring to determine if a GFD is indicated. In addition, duodenal mucosal tTG detection improves the sensitivity of diagnosis in CD for those with very mild histological changes, i.e. Marsh 1 lesions[16]. Thus, the definition of CD may conceivably extend to persons with an architecturally normal mucosal biopsy, but with abnormal CD-associated immunohistochemical changes. Additional studies are needed to confirm, evaluate and further elucidate these interesting observations.

Gluten has specific peptide sequences which show

HLA-DQ2 or HLA-DQ8 restrictive binding motifs across the various gluten proteins. About 40% of the heritability of CD includes the human leukocyte antigen HLA-DQ2 and HLA-DQ8 heterodimers. The HLA DQ2 and HLA-DQ8 molecules are necessary to develop CD, but are not, in themselves, sufficient for phenotypic expression of the disease. Indeed, HLA markers only explain an estimated 40% of the heritable risk for CD. Therefore, other non-HLA genes must also be involved. One of these may relate to genetic variants on chromosome 19, in the myosin IXB gene (i.e. MYO9B), and may potentially predict responsiveness to a GFD[17].

CD-associated HLA-DQ molecules bind and present gluten peptides to antigen-specific T-cells in the intestinal mucosa, and induce T-cell proliferation as well as cytokine secretion. Siblings who share HLA haplotypes have a greater likelihood of concordance with CD than the generally estimated risk for siblings. A small percentage of CD patients are DQ-2 negative, usually being DR4-positive for the class 2 antigen, DQ8. Carrying two copies of DQB1*02 is associated with an even greater risk for CD, but does not predict an earlier age of onset of disease or disease severity. This suggests that assessment of copy number of the DQB1*02 allele could permit stratification of risk[18].

In twin studies in which CD was diagnosed by small bowel biopsy and serology in one twin, monozygotic twin pairs had a high probability of being concordant with CD in the second twin: monozygotic and dizygotic co-twins had 70% and 9% cumulative probability of having symptomatic or "silent" forms of CD, respectively, within 5 years[19]. Under ACE (additive genetic, common and unshared environmental factors/models) with CD prevalences of 1/91 and 1/1000, heritability estimates were 87% and 57%, respectively[19].

The overall risk of siblings of children with CD developing CD was 10% in an Italian population, but the risk estimate ranged from 0.1% to 29% when HLA-DQ information of the proband, parents and sibling was considered[20]. The risk for the sibling developing CD was less than 1% for 40% of the sibs of the probands, 1% to 10% for 30% of the probands, and above 25% for the remaining 30% of the siblings. Thus, information about the risk for a second child to develop CD can be provided to parents with a child with CD. This antenatal estimate of the risk of CD in the child may be useful to provide early diagnosis and management, as well as providing focused and specific follow-up depending upon the risk stratification. Of importance, because CD is treated with a GFD and the resultant quality of life of the CD patient is high, the antenatal diagnosis of CD should not be used as a reason to consider termination of the pregnancy.

A double dose of DR3 (often with DQ2) is associated with an even higher risk of development of CD. HLA genotyping is thought to be useful to exclude CD in family members, or in persons in whom there is an increased risk of CD, such as those with Turner syndrome or Down's syndrome[21].

A strategy that combines gene expression profiling of intestinal biopsy specimens, linkage region information, and different bio-informatic tools for the selection of potential regulatory single-nucleotide polymorphisms (SNPs) has been used to search for novel candidate determinants of predisposition to CD in previously identified linkage regions[22]. Abnormalities in functional proteins have been observed in CD. By using genetic association analysis with a SNPs approach, the tight junction permeability barrier genes, KRD 3 (2SNPs) and MAGI 2 (2SNPs), were shown to be associated with CD in British and Dutch persons[23].

In addition to the involvement of HLA class I restricted CD8+ T-cells, the innate immune system may also be involved in CD. In the mucosa of untreated CD, there is an increase in activated CD8+ T-cells containing large granzyme-B (GrB)-positive granules, as well as cell surface expression of the Fas ligand (FasL). CD8+ T-cell cytotoxicity occurs in the mucosa of patients with active CD (through Fas and FasL-mediated killing of enterocytes). The gliadin interaction for this CD8+ T cell-mediated response (occurring through TCR/HLA class I) induces enterocyte apoptosis[24].

Variation among four closely linked genes on chromosome 4q27 represents a non-HLA genetic risk factor for CD, mapping to a region that contains IL2, IL21, TENR, and K1AA1109[25]. Also, multiple common variants for CD influencing immune gene expression have been defined with second generation genome wide association studies[26].

Genetic studies have also recently identified nine non-HLA loci that contribute to CD risk. Combining HLA and non-HLA risk genotypes increases the sensitivity of CD diagnosis by 6.2% compared with using only HLA for identification, with only a slight decrease in specificity[27]. There may be a quantitative relationship between the type and proportion of DQ heterodimers and the risk of CD[28].

PATHOGENESIS

Gliadins, derived from an alcohol soluble fraction of gluten, are storage proteins that are ingredients in wheat, barley and rye as well as other grains that contain gluten (albeit of less importance). Gliadins are characterized by a high content of glutamine and proline residues. Glutenins are insoluble in aqueous alcohol and are different in structure from the glutens. The early immune response in CD patients is directed towards several of these peptides, while the long-standing inflammatory response may be driven by gluten peptides deamidated or crosslinked by tTG and bound more tightly to HLA-DQ2 and HLA-DQ8. The tTG catalyzed modifications in gliadin are not restricted to single gliadin types or epitopes[29]. Prolamines in barley and rye are known as hordein and secalin, respectively. These barley and rye prolamines induce an mRNA interferon-gamma response in celiac mucosa[30]. The α-2 gliadin-33mer appears to cross the brush border membrane (BBM) of the jejunal enterocyte by a dose-dependent mechanism. Both the uncleaved as well as the degraded form of the 33mer translocate into the enterocyte[31]. Interferon-gamma enhances the trans-

location of the 33mer.

After passage across the BBM, gliadins trigger a Th-1 type-dependent inflammatory reaction. The effects of gliadin peptides and A-gliadin peptide P31-43 on cell lines and cultured small intestinal biopsies are mediated through epidermal growth factor receptor (EGFR) activation by interfering with EGFR endocytosis[32]. Gliadin has an immunogenic effect, but also directly affects cultured cells and intestinal preparations by way of separate peptides such as A-gliadin p31-43 (P31-43). The gliadin-induced delay of EGFR endocytosis in cultured intestinal biopsies suggests a role for EGFR activation in CD[32]. A 33 amino acid fragment of α-2 gliadin is an important trigger of the inflammatory process. In patients with active CD, there is transepithelial translocation of the attack 33mer, as well as incomplete degradation of the 33mer during intestinal transport.

In persons with active CD, there is a marked accumulation of polarized Th-1 cells that produce large amounts of interferon γ (IFNγ). T-bet, a member of the T-box family of transcription factors, is present in CD4+ and CD8+ mucosal T cells in patients with CD. Interleukin 21 (IL-21) is present in activated CD4+ T cells, as well as in natural killer T cells (NK T cells). IL-21 regulates the production of cytokines by T cell subsets. IL-21 increases the expression of Stat4 and T-bet, and stimulates the production of IFNγ in human T cells. In duodenal mucosal biopsies from patients with CD, there is enhanced IL-21 RNA and protein expression, and neutralization of IL-21 largely prevents peptic-tryptic and digest-enhanced IL-21 expression[33,34].

In persons with a genetic susceptibility to develop CD, gliadin interacts with the intestine to trigger disassembly of the inter-enterocyte tight junctions (TJs). The 2α-gliadin 20mer synthetic peptides of gliadin bind to the chemokine receptor, CXCR3. This binding induces MyD88-dependent zonulin release. In turn, zonulin release leads to increased intestinal permeability[35]. Increased intestinal permeability occurs prior to the onset of clinically apparent CD. Even on a GFD, the initially enhanced intestinal permeability does not necessarily return to normal.

Another important aspect related to the pathogenesis of CD may include the intestinal microflora that may be central to the clinical expression of the disease. In one recent report, enrichment in the mucosa-associated microbiota with rod-shaped bacteria in those that developed CD may have contributed to the so-called "epidemic" in Swedish children less than two years of age[36].

Finally, other recent studies related to CD pathogenesis have directly used intestinal biopsy specimens from CD and non-CD persons. For example, IL-15 receptor α mRNA expression is higher in duodenal biopsies from CD compared to non-CD persons, regardless of whether the CD subjects are or are not consuming gluten. IL-15 induces an intense immunological response in CD, with the production of nitrites and IFN gamma[37].

SEROLOGY

Serological markers of significance include EMA and tTG

antibodies. The sensitivity of tTG is 98% and specificity 96%, whereas the EMA is 100% specific and sensitivity is greater than 90%[38]. Assays for tTG antibodies are largely based on the dominant antigen in the EMA test, however, tTG assays are more reliable and more reproducible, largely because the EMA is a qualitative assay and tTG assays are quantitative.

The antibodies to tTG and deamidated gliadin peptide (DGP) have been combined in a multiplex immunoassay of persons suspected as having CD, to potentially provide a complete antibody phenotype[39], and thereby to improve the performance characteristics of the serological testing. A meta-analysis has shown that the tTG antibody test out-performs the DGP antibody test, with a 5.2% greater sensitivity (93.0% *vs* 87.8%) and a 2.4% greater specificity (96.5% *vs* 94.1%), respectively[40].

DGP has been suggested to possibly be a better diagnostic test for CD before institution of a GFD than is the conventional gliadin antibody testing: the sensitivity, specificity, and accuracy of deamidated gliadin-IgA (74%, 95%, and 86%), deamidated gliadin-IgA (65%, 98%, and 84%), and deamidated gliadin-IgA + IgG (75%, 94%, and 86%), were superior to gliadin-IgA (63%, 90%, and 79%) (*P* > 0.05) and gliadin-IgG (42%, 90%, and 60%) (*P* > 0.01), and were similar to tTG-IgA (78%, 98%, and 90%)[39]. Further comparative evaluation with more modern serological assay methods would be useful, including tTG antibodies.

Because the small bowel biopsy in the person with CD does not have a pathognomic histological feature, serological testing may have an important supportive role in providing added information for the diagnosis of CD. Tissue transglutaminase (tTG) catalyzes the Ca^{2+}-dependant formation of cross links between protein-bound glutamine and glycine residues. The glutamine residue can be deamidated to glutamic acid by tTG, including specific glutamines in gluten-containing proteins. Deamidated gluten proteins have enhanced affinity for the HLA-DQ heterodimer of antigen-presenting cells. This activates T-lymphocytes and produces a T-helper type 1 response in the mucosa of celiac patients. The tTG-gluten complex is processed by B-cells, and presented to gluten-specific T cells, that give rise to tTG antibody T-helper type 2 response[41]. The tTG autoantibodies interact with extracellular membrane-bound transglutaminase, and thereby play an important role in proliferation of epithelial cells in persons with predisposition to CD.

The tTG is responsible for post-translational modification of proteins by introduction of lysine crosslinks, as well as deamidation. The IgA anti-tTG responses in CD and in dermatitis herpetiformis are focused on the region of tTG responsible for its transamidation and deamidation reactions, whereas the IgG response targets other regions of the enzyme[42].

The performance of serum anti-tTG may depend on clinical presentation of CD; e.g. classic symptomatic disease or silent asymptomatic disease. In patients estimated to have Marsh-Ⅲ A, B, or C degree of villous atrophy,

the sensitivity, specificity, positive and negative predictive values of the anti-tTG antibody test were 71%, 65%, 91%, and 30%, respectively[43]. The sensitivity was 90% for subjects with total villous atrophy, and only 42% for those with partial villous atrophy. In persons thought to have a high pretest probability of having CD based on symptoms such as weight loss, anemia, or diarrhea, 9.1% were anti-tTG negative[44], indicating that serological testing may miss a substantial number of cases of untreated CD that are antibody negative. Strongly positive tTG assay results without CD biopsy changes have also been recorded[45]. In the latter, it is not known if further biopsies at a later date will reveal the typical morphological changes of untreated CD.

The supply sources for EMA are limited to monkey esophagus or umbilical cord, and many assays are done "in-house" that may not be readily duplicated in other laboratories. EMA are considered to be highly sensitive and specific for serological changes seen in untreated CD. However, EMA assays are expensive, qualitative, and therefore subjective. EMA is increasingly being replaced by serological testing for antibodies to tTG, especially since the anti-tTG assay can be more precisely quantitated.

The EMA binding patterns and serum samples from CD patients are tTG-2 targeted, and the humoral response against tTG occurs at the level of the intestinal mucosa. tTG-2 targeted extracellular IgA deposits have been demonstrated by immunofluorescence in the small bowel mucosa in untreated celiac subjects, even when they are absent from the serum. In those subjects suspected of having CD but who are EMA and anti-tTG negative, finding the tTG-2 targeted antibody in the jejunal mucosa may help to make the diagnosis of CD[46].

Frozen sections of small bowel specimens were evaluated by immuno-fluorescence using rabbit antibody against human IgA. Although at best, semi-quantitative, these immunofluorescent deposits may be better initial markers for gluten sensitivity than small bowel mucosal IEL densities[47]. While architectural changes, such as villous atrophy, may lead to suspicion of untreated CD, tTG-2 specific IgA deposits may potentially be more useful. Further studies are needed.

Seronegative (EMA or tTG) CD occurs in less than 10% of celiacs, particularly in those with lesser degrees of villous atrophy. The presence of EMA in subjects with an architecturally-normal small bowel biopsy could indicate early developing CD. Serum and intestinal celiac anti-autobodies and intra-epithelial lymphocytes have been assessed as possible indicators of developing CD. Celiac autoantibody deposits have been recorded to provide a sensitivity and specificity of 93% and 93%, respectively, in detecting subsequent CD; this is compared to 59% and 57% for CD3+; 76% and 60% for gamma-delta+, and 88% and 71% for villous tip intra-epithelial lymphocytes[48].

Simple "in the office" anti-tTG tests have been developed commercially, and the blood drop-based assay for IgA anti-tTG was reported to have a sensitivity of 90% and a specificity of 95%[49]. The sensitivity and specificity of serum anti-tTG is laboratory-dependent, and assay results may differ for clinical compared to research

laboratories. Because CD does not have a pathognomic histological feature, serology may have a supportive role in making the diagnosis. As CD is defined as a gluten-sensitive enteropathy, a clinical or serological response to a GFD is essential to establish a diagnosis of CD. Sometimes, re-biopsy after a GFD is necessary, or even further evaluation after a gluten challenge may be required.

A normal tTG level does not predict recovery of villous atrophy in celiac subjects on a GFD. For example, 16 of 48 (33%) subjects with CD on a GFD had persistent villous atrophy, but 7 of these 16 (44%) had a normal tTG[50]. In a multicenter, prospective study involving adult subjects attending one of several primary care practices, and in individuals not having symptoms or a condition known to be associated with CD, initial testing was done with anti-tTG. Those with elevated anti-tTG were tested for EMA (IgA), and then those in turn who were positive for EMA underwent an intestinal biopsy and HLA typing[51]. A positive anti-tTG was found in 3.1%, and the prevalence of CD in the serologically screened sample was 2.3%. When a similar study was performed in a university hospital, the prevalence of CD was 3.5%, and a negative HLA-DQ type excluded the diagnosis[52]. However, the "addition of HLA-DQ typing to TGA and EMA testing, and the addition of serological testing to HLA-DQ typing, provided the same measures of test performance as either testing strategy alone"[52].

Because the EMA and anti-tTG responses may remain elevated in CD on a GFD, it may be useful to measure soluble CD163, a scavenger receptor shed by tissue macrophages and correlated with the inflammatory lesion in CD. Those subjects with a more severe (Marsh grade 3) lesion had higher levels of CD163 than did those with a milder (Marsh grade 2, grade 1 or grade 0) lesion[53]. Further studies are needed.

There are three fatty acid binding proteins in the cytosol of the intestine: intestinal FABP (I-FABP), liver FABP (L-FABP), and ileal bile acid binding protein (I-BABP). These are present in increased amounts in the serum of persons with enterocyte damage from, for example, mesenteric thrombosis or necrotizing enteritis. Because I-FABP and L-FABP are found predominantly in the enterocytes in the upper portion of the jejunal villi, it is not surprising that their concentration is increased in the plasma of persons with CD. When measurements were made within one year of the introduction of a GFD, these initially increased I- and L-FABP levels fell to normal[54]. Together with following the patient's symptoms, quality of life, and celiac serology, assessing intestinal permeability may potentially prove to be a useful non-invasive test to follow the histological improvement of CD patients on a GFD.

The current standard for the assessment of adherence to a GFD in adult CD patients is largely based on a personal clinical evaluation. However, most serological assays appear to compare adequately in sensitivity and specificity to a thorough nutritional evaluation of the assessment of adherence to a GFD[55]. This is important, since only approximately 45%-80% of patients with CD adhere strictly to a GFD. This is thought to place them at increased risk

of developing metabolic bone disease, anemia, gastrointestinal symptoms, as well as impaired psychological well-being and quality of life.

MUCOSAL HISTOLOGY

Criteria for the diagnosis of CD include the initial demonstration of small bowel architectural changes including mucosal villous atrophy with crypt hyperplasia, along with increased intra-epithelial lymphocytosis. However, this may be a slowly developing process and the changes are not specific. In addition, some persons may suffer from CD symptoms before histological evidence can be documented. While some authors have suggested that an anti-tTG level can be defined which gives a positive predictive value of 100% for CD[56], it remains the standard of practice to always obtain a biopsy to determine if the histological changes of untreated CD are present before initiation of a GFD.

Some have noted that there may be significant differences between pathologists in mucosal biopsy interpretation[57]. The older Marsh classification, as modified by Oberhuber and colleagues, continues to be used by many pathologists. But for some, it may be considered complex because there are many different diagnostic categories. A simpler grading system has been proposed[57] based on three villous morphologies (A, non-atrophic; B1, atrophic, villous-ratio < 3:1; B2, atrophic, villi no longer detectable), and an intraepithelial lymphocyte count of > 25/100 enterocytes. Compared to the older classification system, this simpler classification schema was thought by the investigators to be superior.

However, the severity of villous atrophy based on histological analysis of biopsy specimens taken from the proximal intestine does not necessarily predict the severity of symptoms in CD for either children or adults. For example, when clinical symptoms of 18 CD patients with a good histological recovery were compared with 13 CD who had persistent small intestinal villous atrophy despite maintaining a GFD, symptoms could be absent despite the persistence of morphological abnormalities[58]. Other authors also noted the lack of association between the histological CD lesion and clinical manifestations[59]. Indeed, the lack of correlation between the degree of villous atrophy and symptoms was stressed in a further study of 499 CD patients, in which 44% had a classical presentation and 56% had atypical or silent CD[60]. These findings are not surprising, however, since the response to a GFD occurs initially in the most distal small bowel. Months to even years on a strict GFD may be needed before improvements in the proximal intestinal mucosa occur.

While duodenal biopsy represents the "gold standard" for the diagnosis of CD, capsule endoscopy (CE) has revealed that over a third of celiac patients have macroscopic mucosal changes extending beyond the duodenum, and in approximately 7%, the entire small bowel was involved[61]. As compared with duodenal biopsy for detecting changes in CD, the sensitivity of CE was reported to be 88%, specificity 91%, positive predictive value 97%, and negative predictive value 71%.

"Latent CD" is defined as abnormal celiac serology and a normal small bowel biopsy (Marsh stage 0). These so-called "latent CD" patients have an increased hazard (HR) ratio for death comparable to those with Marsh 1-2 and Marsh 3: 1.35; 95% CI, 1.14-1.58, median follow-up, 6.7 years; HR, 1.72; 95% CI, 1.64-1.79; median follow-up, 7.2 years; HR, 1.39; 95% CI, 1.33-1.45; median follow-up, 8.8 years, respectively[62]. This corresponded with excess mortality of 1.7 per 1000 person-years in "latent CD", 10.8 in Marsh 1-2, and 2.9 in Marsh 3 stage CD. This raises the possibility that it may be important to diagnose very early CD. However, this label of "latent CD" may differ from the original definition of latent CD (without serological studies) where abnormal small intestinal architectural changes were induced with a high gluten-containing diet (initially reported in dermatitis herpetiformis) and then normalized on a GFD.

Given that duodenal biopsy is still the "gold standard" for the diagnosis of CD, it is of interest to know that when only two duodenal biopsies are obtained, diagnosis of untreated CD is confirmed in 90%, however, increasing the number of biopsies to 3 increased detection to 95%, and to 4 biopsies, 100% respectively[63].

While some present with symptoms and a small bowel biopsy is done to exclude CD, others will present with positive serology and a duodenal biopsy is then obtained. Occasionally lesions may be patchy or detected only in the duodenum, resulting in potential for sampling error and a false-negative result. Confocal endomicroscopy (CEM) is a novel method that permits magnification *in vivo* of the gastrointestinal mucosa by up to 1000-fold. In persons with known CD, accuracy of CEM in diagnosing CD was reported to be excellent, with receiver operator characteristics under the curve of 0.946, sensitivity of 94%, and specificity of 92%[64]. CEM was also sensitive in the detection of histological changes following treatment with a GFD.

"Lymphocytic enteritis" (Marsh 1) may be associated with symptoms, yet serological markers of CD appeared to be of limited value in identifying these individuals. In 130 of 221 first-degree relatives of HLA-DQ2-positive patients with CD, relatives were positive also for HLA-DQ2, and 49% were Marsh 0, 25% Marsh 1, < 1% Marsh 2 and 10% Marsh 3. Only 17 of 221 relatives had positive serological markers for CD[65]. These authors argued that the higher number of symptomatic patients with lymphocytic enteritis (Marsh 1) supports HLA-DQ2 genotyping strategy followed by duodenal biopsy in relatives of CD patients. Further studies to confirm these observations are needed.

Anti-tTG levels have continued to be used in assessing initiation and maintenance of a GFD. It is believed that tTG levels might be followed to reduce the risk of complications and monitor histological changes in the upper small bowel[66].

CLINICAL PHENOTYPES

The ESPGHAN (European Society of Pediatric Gastro-

enterology, Hepatology and Nutrition) criteria distinguish between three different forms of CD so that classification might be more precise: the latent or *potential* form defined by the presence of anti-celiac antibodies; the silent form (*asymptomatic*) defined by the presence of anti-celiac antibodies and villous atrophy of the small intestine; and the symptomatic form defined by the presence of anti-celiac antibodies, villous atrophy and clinical symptoms.

The adult height of children with classical CD (e.g. symptomatic with diarrhea) is influenced by their compliance to a GFD. Children diagnosed with CD after 4 years of age show a slower and less complete catch-up growth. A delayed diagnosis of CD may be associated with a shorter adult height in men, but not in women[67].

While abdominal symptoms may respond quickly to a GFD, it may take up to a year or more after the introduction of a GFD for persons with CD to achieve normalization of their initially abnormal small bowel biopsy. Elderly patients respond more slowly than younger patients to a GFD.

"Gluten sensitivity" may be defined as symptoms, such as diarrhea, apparently induced by gluten-containing foods. These have been reported in the absence of changes in small intestinal histology. In persons with diarrhea-predominant irritable bowel syndrome (D-IBS), stool frequency and the gastrointestinal symptoms score return to normal values in 60% of D-IBS subjects who were positive for HLA-DQ2 and CD-associated serum IgG after six months on a GFD, compared to only 12% who were negative[68].

Among the complications of undiagnosed and, therefore, untreated CD are growth failure in children, infertility, anemia, osteoporosis, small intestinal non-Hodgkin lymphoma[69], and a 3.9-fold increased all-cause mortality rate[70]. Potentially, this may underscore the importance of diagnosing and treating even latent CD.

Celiac patients were reported to have a 5.4-fold higher risk of non-Hodgkin's lymphoma, but no increased risk of Hodgkin's or chronic lymphatic leukemia. A shared susceptibility amongst siblings is observed[69]. It remains controversial whether there is an increased risk of developing lymphoma in CD if the disease is asymptomatic[58,71].

There is a 5-fold increase in risk of lymphoproliferative malignancy in CD in comparison to the general population[72].

CLINICAL ASSOCIATIONS

The prevalence of autoimmune diseases (e.g. autoimmune thyroid disease) is increased in persons with CD, as compared with the healthy control population. Conversely, CD is increased in persons with autoimmune diseases. The cumulative risk of autoimmune disease in patients with CD is 8% at age 15, and 16% at age 30 years. Factors associated with an increased risk of autoimmune diseases associated with CD include a family history of autoimmune disorders, and a diagnosis of CD before the age of 36[73]. Once the diagnosis of CD has been made, patients who are adherent to a GFD have a 6% risk of developing

autoimmune disease at 10 years, *vs* 16% in those who are not compliant with a GFD. Expressed differently, the incidence of autoimmune disease is 5.4 per thousand patient years during adherence to a GFD, *vs* 11.3 per thousand patient years during non-adherence.

Asymptomatic CD is also seen in children and adults with autoimmune hepatitis and autoimmune bile duct disease. CD may be associated with asymptomatic increases in transaminase values. Persons with autoimmune liver disease should be examined for possible CD. In persons with CD who have acute hepatitis, an autoimmune cause should be suspected[74].

More and more clinical associations have been suggested for CD. For example, 42% of CD patients had oral soft tissue lesions, as compared to only 2% of non-CD patients[75]. Recurrent aphthous stomatitis disappeared in 89% of patients after one year of a GFD.

Biopsy-defined CD has a 4-fold higher prevalence in those with irritable bowel syndrome[76]. Mental disorders, non-compliance with the GFD, active medical co-morbidities, and dissatisfaction with doctor/patient communication were associated with reduced CD Questionnaire scores[77].

Up to 10% of patients with CD have neurological symptoms ranging from polyneuropathy, epilepsy, myoclonus, multifocal leukoencephalopathy, dementia, chorea, migraine, memory/attention impairment and peripheral axonal and demyelinating neuropathies as well as acetyl-choline-antibody positive myasthenia gravis[78]. Autoimmunity may act as a mechanism triggering neurological dysfunction[79], and anti-neuronal, anti-gliadin and tTG antibodies may contribute to neurological impairment through Apaf-1 activation with Bax and cytochrome C translocation, leading to impairment of mitochondrial-dependent apoptosis. There is no statistically significant association between CD and subsequent development of Parkinson's disease, Alzheimer's disease, hereditary ataxia, symptoms of ataxia, Huntington's disease, or spinal muscular atrophy[80].

Adult but not pediatric patients with CD have an increased risk of sepsis, particularly pneumococcus infection[81]. In CD there is an increased prevalence of splenic hypofunction[82].

Using community-based cohorts and a record-linkage database, the adjusted relative risk of cardiovascular disease in CD was 2.5 for new EMA positive *vs* EMA negative individuals[83]. This suggests that CD may be associated with an increased risk of cardiovascular outcome. There may also be an association between CD and eosinophilic esophagitis[84].

Aldolase B deficiency causes hereditary fructose intolerance, and this may be associated with CD[85]. In CD patients as compared with individuals with dyspepsia or healthy controls, serum ghrelin concentrations are higher, not correlated to the severity of duodenal histological lesions, and revert to normal during the institution of a GFD, despite persistent duodenal lymphocytic infiltration[86]. It is not clear if these alterations in ghrelin concentrations have any biological importance in CD.

In 18 CD patients, there was increased intestinal 5-HT-enterochromaffin cell numbers, higher peak plasma 5-HT levels and postprandial area under the curve of 5-HT levels after a high-carbohydrate meal, as well as increased platelet 5-HT stores[87]. The authors suggested that serotonin excess may mediate dyspeptic symptoms in untreated CD. Further evaluation is required.

A meta-analysis of serological or histological diagnosis of CD in unselected adults with dyspepsia showed that the numerically increased prevalence was not statistically significant[88]. Another systematic review and meta-analysis by the same group, examining 14 studies with 2,278 persons diagnosed with IBS, had an approximately 4% prevalence of CD. The OR for biopsy-proven CD in IBS cases *vs* controls was 4.34[89]. In children with CD, 40% had elevated transaminase values; of those with elevated transaminase values, 95% were cryptogenic and normalized on a GFD, and 5% had autoimmune hepatitis that required immunosuppression plus a GFD to normalize clinical and biochemical parameters[90].

TREATMENT

Gluten free diet
What is the definition of a GFD? Even "gluten-free" products may not be completely free of gluten. In 1998, the World Health Organization/Food and Agriculture Organizations Commission proposed that foods which are said to be "gluten-free" could not contain more than 200 ppm of gluten. Each individual with CD may have a unique threshold or tolerance to the amount of gluten in the diet. Daily gluten intake of less than 10 mg is unlikely to cause significant histological abnormalities in the intestine of patients with CD[91]. Patients adhering to a GFD report an improved health related quality of life.

A systematic review has revisited the complications and need for long term follow-up in CD[92]. A 16-question disease-specific symptom index has been validated in adults with CD[93]. Such an index might be used to monitor the response of a CD patient to a GFD.

The treatment of CD is the life-long use of a GFD. A primary goal in the care of patients with CD is to improve the quality of their lives, through a collaboration of the stakeholders[94]. Lanzini *et al*[95] assessed in 465 consecutive CD patients, the histological outcome after a GFD consumed for a median of 16 mo. While CD serology became negative in 83% of CD patients with Marsh III lesions on a GFD, mucosal biopsy histology normalized in only 8%, improved except for increased intraepithelial lymphocytes in 65%, was unchanged in 26% and worsened in 1%. The authors concluded that "complete normalization of duodenal lesions is exceptionally rare in adult celiac patients despite adherence to GFD, symptoms disappearance and negative CD related serology".

Early diagnosis and treatment are important in CD, as some of the associated complications may be irreversible, unless the CD is treated[96]. Growth retardation, osteoporosis and abnormal dentition will remain permanent if not treated early. The prevalence of associated depression is up to 37%, similar to that of persons with other chronic conditions[97].

In children with CD, long-term consumption of oats may be well tolerated[98], although concern has been expressed regarding possible contamination of oats with other gluten-containing grains. Other investigators have demonstrated that transamidation of wheat flour inhibits the response to gliadin of intestinal T cells in CD[99]. It has always been assumed that patients with CD must remain on a GFD for life. However, up to 10% of CD patients diagnosed in childhood were reported to develop long-term latency of their CD when returning to a gluten-containing diet[100]. In patients who have been on a GFD and have no symptoms, even if there were small bowel CD-like histological abnormalities which remained, some had no evidence of clinical relapse even though they had been on a gluten-containing "normal" diet for more than 2 years.

Individuals with villous atrophy but no symptoms are said to have "silent" CD. Almost half of CD patients may clinically tolerate a gluten-containing diet, yet continue to have mucosal abnormalities. Indeed, approximately 10% of CD patients diagnosed in childhood may develop clinical tolerance to gluten. In the United Kingdom, about one-third of CD subjects are under no active follow-up[101].

Alternatives to a gluten free diet
There may be poor compliance with the GFD because it is difficult and gluten-free products are expensive. For these reasons, new approaches have been taken in the treatment of CD. Some of these include orally administered endopeptidase, antagonists to S100B protein, IL-15 blockers, elemental diets and transamidation of wheat flour. Lactobacilli added to sourdough for fermentation are able to break down the proline-/glutamine-rich gluten peptide. This may play a role in the future treatment of CD[102]. Supplementation of nutrients may become essential depending upon the severity of malnutrition. One double–blind placebo-controlled multicenter trial showed a significant improvement in general well being after 6 mo of supplementation with vitamin B[103].

Prolyl-endopeptidases are able to digest ingested gluten. Oral therapy with prolyl-endopeptidases, exogenous protease enzymes, represents a new approach to managing CD[104]. Bacterial prolyl-endopeptidase from *Flavobacterium meningosepticum* removes gluten toxicity by cleaving it into small fragments which lack T-cell stimulatory properties[105]. After prolonged exposure to high concentrations of bacterial prolyl-endopeptidase, the amount of immunostimulatory gliadin peptides reaching the local immune system in CD is decreased[106]. The prolyl-endoprotease from *Aspergillus niger* (AN-PEP) is a member of the serine peptidase family, and this degrades gluten peptides rapidly[107]. This AN-PEP is capable of accelerating the degradation of gluten in a gastrointestinal model that closely mimics *in-vivo* digestion[108]. The

pH optimum of the enzyme is compatible with that found in the stomach, and the enzyme is resistant to degradation by pepsin.

The gluten proteins may be purposely modified to abolish their capacity to stimulate the interferon gamma from CD4+ T-cells[109]. Another approach to the therapy of CD is the designing of non-toxic wheat, rye or barley based on their protein homology[110,111].

Other therapeutic approaches would include the binding of gluten to HLA-DQ2 or HLA-DQ8, or blocking the gluten-reactive T cells by immunotherapy (e.g. vaccination). For example, transamidation of wheat flour with a food-grade enzyme and an appropriate amine donor (microbial transglutaminase and lysine methyl ester) can be used to block the T-cell mediated gliadin activity[99]. Gluten contains many immunogenic peptides, but there may be weak varieties with a natural low number of T-cell-stimulatory epitopes[111].

Polymeric binders reduce the deleterious effects of gliadin on intestinal epithelium in cultured cells and transgenic mice[112]. These binders have a strong affinity for gliadin, inhibiting cytoskeleton disorganization and ultrastructural changes in intestinal epithelial cells. Their beneficial use in humans remains to be established.

Antigen-presenting cells include dendritic cells, macrophages and B-cells. A unique subset of dendritic cells appears to be responsible for local activation of gluten-reactive T-cells in the celiac lesion[113]. Enteric glial cells (EGC) release neurotropic factors and are activated by inflammatory insults. EGC-derived S100B protein released in astroglial cells is increased in the duodenum of patients with CD, with increased S100B messenger RNA and protein expression, increased iNOS protein expression, and increased nitrite production in treated CD[114]. This does not occur in those CD patients on a GFD, or in non-CD control subjects. Products derived to block EGC-derived S100B protein may have a therapeutic role.

IL-15 has proinflammatory and anti-apoptotic properties. IL-15 is over-expressed in the enterocytes and lamina propria mononuclear cells of untreated CD, where its level reportedly correlates with the degree of mucosal damage[115]. IL-15 also promotes IEL survival. Blocking IL-15 and suppressing uncontrolled IEL activation and survival has the potential to provide a new therapeutic approach to prevent tissue damage in CD. In the intestinal mucosa of CD patients, IL-15 impairs Smad3-dependant TGF-beta signaling in human T-lymphocytes downstream from Smad3 nuclear translocation[116]. There is upregulation of phosphor-c-jun. This provides further support to the suggestion of the potential therapeutic effect of blocking IL-15.

Intestinal permeability is increased in patients with CD, and is associated with alterations in tight junction proteins (e.g. zonulin). Addition of zonulin may prevent T-cell mediated stimulation in CD. In a double-blind randomized placebo-controlled study of milligram doses of AT-1001, an inhibitor of paracellular permeability derived from *Vibrio cholera*, prevented the expected increases in intestinal permeability in subjects with CD challenged with gluten[117]. AT-1001 use is also associated with a diminution in the anticipated rise of interferon-gamma levels.

REFRACTORY DISEASE

Recurrent symptoms sometimes develop in biopsy-proven CD patients on a GFD. The most common cause of non-responsive CD, which occurs in about 30% of CD patients, is non-adherence to a GFD. A Celiac Dietary Adherence Test (CDAT) consistency in a 7-item questionnaire was developed using a logistic regression, and validated against transglutaminase serology for the assessment of adherence to a GFD[118]. Usually, poor compliance to a GFD is thought to be responsible, although compliance may sometimes be difficult to establish. Intentional dietary indiscretion may be evident, but sometimes, there is limited awareness of gluten-containing substances. Gluten is ubiquitous, being documented in pill capsules and other materials, such as communion wafers.

Other causes, detailed elsewhere[119], may be responsible for recurrent symptoms even though the CD patient appears to be following a strict GFD. Some causes include associated primary or secondary pancreatic insufficiency, small intestinal bacterial overgrowth, collagenous sprue, or lymphocytic or collagenous colitis. Rarely, a complication may be responsible (e.g. lymphoma, carcinoma).

Sometimes, no initial response to a GFD ever occurs and symptoms persist. In these subjects, biopsies may be abnormal, but the gluten-dependent nature of the small bowel abnormalities was never documented. This has been labeled "unclassified sprue" or "sprue-like intestinal disease". Some of these persons may eventually prove to have a lymphoma. As many as approximately half of patients with CD on a GFD for more than two years may be able to tolerate a gluten challenge, even though they have mucosal abnormalities[100]. About 10% of CD patients diagnosed in childhood may develop temporary tolerance to gluten. However, because of the continuing mucosal abnormalities, they remain at risk of developing the complications of CD. Indeed, adolescents who do not adhere to a GFD have a lower quality of life[120].

Immunohistochemical labeling has helped to define an abnormal prognostic profile of intra-epithelial lymphocytes in the small bowel mucosa, so-called "refractory celiac disease, type 2 (RCD 2)" characterized by an aberrant clonal IEL population with loss of IEL antigens. About half of RCD 2 patients develop an enteropathy-associated T-cell lymphoma (EATL) within 5 years, and a particular HLA-DQ subtype, DQ2, if homozygous, predisposes to RCD 2[121].

Complete duodenal mucosal recovery in CD may be limited and may require prolonged periods of a GFD. In one study, remission was seen in 65% or no histological improvement was seen in 26% of patients[95]. This might be anticipated, however, if only duodenal biopsies are being taken since the proximal small intestine is most severely affected and varying periods of time are required for recovery to be significant. An apparent failure to histologically respond to a GFD may only reflect that duo-

denal, rather than more distal small intestinal biopsies were repeated.

Refractory CD has been defined as persistent or recurrent villous atrophy with crypt hyperplasia and increased intraepithelial lymphocytes (IELs) despite a strict GFD for greater than 12 mo (or if severe persisting symptoms necessitate intervention independent of the duration of the GFD)[122]. In assessing the GFD response, the site of re-biopsy and duration on a strict GFD are crucial to the definition of refractory disease. In some, as suggested by this definition, the opportunity for re-evaluation is very limited because of rapid progression of the intestinal disease.

RCD is usually manifested by recurrence of symptoms and intestinal abnormalities, despite adherence to a GFD. RCD can be further defined from a prognostic perspective by the histological appearance of monoclonal or polyclonal intraepithelial lymphocytes (RCD type 2) *vs* normal lymphocytes (type 1)[123]. These changes and the development of an EATL were shown to be adverse factors in the prognosis of CD, particularly in the first two years after CD has been deemed to be refractory[124].

Refractory celiac disease (RCD) type 2 but not type 1 shortens the sufferer's life expectancy[123].

Corticosteroids may improve clinical symptoms in some patients with RCD. Unfortunately, the histological response to steroids has not been consistent[123]. Patients with RCD 1 may benefit from immunosuppressive therapy, whereas those with RCD 2 may respond to Cladribine or to stem cell transplantation. Treatment with cladribine and anti-CD-52 has been shown to be associated with histological improvement. Azathioprine and anti-tumor necrosis factor-α have shown only limited success. The development of an overt lymphoma within 8 wk of treatment was seen in 3 out of 4 of these patients, thereby preventing further use. Alternative strategies that have been suggested include stem cell transplantation to replace the abnormal intra-epithelial lymphocyte population, and the blocking of IL-15[125-129].

CONCLUSION

Celiac disease is being increasingly diagnosed because of the recognition that the disease may be present without significant intestinal symptoms, may be associated with other autoimmune disorders and may be suspected from serological screening. Definition of the disease includes an intestinal biopsy before treatment with a GFD along with documentation of a definitive GFD response. In some patients, this may necessitate further intestinal biopsy after a period on a GFD. Serological testing may be useful in providing additional evidence that CD is present and may be useful in some patients to assess GFD compliance. Recent studies focused on the genetic basis and pathogenesis of CD have emerged to improve understanding of the complex molecular alterations that occur with CD.

Abstract

This article discusses a practical, evidence-based approach to the diagnosis and management of liver cirrhosis by focusing on etiology, severity, presence of complications, and potential home-managed treatments. Relevant literature from 1985 to 2010 (PubMed) was reviewed. The search criteria were peer-reviewed full papers published in English using the following MESH headings alone or in combination: "ascites", "liver fibrosis", "cirrhosis", "chronic hepatitis", "chronic liver disease", "decompensated cirrhosis", "hepatic encephalopathy", "hypertransaminasemia", "liver transplantation" and "portal hypertension". Forty-nine papers were selected based on the highest quality of evidence for each section and type (original, randomized controlled trial, guideline, and review article), with respect to specialist setting (Gastroenterology, Hepatology, and Internal Medicine) and primary care. Liver cirrhosis from any cause represents an emerging health issue due to the increasing prevalence of the disease and its complications worldwide. Primary care physicians play a key role in early identification of risk factors, in the management of patients for improving quality and length of life, and for preventing complications. Specialists, by contrast, should guide specific treatments, especially in the case of complications and for selecting patient candidates for liver transplantation. An integrated approach between specialists and primary care physicians is essential for providing better outcomes and appropriate home care for patients with liver cirrhosis.

INTRODUCTION

Liver cirrhosis is defined in histology as a bridging fibrosis-a late stage of hepatic fibrosis-leading to deranged liver architecture and regenerative nodules. Liver cirrhosis is considered the end stage of a variety of chronic liver diseases, and is irreversible in its advanced stages[1]. Cirrhosis is characterized by poor life expectancy and is a leading cause of morbidity and mortality: in the United States liver cirrhosis is the 12th most common cause of death (9.5/100 000 individuals), while in Italy the incidence of liver cirrhosis is over 26 000 new cases each year, with a prevalence over 120 000 cases (7000 below 45 years), and 20 deaths/100 000 individuals[2,3]. Figures are likely to be even higher in Asia and Africa. Liver cirrhosis carries the

risk of life-threatening complications, partly due to a number of co-morbidities. Medical treatments that may halt the progression of compensated cirrhosis to decompensated cirrhosis are currently being developed[1]. Liver transplantation, however, is the only option in a selected subgroup of patients with end-stage disease. Because of the increasing prevalence of chronic viral hepatitis and (alcoholic-nonalcoholic) steatohepatitis and their high risk evolution toward liver cirrhosis and end-stage liver disease, preventive programs and early management of these conditions are considered an emerging health issue. It is essential that primary care physicians (PCPs) be optimally trained to identify patients with chronic liver disease as early as possible, and to properly manage those with liver cirrhosis[4]. A close interaction is therefore required between PCPs and specialists (i.e. gastroenterologists, hepatologists, and internists) who have a fundamental role as consultants and guides for specific treatments, i.e. in the case of complications and the management of patients approaching liver transplantation.

This article is based on a PubMed search to provide an updated view for comprehensive management of several aspects of liver cirrhosis in different settings.

DATA SOURCES

Full papers were searched on Medline (http://www.ncbi.nlm.nih.gov/PubMed) for guidelines, randomized controlled trials (RCTs), and authored review articles published in English-language journals in the past 25 years. The following MESH headings were used: "ascites", "liver fibrosis", "cirrhosis", "chronic hepatitis", "chronic liver disease", "decompensated cirrhosis", "hepatic encephalopathy", "hypertransaminasemia", "liver transplantation", and "portal hypertension". The reference list was updated as of November 2010. Authors independently assessed articles for relevance and study quality. For each section, evidence levels were scored as follows: (1) LEVEL I (at least one properly conducted RCT, systematic review, or meta-analysis); (2) LEVEL II (other comparison trials, non-randomized, cohort, case-control, or epidemiologic studies, and preferably more than one study); and (3) LEVEL III (expert opinion or consensus statements).

APPROACH TO PATIENTS WITH LIVER CIRRHOSIS

The clinical presentation of liver cirrhosis is often asymptomatic until complications appear. The presence of liver cirrhosis should be suspected in any patient with chronic liver disease and abnormal aminotransferases and/or alkaline phosphatase. Chronic liver disease stigmata should be searched for, and include vascular spiders, palmar erythema, and muscle wasting. Also, a palpable left lobe of the liver, hepatomegaly and splenomegaly are suggestive for liver cirrhosis. The diagnosis becomes much easier in the presence of signs of decompensation, namely jaundice, as-

cites, and asterixis. Additional laboratory tests include those exploring liver synthetic function, such as serum albumin and prothrombin time, while serum bilirubin investigates the ability of the liver to conjugate and excrete bilirubin. A low platelet count is suggestive of portal hypertension and hypersplenism. An AST/ALT ratio above 1 is indicative of liver cirrhosis, but its absence does not exclude cirrhosis (i.e. low specificity). The imaging studies include abdominal ultrasound, CT scan or magnetic resonance and might reveal a nodular liver and splenomegaly. The differential diagnosis of advanced chronic hepatitis relies on liver biopsy, which is still the gold standard for end-stage chronic liver disease. Percutaneous liver biopsy is not necessary in the presence of decompensated cirrhosis or when imaging studies have confirmed the presence of cirrhosis. Thus, liver biopsy is reserved for selected patients and can also be performed in out clinic settings[5,6]. Histology provides information on etiology, disease stage and grade of inflammation. Although the ultimate decision is not currently taken by PCPs, they should repeatedly check the patient with blood tests before referral for liver biopsy (at least two times and at least 2-3 mo apart). If abnormalities persist in spite of second step analyses and a liver ultrasonography has been inconclusive, the decision to perform a liver biopsy must be taken on an individual basis and rely on the patient's age and general health status, as well as the need for prognostic information (LEVEL III)[7]. According to the American Association for the Study of Liver Disease (AASLD), liver biopsy has a major role in diagnosis, assessment of prognosis, assistance in therapeutic decisions, and reinforcement of the patient's compliance (LEVEL II)[5]. Biopsy, however, is a costly procedure which is not free of potential side effects and risks, and is often refused by the patient. A French survey, which interviewed over one thousand PCPs, concluded that liver biopsy may be refused by up to 59% of patients with chronic hepatitis C and that 22% of PCPs share a similar concern[8].

Novel non-invasive methods might provide preliminary information with good diagnostic accuracy for further selection of patients at risk for progressive liver disease. For example, tests might help to evaluate the presence and extent of liver fibrosis, and to differentiate cirrhosis from chronic hepatitis (positive predictive values exceed 85%-90%)[9]. Such policy may be helpful in the primary care setting. Transient elastography (FibroScan®), for example, assesses liver stiffness, with some limitations in the case of morbid obesity, small intercostals spaces, and ascites[10]. Ongoing liver fibrosis is also predicted by using specific algorithms of surrogate serum markers or by the application of standardized procedures (e.g. APRI: the aspartate transaminase to platelets ratio index; FibroTest: haptoglobin, α2-macroglobulin, apolipoprotein A1, γGT, bilirubin: Hepascore: bilirubin, γGT, hyaluronic acid, α2-macroglobulin, age, gender; BARD: Body mass index (BMI), AST/ALT ratio, diabetes). A novel technique based upon ultrasound-based elastography (Fibroscan, Echosens, Paris, France) can assess mean hepatic tissue stiffness[11]. Results are expressed in kilopascals (kPa) and

Table 1 Diagnostic tests, suggested etiology, and current treatment for the most frequent forms of liver cirrhosis in adult patients

Abnormal test(s)	Etiology	Treatment
γGT (high), MCV (high)	Alcohol	Abstinence
HBsAg, HBV-DNA, HBc-IgM, HDV-RNA (positivity)	HBV + Delta virus infection	Interferon α-2b, nucleoside (Lamivudine, Telbivudine, Entecavir) and nucleotide (Adefovir, Tenofovir) analogues
HCV-RNA (positivity)	HCV infection	Interferon plus ribavirin
γGT (high), alkaline phosphatase (high), AMA (positivity)	Primary biliary cirrhosis	Ursodeoxycholate
ANA, ASMA, LKM (positivity)	Autoimmune hepatitis	Prednisone, azathioprine
Ferritin (high), transferring saturation index (> 45%), liver iron content (high), *HFE* gene mutation for hereditary hemochromatosis (C282Y, H63D)	Hemochromatosis	Phlebotomy, deferoxamine
Ceruloplasmin (low), serum (low) and 24 h urine copper excretion (high)	Wilson's disease	D-penicillamine, zinc
HDL-cholesterol (low), glucose (high), triglycerides (high)	NAFLD/NASH	Low caloric diet, exercise, drugs lowering insulin-resistance

AMA: Anti-mitochondrial antibody; ANA: Antinuclear antibody; ASMA: Anti-smooth-muscle antibody; γGT: γ- glutamyltransferase; HBV-DNA: Hepatitis B virus DNA; HCV-RNA: Hepatitis C virus RNA; HBsAg: Hepatitis B surface antigen; HDL: High density lipoprotein; HDV-RNA: Hepatitis delta virus RNA; LKM: Liver kidney microsomes; MCV: Mean corpuscular volume; NASH: Nonalcoholic steatohepatitis; NAFLD: Nonalcoholic fatty liver disease.

the harder or stiffer the tissue, the faster a shear wave propagates, as a marker of hepatic fibrosis. Similar results have been reported with magnetic resonance elastography (MRE)[12]. Likely, the combination of elastography with one of these indices will also help specialists to better select patients suitable for liver biopsy[9,10].

Life expectancy and quality of life in patients with advanced cirrhosis remains poor, despite diagnostic advancement. Patients experience fatigue, pruritus, ascites, bleeding and encephalopathy. Dyspepsia and malnutrition are common. Whereas liver transplantation has changed life expectation for a number of patients, many transplantable patients still die due to long waiting lists. Targeted therapy is crucial in slowing or even halting disease progression and to provide standard medical care. PCPs should identify and address alcohol abusers early, while conditions like nonalcoholic steatohepatitis (NASH), B and C hepatitis, autoimmune disorders, and hemochromatosis should be appropriately counseled and treated. Attention should be given to active immunization, nutrition, and general healthcare.

MANAGEMENT OF PERSISTENT ASYMPTOMATIC ELEVATION OF SERUM TRANSAMINASES

Measurement of serum ALT is part of standard laboratory tests in asymptomatic outpatients, and is a sensitive screening tool for chronic liver disease[13]. Between one and four percent of asymptomatic subjects may have elevated ALT (LEVEL Ⅲ)[7,14,15]. In a recent survey in the Mediterranean area, the most likely cause of elevated serum ALT was an excessive alcohol intake (45.6%), nonalcoholic fatty liver disease (NAFLD) (24%), and HCV infection (18.6%)[14].

Over 20% of subjects with elevated ALT show signs suggestive of relevant chronic liver disease[2]. PCPs are required to carefully investigate most common causes of elevated ALT and for early identification of treatable chronic liver diseases[16,17]. Patient histories should focus on the use of medications, herbal extracts, and alcohol

consumption. The presence of diabetes and thyroid disease (hypothyroidism) must be considered. The problem, however, may be underestimated as about 38% of patients with occasional ALT elevation show normal values at next measurement[16]. Despite the very high number of subjects showing such liver test abnormality in family practice, only a few will need referral, i.e. those patients with doubtful diagnosis after initial evaluation and patients with established diagnosis requiring therapy (LEVEL Ⅲ)[18].

THE IMPORTANCE OF IDENTIFYING ETIOLOGY

The identification of the cause underlying liver cirrhosis is essential in starting preventive measures and designing specific intervention (LEVEL I). Table 1 shows the most appropriate tests for etiologic diagnosis of cirrhosis. Anti-mitochondrial antibodies are specific for primary biliary cirrhosis, HBV-DNA or HCV-RNA positivity for hepatitis B or C, low serum ceruloplasmin levels for Wilson's disease, and high serum ferritin and transferrin saturation index for hereditary hemochromatosis. Of note, liver cirrhosis may result from coexisting etiologic factors (i.e. alcohol and viral infection, obesity and virus, *etc*.).

HOW TO SCORE AND DEFINE PROGN0SIS

Once the diagnosis of liver cirrhosis has been formulated, a further important step is to score the disease. However, neither physical findings nor transaminases are helpful for defining prognosis or scoring the disease. Other laboratory tests (bilirubin, albumin, and prothrombin time), combined with the presence and severity of encephalopathy and ascites, are included in the Child-Pugh score (Table 2), the traditional scale used by many clinicians for assessing the liver disease severity (LEVEL I). Another scoring system is the model for end-stage liver disease (MELD, http://www.mdcalc.com/meld) which provides robust information on mortality in cirrhosis, and is used for prioritizing candidates for transplantation[19] (LEVEL I). Both scores

Table 2 Child-Pugh scoring system for liver cirrhosis and related indication priority for transplantation[20]

Score	1	2	3
Bilirubin (mg/dL)	< 2	2-3	> 3
Prothrombin time (INR)	< 4 sec. (< 1.7)	4-6 sec. (1.7-2.3)	> 6 sec. (> 2.3)
Albumin (g/dL)	> 3.5	3.5-2.8	< 2.8
Ascites	Absent	Mild	Severe
Encephalopathy	Absent	Mild	Severe

The Child-Pugh score is given by the sum of the score (1 to 3) of each of the five parameters. A score of 6 or lower defines the patient as class A, 7 to 9 as class B, and 10 or higher as class C.

Table 3 Current indications and contraindications to orthotopic liver transplantation in adult patients with liver cirrhosis

Indications	Contraindications
Advanced chronic liver failure	Relative
Child-Pugh score > 7	HIV seropositivity
Qualifying MELD score	Methadone dependence
	Stage 3 hepatocellular carcinoma
Acute liver failure	Absolute
Drug, toxins or virus induced	Extrahepatic malignant disease
fulminant hepatitis	AIDS
	Cholangiocarcinoma
	Severe, uncontrolled systemic infection
	Multiorgan failure
	Advanced cardiopulmonary disease
	Active substance abuse
General	
No alternative available treatment	
No absolute contraindications	
Willingness to comply with follow-up care and family assistance	

AIDS: Acquired immunodeficiency syndrome; HIV: Human immunodeficiency virus; MELD: Model for end stage liver disease.

can also be easily applied in primary care. Regardless of the cause, once decompensation has occurred, mortality without transplantation is 85% over 5 years[1]. In general, one-year survival rates for patients with Child-Pugh score A, B and C are 100%, 80% and 45%, respectively[20]. MELD score provides a more accurate prediction[21]. The hepatic clearance of exogenous administered substances, which provides an indication of residual liver functional mass[22,23], are easy to perform and may also meet future applications in family practice.

SELECTION FOR LIVER TRANSPLANTATION

Liver transplantation is considered as a viable treatment option for patients with acute liver failure and end-stage liver disease. In liver cirrhosis, transplantation is generally considered when a patient has suffered from either a complication of portal hypertension or a manifestation of compromised hepatic synthetic function[24]. However, given the high costs, mortality rate, and the paucity of donor organs, transplantation is currently justified only in the case of long-term prognosis, and psychological, intellectual, financial and family support. Accordingly, patients may be considered as current, future or inappropriate candidates. Selection consists of a search for contraindications and PCPs are actively involved in this process (i.e. alcohol and drug use)[25]. Currently, patients are generally put on a waiting list once Child-Pugh class B or a MELD score of over 13 is reached[21]. Onset of complications may anticipate referral, but severely decompensated or debilitated patients are generally discarded. Current indications and relative and absolute contraindications to liver transplantation are reported in Table 3.

TREATMENTS TO BE SHARED BETWEEN PCPs AND SPECIALISTS

Assistance is based on disease stage, complications and grade of self-sufficiency. Stable (compensated) patients are generally self-sufficient and a six month check (blood tests and liver ultrasonography) is indicated. Complicated and decompensated forms require an integrated approach with referral centers. Home care reduces costs[26] and should focus on a chronic care model of patient education and

on empowering both the patient and the family to take responsibility for the care (Table 4)[17]. Several cirrhotic patients can benefit from treatments aimed to slow disease progression (Table 1)[27-31]. In particular, nucleoside (Lamivudine, Telbivudine, Entecavir) and nucleotide (Adefovir, Tenofovir) analogues have shown to be safe and effective in reducing the risk of decompensation and disease progression in patients with HBV infection, while interferon plus ribavirin is a therapeutic option for under-compensated liver cirrhotic patients with HCV infection.

SPECIFIC PROBLEMS

Monitoring alcohol and drug abuse

Alcohol abuse causes 25% of liver cirrhosis and contributes to another 25%-50% of cases. PCPs play a key role in the application of long-term detoxification programs, counseling, support, and monitoring. This step is crucial, since recovered abusers are considered for antiviral therapy or transplantation only after six months of continuous abstinence (LEVEL III).

Ascites

Ascites is the most common complication and cause of hospitalization of cirrhotic patients, but it is also the complication which can be better treated at home. Portal hypertension, reduced albumin synthesis, decreased plasma oncotic pressure, and sodium retention are all determining factors. Paracentesis usually removes a transudative fluid (i.e. albumin < 1 g/dL; serum/ascites albumin gradient > 1.1). Patients exhibiting abdominal pain, tense ascites and fever may have a spontaneous bacterial peritonitis (SBP), a condition characterized by an ascitic granulocyte count exceeding

Table 4 Standard objectives for an efficient out clinic care of cirrhotic patients

1 Early diagnosis of chronic liver disease. Identification of etiology
2 Identification of patients with chronic liver disease at risk of cirrhosis
3 Evaluation of patient's general health status
4 Act on etiologic factors and on factors favoring disease progression. Identify treatment end-points and place the patient within his family and social setting
5 Promote family and cohabitants' participation to primary prevention for infective forms (health education), secondary prevention for inherited or metabolic disorders, support and surveillance for toxic forms (alcohol)
6 Suggest health-dietetic measures and therapeutic remedies
7 Check parameters of effectiveness and control side effects of specific treatments (antiviral, phlebotomy, immune-depressants, β-blockers, *etc.*)
8 Identify and treat associated conditions (diabetes, osteoporosis, malnutrition, *etc.*)
9 Avoid administration of hepatotoxic drugs, drugs promoting renal sodium retention and central nervous system depressants
10 Promote vaccination against flu and pneumonia, including transplanted patients, and against hepatitis A and B virus
11 Supervise for complications by promoting clinical, biochemical and instrumental follow-up
12 Assist specialists in identifying candidates for liver transplantation
13 Assist the patient requiring legal problems

250/mm^3. SBP can precipitate cirrhosis towards renal and liver failure. Therapy includes high doses of albumin to prevent renal failure and intravenous cefotaxime at doses of 2 g twice a day (LEVEL Ⅱ). Long term prophylaxis of SBP recurrence with norfloxacin is indicated in survived patients (LEVEL Ⅰ). Ascites is considered refractory if it persists despite the use of diuretic drugs at the maximum tolerable dose. Although some studies indicate the utility of bed rest as a remedy, no controlled trials have been performed in support to this practice. Therefore, initial treatment is dietary salt restriction[32,33] (LEVEL Ⅰ). Therapy starts with spironolactone at doses ranging from 100 to 400 mg/d. Furosemide may be added (40 to 160 mg/d) when spironolactone does not successfully improve fluid retention (LEVEL Ⅰ). Weight should be monitored daily and electrolytes should be frequently monitored. Albumin infusion is required to prevent post-paracentesis circulatory dysfunction[34] following large volume paracentesis[35]. Such treatments can be managed by PCPs or in an integrated care system with consultant specialists. Preventive measures include the avoidance of NSAIDs, since they promote sodium retention. In the case of recurrent or refractory ascites, before considering the patient for a transjugular intrahepatic portosystemic shunt (TIPS), large volume paracentesis is feasible at home. Paracentesis is safe and rarely precipitates hepatorenal syndrome (LEVEL Ⅱ). Patients with SBP or refractory ascites have a more advanced disease with a poorer prognosis, and so require hospitalization. Patients and their family have to be taught the importance of a daily body weight check, and to refer FD when it increases by 2-4 kg over a brief period of observation.

Hepatorenal syndrome (HRS) is a life-threatening complication in patients with refractory ascites. Diagnosis includes the following criteria: advanced chronic liver failure with portal hypertension; serum creatinine exceeding 1.5 mg/dL or a 24-h creatinine clearance of less than 40 mL/min; absence of shock, ongoing bacterial infection, or recent treatment with nephrotoxic drugs; no sustained improvement in renal function following diuretic withdrawal and the expansion of plasma volume with 1.5 L saline; less than 500 mg/dL proteinuria and no ultrasonographic evidence of obstructive uropathy or parenchymal kidney disease[36]. While awaiting transplantation, patients with HRS, eligible for transplantation, may improve with medications, namely albumin, terlipressin, and vasoactive drugs or TIPS[37].

Portal hypertension
Active variceal hemorrhage accounts for about one-third of all deaths related to cirrhosis. Steps related to the prevention and treatment of variceal hemorrhage includes: prediction of patients at risk, prophylaxis against a first bleed, treatment of an active bleed, and prevention of rebleeding. Diagnosing and treating portal hypertension is a way to prevent esophageal variceal bleeding, and PCPs may play an active role in this respect. Varices appearance should be checked by upper endoscopy every 2-3 years, with a follow-up after 2 years for low-risk bleeding or every year for high-risk bleeding. Non-selective β-blockers are effective in reducing the risk of bleeding by reducing the resting heart rate by 25% (LEVEL Ⅰ). Endoscopic band ligation is indicated for patients susceptible of high-risk bleeding and for those who have already bled[38] (LEVEL Ⅰ). TIPS is an alternative option for patients with previously failed treatments[39] (LEVEL Ⅱ). A recent study has shown that early use of TIPS is associated with significant reductions in treatment failure and mortality[40].

Hepatic encephalopathy
Hepatic encephalopathy is a chronically debilitating complication of hepatic cirrhosis and encompasses a wide spectrum of potentially reversible neuropsychiatric abnormalities seen in patients with liver dysfunction. This condition is deemed as the onset of brain dysfunction due to metabolic abnormalities, which occurs as a consequence of liver failure. Hepatic encephalopathy is mainly caused by a reduced clearance of gut-deriving neurotoxins, and is a potentially reversible condition ranging from subtle personality changes to coma, with flapping tremor as a frequent initial finding. PCPs should search for acid-base and electrolyte disturbances, constipation, infections, gastrointestinal bleeding, and inappropriate use of sedative medications. Treatment consists of identifying and correcting the precipitating factors, colon cleansing and acidification with lactulose (LEVEL Ⅱ). Dietary protein restriction is no longer advocated since it may facilitate malnutrition and the appearance of complications. Rifaximin, a minimally absorbed oral antibiotic, has an antimicrobial effect against enteric bacteria and has received approval from the United States Food and Drug Administration for reducing the risk of overt hepatic encephalopathy recurrence. In a randomized, double-blind, placebo-controlled trial, six-month rifaximin therapy at a dose of 550 mg twice daily was compared with a placebo

in patients with chronic liver disease who were in remission from recurrent hepatic encephalopathy. Rifaximin maintained remission more effectively than the placebo and also significantly reduced the risk of hospitalization for hepatic encephalopathy[41] (LEVEL I). Venous infusion of branched-chain amino acids or flumazenil may be effective in the case of comas (LEVEL II). Patients may be managed at home; admission to hospital is reserved for those who are non-responsive after 12 h treatment.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is a major complication of liver cirrhosis representing an increased cause of mortality; liver transplantation and cost management in most developed countries. As a consequence, screening for HCC is one of the most important tasks in patients with liver cirrhosis. American and European guidelines currently recommend at least one imaging screening/year for HCC (ultrasonography, triphasic CT). Serum alpha-fetoprotein has poor sensitivity and therefore is recommended only as an adjunctive screening marker[37,42]. Once HCC is detected, many treatment options are available, mainly depending on tumor size and number, and local expertise. Surgical resection can be effective; unfortunately most patients do not tolerate liver resection or have microscopic lesions, and so the best option for a cure remains liver transplantation. The Milan criteria are used as a guideline worldwide[43,44], and suggest that a four-year survival rate of 75 percent is achieved if liver transplantation is performed for either a single lesion of less than 5 cm in diameter, or up to 3 lesions with none larger than 3 cm. Outcomes are similar to the expected survival rates for patients undergoing transplantation for cirrhosis without HCC (LEVEL I). Alternative treatments for patients who do not meet the criteria for resection or transplantation are ultrasound guided radiofrequency ablation, chemoembolization and alcohol ablation. These options are considered as a form of "bridging therapy" because it reduces tumor burden and delays tumor progression[45], and do not preclude future liver transplantation, if a donor organ becomes available.

Infections

Sepsis represents a high risk factor for mortality in cirrhotic patients which often do not present the typical signs and symptoms of infection (i.e. absence of leukocytosis due to severe leukopenia or even absence of fever). The active search for infections is important (cultures, X-ray, paracentesis, *etc*.). Most common infections concern the urinary tract (25%-55%), spontaneous bacterial peritonitis (10%-30%), and respiratory tract infection (20%). First line antibiotics include quinolones and cephalosporins[46] (LEVEL III). Hospitalization is required for poor general health and/or the appearance of organ dysfunction.

SYSTEMIC PROBLEMS

Malnutrition

Malnutrition represents a negative prognostic factor for

cirrhosis and consists of muscle wasting, hypoalbuminemia, decreased resistance to infections, and variceal bleeding. Causes include poor oral nutritional intake, malabsorption, ongoing alcohol use, chronic nausea, and early satiety due to abdominal compression from ascites. Nutritional status should be monitored in all cirrhotic patients; multivitamin supplementation is often indicated[47]. Nutritional support should be reserved only for severely malnourished patients scheduled for transplantation[48]. Oral supplementation with a branched chain amino acids has some utility by improving event-free survival in patients with decompensated liver cirrhosis[49]. Dental care is particularly important to allow adequate mastication.

Osteoporosis

In individuals with chronic liver disease, metabolic bone disease (hepatic osteodystrophy), is a potential complication of long-standing hepatic disease. It is therefore essential to prevent the development of fractures in individuals with advanced hepatic disease and those that have undergone liver transplantation[50]. In end-stage cirrhosis, vitamin D deficiency, hypoparathyroidism, and hypogonadism contribute to reduced bone formation. Osteopenia may occur early in patients with cholestasis or in those put on antiviral drugs[51]. This is also the case in patients after orthotopic liver transplantation[52]. Bisphosphonates, together with calcium and vitamin D_3, are effective in improving bone mineral density[53] (LEVEL II).

Diabetes

Diabetes and cirrhosis are strictly interrelated, the first occurring with increased frequency in patients with NASH, hepatitis C or hemochromatosis. In a multivariate analysis, diabetes was an independent negative factor for liver disease evolution[54]. No controlled studies have tested the benefit of different regimens for cirrhotic patients with diabetes. Diet remains the first line remedy to control hyperglycemia. In the case of dietary failure, metformin is generally the first choice. Sulphonylureas can be used, but mindful of the risk of hypoglycemia. Glitazones are a new alternative, although no studies in liver cirrhosis have been performed. In any case, oral anti-diabetic drugs are not indicated in decompensated patients. Insulin represents the best approach, although this requires good self-monitoring (LEVEL III).

PREVENTION

Primary prevention

The role of PCPs is important for this issue. The most attractive form of protection for liver cirrhosis is to prevent or slow the evolution of several risk factors triggering the hepatitis-fibrosis sequence. Mass infant vaccination has proven extremely effective in preventing hepatitis B infection. Screening blood donors effectively reduces hepatitis C transmission (LEVEL I).

Secondary prevention

This step aims at preventing the appearance of cirrhosis

Figure 1 Algorithm for the management of patients with (or with suspected) liver cirrhosis in General Practice.

in patients with chronic liver disease and includes etiologic treatment for viral hepatitis, alcohol abstinence, phlebotomy in hemochromatosis, weight loss and improving insulin resistance in NASH patients[1]. Early detection of HCC by six-monthly ultrasonography and blood alpha-fetoprotein measurement may allow successful liver transplantation or mini-invasive treatments (LEVEL I).

Prevention of infections
Vaccine immunization against hepatitis A and B, pneumococcus and influenza is important in preventing general status deterioration. SBP recurrence can be reduced by antibiotic prophylaxis (once-daily 400 mg norfloxacin or once-weekly 750 mg of ciprofloxacin)[55].

THE ROLE OF PCPs FOR OPTIMIZING CARE
The incidence of liver cirrhosis is expected to increase in the near future. Beside B and C viral infection and alcoholic cirrhosis, nonalcoholic liver steatosis (nonalcoholic fatty liver disease, NAFLD) is considered the hepatic manifestation of a new epidemic: the metabolic syndrome. This frequent condition is a cluster of risk factors for coronary heart disease and type 2 diabetes mellitus that includes visceral obesity, elevated blood pressure, insulin resistance, and dyslipidemia[56,57]. The onset of NAFLD represents a bridging condition between cardiovascular risk and potentially evolutive forms of liver diseases, namely steatohepatitis (NASH), fibrosis, cirrhosis, and hepatocellular carcinoma[58,59]. The PCPs are therefore asked to play a key role in programs involving prevention, treatment, surveillance, and home care of populations at risk (Figure 1)[4,60]. Referral of patients to specialists at

least once is a good practice, since integrated management between PCPs and specialists is indeed associated with better outcomes[61]. Active cooperation is required for etiologic treatments, screening for complications and approaches to liver failure. However, appropriate timing for referral varies on an individual basis according to liver function and general health status, and this should include patient age, level of test abnormality, need for prognosis, and therapeutic decision. The need for a multidisciplinary approach should be considered, which includes feedback from dietitians, psychologists, and physical activity supervisors[62]. This integrated approach optimizes therapy adhesion, but necessitates the regular updating of health personnel[60].

PCPs can manage cirrhotic patients by checking therapy effectiveness and side effects. With the exclusion of major digestive bleeding, even severely decompensated patients or those in an irreversible coma or advanced HCC can be home managed (with the assistance of specialists and specialized nurses). Hepatic encephalopathy can be treated with lactulose (oral or rectal enema) and the minimally absorbed rifaximin, by controlling electrolytes, and treating infections. Ascites can be controlled with diuretics, albumin infusion or paracentesis. Albumin boosts the efficacy of diuretics, and reduces the number of hospital admissions[35]. Home care of cirrhotic patients should be encouraged since it allows a saving of up to two/third of the normal cost (Table 5) (LEVEL II -III).

CONCLUSION
Liver cirrhosis has an increasing prevalence worldwide, which matches the increasing diffusion of viral hepatitis infection, and metabolic steatohepatitis and fibrosis. Managing cirrhotic patients at home is challenging but cost-effective, although this policy requires active collaboration between PCPs and specialists, as well as nurses and paramedical staff. A set of conclusive key messages for practice are reported in Table 6.

Table 5 Features of home assistance in patients with liver cirrhosis

Advantages
  Decreased number of hospitalization and re-admissions
  Decreased costs of treatments
  Assist the patient within his familiar comfort
Criteria of eligibility
  Identification of a clinical status allowing home stay
  Identification of priority criteria
  Presence of a valid family support or of an active aid system
Selection criteria
  Use the Karnofsky Performance Status[1] for patients with decompensated liver cirrhosis and limited self-sufficiency (set to < 50%)

[1]The Karnofsky Performance Scale Index allows patients to be classified as to their functional impairment. This scale is often used in the primary care setting to assess the prognosis in individual patients and to decide a treatment; the lower the score, the worse the survival.

Table 6 Key messages for best management of cirrhotic patients

Statement	Evidence level
1 A compensated liver cirrhosis is suspected with abnormal liver function tests, low platelets count, and prolonged prothrombin time[63]	III
2 Ultrasonography is a reliable, non-invasive, fast, and cost-effective test working as a first-line tool for diagnosing liver cirrhosis[64]	II - III
3 Child-Pugh and MELD scores assess the prognosis of liver cirrhosis[19,20]	I
4 First-line treatment of patients with cirrhotic ascites includes diuretics and sodium restriction. Anti-aldosterone drugs are given with loop diuretics to increase diuretic response or when renal perfusion is impaired. Dietary salt intake should be restricted to approximately 88 mmol/day (2000 mg/d). Marked salt restriction can expose the risk of hyponatremia[32,37]	I
5 Removal of less than 5 liters of fluid does not appear to have a hemodynamic consequence. For larger paracentesis, albumin (6 to 8 g/L of fluid removed) can be administered. Albumin is indicated in patients with PBS to prevent renal failure, and in patients with hepatorenal syndrome. Albumin can be also used to treat refractory ascites. Its infusion at home is safe and cost-effective[37,65]	II
6 β-blockers (e.g. propranolol or nadolol) are recommended for prophylaxis of variceal bleeding at a dosage titrated to a 25 percent reduction in pulse rate[66]	I
7 Liver transplantation is the only definitive care for patients with major complications (ascites, bleeding, HCC) and/or MELD above 13[1]	I
8 Osteoporosis is an important systemic complication of end-stage liver cirrhosis. Management includes vitamin D and bisphosphonates[53]	II
9 Malnutrition is a negative and independent predictor of survival in patients with liver cirrhosis[67]	II
10 An integrated assistance of patients with liver cirrhosis has a better outcome than the management by generalists/specialists alone[61]	II

LEVEL I: At least one properly conducted RCT, systematic review, or meta-analysis; LEVEL II: Other comparison trials, non-randomized, cohort, case-control, or epidemiologic studies, and preferably more than one study; LEVEL III: Expert opinion or consensus statements (see text for details); MELD: Model for end-stage liver disease.

Abstract

Latin America is characterized by ethnic, geographical, cultural, and economic diversity; therefore, training in gastroenterology in the region must be considered in this context**.** The continent's medical education is characterized by a lack of standards and the volume of research continues to be relatively small. There is a multiplicity of events in general gastroenterology and in sub-disciplines, both at regional and local levels, which ensure that many colleagues have access to information. Medical education programs must be based on a clinical vision and be considered in close contact with the patients. The programs should be properly supervised, appropriately defined, and evaluated on a regular basis. The disparity between the patients' needs, the scarce resources available, and the pressures exerted by the health systems on doctors are frequent cited by those complaining of poor professionalism. Teaching development can play a critical role in ensuring the quality of teaching and learning in universities. Continuing professional development programs activities must be planned on the basis of the doctors' needs, with clearly defined objectives and using proper learning methodologies designed for adults. They must be evaluated and accredited by a competent body, so that they may become the basis of a professional regulatory system. The specialty has made progress in the last decades, offering doctors various possibilities for professional development. The world gastroenterology organization has contributed to the speciality through three distinctive, but closely inter-related, programs: Training Centers, Train-the-Trainers, and Global Guidelines, in which Latin America is deeply involved.

INTRODUCTION

Latin America is home to over 50 countries and a population close to 600 million people. The two main languages are Spanish and Portuguese, but there is also long list of native languages. In the last 60 years, the economy of Latin America and the Caribbean grew by 4%, while the population increased by 2.1% annually. Although unemployment has dropped in recent years, it still averages 7.5%. Although the number of poor people in the overall population has dropped by more than 9% between 2002 and 2007, it is still

around 35%, which implies that 210 million people live in poverty in the region, i.e. prior to 1980, 39‰ of the population were poor. More positive results have been obtained for people living in extreme poverty; it is estimated that in 2007, 12.7% of the population lived in indigence, versus 18.6% in 1980; however, in absolute terms, the number of people affected increased from 62 million to 76 million in the same period. The mortality rate of children under five years of age is 27 per 1000 (27‰), that is one third of the average observed in developing countries (81‰). However, some nations like Bolivia (61‰) and Haiti (72‰) lag behind in this regard. With regard to income distribution, the region has experienced some modest progress. One of the elements that have been of concern to the regional economic authorities in 2007 and 2008 has been the rise of inflation in the region. According to ECLAC's (Economic Commission for Latin America and the Caribbean) estimates, since early 2006, and with greater impetus in 2007, consumer prices rose with increasing speed in most economies in the region, with annual increases of 7% to 30% in the various countries and an average close to 16%[1].

Most countries in Latin America and the Caribbean have succeeded in enforcing universal primary education, and they are experiencing an expansion of pre-school, secondary, and tertiary education.

In 2006, there were 16 million students enrolled in further education in Latin America and the Caribbean. The average rate of enrollment in universities went from 21% to 31% between 1999 and 2006, but varied from one country to another (3% in Belize to 88% in Cuba)[2].

To summarize, Latin America is characterized by ethnic, geographical, cultural, and economic diversity; therefore, training in gastroenterology in the region must be considered in the framework of this context.

CURRENT STATUS OF MEDICAL EDUCATION IN GASTROENTEROLOGY IN LATIN AMERICA

The continent's medical education is typically characterized by the following features: a large number of medical schools in some countries, most of which grant no local accreditations; teaching is done by various agencies in the country, with no common programs and without previously agreed requirements for the gastroenterologist's (GE) or the endoscopist's training. In sum, a lack of standards is its main feature.

Current status of scientific research in gastroenterology in Latin America

Despite the efforts of several groups, especially those working in Mexico, Brazil, Peru, Chile, and Argentina, the volume of research continues to be relatively small, highlighting some contributions in the field of *Helicobacter pylori* and Celiac Disease, among others. There is still much to learn and report about the continent, especially with regard to epidemiology.

Table 1 Number of citable papers in all gastroenterology fields indexed at the SCOPUS database originating from three South American countries

Year	Argentina	Brazil	Colombia
2000	20	100	3
2008	28	220	46

Data were extracted from SCImago-Journal and Country Rank (retrieved on July 13, 2010, from http://www.scimagojr.com).

Nevertheless, continued investment in scientific research by government agencies in some countries, such as CONICET (Argentina), CNPq (Brazil) and COLCIENCIAS (Colombia) has been associated in recent years with a remarkable increase in the output of indexed papers in all fields, including gastroenterology, coming from these countries (Table 1).

Scientific events in gastroenterology in Latin America

There is such a multiplicity of events, that they might even be considered excessive. There is usually a succession of general gastroenterology events as well as others that deal with sub-disciplines, both at regional and local levels. Although this results in an undesirable fragmentation of the field, the positive consequence is that these events ensure that many colleagues have access to information, with the caveat that such information may not always be necessarily reliable or of good quality. It is important to address the role of the pharmaceutical industry and medical equipment in the continuing professional development programs (CPDPs).

Needs: Medical education programs must be based on a clinical vision and be considered in close contact with the patients. They should require previous training in Internal Medicine (via a two-year internship or a full postgraduate fellowship).

Proper supervision of the programs must be ensured. It is essential for each institution that the courses be accredited and to have links with the School of Medicine, to ensure that the premises are adequate, and that there is the necessary equipment and clinical support.

It is important to guarantee that the gastroenterologist's (GE's) training course is of an adequate duration (two to three years) with a minimum dedication of six hours a day. The recommendation is to prioritize the training of trainers that have no teaching background.

Moreover, it is essential for the programs to be appropriately defined and evaluated on a regular basis. The programs should guarantee the GE's training concerning the development of their skills and attitudes. The importance of electronic methods (e-teaching, e-learning, the use of the internet) must be emphasized. The syllabus should also contemplate the teaching of basic administration skills.

The disparity between the patients' needs, the scarce resources available, and the pressures exerted by the health systems on doctors are frequently cited by those that complain about their poor professionalism.

Teaching development can play a critical rol in ensuring the quality of teaching and learning in universities. "*A good university teacher is not the one who prepares their students to pass an exam, it is the one who obtains a students valuation of learning and a critical thought. He is also the one who encourages them to solve problems with creativity and curiosity and with ethical commitment as well as with a desire of improving their knowledge in a specific subject.*"[3].

Briefly put, the CPDP activities must be planned on the basis of the doctors' needs, with clearly defined objectives, using proper learning methodologies designed for adults. Andragogy, defined as "the art and science of helping adults learn", is based on five assumptions about how adults learn and their atitude towards, and motivation for, learning: (1) adults are independent and self directing; (2) they have accumulated a great deal of experience, which is a rich resource for learning; (3) they value learning that integrates with the demands of their everday life; (4) they are more interested in immediate, problem centred approaches then in subject centred ones; and (5) they are more motivated to learn by internal drives than by external ones.

The CPDP activities must also be evaluated and accredited by a competent body, so they may become the basis of a professional regulatory system (recertification or others). One of the greatest challenges is to balance the needs of professional employers and health care systems with those of the patients.

WHAT SHOULD THE FUTURE GASTROENTEROLOGIST LEARN?

Future specialists naturally aim at following their vocation, working with dignity and ethics, applying their knowledge, maintaining an ongoing training, and at times, they may seek academic development (teaching or research). The specialty has made progress in the last decades, offering the doctors various possibilities for professional development; it is no longer the outlook faced by the clinical gastroenterologist 50 years ago, or by more recent endoscopists. Today's GE can choose to develop an in-depth knowledge on certain sub-specialties, such as nutrition, hepatology, transplantations, interventional endoscopy, capsule endoscopy, NOTES (Natural Orifice Translumenal Endoscopic Surgery), motility, etc. In sum, the Latin American GE's training must be comprehensive, taking into account both society's interests, as well as the doctors' legitimate objectives.

SOME EXAMPLES ON THE TRAINING OF GASTROENTEROLOGISTS IN LATIN AMERICA

In Argentina, there are no unified criteria to be met to graduate as a gastroenterologist. The courses are dictated by the Argentine Society of Gastroenterology in partnership with the University of Buenos Aires, or by private or state-run schools of medicine in the interior of the country. Overall, there are eight courses that train GEs lasting

for two to three years. Entry to the courses requires the completion of two years of internal medicine. There is no single accreditation body, nor are there any unified requirements for the training of endoscopists or liver experts[4].

In Uruguay, the specialists' training depends on the state School of Medicine's School of Graduates. It does not request a post-graduate degree in internal medicine. The gastroenterology course takes three years on a part-time basis, and it includes theoretical and hands-on activities that also include liver diseases. A degree in endoscopy has been recently created.

In Chile, gastroenterology is viewed as part of internal medicine. A GE is an internist that must go through three additional years in the specialty. There are several university programs in gastroenterology. The universities are recognized by the National Medical Certification Board.

Both Argentina and Chile have implemented mechanisms to regularly renew accreditation to specialists.

In Brazil, specialist training in gastroenterology has been regulated since 1977 by federal legislation, which established a two-year program in accredited institutions for candidates who have already completed a previous two-year basic training in Internal Medicine. Thus, the typical training takes four years, but most programs affiliated to university hospitals offer an additional elective year in sub-specialties, such as endoscopy or hepatology. After completing the specialist training, gastroenterologists are eligible to apply for certification, conferring the specialist title, which is provided by the Brazilian national gastroenterology society, known as Federation of Gastroenterology (FBG), to candidates passing the relevant examinations. Accreditation of institutions is provided by a federal agency, the National Commission for Medical Residency, on the basis of the characteristics of both the institution (infrastructure, number of hospital beds, average of outpatients visits, certified personnel, *etc*) and the program quality (balance between inpatients and outpatients activities, supervision, hours of endoscopy training, *etc*).

CME (Continuous Medical Education) in Brazil has been a compulsory requirement for the renewal of the specialist title since 2005, following the creation of the professional update certificate CAP (acronym for Certificado de *Atualização* Professional). Starting in January 2011, the titles will be renewed only to those who obtained their CAP or acquired a minimum of 100 CME credits in the previous five years. Those who fail have to sit an additional exam to keep their title. The national societies of each specialty, such as the Brazilian FBG, participate in the National Accreditation Committee (CNA) with other organizations, such as the Brazilian Medical Association or the Medical Federal Board. The CNA evaluates organizers' applications for activities that intended to grant CME credits and validates the credits already obtained by doctors. The national societies are requested to organize activities to provide a minimum of 40 credits a year. This is followed strictly by the FBG, which has the organization of CPDP meetings and distance learning activities as one of its main aims. Regarding the Medical Schools and the University hospitals, de Almeida Troncon *et al*[5] thinks that they do not devote enough time

and effort to comply with that requirement. His concerns about the support of the CME activities by the biomedical industry are based on the lack of independence of the programs. Lack of evaluation of the activities is another weakness of the program in Brazil, where the cognitive aspects are emphasized over the acquisition of skills and attitudes. Evidence that the CME activities in Brazil are positive for the quality of medical work is still scarce. Troncon suggests that new ways of implementing CME have to be found: funding must come from the Medical Schools and the working institutions, which should adopt the principles of adult learning, especially in identifying the needs of learners, developing the objectives of the activities, and finally designing the curricula. Finally, he stresses that the evaluation is a key issue in that process.

Venezuela: There are approximately seventy students within the sixteen post-graduate programs in gastroenterology in Venezuela. All of them differ in curriculum, academic and research structure, and even in their own graduation profile. The group led by Lizarzábal *et al*[6] tested their individual and global quality by conducting a users-satisfaction survey, questioning students and program directors. The sample included 46 students who answered anonymously. The students' results showed that 13% of the programs were considered to be of excellent quality (A) and 8.7% of the programs were graded as B (good). An important group (71.7%) was graded as C (bad) and 6.5% as D (very bad). Users' perception differed from the perception of directors, who evaluated the quality of more than half (57%) as A-B, while only 21.7% were graded A-B by the users.

In view of the above results, the Society of Gastroenterology of Venezuela made some recommendations to improve the quality of the postgraduate teaching programs, which are summarized as follows: (1) Implementing structured and explicit curricular designs in 100% of the Venezuelan Gastroenterology Postgraduate Programs; the programs that already have such designs (60%) will be asked to apply consistently unified criteria; (2) Request that 100% of the programs be accredited by the National Universities Council (CNU) before pursuing certification and re-certification; (3) Strengthen a culture of research; (4) Develop evaluation strategies to allow monitoring of the service provided; (5) Improve proficiency of the human resources available. Most of the staff lack the academic training needed to implement an adequate curricular design, evaluation, research, and learning strategies; and (6) Plan and reach consensus on education in Gastroenterology with a broad participation of the stakeholders. The profile and training of the Venezuelan gastroenterologist is still to be defined.

CONTRIBUTIONS OF THE WGO (WORLD GASTROENTEROLOGY ORGANIZATION) TO THE SPECIALITY IN LATIN AMERICA

The current objectives of WGO are enshrined in its mission statement: "to promote, to the general public and health care professionals alike, an awareness of the worldwide prevalence and optimal care of digestive disorders through the provision of high quality, accessible and independent education and training", which signals the commitment of WGO to address two challenges: firstly, providing the gastroenterologist of the future with an optimal training and, secondly, bringing the benefits of digestive health care to those who currently struggle or, indeed, fail to achieve access to it. The primary emphasis of WGO, therefore, is on education and training. These objectives are achieved through three distinctive, though closely interrelated, programs: Training Centers, Train-the-Trainers, and Global Guidelines.

Training Centers most directly address the issue of training specialists in gastroenterology or individuals with additional expertise in gastroenterology to serve previously underserved areas. Each centre represents a direct collaboration between local experts, international faculties, and national and regional societies from Europe and North America to deliver regionally relevant training to those who have limited, or in some cases, no access to such opportunities. The centers in Latin America: La Paz, Bolivia; La Plata, Argentina; Santiago, Chile; Mexico City, Mexico; San José, Costa Rica; and Bogota, Colombia, provide training of variable duration to several hundred young and aspiring gastroenterologists and digestive surgeons from underserved nations in the region. The newest center was inaugurated two years ago in Ribeirao Preto, State of Sao Paulo, Brazil, and is dedicated solely to training in gastrointestinal motility techniques. The centers offer an in-depth view of the various aspects of the field (clinical, endoscopic, and motility). On the other hand, the Inter American Association of Gastroenterology (Asociación Interamericana de Gastroenterología: AIGE) has created scholarships to facilitate the access of six gastroenterologists to the WGO's teaching centers annually.

Finally, it is an important aim for WGO to create an electronic network among all its teaching centers that will include the seven in Latin America. This network should be accessible to all who seek to train in our specialty; thereby, ensuring the highest standards of care for those who suffer from digestive disorders through the world.

Likewise, the WGO has already organized four courses called "Train the Trainers" (TTT) in South America (Uruguay, Brazil, Chile, and Peru), in an attempt to remedy a global problem, i.e. the local faculties' lack of training on educational methodology to teach at university level. Train-the-Trainers courses are uniquely devoted to bringing the very latest in educational techniques to those who will train the gastroenterologists of the future, including those who teach and train at the Training Centers. The TTTs are developed in several modules aimed at teaching educational skills to faculties, in a user-friendly manner, in an informal and friendly atmosphere.

Even if gastroenterologists should nowadays be fluent in English, language can be an issue in such TTT courses in Latin America. The WGO has decided to begin TTTs in Spanish in 2011.

Another activity pushed forward by the WGO, and in which Latin America has been deeply involved, is the devel-

opment of the Clinical Guidelines (CG), with one peculiarity: they are the only ones to consider the availability of resources globally, through the so-called cascade mechanism that enables a professional to adapt the situation to a specific patient, in the patient's own context. To make guidelines more applicable to different resource environments, the concept of "cascades" has been developed. A cascade is a collection of related diagnostic and treatment options arranged hierarchically in terms of conditions and available resources. Whilst guidelines should continue to summarize best known practice, they could also include alternatives for clinicians with limited funding. These alternatives are usually on the basis of cost, but could also take account of local availability, technology, and infrastructure[7].

The complete texts of all the CGs are fully available at the site of the WGO (www.worldgastroenterology.org) in six languages, including Spanish and Portuguese. Outstanding Latin American gastroenterologists were involved in the development of several CGs, such as the one on Celiac Disease or *Helicobacter pylori* in the developing world.

Abstract

Herbal products are increasingly used, mainly in chronic liver disease. Extracts of milk thistle, Silymarin and silybin, are the most prescribed natural compounds, with different indications, but with no definitive results in terms of clinical efficacy. This review analyzes the available studies on the effects of the purified product silybin, both as a free and a conjugated molecule, on liver cells or on experimentally induced liver damage, and in patients with liver disease. We searched PUBMED for articles pertaining to the *in vitro* and *in vivo* effects of silybin, its antifibrotic, anti-inflammatory, and antioxidant properties, as well as its metabolic effects, combined with the authors' own knowledge of the literature. Results indicate that the bioavailability of silybin phytosome is higher than that of silymarin and is less influenced by liver damage; silybin does not show significant interactions with other drugs and at doses < 10 g/d has no significant side effects. Experimental studies have clearly demonstrated the antifibrotic, antioxidant and metabolic effects of silybin; previous human studies were insufficient for confirming the clinical efficacy in chronic liver disease, while ongoing clinical trials are promising. On the basis of literature data, silybin seems a promising drug for chronic liver disease.

INTRODUCTION

The terms milk thistle, flavonoids, silymarin, and silybin are generally used interchangeably; however, each of these compounds has specific characteristics and actions, with an intrinsic beneficial or toxic effect. In the last 10 years, about 12 000 papers have been published on these substances, used as antioxidants or chemopreventives and anticancer agents, and especially as hepatoprotectants. This publication volume indicates that scientific interest in these molecules, or classes of molecules, is high worldwide. In the US and Europe, about 65% of patients with liver disease take herbal preparations; in Europe, the cost of the use of silymarin reaches $180 million in Germany alone. Despite the wealth of literature, no firm clinical evidence exists to recommend the use of these substances in clinical practice[1-10]. This discrepancy is attributable to various factors, such as quality of clinical trials, heterogeneity of diagnoses, lack of standardized preparations, and frequently inconsistent dosing and outcome parameters. At a time when the use of herbal products is increasing, whether driven by individual choice or industry promotion, in our opinion it is necessary to focus more intently on these compounds that may have beneficial, placebo, or toxic effects.

This review analyzes studies of the effects of the

purified product silybin, both as a free and a conjugated molecule, on liver cells or on experimentally induced liver damage, and in patients with liver disease.

DEFINITION AND CHARACTERISTICS OF SILYBIN

As reported, silybin and silymarin are not synonymous[1,3,6]. Silymarin is a complex of at least seven flavonolignans that are the most common class of compounds present in milk thistle extract, and one flavonoid, taxifolin. The relative abundance of each compound may vary depending on the source of botanical material, supplier, and extraction processes. Silybin represents about 50% to 70% of the silymarin extract. Silybin can be resolved into two 1:1 diastereoisomers, silybin A and silybin B. In addition, silybin may be present as isosilybin, a 1:1 mixture of two diastereoisomeric compounds, isosilybin A and isosilybin B[11-17]. The concentrations of silybin in the main pharmaceutical products containing silymarin present in the US and other countries range from 20% to 40%[16].

PHARMACOKINETICS AND PHARMACO-DYNAMIC ASPECTS

Flavonolignans are known for their poor and erratic bioavailability; for example, silymarin absorption rate levels vary between 20% and 50%. Silybin has been separated commercially as a pure substance[11-16], and the study of silybin pharmacokinetics properties using an HPLC method has shown that the concentration-response relationship is linear over a concentration range of 0.5-100 µg/mL[16]. After administration to rats, the disposition of silybin in the plasma and bile fluid is due to rapid distribution and equilibrium between the blood and hepatobiliary system, and the bile levels of unconjugated and total silybin are greater than those in plasma[18-22].

Similarly to other flavolignans, limiting factors for the use of silybin are its low solubility in water, low bioavailability, and poor intestinal absorption. To counteract this aspect, different more soluble derivatives of silybin have been synthesized, such as silybin bis-hemisuccinate, β-cyclodextrin complex, silybin-N-methyl-glucamine, silybin 11-O-phosphate, and silybin-phosphatidylcholine. Another strategy for improving silybin solubility is represented by the enzymatic synthesis of its β-glycosides, such as silybin β-galactoside, silybin β-glucoside, silybin β-maltoside, and silybin β-lactoside. A soluble silybin prodrug has been finally synthesized with a high aqueous soluble polymeric carrier (polyethylene glycol)[23-30].

Some conjugations may in part affect the activity of silybin. For example, the radical-scavenging activity of the silybin 20-O-β-D-glucuronide is considerably lower than that of free silybin. In contrast, a considerable increase in radical-scavenging activity is observed in the other silybin, 7-O-β-D-glucuronide, in which position C-20 is free. The increase in the radical-scavenging activity of this latter

conjugate cannot be simply ascribed to the addition of the glucuronyl moiety. The change in antiradical activity is, therefore, the result of the overall structural change. It is also quite interesting that one diastereoisomer of silybin (B) undergoes conjugation faster than the other (A); this difference indicates that the two silybin diastereoisomers are metabolized at different rates. These findings will aid the development of improved silybin formulations designed to inhibit the C-20 conjugation or, alternatively, to contribute to a modified dosage scheme that maintains free plasma silybin at sufficient levels[31-35]. Both free and conjugated silybin have a rapid plasma and tissue distribution that reaches maximum levels within one hour after 50 mg/kg silybin administration in mice[36]. The protein binding of silybin in rat plasma is 70.3% ± 4.6%[21].

In humans, the pharmacokinetics of silybin was evaluated after the administration of variable doses of silymarin, pure silybin, and silybin conjugated with phytosome in healthy volunteers. Hoh *et al*[37] for the first time identified the silybin plasma metabolites and measured the silybin tissue levels in humans who had ingested silybin. They demonstrated that silybin undergoes multiple conjugation reactions in humans and clearly identified the conjugated species: silybin monoglucuronide, silybin diglucuronide, silybin monosulfate and silybin glucuronide sulfate. The administration in humans of 240 mg of pure silybin induces a peak concentration of 240 ± 54 ng/mL in about 2 h that persists for 4 h. After administration of a single oral dose of 560 or 600 mg silymarin (about equivalent in total to 240 mg of silybin), the fractions of the free, sulfated, and glucuronidated silybin in human plasma are about 17%, 28%, and 55% of the total dose, with a higher plasma percentage of glucuronidated silybin B (71%) than of glucuronidated silybin A. The total percentage of dose recovered in urine, as free and conjugated, is very low, ranging from 1% to 7% of the dose (mean: 2.8 ± 0.6 ng/mL)[29,38-42]. The complex silybin phytosome (silybin + phosphatidylcholine) was recently formulated with the addition of vitamin E (Indena, IBI-Lorenzini spa Italy: Realsil®). This conjugation induces a greater solubility of silybin, as reported in Table 1. In 12 healthy volunteers aged 20-53 years, silybin was administered as Realsil® in two pharmaceutical forms (capsules and granules, both corresponding to 47 mg of silybin). Data were compared to those obtained by administering, in a cross-over manner after 1 wk of wash-out, a silymarin capsule containing 58 mg of silybin and silymarin granules containing 80 mg of silybin[43]. As summarized in Tables 1 and 2, the global results of the pharmacokinetic analysis indicated that the bioavailability of silybin phytosome is much higher than that of silymarin.

EFFECT OF LIVER DAMAGE ON PHARMACOKINETICS OF SILYBIN

In patients with well-compensated liver cirrhosis, silybin was administered as silybin phytosome at a dose of 120 mg

Table 1 Pharmacokinetics of silybin phytosome and silymarin in healthy participants[38-43]

	Silybin phytosome	Silymarin
Peak concentration (ng/mL)	298 ± 96	102 ± 22[a]
Time of peak (h)	1.6 ± 0.3	1.4 ± 0.3
Mean residence time (h)	3.6 ± 0.4	3.5 ± 0.4
AUC (ng/mL/h)	881 ± 207	257 ± 66[b]

[a]$P < 0.05$, [b]$P < 0.01$. NB: The analyses were performed using HPLC.

Table 2 Pharmacokinetics of silybin after administration to 12 healthy volunteers as silymarin or silybin-phosphatidylcholine-vitamine E complex (RA)[43]

Product	Cmax (ng/mL)	Tmax (h)	AUC (ng/mL per hour)
RA granules (47 mg silybin)	213 ± 166	0.5	246 ± 114
RA capsules (47 mg silybin)	117 ± 93	1.0	161 ± 85
Silymarin gran (58 mg silybin)	18 ± 17	0.5	25 ± 18
Silymarin caps (80 mg silybin)	5 ± 7	1.0	11 ± 5

× 3 /d, or as silymarin containing 84 mg of silybin 4 fold/d. The results showed that liver cirrhosis does not modify the kinetics of silybin and that in liver patients, the bioavailability of silybin is higher when it is administered as a phytosome adduct[44]. Similar data were obtained in rats with experimentally induced cirrhosis[45]. Table 3 summarizes the data obtained in humans.

More recently, the pharmacokinetics of silybin has been evaluated in patients with chronic hepatitis [hepatitis C virus (HCV) or non-alcoholic fatty liver disease (NAFLD)] and compensated liver cirrhosis[46,47]. A single, 600 mg p.o. dose of milk thistle extract was administered to healthy volunteers and to three patient cohorts, and blood samples were obtained over 24 h. Silybin A and B accounted for 43% of the exposure to the sum of total silymarin flavonolignans in healthy volunteers and only 31% to 38% in liver disease cohorts as a result of accumulation of silychristin (20%-36%). Area under the curve (AUC, 0-24 h) for the sum of total silymarin flavonolignans was 2.4, 3.3, and 4.7-fold higher for the HCV or NAFLD ($P \leq 0.03$) and HCV cirrhosis cohorts ($P \leq 0.03$), respectively, compared with healthy volunteers. Silymarin kinetics was correlated with plasma levels of caspases as an index of liver inflammation; caspase 3/7 activity correlated with the AUC (0-24 h) for the sum of all silymarin conjugates among all participants ($R^2 = 0.52$) and was 5-fold higher in the HCV cirrhosis cohort ($P \leq 0.005$ versus healthy participants). These findings suggest that the presence of liver damage, particularly as chronic inflammation, may affect the bioavailability of the different components of silymarin, possibly explaining the low beneficial effects of flavonoids in patients with liver damage.

Interactions and toxicity

There are substantial differences between silymarin and silybin in their interactions with metabolizing enzymes, and

Table 3 Comparison between silybin phytosome and silymarin pharmacokinetics in patients with liver cirrhosis[44]

	Silybin phytosome (360 mg)	Silymarin (336 mg)
Cmax (ng/mL)	860 ± 166[b]	83 ± 15
Tmax (h)	2.7 ± 0.7[b]	2.6 ± 2.1
/2 (h)	3.3 ± 0.7[b]	2.6 ± 0.4
AUC	515 ± 665[b]	262 ± 39
Total bioavailability	252 ± 39[b]	19 ± 23

[b]$P < 0.001$.

the reasons for these differences remain unknown. Silybin alone or as silybin β-galactoside, β-glucoside, β-lactoside, or β-maltoside at a final concentration of silybin 100 μmol/L has been tested *in vitro*. Under these conditions, silybin showed slow inhibitory effects ($IC_{50} > 200$ μmol/L) on marker substrates of CYP2E1, CYP2D6, CYP2C19, and CYP2A6. Silybin and silybin β-glycosides did not induce expression of CYP1A2 and CYP3A4 and did not affect the inducible expression of either of these enzymes[48-53].

In *in vivo* work, Sridar *et al*[54] investigated metabolic interactions involving silybin at doses ranging from 25 to 250 μmol/L and substrates metabolized by CYP3A4 or CYP2C9, showing that silybin may be a modulator/inactivator of P450s 3A4 and 2C9. What remains to be elucidated is whether this effect is brought about by competition at the site or inhibition for substrate binding and for metabolism at a particular binding pocket in the active site; another possibility is that it results from a conformational change in the active site. Despite these results, silybin has shown no effect on the metabolism of indinavir[55,56], which is mediated by CYP3A4, and others[57-60] have documented that silybin, at a concentration of 100 μmol/L, has no effect on either basal or inducible expression of CYP3A4 mRNA.

In any case, the silybin-drug interaction of these enzyme substrates is not clinically relevant, and the inhibitory effects of silybin occur only at concentrations that massively exceed the physiologically used doses[60-62]. *In vitro*, silybin inhibits the UGT glucuronyl transferases UGT1A6 and UGT1A9, but it is 14- to 20-fold more selective for UGT1A1[48,49,61-64] (see Table 4 as summary). The clinical relevance of this phenomenon is presently unknown because there are no published reports indicating the existence of a clinical interaction with bilirubin. UGT1A1 is the only enzyme responsible for bilirubin glucuronidation, and it contributes to the glucuronidation of several drugs. In animals, silybin affects the hepatobiliary elimination of various drugs[52,53,57,58,64]; oral feeding of pure silybin at doses of 100 and 200 mg/kg/bw/d showed a moderate to highly significant increase in both glutathione-S-transferase and quinine reductase activities in the liver, lung, stomach, skin, and small bowel in a dose- and time-dependent manner[58]. Recently, Flaig *et al*[27] provided the best evidence that silybin can be administered to humans at doses producing anticancer-relevant concentrations, with minimal or no side effects.

Table 4 Interference of silybin with cytochromes[48-64]

Interference	Possible interference	No interference
UGT1	CYP3A4	CYP2E1
	CYP2	CYP2D6
		CYP2C19
		CYP1A2
		CYP2A6

That study employed the largest doses ever used, ranging from 2.5 to 20 g of silybin-phosphatidylcholine (Indena's Siliphos® "silybin phytosome"), given daily in three divided doses for 4 wk to 13 men with a history of prostate carcinoma. At a dose escalation from 15 to 20 g/d, silybin was discontinued because of asymptomatic hyperbilirubinemia, most likely because of inhibition of the glucuronyl transferase UGT1A1. However, in all patients, this mild hyperbilirubinemia improved with treatment cessation.

The limitations of available clinical trials with regard to establishing safety are the same as those for establishing efficacy. Clinical trials testing safety are poor predictors of the fate of extracts in real-world settings, where patients ingest multiple drugs and herbs, take different formulations of the same product, and add alcohol and other compounds, often for extremely long periods. In the randomized trials that reported adverse effects, their frequency was approximately equal in the silybin and control groups. The majority of the observed adverse events were unrelated to the product or difficult to separate from the concomitant disease, and in available reports, causality is rarely addressed. There are no safety data in children or older adults, as there are no reported studies in children and very few studies that included patients older than 65 years. Adverse effects associated with oral ingestion of silybin include mainly gastrointestinal problems, but these are rare. Headache/dizziness and pruritus were reported in one clinical trial. Asymptomatic liver toxicity has been observed in recent clinical trials performed in cancer patients, in whom hyperbilirubinemia and increases in alanine aminotransferase (ALT) levels were observed; however, these effects were present only when very high dosages of silybin phytosome (between 10 and 20 g/d) were used. At high doses, a laxative effect of silybin phytosome is possible because of increased bile secretion and bile flow. Mild allergic reactions have also been noted, but they were not serious. Therefore, the available data indicate that milk thistle has few side effects when doses lower than 5 g/d are used, with possible adverse effects at doses greater than 10 g/d[6,7,62].

The documented effects of silybin in basic research
In liver cells, as well as in other types of cells, the common effects of silybin may be summarized as follows: (1) Antioxidant; (2) Direct and/or indirect (through the antioxidant capability) modulator of inflammation and fibrogenesis; and (3) indirect and/or direct modulator of some intrahepatic metabolic pathways.

Antioxidant action
The antioxidant effects of silybin have been demonstrated in all cells studied. Silybin acts as an antioxidant because it inhibits radical formation, binds some radical species (scavenger), interferes with lipid peroxidation of membranes (and therefore modulates membrane permeability), and increases the intracellular content of scavengers[65]. In fact, in the presence of oxidative and nitrosative stress, silybin inhibits the formation of superoxide anion radicals and of nitric oxide (NO), increases ATP content through the phosphorylation of ADP, decreases the content of malondialdeyde (MDA) and totally abolishes the decrease of glutathione, of superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase[66-73]. These results, which are dose-dependent, have been documented in isolated rat Kupffer cells, hepatocytes, HEPG2 cells, isolated mitochondria from rat hepatocytes, and in models of ischemia-reperfusion of rat liver. In experimentally induced liver damage, one hour after intragastric administration to rats of conjugated silybin (0.6 g/kg bw), the content of silybin in the microsomes measured using a specific HPLC assay was approximately 2.5 μg/mg of protein, corresponding to a final concentration of 10 μmol/L of silybin. Under these conditions, lipid peroxidation, mitochondrial permeability and respiration, and membrane potential as well as cell death were reversed by silybin, particularly if it was conjugated as silybin + phosphatidylcholine. This last compound, at a dose of 20 μmol/L, directly scavenges hydroxyl, hydroxyethyl, lipodienyl, methyl, and trichloromethyl radicals[74,75].

Finally, silybin acts as an antioxidant because it also serves as an iron chelator[76-78]. More recently, it has been suggested that dehydrosilybin (DHS), an oxidized form of silybin, has greater antioxidant activity than silybin (about three times better), probably because of the presence of unsaturated bonds that contribute to hydrogen-donating capacity. The better scavenger activity of DHS may also be the result of its greater ability to react with cell membranes because it has higher lipophilicity than silybin[32,65].

Table 5 summarizes the main antioxidant effects of silybin.

Anti-inflammatory action
In general terms, silymarin and silybin interfere with the NF-κB-controlled transduction cascade. NF-κB is an inducible and ubiquitously expressed DNA-binding protein, acting as a transcription factor for genes involved in inflammation, cell survival, differentiation, and growth[79,80]. In unstimulated cells, NF-κB is sequestered in the cytoplasm by interaction with inhibitory protein 1 κ B α (IκBα). Upon activation from oxidative stress, NF-κB dissociates from IκBα, and IκBα is degraded. NF-κB translocates to the nucleus and, through kinase phosphorylation, drives the activation of genes supporting inflammation. Consistent with its antioxidant activity, silybin has been demonstrated to inhibit NF-κB activation and translocation through suppression of IκBα phosphorylation and degradation[81-83]. In an acute model of liver damage

Table 5 Antioxidant effects of silybin[65-75]

Doses	Cells	Targets
From 10 to 100 µmol/L	Hepatocytes	Decreased formation of reactive oxygen species from mitochondria; iron chelator
	HepG2	Decreased formation of superoxide anion
Mean dose with documented effects: 20 µmol/L	Kupffer cells	Decrease of NO production
	Monocytes	Scavenger of lipodienyl, methyl, trichloromethyl radicals
	Endothelial cells	Decrease of hydrogen peroxide concentration
	Cancer cells	Block of membrane lipid peroxidation

Table 6 Anti-inflammatory/antifibrotic effects of silybin[79-99]

Doses	Cells	Targets
From 5 to 50 µmol/L	Hepatocytes	Inhibition of NF-κB-mediated signaling
Mean: 15 µmol/L	Endothelial cells	Suppression of IκBα phosphorylation
	Platelets	Inhibition of protein kinase kinase
	Cancer cells	Inhibition of c-jun N-terminal kinase
	Phagocytes	Inhibition of leukotriene formation
	Stellate cells	Inhibition of release of cytochrome c
	HepG2	Inhibition of ERK, MEK, and Raf phosphorylation; inhibition of release of caspase 9 and 3, IL-8, and of PDGF- and TGF-β-mediated signaling; decrease of MMP2; increase of TIMP2; inhibition of HCV replication

in which mice were treated with concanavalin A, silybin reduced plasma levels of transaminases and the plasma and liver content of pro-inflammatory cytokines, inhibited hepatic NF-κB activation, and increased plasma and tissue levels of IL-10[84]. In rats with dimethyl-nitrosamine-induced chronic liver damage, silybin conjugated with phosphatidylcholine and vitamin E (Realsil®, Ibi-Lorenzini, Italy) administered by gastric gavage could prevent loss of body and liver weight, as well as reducing the degree of liver injury, as determined by ALT values and necroinflammatory scores. This outcome was associated with reduced hepatic stellate cell activation and proliferation both after 1 and 5 wk of treatment[85]. The anti-inflammatory action of silybin is also related to its interference with multiple cytokine-induced signaling pathways to down regulate inducible nitric-oxide synthase (iNOS) expression[86-88] and to the inhibition of cyclooxygenase (COX)-2 expression and activity and leukotriene formation in human platelets, white blood cells, and endothelial cells. Finally, silybin inhibits activation of the protein kinases and of a c-jun N-terminal kinase[89-92].

In addition to its antioxidant and anti-inflammatory actions, silybin also shows an antiviral effect. In fact, at a concentration of 20 µmol/L, it inhibits the protein expression and the replication of HCV virus in infected polymorphonucleated cells derived from patients with chronic HCV infection[93-95].

Antifibrotic action

In an *in vitro* model of human hepatic fibrogenesis, silybin demonstrated both direct and indirect antifibrotic properties. In fact, in stellate cells from human liver, silybin reduced platelet-derived growth factor (PDGF)-induced DNA synthesis and cell proliferation at a dose of 25 µmol/L. Silybin also reduced PDGF-induced cell migration in a dose-dependent fashion. Finally, pre-treat-

ment with 25-50 µmol/L of silybin significantly reduced the TGF-β-induced *de novo* synthesis of procollagen type I in cell supernatants[96].

To investigate the role of silybin in modulating the pro-inflammatory properties of hematopoietic stem cells, cells were stimulated with IL-1β (20 ng/ml), a potent pro-inflammatory cytokine; silybin inhibited, in a dose-dependent manner, IL-1-induced synthesis of human MCP-1 (monocyte chemoattractant protein 1) and human IL-8 as detected in cell supernatants. This effect was related to the effect of silybin on the inhibition of IκBα phosphorylation and to its capability to inhibit ERK, MEK, and Raf phosphorylation at any concentration used[96]. Antifibrotic effects were also documented in experimental animals and in humans[85,97-99].

Table 6 summarizes the main anti-inflammatory and antifibrotic effects of silybin.

Metabolic effects

Silybin interferes with some mechanisms of action of insulin. In fact, it modulates the uptake of glucose in adipocytes by blocking the insulin-dependent glucose transporter 4. In rat hepatocytes, silybin, in concentrations ranging from 25 to 100 µmol/L, lowers glucose formation from different gluconeogenic substrates through an inhibitory effect on pyruvate kinase activity[100]. As previously reported in cultured hepatocytes, low doses of silybin reduce reactive oxygen species formation from mitochondria; this reduction leads to a decrease in oxidation of carbons arising from glycolysis[101]. Moreover, silybin inhibits, in a dose-dependent manner, gluconeogenesis and glycogenolysis, both in basal conditions and after a glucagon-dependent stimulation, by blocking glucose-6-phosphate hydrolysis. This effect was demonstrated using different substrates, such as dihydroxyacetone, lactate/pyruvate, glycerol, and fructose[102] (Table 7).

Table 7 Effects of silybin on hepatic metabolism of glucose at doses of 25-100 μmol/L in hepatocytes[100-102]

Doses	Cell	Targets
25-100 μmol/L	Hepatocytes	Inhibition of pyruvate kinase
		Inhibition of glycolytic flux
		Inhibition of glucose-6-phosphate hydrolysis
		Inhibition of glucose-6-phosphatase

Table 8 Other effects of silybin on cellular signaling[106-122]

Induction of apoptosis through an inhibition of IGF-IR
Down regulation of survivin and an increase in p53 expression
Block of cycle-regulator cyclins and promoter activities
Decrease of MMP-1 production
Decrease of angiogenesis
Inhibition of VEGF expression
Inhibition of HIF-1α
Increase of IGFBP-3

In an animal model of type 1 diabetes mellitus[103], in a 6-mo, double-blind, randomized trial in patients with poorly controlled non-insulin-dependent diabetes mellitus and alcoholic liver disease[104], and in a randomized, double-blind, placebo-controlled trial in patients with type II diabetes[105], silybin significantly affected plasma levels of glucose and triglycerides, with a trend toward lower hemoglobin A1c levels.

Other effects on cellular signaling

In cancer cells, silybin alters cell cycle regulators and induces apoptosis, both through antioxidant and anti-inflammatory properties and through the inhibition of growth factor receptor-mediated mitogenic and cell survival signaling, particularly related to the activation of tyrosine kinases[106-111]. PDGF receptor (PDGFR), epidermal growth factor receptor (EGFR), Bcr-Abl, and KIT are examples of tyrosine kinases overexpressed in most human cancers. Silymarin or silybin are particularly effective in inhibiting EGFR signaling with suppression of cyclin-dependent kinase expression (i.e. CDK4) and up regulation of CDK inhibitors (CDKIs). These effects lead to G1 and G2-M arrest in cancer cells[112-119], as recently confirmed in a model of human colon cancer[120,121]. In fact, at a dose ranging from 40-75 μmol/L, silybin significantly inhibited cell proliferation through cell cycle arrest *via* inhibition of cyclin promoter activity.

Because it inhibits constitutive NF-κB activation, silybin can induce apoptosis, consistent with a significant decrease in its nuclear level of p65 subunit. In addition, it activates caspase 3 and caspase 9 and decreases survivin levels[122].

Angiogenesis refers to the growth of capillary vessels from existing blood vessels and is considered obligatory for the growth and progression of solid tumors. Angiogenesis critically depends on several conditions; in fact, endothelial cells must: (1) proliferate to provide the necessary number of cells for the growing vessels; (2) secrete matrix metalloproteinases (MMPs), which are required to break down surrounding tissue matrix; and (3) be capable of movement and migration. In addition, the angiogenic stimuli like hypoxia and the production of angiogenic cytokines, such as vascular endothelial growth factor (VEGF), must be sustained. Silybin treatment decreases secreted VEGF levels and shows a strong, concentration-dependent inhibition of capillary tube formation on matrigel, retraction, and disintegration of preformed capillary network, inhibition of matrigel invasion and migration, and a decrease in MMP-2 secretion[92,106-122].

Table 8 summarizes the main cellular signaling affected by silybin.

The use of silybin in the clinical setting: efficacy and suggestions

The use of silymarin in the clinical setting has a long history; in its native Mediterranean region, it has been employed for liver damage since the Greco-Roman era. As mentioned in the introduction, "herbal therapy" use is consistently increasing worldwide, and some of the most common herbal supplement preparations are derived from the milk thistle plant (*Silybum marianum*). Despite a long history of its use and the large number of people who consume this substance, no conclusive data on its clinical efficacy can be identified. In fact, only a few well designed clinical trials have been performed. Most studies have been conducted using silymarin and with inclusion of patients with alcoholic or viral cirrhosis. Stickel *et al*[8] identified the 10 main controlled trials conducted in liver patients, with numbers of patients ranging from 20 to 200 and doses of silymarin ranging from 210 to 450 mg/d for 7 to 730 d. These clinical studies generally have suffered from the same shortcomings found in many other trials on herbal medicines, such as a small sample size, lack of appropriate randomization and of allocation concealment or blinding, very different periods of treatment, lack of information about type and dose of extract used as well as product characterization, ill-defined patient population, and a lack of etiology, severity of disease, and discussion of potential confounders.

We could argue that the history of studies on silybin reflects, in part, the epidemiological history of liver diseases. When liver cirrhosis was the only clearly identified manifestation of liver damage and alcohol was the only known pathogenetic factor, silymarin and other plant extracts represented the most frequently used drugs. Knowledge about the pathogenetic relationships between hepatitis viruses and liver damage induced researchers and industry to focus attention on antiviral drugs. In response to the discovery of metabolic liver diseases, as well as increased knowledge about the cellular and subcellular mechanisms of both induction and progression of liver damage, researchers in academia and industry have begun to reappraise natural products and to evaluate their therapeutic efficacy using appropriate methods.

The clinical experience with silybin is mainly related to its properties as a detoxifying agent and as a hepatoprotective compound in different acute and chronic liver diseases.

Silybin as a detoxifying and hepatoprotective substance

Several chemotherapeutic agents are metabolized by the liver and can exert hepatotoxicity, with the net result of drug reductions or withdrawal. Chemotherapeutic agents that are likely to produce hepatotoxicity include dactinomycin, daunorubicin, docetaxel, gemcitabine, imatinib, 6-mercaptopurine, methotrexate, and oxaliplatin. Cancer patients taking these therapies often self-medicate with milk thistle because of its reputation as a liver protectant. Clinicians also prescribe it to cancer patients for the same purpose. The rationale of milk thistle use is to provide support to the liver while it performs multiple functions, including responding to the increased metabolic demands caused by tumor growth, assisting in metabolizing products generated when a tumor is killed or reduced by chemotherapy and radiation, and aiding in the processing of drugs prescribed to cancer patients.

Silybin is also considered a potent inhibitor of human intestinal β-glucuronidase, blocking the release and reabsorption of free xenobiotics and their metabolites from their glucuronide conjugates. Because the liver is the primary organ that cleanses and detoxifies the blood, many detoxification programs include a component of liver support or what is often called liver cleansing. For these reasons, silybin is commonly included in detoxification regimens[6,7,62,108-111]. However, only one randomized, double-blind study has reported the effects of milk thistle in patients receiving cancer therapy; 50 children with acute lymphoblastic leukemia and grade 2 or higher hepatic toxicity were randomized to receive a milk thistle supplement (Siliphos, Thorne Research, Dover, Idaho) (5.1 mg/kg/day) or placebo for 28 days. The authors reported significant reductions in AST levels ($P < 0.05$) and a trend toward a significant reduction in ALT levels ($P < 0.07$). A significantly larger number of children in the milk thistle group developed a > 50% reduction in total bilirubin at day 28 compared to placebo ($P < 0.0069$)[123].

Silybin in acute liver damage

The administration of silybin within approximately 48 h after poisoning produced by the mushroom *Amanita phalloides* (death cap) seems to be an effective measure to prevent severe liver damage[124]. A retrospective analysis of 205 cases of clinical poisoning from 1971 to 1980 documented the efficacy of milk thistle silybin extract in increasing survival rates in adults and children exposed to this potentially lethal mushroom[125]. In January 2007, six family members in California suffering from aflatoxin poisoning caused by *A. phalloides* mushrooms were treated with intravenous milk thistle, provided by Madaus Pharma (Brussels, Belgium; division of Madaus AG, Cologne, Germany). The US Food and Drug Administration granted permission for the use of milk thistle after considering that all

patients were at high risk of dying of liver failure. Ultimately, one of the six patients died, while the others had a full recovery after treatment. A case report mentions that silybin may offer protection from liver toxicity caused by the pharmaceutical drug phenytoin[126].

Silybin in chronic liver disease

The various flavonoid compounds that are included in the general term "milk thistle" have been recognized as a "safe and well-tolerated herb" with a limited adverse event profile[1-10]. As previously reported, the majority of studies have been conducted using silymarin and including patients with alcoholic or viral cirrhosis. The Cochrane Collaboration group[4,127] evaluated the studies related to the use of silymarin/silybin in patients with different types of acute and chronic liver diseases. Various items were analyzed to define the quality of trials, such as the number of participants, the criteria of randomization, the blinding, the modalities of follow-up, and the statistical methods. From 1,831 references, 67 publications addressed patients with alcoholic and/or hepatitis B or C liver diseases treated with milk thistle; of these, only 26 were selected according to the agreed criteria, and these were associated with 13 trials. The active treatment consisted of silymarin per os in 10 randomized clinical trials, silybin phytosome per os in two randomized clinical trials, and silybin + phosphatidylcholine in one randomized clinical trial. The Cochrane Collaboration studies concluded that milk thistle does not seem to significantly influence the course of the disease in treated patients. However, all causes of mortality were reduced by 50% in patients with alcoholic liver disease without HCV antibodies who took milk thistle extracts compared to placebo ($P < 0.05$); in trials that studied liver-related mortality, there was a significant effect of silybin (relative risk, 0.50; 95% CI 0.29 to 0.88; $P = 0.02$)[4,8,9,127,128].

Seeff *et al*[5,129] examined the spontaneous use of herbal products in the US in patients affected by HCV chronic infection, including non-responders to a previous treatment with interferon and ribavirin. In 1145 patients, about 50% used herbal products; of these, silybin was used by 70%. Even if no changes in liver tests and/or in HCV-RNA serum levels were observed, the univariate analysis documented a lower incidence of symptoms and a better quality of life in patients who consumed silybin relative to those who did not. On multivariate analysis, adjusted for age, gender, educational status, alcohol use (n. drinks/d), physical activity, body mass index, and smoking, silybin positively affected more than one aspect of quality of life. An examination of the total number of patients treated with silymarin/silybin in both well-conducted trials and in pilot studies with a high quality identified about 2000 patients with liver cirrhosis or with chronic hepatitis of different etiology, with a mean duration of treatment of six months and a dose of silybin ranging from 160 to 360 mg/d (except in two cases, see below).

The main results regarding the efficacy of silybin in

Table 9 Main studies performed by using purified silybin as drug

Authors	Type of study, number of patients	Drug used, dose and duration of treatments	Outcomes	Results	Clinical relevance
Vailati *et al*[146]	A phase II randomised, open trial on 60 patients with chronic alcoholic or viral hepatitis	Three doses (160, 240, 360 mg) of silybin and phosphatidylcholine (IdB 1016, Indena, Italy) for two weeks. No placebo or no intervention group was used	Liver tests	Improvement of liver enzymes with all used doses	Scarce
Buzzelli *et al*[147]	Double blind with identical placebo. Twenty patients with HBV and/or HCV chronic active hepatitis	IdB1016 (complex with phosphatidylcholine and silybin) two capsules, twice a day (equivalent to 120 mg of silybin in each capsule) (480 mg/d). Duration of treatment and of follow-up: two months in total	Mortality. Liver biochemistry	Improvement of liver enzymes and bilirubin	Scarce
Buzzelli *et al*[148]	Unclear, described as double blind but the method to achieve this was not described. Trial characteristics: cross over design. Patients were assigned to the Silipide group for two months treatment, and one month washout. Ten patients with chronic hepatitis C. (non-responders) to a previous treatment with recombinant interferon α	Silipide (IdB1016) capsules 360 mg/d. Control group: placebo capsules. Duration of treatment and follow-up: two months of treatment and one month of washout	Mortality. Liver biochemistry	Results were not reported separately, only overall results. Improvement of liver tests	Data published only in abstract form
Lirussi *et al*[104]	Blinding: adequate, double blind with placebo of identical appearance. Sixty out-patients with chronic alcoholic liver disease and non-insulin dependent type 2 diabetes	Silybin-β-cyclodextrin (135 mg silybin) sachets t.i.d Duration of treatment: 6 mo	Mortality. Liver biochemistry	Decrease of fasting glucose and lipid peroxidation markers	Good
Bares *et al*[138]	Randomized study to 1 of 3 oral doses. Thirthy seven patients with chronic hepatitis C non responders to a previous IFN treatment	IdB1016 at 314, 628, 942 mg t.i.d.(120,240 and 360 mg t.i.d. silybin equivalents, respectively) for 12 wk	Effects on serum markers of iron status	There was a significant decrease in serum ferritin, that was independently associated with the stage III-IV of liver fibrosi	Good
Falasca *et al*[134]	Observational study on forthy naïve HCV positive patients (30 treated and 10 observed without treatments)	Silybin-Vitamine E-Phospholipid Complex (Realsil®- Ibi-Lorenzini-Italy) in a dose of 4 pills per day (each pill: 47 mg of silybin) for 3 mo	Hepatoprotection and anti-inflammatory effect by determining cytokine pattern and markers of liver disease	Improvement of liver enzymes and of Il2 plasma levels. Improvement of insulin resistance markers in patients with contemporaneous liver steatosis	Medium
Federico *et al*[141]	Observational study on 85 outpatients: 59 with NAFLD and 26 with HCV related chronic hepatitis in combination with NAFLD, non-responders to previous antiviral treatment. 53 (39 NAFLD and 14 HCV) were treated, while the other 32 patients (20 NAFLD and 12 HCV) served as a control group (no treatment)	The complex silybin-vitamin E-phospholipids (Realsil®) 4 pieces/d for six months followed by another six months of follow up	Effects on insulin resistance and liver damage	US steatosis, liver enzymes, hyper-insulinaemia, and indices of liver fibrosis were improved in both treated groups	Suggestive
Ferenci *et al*[139]	Observational study on 36 patients with HCV chronic hepatitis non responders to IFN + ribavirin. Duration of the study: 7 d	Silybin i.v. (Madaus, Germany) at 5, 10, 15 and 20 mg/kg per day for 14 d	Effect on viral load. Safety	Good compliance, no side effects and potent antiviral effect against HCV	High

liver disease patients are summarized as follows.

In the past, most studies were focused on liver cirrhosis, particularly alcoholic cirrhosis, and the efficacy of silybin was evaluated in terms of improvement in liver test abnormalities and/or in mortality rate (see above for results)[126-128]. Silybin β-cyclodextrin has been studied as an antidiabetic drug in patients with alcoholic liver disease and concomitant non-insulin-dependent diabetes mellitus; in these patients, the drug (at a dose of 135 mg/d) did not influence liver function test results or insulin secretion but significantly reduced fasting glucose ($P < 0.03$) and serum triglyceride levels ($P < 0.01$) compared to placebo. The effects seem to be related to a reduction in insulin resistance[104].

More recently, studies have focused on chronic hepatitis, particularly that induced by HCV. Silybin phytosome, at a dose ranging from 240 mg/d to 942 mg t.i.d. (the highest dose used in patients with liver damage) was well tolerated without adverse effects and significantly improved liver damage as expressed by transaminase levels, oxidative stress (serum malondialdehyde levels) and both ferritin serum levels and iron global body storage[130-138]. Today, the attention of researchers is focused on a possible antiviral effect of silybin against HCV infection.

Polyak *et al*[95] tested the anti-inflammatory and antiviral action of different extracts from silymarin on polymorphonuclear cells from patients with chronic HCV infection, documenting an anti-inflammatory and antiviral effect of milk thistle extract, mainly for silybin, which presented the strongest anti NF-κB and anti-HCV replication effect. Ferenci *et al*[139] and Biermet *et al*[140] have demonstrated that silybin is a potent antiviral agent in patients with chronic hepatitis C not responding to pegylated interferon/ribavirin therapy. These studies also showed that very high doses of silybin i.v. (from 5 to 20 mg/kg/d for 14 d) were free of toxic effects.

Finally, non-alcoholic fatty liver disease (NAFLD) may occur as an expression of a metabolic syndrome or in association with HCV chronic infection. The simultaneous presence of NAFLD in this latter group of patients may negatively affect the progression of fibrosis and the response to antiviral treatment. Patients affected by primitive NAFLD and/or chronic HCV-related hepatitis in combination with NAFLD, all non-responders to previous antiviral treatment, were treated with four pieces/d of the complex silybin-vitamin E-phospholipids corresponding to about 200 mg of pure silybin/d for three or six months. The treatment induced a significant reduction of plasma markers of chronic inflammation (C-reactive protein and cytokines), metabolic parameters (triglycerides, cholesterol, insulin resistance), liver tests (transaminases and gamma-glutamyl transpeptidase), degree of ultrasonographic liver steatosis and, finally, of main indices of liver fibrosis TGF-β, hyaluronic acid and metalloproteinase 2)[99,141,142].

In a rodent model of non-alcoholic steatohepatitis, the same silybin phospholipid complex prevented mitochondrial dysfunction[143], and preliminary results in a large, multicenter Italian trial *vs* placebo indicate that complex silybin-vitamin E-phospholipids significantly improved liver damage in patients with NAFLD and markers of liver fibrosis in patients with HCV chronic hepatitis[144].

In Table 9 the main studies performed with silybin are reported and discussed.

CONCLUSION

The data reported in this review clearly indicate the increasing interest in silybin and its compounds as well as the continuous improvement in knowledge about the molecular actions of this substance. However, in the clinical setting, there is currently a lack of definitive data about its efficacy in patients with chronic liver disease. The only well-defined finding is the absence of adverse events at high doses. Generally, all clinical studies on herbal products suffer from similar limitations, in part related to the fact that well-designed trials require resources and natural products industries do not sponsor them with significant budgets. In addition, in the majority of cases, herbal products differ from pharmaceutical compounds because multiple ingredients could act through multiple pathways to therapeutically affect the host. In the case of silybin, clinical studies on the pure extract and/or its derivatives are few and with a limited number of patients. Silybin is the most active flavonolignan in silymarin, and most capsules are standardized to this compound, but many variations of complex mixtures and single extracts are available and may critically affect clinical outcome. A full phytochemical and biological profile is preferable before commencing any clinical study. Today, analytical techniques that examine a suite of compounds, including their respective ratios, provide a more rational approach to authentication and quality assessment of the products. There must be assurance that the administered dose increases plasma and/or target tissue concentrations consistent with those required to produce effects *in vitro*. One primary fault of many clinical studies of botanicals is that adequate pharmacokinetic analyses are not completed before initiating efficacy trials. Some botanicals may fail in efficacy trials, not because the botanical is itself without activity but because the dosing was not sufficient to achieve pharmacologically meaningful concentrations.

Several silybin clinical trials are ongoing at this time (see also online at www.nccam.nih.gov). In addition, manufacturers of milk thistle extracts are conducting clinical trials with their own products that will elucidate the effects of specific preparations.

There is a need to enhance the funding opportunities to evaluate these long-used products with evidence-based knowledge, but there is also a need to reiterate Kroll *et al*[60], "As biological studies progress, it remains important to make the distinction between silymarin and silybin and their respective and distinct compositions". This latter point should also be considered when clinical investigators turn to pooling existing studies for meta-analyses. The epidemiology of chronic liver disease is changing

worldwide: viral infections are declining, and patients with HCV/HBV chronic hepatitis are older; NAFLD and alcoholic liver diseases are increasing, and generally patients with these pathologies are younger. Finally, alcohol-related problems, metabolic disruptions, and viral infections frequently coexist in the same patient[145]. Therefore, in clinical practice, there is the need for drugs that can be used in the long term without serious adverse events. Researchers should definitively demonstrate if silybin has potential in this regard. Lastly, the absence of significant adverse effects of silybin even at high doses, the good compliance by the patient, the availability of a purified form of the compound, represent characteristics that allow to obtain commercially available products containing almost 600 mg of pure silybin to ensure a good concentration in tissues.

Abstract

AIM: To evaluate double balloon enteroscopy (DBE) in post-surgical patients to perform endoscopic retrograde cholangiopancreatography (ERCP) and interventions.

METHODS: In 37 post-surgical patients, a stepwise approach was performed to reach normal papilla or enteral anastomoses of the biliary tract/pancreas. When conventional endoscopy failed, DBE-based ERCP was performed and standard parameters for DBE, ERCP and interventions were recorded.

RESULTS: Push-enteroscopy (overall, 16 procedures) reached enteral anastomoses only in six out of 37 post-surgical patients (16.2%). DBE achieved a high rate of luminal access to the biliary tract in 23 of the remaining 31 patients (74.1%) and to the pancreatic duct (three patients). Among all DBE-based ERCPs (86 procedures), 21/23 patients (91.3%) were successfully treated. Interventions included ostium incision or papillotomy in 6/23 (26%) and 7/23 patients (30.4%), respectively. Biliary endoprosthesis insertion and regular exchange was achieved in 17/23 (73.9%) and 7/23 patients (30.4%), respectively. Furthermore, bile duct stone extraction as well as ostium and papillary dilation were performed in 5/23 (21.7%) and 3/23 patients (13.0%), respectively. Complications during DBE-based procedures were bleeding (1.1%), perforation (2.3%) and pancreatitis (2.3%), and minor complications occurred in up to 19.1%.

CONCLUSION: The appropriate use of DBE yields a high rate of luminal access to papilla or enteral anastomoses in more than two-thirds of post-surgical patients, allowing important successful endoscopic therapeutic interventions.

Raithel M, Dormann H, Naegel A, Boxberger F, Hahn EG, Neurath MF, Maiss J. Double-balloon-enteroscopy-based endoscopic

INTRODUCTION

With the technique of push-and-pull enteroscopy by a double balloon endoscope, it is possible to advance much deeper into the small intestine than using a conventional push-enteroscope[1-3]. Double balloon enteroscopy (DBE) has been successfully applied for diagnosis and treatment of various small intestinal diseases, such as mid-gastrointestinal bleeding, polyposis syndromes, Crohn's disease, lymphoma, foreign body impaction, or other inflammatory or neoplastic diseases in the jejunum or ileum[1-3]. Although the introduction of DBE by Yamamoto has brought a significant benefit for the management of various small intestinal diseases, its value in the diagnosis and treatment of biliary or pancreatic diseases in patients after complex abdominal or bilio-pancreatic surgery has recently been reported in some case studies of selected patients[4-10]. The emerging role of DBE in postoperative endoscopic procedures arises from the fact that conventional endoscopy using side viewing endoscopes, forward viewing push-enteroscopes, or (pediatric) colonoscopes has often been reported to be unsatisfactory in patients after partial or total gastrectomy (Billroth II gastrojejunostomy, Roux-en-Y reconstruction), Whipple resection or bilio-pancreatic reconstructions (pancreaticojejunostomy, choledocho-choledochostomy, hepaticojejunostomy)[4,5,10-12]. For example, in the pre-DBE era, conventional endoscopic access to the afferent loop and/or choledocho-, hepatico- or pancreaticojejunostomy was extremely difficult because of various lengths of bowel to be traversed, unfortunate locations of low jejunal anastomoses, jejunal loops of differing lengths, fixed jejunal loops, angulation or postoperative strictures and changes[4,5,10-12].

Failure of endoscopic access and therapy in post-surgical patients with normal papilla, choledocho-, hepatico- or pancreaticojejunostomy often results in more invasive and cost-intensive procedures such as percutaneous transhepatic cholangiodrainage (PTCD), computed tomography (CT)-guided pancreatic drainage, or repeated surgery. A training model for balloon-assisted enteroscopy and hepatobiliary interventions has been established by our group to learn, facilitate and adequately perform modern enteroscopic interventions[13-17]. Therefore, this study describes our clinical results from the prospective use of DBE in performing cholangio- and pancreatography, including therapeutic interventions of the biliary and pancreatic tract in a group of 37 consecutive post-surgical patients.

MATERIALS AND METHODS

Patient population

Between August 2005 and December 2008, 45 consecutive patients after complex abdominal surgery were admitted to the Department of Medicine 1 of the University Erlangen-Nürnberg because of abdominal pain, cholestasis, inflammatory symptoms, cholangitis, choledocholithiasis, or for an enlarging pancreatic pseudocyst. During this study period, eight patients with partial gastrectomy (Billroth II) and both afferent and efferent loops at the gastrojejunostomy were excluded from the study, because six could initially be successfully treated using the treatment gastroscope and two using the side-viewing duodenoscope.

Thirty-seven consecutive post-surgical patients were included in this study after having obtained informed consent and agreement to participate and for scientific documentation of the examination results. This clinical trial was carried out in accordance with the Helsinki declaration. The different indications for ERCP, previous surgery, localization of foot-point anastomosis, and depth of papilla or ostium localization are listed in Tables 1 and 2. In this prospective protocol, all patients underwent first usual, conventional endoscopy at least once using esophago-gastroduodenoscopy (GIF-Q160, GIF-1T140; Olympus, Hamburg, Germany), side-viewing duodenoscopy (TJF160; Olympus) and push-enteroscopy (PE; SIF Q140; Olympus) to exclude other diseases and to document postoperative anatomy, type of surgery, depth of anastomoses and, if possible, of papilla or biliary or pancreatic enteroanastomoses. Thirteen percent of all patients had two PEs in order to clarify the post-surgical situation and to reach the entero-anastomosis.

If this approach by conventional endoscopy failed to gain access to the papilla, the ostium of the bilio-digestive or pancreatico-digestive anastomosis, push-and-pull enteroscopy (DBE, EN-450T5; Fujinon Europe, Willich, Germany) was tried before admitting the patient for re-operation, CT-guided drainage or PTCD. Among these DBE examinations, the p-type enteroscope (EN-450P5/20; Fujinon Europe) was used in 13.7% and the t-type enteroscope (EN-450T5) in 86.2% of the patients.

All enteroscopic procedures were performed during conscious sedation (midazolam/pethidine or propofol/pethidine) by two experienced examiners (> 1500 ERCP) and two endoscopy assistants. Butylscopolamine was only used after reaching the end of the afferent loop for ERCP or at withdrawal of the enteroscope, respectively, in cases of vigorous peristalsis, to identify postoperative anatomy, hidden ostium or to facilitate cannulation of the ostium of the biliodigestive anastomosis.

PE

PE was started in the left lateral position using the Olympus SIF-Q140 forward-viewing enteroscope (working length 2.50 m, no elevator lever) without overtube[18]. If PE failed to come forward, the patient was turned to the prone position and X-rays were used to localize loops, to straighten the enteroscope, to direct manual compression to guide the enteroscope forward, or to minimize pain by adequate withdrawal of the enteroscope[18-21]. Post-surgical

anatomy, location of the foot-point anastomosis and the route to the afferent loop were each exactly documented, as well as time requirements for each diagnostic and therapeutic step. Foot-point anastomosis and the afferent loop were marked by India ink. Forward-viewing PE-based ERCP was performed using the typical ERCP technique as described previously[18-21].

DBE
DBE was performed using a standard technique, starting in the left lateral position, and thereafter changing to the prone position as described by Yamamoto and other authors[1-4]. At times, manual compression to guide the enteroscope in the abdomen and radiography were necessary. Provided that the anatomical situation and access to papilla or ostium of the enteroanastomoses were clarified, the afferent loop in proximity to the foot-point anastomosis was marked with clips and Indian ink on retraction of the enteroscope, so that this location would be found quicker in a future examination. Using a standardized protocol, the advance was exactly documented during DBE, and the respective anatomical depth of foot-point anastomosis, and papilla and ostium region were determined with the retracted and (as much as possible) straightened enteroscope. The time taken for this procedure and the whole procedure were also recorded. If during enteroscopy, advance failed, the enteroscope slid back, or if pain was experienced by the patient, radiography was applied to avoid kinking, to straighten loops and to retract the enteroscope carefully.

DBE-based ERCP
When papilla or pancreatico-, choledocho-, or hepaticojejunostomy were needed, ERCP was applied using the push-and-pull enteroscope, a forward-viewing endoscope of 2 m working length, without elevator lever[19-21]. This was assisted by X-rays for radiographic imaging of bile ducts and/or pancreatic ducts or a pancreatic cyst. Appropriate stabilization of the enteroscope with the overtube and/or enteroscope balloon was often required before performance of ERCP.

After administration of contrast medium and diagnosis, papillotomy or, an initial bougienage and/or incision of a stenotic ostium of the hepaticojejunostomy was performed. This was achieved by the use of a 5 and 6 Fr Huibregtse catheter and/or a 6 Fr papillotome (Olympus, intended for SIF Q140 enteroscope), or a snare. Further interventions aided by a 5-m guide wire (Metro guide wire; Cook, Limerick, Ireland) were implantation of endoprostheses (5-8 Fr) or of biliary 7 Fr nasobiliary probes, stone removal, or ostium and papilla dilation using either a CRE-dilation balloon (CRE 8-10mm balloon; Cook) or a basket.

With regard to prosthesis change, the old prosthesis was at first mobilized with a foreign-body forceps or a loop, and extracted and placed in the afferent loop. After DBE-ERCP implantation of the new prostheses was completed, the old prostheses were fixed again with the

loop and extracted from the patient during the final retraction of the double balloon enteroscope.

RESULTS
Patient population
During the period between August 2005 and December 2008, 45 post-surgical patients were admitted to hospital for endoscopy. Eight of these patients with partial gastrectomy (Billroth Ⅱ, without Roux-en-Y reconstruction) could initially be successfully treated with gastroduodenoscopy or side-viewing duodenoscopy alone, and were therefore excluded from the prospective study. In the remaining 37 patients with complex abdominal surgery, neither a gastroscope nor duodenoscope gained initial access to the papilla or ostium, such that PE, and if it failed, then DBE were necessary.

Previous types of abdominal surgery
Previous abdominal surgery of the remaining 37 patients (Table 1) was partial gastrectomy in eight patients (Billroth Ⅱ-resection, 21.6%, four patients had further resections after B-Ⅱ-resection, five patients with Roux-en-Y reconstruction); total gastrectomy with Roux-en-Y loop in seven patients (18.9%), and classical or modified Whipple operation with Roux-en-Y loop in seven patients (18.9%). Fifteen patients had normal stomach anatomy after biliary surgery with reconstruction of a choledocho- or hepaticojejunostomy *via* Roux-en-Y loop (40.5%).

Thus, 34 patients had previously undergone Roux-en-Y construction (91.8%), whereas only three had an end-to-side gastrojejunostomy that contained an afferent and efferent loop (8.1%).

Among all post-surgical patients, 24/37 patients (64.8%) had a final diagnosis of choledocho- or hepaticojejunostomy (23 Roux-en-Y, one dorsal gastrojejunostomy), while 13 patients (35.1%) still had a normal papilla. The pancreaticojejunostomy had to be searched additionally in only three of these patients (8.1%) (Table 2).

Indications for ERCP and interventional procedures
With regard to the indication, it was necessary to radiograph the bile ducts of 34 patients (91.8%), because these patients were admitted for cholestasis (59.3%), cholangitis (28.1%), or choledocholithiasis (13.3%), with a view to PTCD or re-operation. Radiography of the pancreatic duct was required in only three patients (8.1%), because of the presence of a pancreatic pseudocyst and suspected or advanced chronic pancreatitis, respectively (Table 1).

Due to the complex anatomical situation in seven patients (18.9%) with recurrent disease, 37 PTCDs had already been performed in these individuals before the introduction of DBE-ERCP (Table 2).

Access to papilla and entero-anastomoses by PE and DBE
The individual endoscopic accessibility and anatomical

Table 1 Characteristics of post-surgical patients receiving push-enteroscopy or double balloon enteroscopy-endoscopic retrograde cholangiopancreatography

Pts.	Age/sex	Indication	Previous surgery	Access by G/T/P
1	72 f	Recurrent cholangitis	LTX, Roux Y, hepaticojejunostomy	No

31	74 m	Choledocholithiasis	Total gastrectomy, Roux Y	No
32	61 m	Recurrent cholangitis	LTX, bile duct revision, Roux Y, choledochojejunostomy	P
33[3]	55 m	Suspected malignant cholestasis, chronic pancreatitis	Whipple resection, Roux Y, hepatico- & pancreatico-jejunostomy	No
34	34 f	Biliary colics, benign cholestasis hepatitis C	LTX, Roux Y, hepaticojejunostomy	P
35[3]	64 m	Suspected malignant cholestasis, chronic pancreatitis	Whipple resection, Roux Y, hepatico- & pancreatico-jejnostomy	No
36	51 f	Suspected choledocholithiasis, right abdominal pain	LTX, Roux Y, choledochojejunostomy	No
37	61 m	Recurrent cholangitis	Complicated CHE, Roux Y, hepaticojejunostomy	No

[1]Only after previous double balloon enteroscopy; [2]Only after previous double balloon enteroscopy and by use of a short-specialised, large caliber overtube (16.8 mm); [3]Patients indicate initial failure of DBE-based ERCP. G: Gastroscope; T: Side-viewing duodenoscope; P: Push-enteroscope; CHE: Cholecystectomy: BⅡ: Billroth Ⅱ resection; LTX: Liver transplantation; DBE: Double balloon enteroscopy; ERCP: Endoscopic retrograde cholangiopancreatography.

depth of the anastomoses, as well as of the papilla and the ostium of the choledocho- or hepaticojejunostomy and of the pancreaticojejunostomy using PE and DBE are described in Tables 1 and 2. The average depth of all anastomoses (three Billroth Ⅱ gastrojejunostomy, 34 foot-point anastomoses jejunojejunostomy) was 71 ± 21 cm, and the length of the afferent loop to the papilla or entero-anastomosis measured a further 53 ± 26 cm.

In total, a median of four (2-19, 25th-75th percentile) balloon-assisted enteroscopic cycles had to be performed after the passage of the anastomosis in the afferent loop, until the papilla or ostium were reached by DBE. Manual compression to guide the enteroscope was necessary in most patients.

The push-enteroscope could reach the papilla or the enteroanastomoses in only 6/37 cases (16.2%), while DBE had to be applied in 31 post-surgical patients (83.7%).

With DBE, access to papilla, choledocho-, hepatico- or pancreaticojejunostomy could be successfully and re-peatedly achieved in 23 out of 31 patients (74.1%).

A total of 86 DBE-ERCPs were undertaken in those 31 patients, who failed to be successfully examined by PE. Seventy-five of the 86 DBE examinations (87.2%) were successfully carried out as a diagnostic or therapeutic

Table 2 Results of push-enteroscopy and double balloon enteroscopy-endoscopic retrograde cholangiopancreatography: postoperative anatomy and final diagnosis

Pts.	Foot-point anastomosis (cm)	Papilla/ ostium (cm)	ERCP diagnosis	PTCD before /after DBE
1	84	162	Stenotic hepaticojejunostomy (mucosal and intramural stricture 3 mm), putrid cholangitis	(2) Yes
2[1]	67	Not found	Swelling of anastomosis, afferent loop not found	No
3	65	90	Stenotic hepaticojejunostomy (mucosal, 11 mm stricture), cholangitis	No
4 P	75	110	Sludge, stenotic hepaticojejunostomy (mucosal, 3 mm stricture)	No
5[1]		Not found	PTCD stenotic hepaticojejunostomy (12 mm stricture)	(8) Yes(6)
6 P	52 (B Ⅱ)	78	Distal bile duct leakage and adhesion to abd. drainage	No
7	80	165	Stenotic hepaticojejunostomy (mucosal, 2 mm stricture), cholangitis	No
8	85	107	Normal choledochojejunostomy pancreaticojejunostomy with 10 mm diameter, 10 mm pancreatic	No
	85	118	Duct stricture, pancreatic pseudocyst	
9	85	130	Normal hepaticojejunostomy, bile duct kinking	No
10	77	142	Stenotic hepaticojejunostomy (intramural, 4 mm) and stricture, common hepatic duct 4mm, bilioma	No
11	46	62	Obstructed hepaticojejunostomy by sludge/stones (hepaticolithiasis)	No
12	70	105	Papilla stenosis, bile duct kinking and stricture 3 mm	No
13	60	84	Bile duct stricture 18 mm due to papilla tumor	Yes (2)
14[1]	95	Not found	PTCD stenotic hepaticojejunostomy (12 mm stricture)	(12) Yes (6)
15[1]	57	110	PTCD edematous, tumorous papilla	Yes (2)
16	65	120	Stenotic hepaticojejunostomy (mucosal, 4 mm stricture)	(10) Yes
17	65	92	Malignant proximal bile duct stricture 22 mm	No
18	100	175	Hepaticolithiasis, normal hepaticojejunostomy	No
19	70	120	Stenotic hepaticojejunostomy (intramural, 12 mm stricture), cholestasis due to bile duct bleeding	(1) Yes
20	60	78	Papilla & bile duct stenosis due to chronic, pancreatitis, pancreatic duct stenosis	No
21	55	85	Stenotic hepaticojejunostomy,(mucosal, 2 mm stricture) & intrahepatic stricture	No
22	75	110	Distal bile duct stricture 45 mm due to ampullary tumor	No
23[1]		Not found	PTCD complete malignant stricture of hepaticojejunostomy due to progredient metastasis	Yes (1)
24	60	120	Hilar and hepatic duct strictures 9 and 26 mm, normal hepatico jejunostomy	No
25 P	65	110	Malignant obstruction biliary metal stent, sludge, cholangitis	(4) Yes
26	110	158	Stenotic hepaticojejunostomy, (intramural, 10 mm stricture)	No
27	76	112	22 mm bile duct stricture due to chronic pancreatitis	(2) Yes
28[1]	88	145	Polypoid papilla tumor	Yes (4)
29	100	140	Distal bile duct stricture 35mm due to suspected pancreatic tumor	No
30	105	151	Bile duct with sludge, normal choledochojejunostomy	No
31	51	165	Choledocholithiasis	(2) Yes (2)
32 P	78	147	Stenotic choledochojejunostomy, (intramural, 6 mm stricture) and bilioma segment Ⅳ	No
33[1]	66	Not found	PTCD: malignant stenotic hepatico-jejunostomy (filia), but normal pancreaticojejunostomy and	Yes (3)
	66	126	chronic pancreatitis -	
34 P	80	132	Stenotic hepaticojejunostomy & hilar stenosis in ischemic cholangiopathy	No
35[1]	68	114	PTCD: recurrence of pancreatic tumor with malignant stenosis at hepaticojejunostomy, bile ducts	Yes (5)
	68	131	and small intestine normal pancreaticojejnostomy and chronic pancreatitis	
36	70	131	Normal choledochojejunostomy	No
37	78	139	Stenotic hepaticojejunostomy (mucosal 2mm stricture)	No

[1]Patients indicate initial failure of double balloon enteroscopy (DBE)-based endoscopic retrograde cholangiopancreatography (ERCP). PTCD: Percutaneous transhepatic cholangiodrainage; PE: Push-enteroscopy.

DBE-ERCP (Tables 1-3), while 11 examinations (12.7%) in eight patients were unsuccessful.

After the initial, successful DBE-ERCP in two patients, the papilla and ostium of the hepaticojejunostomy, respectively, could be reached afterwards with the side-viewing endoscope or gastroscope. However, both treatments only worked after previous DBE, during which a large caliber overtube (17 mm, length 110 cm; Fujinon Europe) was inserted as a guide bar and the hepaticojejunostomy, located in an intestinal loop, was made visible through an inserted prosthesis.

Failure of PE and DBE to reach papilla or enteroanastomoses

In 8/31 patients (25.8%), despite DBE application, access to the bile ducts could not be achieved for a number of reasons (Tables 1 and 2): the anastomosis region was considerably swollen (one patient) or not visible because of metastasis (one patient); the afferent loop was technically not intubatable (one patient); the papillary or ostial region was infiltrated or covered by a tumor (four patients); or the ostium of the hepaticojejunostomy could not be found (one patient). Seven of these 8 patients (87.5%)

underwent subsequent PTCD or surgery (one patient, 12.5%).

Diagnosis, results and interventions at normal and malignant choledocho- and hepaticojejunostomy

In choledocho- or hepaticojejunostomies, 14 out of 24 (58.3%) were cicatricially changed, three were infiltrated by malignant tissue (12.5%), and seven (29.1%) appeared normal in width and were intact (Table 2).

DBE was able to achieve access to 15 of the 24 choledocho- or hepaticojejunostomies (62.5%), while PE reached only four out of 24 (16.6%), and the remaining five patients with failure of the enteroscopic approach (20.8%) had to undergo PTCD.

Among the seven normal appearing ostium of the choledocho- or hepaticojejunostomies (29.1%), sludge and

Figure 1 Endoscopic finding of stenotic hepaticojejunostomy in recurrent cholangitis with putrid secretion after careful ostium incision during double balloon enteroscopy-endoscopic retrograde cholangiopancreatography in prograde technique.

Figure 2 Radiological findings of stenotic hepaticojejunostomy in recurrent cholangitis with unsuccessful percutaneous drainage (A), but selective access to dilated bile ducts (width 8 mm) through a high-grade stricture (3 mm long, arrow) by double balloon enteroscopy-endoscopic retrograde cholangiopancreatography in prograde technique (B).

concrements had to be removed from one normal choledocho- and three normal hepaticojejunostomies in one patient suffering from cholangitis and choledocholithiasis, and three patients with hepaticolithiasis, respectively. In addition, endoprosthesis and/or nasobiliary probe insertion *via* the normal choledocho- or hepaticojejunostomy were necessary in two of these patients and in one with hilar and hepatic duct strictures, respectively.

Out of three tumor-induced malignant ostium stenoses (12.5%), the precise location of the enteroanastomosis could be identified twice, but in neither case could the stenosis be passed by a flexible hydrophilic guidewire and successfully treated. All three patients with tumorous hepaticojejunostomies required PTCD.

Diagnosis and results in post-surgical stenotic choledocho- and hepaticojejunostomy

Eight patients out of 14 (57.1%) with cicatricial ostial stenosis at the choledocho- or hepaticojejunostomy were treated successfully *via* DBE-ERCP, and a further four *via* PE (28.5%), while the remaining two patients (14.2%) required PTCD (Tables 2 and 3).

In one case with stenotic hepaticojejunostomy and previous PTCD (suspected hepaticolithiasis) at an outlying hospital, DBE-ERCP revealed blood in the afferent loop, bile duct bleeding from PTCD, and obstruction of the stenotic ostium including bile ducts due to blood clots. Thus, extraction of sludge and blood clots was performed, and insertion of a temporary nasobiliary drainage for irrigation of the bile duct. Then, after 3 d, a first DBE-based rendezvous technique was applied *via* the PTCD with successful extraction of the percutaneous drainage and endoscopic insertion of two internal stents.

Of note, a successful rendezvous technique was further achieved in three patients with non-malignant disease who were admitted to our hospital after construction of a PTCD, and in one patient with initial failure of DBE (Table 3). Thus, these four patients had most significant benefit from DBE-ERCP because they had endoscopically inserted endoprotheses and lost their percutaneous drainage within 1 wk.

Ostium incision and dilation and endoprosthesis insertion at post-surgically strictured choledocho- and hepaticojejunostomy

Initial endoscopic interventions at the non-malignant post-surgical biliary anstomosis (choledocho- or hepaticojejunostomy), which could not be cannulated by a flexible guidewire, included a careful, 1-3-mm ostium incision (by snare and/or 6 Fr papillotome) of each narrowed ostium in 6 out of 12 cases (50.0%) during DBE-ERCP. Five ostial incisions were made during DBE-ERCP, and one during PE-based ERCP. All incisions resulted in significant widening of the ostium with subsequent successful cannulation and intervention in the biliary system. Perforation occurred in one of the 5 patients treated with ostial incision by DBE-ERCP (20.0%), which had to be treated surgically. None (0%) of the ostial incisions caused relevant bleeding, but in two cases (40.0%), pus was discharged from the opened ostium (Figures 1 and 2).

The other six patients (50.0%) with post-surgically strictured choledocho- or hepaticojejunostomy were initially cannulated using a guidewire and were treated either with a bougienage *via* a papillotome or nasobiliary probe, to widen the ostium ready to implant subsequently a prosthesis, or by dilation using a colonic CRE balloon.

Overall, in patients with cicatricial changed choledocho- or hepaticojejunostomies, on average 1.5 ± 0.7 endoprostheses were implanted per DBE-ERCP examination

Figure 3 Endoscopic finding of stenotic hepaticojejunostomy in recurrent cholangitis after ostial incision and insertion of two endoprotheses during double balloon enteroscopy-endoscopic retrograde cholangiopancreatography in prograde technique.

(one double pigtail 5 Fr, 18 double pigtail 7 Fr and three double pigtail 8 Fr, as well as four straight 7 Fr endoprotheses and two 7 Fr nasobiliary probes; Figure 3).

At present, four patients with cicatricially changed ostium of the choledocho- and hepaticojejunostomy were treated several times by DBE-ERCP over a period of 1 year, with a regular exchange of prostheses every 3 mo (Table 3). After prosthesis implantation, all four patients had no further problems with cholangitis and cholestasis. In three out of four patients (75%), a sufficient widening of the ostium was achieved after the 1-year prosthesis therapy. Consequently, prosthesis therapy was no longer required and the cholestasis parameters stayed within the normal range over a prolonged period of time. However, the prosthesis exchange proved to be more difficult than the initial prosthesis implantation, because this procedure carries varying degrees of difficulty. In addition, an average treatment time of 12 ± 41 min had to be calculated for prostheses extraction and their temporary placing in the intestines.

DBE-ERCP with interventions at the pancreatic anastomosis
Among the 31 post-surgical patients, pancreaticojejunostomy was also found *via* DBE in three patients (9.6%) because of recurrent abdominal pain, inflammatory symptoms and an expanding cystic lesion in the pancreatic region. This could only be achieved successfully by DBE (Tables 1 and 2). The pancreaticojejunostomies (mean insertion depth: 128 ± 7 cm) were located mostly at 3-8 cm aborally of the biliodigestive anastomosis, and hence, required 1 ± 1.7 balloon-assisted cycles more to identify the pancreaticojejunostomy and to stabilize the DBE in front of it.

During the DBE-based pancreatography, two duct systems in patients with recurrent pancreatic tumor presented a similar appearance to those with chronic pancreatitis (clotted side branches, duct irregularities, but no acute strictures). In addition, one significantly dilated residual pancreatic duct was detected merging into a cystic lesion (pseudocyst). In the latter case, for the first time a 7 Fr double pigtail pros-

thesis had to be inserted for drainage of the pseudocyst *via* DBE-ERCP, because the patient suffered evidently from pain, weight loss, and inflammatory symptoms. After 2 d, the patient was free of symptoms. However, a mild lipase increase occurred post-interventionally, but there was no manifestation of post-ERCP pancreatitis. Within a week, the pseudocyst regressed noticeably, which was sonographically controlled and later documented with endoscopic ultrasound and CT. The prosthesis was removed 2 mo after insertion.

DBE-ERCP with interventions *via* the afferent loop at the papilla
Thirteen (41.9%) of the 31 patients still had a normal papilla. In 11 out of 13 patients (84.6%), the papilla was accessible *via* a Roux-en-Y loop, and only in two patients (15.3%) was it directly accessible from the Billroth II stomach anastomosis *via* the afferent loop (Table 1).

The papilla could be reached with conventional PE in two of these 13 (15.3%) cases, and ERCP could be successfully performed with this forward-viewing enteroscope.

In the remaining 11 patients (84.6%) with normal papilla and prior abdominal surgery, the papilla had to be searched by push-and-pull-enteroscopy. DBE-ERCP could only be performed after appropriate stabilization of the enteroscope in front of the papilla, partly by use of the balloons. The DBE-ERCP and treatment was successful in eight of the 11 cases (72.7%; Tables 2 and 3), while in three cases (27.2%), DBE-based endoscopic retrograde cholangiography (ERC) failed because of tangential position to the papilla, or because of a papillary tumor (re-operation in one patient, and PTCD in two).

In the eight successful DBE-ERCs, seven patients (87.5%) had papillotomies of 3-7 mm in length using a 6 Fr papillotome, whereby moderate pancreatitis and bleeding (14.2% for each) occurred as side effects. In total, 1.2 ± 0.4 endoprotheses were successfully placed *via* the forward-viewing enteroscope (four double pigtail 7 Fr prostheses, one double pigtail 8 Fr prosthesis, seven straight 7 Fr endoprosthesis, and one 7 Fr nasobiliary probe).

In addition, apart from bougienage with the 6 Fr papillotome, dilatations using a CRE dilation balloon (8-10 mm, Cook) and removal of 5 ± 11 concrements and sludge using baskets were carried out in cases of papillary or distal bile duct stenoses. For treatment of purulent cholangitis with concrements, a nasobiliary drainage for irrigation was also placed *via* the enteroscope and left for 3 d to perform endoscopic shockwave lithotripsy and clean the bile system.

Laboratory results before and after DBE-ERCP with interventions
Before intervention, laboratory testing determined that the patients presented with distinct cholestasis and bilirubin elevation (2.8 ± 3.1 mg/dL) and/or inflammatory symptoms (leukocytes 12 800 ± 10 200/μL, C-reactive protein 51 ± 37 mg/L). By performing DBE-ERCP with ostial incisions, papillotomies and/or implantation of biliary endoprostheses, a clear reduction of cholestasis and chol-

angitis parameters was obtained. Values for bilirubin (1.6 ± 2.0 mg/dL), leukocytes (6800 ± 4000/μL) and C-reactive protein (18 ± 21 mg/L) decreased significantly ($P < 0.05$).

Complications of DBE-ERCP with interventions

Among 86 DBE-ERCPs, post-interventional cholangitis was not observed in any of the 31 patients treated by DBE-ERCP. However, after six of 86 examinations (6.9%) in 31 patients (19.3%), a lipase increase of more than twice the norm was seen on the day after DBE, whereas clinically significant post-ERCP pancreatitis (one mild and one moderate) was only seen after two examinations (2.3%) in two patients.

Post-interventional bleeding occurred in one of 86 examinations (1.1%) in 31 patients (3.2%) after papillotomy, which required emergency endoscopy, intensive care treatment, and blood transfusion.

Post-interventional stomach pain was experienced after six of 86 examinations (6.9%) in 31 patients (19.3%), whereas perforation occurred in two DBE-ERCPs (2.3%). One perforation developed immediately after ostial incision, while the second became evident 8 h later, with ileal perforation. Both perforations could be treated surgically, and no patient died due to complications of DBE-ERCP. No other fatalities following DBE-ERCP were recorded.

After two of 86 examinations (2.3%), two patients complained of abdominal pain that lasted > 24 h, and raised temperature developed on the day after the examination. Of note, one patient developed tonsillitis after DBE-ERCP (1.1%). No other serious side effects occurred.

Examination and radiography times and premedication during DBE-ERCP

The average duration of all DBE-ERCPs was 111 ± 54 min, and radiography took 9.0 ± 5.5 min with a dose of 2465 ± 1295 cGy/m². The individually required examinations for each patient are listed in Table 3, which included the exact therapeutic procedures, time measurements, and premedication.

With regard to premedication, an average of 11.7 ± 2.8 mg midazolam and 124.9 ± 45 mg pethidine or 1156 ± 593 mg propofol was needed per patient undergoing DBE-ERCP. In addition, butylscopolamine was administered at an average dose of 44.8 ± 20 mg. During conscious sedation for DBE-ERCP, one patient each developed hypoxia induced by midazolam/pethidine or propofol, which led in each case to abortion of the examination.

DISCUSSION

The difficulties involved with endoscopic access to the bile ducts and the pancreas in patients with prior abdominal surgery before the introduction of DBE have been described previously[4-6,10-12,19-21]. The success rate of ERCP with a side-viewing endoscope, push-enteroscope or pediatric colonoscope in patients with previous surgery depends on a number of factors, e.g. type of previous surgery, length of afferent loop, post-surgical changes, or experience of the endoscopist. Usually, results tend to be very variable (e.g. success rate of Billroth Ⅱ gastrojejunostomy up to 92%, Roux-en-Y reconstruction, 33%, and pancreaticojejunostomy, 8%) accompanied by high complication rates[4,6,19-21].

Access through conventional endoscopy was particularly difficult in our patients after several rounds of complex abdominal surgery (91.8% Roux-en-Y reconstruction, 8.1% gastrojejunostomy), and initially, access or treatment by gastroscope or duodenoscope was not possible. As recently outlined by several other investigators in small patients series[5-10,22-24], our stepwise approach with PE and DBE in 37 non-selected, consecutive post-surgical patients found that DBE-ERCP was clearly more efficient than PE. By the appropriate use of DBE in over two-thirds of cases, enteroanastomoses or papilla could be repeatedly reached, identified and satisfactorily visualized. The enteroscope could be stabilized also for bilio-pancreatic intervention. DBE-ERCP could be successfully conducted in 74.1% of the cases *via* the enteroscope, while PE reached biliary anastomoses or papilla in only 16.2% of the patients, which resulted in successful ERCP in only a minority of patients. Both results are in good agreement with recently published data for the approach by double- or single-balloon enteroscopy[5-10,22-26], as well as for earlier published data on postoperative or PE-based ERCP[4,11,19-21].

However, until a successful DBE-ERCP was achieved, several balloon-assisted enteroscopic cycles over an average length of 124 ± 47 cm of the small intestine, application of X-rays, and manual guidance of the enteroscope were necessary. In addition, a substantial effort in time, staffing and sedation had to be afforded. Compared with PE, the push-and-pull method by DBE proved to be markedly more effective, because pushing and stretching of small intestinal loops is reduced by regular retractions of the DBE cycle. The threading of the small intestine onto the DBE and the option to block the balloons at the enteroscope provides the enteroscope tip with a greater possibility of movement for identifying the biliary or pancreatic anastomoses or the papilla. In addition, sliding back of the enteroscope may be prevented by inflated balloons, which, compared with PE, explains the significantly higher effectiveness of interventions during DBE-ERCP.

Out of the 37 post-surgical patients with significant cholestasis and cholangitis, PE achieved a successful bile duct drainage in six (16.2%), whereas, before DBE was introduced, a far more invasive procedure, either PTCD or surgery, would have been carried out in the remaining 31 patients. PTCD carries a significantly higher morbidity and mortality risk compared to the endoscopic procedure[12,14-17,27,28], therefore, all consecutive patients with previous abdominal surgery were included in this prospective treatment protocol after DBE had been introduced in August 2005 at the University of Erlangen–Nuremberg. Of note, DBE facilitated successful ERCP with biliary

Figure 4 Radiological finding of insertion of a nasobiliary probe for irrigation in recurrent cholangitis with sludge after liver transplantation and hepaticojejunostomy by double balloon enteroscopy-endoscopic retrograde cholangiopancreatography through 120 cm of small bowel.

interventional procedures leading to significant reduction of cholestasis or cholangitis in 23 of 31 patients (74.1%). Thus, PTCD could be avoided in those 23 post-surgical patients, because endoscopic biliary drainage was achieved.

In comparison to reported PTCD-induced complication and infection rates of up to 55%, and even mortality[12,14-17,27,28] only one case of post-papillotomy bleeding (3.2%), two of post-ERCP pancreatitis (6.4%) and two perforations (6.4%) occurred following DBE-ERCP, but no cholangitis or mortality has been recorded to date. Thus, this first prospective investigation from a university tertiary referral center confirms that DBE-ERCP has considerable potential to treat successfully benign (postoperative) or malignant biliary and papillary stenoses, bile duct concrements, and cholangitis, even in non-selected post-surgical patients[4-10], and it helps to reduce the number of percutaneous approaches. Only in eight of 31 patients (25.8%), in whom the biliary or pancreatic anastomoses or papilla could not be found *via* DBE, was PTCD finally necessary. Even when the biliodigestive anastomoses could not be found and/or DBE-ERCP failed because of tumor-changed papilla or choledocho- and hepaticojejunostomy, a change in treatment procedure could be attempted after construction of PTCD by using DBE. After introduction of the percutaneous tube into the small intestine, percutaneous drainage was successfully changed in four patients to internal drainage inserted *via* DBE (Table 3). This was achieved by application of a DBE-PTCD rendezvous procedure, which was performed for the very first time in Erlangen in 2006. Before the DBE era, a longer-lasting bougienage and Yamakawa prosthesis therapy or biliary metal stent implantation were often indicated after the initial PTCD puncture[12,14-17]. By the use of DBE-ERCP, however, the external drainage could be extracted from all four patients after 1 wk. Practically, methylene blue injected externally through the PTCD helps to identify the afferent loop and/or biliary anastomoses or papilla, so that these are more easily and quickly detected by the subsequent DBE.

The key benefits of DBE-ERCP in the care of post-surgical patients with cholestasis/cholangitis and patients with installed percutaneous drainage are somewhat limited by the small caliber of bile duct prostheses that are applied *via* the enteroscope. According to the present state of technology, only an implantation of 5-8 Fr prostheses through an operating channel of 2.8 mm is possible. Consequently, several prostheses (1.5 ± 0.7) were implanted in our patients. In the case of strongly soiled bile ducts and concurrent cholangitis or sump syndrome, it is recommended first to apply a nasobiliary probe for irrigation of the bile ducts (Figure 4) to prevent rapid clogging of the small caliber bile duct prostheses.

The sequential coupling of two examinations (DBE and ERCP) explains the lengthy examination times, high doses of sedation, and applied fluoroscopy dosage. Considering the enormous benefit of DBE-ERCP with an approximately 74% successful biliary drainage and a significantly smaller complication rate than PTCD[11,12,14-17,27-29], the effort involved in such an examination seems justified.

In comparison to the more frequent cholestatic patients, only three of 37 patients also required radiography and interventions of the pancreatic duct after pancreatic resection. Overall, only a limited view could be gained as to which role DBE-ERCP might play in this area. In all three patients, the position of the pancreaticojejunostomy was only reached by DBE and was located deeper in the small intestine or considerably closer to the blind end of the afferent loop than was the choledocho- or hepaticojejunostomy. The technical conduction of the endoscopic retrograde pancreatography *via* DBE was undertaken in the same manner as described for ERCP. The ostium, however, was smaller, but in none of the cases stenotic. The main pathological changes of chronic pancreatitis were limited to the remaining pancreatic duct in the corpus area. During DBE-based pancreatography, a cystic lesion (pseudocyst) could be successfully drained *via* insertion of a 7 Fr double pigtail prosthesis for the first time, which led to a noticeable improvement of the patient, and regression of the pseudocyst within a week. Therefore, DBE offers also a novel option for pseudocyst drainage in postsurgical patients.

In conclusion, this prospective study from a single university tertiary referral center confirms the results from other investigators and shows that DBE-ERCP achieves a high rate of successful cholangiography and drainage in post-surgical patients[5-10,22-26,29], allows further treatment of pancreatic cystic lesions *via* pancreaticojejunostomy, and offers new possibilities in patients with PTCD as DBE-based rendezvous techniques are applicable.

ACKNOWLEDGMENTS

COMMENTS

Background
Abdominal surgery involving the stomach, small bowel, pancreas, liver or biliary tract may change significantly the anatomy of these organs, with construction of small bowel anastomoses and small bowel limbs of differing length, angles or fixation. Thus, postoperative endoscopy with conventional endoscopes to reach the biliary tract or pancreas through small bowel limbs has often been described as unsatisfactory in postoperative disease.

Research frontiers
Balloon-assisted endoscopy has been developed since 2004, with the introduction of a double balloon enteroscopy (DBE) system, followed later by single balloon endoscopy or balloon-guided enteroscopy techniques. All balloon-assisted endoscopy techniques have the potential to access more deeply into the small bowel than conventional endoscopes, and they allow one to examine the whole small bowel (4-7 m long). Thus, this study investigated the value of the DBE for examination of postoperative patients with diseases of the biliary tract or pancreas.

Innovations and breakthroughs
Before the era of balloon-assisted endoscopy, only 20%-30% of patients with diseases of the biliary tract or pancreas (e.g. tumor, stones, inflammation, stenosis) could be effectively managed by conventional endoscopy, whereas the other 70%-80% had to be treated by more invasive percutaneous puncture techniques, external tube insertion, drainage procedures, and more cost-intensive computed tomography (CT)-based therapies, or even re-operation. This paper describes, in a large number of consecutive patients, successful use of DBE to perform effective endoscopic treatment in a majority (74%) of post-surgical patients with bilio-pancreatic diseases.

Applications
DBE-based examination of the biliary tract or pancreas represents a further important endoscopic treatment modality for postoperative patients after complex abdominal resections. It allows successful application and interventions in post-surgical patients with bile duct stenosis, obstruction, stones or pancreatic diseases (chronic inflammation, tumor) in terms of performing incision of the bile duct ostium, or papillotomy, endoprosthesis insertion, or stone extraction.

Terminology
DBE-based examination of the biliary tract and pancreas is achieved by forward-viewing optics in post-surgical patients, and requires examination of the small bowel by DBE, and includes endoscopic–radiological examination of the bile duct and/or pancreatic duct, with the aim of performing interventions in the case of bile duct, liver or pancreatic disease. This whole procedure is called DBE-based retrograde cholangiopancreaticiography and is indicated only when conventional endoscopy fails to reach the biliary tract or pancreas.

Peer review
This study describes the utility of modern enteroscopy, especially DBE, in symptomatic patients with cholestasis and cholangitis after complex abdominal surgery. A high rate of enteroscopic access and successful biliary interventional procedures, with a new intervention, ostial incision at biliary anastomoses is presented, which resulted in a substantial reduction in more invasive procedures such as transhepatic percutaneous biliary interventions or CT-guided punctures.

Abstract

AIM: To demonstrate that (-)-Epigallocatechin-3-gallate (EGCG) inhibits vascular endothelial growth factor (VEGF) expression and angiogenesis induced by interleukin-6 (IL-6) *via* suppressing signal transducer and activator of transcription 3 (Stat3) activity in gastric cancer.

METHODS: Human gastric cancer (AGS) cells were treated with IL-6 (50 ng/mL) and EGCG at different concentrations. VEGF, total Stat3 and activated Stat3 protein levels in the cell lyses were examined by Western blotting, VEGF protein level in the conditioned medium was measured by enzyme-linked immunosorbent assay, and the level of VEGF mRNA was evaluated by reverse transcription polymerase chain reaction (RT-PCR). Stat3 nuclear translocation was determined by Western blotting with nuclear extract, and Stat3-DNA binding activity was examined with Chromatin immunoprecipitation (ChIP) assay. IL-6 induced endothelial cell proliferation was measured with 3-[4, 5-dimethyl-thiazol-2-yl]-2, 5-diphenyl tetrazoliumbromide assay, *in vitro* angiogenesis was determined with endothelial cell tube formation assay in Matrigel, and IL-6-induced angiogenesis *in vitro* was measured with Matrigel plug assay.

RESULTS: There was a basal expression and secretion of VEGF in AGS cells. After stimulation with IL-6, VEGF expression was apparently up-regulated and a 2.4-fold increase was observed. VEGF secretion in the conditioned medium was also increased by 2.8 folds. When treated with EGCG, VEGF expression and secretion were dose-dependently decreased. IL-6 also increased VEGF mRNA expression by 3.1 folds. EGCG treatment suppressed VEGF mRNA expression in a dose-dependent manner. EGCG dose-dependently inhibited Stat3 activation induced by IL-6, but did not change the total Stat3 expression. When treated with EGCG or AG490, VEGF expressions were reduced to the level or an even lower level in the tumor cells not stimulated with IL-6. However, PD98059 and LY294002 did not change VEGF expression induced by IL-6. EGCG inhibited Stat3 nucleus translocation, and Stat3-DNA binding activity was also markedly decreased by EGCG. Furthermore, EGCG inhibited IL-6 induced vascular endothelial cell proliferation and tube formation *in vitro* and angiogenesis *in vitro*.

CONCLUSION: EGCG inhibits IL-6-induced VEGF expression and angiogenesis *via* suppressing Stat3 activity in gastric cancer, which has provided a novel mechanistic insight into the anti-angiogenic activity of EGCG.

INTRODUCTION

(-)-Epigallocatechin-3-gallate (EGCG), the most abundant and active component of green tea, has shown to have chemopreventive and chemotherapeutic properties for a variety of cancers[1,2]. Previous studies demonstrated that EGCG inhibited tumor growth by anti-angiogenesis, as well as by inhibiting proliferation and inducing apoptosis[3,4]. Angiogenesis is necessary for the growth and metastasis of solid tumors, and vascular endothelial growth factor (VEGF) is the most potent angiogenic factor. EGCG inhibited angiogenesis mainly by targeting VEGF signaling pathway[5-7]. Recent studies have shown that EGCG directly inhibits VEGF expression in multiple tumors[8-10]. We also demonstrated that EGCG reduced VEGF production in gastric cancer, and the inhibitory effect was at transcriptional level, suggesting that EGCG inhibited VEGF expression by reducing VEGF gene transcription[11]. However, the detailed molecular mechanism underlying the inhibitory effect of EGCG on VEGF expression is not fully understood.

VEGF expression associates with a variety of cytokines, growth factors, transcription factors, and oncoproteins, such as interleukin-6 (IL-6)[12,13]. Significantly, many of these molecules transmit signals through signal transducer and activator of transcription 3 (Stat3), a member of Janus-activated kinase (JAK)/STAT signaling pathway[12-15]. Activation by phosphorylation of tyrosine residue is required for the activity of Stat3, which is normally a transient and tightly regulated process. Once activated, Stat3 translocates into nucleus, binds to specific DNA promoter sequence and induces downstream gene expression[15]. Aberrant activation of Stat3 is found in a variety of tumors and contributes to oncogenesis by enhancing proliferation and preventing apoptosis[16,17]. Recent studies showed that abnormal Stat3 activation directly promoted VEGF expression and angiogenesis, and blockage of Stat3 activation inhibited these effects[18-20]. Abnormal Stat3 activation is also found in various gastric cancer cell lines and specimens, and associated with tumor status[21-23].

Phosphorylated Stat3 expression is significantly correlated with VEGF expression and microvessel density in gastric cancer, and is an independently prognostic factor of poor survival[22,23]. Blockade of Stat3 activation induced cell apoptosis and growth inhibition in gastric cancer[21,22]. Furthermore, gastric cancer cells transfected with dominant-negative Stat3 exhibits a decreased VEGF expression and less angiogenic phenotype[23], suggesting that blockade of Stat3 activation could inhibit VEGF expression and angiogenesis in gastric cancer. Our recent study showed that EGCG inhibited Stat3 activation and VEGF expression in gastric cancer[11]. Previous studies also demonstrated that EGCG inhibited activation of Stat3 in multiple tumor cells[9,24,25]. However, to our knowledge, whether EGCG inhibits VEGF expression and angiogenesis *via* Stat3 remains to elucidate.

An etiologic relation between high risk of gastric cancer and chronic gastritis with *Helicobacter pylori* has been firmly established[26]. Consequently, various cytokines have been implicated in the pathogenesis of gastric cancer. As a multifunctional cytokine, IL-6 has received particular attention. IL-6 promotes tumor growth and metastasis by up-regulating VEGF expression and VEGF-mediated angiogenesis, and is closely associated with disease status and outcome of gastric cancer[27,28]. Recent studies demonstrated that IL-6 induced VEGF expression and angiogenesis *via* Stat3 in multiple tumors[29-31] and gastric cancer[32]. Blocking Stat3 signaling pathway down-regulated VEGF promoter activity, and effectively abolished IL-6-induced VEGF expression and angiogenesis[33,34]. Therefore, this study was designed to demonstrate that EGCG inhibited IL-6-induced VEGF expression and angiogenesis *via* suppressing Stat3 activity in gastric cancer in an attempt to further understand the molecular mechanism underlying the anti-angiogenic activity of EGCG.

MATERIALS AND METHODS

Cell culture

Human gastric cancer (AGS) cells (Cell Bank of Sun Yet-San University, Guangzhou, China) were maintained in RPMI-1640 medium supplemented with 10% (v/v) fetal bovine serum (FBS), (Gibco BRL, Gaithersburg, MD) and incubated at 37℃ in a humidified incubator at 5% CO_2. Human umbilical vein endothelial cells (HUVECs) were prepared from fresh human umbilical cord obtained from the Department of Obstetrics and Gynecology, First Affiliated Hospital, Sun Yat-Sen University, Guangzhou, China as described previously[11], and grown in human endothelial-serum free medium (Gibco BRL, Gaithersburg, MD) supplemented with 10% FBS, 100U penicillin, streptomycin and fungizone, and incubated at 37℃ in a humidified incubator at 5% CO_2. To maintain a uniform condition, all experiments were carried out between cell passages 4-6.

Western blotting

After serum starvation for 24 h, AGS cells (5×10^5 cells/well)

seeded in 90 mm plates were stimulated with IL-6 (50 ng/mL, R&D systems, Minneapolis, Minn., USA) in the presence of EGCG (Sigma-Aldrich Chemical Co., St Louis, MO, USA) at concentrations indicated for another 24 h to determine the VEGF protein level or for 1 h to determine the Stat3 protein level. Total protein was extracted from the cell lysates with mammalian cell lysis kit (Bio Basic Inc., Ontario, Canada). Protein level was quantified with Bio-Rad protein assay kit (Bio-Rad Laboratories, Richmond, CA). Total protein (100 μg) was separated in 12% sodium dodecyl sulfate (SDS)-PAGE, and transferred onto PVDF membrane (Invitrogen, Carlsbad, CA, USA). The membrane was blocked with 5% skim milk and incubated at 4℃ overnight with a rabbit polyclonal anti-VEGF antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA), a rabbit polyclonal anti-Stat3 antibody (Santa Cruz), or a goat polyclonal anti-p-Stat3 antibody [Phospho-Stat3 (tyr-705); Santa Cruz]. After being washed with 0.1% Tween 20 in Tris-saline three times, the membrane was incubated with biotin-labeled anti-rabbit or anti-goat IgG for 1 h at room temperature with agitation. The probe proteins were detected using enhanced chemiluminescence system (Amersham International, Piscataway, NJ, USA). The same membrane was stripped and re-blotted with an antibody specific to β-actin (Santa Cruz). Protein expression levels were normalized by β-actin.

Enzyme-linked immunosorbent assay

AGS cells were seeded in 90 mm plates at 5×10^5 cells per well and stimulated with IL-6 (50 ng/mL) for another 24 h in the presence of EGCG at concentrations indicated after serum starvation for 24 h. The conditioned media were harvested and centrifuged. VEGF concentrations in the supernatant were measured using VEGF enzyme-linked immunosorbent assay (ELISA) kit (R&D systems).

Reverse transcription polymerase chain reaction

AGS cells (5×10^5 cells/well) were seeded in 90 mm plates. After serum starvation for 24 h, the cells were stimulated with IL-6 (50 ng/mL) for 12 h in the presence of EGCG at concentrations indicated. Total RNA was extracted with TRIzol reagent (Invitrogen) according to the manufacturer's instructions. The levels of human VEGF mRNA were evaluated by reverse transcription polymerase chain reaction (RT-PCR). Reverse transcription was performed with 1 μg total RNA and 100 pmol random hexamers in a total volume of 20 μL to produce first-strand cDNA. PCR experiments were performed with 1 μL of the first-strand cDNA in a 50 μL reaction mixture. Human VEGF cDNA was amplified with specific primers (sense primer, 5'-TGCATTCACATTT-GTTGTGC-3'; antisense primer, 5'-AGACCCTGGTG-GACATCTTC-3'; a 200 bp product) and β-actin specific primers (sense primer, 5'-TCATCACCATTGGCAAT-GAG-3'; antisense primer, 5'-CACTGTGTTGGCGTA-CAGGT-3'; a 150 bp product). Amplification protocol was as follows: denaturation at 94℃ for 1 min, annealing at 60℃ (for β-actin, 55℃) for 1 min, and extension at 72℃ for 1 min. All PCRs were linear up to 30 cycles. The

PCR products were subjected to 2.5% agarose gel electrophoresis, stained with ethidium bromide and quantified by densitometry using the Image Master VDS system and associated software (Pfizer, NY, USA).

Signaling inhibitors blocking the VEGF induction by IL-6

AGS cells were seeded into a 90 mm plate at 5×10^5 cells per well. After serum starvation for 24 h, the cells were stimulated with IL-6 (50 ng/mL) for another 24 h in the presence or absence of 50 μmol EGCG or signaling inhibitors: 20 μmol AG490 (Calbiochem, La Jolla, Calif., USA), 25 μmol PD98059 (Sigma) or 25 μmol LY294002 (Sigma). AG490 is a JAK2 inhibitor, PD98059 is a MAPK/ERK kinase (MEK) inhibitor, and LY294002 is a phosphatidylinositol-3-kinase (PI3K) inhibitor. Total proteins were extracted from the cell lysates and subjected to Western blotting analysis for VEGF expression.

Stat3 nuclear translocation

AGS cells (5×10^5 cells/well) were seeded in 90 mm plates. After serum starvation for 24 h, the cells were stimulated with IL-6 (50 ng/mL) for 1 h in the presence or absence of 50 μmol EGCG. The cells were washed with cold phosphate buffered saline and collected with a policeman cell scraper. The cells were suspended in a hypotonic buffer (10 mmol HEPES, 2 mmol MgCl₂, 10 mmol KCl, 0.1 mmol EDTA, 1 mmol DTT, 0.5 mmol phenylmethylsulfonyl fluoride and 0.5% Nonidet P-40) and incubated on ice for 10 min. The cell lysates were then centrifuged at $15\,000 \times g$ for 5 min and the pellets were resuspended in a high salt buffer (50 mmol HEPES, 300 mmol NaCl, 50 mmol KCl, 0.1 mmol EDTA, 1 mmol DTT, 0.5 mmol phenylmethylsulfonyl fluoride and 10% glycerol), and then incubated with rotation for 30 min at 4℃. Lysates were centrifuged at $15\,000 \times g$ at 4℃ for 30 min. The supernatant was collected as a nuclear fraction and used for Stat3 nuclear translocation assay with an anti-p-Stat3 antibody, Phospho-Stat3 (tyr-705; Santa Cruz) by Western blotting.

Chromatin immunoprecipitation assay

AGS cells (1×10^7 cells) were seeded in 90 mm plates. After serum starvation for 24 h, the cells were stimulated with IL-6 (50 ng/mL) for 6 h in the presence or absence of 50 μmol EGCG. Chromatin immunoprecipitation (ChIP) assays were performed essentially as previously described[35]. Briefly, cells were cross-linked using 1% formaldehyde at room temperature for 10 min. After sonication, the soluble chromatin was diluted 10-fold with ChIP dilution buffer (0.01% SDS; 1.1% Triton X-100; 1.2 mmol EDTA; 16.7 mmol Tris-HCl, pH 8.1; 167 mmol NaCl), and precleared with Protein A beads blocked with 1% salmon sperm DNA and 1% BSA. The precleared chromatin solution was immunoprecipitated by anti-p-Stat3 antibody (Santa Cruz) overnight at 4℃ with rotation. The immunoprecipitates were then pelleted, washed, and the antibody/protein/DNA complex was eluted off the beads by resuspending the pellets in 50 mmol NaHCO₃ and 1% SDS for 30 min. Cross-linking was reversed, and protein and RNA were removed by

adding 10 μg Proteinase K and 10 μg RNase A, followed by incubation at 42℃ for 3 h. Purified DNA was subjected to PCR with primers for VEGF promoter as follows: forward: 5'-AGACTCCACAGTGCATACGTG-3' and reverse: 5'-AGTGTGTCCCTCTGACAATG-3', which amplify 235 bp fragments flanking the Stat3 binding element. The final products were subjected to 2.5% agarose gel electrophoresis, stained with ethidium bromide and quantified by densitometry.

HUVECs proliferation and tube formation assay for in vitro angiogenesis

AGS cells seeded in 90 mm plates at 5×10^5 cells per well were stimulated with 50 ng/mL IL-6 for another 24 h in the presence or absence of 50 μmol EGCG or 20 μmol AG490 after serum starvation for 24 h. The conditioned media were generated from the supernatants centrifuged using Amicron® Ultra-15 Centrifugal Filter Devices (Millipore Filter, Bedford, Mass., USA) at $4000 \times g$ for 15 min.

For proliferation assay, HUVECs were seeded in 96-well plates pre-coated with 1% gelatin at 5×10^3 cells per well and cultured with 100 μL conditioned media supplemented with 2% FBS in the presence or absence of 10 ng/mL VEGF neutralizing antibody. After cultured for 48 h, the viable cells were quantified by 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazoliumbromide assay.

For tube formation assay, Matrigel was thawed at 4℃ in an ice-water bath. Matrigel (300 μL per well) was carefully added to a pre-chilled 24-well plate using a cold pipette and allowed to polymerize for 1h at 37℃. After polymerization, HUVECs (5×10^4 cells/well) in the conditioned media supplemented with 2% serum in the presence or absence of 10 μg/mL VEGF neutralizing antibody were layered on the top of the polymerized gel. Cells were incubated for 48 h at 37℃ in a humidified incubator at 5% CO₂, and the formed tubes were fixed with 10% buffered neutral formalin, stained with Diff-Quick Solution Ⅱ (Baster, McGraw Park, IL), and photographed (100 ×). For quantification of tube formation, the total length of tubes formed in a unit area was measured using national institute of health image program.

Matrigel plug assay for in vivo angiogenesis

Matrigel plug assay was performed as described previously with some modifications[36]. Briefly, 6-8-wk female BALB/c nude mice, weighing 18-22 g (Experimental Animal Center of Sun Yet-san University, Guangzhou, China) were subcutaneously injected with 0.5 mL of a liquid mixture composed of Matrigel (350 μL, 10mg/mL) and the conditioned media (150 μL) prepared as described above with or without 10 μg/mL of VEGF neutralizing antibody near the abdominal midline. The Matrigel was quickly polymerized *in vivo* to form a single and solid gel plug, which allowed the angiogenic factors to release and stimulate angiogenesis. One week later, the Matrigel plugs were harvested, weighed, and then minced and digested in 5 mL Drabkin reagent (Drabkin reagent kit 525; Sigma) for hemoglobin content measurement. Final he-

moglobin concentration was calculated from a standard calibration curve.

Statistical analysis

All data were presented as means ± SE. Statistical significance was calculated using unpaired Student's *t* test. A *P* value less than 0.05 was considered statistically significant. All analyses were performed using SPSS version 13.0 (SPSS Inc, USA).

RESULTS

EGCG inhibits VEGF induction by IL-6 in AGS cells

To assess the effect of EGCG on VEGF expression induced by IL-6 in human gastric cancer, we first examined VEGF expression induced by IL-6 in AGS cells treated with EGCG. AGS cells were treated with EGCG at different concentrations and stimulated with IL-6 (50 ng/mL) for 24 h. VEGF protein levels in tumor cell lysates were analyzed by Western blotting. As shown in Figure 1A, there was a basal expression of VEGF in AGS cells. After stimulation with IL-6, VEGF expression was apparently up-regulated and a 2.4-fold increase was observed. When treated with EGCG, VEGF expressions were dose-dependently decreased. This inhibitory effect was not due to the toxic effect of IL-6, because IL-6 at the concentration less than 100 ng/mL did not cause growth inhibition of AGS cells within 24 h (data not shown).

VEGF secretion is a crucial step for tumor-induced angiogenesis, so we further evaluated the effect of EGCG on VEGF secretion induced by IL-6. VEGF protein levels in the conditioned medium were measured by ELISA. IL-6 also induced VEGF secretion in AGS cells and a 2.8-fold increase was observed. Consistent with the result of Western blotting analysis, the secreted proteins of VEGF induced by IL-6 in the conditioned media were reduced by EGCG in a dose-dependent manner (Figure 1B). These data provided direct evidence that EGCG inhibited VEGF production induced by IL-6 in gastric cancer cells.

EGCG inhibits IL-6-induced VEGF expression at transcription level

To determine whether the inhibitory effect of EGCG on IL-6-induced VEGF expression was at transcriptional level in gastric cancer, we examined VEGF mRNA expression in AGS cells by RT-PCR. We found that IL-6 induced VEGF mRNA expression in AGS cells. When stimulated with IL-6 (50 ng/mL) for 12 h, a 3.1-fold increase in VEGF mRNA expression was observed. Treated with EGCG, VEGF mRNA expressions were dose-dependently reduced (Figure 1C). These findings suggested that EGCG inhibited VEGF expression induced by IL-6 in gastric cancer cells at transcriptional level.

EGCG inhibits IL-6-induced VEGF expression *via* Stat3 pathway

IL-6 is known to signal through Stat3, MAPK and PI3K in gastric cancer[32]. To elucidate the signaling pathway that

Figure 1 (-)-Epigallocatechin-3-gallate inhibits vascular endothelial growth factor production induced by interleukin-6 in human gastric cancer cells. A: When treated with (-)-Epigallocatechin-3-gallate (EGCG), vascular endothelial growth factor (VEGF) expression was dose-dependently decreased; B: Enzyme-linked immunosorbent assay showed that interleukin-6 (IL-6) induced VEGF secretion in human gastric cancer (AGS) cells and a 2.8-fold increase was observed. EGCG treatment dose-dependently reduced VEGF protein level in the conditioned medium. C: IL-6 also induced VEGF mRNA expression and a 3.1-fold increase in VEGF mRNA expression was observed. When treated with EGCG, VEGF mRNA expression was dose-dependently decreased. Values are expressed as percent of control (means ± SE, *n* = 3, [a]*P* < 0.05, [b]*P* < 0.01).

EGCG inhibited VEGF expression in gastric cancer, we tested the effect of several signaling pathway inhibitors, including JAK/STAT, MAPK and PI3K signaling pathway. IL-6 markedly increased VEGF expression in AGS cells. When treated with 50 μmol EGCG or 20 μmol AG490, VEGF expressions were reduced to near the basal level or even lower. However, the other two groups treated with PD98059 or LY294002 still exhibited enhanced VEGF expression, approximating the level of that stimulated with IL-6 (Figure 2). Because PI3K, MEK/ERK, and Stat3 activities could all be suppressed by EGCG, we further analyzed the combined effect of EGCG and the specific inhibitors on IL-6-induced VEGF expression. We found that treatment with 50 μmol EGCG or 20 μmol AG490 alone apparently inhibited IL-6-induced VEGF expression. However, EGCG treatment combined with AG490 did not suppress VEGF expression, and EGCG or AG490 treatment combined with PD98059 or LY294002 did not

suppress VEGF expression either (data not shown). These data suggested that EGCG reduced VEGF expression induced by IL-6 *via* Stat3 signaling pathway in gastric cancer.

EGCG reduces IL-6-induced Stat3 activation in AGS cells

We previously demonstrated that EGCG inhibited Stat3 activation without changing Stat3 expression in gastric cancer[11]. In this study, we further assessed the effect of EGCG on Stat3 expression and activation induced by IL-6 in gastric cancer. AGS cells were treated with or without EGCG at different concentrations and stimulated with 50 ng/mL IL-6 for 1 h. Total Stat3 and phospho-Stat3 protein levels were examined using Western blotting with anti-Stat3 antibody to detect total Stat3 protein expression, and with anti-p-Stat3 antibody (specific for tyr-705) to detect phospho-Stat3, respectively. As shown in Figure 3, Stat3 was constitutively activated in AGS cells. When stimulated

B

Figure 2 (-)-Epigallocatechin-3-gallate inhibits interleukin-6-induced vascular endothelial growth factor expression in human gastric cancer cells *via* JAK/STAT pathway. Human gastric cancer (AGS) cells were stimulated with interleukin-6 (IL-6) (50 ng/mL) for 24 h in the presence of 50 μmol (-)-epigallocatechin-3-gallate (EGCG) or signaling inhibitors. Vascular endothelial growth factor (VEGF) protein levels in tumor cell lysates were analyzed by Western blotting. IL-6 markedly increased VEGF expression in AGS cells. When treated with EGCG or AG490, VEGF expression was significantly reduced. PD98059 and LY294002 did not change IL-6-induced VEGF expression. 1: Without IL-6 stimulation; 2: Stimulated with IL-6; 3-6: Treated with 50 μmol EGCG or signaling inhibitors of 20 μmol AG490, 25 μmol PD98059 or 25 μmol LY294002.

with IL-6 (50 ng/mL) for 1 h, phosphorylation of Stat3 at tyrosine 705 increased by 2.9 folds and the total Stat3 expression increased by 2.3 folds. EGCG treatment inhibited IL-6-induced activation of Stat3 in a dose-dependant manner, without affecting total Stat3 expression. These findings suggested that EGCG reduced IL-6-induced VEGF expression in gastric cancer by inhibiting Stat3 activation instead of Stat3 expression.

EGCG inhibits Stat3 nuclear translocation and DNA binding activity

Our results showed that EGCG inhibited Stat3 activation and reduced VEGF expression at transcriptional level in gastric cancer. Activated Stat3 acts as a transcription activator, and is capable of translocating into nucleus, binding to the Stat3 consensus sequence in VEGF promoter region, thereby up-regulating VEGF expression[15]. To clarify whether EGCG affected Stat3 nuclear translocation and DNA binding activity, we first performed Western blotting with extraction of nuclear protein to visualize the nuclear translocation of phospho-Stat3 after IL-6 stimulation. As shown in Figure 4A, before IL-6 stimu-

A

B

Figure 3 (-)-Epigallocatechin-3-gallate inhibits signal transducer and activator of transcription 3 activation induced by interleukin-6 in human gastric cancer cells. Human gastric cancer (AGS) cells were stimulated with interleukin-6 (IL-6) (50 ng/mL) in the presence of (-)-epigallocatechin-3-gallate (EGCG) at concentrations indicated for 1 h. Total signal transducer and activator of transcription 3 (Stat3) and activated Stat3 were examined by Western blotting. Stat3 was constitutively activated in AGS cells. After stimulated with IL-6, total Stat3 and activated Stat3 expression were both markedly increased by 2.3 folds and 2.9 folds, respectively. When treated with EGCG, activated Stat3 expression decreased in a dose-dependant manner, but total Stat3 expression remained unchanged.

lation, less phospho-Stat3 was localized in the nucleus. Once stimulated with IL-6 for 1 h, phospho-Stat3 was apparently increased and translocated into the nucleus. After EGCG treatment, phospho-Stat3 in the nucleus was markedly decreased.

To further evaluate the Stat3-DNA binding activity, ChIP assay was performed. Immunoprecipitation was conducted with an anti-p-Stat3 antibody followed by PCR using oligonucleotide primers that amplified a 235 bp region spanning Stat3 binding site in VEGF promoter. IL-6 apparently increased this band in AGS cells, suggesting that IL-6 up-regulated VEGF expression by promoting Stat3 binding to VEGF promoter and activating VEGF transcription. When treated with EGCG, Stat3-DNA binding activity was markedly decreased (Figure 4B). Taken together, these data provided direct evidence that EGCG down-regulated VEGF expression induced by IL-6 through inhibiting Stat3 translocating into nucleus and binding to VEGF promoter in gastric cancer.

EGCG inhibits IL-6-induced angiogenesis in vitro

We further evaluated the effect of EGCG on IL-6-induced angiogenesis *in vitro* by assessing proliferation and

Figure 4 (-)-Epigallocatechin-3-gallate inhibits signal transducer and activator of transcription 3 nuclear translocation and DNA binding activity in human gastric cancer cells. Signal transducer and activator of transcription 3 (Stat3) nuclear translocation was determined by Western blotting with extraction of nuclear proteins. A: After treated with 50 μmol (-)-epigallocatechin-3-gallate (EGCG) and interleukin-6 (IL-6) (50 ng/mL) for 1 h, phospho-Stat3 in the nucleus was visualized with an anti-p-Stat3 antibody; B: IL-6 apparently increased phospho-Stat3 expression in the nucleus, but EGCG treatment markedly decreased this effect. Stat3-DNA binding activity was determined by chromatin immunoprecipitation (ChIP) assay. Immunoprecipitation was conducted with Stat3 antibody followed by polymerase chain reaction (PCR) using oligonucleotide primers that yielded a 235 bp band spanning Stat3 binding site in vascular endothelial growth factor promoter. IL-6 apparently increased Stat3-DNA binding activity. When treated with EGCG, Stat3-DNA binding activity was also markedly decreased.

tube formation of HUVECs cultured in the conditioned media. As shown in Figure 5A and B, the conditional media stimulated with IL-6 promoted HUVECs proliferation and tube formation when compared with the non-stimulated cell culture media. VEGF neutralizing antibody effectively blocked the enhancement of proliferation and tube formation of HUVECs cultured in the IL-6-stimulated conditional media, suggesting that IL-6 increased the angiogenic ability of AGS cells through up-regulating VEGF induction. Treatment with EGCG or AG490 also abrogated the effect of IL-6 on HUVECs cell proliferation and tube formation. These data further confirmed that EGCG inhibited angiogenesis induced by IL-6 through targeting Stat3/VEGF signaling pathway.

EGCG inhibits IL-6-induced angiogenesis in vivo

The effect of EGCG on angiogenesis induced by IL-6 *in vivo* was assessed using Matrigel plug assay. Matrigel plugs were harvested on the 7th d and examined by measuring the density of hemoglobin, as an indicator of vascularization. Hemoglobin concentrations were determined and normalized to represent the vascular densities in the plug. Grossly, the Matrigel plugs embedded with

the conditioned media from IL-6-stimulated AGS cells developed substantial vasculature, as compared with the non-stimulated media. However, plugs that contained the conditioned media treated with VEGF neutralizing antibody, EGCG and AG490 exhibited considerably less vascularization (Figure 5C). Collectively, Matrigel plug assay demonstrated that IL-6 markedly potentiated AGS cells to enhance angiogenesis *in vivo* by inducing VEGF production, and EGCG abolished the pro-angiogenesis ability of AGS cells induced by IL-6 through inhibiting VEGF induction *via* Stat3.

DISCUSSION

Both VEGF over-expression and Stat3 over-activation occur at high frequency in human tumors[12-23], and IL-6 has shown to induce VEGF expression and angiogenesis by promoting Stat3 activity[29-31]. In gastric cancer, IL-6 induces VEGF expression *via* Stat3 signaling pathway[32], and is associated with tumor angiogenesis and disease status[27,28]. Previous studies have indicated that EGCG inhibits VEGF expression and Stat3 activation in multiple cancers[9,11,24,25]. However, whether EGCG inhibits

C

Figure 5 (-)-Epigallocatechin-3-gallate inhibits interleukin-6 induced angiogenesis *in vitro* and in *vivo*. The *in vitro* angiogenesis was determined by 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazoliumbromide (MTT) and tube formation assay. Human umbilical vein endothelial cells (HUVECs) were cultured with the conditioned media in the presence of vascular endothelial growth factor (VEGF) neutralizing antibody, (-)-epigallocatechin-3-gallate (EGCG) or AG490. After 48 h incubation, the viable cells were quantified by MTT assay (A), and the formed tubes were fixed, stained, photographed and analyzed (B). The *in vivo* angiogenesis was determined by Matrigel plug assay. Matrigel plugs containing the conditioned media with VEGF neutralizing antibody, EGCG or AG490 were subcutaneously injected into nude mice. One week later, the Matrigel plugs were harvested and examined by measuring the density of hemoglobin (C). interleukin-6 (IL-6) apparently promoted vascular endothelial cell proliferation and tube formation *in vitro* and vascularization of Matrigel plugs *in vivo*. VEGF neutralizing antibody, EGCG and AG490 all markedly decreased these effects. 1: Without IL-6 stimulation as a negative control; 2: With IL-6 stimulation as a control; 3-5: With IL-6 stimulation and VEGF neutralizing antibody, EGCG or AG490. Values are expressed as percent of control (means ± SE, *n* = 3, $^a P < 0.05$, $^b P < 0.01$).

VEGF expression and angiogenesis *via* Stat3 remains to be elucidated. In this study, we demonstrated that EGCG inhibited IL-6-induced VEGF expression and angiogenesis in gastric cancer *via* suppressing Stat3 activity.

EGCG has shown to inhibit VEGF expression and angiogenesis in a variety of tumors[8-11], and is most effective in inhibiting VEGF expression and angiogenesis among the four main catechins of green tea[7]. However, the exact mechanism for the inhibitory effect of EGCG on VEGF expression and angiogenesis is not well understood. IL-6 is reported to induce VEGF expression and tumor vasculature in gastric cancer[27,28]. To evaluate the effect of EGCG on VEGF expression induced by IL-6 in gastric cancer, we examined VEGF expression in AGS cells treated with EGCG and IL-6. As shown in Figure 1A and B, after stimulated with 50 ng/mL of IL-6,

a 2.4-fold increase of VEGF protein in tumor cells and a 2.8-fold increase in the conditioned media were observed. When treated with EGCG, VEGF expression and secretion were decreased in a dose-dependent manner. EGCG also dose-dependently inhibited VEGF mRNA expression in AGS cells (Figure 1C). Here we demonstrated that EGCG inhibited IL-6-induced VEGF expression in gastric cancer cells, and this inhibitory effect was at transcriptional level.

The important role of VEGF in angiogenesis has been well established. Therefore, we further evaluated the effect of EGCG on IL-6-induced angiogenesis both *in vitro* and *in vivo*. As shown in Figure 5, the conditioned media promoted vascular endothelial cell proliferation and tube formation *in vitro* and vascularization of Matrigel plugs *in vivo*. VEGF neutralizing antibody effectively

blocked these effects, confirming that IL-6-induced angiogenesis is VEGF-dependent. EGCG treatment also abrogated IL-6-induced angiogenesis *in vitro* and *in vivo*. These findings suggested that EGCG inhibited IL-6-induced angiogenesis *via* down-regulation of VEGF production in gastric cancer.

Several mechanisms have been proposed for the inhibitory effect of EGCG on VEGF expression[3-11]. In the present study, we found that EGCG inhibited IL-6-induced VEGF expression in AGS cells. IL-6 might act through several classic protein kinase cascades, such as MAPK, PI3K and Stat3[31,32]. To elucidate the signaling pathway that EGCG inhibited VEGF expression induced by IL-6 in AGS cells, we tested the effect of several signaling pathway inhibitors, and found that PD98059 and LY294002 did not affect IL-6-induced VEGF expression, suggesting that IL-6 did not induce VEGF expression in AGS cells through MAPK or PI3K signaling pathway, which was consistent with a previous study[32]. In contrast, EGCG and AG490 effectively inhibited VEGF expression induced by IL-6. In addition, EGCG and AG490 also effectively inhibited IL-6-induced vascular endothelial cell growth and tube formation *in vitro* and vascularization of Matrigel plug *in vivo*, indicating that EGCG inhibited IL-6-induced VEGF expression and angiogenesis *via* Stat3 signaling pathway. A previous study also demonstrated that Stat3 pathway was predominantly involved in the signaling of IL-6 stimulation in VEGF expression in gastric cancer[32]. These data suggested that EGCG inhibited IL-6-induced VEGF expression and angiogenesis *via* Stat3 signaling pathway in gastric cancer, and provided a novel mechanistic insight into the effect of EGCG on VEGF expression.

Activation by tyrosine phosphorylation is an indispensable prerequisite for the activity of Stat3. Compared with normal cells and tissues, abnormally activated Stat3 has been detected in a wide variety of human cancer cells and tissues, and associate with VEGF expression and tumor angiogenesis[14-23]. Previous studies have shown that EGCG inhibits activation of Stat3 in various cancer cells[9,24,25]. Our study also demonstrated that EGCG inhibited activation of Stat3 and VEGF expression in gastric cancer[11]. In this study, we found that Stat3 was constitutively activated in AGC cells. IL-6 induced a remarkable increase in Stat3 expression and activation. When treated with EGCG, Stat3 activation was inhibited in a dose-dependent manner, but the total Stat3 expression remained unchanged when compared with the control. EGCG treatment did not affect Stat3 mRNA expression, either (data not shown). These findings suggested that EGCG reduced VEGF expression in gastric cancer by suppressing Stat3 activation.

Once activated, Stat3 translocates into the nucleus, binds to specific DNA promoter sequence and induces downstream gene expression[15]. Stat3-binding site in VEGF promoter has been identified, providing evidence that VEGF is a direct target gene of Stat3. The activated Stat3 acts as a transcriptional activator and is capable of binding directly to the Stat3 consensus sequence in VEGF promoter region, thereby promoting the VEGF expression[18-20]. Previous studies showed that IL-6 up-regulated VEGF expression by promoting Stat3 binding to VEGF promoter[29-31]. Furthermore, blockage of Stat3 activation was associated with a decline in Stat3-DNA binding activity and VEGF mRNA expression in gastric cancer[32]. In this study, we found that IL-6 stimulation apparently increased Stat3 translocation into nucleus and Stat3-DNA binding activity. When treated with EGCG, Stat3 nuclear translocation and Stat3-DNA binding activity was markedly decreased. Masuda *et al*[9] also found that inhibition of Stat3 by EGCG significantly decreased VEGF promoter activity. Taken together, these data provided direct evidence that EGCG down-regulated VEGF expression induced by IL-6 *via* suppressing Stat3 activation, nuclear translocation and Stat3-DNA binding activity.

Increasing evidences have suggested that cytokine/Stat3 signaling pathway plays an important role in tumor development and progression. Stat3 represents a point of convergence for these cytokine signaling pathways and has become a novel promising molecular target for intervention in cancer treatment. Great efforts have been made to disrupt Stat3 signaling pathway for inhibiting angiogenesis and tumor growth[37]. However, the toxicity with these approaches might be increased because multiple down-stream targets are affected. Recently, pharmacological approaches to Stat3 inhibition aim to identify natural products as inhibitors of Stat3 signaling pathway[38,39]. In this study, we demonstrated that EGCG inhibited IL-6-induced VEGF expression and angiogenesis in gastric cancer by the suppression of Stat3 activation, nuclear translocation and Stat3-DNA binding activity. As a natural, low cost and non-toxic product, EGCG has drawn special attention, and may become a promising inhibitor of Stat3 and an angiogenic inhibitor.

COMMENTS

Background
(-)-Epigallocatechin-3-gallate (EGCG), the most abundant and active component of green tea, has shown to have chemopreventive and chemotherapeutic properties for a variety of cancers, especially gastrointestinal cancers. Anti-angiogenic activity is one of its main effects against cancer. However, the detailed molecular mechanism is not fully understood.

Research frontiers
Angiogenesis is necessary for solid tumor growth and metastasis. Vascular endothelial growth factor (VEGF) is the most potent angiogenic factor, and EGCG has shown to inhibit angiogenesis and tumor growth *via* suppressing VEGF expression. However, the molecular mechanism remains unclear.

Innovations and breakthroughs
Increasing evidences suggest that cytokine/Stat3 signaling pathway plays an important role in tumor development and progression. Signal transducer and activator of transcription 3 (Stat3) represents a point of convergence for cytokine signaling pathways and has become a novel promising molecular target for intervention in cancer therapy. In this study, the authors demonstrate that EGCG inhibited IL-6-induced VEGF expression and angiogenesis *via* suppressing Stat3 activity in gastric cancer, and provided further evidence of the molecular mechanism underlying the anti-angiogenic activity of EGCG.

Applications
By understanding how EGCG inhibits IL-6-induced VEGF expression and

angiogenesis *via* suppressing Stat3 activity, this study may represent a future strategy for therapeutic intervention in the treatment of gastric cancer.

Terminology

Stat3 represents a point of convergence for cytokine signaling pathways. IL-6 induces VEGF expression and angiogenesis *via* Stat3 in multiple tumors. Non-surprisingly, EGCG down-regulates VEGF expression induced by IL-6 *via* suppressing Stat3 activation, nuclear translocation and Stat3-DNA binding activity.

Peer review

The authors for the first time examined how EGCG inhibits IL-6-induced VEGF expression and angiogenesis *via* suppressing Stat3 activity. It provided direct evidence that EGCG down-regulated VEGF expression induced by IL-6 *via* suppressing Stat3 activation, nuclear translocation and Stat3-DNA binding activity. The results may represent a new molecular mechanism of anti-angiogenic activity of EGCG, and identified a new natural product as an inhibitor of Stat3 signaling pathway.

Abstract

AIM: To explore the associations of polymorphisms of lipopolysaccharide binding protein (LBP), cluster of differentiation 14 (CD14), toll-like receptor 4 (TLR-4), interleukin-6 (IL-6) and tumor necrosis factor α (TNF-α) with the colorectal carcinoma (CRC) risk in Han Chinese.

METHODS: Polymorphisms of LBP (rs1739654, rs2232596, rs2232618), CD14 (rs77083413, rs4914), TLR-4 (rs5030719), IL-6 (rs13306435) and TNF-α (rs35131721) were genotyped in 479 cases of sporadic colorectal carcinoma and 486 healthy controls of Han Chinese in a case-control study. Single-nucleotide polymorphisms (SNPs) between cases and controls were analyzed by unconditional logistic regression.

RESULTS: GA and GG genotypes of LBP rs2232596 were associated with a significantly increased risk of CRC [odds ratio (OR) = 1.51, 95% confidence interval (CI) 1.15-1.99, *P* = 0.003; OR = 2.49, 95% CI 1.16-5.38, *P* = 0.016, respectively]. A similar association was also observed for the CG genotype of CD14 rs4914 (OR= 1.69, 95% CI 1.20-2.36, *P* = 0.002). In addition, a combination of polymorphisms in LBP rs2232596 and CD14 rs4914 led to a 3.4-fold increased risk of CRC (OR = 3.44, 95% CI 1.94-6.10, *P* = 0.000).

CONCLUSION: This study highlights the LBP rs2232596 and CD14 rs4914 polymorphisms as biomarkers for elevated CRC susceptibility in the Chinese Han population.

INTRODUCTION

Colorectal carcinoma (CRC) is one of the major causes of cancer death throughout the world. In China, the incidence rate of newly diagnosed CRC cases is increasing rapidly[1]. Both environmental and genetic factors contribute to the tumorigenesis of CRC. The classical adenoma-carcinoma sequence model proposes that genetic mutations of K-ras, adenomatous polyposis coli (APC), the deleted in colorectal cancer (DCC), and p53 play important roles in the malignant transformation and cancer progression

of CRC[2]. Recent studies have demonstrated that chronic inflammation is also an important factor in the carcinogenesis of CRC[3,4]. In the tumor microenvironment, inflammatory cells, especially the so-called tumor-associated macrophages (TAMs), induce suppression of host anti-tumor activities, stimulate tumor cell growth, and promote malignant transformation, angiogenesis and metastasis[4-8].

TAMs are key regulatory components of cancer-related inflammation. TAMs mainly derive from monocytic precursors in blood circulation, and are recruited to the tumor sites by tumor-derived chemokines such as C-C motif ligand 2 (CCL2) as well as cytokines in the tumor microenvironment, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), transforming growth factor (TGF) and macrophage colony stimulating factor (M-CSF). These chemokines and cytokines also regulate the survival and differentiation of TAMs[7,9]. Further studies have demonstrated that TAMs are defective in IFN-γ/lipopolysaccharide (LPS) responsiveness to bacterial invasion[10,11]. In solid tumors, TAMs are reprogrammed to have pro-tumor properties and therefore fail to respond to LPS stimulation that should have killed the cancer cells[12]. Whether LPS-induced signaling pathways play important roles in tumor progression warrants further investigation.

Lipopolysaccharide binding protein (LBP), cluster of differentiation 14 (CD14), and toll-like receptor 4 (TLR-4) are pattern-recognition receptors (PRRs) that mediate innate immune response to LPS challenge[13,14]. LBP is a secretory class I acute phase protein, which can drastically increase LPS-induced activation of immune cells by binding with LPS and transferring it to CD14. CD14 is a glycosylphosphatidylinositol (GPI)-linked LPS receptor which exists as either membrane-bound forms on the surface of immune cells or soluble forms in the serum. TLR4 belongs to a family of innate immune receptors expressed on the surface of monocytes and macrophages, recognizing pathogen-associated molecular patterns (PAMPs) such as LPS. In the LPS signaling pathway, TLR4 can specifically recognize LPS with the aid of LBP, CD14 and MD-2 molecular complex and activate macrophages in response to LPS-induced inflammation.

Genetic variations of inflammatory factor genes are correlated with increased risk in several malignant tumors. Previous studies have demonstrated a strong association between IL-1beta, IL-8 polymorphisms and gastric carcinoma[15,16], IL-6 polymorphism and cervical carcinoma[17], IL-8, IL-10, TLR4 polymorphisms and prostate carcinoma[18,19], TNF-α polymorphism and non-small cell lung cancer[20]. However, the association between polymorphisms of LPS-signaling-related genes and CRC susceptibility in the Chinese Han population remains elusive. In this study, we directly addressed this issue and investigated the association between polymorphisms of LBP, CD14, TLR4, IL-6 and TNF-α genes and the CRC risk in a case-control study.

ple living in the southwest region of China. The characteristics of CRC cancer patients and controls included in this study are summarized in Table 1. Patients were chosen from Chongqing Xinqiao Hospital, the second affiliated hospital of Third Military Medical University who were treated from 2008 to 2010. The diagnosis of CRC was confirmed histologically. Patients with histories of previous cancers other than CRC and radiotherapy or chemotherapy were excluded. The controls were healthy people matched to cases by age, sex and dietary habits. Informed consent was obtained from all subjects and the study was approved by the Ethical Committee of Third Military Medical University. Individuals who had smoked over 100 cigarettes were classified as smokers, including current smokers and former smokers who had stopped smoking for at least one year. Individuals who had been drinking alcohol at least once a week for more than 6 months were labeled as drinkers, including current drinkers and former drinkers. Former drinkers were those who had abstained from drinking for more than one year.

DNA extraction, polymorphism selection and genotyping

Genomic DNA was extracted from whole blood samples of subjects by the TIANamp Blood DNA Kit (Tiangen, China) according to the manufacturer's instructions. Eight polymorphisms in 5 genes (rs1739654, rs2232596 and rs2232618 in LBP; rs4914 and rs77083413 in CD14; rs5030719 in TLR4; rs13306435 in IL-6; and rs35131721 in TNF-α) examined in our study have been reported with

the minor allele frequency over 1%[21]. SNP genotyping was carried out by the two-step SNaPshot assay. The first step was amplification of gene fragments containing these polymorphic sites. The polymerase chain reaction (PCR) was performed in 25 μL reaction mixture containing 1 × master mix (Tiangen, China), 30 ng genomic DNA templates and 0.4 μmol/L primer sets. Primer sequences (5' to 3') were presented in the order of forward, reverse and SNaPshot sequences, including LBP rs1739654: ACAGAAATGCAG-GGACACCTCT, CCTGAGGCTCTCTCTTCCTCAC, GCGGCCCAGGAGGGGCTATT; LBP rs2232596: TC-CAACTGGACCCTAGTGGAGT, CGCCTGGCCCT-TAATTTTTACT, CCATGTTTTTCAGATTTGCGA AATGATCCAGAAATC; LBP rs2232618: TATGTTGGC ACACACAGAACCA, CACTTCCATGTGTCCCTCT-GTC, GCTCCTCAACTATTACATCCTTAACACC; CD14 rs77083413: TGAATTGGTCGAAAAGTCCTCA, CCCTGAACTCCCTCAATCTGTC, TTTTTTTTTT TTTTTTTTTTTTTTTTTTTTTTGACCACGCCG-GAGTTCATTGAGCCCTCGTG; CD14 rs4914: ACACGGACCCGTTGTTTAAGAT, TGGAACAG-GTGCCTAAAGGACT, TTTTTTTTTTTTTTCTT-GGATCTTAGGCAAAGCCCCGGGCCCCTTGGAG; TLR4 rs5030719: CAGAGTTGCTTTCAATGGCATC, TGCAGGAAACTCTGGTGTTCA, TTTTTTTTTTTTTT TTTTTTTTTTCCTGGACCTCTCTCAGTGT-CAACTGGAGCA; IL-6 rs13306435: ATGGAAG-GGTCCTACTCAGAGC, CATAAGTTCTGT-GCCCAGTGGA, CCCCCCCCCCCCCCCCCCCCCC CCCCCCCCCACTTTCATTTTCCTTCAGGCAAA-GAATCTAGA; TNF-α rs35131721: GCGGGAAATAT-GACAGCTAAGG, CTCCCCCAAGACCAAAACTTTA, TTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTTT TTTTTAACCATTCTCCTTCTCCCCAACAGTTCC. A similar amplification condition was used for all genes: one cycle of denaturation at 94℃ for 3 min; 30 cycles of denaturation at 94℃ for 30 s, annealing at 68℃ for 30 s, elongation at 72℃ for 40 s; and an eventual elongation at 72℃ for 5 min. The size of PCR products were confirmed by 1.5% agarose gel electrophoresis. The second step was genotyping using the SNaPshot Multiplex Kit (Applied Biosystems, USA). Three μL PCR amplification products were mixed with 5 μL SNaPshot Multiplex Kit and 1 μL 10 μmo/L SNaPshot primer. The SNaPshot PCR condition was 25 cycles of 10 s at 96℃, 5s at 50℃ and 30 s at 60℃. Subsequently, samples were mixed with Liz120 (Applied Biosystems, USA) and were electrophoresed using Genetic Analyzer 3130 instrument (Applied Biosystems, USA). The data were analyzed using the 4.0 Genemapper software (Applied Biosystems, USA).

Statistical analysis
Differences in demographic variables, smoking status, drinking status, grouped genotypic frequencies between cases and controls were evaluated by Student's *t* test and χ^2 test. Two-sided *P* values were considered significant at levels less than 0.05. The associations between polymorphisms of LPS-signaling-related genes and CRC risk were estimated from unconditional regression analysis using the SPSS 13.0 software (PASW, USA). All the eight SNPs were tested for the Hardy-Weinberg equilibrium.

RESULTS
The characteristics of 479 CRC cases and 486 healthy controls are summarized in Table 1. In this case-control study, eight polymorphisms of five genes involved in the LPS-signaling pathway were assayed, in which TLR4 rs5030719 and TNF-α rs35131721 SNPs were excluded due to data bias. All the other six polymorphisms satisfied the Hardy-Weinberg equilibrium (*P* > 0.05).

The effects of the polymorphisms of LPS-signaling-related genes on the risk of colorectal cancer are shown in Table 2. In the genetic model, the G allele of LBP rs2232596 SNP was significantly associated with CRC (GA genotype: odds ratio (OR) = 1.51, 95% confidence interval (CI) 1.15-1.99, *P* = 0.003; GG genotype: OR = 2.49, 95% CI 1.16-5.38, *P* = 0.016). Similarly, the G allele of CD14 rs4914 SNP showed a strong association with the risk of CRC (CG genotype: OR = 1.69, 95 %CI 1.20-2.36, *P* = 0.002). To examine the interaction between epidemiological factors and genetic variances, stratified analysis using logistic regression was performed and no significant difference was found in the genotype distribution of LBP rs2232596 and CD14 rs4914 with respect to age, sex, tumor location and stages (data not shown).

Gene-tobacco exposure interactions and gene-alcohol exposure interactions were also evaluated by stratification analysis using logistic regression (Tables 3 and 4). Smokers with GA genotype of LBP rs2232596 SNP had a significant association with the CRC risk (OR = 1.68, 95% CI 1.17-2.40, *P* =0.005), whereas in non-smokers, an increased CRC risk with CG genotype of CD14 rs4914 SNP (OR = 2.82, 95% CI 1.64-4.85, *P* =0.000) was observed. In alcohol drinkers, the presence of GA and GG genotypes of LBP rs2232596 SNP (OR = 1.61, 95% CI 1.23-2.11, *P* = 0.001) and CG genotype of CD14 rs4914 SNP (OR = 1.80, 95% CI 1.28-2.55, *P* = 0.001) was associated with increased risk of CRC.

Further evaluations of the combinatory effects of LBP rs2232596 and CD14 rs4914 SNPs were conducted using logistic regression analysis (Table 5). Subjects carrying risk genotypes in both LBP and CD14 (GA and GG in LBP rs2232596, CG in CD14 rs4914) showed synergistic effects on the associations with the CRC risk (OR = 1.46, 95% CI 1.11-1.92, *P* = 0.007 and OR = 3.44, 95% CI 1.93-6.10, *P* = 0.000).

DISCUSSION
Our study aimed to investigate the association of SNPs in LPS-signaling-related genes and the risk of CRC in the Chinese Han population. We found that the G alleles of both LBP rs2232596 and CD14 rs4914 were significantly associated with CRC. In addition, a combination of these two polymorphisms dramatically increased the CRC risk. To our knowledge, this is the first report on the relationship of these two polymorphisms with gastrointestinal malignancies.

The LPS-signaling pathway is a crucial player in the innate immunity regulatory system, which includes LBP, CD14, TLR4/MD2 and other molecules involved in LPS-induced NF-κB activation such as MyD88, TIR, IRAK and TRAF6[22]. In intestinal mucosa, continuous exposure to LPS activates M1 type macrophages to perform tumoricidal tasks. TAMs in the cancer micro-environment belong to M2 macrophages and, on the contrary, promote tumor growth. In the presence of M2 macrophages, the LPS signaling pathway is down-regulated but the mechanisms remain unclear[10-12].

Previous studies in this field mainly focused on the effects of genetic variations of aforementioned genes in non-tumoral diseases such as bacterial infections[23,24], sepsis[25] and myocardial infarction[26]. Recently, how these genetic variations contribute to the risk of developing var-

ious cancers has drawn much attention. Polymorphisms in the CD14 promoter can affect the susceptibility to CRC[27] and *Helicobacter pylori* infection–related gastric carcinoma[28] in Chinese patients, and prostate cancer in African American men[29]. Effects of polymorphisms of TLR4 and other PRRs on cancer risk have also been reported[30,31].

Our study of the genetic variances in LBP rs2232596 and CD14 rs4914 provided strong evidence of interactions between LPS-signaling-related genes and the risk of CRC, indicating that the genetic modulation of LPS-induced inflammation may contribute to CRC development and progression. TAMs with defective LPS responsiveness are common components of the micro-environment of different cancers. In addition, the current study and several previous studies revealed that functional polymorphisms in LPS-signaling-related genes are associated with various cancer risks. More studies are needed to shed light on the underlying genetic mechanisms.

Tobacco and alcohol exposure have been identified as high-risk factors for CRC[32, 33]. However, our data failed to show any significant associations of tobacco and/or alcohol exposure with CRC susceptibility. We found that smokers and drinkers carrying LBP rs2232596 polymorphisms had a higher risk of CRC. But only drinkers carrying CD14 rs4914 polymorphism showed modest risk of

CRC. One possible explanation is that different mechanisms regulate tobacco-gene and alcohol-gene interactions. This study lacked detailed information on the smoking and drinking status of the subjects. Further stratification analysis is needed to evaluate the risk of lifestyle factors.

What mediates the observed association between gene polymorphisms and CRC susceptibility still remains unknown. It would be interesting to compare the serum levels of LBP and CD14 from different genotypes to examine the relationship between gene polymorphisms and their expression levels.

In conclusion, the functional G alleles in both LBP rs2232596 and CD14 rs4914 SNPs showed significant associations with a high CRC risk. Further studies are needed to elucidate the effects of these genotypes on gene transcription, expression and functions in CRC and other types of malignancies.

COMMENTS

Background
Colorectal carcinoma (CRC) is a leading cause of cancer death in China and throughout the world. Chronic inflammation is considered to be important in the carcinogenesis of CRC. In this study, the authors examined the association between the gene polymorphisms of several lipopolysaccharide (LPS)-signaling factors and the risk of CRC to better elucidate the mechanism of inflammation in tumorigenesis.

Research frontiers
LPS-induced signaling is an important innate immune response that involves many different molecules, such as lipopolysaccharide binding protein (LBP), cluster of differentiation 14 (CD14), and toll-like receptor 4 (TLR-4). Recently, it has become a hot area to employ polymorphism analysis to identify genetic mutations in the immune system that are significantly correlated with tumor development.

Innovations and breakthroughs
To date, there has been no study on the polymorphisms of LPS-signaling-related genes and CRC susceptibility in the Chinese Han population. In this study, the authors directly addressed this issue and performed genetic analysis to screen for polymorphisms that are associated with increased CRC risk. The authors also explored the gene-environment interactions by studying the effects of smoking or drinking exposure on CRC susceptibility.

Applications

By demonstrating the association of LBP rs2232596 and CD14 rs4914 polymorphisms with increased CRC risk, the authors identified two important biomarkers for predicting CRC and further improved the understanding of the inflammation-related mechanisms in CRC development.

Terminology

Single-nucleotide polymorphism (SNP): a DNA sequence variation occurring when a single nucleotide in the genome differs between members of the same biological species or paired chromosomes in an individual. SNP analysis can shed light on how genetic variations affect disease development in humans.

Peer review

This is an interesting well-conducted and well-written study.

Abstract

AIM: To identify pancreatographic findings that facilitate differentiating between autoimmune pancreatitis (AIP) and pancreatic cancer (PC) on endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP).

METHODS: ERCP findings of 48 AIP and 143 PC patients were compared. Diagnostic accuracies for AIP by ERCP and MRCP were compared in 30 AIP patients.

RESULTS: The following ERCP findings suggested a diagnosis of AIP rather than PC. Obstruction of the main pancreatic duct (MPD) was more frequently detected in PC ($P < 0.001$). Skipped MPD lesions were detected only in AIP ($P < 0.001$). Side branch derivation from the narrowed MPD was more frequent in AIP ($P < 0.001$). The narrowed MPD was longer in AIP ($P < 0.001$), and a narrowed MPD longer than 3 cm was more frequent in AIP ($P < 0.001$). Maximal diameter of the upstream MPD was smaller in AIP ($P < 0.001$), and upstream dilatation of the MPD less than 5 mm was more frequent in AIP ($P < 0.001$). Stenosis of the lower bile duct was smooth in 87% of AIP and irregular in 65% of PC patients ($P < 0.001$). Stenosis of the intrahepatic or hilar bile duct was detected only in AIP ($P = 0.001$). On MRCP, diffuse narrowing of the MPD on ERCP was shown as a skipped non-visualized lesion in 50% and faint visualization in 19%, but segmental narrowing of the MPD was visualized faintly in only 14%.

CONCLUSION: Several ERCP findings are useful for differentiating AIP from PC. Although MRCP cannot replace ERCP for the diagnostic evaluation of AIP, some MRCP findings support the diagnosis of AIP.

Utility of pancreatography for diagnosing autoimmune pancreatitis. *World J Gastroenterol* 2011; 17(18): 2332-2337 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i18/2332.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i18.2332

INTRODUCTION

Autoimmune pancreatitis (AIP) is a newly described entity of pancreatitis, the pathogenesis of which appears to involve autoimmune mechanisms[1-4]. Clinically, AIP patients and patients with pancreatic cancer (PC) share many features, such as preponderance of elderly males,

frequent initial symptom of painless jaundice, development of new-onset diabetes mellitus, and elevated levels of serum tumor markers. Radiologically, focal swelling of the pancreas, the "double-duct sign", representing strictures in both biliary and pancreatic ducts, and encasement of peripancreatic arteries and portal veins are sometimes detected in both AIP and PC[4-6]. AIP often mimics PC, and 2.4% of 1808 pancreatic resections in the USA were reported to have AIP on histological examination[7]. AIP responds dramatically to steroid therapy; therefore, accurate diagnosis of AIP can avoid unnecessary laparotomy or pancreatic resection.

Serum IgG4 levels were elevated in 77%[8]-81%[9] of AIP patients, but they were also elevated in 4%[8]-10%[10] of PC patients. There is no definite serological marker for AIP; therefore, AIP is currently diagnosed using a combination of characteristic radiological, serological, and pathological findings. Irregular narrowing of the main pancreatic duct (MPD) on endoscopic retrograde cholangiopancreatography (ERCP) is a characteristic radiological feature of AIP, and this pancreatographic finding on ERCP is mandatory in the Japanese diagnostic criteria for AIP[11]. We previously compared the pancreatograms of 17 AIP patients having a mass-forming lesion in the pancreatic head and 40 patients with pancreatic head cancer[6]. In the present study, we further compared pancreatograms of 48 AIP patients and 143 PC patients, and evaluated more accurately by further date.

Although pancreatographic findings are useful to differentiate AIP and PC, ERCP can cause adverse effects, such as pancreatitis. Since magnetic resonance cholangiopancreatography (MRCP) has become popular as a non-invasive method for obtaining high quality images of the pancreaticobiliary tree, MRCP is replacing diagnostic ERCP in many pancreatobiliary diseases. In the new Korean diagnostic criteria, AIP can be diagnosed by MRCP without the need for ERCP[12]. In our previously study of the utility of MRCP for diagnosing AIP in 20 AIP patients who were examined before 2008, MRCP could not replace ERCP, because narrowing of the MPD in AIP was not visualized on MRCP[13]. However, with development of MRCP models, spatial resolution of the pancreatic duct has improved on MRCP. We again studied the usefulness of MRCP for diagnosing AIP in 30 AIP patients and assessed whether MRCP could replace ERCP for diagnosing AIP.

MATERIALS AND METHODS

From 1992 to August 2010, pancreatograms on ERCP were obtained in 48 AIP patients [34 males, 14 females; age, 64.1 ± 12.1 (mean ± SD) years; age range, 27-83 years]. They were diagnosed as having AIP according to the Asian Diagnostic Criteria for AIP[12]: pancreatic enlargement on computed tomography (CT) and ultrasonography (US) ($n = 48$), irregular narrowing of the MPD on ERCP ($n = 48$), elevated serum IgG4 ($n = 42$), presence of autoantibodies ($n = 26$), histological findings of lymphoplasmacytic sclerosing pancreatitis (LPSP, $n = 18$), and ste-

roid responsiveness ($n = 38$). Overall, 23 patients had diffuse enlargement of the pancreas, and 25 patients had segmental enlargement of the pancreas (head, $n = 17$; body and/or tail, $n = 8$). An initial dose of oral prednisolone of 30-40 mg/d was administered for 2-3 wk. It was then tapered by 5 mg every 1-3 wk until it reached 5 mg/d. After about three months of induction, maintenance therapy of 2.5-5 mg/d was administered for six months to 143 mo. Malignant diseases, such as pancreatic or biliary cancers, were excluded by long follow up in the 30 patients without histological examination. During the same period as the AIP cases, ERCP pancreatograms were examined in 143 PC patients (81 males, 62 females; age, 63.5 ± 10.9 years; range, 42-79 years). These PCs were resected or histologically confirmed after adequate imaging studies, such as US, CT, and magnetic resonance imaging (MRI). The locations of PC were confirmed to include the head ($n = 88$), body ($n = 37$), and tail ($n = 18$) on these imaging examinations.

The pancreatographic findings were evaluated in the 44 AIP patients and the 143 PC patients to measure the length of the narrowed MPD and the diameter of the upstream MPD (dilated MPD above the narrowed part). It was also determined whether obstruction and skipped lesions in the MPD (discrete narrowed lesions scattered in the almost normal MPD) or side branch derivation from the narrowed portion of the MPD were present. The length of the narrowed MPD and the maximal diameter of the dilated upstream MPD were measured using measuring function on computerized images or a manual goniometer. The cholangiographic findings were evaluated to identify morphological modifications in the 38 AIP patients and 77 PC patients with bile duct involvement.

Furthermore, 30 of the 48 AIP patients also underwent MRCP within three weeks, and MRCP and ERCP findings were compared. MRCP was performed using a 1.5-T magnetic resonance imaging machine (INTERA, Philips Co. Ltd., The Netherlands) by two-dimensional (up to 2005) and three-dimensional (2006-2010), coronal, heavily T2-weighted, signal-shot, rapid acquisition with relaxation enhancement. Since 2006, a 1.5-T magnetic resonance imaging machine (MAGNETOM Avanto, Siemens Co. Ltd., Germany) was also used. Diagnostic accuracies for AIP on ERCP and MRCP were compared separately in diffuse-type AIP patients ($n = 16$) and segmental-type AIP patients ($n = 14$). Two endoscopists and radiologists, who were blind to clinical information, reviewed the radiological findings.

Statistical analyses were performed with the Mann-Whitney's *U* test and Fisher's exact probability test. *P* values of less than 0.05 were considered significant.

RESULTS

Pancreatographic differences between AIP and PC

Whereas obstruction of the MPD was more frequently detected in PC (AIP: 4% *vs* PC: 69%, $P < 0.001$), skipped lesions of the MPD were detected only in AIP (27% *vs* 0%,

Figure 1 Pancreatography of autoimmune pancreatitis. A: Endoscopic retrograde cholangiopancreatography finding of autoimmune pancreatitis showing skipped lesions of the main pancreatic duct (short and long arrows); B: On magnetic resonance cholangiopancreatography, skipped lesions (short and long arrows) on endoscopic retrograde cholangiopancreatography were not visualized; C: Endoscopic retrograde cholangiopancreatography finding of autoimmune pancreatitis showing side branch derivation from the narrowed portion of the main pancreatic duct; D: Recent magnetic resonance cholangiopancreatography could show diffuse narrowing of the main pancreatic duct fairly well; E: Endoscopic retrograde cholangiopancreatography finding of autoimmune pancreatitis showing a short narrowed main pancreatic duct (arrow) with upstream dilatation less than 5 mm; F: On magnetic resonance cholangiopancreatography, the narrowed portion (arrow) was not visualized.

Figure 2 Endoscopic retrograde cholangiopancreatography finding of autoimmune pancreatitis showing stenosis of the hilar and intrahepatic bile duct.

$P < 0.001$ (Figure 1A), and side branch derivation from the narrowed portion of the MPD was more frequent in AIP (81% *vs* 22%, $P < 0.001$) (Figure 1C). The narrowed MPD was longer in AIP (7.6 ± 4.3 cm *vs* 2.5 ± 0.9 cm, $P < 0.001$), and a narrowed MPD longer than 3 cm was more frequent in AIP (90% *vs* 27%, $P < 0.001$). The maximal diameter of the upstream MPD was smaller in AIP (2.9 ± 0.8 mm *vs* 6.8 ± 2.1 mm, $P < 0.001$), and upstream dilatation of the MPD less than 5 mm was more frequent in AIP (95% *vs* 27%, $P < 0.001$) (Figure 1E) (Table 1). A short narrowed MPD was difficult to differentiate from stenosis of the MPD in PC (Figure 1E).

Cholangiographic differences between AIP and PC

Stenosis of the lower bile duct was smooth in 33 (87%)

AIP patients, but irregular in 50 (65%) PC patients ($P < 0.001$). Left-side deviation of the lower bile duct was detected in both groups. Stenosis of the intrahepatic or hilar bile duct was detected in only six AIP patients ($P = 0.001$) (Figure 2) (Table 2).

Diagnostic accuracy for AIP by ERCP and MRCP

In diffuse-type AIP, diffuse narrowing of the MPD on ERCP was shown as skipped non-visualized lesions in 50% (Figure 1B), faint visualization in 19%, and non-visualization in 31% on MRCP. Diffuse narrowing of the MPD could be fairly well visualized in two recent patients (Figure 1D). Side branches from the narrowed portion of the MPD shown on ERCP were visualized faintly only in 21% on MRCP. Stenosis of the bile duct was also detected on MRCP. After steroid therapy, the MPD was visualized in 100%, and the branches were visualized in 50% on MRCP. Resolution of bile duct lesions was seen completely in 53% and incompletely in 47% on MRCP (Table 3).

In segmental-type AIP, segmental narrowing of the MPD on ERCP was shown as faint visualization in 14% and non-visualization in 86% on MRCP (Figure 1F). Side branches from the narrowed MPD shown on ERCP were visualized faintly only in 18% on MRCP. After steroid therapy, the MPD was visualized in 100%, and the branches were visualized in 60% on MRCP. Resolution of bile duct lesions was seen completely in 50% and incompletely in 50% on MRCP (Figure 3A and B) (Table 4).

		Incomplete 7/15 (47%)

ERCP: Endoscopic retrograde cholangiopancreatography; MRCP: Magnetic resonance cholangiopancreatography; MPD: Main pancreatic duct.

DISCUSSION

AIP responds dramatically to steroid therapy; therefore, it is of the utmost importance that AIP be differentiated from PC to avoid unnecessary laparotomy or pancreatic resection. Histopathological findings of AIP in Japan are characterized by dense infiltration of T lymphocytes and IgG4-positive plasma cells, storiform fibrosis, and obliterative phlebitis in the pancreas; this is called LPSP. Abundant lymphoplasmacytic cells infiltrate around interlobular ducts with fibrosis, especially the medium and large ducts, including the MPD. The periductal inflammation is usually extensive and distributed throughout the entire pancreas. However, the degree and extent of periductal inflammation differ from duct to duct according to the location of the involved pancreas. The infiltrate is primarily subepithelial, with the epithelium only rarely being infiltrated by lymphocytes. It encompasses the ducts and narrows their lumen by infolding of the epithelium. If the inflammatory pro-

cess affects the pancreatic head, it usually also involves the lower common bile duct, where it leads to a marked thickening of the bile duct wall due to fibrosis with lymphoplasmacytic infiltration. The epithelium of the bile duct is also well preserved. The thickening of the bile duct wall sometimes spreads extensively to the bile duct, where stenosis is not apparent on cholangiography[4,14-16]. On the other hand, PC cells infiltrate scirrhously, destroy the epithelium of the pancreatic and bile ducts, and frequently obstruct the main and branch pancreatic ducts. These histopathological differences around the ducts represent the different cholangiopancreatographic findings between AIP and PC. Pancreatographic findings, such as no obstruction of the MPD, skipped lesions of the MPD, side branch derivation from the narrowed portion of the MPD, narrowed portion of the MPD > 3-cm-long, a maximal diameter < 5 mm of the upstream MPD, and smooth stenosis of the lower bile duct are highly suggestive of AIP rather than PC. Stenosis of the intrahepatic or hilar bile duct is recognized as other

organ involvement of AIP and supports the diagnosis of AIP rather than PC, although it should be distinguished from cholangiocarcinoma and primary sclerosing cholangitis[17,18]. Wakabayashi et al[19] compared pancreatograms of nine segmental-type AIP patients and 80 PC patients. They reported that obstruction of the MPD was frequent in PC [11% (1/9) vs 60% (48/80)]. A narrowed portion of the MPD ≥ 3-cm-long [100% (8/8) vs 22% (6/27)] and a maximal diameter < 4 mm of the upstream MPD [(67% (4/6) vs 4% (1/23)] were frequently detected in AIP, and side branch derivation from the narrowed portion of the MPD was detected in 50% (4/8) of AIP patients[19]. In Nakazawa's cholangiopancreatographic study of 37 AIP patients, skipped lesions of the MPD were detected in six (16%) patients, and stenosis of the intrahepatic or hilar bile duct was detected in 16 (43%) patients[20].

The major problem with MRCP for diagnosing AIP is that the narrowed MPD seen on ERCP cannot be visualized on MRCP, because of the inferior resolution of MRCP compared with ERCP. Segmental narrowing of the MPD seen on ERCP was not visualized in 86% on MRCP, and distinguishing between AIP and PC was quite difficult on MRCP. However, in these cases, less upstream dilatation of the MPD on MRCP may suggest AIP rather than PC. In diffuse-type-, diffuse narrowing of the MPD on ERCP was shown as skipped, non-visualized lesions in 50% and faintly visualized in 19% on MRCP. With the

development of MRCP models, diffuse narrowing of the MPD could be visualized fairly well on MRCP in two recent patients. Skipped, non-visualized lesions and a faintly visualized, narrowed MPD can suggest AIP with typical diffuse enlargement of the pancreas on CT or MRI. Side branch derivation from the narrowed portion of the MPD is a useful pancreatographic finding suggesting AIP, but the finding can rarely be seen on MRCP. However, stenosis of the bile duct was also detected on MRCP and resolution of the pancreatic and bile ducts after steroid therapy can be fully evaluated on MRCP. Park et al[21] also reported that skipped MPD narrowing and less upstream MPD dilatation on MRCP suggest AIP. Although secretin is not available in Japan currently, secretin-MRCP is reported to enable demonstration of the integrity of the MPD and lead to a correct diagnosis of AIP[22].

In conclusion, the following ERCP findings are fairly specific for AIP and are useful to differentiate AIP from PC: less obstruction of the MPD, skipped lesions of the MPD, side branch derivation from the narrowed portion of the MPD, length of the narrowed MPD > 3 cm, maximal diameter of the upstream < 5 mm, smooth stricture of lower the bile duct, and stenosis of intra or hilar bile duct. Although MRCP cannot fully replace ERCP for the diagnostic evaluation of AIP, MRCP may deserve to be used in some diffuse-type AIP cases and is useful for follow-up of AIP.

COMMENTS

Background
Autoimmune pancreatitis (AIP) is a peculiar type of pancreatitis of presumed autoimmune etiology. Since AIP responds dramatically to steroid therapy, it is most important that AIP be differentiated from pancreatic cancer (PC) to avoid unnecessary laparotomy or pancreatic resection. However, some cases were still difficult to distinguish between AIP and PC.

Research frontiers
Pancreatographic findings to facilitate differentiating between AIP and PC on endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) were investigated.

Innovations and breakthroughs
Obstruction of the main pancreatic duct (MPD) was more frequently detected in PC. Skipped MPD lesions and side branch derivation from the narrowed MPD were detected in AIP. The narrowed MPD was longer in AIP. Maximal diameter of the upstream MPD was smaller in AIP. Stenosis of the lower bile duct was smooth in AIP and irregular in PC patients. Stenosis of the intrahepatic or hilar

bile duct was detected only in AIP. Diffuse narrowing of the MPD on ERCP was shown as a skipped non-visualized lesion in 50% and faint visualization in 19% on MRCP.

Applications

Several ERCP findings are useful to differentiate AIP from PC. MRCP cannot replace ERCP for the diagnostic evaluation of AIP, but some MRCP findings support the diagnosis of AIP.

Peer review

This is a well-written manuscript about pancreatography for diagnosing autoimmune pancreatitis and is of some interest.

Abstract

AIM: To determine whether absorbable sutures or non-absorbable sutures are better in preventing surgical site infection (SSI), in this paper we discuss the results of a randomized clinical trial which examined the type of sutures used during hepatectomy.

METHODS: All hepatic resections performed from January 2007 to November 2008 at the Department of Surgery at Iizuka Hospital in Japan were included in this study. There were 125 patients randomly assigned to an absorbable sutures (Vicryl) group or non-absorbable sutures (Silk) group.

RESULTS: SSI was observed in 13.6% (17/125) patients participating in this study, 11.3% in the Vicryl group and 15.8% in the Silk group. Incisional SSI including superficial and deep SSI, was observed in 8% of the Vicryl group and 9.5% of the Silk group. Organ/space SSI was observed in 3.2% of the Vicryl group and 6.0% of the Silk group. There were no significant differences, but among the patients with SSI, the period for recovery was significantly shorter for the Vicryl group compared to the Silk group.

CONCLUSION: The incidence of SSI in patients receiving absorbable sutures and silk sutures is not significantly different in this randomized controlled study; however, the period for recovery in patients with SSI was significantly shorter for absorbable sutures.

INTRODUCTION

Despite recent developments in surgery and patient management during the perioperative period, critical complications still develop in a few patients who undergo hepatic resection[1,2]. Surgical site infection (SSI) is one of the most important morbidities of surgery and leads to prolonged hospital stays. Previous studies revealed absorbable suture material in gastrointestinal surgical procedures to reduce the risk of SSI[3,4] although most of those studies have been limited to skin closures. Absorbable sutures are used in most hospitals in the United States and Europe based on the available clinical studies. On the other hand, silk sutures are still used in most hospitals in Japan. A

study by Kobayashi *et al*[5] revealed patients with intraoperative bowel injury, blood loss > 2000 mL, and age > 65 years are at risk of developing SSI after hepatectomy for liver cancers and then all blood vessels and bile ducts were ligated with silk or vessel clips during parenchymal resection. Absorbable sutures are now widely used for abdominal closure in Japan according to the CDC guidelines[6]. During the resection of the liver, silk sutures are generally used for the vessels in Japan, because silk sutures are easier to handle and less expensive than absorbable sutures. However, foreign materials, especially silk, are known to accelerate infection[6,7] and thus lead to a prolonged hospital stay. Togo *et al*[8] reported the usefulness of absorbable sutures to prevent SSI with a historical control study using an animal model. There has been no known randomized clinical trial for suture material used in the ligation of the cut surface of the liver. In this paper the authors provide the outcome of a randomized clinical trial investigating the type of sutures used during hepatectomy to determine which is better in preventing SSI, absorbable sutures or non-absorbable sutures.

MATERIALS AND METHODS

Study design

All hepatic resections without biliary reconstruction performed from January 2007 to November 2008 at the Department of Surgery at Iizuka Hospital in Japan were included in this study. Only patients who met the following criteria were enrolled: (1) liver resection without biliary reconstruction; (2) without other malignancy; and (3) until compensated cirrhosis with Child-Pugh class A or B. At the author's department, the rate of SSI during hepatectomy was 25% according to previous data. The sample size required to detect a difference by chi-square test with 80% power at the 5% significance level was 124 patients. There were 130 patients enrolled in this study. One patient refused to participate in the study. The authors obtained approval from the local ethics committee and obtained informed consent from the other patients. Finally 125 patients were randomly assigned to an absorbable sutures (Vicryl, Johnson & Johnson Corp., Tokyo, Japan) or a non-absorbable sutures (Silk) group. Because the operative procedure used on 4 patients was either conversion to radiofrequency ablation or biliary reconstruction (Figure 1) they were not included in the study. Randomization was achieved by providing sealed envelopes to be opened by the operator before laparotomy. Data analysis was performed for 125 patients.

Liver function was evaluated preoperatively using Child classification and indocyanine green retention test at 15 min (ICGR15) in patients with underlying liver disease. The presence of ascites and ICGR15 test value of more than 40% were considered an absolute contraindication for resection. Hepatitis B surface antigen (HBs Ag) and hepatitis C antibody (HCV Ab) were routinely measured preoperatively.

Surgical technique and intra-operative care were stan-

Figure 1 The trial profile of the patients in this study. RFA: Radiofrequency ablation.

dardized by the same team in this study. These included a J-shaped incision for routine abdominal access, a slow and gentle hepatic dissection using an ultrasonic dissector with coagulator (CUSA Excel, Integra Co., USA), with systematic ligation of all sizable vessels, and close ultrasonographic guidance along the transection line. Cholecystectomy was performed in all patients if the gallbladder was present. Intraoperative bile leakage test was routinely performed to identify bile leakage[9]. With this procedure, we recognized small bile leakage sites on the cut liver surface and could repair these sites by Z-suturing using 6-0PDSII (Johnson & Johnson Corp., Tokyo, Japan). Intraoperative vascular control was achieved using the Pringle maneuver[10]. In order to prevent backflow bleeding central venous pressure was decreased to as low as 5 mm Hg when possible with careful circulating volume and respiratory assistance. When central venous pressure control was insufficient, outflow control was achieved by selective vascular exclusion, or by clamping of the infrahepatic inferior vena cava[11]. One or two closed drains were inserted close to the cut surface of liver parenchyma. Before the subcutaneous tissue was closed, the wound was washed with 1 L saline. Vicryl (Johnson & Johnson Corp., Tokyo, Japan), an absorbable suture material, was used during abdominal wound closure. Drains were removed when no bleeding or bile leakage were observed within 3 d. Bile leakage was defined as the drainage of macroscopic bile from the surgical drains for more than 7 d after surgery[9]. If bile leakage is clinically suspected after the removal of drains, percutaneous drainage is performed. Intravenous ampicillin/sulbactam (ABPC/SBT) 1.5 g was administered 30 min before surgery and additional ABPC/SBT was administered every 3 h. Systemic antibiotics were used for only two days after surgery. During the operation gloves were changed every 3 h.

Postoperative infection

SSI was defined as a condition in which purulent dis-

charge was observed from any incision or space that was manipulated during an operation with or without microbiological evidence as in the guideline issued by CDC[6] and it was identified prospectively by direct observation of the surgical site. Patients were followed up 30 d after hospital discharge. SSI occurring after hospital discharge was included in this study. Remote infection was defined as a condition in which fever and leukocytosis were present with bacteria in sputum, urine, catheter-tip, blood, or other body fluid/space with or without microbiological evidence.

Statistical analysis

We analyzed associations between the continuous and categorical clinico-pathologic variables using the Student's *t* tests and χ^2 tests, respectively. Multivariate analysis was performed with a logistic regression test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Incidence of postoperative infection

The clinicopathological factors between the Vicryl and Silk groups were compared (Table 1). No significant differences were recognized during the evaluation of the host factors and the operative factors. SSI was observed in 13.6% (17/125) of patients in this study, 11.3% in the Vicryl group and 15.8% in the Silk group (*P* = 0.620). Incisional SSI including superficial and deep SSI, were observed in 8% of the Vicryl group and 9.5% of the Silk group (*P* =

0.999). Organ/space SSI was observed in 3.2% of the Vicryl group and 6.0% of the Silk group (*P* = 0.680). Organ/space SSI was namely abdominal abscess and percutaneous drainage was needed. Remote infection was observed with an incidence of 3.2% in the Vicryl group and 1.6% in the Silk group (*P* = 0.546). Pneumonia and urinary tract infection were observed in the Vicryl group and pneumonia in the Silk group. There were no significant differences. There was no hospital mortality in this study.

Risk factor for SSI

In the univariate analyses, operation time > 265 min, blood loss > 1000 g, and bile leakage differed significantly as predictive factors of SSI (Table 2). The type of sutures was not significant. Five factors including operation time > 265 min, blood loss > 1000 g, bile leakage and the type of sutures were analyzed with multivariate logistic regression. Results are given in Table 3. Blood loss > 1000 g was the only independent variable among the five factors.

Comparison of duration to recovery in the patients with SSI

Among the patients with SSI, the period for recovery in the Vicryl group was significantly shorter compared to the Silk group (Table 4).

DISCUSSION

Togo *et al*[8] reported the usefulness of absorbable sutures to prevent SSI with a historical control study using an animal model. This is the only report that the use of

Table 3 Multivariate logistic stepwise regression analysis for predictive factors of surgical site infection

	Adjusted odds ratios (95% CI)	*P* value

> 1000 g	7.598 (1.396-41.364)	< 0.01

Table 4 Comparison of the period for recovery in patients with surgical site infection

Vicryl	28 ± 11 d
Silk	54 ± 30 d

P < 0.05.

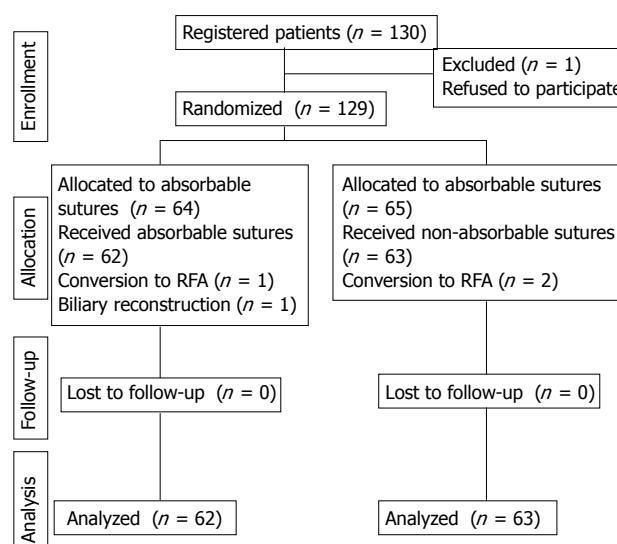
absorbable sutures contributed significantly to the prevention of development of SSI. In our prospective study, the incidence of SSI in the Vicryl group was lower compared to the Silk group for both incisional SSI and organ/space SSI, however there were no other significant differences. Watanabe *et al*[12] reported the use of absorbable sutures in seromuscular suturing or intra-abdominal ligation was associated with a significantly lower incidence of SSI than non-absorbable sutures in the lower alimentary tract procedure, but not in the upper. The incidence of SSI is low so any significant difference is difficult to observe. The duration for recovery from SSI was significantly shorter in the Vicryl group than in the Silk group. Since SSI increases treatment costs and diminishes patient satisfaction markedly, the use of an absorbable suture is recommended in view of the medical economy and patient's quality of life.

The incidence of SSI as a form of postoperative infection was previously reported to be 20%-25%[8,13,14]. In our clinical experience, the incidence of SSI was observed to be 13.1% in this study and the rate of occurrence is decreasing every year because of SSI surveillance and development of surgical techniques such as closed suction drain and the prevention of bile leakage. Togo *et al*[8] reported the incidence of postoperative infection gradually decreased significantly with additional countermeasures. A larger sample size as well as a multi-institutional study is required for a randomized controlled study. Intraoperative blood loss, long operation time and bile leakage were associated with SSI in our study. Both transfusion and operation time are reported to be risk factors of SSI in hepatectomy or other surgery[5,15]. Transfusion could induce immunosuppression in postoperative patients by reduction of the natural killer cell and cytotoxic T-cell populations[16,17]. Operation time could influence the concentration of systemic antibiotics, leading to the incidence of SSI. Bile leakage was observed at 4.8% (6/125) in this study. Generally the incidence of bile leakage was 4.0%-7.2% in recently reported large series[9,18-20]. The presence of bile, blood, and devitalized tissues in the dead space after hepatectomy may provide the ideal environment for bacterial growth and development of organ/space SSI, which frequently results in liver failure. To reduce organ /space SSI, it is most impor-

tant to prevent bile leakage.

In conclusion, there were no significant differences between absorbable sutures and silk sutures on the incidence of SSI during the resection of the liver in this randomized control study; however, the period for recovery in patients with SSI was significantly shorter for absorbable sutures. Further study is needed to provide evidence on the use of absorbable or non-absorbable suture materials in a multi-institutional randomized clinical trial.

COMMENTS

Background
Surgical site infection (SSI) is one of the most important morbidities of surgery and leads to prolonged hospital stays. In this paper the authors provide the outcome of a randomized clinical trial investigating the type of sutures used during hepatectomy to determine which is better in preventing SSI, absorbable sutures or non-absorbable sutures.


Research frontiers
During the resection of the liver, silk sutures are generally used for the vessels in Japan, because silk sutures are easier to handle and less expensive than absorbable sutures.

Innovations and breakthroughs
This is a randomized clinical trial investigating the type of sutures used during hepatectomy.

Applications
The incidence of SSI was not significantly different between absorbable sutures and silk sutures in this randomized controlled study; however, the period for recovery in patients with SSI was significantly shorter for absorbable sutures.

Terminology
Vicryl is an absorbable suture material and silk is a non-absorbable suture material, which is widely used in Japan.

Peer review
Authors report prospective randomized study of surgical site infection comparing silk to vicryl ties in liver resection.

Abstract

AIM: To evaluate the association between xeroderma pigmentosum group D (XPD), genetic polymorphism Lys751Gln and esophageal cancer risk.

METHODS: We searched PubMed up to September 1, 2010 to identify eligible studies. A total of 10 case-control studies including 2288 cases and 4096 controls were included in the meta-analysis. Statistical analysis was performed with Review Manage version 4.2. Odds ratios (ORs) with 95% confidence intervals (CIs) were used to assess the strength of the association.

RESULTS: The results suggested that there is no significant association between XPD Lys751Gln polymorphism and esophageal cancer susceptibility in the overall population. However, in subgroup analysis by histology type, a significant association was found between XPD Lys751Gln polymorphism and esophageal adenocarcinoma (for CC *vs* AA: OR = 1.25, 95% CI = 1.01-1.55, *P* = 0.05 for heterogeneity).

CONCLUSION: Our meta-analysis suggested that XPD Lys751Gln polymorphism may be associated with increased risk of esophageal adenocarcinoma.

INTRODUCTION

Esophageal cancer, with a 5-year survival rate of < 20%, is considered as one of the most deadly malignancies[1,2]. It has already been identified that cigarette smoking, alcohol drinking, obesity, dietary factors, history of Barrett's esophagus, and esophageal reflux disease can contribute to the development of esophageal cancer[3-6]. However, only a fraction of exposed individuals develop esophageal carcinoma, which suggests that genetic variations in sensitivity to carcinogen exposure and DNA repair capacity

might be important inherited risk components in carcinogenesis[7,8]. DNA damage caused by exogenous, endogenous carcinogens or mutants is viewed as a crucial event in carcinogenesis. It can be repaired through activation of various pathways such as the nucleotide excision repair pathway (NER), base excision repair pathway (BER) and double-strand break pathway. The xeroderma pigmentosum group D (XPD) enzyme is involved in the NER pathway which plays an important role in the repair of bulky DNA adducts, such as pyrimidine dimmers, photoproducts and cross-links[9]. Several single-nucleotide polymorphisms (SNPs) have been identified in the XPD gene. Among them, a polymorphism in the XPD gene, codon 751 A to C, resulting in an amino acid alteration from lysine (Lys) to glycine (Gln) has been reported to be associated with an increased susceptibility to lung cancer, and head and neck carcinoma[10-12]. Other malignancies such as esophageal cancer have also been investigated.

To date, many molecular epidemiological studies have explored the association between XPD Lys751Gln polymorphism and esophageal cancer risk[12-23]. However, results of these studies are controversial, which may be caused by the limitation of individual studies. Therefore, we performed a meta-analysis of 10 published case-control studies covering 6384 subjects in order to get a more precise evaluation of the relationship between the XPD Lys751Gln polymorphism and esophageal cancer risk.

MATERIALS AND METHODS

Search strategy

We conducted a comprehensive search in the US National Library of Medicine's PubMed database (as of September 1, 2010) using search terms including "XPD", "xeroderma pigmentosum group D", "ERCC2", "excision repair cross-complementing rodent repair deficiency", "polymorphism", "esophageal", "esophagus" and the combined phrases for all genetic studies on the relationship between XPD polymorphism and esophageal cancer. Moreover, we reviewed the references from original articles to search for more studies. No language restrictions were imposed. Two investigators conducted all searches independently. Studies were absorbed in this meta-analysis if they met the following criteria: (1) a case-control study of the XPD Lys751Gln polymorphism and esophageal cancer risk; and (2) the authors must offer the size of the sample, odds ratios (ORs) with 95% confidence intervals (CIs) or the information that can help infer the results in the articles. If data were reported in more than one study, the most recent and complete study was chosen for this analysis.

Data extraction

Two investigators independently extracted data and reached a consensus on all of the items. Information was collected from each article, including the first author's name, year of publication, country of origin, racial descent of the subjects (categorized as Asian, European and mixed populations), sources of controls, genotyping method, histological type (categorized as esophageal adenocarcinoma and squamous cell carcinoma), number of different genotypes in cases and controls, Hardy-Weinberg equilibrium (HWE), and minor allele frequency in controls.

Statistical analysis

We assessed the strength of association between XPD Lys751Gln polymorphism and esophageal cancer risk by using ORs with 95% CIs which were obtained from the data given in the eligible studies. We evaluated the risk of codominant model (CC *vs* AA, CA *vs* AA), the dominant model (CA/CC *vs* AA), and recessive model (CC *vs* AA/CA), respectively. The between-study heterogeneity was investigated by Chi-square based Q-test[24], and it was considered significant if $P < 0.05$. The random-effects model (DerSimonian and Laird method) was then selected to pool the data[25]. Otherwise, the fixed-effects model (Mantel-Haenszel method) was used[26]. If heterogeneity was absent, these two models provided similar results. We used the funnel plot and the Egger weighted regression method ($P < 0.05$ was considered representative of statistical significance) to test possible publication bias in this meta-analysis[27]. All statistical analyses were performed in Statistical Analysis System software (v.9.13; SAS Institute, Cary, NC), and Review Manage (v.4.2; Oxford, England). All the tests were two-sided and the significant level was 0.05.

RESULTS

Eligible studies

A total of 12 potential relevant studies that described the association between the XPD genetic polymorphisms and esophageal cancer were retrieved through PubMed. After reading the full articles, one study by Liu *et al*[17] was excluded since the subjects had also been included in a study by Tse *et al*[20]. One other study was excluded because it did not list data clearly enough for further analysis[23]. Finally, we identified 10 eligible studies including 2288 cases and 4096 controls in total. As summarized in Table 1, four studies were conducted in Asians, four studies in Europeans, and two in mixed subjects. In terms of histology type, there were 4 studies of esophageal adenocarcinoma (EADC), 4 studies of esophageal squamous cell carcinoma (ESCC) and 2 of both EADC and ESCC. Diverse genotyping methods including PCR-RFLP, TaqMan and iPLEX™ were used. The classic PCR-RFLP assay was used in 60% (6/10) studies. Six studies mentioned the quality control. The genotype distributions in the controls of all the included studies were in accordance with HWE.

Meta-analysis

The main results of the meta-analysis on the association between XPD Lys751Gln polymorphism and esophageal cancer risk are shown in Table 2. Overall, no significant association was found between XPD Lys751Gln polymorphism and esophageal cancer risk (for CC *vs* AA: OR = 1.19, 95% CI = 0.84-1.69, $P = 0.01$ for heterogeneity, Figure 1; for CA *vs* AA: OR = 1.03, 95% CI = 0.83-1.27, $P = $

Figure 2 Odds ratio of esophageal cancer associated with xeroderma pigmentosum group D Lys751Gln polymorphism for the CC genotype compared with the AA/AC genotypes. XPD: Xeroderma pigmentosum group D; OR: Odds ratio.

Figure 3 Funnel plot analysis to detect publication bias. Each point represents a separate study for the indicated association. The Odds ration is plotted on a logarithmic scale against the precision (the reciprocal of the SE).

further analysis by histological type revealed that individuals carrying the variant homozygote CC genotype showed an elevated risk to EADC compared to those with the wild-type AA genotype (OR = 1.25, 95% CI = 1.01-1.55, $P = 0.05$ for heterogeneity).

Publication bias

Funnel plot and the Egger's test were performed to assess possible publication bias. As shown in Figure 3, no publication bias was revealed by the funnel plots, which was approximately symmetrical for the codominant model CC *vs* AA and the recessive model CC *vs* CA/AA. Statistical evidence from the results of Egger's test confirmed the funnel plot symmetry (for CC *vs* AA: $t = 2.23$, $P = 0.06$; for CA *vs* AA: $t = 2.03$, $P = 0.08$; for CA/CC *vs* AA: $t = 1.48$, $P = 0.18$; for CC *vs* CA/AA: $t = 2.33$, $P = 0.05$).

DISCUSSION

Through analyzing data from the 10 eligible studies on

relationship between XPD Lys751Gln polymorphism and esophageal cancer risk, we found no significant association between XPD Lys751Gln polymorphism and esophageal cancer risk in overall population. However, in the stratified analysis according to histological type, positive association were observed between XPD Lys751Gln polymorphism and elevated susceptibility to EADC.

The XPD gene has been mapped in chromosome 19q13.3. It spans over 20 kb, contains 23 exons and encodes the 761-amino acid protein. The XPD protein possesses both single-strand DNA-dependant ATPase and 5'-3' DNA helicase activities, which is essential for NER pathway and transcription[28]. The NER pathway generally removes bulky adducts caused by exogenous carcinogens, especially from cigarette smoking which is a well defined risk factor for EADC[29]. Any functional variation in NER pathway such as SNPs of key repair genes may lead to a deficiency in the DNA repair capacity (DRC) which is associated with a higher risk of cancer[28,30-32]. Benhamou *et al*[33] found that the single nucleotide substitution from A to C at codon 751 in the XPD gene leads to a complete change in the electronic configuration of the resulting amino acid, and reduces DNA repair efficiency. Many epidemiological studies have investigated the association between XPD Lys751Gln polymorphism and esophageal cancer, but the results were inconclusive. Xing *et al*[12] first explored the polymorphisms of DNA repair gene XPD and their associations with risk of esophageal squamous cell carcinoma in a Chinese population, but a Lys751Gln polymorphism in the XPD gene did not influence risk of ESCC in this study. However, two other studies on the relationship between XPD Lys751Gln polymorphism and ESCC revealed a contradictive result which suggested an increased risk of ESCC in association with the XPD 751 Gln/Gln genotype[13,15]. The more interesting finding revealed by Zhai *et al*[22] suggested an inverse association, which indicated that the XPD codon 751Gln allele was a protective factor rather than a risk factor to ESCC (OR = 0.628, 95% CI = 0.400-0.986). The first study

on the association between XPD 751 codon polymorphism and EADC was conducted by Casson, who observed the protective effect of the homozygous variant of XPD Lys-751Gln for EADC (OR = 0.24, 95% CI = 0.07-0.88)[14]. However, this result has not been supported by more studies. Both studies of Ye *et al* and Tse *et al* suggested that the XPD 751Gln allele was associated with an elevated risk for esophageal adenocarcinoma which is consistent with the result of our meta-analysis.

Some limitations of our meta-analysis should be acknowledged. Firstly, though it is known that the XPD gene has more polymorphisms than just Lys751Gln, we focused our meta-analysis on the most studied Lys-751Gln polymorphism due to limited evidence on others. Secondly, some studies on this relationship were modified by some other potentially suspected factors such as BMI, smoking status, alcohol consumption, history of gastroesophageal reflux disease and lifestyle; however, our results were based on unadjusted estimates due to a lack of the original data. Finally, the XPD gene may influence susceptibility to esophageal cancer with other genes, but we did not conduct the gene-gene interactions analysis in our study.

In conclusion, our meta-analysis suggested that XPD Lys751Gln polymorphism may be a risk factor for esophageal adenocarcinoma. Large and well designed epidemiological studies will be necessary to combine genetic factors together with other potential risk factor such as smoking status, alcohol consumption and history of gastroesophageal reflux disease in order to validate the relationship between XPD Lys751Gln polymorphism and esophageal cancer risk.

ACKNOWLEDGMENTS

COMMENTS

Background

Esophageal cancer is one of the most deadly malignancies. Many studies have explored the association between the Xeroderma pigmentosum group D (XPD) genetic polymorphism Lys751Gln and esophageal cancer risk, but the results are inconclusive and even controversial. It is, therefore, necessary to perform a meta-analysis in order to get a more precise evaluation of the relationship between the XPD Lys751Gln polymorphism and esophageal cancer risk.

Research frontiers

The XPD gene is responsible for bulky adducts and repair of UV-induced DNA damage. To date, there have been many case-control studies on the association between XPD Lys751Gln and esophageal cancer risk, but few meta-analyses were conducted on this topic.

Innovations and breakthroughs

Our meta-analysis suggested that XPD Lys751Gln polymorphism might alter individuals' susceptibility to esophageal adenocarcinoma. Further studies are needed to confirm it.

Applications

The finding that individuals carrying the variant homozygote CC genotype showed an elevated risk to esophageal adenocarcinoma indicates that genetic variations in the DNA repair protein may contribute to the risk of EADC. This meta-analysis gave a structured and systematic integration of information on the etiology of esophageal cancer, and the result may provide valuable information for researchers and clinicians.

Peer review

This is a review of the ten previously published association studies and extracted the importance of esophageal adenocarcinoma. This information is worthwhile.

Abstract

Lapatinib is an inhibitor of the tyrosine kinases of human epidermal growth factor receptor type 2 (HER2) and epidermal growth factor receptor type 1, with clinical activity in HER2-positive metastatic breast cancer. We present here a 60 year-old patient with metastatic breast cancer who presented with jaundice and increased serum aminotransferase levels and who had been treated with lapatinib for the previous 14 days. Laboratory tests excluded other causes of acute liver injury. Liver biopsy revealed lesions compatible with drug-induced hepatotoxicity. Bilirubin and liver enzymes returned to normal within three months of lapatinib discontinuation. Lapatinib should be included among the causes of drug-induced hepatitis.

INTRODUCTION

Metastatic breast cancer is the leading cause of death from cancer among women worldwide[1]. The overexpression of human epidermal growth factor receptor type 2 (HER2) predisposes patients to a greater risk for disease progression and death than women whose tumors do not overexpress HER2[2]. Therapeutic approaches to block HER2 signaling pathways include both trastuzumab (a recombinant, humanized, monoclonal antibody that binds to the extracellular domain of the HER2) and lapatinib. Lapatinib is an orally administered small molecule that inhibits the tyrosine kinases of HER2 and epidermal growth factor receptor type 1 (EGFR). A number of studies have shown that lapatinib has clinical activity in patients with HER2-positive breast cancer, with a significant reduction in the risk of disease progression[3]. Lapatinib is generally well tolerated and the most common treatment-related adverse events include rash, diarrhea, and nausea[4].

We report here a case of advanced breast cancer treated with lapatinib with drug induced hepatitis. Upon discontinuation of lapatinib, levels of serum aspartate amino transferase (SGOT) and serum alanine amino transferase (SGPT) declined progressively.

CASE REPORT

A 60 year-old woman presented with metastatic breast cancer in the lung. Three years earlier she was diagnosed with invasive ductal adenocarcinoma of the right breast

Figure 1 Photomicrograph. A: Areas of bridging necrosis (HE x 200); B: Areas of centrilobular hepatocellular dropout, hemorrhage and macrophages (HE x 200).

(pT1cN0M0). Immunohistochemistry was positive for estrogen (70% positive cells), progesterone (2% positive cells) receptors and for HER-2. She was treated with lumpectomy and axillary lymph node dissection. Subsequently she received adjuvant chemotherapy (four cycles of epirubicin/cyclophosphamide followed by 4 cycles of paclitaxel) and treatment with the monoclonal antibody trastuzumab for one year. Furthermore, radiotherapy was given to the entire breast as an adjunct to breast conservation treatment and hormonal therapy with the aromatase inhibitor exemestane was started. She remained free of disease for three years.

In terms of periodic reassessment, the patient had a computed tomography (CT) of the chest in January 2010 and was found to have three nodules in the right lung compatible with metastatic sites. A CT of the brain and abdomen showed no abnormalities and a mammogram of both breasts and a bone scan were also normal. According to laboratory data, there were no abnormal values.

The patient commenced therapy with capecitabine (1000 mg/m^2 twice daily, day 1-14) and lapatinib (1250 mg/d), while exemestane was discontinued after two and a half years of continuous administration. After ten days, capecitabine was discontinued due to grade 2 diarrhea and the patient continued to receive lapatinib only.

Two weeks later, the patient developed jaundice without any other clinical signs such as asthenia or pruritus and she was evaluated in the Department of Clinical Oncology.

Physical examination was unremarkable except for jaundice and mild hepatomegaly. Laboratory results showed: SGPT 583 U/L units (normal range: 5-45), SGOT 457 U/L (normal range: 5-40), ALP 348 U/L (normal limits < 270), g-glutamyl transpeptidase 213 U/L (normal range: 10-55), total bilirubin 4.1 mg/dL (normal range: 0-1.5), LDH 305 units (normal range: 100-240), total protein 6.4 g/dL (normal range: 6-8.4), albumin 3.7 g/dL (normal range: 3.4-5), white blood cells 7500/mm^3, Hb 12.8 g/dL, Hct 38.8%, platelets 118 000/mm^3 and international normalized ratio-1.14 (normal range: 0.8-1.2). Other blood chemistry results, including glucose, cholesterol, triglycerides, serum amylase, uric acid, creatinine, BUN, Na, K, Ca as well as urinalysis were normal.

Serology tests for hepatitis A, B, and C viruses were

negative. Immune serology was also negative for ANA, anti-DNA, c-ANCA, p-ANCA, antismooth muscle, and antimitochondrial antibodies. Furthermore, thyroid hormone tests, a1-antitrypsin, IgG, IgA, IgM and blood ceruloplasmin levels were within normal limits.

Abdominal ultrasound demonstrated an increased-sized liver with non-homogeneous and diffuse echogenicity, without biliary tract abnormalities. Normal blood flow was seen in the portal vein, hepatic artery, hepatic veins, and inferior vena cava. A new abdominal CT showed hepatomegaly without biliary tract obstruction.

Fifteen days after the clinical evolution, a liver biopsy was performed and showed necrosis of contiguous hepatocytes in portal-to-portal and portal-to-central fashion (bridging necrosis). Foci of severe hemorrhage and hepatocellular dropout around the centrilobular areas were also demonstrated (Figure 1). Eosinophils were observed in more than twelve portal spaces without granulomas.

The patient was not taking other concomitant hepatotoxic medications, herbal or dietary supplements and did not have any underlying liver dysfunction, chronic hepatitis or alcohol use history.

Lapatinib was discontinued and both the patient's jaundice and liver function tests gradually improved and returned to normal range within 3 mo (Table 1).

DISCUSSION

Lapatinib combined with capecitabine has been approved for the treatment of patients with HER-2 positive metastatic breast cancer improving median time to disease progression[3].

Furthermore, recent studies suggest that single-agent lapatinib has clinical activity with manageable toxicity in HER2-overexpressing breast cancer that progressed on trastuzumab-containing therapy[4,5]. The fact that lapatinib inhibits EGFR signaling may also contribute to its activity in the context of refractory HER2-positive breast cancer.

No significant liver dysfunction has been recorded to lapatinib administration in any daily dose (500-1600 mg) in many phase I and II studies[5,6]. Hence, grade 3 and 4 liver toxicity with elevations in transaminases are uncommon after single agent lapatinib administration and only one out

Table 1 Evolution of laboratory tests after lapatinib discontinuation

	SGPT (U/L)	SGOT (U/L)	ALP (U/L)	GGT (U/L)	TBIL (mg/dL)
Baseline (before initiation of capecitabine/lapatinib)	24	21	120	11	0.8
Ten days later (capecitabine discontinuation due to diarrhea)	30	22	110	20	0.7
Two weeks after capecitabine discontinuation (lapatinib discontinuation)	583	457	348	213	4.1
Two weeks after lapatinib discontinuation	481	589	310	294	11.8
1 mo after lapatinib discontinuation	260	238	318	160	2.7
2 mo after lapatinib discontinuation	229	180	298	140	2.3
3 mo after lapatinib discontinuation	44	36	246	42	0.9

SGPT: Serum glutamic pyruvic transaminase; SGOT: Serum glutamic oxaloacetic transaminase; ALP: Alcaline phosphatase; GGT: Gamma-glutamyl transpeptidase; TBIL: Total Bilirubin.

of 37 patients experienced grade 3 elevation of transaminases in a phase Ⅱ trial in patients with brain metastases from HER-2 positive breast cancer[7].

Lapatinib is predominantly metabolized in the liver *via* the cytochrome P450 system, by the enzyme P450 3A4 and < 2% of the drug is excreted unchanged in urine.

Concurrent administration of the strong CYP3A4 inhibitor ketoconazole increases the lapatinib area under the curve and prolongs the t1/2. For this reason, strong inhibitors of CYP3A4, including grapefruit juice, should be avoided, as they may increase plasma concentrations of lapatinib and thus lapatinib toxicity[8].

Furthermore, it can be assumed that polymorphisms of the CYP3A4 gene may affect lapatinib disposition[9]. However, pharmacogenomical studies on the same gene did not show any correlation between gene polymorphisms and commonly observed toxicities such as exanthema or diarrhea caused by the use of erlotinib, an epidermal growth factor receptor tyrosine-kinase inhibitor[10].

The patient described in our case developed severe hepatic enzyme disturbances during lapatinib treatment and liver biopsy showed acute drug-induced hepatitis.

The patient did not take any other drug except lapatinib and recovered when the treatment was discontinued. There was no evidence of viral or autoimmune hepatitis or any other cause of hepatitis. Hepatic enzymes normalized rapidly after discontinuation of lapatinib.

The time to onset of jaundice and laboratory test abnormalities as well as the time and course of recovery, while the patient did not receive other medications, led us to support the idea that lapatinib is the most likely cause of hepatic injury. Exemestane appears not to be an important risk factor for the development of hepatitis because this medication was administered for two and a half years, without any clinical symptoms or abnormal laboratory tests.

Based on the fact that capecitabine was stopped only two weeks before the onset of symptoms, it was necessary to assesss the likelihood of the agent being causative. Capecitabine has not been implicated in hepatocellular injury and hepatitis with the specific histological features. Furthermore in order to confirm that liver injury was due to lapatinib, we used the Roussel Uclaf Causality Assessment Method, a scoring system which assigns attribution for drug-induced liver injury[11]. The summed points

grouped lapatinib into highly probable category, confirming our suggestion.

Our case demonstrates the potential risk of developing toxic hepatitis during treatment with lapatinib.

To conclude, to our knowledge this is the first case of acute drug-induced hepatitis secondary to lapatinib. Given that lapatinib is now often used in the treatment of HER-2 positive advanced breast cancer, it is mandatory for medical oncologists to be aware of this potential side effect in clinical practice.

Abstract

Transcatheter arterial chemoembolization (TACE) has become the standard treatment modality for unresectable hepatocellular carcinoma (HCC). Nonetheless, the clinical outcomes in patients with unresectable HCC are often unsatisfactory, especially in those with recurrent HCC. H101, an E1B gene deleted adenovirus, is known to have a significant antitumor activity. In addition, local injection of H101 can enhance the effect of antitumor therapies (chemotherapy and radiotherapy). Transarterial H101 gene injection in combination with TACE may help to control refractory and recurrent HCC. In this study, we report a 55-year-old patient with recurrent HCC which was treated with transarterial injection of H101 in combination with TACE, leading to a good clinical prognosis of the patient.

Transarterial injection of H101 in combination with chemoembolization overcomes recurrent hepatocellular carcinoma. *World J Gastroenterol* 2011; 17(18): 2353-2355 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i18/2353.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i18.2353

INTRODUCTION

It is difficult to eradicate hepatocellular carcinoma (HCC) because of its repeated recurrence in the liver. Surgical resection and transcatheter arterial chemoembolization (TACE) are the mostly used effective modalities for HCC, but it still frequently recurs after treatment with such modalities[1,2]. Gene therapy for tumors is a new hope in the 21st century. It is coming to be widely used in clinic and has achieved relatively well results especially when it is directly injected into the tumor[3-9]. Since combined TACE and gene injection may help to manage recurrent HCC, we tried to use the H101 gene in combination with TACE to treat our patient with recurrent HCC and achieved a good clinical prognosis.

CASE REPORT

A 55-year-old man was diagnosed with HCC in the right liver lobe, which was histologically proven (Figure 1A) in June 2006. The patient underwent six rounds of TACE from June 2006 to September 2008 (Figure 1B). His α-fetoprotein (AFP) level was 595.4 ng/mL after the six rounds of TACE, and decreased to 10.99 ng/mL after a partial hepatectomy. In February 2009, a recurrent nodule was found in the remnant liver at a routine postoperative computed tomography (CT) scan. At that time, his AFP level was 724 ng/mL. Because the effect of TACE was poor on HCC (Figure 2A), we decided to treat the patient with combined TACE and H101, a recombinant human type-5 adenovirus (Ad5), in which the E1B-55 kDs gene

is totally deleted (Oncorine, Shanghai Sunway Biotech, China). First, we injected 5-fluoro-2-deoxyuridine (1.0 g), vinorelbine (40 mg), and cisplatin (80 mg) into the celiac trunk. Then, H101 and iodized oil were injected into the artery that supplies the tumor. A total of 1×10^{12} virus particles (VP) and 10 mL iodized oil were administered.

The patient had no discomfort after the procedure. Two months later, routine follow-up CT showed a fairly good

result (Figure 2B) and the AFP level in the patient decreased to 338.4 ng/mL from 724 ng/mL before the treatment. We repeated this therapy 2 times at 2-mo interval. At the last admission, abdominal CT demonstrated complete deposit of oil with no signs of recurrence (Figure 2C). Furthermore, his AFP was within the normal reference range (4.56 ng/mL).

Eighteen months following the last H101/TACE treatment, the patient showed no evidence of recurrence and no abnormal liver function, but had a normal serum AFP level. The AFP levels in the patient during the therapy are listed in Table 1.

DISCUSSION

Although TACE has become the standard treatment modality for unresectable HCC, it is frequently unsuccessful[1,2].

Figure 3 Changes in α-fetoprotein levels during and after treatment.

Similarly, HCC recurs frequently following its resection. Although TACE was effective in our patient, HCC recurred and failed the seventh TACE. The recurred HCC was unresectable because it occupied the entire caudate lobe and was close to the vena cava and abdominal aorta. Thus, H101 in combination with TACE was attempted for the patient with a fairly good outcome without any complications. From Table 1 and Figure 3, we can see that the AFP level in the patient decreased significantly following treatment with TACE plus H101. Both the initial series of TACE and tumor resection failed to prevent recurrent HCC although AFP was controlled, whereas combined H101 and TACE appeared to be effective and well-tolerated.

H101 is a recombinant human type-5 adenovirus in which E1B-55 kDs gene is totally deleted. The H101 virus produced by Shanghai Sunway Biotech also contains a deletion in the E3 region with a significant antitumor activity. This recombinant adenovirus has a replication-selective property and replicates only in tumor cells. Before modification, the E1B region of the wild adenovirus type 5 expresses early gene products that bind to and inhibit the function of p53, a tumor suppressor. Deletion or mutation of the E1B region confers p53-selective replication of oncolytic viruses which infect tumor cells and induce massive accumulation of normal p53. By this way, the adenovirus causes direct cytotoxicity only to tumor cells during replication. The E3 region is related to the inhibition of host immunity, which enhances the virus replication and spread in tumors[3,4]. The virus replication and spread can be enhanced by repeated injection of H101. By sacrificing the spread ability, the virus may activate the host immune response to virus-infected tumor cells and help the host immune system to recognize tumor cells, thus benefiting patients under such a therapy. Metastasis is prevalent in patients with malignant tumors, leading to treatment failure and death of patients. Moreover, patients may have more than one tumor lesion, and some of these lesions may be hard to reach in order to be injected with H101. Therefore, the ability of H101 to activate the host immune response seems crucial. Treatment with the E3 region deleted adenovirus, H101, may have additional benefits to patients.

H101 is formulated as a sterile viral solution in phosphate buffered saline and kept at -20℃. Each vial contains 0.5 mL virus solution with 5×10^{11} viral particles and titered less than 1/60 of 50% tissue culture infectious dose.

Sterile and purified viruses were produced for clinical use by Shanghai Sunway Biotech (Shanghai, China), and tested for the titer, sterility, and general safety by National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Its safety has been demonstrated in a number of clinical trials[5-8].

Although the anticancer activity of H101 has been proved in a wide type of advanced cancer by intra-tumor injection, its clinical efficacy against liver cancer has been rarely reported[9-11]. Transcatheter arterial injection of H101 was effective against liver cancer in our patient, suggesting that H101 in combination with TACE is useful for recurrent HCC. However, subsequent large, multi-center randomized, controlled studies are needed to facilitate the introduction of genetically engineered and reinforced viruses as novel therapeutic platforms for the treatment of cancers.

Abstract

Bron *et al* presented a retrospective study regarding the prophylactic use of antibiotics for variceal hemorrhage. Antibiotics appeared to improve the survival rate of patients without increasing clostridium difficile infection (CDI). We argue against the conclusion of the authors and consider that this result may be simply due to concurrent use of metronidazole, a therapeutic agent against CDI.

TO THE EDITOR

Brown *et al*[1] presented a retrospective study regarding prophylactic use of antibiotics in treatment of variceal hemorrhage. The data show that antibiotics appear to improve the survival rate of patients without increasing Clostridium difficile infection (CDI). However, 70.3% of the patients who were given antibiotics received metronidazole, a therapeutic agent against CDI. No apparent increase in CDI may be simply due to the suppression of the organism by metronidazole. As pointed out in the article, currently recommended antibiotic for this purpose is ceftriaxone[2,3], which is known to predispose to CDI[4]. The result of the article should not be interpreted as the currently recommended use of ceftriaxone posing a low risk of CDI.

World Journal of Gastroenterology

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of

Gastroenterology

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (1), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

ABOUT COVER

Kwan LY, Targan SR, Shih DQ. A case of steroid-dependent myeloid granulocytic sarcoma masquerading as Crohn's disease. *World J Gastroenterol 2011*; 17(19): 2446-2449

http://www.wjgnet.com/1007-9327/full/v17/i19/2446.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Voltage-gated sodium channels (VGSCs) play a fundamental role in controlling cellular excitability, and their abnormal activity is related to several pathological processes, including cardiac arrhythmias, epilepsy, neurodegenerative diseases, spasticity and chronic pain. In particular, chronic visceral pain, the central symptom of functional gastrointestinal disorders such as irritable bowel syndrome, is a serious clinical problem that affects a high percentage of the world population. In spite of intense research efforts and after the dedicated decade of pain control and research, there are not many options to treat chronic pain conditions. However, there is a wealth of evidence emerging to give hope that a more refined approach may be achievable. By using electronic databases, available data on structural and functional properties of VGSCs in chronic pain, particularly functional gastrointestinal hypersensitivity, were reviewed. We summarize the involvement and molecular bases of action of VGSCs in the pathophysiology of several organic and functional gastrointestinal disorders. We also describe the efficacy of VGSC blockers in the treatment of these neurological diseases, and outline future developments that may extend the therapeutic use of compounds that target VGSCs. Overall, clinical and experimental data indicate that isoform-specific blockers of these channels or targeting of their modulators may provide effective and novel approaches for visceral pain therapy.

Key words: Voltage-gated sodium channel; Dorsal root ganglion; Visceral pain; Functional gastrointestinal disorders; Treatment

INTRODUCTION

Treating chronic pain remains a significant clinical challenge, and in particular, current treatments for visceral pain conditions are still based mainly on empirical rather than mechanistic evidence. Search for a consistently effective pharmacological agent to treat these pain conditions remain elusive. Functional gastrointestinal (GI) pain, one of the most prevalent forms of chronic visceral pain, is commonly interpreted as a consequence of hypersensitivity of GI nociceptive pathways, either of the peripheral sensory nociceptors in the gut or of the central neurons[1,2]. Human and animal studies have identified several channels as pivotal for enhanced signal transmission along

the pain axis, including voltage-gated sodium channels (VGSCs) Na$_v$1.3, Na$_v$1.7, Na$_v$1.8, and Na$_v$1.9, with the latter three preferentially expressed in peripheral sensory neurons[3-5]. VGSCs are integral membrane glycoproteins that are essential for generation and conduction of electrical impulses in excitable cells. Many of the most common neurological disorders, such as epilepsy, migraine, neurodegenerative diseases, and chronic pain involve abnormalities of neuronal excitability[6,7]. There is a growing body of evidence that implicates abnormal expression and function of VGSCs in these disorders[8-12]. Although there is an incomplete understanding of these channels and/or primary site of action at which these compounds exert their effects and significant side effects are often encountered, there is enough evidence emerging to give hope that a more refined approach may be achievable[13]. This article does not aim to provide an exhaustive list of potential targets, but to focus on some of the most recent advances in the field of pain research and medicine and to highlight where therapeutic strategies for relieving visceral pain may emerge in the near future.

BIOPHYSICAL AND MOLECULAR PROPERTIES OF VGSCS

VGSCs are integral membrane glycoproteins that consist of a central α-subunit of 260 kDa associated with one or more auxiliary β-subunits of about 35 kDa (Figure 1A)[5,14]. Nine α-subunit subtypes have been cloned and functionally expressed. These subtypes are designated Na$_v$1.1-Na$_v$1.9 for the proteins and *SCN1A-SCN5A* and *SCN8A-SCN11A* for the genes; *SCN6A/SCN7A* codifies the related protein Na$_x$. The VGSC α-subunit, which forms the ion-conducting pore and the channel gate for activation and inactivation, contains four domains (D I -D IV), each with six α-helical transmembrane segments labeled S1-S6 (Figure 1A). Pore loops between S5 and S6 (highlighted in red) in each of the four domains form the selectivity filter of the channel. Each pore loop contributes a single amino acid (aspartate from D I, glutamate from D II, lysine from D III, and alanine from D IV), which together form a narrow ring that is mainly responsible for conferring Na$^+$ selectivity. The four S6 segments form the cytoplasmic end of the pore, which binds various types of therapeutically important pore-blocking compounds, including local anesthetics, and antiarrhythmic drugs. The S4 segments (highlighted in green) in each of the four domains contain regularly spaced, positively charged amino acid residues and serve as voltage-sensors, coupling membrane depolarization to channel activation. The intracellular loop between D III and D IV forms the fast-inactivation gate that occludes the cytoplasmic end of the pore when the channel inactivates. The C-terminal cytoplasmic domain is important for setting some of the properties of fast inactivation and contains binding sites for interacting proteins. In addition to fast inactivation, a distinct process called slow inactivation develops during prolonged depolarizing plateaus and during high frequency repetitive firing. The

Figure 1 Schematic of a voltage-gated sodium channel polypeptide and Nav1.8 positive colon specific dorsal root ganglion neurons. A: The transmembrane organization includes four domains (D I -D IV) joined by three intracellular loops (L1-L3) and the intracellular N and C termini. Cylinders represent probable α-helical segments. P in circles, sites of demonstrated protein phosphorylation by protein kinase A (PKA) or PKC; green, S4 voltage sensors; h in which square, inactivation particle in the inactivation gate loop (modified, with permission, from Catterall[14]); B: Colon specific dorsal root ganglion neurons labeled by DiI (red); C: Nav1.8 positive neurons (green). Colon specific Nav1.8 positive neurons are stained yellow. Bar = 50 μm for both B and C.

kinetics of onset and recovery of slow inactivation are about four orders of magnitude slower than those of fast inactivation. Slow inactivation does not depend on the fast inactivation gate formed by the intracellular loop between D III and D IV, but instead mainly involves rearrangements of the pore of the channel[15].

VGSCS IN PRIMARY SENSORY NEURONS INNERVATING VISCERAL ORGANS

Primary sensory neurons, with their cell bodies located in the dorsal root ganglion (DRG), are the first link in the so-

Figure 2 A model showing the three states of the sodium channel. Tissue damage/inflammation leads to activation of the sodium channel from a closed state. Once activated, sodium ions entered through the channel and evoke the action potential of the cell membrane, eventually producing the sensation of pain. Once the channel becomes inactivated, it must go to a closed state before being activated again. Action potentials and inward currents were recorded from a colon specific dorsal root ganglion neuron from a healthy rat.

matosensory pathway. They encode their messages in the form of a series of action potentials whose depolarizing upstroke is produced by sodium channels[3-5,16]. Most neuroscientists and neurologists are familiar with the textbook description of VGSC function (Figure 2). VGSCs contribute to the control of membrane excitability and underlie action potential generation. They are closed at resting membrane potentials characteristic of quiescent neurons. In response to membrane depolarization, they open within a few hundred microseconds (a process termed activation), resulting in an inward sodium ion (Na$^+$) current, and then convert within a few milliseconds to a non-conducting inactivated state through a process called fast inactivation. Transient Na$^+$ influx through thousands of rapidly opening and inactivating VGSCs results in the familiar transient macroscopic Na$^+$ current detected in whole-cell voltage clamp studies[16]. This transient current gives rise to the depolarizing phase of the action potential in neurons, and eventually causes the sensation of pain (Figure 2).

Distinct distribution

Expression of the different subtypes of VGSCs is tissue- and/or cell-specific. The main subtypes expressed in adult brain neurons are Na$_v$1.6. Na$_v$1.2 in unmyelinated axons and in myelinated axons early in development (before being replaced by Na$_v$1.6), and Na$_v$1.1 in the neuronal somata. In rodents, Na$_v$1.3 is expressed primarily in embryonic neurons; however, expression in the human central nervous system remains comparatively high into adulthood. Na$_v$1.4 is the main subtype in adult skeletal muscle, whereas Na$_v$1.5 is expressed in cardiac muscle, and it is also expressed in some neurons. In DRG neurons, Na$_v$1.6 is the major sodium channel isoform at the nodes of Ranvier[17], is present in unmyelinated fibers in the sciatic nerve[18,19] and is preferentially expressed by TrkC (tyrosine receptor kinase C) neurons. Na$_v$1.7, Na$_v$1.8, and Na$_v$1.9 are found in peripheral primary sensory afferents. They are more abundant in C-fiber neurons[16,20]. Small diameter DRG neurons can be broadly classified into isolectin B4 (IB4)(+) and IB4(-) neurons. James Brock had reviewed sensory and biophysical properties differences between IB4(+) and

IB4(-) neurons[21]. Our preliminary experiments showed that most colon specific DRG neurons are Na$_v$1.8 positive (Figure 1B and C).

Developmentally regulated expression

Expression of the different subtypes is developmentally regulated in DRG neurons[22-24]. Na$_v$1.3 is overexpressed at embryonic day E1, peaks at E17, is reduced by postnatal day P15, and is not detectable by P30. Na$_v$1.6 is upregulated from E17 only in large neurons. Expression of both Na$_v$1.8 and Na$_v$1.9 increases with age, beginning at E15 and E17, respectively, and reaching adult levels by P7. Their distribution is restricted mainly to those subpopulations of primary sensory neurons in developing and adult DRGs that give rise to unmyelinated C-fibers (neurofilament 200 negative). Na$_v$1.8 is expressed in a higher proportion of neuronal profiles than Na$_v$1.9 at all stages during development, as in the adult[24]. It is worthy of note that nerve injury would evoke expression of some of these channels that are not present in the sensory nerve system in the adult, and may contribute to abnormal pain sensation[20,25,26].

Expression in glial cells

Na-G, a distinct type of "glial" Na channel expressed at high levels in Schwann cells *in vivo*[27,28], was thought to play a role in regulation of cytoplasmic Na$^+$ homoeostasis. However, recent studies show that action potential-like events have been recorded in glial precursor cells, astrocytes and a subset of oligodendrocyte precursor cells. More recently, Frieboes reported *de novo* expression of Na$_v$1.8 in endoneurial Schwann cells following injury[10]. This is surprising since Na$_v$1.8 expression is thought to be restricted to sensory neurons. No similar studies have been reported under pathophysiological conditions in visceral organs. Nevertheless, these data indicate a sodium channel in glial cells is linked to the development of neuropathic pain. Further investigation of the underlying molecular basis of VGSCs in glial cells and neural-glial interaction could yield promising targets for treatment of chronic pain.

VGSCS AND CHRONIC VISCERAL PAIN

There are relatively few published studies on roles of sodium channels in visceral pain and a uniform theme has not emerged. Saito *et al*[29] demonstrated a mutation in the cardiac sodium channel gene *SCN5A* in interstitial cells of Cajal (ICC) in irritable bowel syndrome (IBS) patients, suggesting *SCN5A* as a candidate gene in the pathophysiology of IBS. Additionally, Verne *et al*[30] showed there was a reduction in abdominal pain in IBS patients receiving intrarectal lidocaine, indicating a possible normalization of abnormal sodium channels in IBS patients. Yiangou *et al*[31] carried out an immunohistochemistry study on biopsies from patients with idiopathic rectal hypersensitivity which showed that the nerve fibers immunoreactive to the sodium channel Na$_v$1.7 were significantly increased in this group compared with controls. Collectively, these clinical data suggest that voltage-

gated sodium channels appear to play an important role in visceral pain[5,9].

Since no pharmacological tools to separate sodium currents are available, it is hard to relate the channel current to its molecular subtype. However, tetrodotoxin (TTX) is the most used drug to separate the TTX-S (sensitive) and TTX-R (resistant) sodium channel currents. Whole-cell patch-clamp recording of fast blue-labeled bladder afferent neurons demonstrated that the majority (70%) of bladder neurons that were small in size had capsaicin-sensitive TTX-R sodium channels[32,33]. More than 80% of gastric DRG neurons displayed TTX-R action potentials[34]. These data demonstrated that visceral sensory neurons expressed the TTX-R sodium channels that are thought to contribute to pain processing.

Sensitization of VGSCs

Several animal models have been used to determine the role for VGSCs under visceral pain conditions. These included the trinitrobenzenesulphonic acid (TNBS)-induced colitis, painful chronic pancreatitis, and acetic acid-induced gastric ulcers. TNBS-induced colitis significantly enhanced neuronal excitability of colon specific DRG neurons, which is associated with a significant potentiation of slow inactivating TTX-R Na$^+$ current density in mice[35] and in guinea pigs[36]. Changes in expression of Na$_v$1.7, 1.8 and 1.9 protein and mRNA during TNBS colitis were measured using Western blotting and quantitative polymerase chain reaction. On day 7 of colitis, there was a 3-fold increase in Na$_v$1.8 protein in ganglia from T$_{9-13}$, but Na$_v$1.7 and 1.9 levels remained unchanged. Surprisingly, there was no corresponding change in the Na$_v$1.8 α-subunit mRNA levels[37], indicating that the TNBS specifically evoked an increase in the numbers of Na$_v$1.8 channels, which contributed to an increased current. In a rat model of gastric hyperalgesia, Gebhart and colleagues reported that ingestion of iodoacetamide increased the peak TTX-R sodium current which was associated with a left-shifted voltage-dependent activation in DRG neurons[38]. In a rat model of painful chronic pancreatitis, however, no change in sodium peak current density was observed in pancreas-specific DRG neurons (Xu *et al*[39], unpublished data) although there was an alteration in voltage-gated potassium channel function in the same model. Although the data from different models are complicated and somehow controversial, they point out the fact that changes in function and expression of VGSCs are organ or/and disease specific.

As mentioned previously, no pharmacological tools to separate TTX-R currents are available. However, researchers have employed antisense oligodeoxynucleotide or Na$_v$1.8 and Na$_v$1.9 null mice to evaluate their current roles in animal models of visceral hypersensitivity. Inhibition of expression of Na$_v$1.8 (PN3/SNS) sodium channels by an antisense oligodeoxynucleotide injected intrathecally suppressed bladder hyperactivity and c-fos expression in the spinal cord induced by chemical irritation of the urinary bladder in rats[32]. In *Nippostrongylus brasiliensis* infection-induced transient jejunitis, hyperexcitability was absent in Na$_v$1.8$^{-/-}$ mice[40]. Further experiments showed that Na$_v$1.8-null mice displayed normal nociceptive behavior provoked by acute noxious stimulation of abdominal viscera. Na$_v$1.8-null mice also showed weak pain and no referred hyperalgesia to intracolonic capsaicin and mustard oil[41]. In a model of cyclophosphamide-induced bladder cystitis, Na$_v$1.8 null mice showed normal responses. These data suggest that Na$_v$1.8 plays an essential role in mediating spontaneous activity in sensitized nociceptors. However, the role for Na$_v$1.9 is inconsistent. Hillsley *et al*[40] reported that Na$_v$1.9$^{-/-}$ mice maintained hyperexcitability in *Nippostrongylus brasiliensis* infection-induced transient jejunitis. On the other hand, Martinez reported that R-848 (the toll-like receptor 7 activator)-induced hypersensitivity was blunt in Na$_v$1.9-null mice although their normal pain responses were similar to those of wild-type mice[42]. Hence, they suggested that Na$_v$1.9 channels do not significantly contribute to normal visceral pain responses to acute colonic mechanical stimulation but may be important for the development of inflammation-related visceral hyperalgesic responses. This idea was further supported by a recent report that peripheral nerve recordings from pelvic afferents in Na$_v$1.9-null mice revealed a lack of sensitization to intravesicularly applied prostaglandin (PG) E2[43]. Again, this points out that the role for Na$_v$1.9 may be organ and/or disease specific.

Modulation of VGSCs

There is growing evidence to support the hypothesis that inflammatory mediators are involved in the modulation of VGSCs function and expression under pathophysiological states (Figure 3). Among these are well-studied nerve growth factor (NGF) and PGE2. Blockade of NGF and tyrosine kinase receptors inhibits peripheral mechanical sensitivity accompanying cystitis in rats[44]. NGF continuously infused into the intrathecal space at the L6-S1 level of the spinal cord for 1 or 2 wk using osmotic pumps (0.5 μL/h) significantly lowered the threshold for spike activation. In addition, the number of TTX-R action potentials during 600 ms depolarizing pulses was significantly and time-dependently increased[33]. Another inflammatory messenger PGE2 induced a rapid (< 15 s) increase in TTX-R I_{Na} that was associated with a hyperpolarizing shift in the conductance-voltage curve (3.4 ± 0.7 mV), an increase in the rate of inactivation (4.21 ± 0.7 ms at 0 mV), and no change in steady-state availability. These results do suggest that modulation of TTX-R I_{Na} by NGF and PGE2 in colonic afferents is an underlying mechanism of hyperalgesia associated with inflammation of the colon, and that this current constitutes a novel target for therapeutic relief of visceral inflammatory pain[45-47]. Other modulators include, but are not limited to, aquaporins (AQP-1), interleukin (IL)-1β and gaseous modulators/transmitters. AQP-1 may directly interact with Na$_v$1.8 channels in DRG neurons[48], while IL-1β may act *via* a p38 mitogen-activated protein kinase pathway[49]. Hydrogen sulfide (H$_2$S), as an endogenous novel third gaseous modulator/transmitter, might directly or indirectly modulate the function of VGSCs since it enhanced excitability of primary sensory neurons,

Figure 3 Possible mechanisms underlying the modulation of voltage-gated sodium channel activity. Inflammatory mediators such as nerve growth factor (NGF), prostaglandin (PG) E2, interleukin (IL)-1β may sensitize sodium channels by different intracellular signal transduction pathways such as protein kinase A (PKA), protein kinase C (PKC), mitogen-activated protein kinase and calmodulin (CaM). In addition, a recent study showed that aquaporin (AQP)-1 directly interacted with the sodium channel, thus contributing to the perception of pain[48]. TTX: Tetrodotoxin; LIF: leukemia inhibitory factor; Trk: Tyrosine receptor kinase; TNF: Tumor necrosis factor; TRAF: Tumor necrosis factor receptor-associated factor; TRADD: TNF receptor-associated death domain protein.

and its endogenous generating enzyme was upregulated under visceral pain conditions[50].

The regulation of VGSCs by intracellular protein kinases is another important mechanism for maintenance of persistent behavioral hypernociception. Direct phosphorylation of Na$_v$1.7 by pERK1/2 and modulation of Na$_v$1.8 by p38 regulated the gating properties of these channels[49,51]. In addition, functional regulation of the Na$_v$1.8 by PKA and PKCε in the primary sensory neuron is important for the development of the peripheral pro-nociceptive state induced by repetitive inflammatory stimuli and for the maintenance of behavioral persistent hypernociception[52]. Since the Na$_v$1.8 C-terminus carries a conserved calmodulin-binding isoleucine-glutamine motif, it is reasonable to speculate that these two proteins can interact *in vivo*. Indeed, calmodulin demonstrated a regulation of Na$_v$1.8 currents[53]. Unfortunately, our understanding of regulation of VGSCs in visceral pain conditions lags behind our knowledge of mechanisms of somatic pain. Future experiments are warranted to determine whether and how Na$_v$1.8 channels are modulated by inflammatory and stress mediators in the peripheral nerve system.

MANAGEMENT OF VISCERAL PAIN WITH VGSC BLOCKERS

Treating chronic pain remains a significant clinical challenge, and in particular current treatment options for visceral pain are very limited and marginally effective. Na$^+$ channel blockade is one of the most powerful and best-proven analgesic principles, beginning with the use of local anesthetics for sensory blockade and then with the discovery that Na$_v$-blocking anticonvulsants also have benefit as pain therapy clinically[5,13,16,54-57]. Based on their mechanism of action, sodium channel blockers are divided into

the following categories: (1) Extracellular blockers, which bind to and occlude the extracellular pore of the channel, e.g. TTX and saxitoxin; (2) Intracellular blockers, which block from the intracellular side of the channel, including local anesthetics, class I antiarrhythmic agents, and some anticonvulsants; and (3) Unknown mechanisms of inhibition of the sodium current in ventricular cells of guinea pigs by e.g. caffeine[58], or A-803467, a specific blocker of the Na$_v$1.8 channel (SCN10A)[59].

Among the neuronal Na$^+$ channel subtypes, Na$_v$1.8 is believed to be of importance for certain visceral pain states, and Na$_v$1.8-preferring channel blockers should be able to relieve pain without causing severe effects (due to the restricted expression of this channel type). The compounds are lidocaine, mexiletine, benzocaine, and ambroxol, which are clinically used to treat pain after local or systemic administration. Of these compounds, ambroxol has been reported to effectively suppress pain symptoms in animal models of chronic, neuropathic and inflammatory pain[60]. The analgesic effects of ambroxol by either systemic administration to animals, or by topical application in humans can be explained by ambroxol-induced blockade of ion channels in peripheral neurons. However, this has not yet been used to treat visceral pain. Pregabalin effectively inhibits TNBS-induced chronic colonic allodynia in the rat[61]. Pregabalin increased distension sensory thresholds to normal levels in IBS patients with rectal hypersensitivity[62]. Although downregulation of the α$_2$δ calcium channel subunit may be one of the mechanisms underlying the analgesic effect of pregablin[63], the precise mechanism of pregabalin action is not fully understood. Nevertheless, these findings support the idea that pharmacological substances that modify the function of VGSCs would be potentially useful in treating pain conditions[11]. Further experiments are needed to provide more evidence for physicians to treat visceral pain with these pharmacological substances.

Numerous natural toxins have evolved to target sodium channels, either by blocking current through the pore or by modifying channel gating. Among well-studied toxins, the peptide conotoxins from marine snail venoms and δ-atracotoxin and scorpion venom toxins (e.g. birtoxin) constitute another promising source of such modulators. These peptide toxins are of considerable interest not only as probes for investigating the functioning of ion channels and receptors but also as potential therapeutics for neurological disorders, including neuropathic pain and epilepsy[64,65]. There are three classes of conopeptides that modulate VGSCs: the pore-blocking μ-conotoxins, the δ-conotoxins which delay or inhibit VGSC inactivation, and the μO-conotoxins which inhibit VGSC Na$^+$ conductance independent of the TTX binding site. Some of these toxins have been evaluated in animal studies and in preliminary clinical studies, but others are highly novel and may develop into potential drugs for the treatment of pain states by engineering a selective μ-conopeptide that has high affinity and efficacy.

It is noted that until now none of the known neurotoxins or small molecule VGSC inhibitors/modulators is

highly selective for a specific VGSC subtype. However, the recent discovery of a genetic link in inherited pain syndromes has advanced our understanding of the contribution of sodium channels to pain in humans and given us hope that it is possible to generate subunit specific blockers. "Gain-of-function" mutations in SCN9A, the gene which encodes Na$_v$1.7, have been linked to two human-inherited pain syndromes, inherited erythromelalgia and paroxysmal extreme pain disorder, while "loss-of-function" mutations in SCN9A have been linked to complete insensitivity to pain[12,66]. Inhibition of expression of Na$_v$1.8 (PN3/SNS) sodium channels by an antisense oligodeoxynucleotide[32] or by Na$_v$1.8 knockdown[40,41] would be useful tools for treatment of chronic visceral pain in the future.

CONCLUSION

An emerging theme that unifies many supposedly diverse functional GI disorders is altered neuronal excitability, caused by abnormal expression and function of membrane ion channels in organ-specific primary sensory neurons. VGSCs as the main determinants of intrinsic neuronal excitability are particularly appealing targets for pharmacological intervention. Other ion channels such as vanilloid receptor, ATP receptors or potassium channels, which are certainly involved in pain processing, have not been discussed in this review. Nevertheless, the advent of new experimental medicine techniques presents us with an opportunity to test the effectiveness of novel medicines in great detail. The ability to perform hypothesis-driven research with tool compounds in targeted patients with demonstrable visceral hypersensitivity is a stimulating prospect. As VGSCs are expressed in the glial cells, future studies should be directed toward understanding whether glia-neuron interaction is involved in the peripheral sensitization of nociceptors under visceral pain conditions. Since Na$^+$ channel subtypes are expressed in a regionally and temporally specific pattern and current VGSC blockers offer little discrimination between various VGSC subtypes, the development of selective blockers could increase their clinical usefulness. For example, a drug that selectively inhibits the Na$_v$1.8 VGSC, which appears to be crucially and specifically involved in visceral nociception, would presumably act as a novel and powerful analgesic, with few side effects in most indications.

Abstract

Pancreatic cancer is difficult to diagnose at an early stage and is associated with a very poor survival. Ten percent of pancreatic cancers result from genetic susceptibility and/or familial aggregation. Individuals from families with multiple affected first-degree relatives and those with a known cancer-causing genetic mutation have been shown to be at much higher risk of developing pancreatic cancer. Recent efforts have focused on detecting disease at an earlier stage to improve survival in these high-risk groups. This article reviews high-risk groups, screening methods, and current screening programs and their results.

INTRODUCTION

Pancreatic cancer is a deadly disease with more than 277 668 new cases and 266 029 deaths worldwide in 2008[1]. The median age at diagnosis is 72 years, with an age-adjusted incidence rate of 11.7 per 100 000 men and women[2]. Unfortunately, mortality rates for pancreatic cancer have not significantly changed for several decades. For example, in the United States, pancreatic cancer is the fourth commonest cancer killer. Although accounting for only 3% of new cases, pancreatic cancer is responsible for 6% of all cancer deaths each year[3]. Most patients with symptomatic pancreatic cancer have advanced and/or metastatic disease at presentation, and as a result, the overall 5-year survival rate is only 5.6%[2]. Even patients with resected, margin-negative pancreatic cancers have only a 22% chance of being alive at 5 years[2,4].

As patients with pancreatic cancer have a median survival of 6 mo from diagnosis, recent efforts have focused on detecting disease at an earlier stage as a way of improving survival. Because the disease is uncommon, and because we lack a simple, cheap and safe, non-invasive test, general population screening programs are neither feasible nor cost-effective. However, 10% of pancreatic cancers result from genetic susceptibility and/or familial aggregation[5]. Individuals from families with multiple affected first-degree relatives with pancreatic cancer, and those with a known cancer-causing genetic mutation have been clearly shown to be at much higher risk of developing pancreatic cancer. Accumulating data suggests that screening of these high-risk groups might be of benefit.

DEFINITION OF HIGH-RISK INDIVIDUALS

Individuals at high risk of developing pancreatic cancer are either part of inherited pancreatic cancer syndromes with a known genetic mutation or are members of a family with at least two first-degree relatives affected by the disease. At present, screening programs are usually targeted at individuals with 5% or greater lifetime risk of developing pancreatic cancer.

Inherited pancreatic cancer syndromes

Peutz-Jeghers Syndrome (PJS) is an autosomal disorder caused by germline mutations in the STK11/LKB1 tumor suppressor gene. These patients are at risk of esophageal, gastric, small intestine, lung, breast, uterine, ovarian and pancreatic cancer. Giardiello *et al*[6] have demonstrated that the risk for pancreatic cancer in patients with PJS is very high, with a relative risk of 132 and the cumulative life time risk by age 65 years of 36%.

Hereditary pancreatitis is a rare autosomal dominant disorder, caused in more than two-thirds of cases by a mutation in SPINK1 gene, with a high risk of pancreatic cancer. In this population, the cumulative risks of pancreatic cancer at age 50 and 75 years are 11% and 49% for men and 8% and 55% for women[7]. In individuals with a paternal inheritance, the cumulative life time risk for pancreatic cancer is as high as 75%[8]. In patients with hereditary pancreatitis, smoking has been shown to double their risk of cancer and lower the age of onset by approximately 20 years[9].

Familial atypical multiple mole melanoma syndrome is an autosomal dominant syndrome caused by a germline mutation in CDKN2A (or p16) gene on chromosome 9p21, or in a minority of cases, in the CDK4 gene on chromosome 12[10,11]. Patients with this syndrome are predisposed to develop multiple (more than 50) atypical nevi and multiple malignant melanomas. The individuals with this syndrome have a 20%-34% relative risk of developing pancreatic cancer and a 16% lifetime risk of pancreatic cancer[12].

Hereditary breast ovarian cancer syndrome is associated with germline mutation in the BRCA2 and BRCA1 genes. It is estimated that BRCA2 germline mutation carriers have a 5% lifetime risk of pancreatic cancer[13]. The risk of pancreatic cancer in BRCA1 mutation is 2.26 times that of the normal population[14]. A characteristic single mutation of 6174delT in the BRCA2 gene has been discovered in high-risk breast ovarian cancer families with pancreatic cancer of Jewish Ashkenazi origin.

Lynch syndrome is an autosomal dominant condition caused by defects in mismatch repair genes (MLH1, MSH2, MSH6 or PMS2). Recently, it has been shown that, in addition to colorectal and endometrial cancers, these individuals have a ninefold increased risk of developing pancreatic cancer compared with the general population[15]. Data on 6342 individuals from 147 families with mismatch repair gene defects have been analyzed and 21% of families reported at least one case of pancreatic cancer[15]. This study showed that the estimated relative risk of pancreatic cancer was higher for younger individuals (aged between 20 and 49 years), and concluded that individuals with Lynch syndrome and a family history of pancreatic cancer should be included in screening programs.

Familial pancreatic cancer

Individuals from families with a strong history of pancreatic cancer have an inherited predisposition of developing the disease themselves. Familial pancreatic cancer (FPC) families have been defined as families with at least two first-degree relatives, suggesting an autosomal dominant penetrance[16]. In addition, expert opinion recommends a subset of these people to be considered high risk and be included into screening: these are individuals with three or more affected family members; one of whom must be a first-degree relative[17]. Families that do not meet these criteria (i.e. families with only one relative with pancreatic cancer or with multiple pancreatic cancers in more distant relatives) are defined as sporadic pancreatic cancer and are not currently considered for screening. Due to the complex nature of pedigrees in pancreatic cancer, in order to take into account the current age of the subject, the age of onset of pancreatic cancer in the family and the exact relationships between family members, a computer-based risk assessment tool, named PancPRO was developed in 2007. The model has been shown to provide an accurate risk assessment for kindreds with familial pancreatic cancer[18], and further studies are underway to validate this. The program is available free of charge as part of UTSW Medical Centre Dallas at and Bayes Medel Group at John Hopkins Cancer Gene package at John Hopkins (http://www4.utsouthwestern.edu/breasthealth/cagene, accessed 15th June 2010).

Unfortunately, the genetic basis for most cases of FPC is not known but studies using segregation analysis have suggested that it is due to at least one rare novel major gene that has not yet been identified[19]. Germline mutation in the BRCA2 gene is present in 6%-16% of patients with pancreatic cancer[20,21]. The association between BRCA1 and pancreatic cancer is weaker but there are reports of pancreatic cancers in documented BRCA1 patients[22]. A mutation in the paladin gene[23] has been described in the affected members from families with FPC under surveillance at Washington University but this has not been confirmed in other studies. The *4q32-34* region has been previously identified as a potential locus for FPC in a large American family, however, this locus seems unlikely to harbor an FPC gene in European families[24]. Sequence analysis in FPC has revealed six genes previously described in neoplasia/carcinogenesis: *Apolipoprotein A4, CEA, Keratin 19, Stratifin (14-3-3 sigma), Trefoil Factor,* and *Calcium Binding Protein S100 A6*. The pattern of frequency suggests that these genes are associated with conditions that produce significant desmoplastic responses and are difficult to differentiate from chronic inflammatory processes. *Apolipoprotein A4* is preferentially expressed in familial patients, suggesting the importance of fatty acid synthesis in carcinogenesis but this requires further investigations[25]. A more recent study has identified the PALB2 gene as a pancreatic cancer susceptibility gene[26].

Even without knowing the gene that causes FPC, the

risk of pancreatic cancer in these kindreds has been estimated. Prospective analysis of incident pancreatic cancers in Johns Hopkins' National Familial Pancreas Tumor Registry kindreds, performed as part of the Johns Hopkins GI SPORE study, has demonstrated that the relative risk of pancreatic cancer in persons with two affected first-degree relatives is 6.4% and the cumulative life time risk is 8%-12%. In individuals with three affected first-degree relatives, the relative risk for pancreatic cancer is 32% and the cumulative life time risk is 16%-32%[19]. People with a pair of relatives related by first degree have an 18-fold increase in risk and an estimated life time risk of 9%-18%[27].

The age of onset in pancreatic cancer kindreds appears to be important. The risk of pancreatic cancer is higher among members of FPC kindreds with a young onset (age < 50 years)[28]. Risk survival analysis shows that the life time risk of pancreatic cancer in FPC kindreds increases with decreasing age of onset in the kindred. Interestingly, this was not true for sporadic pancreatic cancer. For example, the life time (by age 80 years) risk of pancreatic cancer was 15.7% for individuals with one or two first-degree relatives with pancreatic cancer who came from a family in which one of the members of the family was diagnosed at age 40 years. In this family history group, the cumulative incidence of pancreatic cancer decreased to 7.1% when the youngest age of onset of pancreatic cancer was at 60 years and to 3.1% when the youngest age was at 80 years. The life time risk rose to 38.9% for individuals with three first-degree relatives with pancreatic cancer who came from a family in which one of the members of the family was diagnosed at age 40 years[28]. Smoking is a strong risk factor in FPC kindred, particularly in men and people younger than 50 years of age, because it increases the risk of pancreatic cancer by 2-3.7 times over the inherited predisposition and lowers the age of onset by 10 years[29].

CANCER SEQUENCE

There are three known precursor lesions to pancreatic cancer: intraductal papillary mucinous neoplasm (IPMN), mucinous cystic neoplasia (MCN) and pancreatic intra-epithelial neoplasia (PanIN). Main duct IPMN has a higher frequency of malignancy (range: 60%-92%, mean 70%) compared with branch duct IPMN (range: 6%-46%, mean 25%)[30]. PanIN is by far the commonest lesion and three grades of PanIN have been described as cellular atypia progresses from low-grade dysplasia (PanIN-1) to high-grade dysplasia (PanIN-3). Molecular studies have revealed K-ras activation in PanIN-1, inactivation of p16 in PanIN-2 and inactivation of p53, DPC4, and rarely BRCA2 mutation in PanIN-3 and invasive adenocarcinoma[31,32]. Non-invasive multifocal precursor lesions, such as PanINs and IPMNs, are more common in patients with a strong family history of pancreatic cancer than in patients with sporadic disease, and precursor lesions are of a higher grade in patients with a strong family history of pancreatic cancer[33]. Studies on pancreases resected from patients with FPC have shown that precursor lesions, even the low-grade PanIN-1 lesions, are often directly associated with lobular atrophy of the surrounding pancreatic parenchyma[34]. In addition, animal studies have shown

Table 1 Potential pancreatic cancer biomarkers under study %						
Biomarker	**CEACAM-1**	**Span-1**	**DUPAN-2**	**MIC-1**	**Alpha4GnT**	**PAM4**

MIC-1: Macrophage inhibitory cytokine-1; CEACAM-1: Carcinoembryonic antigen-related cell adhesion molecule 1; SPan-1: Monoclonal antibody; DU-PAN 2: Pancreatic cancer associated antigen; Alpha4GnT: alpha1,4- N-acetyl-glucosaminyltransferase; PAM4: Anti-MUC1 monoclonal antibody.

that it is not the atrophy that causes the PanINs to develop, but rather that it is the PanINs which develop first, producing multiple foci of small duct obstruction, which in turn progress to multifocal lobulocentric atrophy[33,35]. The lobular atrophy associated with these precursor lesions provides an explanation for the chronic pancreatitis-like changes seen in these pancreases. The multifocality of the precursor lesions suggests that an inherited mutation of a gatekeeper gene is responsible for some cases of FPC.

While main duct IPMN and large MCN can be detected by computer tomography (CT) and magnetic resonance imaging (MRI), small MCN, branch duct IPMN and chronic pancreatitis like changes are best detected by endoscopic ultrasound (EUS).

SCREENING METHODS

As pancreatic cancer has such poor survival, the aim of screening is to detect precursor lesions or early pancreatic cancers. A study from the Japanese National Pancreatic Cancer Registry on operated pancreatic cancers has shown that stage I tumors less than 2 cm have a much better survival (58% alive at 5 years) compared with stage II b (17% alive)[36]. Even more, another Japanese study showed 100% survival in 79 patients with tumors less than 1 cm undergoing curative resection[37].

Unfortunately, premalignant lesions and small pancreatic cancers are asymptomatic. Therefore, screening programs have tried to use biomarkers and imaging tests to identify these early lesions. There are no validated biomarkers in use for detection of early pancreatic cancer. CA19-9 is neither specific nor sensitive enough for reliable detection of early pancreatic cancer or pancreatic precursor lesions. In a study of 71 000 asymptomatic patients undergoing abdominal ultrasound, CA19-9 was found to have a positive predictive value less than 1% using a cut off value of 37 U/mL[38]. Currently, many biomarkers have been researched but none is yet in routine clinical use (Table 1)[39].

Fasting blood glucose has been shown to be a marker for early cancer in sporadic cases[40] and is currently used by EUROPAC study in high-risk individuals. Molecular analysis of pancreatic juice for K-ras mutation, p53 mutation and p16 promoter methylation is also evaluated in the EUROPAC study.

EUS is the main imaging modality for screening these high-risk individuals. In addition to EUS, other imaging modalities have been used in different protocols such as computed tomography (CT), magnetic resonance imag-

ing (MRI) magnetic resonance cholangiopancreatography (MRCP), MRI with secretin, and endoscopic retrograde cholangiopancreatography (ERCP).

EUS has been shown to be the best modality to stage pancreatic cancers (sensitivity of 84% and specificity of 97%)[41] and for diagnosing small tumors (Figure 1) and IPMN (Figure 2). EUS fine needle aspiration (FNA) allows cytological sampling of abnormal areas and has an accuracy of 92%[42]. Multifocal non-invasive epithelial precursor lesions (PanINs, small IPMN) are associated with chronic pancreatitis-like changes, including abnormalities of the ducts (ectasia, irregularity, saccules) and parenchyma (heterogeneity, lobularity) and are best observed at EUS. Two thirds of patients screened in the CAPS 1 and CAPS 2 studies were found to have these chronic pancreatitis changes by EUS and ERCP[43,44]. These changes correlate with markers of neoplasia including abnormal DNA methylation in the pancreatic juice[45], and were significantly more common and more severe in individuals from FPC kindreds than in controls, even after adjusting for age and alcohol exposure. In addition, Canto *et al*[43] have reported high-grade PanINs and invasive adenocarcinoma arising in patients with benign IPMN, suggesting that in this high-risk cohort, IPMN can be a marker of a field effect of neoplasia.

CT and MRI remain the standard of care modalities to identify pancreatic cancers larger than 2 cm. CT use for screening has been discouraged because it is associated with delivering ionizing radiation (10mSv) to patients who most likely have a DNA repair defect. MRI with secretin has better results than MRI and MRCP but it is still unable to visualize very small lesions and can be associated with movement artefacts and claustrophobia. John Hopkins researchers have compared EUS with CT and MRI/MRCP in detecting FPC. MRI/MRCP is superior to CT particularly for detecting IPMNs (71% *vs* 14%) and EUS detected twice as many neoplastic lesions as CT/MRCP[46]. Some centers have used ERCP to detect saccular dilatation in the pancreatic duct said to be associated with PanIN lesions[44]. However, its use must be weighed against the potential risk of procedure-related acute pancreatitis (3%-5%).

Genetic counseling is an essential part of all current screening programs, and practice recommendations about counseling these people about their individual risk, possible preventive and surveillance measures were made at the Fourth International Symposium of Inherited Diseases of the Pancreas in 2007[17].

REVIEW OF SCREENING PROGRAMS

Currently, there are multiple international programs that screen for pancreatic cancer in high-risk individuals in a research setting. The optimal approach to screening for early pancreatic neoplasia has not yet been established and each protocol is slightly different, but all use EUS as the main imaging modality.

The largest program is led by John Hopkins University and involves 24 American Centers of Excellence (CAPS study). The results from the CAPS 1 and CAPS 2 studies have been published and they show that early pancreatic

Table 2 Results of screening programs for pancreatic cancer in high-risk groups

Study	CAPS 1[44]	CAPS 2[43]	Washington[47,48]	FaPaCa[49]	Dutch study[50]
Yield of screening	5.30% (2/38)	10% (8/78)	13% (10/75)	1.30% (1/76)	23%[1] (10/44)

[1]7% diagnostic yield of pancreatic cancer and 16% diagnostic yield of pre-malignant IPMN lesions. CAPS: Cancer of the Pancreas Screening Study; FaPaCa: Familial Pancreatic Cancer Study Germany.

neoplasia can be detected through a screening program in asymptomatic patients. In the CAPS 1 study, 36 patients were screened using only EUS. Six masses were found and these patients went to surgery. The histology showed that two of them had malignant and premalignant lesions (invasive adenocarcinoma and IPMN). In this study, the diagnostic yield of screening was 5.3% (Table 2). Most importantly, the patient with pancreatic cancer is still alive and disease free more than 5 years after surgery[44].

The CAPS 2 study found a 10% diagnostic yield of screening for pre-invasive malignant lesions. In this study, screening was performed using annual EUS and CT. If an abnormality was detected, ERCP was offered. Seventy-eight high risk patients (72 from FPC kindreds with three or more affected members, six PJS) and 149 control patients were studied. Of these, eight patients had confirmed pancreatic neoplasia by surgery or FNA (10% yield of screening): six patients had IPMN with diffuse multifocal PanIN lesions, one had an IPMN with invasive ductal adenocarcinoma, and one had high-grade pancreatic intraepithelial neoplasia (PanIN-3). Five patients had complications (pancreatitis) following ERCP and one patient developed metastatic pancreatic cancer while under surveillance. EUS and/or CT also diagnosed three patients with extra-pancreatic neoplasms (ovarian cancer, renal cancer, ovarian cystadenoma) suggesting that the diagnostic yield for screening and the potential clinical impact may be even greater[43]. The CAPS 3 study is a multicentric prospective controlled cohort study that involves annual screening using EUS and MRCP, MRI with secretin and a panel of candidate DNA and protein markers in serum and pancreatic juice [CA19-9, macrophage inhibitory cytokine-1 (MIC-1), DNA hypermethylation, and KRAS gene mutations] as indicators of pancreatic neoplasms. The study has recently been completed and the results are awaited.

Another well-established formal screening program in high-risk individuals is at the University of Washington. Subjects are screened using EUS and the screening begins 10 years prior to the earliest pancreatic cancer death in the family. Patients with normal EUS findings are followed up with repeat EUS at 2-3 year intervals depending of the age when the youngest affected relative had pancreatic cancer. The subjects with abnormal EUS are referred for ERCP and if this is abnormal, patients are offered surgery (laparoscopic resection of the tail to look for PanIN)[47]. Patients with abnormal EUS but normal ERCP are offered annual EUS. Out of 75 subjects screened, 15 had abnormalities on EUS and ERCP and went to surgery. The his-

Figure 1 Radial endoscopic ultrasound image of a small (12 mm) early pancreatic cancer, seen as an irregular hypoechoic mass lesion in the pancreatic head.

Figure 2 Endoscopic ultrasound image of 17 mm × 7 mm main-duct type intraductal papillary mucinous neoplasm. The duct is markedly dilated and villous papillary projections can be seen arising from the duct wall. Pathology after surgical resection showed high-grade dysplasia.

tology revealed premalignant lesions in all: PanIN-3 in 10 cases and PanIN-2 in five[48]. This would give a diagnostic yield of 13% for detecting premalignant lesions. Unfortunately, one patient developed unresectable pancreatic cancer while under annual surveillance[16].

In Europe, a European Registry for Familial Pancreatic Cancer and Hereditary Pancreatitis (EUROPAC) has been created specifically to screen high-risk individuals and this uses EUS, ERCP and molecular analysis of the pancreatic juice looking for early mutations (mt p53, K-ras, P16). The results have not yet been published. A German Study (FaPaCa) enrolled 76 patients in a screening program using yearly EUS, MRCP and laboratory tests (genetic analysis of CDKN2a and BRCA2 gene, Ca 19-9 and CEA). Any suspicious lesion had a control EUS ± FNA after 6 wk and a close follow up at 12 wk. If changes were detected, the patient would undergo operative exploration with intraoperative ultrasound, limited pancreatic resection with frozen section, and if cancer was detected, total pancreatectomy. Ten solid lesions were seen on EUS but only seven could be detected by MRCP. Out of the seven patients, six had limited resections and the histology showed PanIN-3 in one patient, PanIN-2 in one, PanIN-1 in one, and three benign lesions. These results gave a diagnostic yield

of 1.3% in detecting PanIN-3, which is much lower than in previous studies[49].

Given the low yield and taking into consideration the high cost and psychological stress, the German researchers concluded that screening is not justified. These results may be explained by the fact that they were screening a large number of patients who had only a moderate risk of pancreatic cancer (58% of the patients) as they had only two affected family members. The study is ongoing as they still have 17 patients with EUS abnormalities under close surveillance. A recent study from The Netherlands that used only EUS as the first screening modality in 44 high-risk asymptomatic subjects showed a 7% diagnostic yield for asymptomatic cancers and 16% diagnostic yield for premalignant lesions (IPMN like lesions)[50].

Most programs continue screening with yearly EUS if no abnormalities are detected. Pancreatic cancer screening programs have reported high compliance rates (64%-94%)[51]. A recent study has found that participation in a pancreatic cancer screening program does not lead to a significant increase in risk perception, cancer worry or general distress[52]. Data from John Hopkins shows that patients have found genetic counseling before screening very helpful and these patients perceive their personal cancer risk to be high and would seek predictive genetic testing if it were available[53].

COST-EFFECTIVENESS

Two studies have looked at cost-effectiveness of screening in high-risk individuals. In the first, a decision analysis was used to compare one time screening for pancreatic dysplasia with EUS to no screening. Abnormal EUS findings were confirmed by ERCP and patients with abnormalities were offered total pancreatectomy. The life time medical costs and life expectancy were compared (assuming a 20% incidence of dysplasia and a 90% sensitivity of EUS and ERCP). The study concluded that screening was cost-effective with an incremental cost-effectiveness ratio of $16 885/life-year saved[54]. Screening remained cost-effective as long as the prevalence of dysplasia was > 16% and the sensitivity of EUS was > 84%. Rubenstein *et al*[55] have performed a clinical and economic evaluation of EUS for patients at risk for familial pancreatic adenocarcinoma using a Markov model. In his model "Do nothing strategy" provided the lowest cost, the greatest remaining years of life and greatest quality adjusted life years, whereas total pancreatectomy provided the longest life expectancy if the lifetime risk of pancreatic was at least 46%.

FUTURE DIRECTIONS

In the near future, screening of high-risk patients may incorporate biomarkers with high specificity and sensitivity in addition to EUS imaging. Contrast-enhanced EUS may also be a promising technique to differentiate between focal pancreatitis and malignancy[56] but it remains to be seen if it will be useful in further characterizing lesions in high-risk individuals. The use of neural network analysis of dynamic sequences of EUS-elastography is a promising new technique

that may provide important additional information in distinguishing benign and malignant pancreatic lesions. Further investigations are required to determine if this technique can guide EUS-FNA to regions most likely to harbor cancer and to exclude cancer in patients with a low probability[57]. More work is required to determine if laparoscopic resection of the pancreatic tail in patients with imaging abnormalities is reliable in detecting PanIN changes, and hence, in establishing real future cancer risk that enables subsequent recommendations for total pancreatectomy.

CONCLUSION

Current screening programs have shown that premalignant lesions and early cancers can be detected by screening but two interval cancers have been missed. The risk of cancer in these groups is sufficiently high to perform screening but methodology needs to be improved. Based on these limited data, the estimated diagnostic yield and potential clinical impact of screening for early pancreatic neoplasms appears to exceed that for other standard indications such as breast cancer screening in high-risk women (95% of women with abnormal mammograms do not have breast cancer)[58]. As we learn more about the natural history of premalignant lesions, studies with long-term follow-up are needed. Given the complexities involved, it seems essential that screening of this cohort is coordinated in a multidisciplinary setting and should take place in a limited number of centers with appropriate expertise and facilities.

Abstract

Accompanying rapid developments in hepatic surgery, the number of surgeries and identifications of histological types of primary hepatic space-occupying lesions (PHSOLs) have increased dramatically. This has led to many changes in the surgicopathological spectrum of PHSOLs, and has contributed to a theoretical basis for modern hepatic surgery and oncological pathology. Between 1982 and 2009 at the Eastern Hepatobiliary Surgery Hospital (EHBH) in Shanghai, 31901 patients underwent surgery and were diagnosed as having a PHSOL. In this paper, we present an analysis of the PHSOL cases at the EHBH for this time period, along with results from a systematic literature review. We describe a surgicopathological spectrum comprising more than 100 types of PHSOLs that can be stratified into three types: tumor-like, benign, and malignant. We also stratified the PHSOLs into six subtypes derived from hepatocytes; cholangiocytes; vascular, lymphoid and hemopoietic tissues; muscular, fibrous and adipose tissues; neural and neuroendocrine tissues; and miscellaneous tissues. The present study provides a new classification system that can be used as a current reference for clinicians and pathologists to make correct diagnoses and differential diagnoses among various PHSOLs.

Surgicopathological classification of hepatic space-occupying lesions: A single-center experience with literature review. *World J Gastroenterol* 2011; 17(19): 2372-2378 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i19/2372.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i19.2372

INTRODUCTION

Liver neoplasms are one of the most common tumors worldwide, especially in China and other developing countries. Rapid developments in liver surgery and liver pathology have led to many new types of primary hepatic space-occupying lesions (PHSOLs) being surgically resected and pathologically diagnosed, which has greatly increased the surgicopathological spectrum of PHSOLs. Indeed, insights into tumor pathological characteristics have illuminated the need for an improved practical guide for oncological clinicians and pathologists to make correct diagnoses and differential diagnoses among PH-

SOLs[1]. However, to the best of our knowledge, there is no report in the English literature that thoroughly assesses the whole spectrum of PHSOLs.

During the period from January 1982 to December 2009, 31 901 surgically resected PHSOLs were deposited in the archives of the Department of Pathology, Eastern Hepatobiliary Surgery Hospital (EHBH) in Shanghai. In this paper, we present an analysis of the above 31 901 PHSOL cases, along with results from a systematic literature review. To the best of our knowledge, this is the largest series of PHSOLs presented from a single center. Based on the EHBH archival data and literature reviews using MEDLINE and PUBMED, more than 100 types of PHSOLs have been described. In this article, we suggest a surgicopathological classification of PHSOLs comprising three types: tumor-like PHSOLs, benign PHSOLs, and malignant PHSOLs. We also stratified the PHSOLs into six subtypes: lesions derived from hepatocytes; cholangiocytes; vascular, lymphoid and hemopoietic tissues; muscular, fibrous and adipose tissues; neural and neuroendocrine tissues; and miscellaneous tissues.

TUMOR-LIKE PHSOLS

Tumor-like PHSOLs are usually a type of space-occupying lesion within the hepatic parenchyma or intrahepatic bile ducts, but without a truly neoplastic nature. At least 31 kinds of tumor-like PHSOLs have been reported, as summarized in Table 1[2-25]. In the EHBH series, tumor-like PHSOLs accounted for 4.3% ($n = 1370$) of the 31 901 cases. Of the tumor-like PHSOLs, focal nodular hyperplasia (FNH) accounted for 51.5% ($n = 705$), solitary necrotic nodules accounted for 19.6% ($n = 269$), and hepatic inflammatory pseudotumors (HIP) accounted for 12.0% ($n = 165$). These are the three most common tumor-like PHSOLs.

In the latest edition of the World Health Organization (WHO) classification report (2010 Edition), FNH and HIP were grouped as benign liver tumors[26]. However, most scholars, and the present authors, prefer to regard FNH and HIP as a kind of non-neoplastic lesion or a tumor-like lesion[6,27]. FNH is a regenerative hepatocellular nodule that is frequently related to factors that stimulate the hyperperfusion of either the artery or the portal vein. Clonal analysis using the human androgen receptor locus test demonstrated the reactive polyclonal nature in 50%-100% of the FNH cases. Genetic analysis of FNH failed to identify somatic gene mutations that occurred in hepatocellular adenoma (HCA)[28]. Currently, most FNH are considered as polyclonal, and there was neither recurrence nor substantiated malignant transformation in all 705 FNH cases included in the EHBH series after surgery, even though FNH may occasionally coexist with hepatocellular carcinoma (HCC)[29].

Either clinically or pathologically, FNH should be distinguished from other hepatocellular nodules, such as HCA and highly differentiated HCC. Hepatocyte paraffin 1 (Hep Par 1) and polyclonal carcinoembryonic antigen

Table 1 Histological classification of tumor-like primary hepatic space-occupying lesions

Hepatocellular lesions
  Focal nodular hyperplasia[2]
  Nodular regenerative hyperplasia[2]
  Partial nodular transformation[3]
  Adenomatoid hyperplasia (dysplastic nodules)[2]
  Compensatory lobar or segmental hyperplasia[4]
  Focal fatty change[2]
  Accessory lobe[5]
Bile duct lesions
  Biliary microhamartoma (Von Meyenburg complex)[2]
  Cyst and polycystic liver[6]
  Ciliated foregut cyst[7]
  Epidermoid cyst[8]
  Endometrial cyst[9]
  Intrahepatic peribiliary gland cyst[2]
  Mesothelial cyst[10]
  Cystic echinococcosis[11]
  Biloma[12]
Miscellaneous lesions
  Mesenchymal hamartoma[2]
  Inflammatory pseudotumor[2]
  Pseudolymphoma[13]
  Solitary necrotic nodule[14]
  Peliosis hepatis[15]
  Hereditary hemmorrhagic telangiectasia[16]
  Sarcoidosis[17]
  Nodular extramedullary hematopoiesis[18]
  Abscess[19]
  Tuberculoma[20]
  Botryomycosis[21]
  Malacoplakia[22]
  Ectopic tissue[23] and adrenal rest tumor[24]
  Pseudolipoma[2]
  Granulomas[25]

(CEA) are special hepatocellular markers, which cannot, however, differentiate between benign and malignant natures; therefore, we prefer to use CD34 immunostaining to sensitively and specifically outline microvasculatures to differentiate hepatocellular nodules[6,30,31]. FNH usually presents in a focal distribution pattern of microvasculatures around fibrous scars (Figure 1A and B), whereas HCA shows a chaotic distribution pattern, usually with thin-walled vascular staining (Figure 1C and D). HCC presents in a diffuse distribution pattern occupying a greater proportion of the lesion area (Figure 1E and F). Although glypican-3 (GPC-3) has recently been reported to be overexpressed in HCC, the lack of GPC-3 immunostaining could not exclude the diagnosis in at least 25%-30% of HCC[32].

BENIGN PHSOLS

At least 30 types of benign PHSOLs have been reported, as summarized in Table 2[2,33-56]. In the EHBH series, benign tumors accounted for 12.1% of the cases ($n = 3847$), among which hepatic cavernous hemangioma ($n = 3191$, 82.9%), hepatic angiomyolipoma (HAML, $n = 153$, 4.0%), and HCA ($n = 148$, 3.8%) were the most frequent types in this group.

Table 2 Histological classification of benign primary hepatic space-occupying lesions

Hepatocellular tumors
  Hepatocellular adenoma[2] and hepatic adenomatosis[33]
Intrahepatic bile duct tumors
  Bile duct cystadenoma[2]
  Intraductal papillary neoplasm[34] and intraductal papillomatosis[2]
  Bile duct adenoma[2]
  Biliary adenofibroma[35]
Vascular and lymphoid tumors
  Cavernous hemangioma[2]
  Perivascular epithelioid cell tumor[36]
  Hemangioblastoma[37]
  Infantile hemangioendothelioma[2]
  Lymphangioma and lymphangiomatosis[2]
Muscle, fibrous and adipose tumors
  Angiomyolipoma[2]
  Leiomyoma[38]
  Solitary fibrous tumor[2]
  Lipoma[39]
  Myelolipoma[40]
Neuronal and neuroendocrine tumors
  Neurilemmoma[41]
  Plexiform neurofibroma[42] and plexiform neurofibromatosis[43]
  Paraganglioma[44]
  Pheochromocytoma[45]
  Gastrinoma[46]
  Vascoactive intestinal peptide tumor[47]
  Somatostatinoma[48]
Miscellaneous tumors
  Teratoma[49]
  Mesothelioma[50]
  Endometrioma[51]
  Chondroma[52]
  Myxoma[53]
  Langerhan's cell histiocytosis[54]
  Desmoplastic nested spindle cell tumor[55]
  Spongiotic pericytoma[56]

In Western countries, patients with HCA or hepatic adenomatosis are mostly estrogen/androgen dependent types, with a female gender bias (> 90%). Among them, 78% have a history of taking contraceptive drugs, and 4% to 4.7% may develop HCC[57]. However, the 148 cases of Chinese HCA in the EHBH series were the spontaneous type with a female:male ratio of 1:2.2. Recently, HCA has been categorized into three molecular subgroups including those with: (1) hepatocyte nuclear factor 1α mutations; (2) β-catenin mutations; and (3) no mutation, with or without inflammatory infiltrates. HCA with a β-catenin mutation has a risk odds of malignant transformation of 46%[58]. It has also been reported that 4% to 17.6% of HCA may have had histologically confirmed malignant transformation[58]. However, after being followed up for more than 5 years after surgery, there was neither a recurrence nor malignant transformation in all 148 cases of HCA in the EHBH series. No case, so far, has had recurrence or tumor canceration, suggesting that Chinese patients with HCA may have differences in etiology, genetics, and HCA-related HCC risk, compared to Western countries.

The above research suggests that the detection of molecular biological or immunohistochemical markers before or after surgery is essential for providing an active radical radiotherapy cure. In addition, more attention should be paid to the careful follow-up of patients with a high potential for transformation of β-catenin activated HCA to prevent HCA transformation or recurrence[26]. Thus, the treatment roadmap based on HCA molecular characteristics has also been described[59].

In 1993, we reported the first case of primary HAML in China. During the last 3 years of the study period, 85 cases of primary HAML and 66 cases of HCA were surgically resected at the EHBH. HAML is generally considered as a miscellaneous benign tumor; however, we find that some cases of HAML can show doubtful growth patterns, such as multi-focus, boundary infiltration along the sinusoids (Figure 2A and B), or even intravascular aggregation of conspicuous HMB45 positive cells (Figure 2C and D), which are similar to malignant behaviors. However, none of the 153 cases of HAML in the EHBH series showed evidence of malignant transformation or postoperative recurrence up to the time of the termination of this study. The presence of malignant HAML or malignant transformation of HAML[60,61] indicates that surgical excision should be considered as a preferred therapeutic, and a long-term follow-up after liver surgery is needed.

MALIGNANT PHSOLS

At least 41 malignant PHSOLs were reported, as summarized in Table 3[2,60-92]. In the EHBH series, malignant PHSOLs accounted for 83.6% (*n* = 26 684) of the cases, among which, HCC (*n* = 24 075, 90.2%) and intrahepatic cholangiocarcinoma (ICC, *n* = 2188, 8.2%) were the two most common malignant tumors. In contrast, undifferentiated embryonal sarcoma (UES, *n* = 34, 0.1%) and hepatoblastoma (HB, *n* = 33, 0.1%) ranked third, with a similar incidence.

Histopathologically, HCC, which comprises more than 10 histological varieties[6], is always the central point of differentiated diagnoses among PHSOLs and metastatic tumors. We propose that CD34 immunostaining is one of the most effective methods to distinguish well-differentiated HCC from benign hepatocellular tumors (Figure 1)[6,26]. When HCC appears as a tubular-like arrangement, with solid nest structures and a pseudoglandular pattern, it is difficult to distinguish from ICC or metastatic adenocarcinomas. Based on scanning a panel of immunohistochemical markers, we propose that, for the diagnosis of HCC, Hep Par 1, CD34, and polyclonal CEA are first-line antibodies, and CK19 and MUC-1 are first-line antibodies for ICC[30,31].

UES is a unique hepatic malignant tumor that usually affects the pediatric population. To the best of our knowledge, only 70 cases of UES in adults have been reported worldwide[75,93]. Histologically, UES is characterized by a huge hemorrhagic mass and is composed of pleomorphic cells with eosinophilic cytoplasmic globules entrapped in a loose myxoid stroma[75]. Among 34 cases of UES in

Figure 1 Atypical focal nodular hyperplasia with minimal fibrous septa (A, HE stain, × 200) shows focal microvessels around the periphery of the fibrous septa (B, CD34 immunostaining, × 200). Hepatocellular adenoma is composed of benign-looking hepatocytes with mild steatosis, without a capsule around the periphery (C, HE stain, × 200), and shows a chaotic microvessel distribution pattern with thin-walled vascular staining (D, CD34 immunostaining, × 200). Highly differentiated hepatocellular carcinoma is arranged in a thin trabecular pattern (E, HE stain, × 400) and shows a sinusoidal capillarization pattern (F, CD34 immunostaining, × 200).

Figure 2 Infiltration of neoplastic cells of hepatic angiomyolipoma within the hepatic sinusoid (A, HE stain, × 200) with strong HMB45 positive staining (B, immunostaining, × 200), and within a branch of the portal vein (C, HE stain, × 100) with strong HMB45 positive staining (D, immunostaining, × 200).

the EHBH series, 32.4% (*n* = 11) and 29.4% (*n* = 10) occurred in patients less than 12 and older than 50 years of age (range 5-70 years), respectively, and 32.4% (*n* = 11)

had hepatitis B virus (HBV) infection, suggesting a possible causal link between chronic HBV infection and UES development.

Table 3 Histological classification of malignant primary hepatic space-occupying lesions

Hepatocellular tumors
  Hepatocellular carcinoma[2]
  Hepatoblastoma[2]
  Combined hepatocellular and cholangiocarcinoma[2]
Intrahepatic bile duct tumors
  Intrahepatic cholangiocarcinoma[2]
  Cholangiolocellular carcinoma[62]
  Bile duct cystadenocarcinoma[2]
  Biliary rhabdomyosarcoma[63]
  Solid-pseudopapilary tumor[64]
Vascular, lymphoid and haemopoietic tumors
  Angiosarcoma[2]
  Malignant angiomyolipoma[60]/malignant perivascular epithelioid
  cell tumor[61]
  Malignant hemangiopericytoma[65]
  Epithelioid hemangioendothelioma[2]
  Kaposi's sarcoma[2]
  Lymphoma[2]
  Follicular dendritic cell sarcoma/tumor[66]
  Extramedullary plasmacytoma[67]
Muscle, fibrous and adipose tumors
  Leiomyosarcoma[68]
  Rhabdomyosarcoma[69]
  Fibrosarcoma[70]
  Malignant fibrous histocytoma[71]
  Liposarcoma[72]
Neuronal and neuroendocrine tumors
  Carcinoid tumor[73]
  Malignant neurilemmoma[74]
Miscellaneous tumors
  Undifferentiated embryonal sarcoma[75]
  Undifferentiated carcinoma[76]
  Carcinosarcoma[2]
  Lymphoepithelioma-like carcinoma[77]
  Squamous cell carcinoma[78]
  Germ cell tumor[79]
  Chorioepithelioma[80]
  Yolk sac tumor[81]
  Immature teratoma[82]
  Malignant rhabdoid tumor[83]
  Malignant mesothelioma[84]
  Synovial sarcoma[85]
  Epithelial-myoepithelial carcinoma[86]
  Gastrointestinal stromal tumor[87]
  Osteosarcoma[88]
  Osteoclast-like giant cell tumor[89]
  Desmoplastic small round cell tumor[90]
  Nested stromal-epithelial tumor[91]/ossifying stromal epithelial
  tumor[92]

The incidence of primary hepatic lymphoma (PHL, 0.09%, *n* = 23) was similar to that of UES and HB (0.1%). It has been reported that hepatitis C virus (HCV) plays a role in the pathogenesis of lymphoma, with an HCV prevalence rate of 9% to 42%, especially in Western countries[94]. In contrast, the prevalence of HCV in our patients with PHL was only 4.3% (1 of 23 cases), whereas 56.5% (13 of 23) were positive for HBV, and three of them underwent surgical resections for simultaneous co-existence of PHL with HCC as two independent masses in the liver. Thus, we hypothesize that HBV, as a kind of lymphotropic virus, may play an important pathogenic role in the development of PHL in China.

CONCLUSION

In summary, based on the large number of surgically resected PHSOLs in the EHBH series, we propose a comprehensive surgicopathological classification system that comprises more than 100 kinds of PHSOLs, with three basic types and six subtypes. Our classification system covers all the entities in the new histological classification system generated by the WHO, which included about 30 kinds of PHSOLs, except for microscopic cellular abnormalities[26]. We do not describe details concerning molecular genetics, diagnostic criteria, biological behaviors, treatment strategies, and clinical prognoses for each PHSOL, as they can be found in the given references. Although it is still possible that new types of PHSOLs will be discovered, we think that the above brief summary may provide useful information as a new classification system and current reference for clinicians and pathologists to understand the features of histological spectrum, as well as the differential diagnostic features, of PHSOLs.

Abstract

AIM: To investigate the effects of schisandrin B (Sch B) on free fatty acid (FFA)-induced steatosis in L-02 cells.

METHODS: Cellular steatosis was induced by incubating L-02 cells with a FFA mixture (oleate and palmitate at the ratio of 2:1) for 24 h. Cytotoxicity and apoptosis were evaluated by 3-(4, 5-dmethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide assay and Annexin V/propidium iodide staining, respectively. Cellular total lipid was determined using a photocolorimetric method after Nile red staining, and triglyceride content was measured using an enzymatic kit. To study the effects of Sch B on steatosis, L-02 cells were treated with Sch B (1-100 μmol/L) in the absence or presence of 1 mmol/L FFA for 24 h, and cellular total lipid and triglyceride levels were measured. To explore the mechanisms of action of Sch B in the steatotic L-02 cells, mRNA levels of several regulators of hepatic lipid metabolism in-cluding adipose differentiation related protein (ADRP), sterol regulatory element binding protein 1 (SREBP-1), peroxisome proliferator-activated receptor (PPAR)-α and PPAR-γ were measured by quantitative real-time polymerase chain reaction (PCR), and protein levels of ADRP and SREBP-1 were measured by immunoblotting.

RESULTS: Treatment with 1 mmol/L FFA for 24 h induced intracellular lipid accumulation in L-02 cells comparable to that in human steatotic livers without causing apparent apoptosis and cytotoxicity. Sch B mitigated cellular total lipid and triglyceride accumulations in the steatotic L-02 cells in a dose-dependent manner. Quantitative real-time PCR and Western blot analyses revealed that treatment of L-02 cells with 100 μmol/L Sch B reverted the FFA-stimulated up-regulation of ADRP and SREBP-1.

CONCLUSION: Sch B inhibits FFA-induced steatosis in L-02 cells by, at least in part, reversing the up-regulation of ADRP and SREBP-1.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) has emerged

as a serious and widespread metabolic disease, which entails a wide spectrum of liver disorders and damages ranging from simple steatosis through steatohepatitis and fibrosis to end stage liver diseases including cirrhosis and hepatocellular carcinoma[1]. The clinical significance of NAFLD is largely due to its high prevalence of around 20% in general populations and up to 80% in obese and diabetic individuals worldwide[2]. Although the pathogenesis of NAFLD has not been clearly defined, hepatic steatosis characterized by uncontrolled triglyceride accumulation in hepatocytes and oxidative stress are believed to play a crucial role[3]. Therefore, agents that are capable of lowering hepatic lipid levels and alleviating oxidative stress may be beneficial to the control of NAFLD.

Schisandrin B (Sch B) (Figure 1) is the most abundant and active dibenzocyclooctadiene derivative isolated from the fruits of *Schisandra chinensis*, a traditional Chinese medicinal herb commonly used in treatment of viral and chemical hepatitis. A growing body of evidence has shown that Sch B can protect liver from damage caused by oxidative stress. Sch B may inhibit oxygen free-radical lipoperoxidative damage to plasma membrane of rat hepatocytes *in vitro*[4]. Sch B pretreatment protects mouse livers against tumor necrosis factor α-induced apoptosis in a dose-dependent manner[5]. In addition, Sch B can protect mice against carbon tetrachloride-induced hepatic toxicity by inhibiting lipid peroxidation[6]. Recently, we have reported that Sch B has hepatic lipid lowering effects in mice fed a high-fat diet[7]. These lines of evidence underscore both hepatic lipid-lowering and antioxidant effects of Sch B, making it a promising candidate for the treatment of NAFLD. Although the antioxidant role of Sch B has been well investigated, the mechanism underlying its hepatic lipid-lowering action remains unknown. This study was designed to investigate the anti-hepatosteatotic effects and mechanisms of Sch B using cultured steatotic cells.

NAFLD patients exhibit an elevated lipolysis and high circulating free fatty acid (FFA) levels[8]. High circulating FFA levels can trigger a series of biological changes in hepatic lipid metabolism, thus ultimately leading to hepatic steatosis[9]. Therefore, cellular FFA loading is commonly utilized to develop *in vitro* models of steatosis. These models can reliably reproduce the key features of hepatic steatosis in human beings[10-12], rendering them useful for the identification of potential therapeutic targets and effective intervention approaches against NAFLD. Human hepatocytes in primary culture represent the model closest to human liver tissues. Nevertheless, their use is often greatly hampered due to scarcity of liver samples[13]. HepG2 and Huh-7, two human hepatoma cell lines, are frequently used in establishing *in vitro* steatosis models. However, the validity of cancer cell-based models is concerned because metabolic regulation is often altered in cancer cells. For example, it has been highlighted that cancer cells may carry out an increased fatty acid *de novo* synthesis irrespective of the extracellular lipid levels[13]. Therefore, in this study, we first established FFA-induced

steatotic cells using an immortalized normal human hepatocytes-derived cell line L-02[14,15]. Then, we investigated the *in vitro* effects of Sch B on hepatosteatosis in the steatotic L-02 cells, and explored the underlying mechanisms.

MATERIALS AND METHODS

Cell culture and treatment
L-02 (Institute of Biochemistry and Cell Biology, Shanghai Institute for Biological Sciences, Shanghai, China) and HepG2 (ATCC) cells were grown in Dulbecco's modified Eagle's medium (DMEM, GIBCO) supplemented with 10% fetal bovine serum (FBS, GIBCO, USA) and 1% penicillin/streptomycin (P/S, GIBCO, USA) at 37℃ in an atmosphere containing 5% CO_2. When FFA mixture (sodium salts of oleate and palmitate, Sigma, Malaysia) was added, bovine serum albumin (BSA) was supplemented to a final concentration of 1% in the culture medium. Cell cultures were used in experiments when they reached 75% confluence.

Sch B was purchased from Ningli Technology Co. Ltd. (Kunming, China) with a purity of 98% as determined by HPLC. A stock solution of Sch B (100 mmol/L) was prepared in dimethylsulfoxide (DMSO). The concentration of vehicle DMSO was 0.1% in treated cell cultures.

Cell viability assay
Cytotoxicity of FFA to L-02 cells was assessed by 3-(4, 5-dmethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide (MTT) assay. L-02 cells in 96-well plates were treated with FFA. After incubated for 24 h, 20 μL of MTT solution (5 mg/mL, USB, Austria) was added to each well and the plates were further incubated at 37℃ for 4 h. After medium removal, 100 μL of DMSO was added to each well of the plates which were then gently shaken for 5 min. Optical absorbance was determined at 570 nm with a microplate spectrophotometer (BD Bioscience, USA). Each treatment was performed in triplicate.

Quantification of apoptosis
Early and late phase apoptotic cells were assessed using the Annexin V-fluorescein isothiocyanate (FITC) apoptosis detection kit I (BD Bioscience, USA) following the manufacturer's instructions. After treatment with FFA, L-02 cells were harvested and rinsed twice with cold PBS, resuspended in the binding buffer, and incubated with Annexin V-FITC and propidium iodide (PI) staining solution. Samples of 10 000 stained cells were analyzed using a flow cytometer (BD Bioscience, USA).

Nile red staining
L-02 cells in F96 microwell black plates (Nunc, Denmark) were treated with FFA in the presence or absence of Sch B for 24 h. Photocolorimetric measurement of intracellular lipid contents in Nile red stained cells was performed as previously described[16]. Each treatment was performed in triplicate.

Figure 1 Chemical structure of schisandrin B.

Phase-contrast and fluorescence microscope imaging

L-02 cells in 6-well plates were treated with FFA for 24 h, washed with PBS, stained with 1 μmol/L Nile red in HBSS for 15 min and then examined under phase-contrast (Leica, Germany) and fluorescence (Nikon, Japan) microscopes.

Measurement of intracellular triglyceride content

Cellular triglyceride content was measured using an enzymatic kit (Zhongsheng Beikong Biotechnology and Science Inc, China) following the manufacturer's instructions. Triglyceride content was expressed in microgram of triglycerides per microgram protein. Protein concentration was measured by Bio-Rad protein assay (Bio-Rad, USA). Each treatment was performed in triplicate.

Semi-quantitative and real-time quantitative polymerase chain reaction analyses

Total RNA was extracted with Trizol reagent (Invitrogen, USA), and 2 μg of RNA was reverse-transcribed with oligo-dT using the M-MLV reverse transcriptase (Promega, USA) according to the manufacturer's protocol. For semi-quatitative polymerase chain reaction (PCR), the resultant cDNA was subjected to 25-30 cycles of PCR amplification (denaturing at 95℃ for 30 s, annealing at 55-60℃ for 30 s, extension at 72℃ for 60 s). The PCR products were separated by electrophoresis on a 2% agarose gel and visualized with ethidium bromide staining. Quantitative real-time PCR was performed using SYBR green reaction mixture in the ABI 7500 fast real-time PCR system (Applied Biosystems). The PCR conditions were one cycle at 55℃ for 2 min and at 95℃ for 10 min, followed by 40 cycles of amplification at 95℃ for 15 s and at 60℃ for 1 min. The fluorescent signals were detected using the ABI Prism 7500HT sequence detection system (Applied Biosystems). The gene expression data were normalized to the endogenous control β-actin. The relative expression levels of genes were measured according to the formula $2^{-\Delta Ct}$, where ΔCt is the difference in threshold cycle values between the targets and β-actin. All samples were analyzed in triplicate. The specific primer pairs used for detecting messenger RNA are listed in Table 1.

Western blot analysis

L-02 cells were harvested and lysed on ice with the RIPA buffer consisting of 50 mmol/L Tris-Cl, 1% NP-40, 0.35% sodium-deoxycholate, 150 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, pH 7.4, 1 mmol/L phenylmethylsulfonyl fluoride, 1 mmol/L NaF, 1 mmol/L Na_3VO_4 and 10 μg/mL each of aprotinin, leupetin and pepstatin A. Protein concentration in each sample was measured by the Bio-Rad protein assay. Protein samples (each 15 μg) were separated by SDS-PAGE and then electro-transferred onto nitrocellulose membranes (Amersham Biosciences, USA), which were blocked for 30 min with 5% skim milk in the TBST buffer containing 50 mmol/L Tris (pH 7.6), 150 mmol/L NaCl and 0.1% Tween-20 and incubated with specific antibodies against adipose differentiation related protein (ADRP) (Abcam), sterol regulatory element binding protein 1 (SREBP-1) (Santa Cruz) or β-actin (Santa Cruz) overnight at 4℃. The membranes were then incubated with HRP-conjugated secondary antibodies, and immunoreactive bands were visualized using the ECL detection kit (Amersham Biosciences, USA) following the manufacturer's instructions.

Statistical analysis

All results were expressed as mean ± SE. The difference between two groups was analyzed using the Student's *t* test.

RESULTS

Cytotoxic effect of FFA treatment on L-02 cells

L-02 cells were treated with 0.5-2 mmol/L a FFA mixture (oleate and palmitate at the ratio of 2:1) for 24 h and the cytotoxicity of FFA to L-02 cells was detected by MTT

Figure 2 Cytotoxic and apoptotic effects of free fatty acid treatment on cultured cells. A: L-02 cells were treated with a free fatty acid (FFA) mixture (oleate and palmitate at the ratio of 2:1) at various concentrations for 24 h. Cell viability was determined by the 3-(4,5)-dimethylthiahiazo (-z-y1)-3,5-di- phenytetrazoliumromide (MTT) assay. [b]P < 0.01 *vs* control group; B: L-02 and HepG2 cells were treated with 1 mmol/L FFA mixture (oleate and palmitate at the ratio of 2:1) for 24 h and stained with Annexin V-fluorescein isothiocyanate (FITC) and propidium iodide. Apoptotic and necrotic cells were monitored by flow cytometry. Normal, early and late apoptotic cells as well as necrotic cells were shown in Q3, Q4, Q2 and Q1 quadrants, respectively. The percentage of cells in each quadrant was displayed. Results were the representative of three independent experiments; C: Quantification of early phase apoptotic cells in response to FFA treatment. [b]P < 0.01 *vs* HepG2 control group.

assay. No apparent cytotoxic effect of FFA was observed on L-02 cells after treatment with FFA at the concentration of 0.5 or 1 mmol/L, while the cell viability was decreased by 40% when L-02 cells were treated with FFA at the concentration of 2 mmol/L (Figure 2A). These results suggest that 0.5 or 1 but not 2 mmol/L FFA can be used to prepare steatotic L-02 cells.

Apoptotic effect of FFA treatment on L-02 cells
To evaluate the apoptotic effect of FFA treatment on L-02 cells, the L-02 cells were treated with 1 mmol/L FFA (oleate and palmitate at the ratio of 2:1) for 24 h, and then stained with Annexin V/PI. Apoptosis of L-02 cells was monitored by flow cytometry. For comparison, apoptosis of HepG2 cells induced by FFA treatment was also analyzed. FFA treatment did not trigger early- or late-stage apoptosis of L-02 cells but significantly induced early-stage apoptosis of HepG2 cells (Figure 2B and C). The percentage of apoptotic HepG2 cells was increased from 1.500% ± 0.473% in control cells to 9.267% ± 0.203% in FFA-treated cells (Figure 2C), which is consistent with previous reports showing that FFA causes apoptosis of HepG2 cells under the same conditions[11,12]. These results suggest that L-02 and HepG2 cell lines do have different responses to FFA treatment.

FFA treatment induced lipid accumulation in L-02 cells
We next examined the cellular lipid accumulation in L-02

cells treated with the FFA mixture for 24 h at the concentration of 0.5 mmol/L or 1 mmol/L using Nile red staining. The results showed that FFA induced lipid accumulation (Figure 3A) in L-02 cells in a dose-dependent manner, which was confirmed by fluorescent microscopy (Figure 3B). When the L-02 cells were treated with FFA mixture at the concentration of 1 mmol/L, the intracellular lipid content was increased by 5.34 ± 0.65-fold in L-02 cells compared to that in FFA-untreated controls (Figure 3A). The cellular lipid accumulation level in L-02 cells treated with FFA at the concentration of 1 mmol/L was comparable to that in human steatotic livers, which is 5.5-fold over non-steatotic livers[13].

We also measured the intracellular triglyceride levels in L-02 cells treated with FFA mixture at the concentration of 1 mmol/L. The triglyceride content was increased by about 2.5-fold from 0.108 ± 0.027 μg/μg protein in control cells to 0.241 ± 0.030 μg/μg protein in FFA-treated cells (Figure 3C), which is similar to the results obtained from human liver samples. The triglyceride content is about 2.7-fold higher in human steatotic livers than in non-steatosis livers[13].

The above data indicate that steatotic cells can be prepared by incubating L-02 cells with a FFA mixture (oleate and palmitate at the ratio of 2:1) at the concentration of 1 mmol/L for 24 h, in which lipid accumulation can reach a level similar to that in human steatotic livers in the absence of apoptosis.

Figure 3 Free fatty acid induced lipid accumulation in L-02 cells. A: L-02 cells were incubated with a free fatty acid (FFA) mixture (oleate and palmitate at the ratio of 2:1) for 24 h. Intracellular lipid accumulation was evaluated after Nile red staining. Results were expressed as mean ± SE of three independent experiments. [b]$P < 0.01$ *vs* control group; B: Representative micrographs showing intracellular lipid accumulation in L-02 cells as observed by phase-contrast microscopy (panels a-c) and fluorescence microscopy (panels d-f). Panels a/d, b/e and c/f are control cells, cells treated with 0.5 and 1 mmol/L FFA, respectively; C: Triglyceride levels in L-02 cells treated with 1 mmol/L FFA. Results were expressed as mean ± SE of three independent experiments. [b]$P < 0.01$ *vs* control group.

Sch B treatment alleviated FFA-induced lipid accumulation in L-02 cells

To investigate the anti-steatotic effect of Sch B in L-02 cells, L-02 cells were exposed to various concentrations of Sch B (1-100 μmol/L) in the absence or presence of FFA mixture at the concentration of 1 mmol/L for 24 h. The intracellular total lipid levels in L-02 cells were measured after Nile red staining and the triglyceride contents were assayed using an enzymatic kit. Nile red staining assay showed that Sch B at all concentrations had no significant effect on the cellular lipid content in L-02 cells in the absence of FFA, but substantially ameliorated the lipid accumulation induced by FFA in a dose-dependent manner (Figure 4A). The lipid-lowering effect of Sch B at the concentration of 100 μmol/L was further confirmed

by microscopic examination of the fluorescence of Nile red-stained L-02 cells (Figure 4B). The intracellular triglyceride measurements showed that Sch B inhibited the fat accumulation in a dose-dependent manner, and exerted a significant inhibitory effect in L-02 cells treated with FFA at the concentration of 1 mmol/L (Figure 4C). It was noteworthy that Sch B at each tested concentration did not elicit apparent cytotoxicity or apoptosis in L-02 cells in the presence or absence of 1 mmol/L FFA at 24 h (data not shown).

Sch B decreased mRNA and protein expression levels of ADRP and SREBP-1 in FFA-induced steatotic L-02 cells

To explore the mechanisms underlying Sch B-mediated lipid-lowering action in L-02 cells, the mRNA expression lev-

Figure 4 Effect of schisandrin B on free fatty acid-induced fat accumulation in L-02 cells. A: L-02 cells were treated with schisandrin (Sch B) (1 μmol/L, 10 μmol/L or 100 μmol/L) in the presence or absence of 1 mmol/L free fatty acid (FFA) mixture (oleate and palmitate at the ratio of 2:1) for 24 h. Intracellular total lipid levels were measured after Nile red staining; B: Representative micrographs showing intracellular lipid accumulation in Nile red stained L-02 cells after treatment with 100 μmol/L Sch B in the presence of 1 mmol/L FFA examined by fluorescent microscopy; C: L-02 cells were treated with Sch B at the indicated concentrations for 24 h and cellular triglyceride levels were measured using an enzymatic kit. [b]$P < 0.01$ *vs* FFA-untreated control groups; [c]$P < 0.05$, [d]$P < 0.01$ *vs* FFA-treated groups. Data are from three independent experiments.

els of ADRP, SREBP-1, peroxisome proliferator-activated receptor (PPAR)-α and PPAR-γ, four important regulators of hepatic lipid metabolism, were first measured by semi-quantitative PCR and quantitative real-time PCR, respectively. Sch B attenuated the FFA-induced fat accumulation most effectively at the concentration of 100 μmol/L, thus this dosage of Sch B was used in this experiment. The mRNA expression level of PPAR-α remained unchanged in FFA-treated L-02 cells, while the mRNA expression levels of the other three genes were up-regulated (Figure 5A and B). Concurrent treatment with Sch B at the concentration of 100 μmol/L for 24 h restored the FFA-upregulated ADRP and SREBP-1 expression to normal levels, but did not affect FFA-stimulated PPAR-γ mRNA expression. In addition, Sch B treatment did not obviously influence the expression of PPAR-α in L-02 cells in the presence of FFA.

Immunoblot analysis showed that the protein levels of ADRP and SREBP-1 were dramatically elevated in L-02 cells in response to FFA treatment, but returned to normal levels after concurrent treatment with Sch B (Figure 5C).

DISCUSSION

FFA-induced hepatocellular steatosis models have been widely applied in studies on NAFLD pathogenesis and anti-NAFLD drugs[13,17]. Although human hepatocytes in primary culture represent the most stringent model of the human liver, they are tedious to prepare and the reproducibility of experimental results is often a big problem[18,19]. On the other hand, the use of liver cancer cell lines including HepG2 and Huh-7 is often questioned about their acquired genetic and epigenetic alterations which may endow them with numerous properties including metabolism regulation distinct from normal hepatocytes[20]. In the present study, we successfully prepared FFA-induced steatotic cells using a normal human hepatocytes-derived cell line L-02. The steatotic L-02 cells behave similarly to human steatotic livers in two aspects. First, 24 h treatment with a FFA mixture (oleate and palmitate at the ratio of 2:1) at the concentration of 1 mmol/L caused no apparent toxicity to L-02 cells. Second, the induced fat accumulation in L-02 cells was comparable to that in human steatotic livers[13]. These aforementioned attributes make FFA-induced steatotic L-02 cells suitable for the investigations of NAFLD pathogenesis and anti-NAFLD agents.

High circulating FFA concentration may aggravate hepatic fat accumulation by disrupting lipid metabolism in NAFLD patients, and thus studying how FFA overload influences metabolic regulators will further improve our

Figure 5 Effect of schisandrin B on mRNA and protein expression levels of several lipid metabolism-related molecules in free fatty acid-treated L-02 cells.

understanding about the pathogenesis of NAFLD. Given that palmitic and oleic acids are the most abundant fatty acids in liver triglycerides in both normal subjects and NAFLD patients[21], clarification of their effect on hepatocytes is of great importance. In the present study, treatment of L-02 cells with a FFA mixture (oleate and palmitate at the ratio of 2:1) did not significantly affect PPAR-α mRNA expression level but increased the mRNA expression levels of ADRP, SREBP-1 and PPAR-γ. The unchanged PPAR-α mRNA expression in L-02 cells treated with FFA suggests that PPAR-α-mediated mitochondria fatty acid β-oxidation may not been affected by FFA in our experimental conditions. The increased SREBP-1 and PPAR-γ mRNA expression levels in response to FFA treatment are in good accord with a recent report assuming that the up-regulations of SREBP-1 and PPAR-γ are linked to the steatogenic property of oleic acid[17]. Moreover, the ADRP mRNA expression was elevated in L-02 cells challenged with FFA, which is in agreement with the reported observations in other cell lines treated with FFA[22,23]. ADRP is a lipid storage droplet-associated protein found in most cells and tissues, and has been suggested to be a marker of lipid accumulation, because the cellular level of ADRP is proportional to the total mass of neutral lipids within the cells[24]. Fatty acids have been implicated as ligands for PPAR family members including PPAR-α and PPAR-γ, it is thus believed that the stimulation of ADRP gene by FFA is at least in part due to PPAR activation. It has been shown that the activated PPAR can complex with retinoid X receptor and bind to the PPAR response element in the promoter of ADRP gene[25,26]. As both PPAR-α and PPAR-γ were detectable in L-02 cells, further studies are needed to ascertain whether one or both of them are required for the up-regulation of ADRP gene expression induced by FFA treatment. These findings suggest that exposure to exogenous FFA may interfere with lipid metabolism through the modulation of metabolic regulators in L-02 cell line derived from normal human hepatocytes.

We demonstrated that Sch B exerted a drastic inhibitory effect on FFA-induced steatosis in L-02 cells. This finding and the hepatic lipid-lowering action of Sch B observed in high-fat diet-fed mice[7] strongly highlight the anti-steatosis potential of Sch B. Since FFA overloading contributed to hepatic fat accumulation through modulation of lipid metabolism- related genes in our established steatotic L-02 cells, it is conceivable that Sch B may attenuate fat accumulation by counteracting or reversing the unfavorable changes in expression of genes evoked by FFA. In this study, Sch B treatment restored the FFA-induced up-regulation of both mRNA and protein levels of ADRP and SREBP-1 to normal levels, indicating that ADRP and SREBP-1 are the potential targets of Sch B in relation to its lipid-lowering property.

ADRP expression is closely associated with intracellular lipid droplets and up-regulated in hepatic steatosis in human and mouse models[27,28]. It has been reported that ADRP overexpression may promote lipid accumulation in fibroblasts and macrophages without changing the expression of adipogenic genes and genes involved in lipid efflux[29,30]. Intriguingly, ADRP overexpression may facilitate the uptake of long chain FFA in COS-7 cells[31]. Moreover, Edvardsson *et al*[32] have recently proposed that ADRP may enhance cellular triglyceride accumulation in hepatocytes by increasing fatty acid uptake, driving fatty acids to triglyceride formation as well as preventing the use of triglyceride in VLDL assembly. In this connection, the down-regulation of ADRP may contribute to the anti-hepatosteatotic effect of Sch B by inhibiting the uptake of exogenous long chain FFA, decreasing the incorporation of FFA into triglyceride and increasing the availability of triglyceride for VLDL assembly. It has been demonstrated that ADRP-deficient mice produced by either knock-out or anti-sense oligonucleptide technology do not acquire diet-induced hepatic steatosis[26,33,34], raising the possibility that ADRP may become a putative molecular target for the prevention of NAFLD，thus screening for compounds that can repress hepatic ADRP expression may provide a new direction for the identification of potential therapeutic agents against NAFLD. It has been recently demonstrated that pycnogenol, a French maritime pine bark extract, can reduce oleic acid-induced lipid droplet formation in mouse liver epithelial cells MMuLi by inhibiting ADRP expression, and interestingly the suppression of ADRP expression is mediated in part by facilitating mRNA degradation[23]. How Sch B impairs ADRP expression in steatotic L-02 cells remains to be evaluated.

SREBP-1 is the most important transcription factor regulating *de novo* lipogenesis in the liver. There is compelling evidence that supports the involvement of SREBP-1 in NAFLD development. It has been reported that SREBP-1 expression is significantly elevated in livers from NAFLD and obesity patients, and from insulin-resistant and hyperinsulinemic *ob/ob* mice[27,35,36]. Overexpression of SREBP-1 in cultured hepatocytes or mouse livers can increase hepatic triglyceride deposition and mRNA expression of genes involved in lipogenesis[37-39]. Moreover, in Lep[ob/ob] mice deficient in SREBP-1, hepatic steatosis is markedly attenuated, which is accompanied by decreased mRNA levels of lipogenic enzymes[40]. These lines of evidence strongly suggest that SREBP-1 plays a pivotal role in the regulation of hepatic lipid metabolism, thus pharmacological manipulation of SREBP-1 may be beneficial to the management of NAFLD. In this study, Sch B could reverse FFA-induced up-regulation of SREBP-1. Therefore it is plausible to infer that the down-regulation of SREBP-1 may partly contribute to the lipid-lowering activity of Sch B by inhibiting *de novo* lipogenesis. Since SREBP-1 may transcriptionally activate a variety of genes required for lipogenesis in the liver[41], it is of interest to investigate which SREBP-1 target genes are regulated by Sch B. Another question is how Sch B regulates the expression of SREBP-1. A most recently study showed that resveratrol inhibits palmitate-induced lipid accumulation in HepG2 cells by reducing the up-regulation of SREBP-1 *via* the Sirt1-FOXO1 pathway[42]. Whether the Sirt1-FOXO1 pathway is involved in Sch B-mediated down-regulation of SREBP-1 remains to be clarified.

In summary, Sch B has an inhibitory effect on FFA-induced steatosis in L-02 cells, and the decreased expression of ADRP and SREBP-1 may account for the inhibitory effect of Sch B by reducing FFA uptake, incorporation of FFA into triglycerides and *de novo* fatty acid synthesis, as well as by increasing VLDL assembly. Changes in ADRP and SREBP-1 expression may also provide mechanistic explanations for the hepatic lipid-lowering effect of Sch B in mice fed a high-fat diet as reported previously by us. The results of this study provide the molecular evidence for developing Sch B as a therapeutic agent against NAFLD.

COMMENTS

Background

Non-alcoholic fatty liver disease (NAFLD), characterized by fatty infiltration of the liver (hepatic steatosis), is posing a definite threat to global human health. So far, no satisfactory therapeutic agent is available against NAFLD. Schisandrin B (Sch B), a bioactive constituent isolated from Fructus Schisandrae, has been recently reported to exhibit hepatic lipid-lowering effect in mice fed with a high-fat diet. However, the mechanisms of action remain to be elucidated.

Research frontiers

The circulating free fatty acid (FFA) levels are often elevated in NAFLD patients, which may promote the disease progression by interfering with hepatic lipid metabolism through modulating the expression of important metabolic regulators. Cellular FFA loading is commonly utilized to develop *in vitro* models of steatosis valuable for the study of anti-steatosis agents.

Innovations and breakthroughs

The use of human hepatocarcinoma cell lines in developing cellular steatosis models has been questioned due to the altered metabolic regulation in cancerous cells. In this study, FFA-induced steatotic cells were successfully prepared using a normal human hepatocytes-derived cell line L-02. Using this model, the authors demonstrated that Sch B effectively attenuated FFA-induced fat accumulation by abrogating up-regulations of two key metabolic regulators, namely adipose differentiation related protein (ADRP) and sterol regulatory element binding protein 1 (SREBP-1).

Applications

FFA-induced steatotic L-02 cells can be used in investigations of anti-steatosis agents and NAFLD pathogenesis. By understanding how Sch B alleviates cellular steatosis, this study provides the molecular evidence for developing Sch B as a therapeutic agent against NAFLD.

Terminology

ADRP and SREBP-1 are important proteins involved in lipid metabolism in normal livers, and their aberrant expression is believed to contribute to the development of NAFLD.

Peer review

The authors examined the anti-steatotic effects of Sch B on human hepatocytes line treated *in vitro* with FFAs to induce steatosis. Sch B reduced cellular total lipid and triglyceride levels in a dose dependent manner, which is consistent with the earlier findings. The novel aspect of this study is that the expression of ADRP and SREBP-1, two lipid metabolism regulators, is reduced by Sch B, which provides some insights into the mechanism of action of Sch B.

Abstract

AIM: To investigate the role of CXC chemokine recep-
tor-4 (CXCR4) and stromal cell-derived factor-1 (SDF-1)
in lymph node metastasis of gastric carcinoma.

METHODS: In 40 cases of gastric cancer, expression
of CXCR4 mRNA in cancer and normal mucous mem-
brane and SDF-1 mRNA in lymph nodes around the
stomach was detected using quantitative polymerase
chain reaction (PCR) (TaqMan) and immunohistochem-
istric assay. SGC-7901 and MGC80-3 cancer cells were
used to investigate the effect of SDF-1 on cell prolifera-
tion and migration.

RESULTS: Quantitative reverse transcription PCR and
immunohistochemistry revealed that the expression level
of CXCR4 in gastric cancer was significantly higher than

that in normal mucous membrane (1.6244 ± 1.3801
vs 1.0715 ± 0.5243, *P* < 0.05). The expression level
of CXCR4 mRNA in gastric cancer with lymph node
metastasis was also significantly higher than that with-
out lymph node metastasis (0.823 ± 0.551 *vs* 0.392 ±
0.338, *P* < 0.05). CXCR4 expression was significantly
related to poorly differentiated, high tumor stage and
lymph node metastasis. Significant differences in the
expression level of SDF-1 mRNA were found between
lymph nodes in metastatic gastric cancer and normal
nodes (0.5432 ± 0.4907 *vs* 0.2640 ± 0.2601, *P* < 0.05).
The positive expression of SDF-1 mRNA in lymph nodes
of metastatic gastric cancer was consistent with the
positive expression of CXCR4 mRNA in gastric cancer (*r*
= 0.776, *P* < 0.01). Additionally, human gastric cancer
cell lines expressed CXCR4 and showed vigorous prolif-
eration and migratory responses to SDF-1. AMD3100 (a
specific CXCR4 antagonist) was also found to effectively
reduce the migration of gastric cancer cells.

CONCLUSION: The CXCR4/SDF-1 axis is involved in
the lymph node metastasis of gastric cancer. CXCR4
is considered as a potential therapeutic target in the
treatment of gastric cancer.

INTRODUCTION

Gastric cancer is one of the most commonly diagnosed malignancies and the main cause of cancer-related deaths in Asian populations. Most deaths from gastric cancer are caused by metastasis, of which lymph node metastasis is the most common cause, which leads to the failure of surgery, chemotherapy or radiotherapy. Therefore, inhibition of metastatic gastric cancer is an important therapeutic strategy. However, the molecular mechanisms involved in this process have not been fully elucidated.

Chemokines are a family of small heparin-binding and secretory proteins, and through interactions with their corresponding receptors, they can control and activate many types of cells. According to the position of the four conserved cysteine residues in the amino acid sequence, they are classified into four groups (CXC, CX3C, CC and C). Stromal cell-derived factor (SDF)-1 is a member of the CXC subfamily, which was first cloned from murine bone marrow[1]. SDF-1 exerts an effect through interaction with its specific receptor CXC chemokine receptor-4 (CXCR4). Many studies have proven that CXCR4 is the major chemokine receptor expressed in many types of cancer cells[2,3]. and demonstrated that the CXCR4/SDF-1 axis plays a major role in cell survival, proliferation, migration and adhesion of several tumor cells, including those from colon cancer[4], breast cancer[5,6], non-small cell lung cancer[7], prostate cancer[8], melanoma[9,10], cholangiocarcinoma[11], and oral squamous cell carcinoma[12], However, most of the studies about SDF-1 and CXCR4 have been conducted *in vitro*, and the definitive pathophysiological functions of the CXCR4/SDF-1 axis in human diseases, especially cancer, require further research.

Recently, it has been suggested that the interaction between CXCR4 and SDF-1 plays an important role in the development of peritoneal carcinomatosis from gastric cancer[13]. We hypothesize that the CXCR4/SDF-1 axis also participates in lymph node metastasis of gastric cancer. To verify the hypothesis, we examined the expression of CXCR4 and SDF-1 in gastric cancers, normal mucous membranes, and their related lymph nodes. We also investigated the relationship between CXCR4 expression and clinicopathological features, and determined whether CXCR4 expression influenced the proliferation and migration of gastric cancer cells *in vitro*.

MATERIALS AND METHODS

Patients and tissue samples

A total of 40 patients with gastric cancer who underwent surgery at the Department of General Surgery, Beijing Chaoyang Hospital, between 2008 and 2009 were enrolled. The patient population consisted of 31 men and nine women, with a mean age of 55 years (range, 31-76 years). Patients who were receiving preoperative chemotherapy and/or radiotherapy were not included. The specimens included the tumor tissue, normal mucous membranes (5 cm away from the tumor), and the lymph nodes around the stomach. All the specimens were collected within 30 min after resection and each specimen was divided into two parts: one was fixed in 4% formalin and embedded in paraffin; and the other was snap-frozen in liquid nitrogen and kept at -80℃. Tumor stage was determined according to the TNM classification system of the International Union against Cancer. Histological diagnosis was confirmed for each specimen. Informed consent was obtained from all patients.

Cell culture

The SGC-7901 and MGC-803 gastric cancer cell lines were grown in RPMI 1640 medium (Sigma, USA) that contained 10% fetal bovine serum (FBS; Sijiqing, Hangzhou, China), 100 U/mL penicillin and 100 μg/mL streptomycin (Sigma). The suspension was placed into T25 flasks and allowed to incubate at 37℃ in a humidified chamber that contained 5% CO_2. The adherent cells were then cultured with medium changed at a 3-d interval. Cells at passage 1-6 were used for all experiments.

Cell proliferation assay

Gastric cancer cells (SGC-7901 and MGC-803) were seeded into 96-well plates at a density of 5×10^3 cells per well without FBS. After 24 h, the cultures were washed and re-fed with medium alone (control) or with medium that contained SDF-1 at various concentrations. After 3 d, the number of viable cells was counted using an MTT assay (Beyotime, China) according to the manufacturer's instructions. The quantity of formazan product measured at 490 nm was proportional to the number of live cells in the culture. The experiments were repeated in triplicate.

Cell migration assays

The invasion potential of cancer cells was assayed using 24-well chemotaxis chambers (Corning, Corning, NY, USA). The upper and lower cultures were separated by 8-μm-pore-size polyvinylpyrrolidone-coated polycarbonate filters. Gastric cancer cells were suspended at 1×10^5 cells/mL in serum-free medium, and 0.2 mL cell suspension was added to the upper chamber. Then 0.5 mL serum-free medium with various concentrations of SDF-1 was added to the lower chamber. In another set of experiments, 0.5 mL serum-free medium with 10 nmol/L SDF-1 (fixed concentration) plus various concentrations of AMD3100 (Sigma) was added to the lower chamber. The chambers were incubated for 12 h at 37℃ in a humid atmosphere of 5% CO_2. After incubation, non-migrated cells were removed from the upper surface of the filters, and the migrated cells adherent to the filters were fixed with ethanol and stained with Giemsa solution. Each experiment was done in triplicate, and cells migrated to the underside of the filter were counted in five fields (10 × magnification) in each well under light microscope.

Immunohistochemistry

Immunohistochemistry was performed using the Histostain-SP kits (Boster, Wuhan, China) according to the manufacturer's recommendations. Sections (4 μm thick) were de-

paraffinized, placed in 0.01 mol/L citrate buffer (pH 6.0), and treated by microwave heating for 15 min. The sections were then placed in a solution of 97% methanol and 3% hydrogen peroxide for 10 min at room temperature, to quench endogenous peroxidase activity. Subsequently, the slides were pretreated with 1% bovine serum albumin in phosphate-buffered saline (PBS) and incubated with anti-SDF-1 antibody (Boster; dilution 1:100) and anti-CXCR4 antibody (Boster; dilution 1:50) for 1 h at room temperature. The primary antibody was washed away with PBS, and the biotinylated secondary antibody was used. After 20 min, the sections were washed with PBS, and treated with peroxidase-conjugated streptavidin for 20 min. Finally, the slides were incubated in 3,3'-diaminobenzidine tetrahydrochloride with 0.05% H_2O_2 for 3 min and counterstained with Carazzi's hematoxylin, dehydrated and mounted.

Evaluation of immunostaining

The slides were examined blindly by three pathologists who had no clinicopathological knowledge of the patients. The intensity of staining and percentage of positive cells were determined by the three observers. The intensity, staining percentage, and pattern of staining (nuclear and cytoplasmic) were assessed for CXCR4 and SDF-1. The intensity of staining (brown color) was scored semi-quantitatively as follows: +, weak; ++, medium; +++, strong; and ++++, very strong. The immunostained sections were scanned under light microscope. Samples with a score of ++ or greater were considered CXCR4 or SDF-1-positive.

Determination of CXCR4 and SDF-1 mRNA expression

Total RNA (500 ng) was isolated from frozen tissues and cell pellets using RNArose reagent (Fulin, Qingdao, China) according to the manufacturer's instructions. Reverse transcription was performed in a final volume of 10 μL that contained 5 × PrimeScript™ Buffer (2 μL), PrimeScript™ RT Enzyme Mix (2 μL), Oligo dT Primer (50 μmol/L) (0.5 μL), Random 6 mers (100 μmol/L) (0.5 μL), RNase Free dH$_2$0 (4.5 μL) using a Reverse Transcription System kit (Takara, Japan). The reverse transcription reaction was performed at 37℃ for 15 min, and 85℃ for 5 s. Gene expression of CXCR4 and SDF-1 was detected by quantitative real-time polymerase chain reaction (PCR) (TaqMan) using the 7500 sequence detector (AB Applied Biosystems, USA) and SDS analysis software. The primers and fluorescent probe for human CXCR4, SDF-1 and GAPDH are shown in Table 1. GAPDH served as a control for efficiency of the amplification in the reactions. Thermal cycle conditions were 95℃ for 10 s for one cycle, followed by 40 cycles of 95℃ for 5 s, and 60℃ for 45 s. The expression level of CXCR4 mRNA and SDF-1 mRNA was obtained by $2^{-\Delta\Delta CT}$ calculation. All PCR products were analyzed on a 2% agarose gel with ethidium bromide staining.

Statistical analysis

The SPSS version 12.0 software was used for statistical analysis. The Pearson χ^2 test or Fisher exact test was used to compare qualitative variables. Quantitative variables were analyzed using Student's *t* test. Results were presented as mean ± SE. Pearson correlation analysis was used for correlation analysis. Probability values < 0.05 were considered significant. All experiments were repeated two or three times with triplicate samples, and similar results were obtained.

Table 1 Primers and fluorescent probe for human CXC chemokine receptor-4, stromal cell-derived factor-1 and GAPDH

Primers	5'-3'	Product (bp)
CXCR4	Forward: TGGCCTTATCCTGCCTGGTAT Reverse: GGAGTCGATGCTGATCCCAAT Taqman: AGAAGCGCAAGGCCCTCAAGACCA	173

CXCR4: CXC chemokine receptor-4; SDF-1: Stromal cell-derived factor-1; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Figure 1 Effect of stromal cell-derived factor-1 on proliferation of gastric cancer cells. Gastric cancer cells were grown in serum-free medium with or without the indicated doses of stromal cell-derived factor-1 (SDF-1). SDF-1 significantly increased the number of SGC-7901 and MGC-803 cells. Maximum effect was observed with 10 nmol/L SDF-1 (^aP < 0.05).

RESULTS

Effect of SDF-1 on gastric cancer cell proliferation

The effect of SDF-1 on cell proliferation was examined in gastric cancer cell lines SGC-7901and MGC-803. After incubation for 72 h, cell proliferation was significantly and dose-dependently enhanced by SDF-1 at concentrations from 0.1 to 200 nmol/L (Figure 1).

Effect of AMD3100 on SDF-1-induced migration of gastric cancer cells

SDF-1 stimulated migration of gastric cancer cells (Figure 2). Maximal effect was observed at 10 nmol/L SDF-1 in all gastric cancer cell lines. The inhibitory effect of AMD3100 on SDF-1-induced migration was tested. The migration induced by SDF-1 at 10 nmol/L was inhibited by AMD3100 in SGC-7901 and MGC-803 cells (Figure 3).

Figure 2 Effect of stromal cell-derived factor-1 on migration of gastric cancer cells. Stromal cell-derived factor-1 (SDF-1) stimulated migration of cancer cells. Maximum effect was observed at 10 nmol/L of SDF-1 ([a]$P < 0.05$).

Figure 3 Effect of AMD3100 on stromal cell-derived factor-1-stimulated migration of gastric cancer cells. Gastric cancer cells were stimulated by stromal cell-derived factor-1 (SDF-1) at 10 nmol/L and various concentrations of AMD3100. Cell migration was decreased as the concentration of AMD3100 increased ([a]$P < 0.05$).

Expression of CXCR4 in gastric cancer tissues and paired normal samples

In the normal gastric epithelium adjacent to the tumor, weak immunoreactivity for CXCR4 was detected in the non-neoplastic epithelial cells. In gastric cancer tissues, CXCR4 immunoreactivity was strong in cancer cells. Staining was observed predominantly in the cytoplasm and plasma membrane of tumor cells (Figure 4A). Twenty (50%) of the 40 gastric cancers were positive for CXCR4 expression at the invasive front, whereas only three (7.5%) of 40 normal mucous membranes were positive for CXCR4. The levels of CXCR4 mRNA were significantly higher in gastric cancers (1.624 ± 1.380) than in its normal counterpart (1.072 ± 0.524, $P = 0.015$) (Figure 5A and Table 2). The levels of CXCR4 mRNA were significantly higher in gastric cancers with lymph node metastasis (32/40) (0.823 ± 0.551) than in those without (8/40) (0.392 ± 0.338, $P = 0.042$) (Table 3).

Localization of CXCR4 proteins in gastric cancer cell lines

Total RNA from the gastric cancer cell lines SGC-7901 and MGC-803 was isolated using RNArose reagent (Fulin,

Table 2 Expression of CXC chemokine receptor-4 in primary gastric carcinoma and normal mucous membrane (mean ± SE)

Tissues	No.	CXCR4-mRNA	*t*	*P*
Gastric cancer	40	1.6244 ± 1.3801	2.554	0.015
Normal mucous membrane	40	1.0715 ± 0.5243		

CXCR4: CXC chemokine receptor-4.

Table 3 Expression of CXC chemokine receptor-4 in primary gastric carcinoma with or without lymph nodes metastasis (mean ± SE)

Absent	8	0.392 ± 0.338		

CXCR4: CXC chemokine receptor-4.

Qingdao, China) according to the manufacturer's instructions. Reverse transcription PCR was carried out as described above. The PCR products were analyzed on a 2% agarose gel with ethidium bromide staining. We found that both SGC-7901 and MGC-803 cells expressed CXCR4 protein (Figure 5B).

Relationship between CXCR4 expression and clinicopathological features in gastric cancer

CXCR4 expression was significantly positive in gastric cancer with poor differentiation, high tumor stage and lymph node metastasis. However, other parameters, age, sex, tumor location and tumor size, had no significant relationship with CXCR4 expression. Clinical and pathological characteristics of patients are listed in Table 4.

Expression of SDF-1 in lymph nodes with or without cancer cell metastasis

Among the 40 lymph nodes that we collected, 24 (60%) had cancer cell metastasis and the remaining nodes were normal. Sixteen (66.7%) of 24 lymph nodes with cancer cell metastasis were positive for SDF-1 expression, whereas only 5/16 (31.3%) were positive in the lymph nodes without metastasis (Figure 4C and D). The levels of SDF-1 mRNA were also significantly higher in the lymph nodes with metastasis (0.5432 ± 0.4907) than in their normal counterparts (0.2640 ± 0.2601, $P = 0.025$) (Figure 5C and Table 5).

Correlation analysis of SDF-1 expression in lymph nodes and CXCR4 expression in gastric cancer

Pearson correlation analysis showed that the positive expression of SDF-1 mRNA in lymph node metastasis of gastric cancer was consistent with the positive expression of CXCR4 mRNA in gastric cancer ($r = 0.776$, $P < 0.01$).

DISCUSSION

The mechanisms of lymph node metastasis in gastric

cancer are complex. The process involves the proteolysis of extracellular matrix, altered cancer cell adhesiveness, local invasion, angiogenesis, vascular dissemination, immune evasion and cancer cell survival in a new microenvironment. Some types of tumors show an organ-specific pattern of metastasis, and the "seed (cancer cells) and soil (factors in the organ environment)" hypothesis has been

SDF-1: Stromal cell-derived factor-1.

introduced[14,15]. To date, the role of the CXCR4/SDF-1 signaling axis in the process of tumor metastasis has been extensively investigated. Most results have confirmed that increased expression of CXCR4 is mainly found in cancers, whereas SDF-1 tends to be overexpressed in normal tissues[16-18]. It has been reported that the signaling axis is involved in lymph node metastasis of breast cancer[13], colorectal cancer[19], nasopharyngeal cancer[20] and thyroid carcinoma[21], and also mediates melanoma metastasis to the lungs[22], prostate cancer metastasis to the bone[23], neuroblastoma metastasis to bone marrow[24], hepatocellular cancer metastasis to the bone[25], non-small cell lung cancer metastasis to the pleural space[26], and gastric cancer metastasis to the peritoneum[13]. Therefore, the CXCR4/SDF-1 signaling axis is essential for organ-specific metastasis, and has become a key determinant of tumor metastasis. The lymph nodes might also serve as the soil to promote the survival and proliferation of cancer cells that then cause lymph node metastasis.

Taking all of these results together, we hypothesize that CXCR4/SDF-1 interaction is generally important for lymph node metastasis of gastric cancer. In the present study, we found that CXCR4 was expressed in 50% of gastric cancers and CXCR4 was upregulated more in gastric cancer than in normal gastric tissues, which confirmed the previous data[13]. We also found a significant increase in SDF-1 mRNA in lymph nodes with cancer cell metastasis in comparison with normal lymph nodes, which confirmed that cancer cells can migrate towards an SDF-1 gradient established in specific target organs. It has been shown that higher levels of SDF-1 in target organs such as liver or lymph nodes attract and recruit cancer cells, which subsequently form lymph node metastases[16]. Therefore, these studies strongly support our hypothesis that the CXCR4/SDF-1 signaling axis plays an important role in the process of lymph nodes metastasis of gastric cancer. In supporting this idea, our clinicopathological study revealed that CXCR4 expression was significantly positive in gastric cancers with a high tumor stage and lymph nodes metastasis. No significant correlation between CXCR4 expression and other clinicopathological factors was found. Our study involved a limited group of patients, and more studies with a larger number of cases are necessary to determine the exact role of the CXCR4/SDF-1 axis in the development of lymph node metastasis of gastric cancer.

In our *in vitro* studies, expression of CXCR4 was also found in the gastric cancer cell lines SGC-7901 and MGC-803. The two cell lines showed significant chemo-

tactic responses to SDF-1 in a dose-dependent manner and the chemotactic responses were significantly blocked by neutralizing anti-CXCR4 antibody. SDF-1 also significantly and dose-dependently enhanced cancer cell proliferation. A similar result has been found in several other tumor cell lines, including small cell lung cancer[27], prostate cancer[28], and squamous cell carcinoma of the neck[29]. In contrast, some studies have demonstrated that SDF-1 has no proliferative effects on pancreatic cancer cell lines[30], rhabdomyosarcoma[31], and lymphohematopoietic cells[32]. These differences may be due to the different culture system or the different target cells used.

It has been shown that chemokine receptor CCR7-positive carcinoma cells were detected in 42 (66%) of 64 cases, and that there was a significant difference in lymph node metastasis and lymphatic invasion between CCR7-positive and CCR7-negative cases, which indicates that CCR7 and its ligands interaction are associated with preferential lymph node metastasis of gastric carcinoma[33]. Arigami *et al*[34] have found recently that levels of combined CCR7 and CXCR4 expression are significantly correlated with lymph node metastasis. Similar results have been also observed in esophageal squamous cell carcinoma[35] and oral[36] squamous cell carcinoma. Additionally, nuclear factor-κB[37], c-erbB-2[38], hypoxia-inducible factor 1[39] or nitric oxide[40] can induce CXCR4 expression, which then plays an important role in lymph node metastasis. Therefore, there are certainly many more factors and/or signaling pathways than we thought that are involved in the process of lymph node metastasis and the exact mechanisms need further studies.

In conclusion, the results in this study indicate that the CXCR4/SDF-1 signaling axis appears to be involved in lymph node metastasis of gastric cancer. CXCR4 overexpression in primary gastric cancers might be an independent risk factor for lymph node metastasis. CXCR4 receptor antagonists can inhibit chemotactic behavior of gastric cancer cells. Based on these results, specific therapies with chemokine receptor antagonists could be helpful in the treatment of patients with gastric cancer metastasis.

COMMENTS

Background
Gastric cancer is one of the most commonly diagnosed malignant tumors. Most deaths from gastric cancer are caused by metastasis, of which lymph node metastasis is the most common cause, which leads to treatment failure. Therefore, inhibition of gastric cancer metastasis is thought to be an important therapeutic strategy. However, the molecular mechanisms involved in this process have not been fully elucidated.

Research frontiers
Many researchers have shown that CXC chemokine receptor-4 (CXCR4) seems to be the major chemokine receptor that is expressed in many types of cancer cells. The CXCR4/ and stromal cell-derived factor-1 (SDF-1) axis plays a major role in survival, proliferation, migration and adhesion of many kinds of tumor cells. However, most of the studies about SDF-1 and CXCR4 have been conducted *in vitro*, and the definitive pathophysiological function of the CXCR4/SDF-1 axis in lymph node metastasis of gastric cancer needs further research.

Innovations and breakthroughs
Recent reports have highlighted the importance of the CXCR4/SDF-1 axis in

cancer metastasis. This study has found that the CXCR4/SDF-1 axis is also involved in lymph node metastasis of gastric cancer. Furthermore, this *in vitro* study has suggested that CXCR4 receptor antagonists could suppress the proliferation and migration of gastric cancer cells.

Applications

By understanding how the CXCR4/SDF-1 axis is involved in lymph node metastasis of gastric cancer, this study could represent a future strategy for therapeutic intervention in patients with lymph node metastasis from gastric cancer.

Terminology

Chemokines are a family of small heparin-binding and secretory proteins, and through interactions with their corresponding receptors, they can control and activate many types of cells. According to the position of the four conserved cysteine residues in the amino acid sequence, they are classified into four groups: CXC, CX3C, CC and C. SDF-1 is a member of the CXC subfamily. CXCR4 is the only receptor of SDF-1 and is expressed in many kinds of tumor cells.

Peer review

This is a nice manuscript with good data. The conclusions fit the data.

Abstract

AIM: To investigate whether the function of hepatocytes co-cultured with bone marrow mesenchymal stem cells (MSCs) could be maintained in serum from acute-on-chronic liver failure (ACLF) patients.

METHODS: Hepatocyte supportive functions and cytotoxicity of sera from 18 patients with viral hepatitis B-induced ACLF and 18 healthy volunteers were evaluated for porcine hepatocytes co-cultured with MSCs and hepatocyte mono-layered culture, respectively. Chemokine profile was also examined for the normal serum and liver failure serum.

RESULTS: Hepatocyte growth factor (HGF) and Tumor necrosis factor; tumor necrosis factor (TNF)-α were remarkably elevated in response to ACLF while epidermal growth factor (EGF) and VEGF levels were significantly decreased. Liver failure serum samples induced a higher detachment rate, lower viability and decreased liver support functions in the homo-hepatocyte culture. Hepatocytes co-cultured with MSCs could tolerate the cytotoxicity of the serum from ACLF patients and had similar liver support functions compared with the hepatocytes cultured with healthy human serum *in vitro*. In addition, co-cultured hepatocytes maintained a proliferative capability despite of the insult from liver failure serum.

CONCLUSION: ACLF serum does not impair the cell morphology, viability, proliferation and overall metabolic capacities of hepatocyte co-cultured with MSCs *in vitro*.

INTRODUCTION

Patients with fulminant hepatic failure (FHF) or acute-on-chronic liver failure (ACLF) represent a major challenge with a high mortality rate despite advances in critical care[1]. Orthotopic liver transplantation (OLT) is one of the choices for the treatment of acute liver failure and end-stage liver diseases although the donors are still insufficient[2]. In addition, OLT is not suitable for the rapidly deteriorating patients due to the irreversible brain damage caused by the cerebral edema and intracranial hypertension. Therefore, alternative therapies are needed to stabilize such patients until an organ is available for transplantation[3]. In the last few years, the isolated, viable and functional cells have been used as a promising therapeutic tool[3]. Applications of cell-based therapy in liver diseases include the development of extracorporeal liver support devices, commonly known as bioartificial livers (BAL), and hepatocyte transplantation, which would ideally serve as a bridge to transplantation or liver regeneration via providing temporary hepatic support[4,5].

To date, several designs for BAL and hepatocyte transplantation have been completed or are being assessed in animal models and human trials[6-8]. It is generally agreed that none of the cell-based therapy currently available can be used as a well defined and practical option in clinical settings, although convincing evidences have validated the usefulness of these modalities in some biochemical parameters and clinical manifestations[6-8]. This is primarily due to the accumulation of a wide range of putative toxic substances within the circulation of hepatic failure patients, which potentially diminish the efficacy of BAL devices or cell transplant[9-10]. *In vitro* studies have demonstrated that serum of patients with acute hepatic failure or FHF can inhibit DNA, RNA and protein synthesis and disrupt cellular integrity, ion transport and metabolic functions in hepatocytes[9-13]. Given that most of the studies concerning the effects of patients' plasma or serum on liver cells use monolayer-cultured hepatocytes or transformed cell lines, and direct contact exists between the patient's serum, plasma or blood and the exogenous hepatocytes in the current cell-based therapy, it is necessary to investigate whether three-dimensional (3-D) hepatocyte culture system could resist the cytotoxicity of circulating inhibitory factors in the serum or plasma of the liver failure patients[14-15].

In our previous studies, we reported a new-brand BAL configuration for the development of a 3-D porcine hepatocyte culture system by co-culturing with bone marrow mesenchymal stem cells (MSCs) *in vitro*[16-18]. Inductions of albumin production, urea synthesis and cytochrome P4503A1 activities were maximally achieved at a seeding ratio of 2/1 for hepatocytes versus MSCs[17]. Hepatocytes co-cultured with MSCs were largely accumulated in the G2-S phase, while less accumulated in the G0-G1 phase compared with the control[17]. In addition, high levels of diversified extracellular matrix (ECM) and soluble cytokines synthesis were confirmed within the distinct cells in hepatocyte homeostasis[17,18]. The aim of the present study was to investigate the *in vitro* effects of the sera from patients with viral hepatitis B-induced ACLF in China on the metabolic functions and proliferation of 3-D hepatocytes spheroids by co-culturing with bone marrow MSCs, which to a great extent approaches to the clinical reality when extracorporeal BAL and hepatocyte transplantation occur.

MATERIALS AND METHODS

Animals and reagents

Three outbred white female pigs (15-20 kg) received humane care and all animal procedures were approved by the Animal Care Ethics Committee of Nanjing Drum Tower Hospital, and complied with the Guide for the Care and Use of Laboratory Animals published by the US National Institutes for Health (NIH Publication 85-23 revised 1996). All chemicals were of analytical grade and purchased from GIBCO (Grand Island, NY) unless otherwise stated.

Human plasma samples

Serum samples were obtained from 18 male patients with ACLF due to severe viral hepatitis B at the onset of plasmapheresis or plasma exchange. Diagnosis of these patients was based on the criteria of severe hepatitis described in the Viral Hepatitis Protection, and the Cure Guideline established by the Chinese Society of Infection and Hepatology. Informed consent was obtained from all the study subjects. A sample of blood was collected from the patients for measurement of biochemical parameters (Table 1), and normal serum was collected from 18 healthy volunteers.

Chemokine assays

Chemokines in human serum were quantified using the following commercially available enzyme-linked immunosorbent assay (ELISA) kits in accordance with the manufacturer's instructions: hepatocyte growth factor (HGF), epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and tumor necrosis factor-α (TNF-α) (Biosource International, Camarillo, CA).

Porcine MSCs isolation and characterization

Porcine MSCs were isolated by bone marrow aspirates from the iliac crest of pigs as described previously[16-18]. The surface marker of the cultured MSCs was determined by fluorescein isothiocyanate (FITC)-labeled monoclonal antibody against CD45 (Antigenix America, Huntington Station, NY) and phycoerythrin (PE)-conjugated antibodies against CD29 (VMRD, Pullman, WA), CD44 and CD90 (Becton Dickinson) using a FACScan (Becton Dickinson, San Diego, CA). Isotypic antibodies served as controls.

Porcine hepatocyte isolation and culture

Primary hepatocytes were harvested by a two-step *in situ* collagenase perfusion technique[16-18]. The viability of the isolated hepatocytes determined by Trypan blue exclusion

ALB: Albumin; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; CHE: Concentrations of acetylcholine; LDH: Lactate dehydrogenase.

was higher than 95%. The percentage of nonparenchymal cells, as judged by their size (< 10 μm in diameter) and morphology (nonpolygonal or stellate), was less than 1%, which was also verified by immunocytochemical analysis of albumin and cytokeratin 18.

Establishment of homo-culture and co-culture system

To culture the pure primary hepatocytes, serum free DMEM-LG was removed 4 h after seeding 4×10^5 cells per well onto the 6-well culture plates (Corning Incorporated, Corning, NY), and 10% fetal bovine serum (FBS) fresh medium with 1 mm dexamethasone, 5 mg/mL insulin, 5 mg/mL transferrin, 5 mg/mL selenium, 100 IU/mL penicillin and 100 mg/mL streptomycin were added and exchanged every day thereafter. In heterotypic culture system, hepatocytes (4×10^5) were co-cultured with MSCs (2×10^5) during passages 3-5 in the 6-well culture plates.

Intervention with human serum

The culture medium was replaced with fresh FBS-free medium containing pooled normal serum or ACLF serum at concentrations ranging from 10% to 100% for 24 h. To closely simulate BAL intervention and exclude the direct contact between porcine cells and immunoglobulin as well as complements derived from patients, human serum was co-cultured using a 35-mm Millicell culture insert (Millipore, Bedford, MA). Cell morphology, albumin expression levels, and cell cycles in different groups were measured to determine the optimal concentration of human serum for culturing hepatocytes. All the medium samples were subsequently collected and stored at -80℃ for biochemical analysis, which represented the porcine hepatocyte-specific support functions on human serum.

Cell cycle analysis

For cell cycle analysis, MSCs pre-labeled with 10 μm solu-

tion of carboxyfluorescein diacetate succinimidyl ester (CFSE; Molecular Probes, Eugene, OR) for 10 min at 37℃ were incubated in fresh medium for 30 min prior to co-culture with hepatocytes. Subsequently, cells of homo-culture and co-culture subgroups were stained with the CycleTEST PLUS DNA reagent kit (Becton Dickinson) according to the manufacturer's instructions, respectively. The cell cycle profiles of samples were analyzed by FACScan (Becton Dickinson).

Biochemical parameters

The concentrations of acetylcholine (CHE), glutamine (Gln), superoxide dismutase (SOD) and glucose (Glu) in medium samples were measured by commercial kits (Jiancheng Bioengineering, Nanjing, China) according to the manufacturer's instructions. Secreted albumin in the culture medium was quantified by ELISA using purified goat anti-albumin and horseradish peroxidase-conjugated antibodies (Bethyl Laboratories, Montgomery, TX).

Incubation with FBS

Both hepatocyte homo-culture and co-culture groups with the determined optimal concentration of serum from normal population or liver failure patients were thereafter replaced with fresh DMEM-LG supplemented with 10% FBS and re-incubated for another 24 h.

Transmission electron microscopy

Transmission electron microscopy (TEM) analysis was performed according to the standard protocol.

Hepatocyte viability

A live/dead assay was performed using calcein-AM and SYTOX Orange dye (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. Hoechst 33258 (Sigma-Aldrich, St. Louis, MO) staining was used for visualization

Table 2 Chemokine profiles in liver failure serum *vs* normal serum

	NS group (*n* = 18)	FS group (*n* = 18)	*P* value
HGF (pg/mL)	469.47 ± 134.87	5253.70 ± 1876.35	0.002
EGF (pg/mL)	282.56 ± 41.55	74.63 ± 18.36	0
VEGF (pg/mL)	99.27 ± 19.42	ND	0
TNF-α	66.48 ± 28.56	168.86 ± 38.69	0.001

NS: Normal serum; FS: Liver failure serum; ND: Undetectable; HGF: Hepatocyte growth factor; EGF: Epidermal growth factor; VEGF: Vascular endothelial growth factor; TNF-α: Tumor necrosis factor-alpha.

Table 3 Hepatocyte ratio of G2-S phase in Hep-F group and Co-F group

	Concentration of serum %					
	10	20	40	60	80	100
G2-S phase in Hep-F group	9.26	13.47	18.66	23.43	13.99	7.81
G2-S phase in Co-F group	16.02	23.28	28.25	32.08	31.24	9.94

Hep-F: Homo-hepatocytes cultured by various concentrations of liver failure serum; Co-F: Albumin in the medium of both liver failure serum; G2-S: Gap 2-Synthesis.

of nuclei. Cells were visualized under a fluorescence microscope (Zeiss, Jena, Germany).

Cytotoxicity assay

Lactate dehydrogenase (LDH) activities in culture media were measured with a kit (Jiancheng Bioengineering, Nanjing, China) in accordance with the manufacturer's instructions.

Fluorescence-activated cell sorting

To separate hepatocyte from co-cultures, CD44⁻CD45⁻ cell population was sorted out using a fluorescence-activated cell sorting (FACS) caliber flow cytometer (Becton Dickinson). Briefly, cell suspension was simultaneously incubated with FITC-conjugated monoclonal antibody against CD45 and PE-conjugated antibody against CD44 at room temperature for 15 min. CD45 negative cells were gated and then analyzed for red fluorescence. Hepatocytes and MSCs alone served as controls, respectively.

Western blotting

Western blotting was performed using anti-PCNA monoclonal primary antibody (Chemicon, Melbourne, Australia) and HRP-conjugated secondary antibody (Jackson Immunoresearch Laboratories, West Grove, PA). Enhanced chemiluminescence reagents (Pierce Biotechnology, Rockford, IL) were used for visualization.

Statistical analysis

Means of three independent experiments were reported. The two-tailed unpaired Student's *t* test or one-way analysis of variance was used to evaluate the statistical differences.

RESULTS

Differential expression of chemokines in normal and liver failure serum

HGF and tumor necrosis factor (TNF)-α level of liver failure serum (5253.70 ± 1876.35 and 168.86 ± 38.69 pg/mL) (mean ± SD) was significantly higher than that of healthy human serum (469.47 ± 134.87 and 66.48 ± 28.56 pg/mL) (*P* = 0.002 and 0.001). In contrast, other two growth factors, EGF and VEGF, in the serum of ACLF patients (74.63 ± 18.36 pg/mL and undetectable) were lower than those in the normal serum (282.56 ± 41.55 pg/mL and 99.27 ± 19.42 pg/mL) (*P* = 0.000) (Table 2).

Optimal concentration of human serum for co-culturing hepatocytes

The morphology of hepatocyte homo-culture underwent a dramatic change (rounding and detachment) after 24 h of culture in the medium containing 10% liver failure serum. With increasing serum concentrations in the culture medium, less cell sheet exposure to 100% liver failure serum could constitute a confluent monolayer and the membranes of the hepatocytes became indistinct (Figure 1A). On the other hand, hepatocytes co-cultured with MSCs maintained anchored spherical multi-cellular aggregates and displayed minor difference when incubated with different concentrations of liver failure serum (Figure 1B), indicating that 3-D hepatocyte spheroids co-cultured with MSCs were not affected by liver failure serum upon 24 h incubation. There was no significant difference of albumin secretion between homo-hepatocytes cultured by various concentrations of liver failure serum (Hep-F) and those cultured by normal serum (Hep-N) (Figure 1C). As for the co-culture system, the albumin in the medium of both liver failure serum (Co-F) and normal serum (Co-N) groups were significantly higher than those of Hep-F and Hep-N (*P* < 0.01). When the concentration of serum reached or surpassed 40%, albumin in the medium of Co-F group was significantly higher than that in the Co-N group (*P* < 0.05) (Figure 1C). The largest amount of albumin secretion was observed in the co-cultured hepatocytes with 60% of serum (*P* < 0.01) (Figure 1C). The ratio of G2-S phase cells in Hep-F group ranged from 7.81% to 23.43%, while larger populations of CFSE-negative cells (hepatocytes) were accumulated in G2-S phase in response to MSCs, peaking in the 60% serum subgroup with 32.08% (Table 3). Taken together, 60% liver failure serum in culture medium was used for the following investigations.

Hepatocyte-specific support functions of MSCs on human serum

To investigate the hepatocyte's supportive functions when incubated with liver failure serum, the metabolic capacity of medium samples from the 60% serum subgroups upon the first 24 h incubation was determined. As shown in Figure 2A, CHE activity in Hep-F and Co-F groups was significantly lower than that in the Hep-N and Co-N groups, respectively (*P* = 0.000) (Figure 2A). Fortunately, CHE activity in Co-F was 2-folds that in Hep-F (123.90 ± 28.15 U/mL *vs* 60.53 ± 13.97 U/mL, *P* = 0.043). There was no significant difference of Gln synthesis between Co-N and Co-F

Figure 1 Optimal serum concentrations for co-cultured hepatocytes. A: Morphology of homo-cultured hepatocytes at different concentrations of liver failure serum (magnification x 100); B: Morphology of hepatocytes co-cultured with mesenchymal stem cells (MSCs) at different concentrations of liver failure serum (magnification x 100); C: Albumin secretion in hepatocytes homo-cultured with normal serum (Hep-N), liver failure serum (Hep-F) and hepatocytes co-cultured with normal serum (Co-N) and liver failure serum (Co-F). [a]Represents the significant difference *vs* Co-N group; [b]Represents the largest significance *vs* Co-N group.

Figure 2 Hepatocyte-specific support functions in human serum. Concentrations of acetylcholine (CHE) activity (A), glutamine (Gln) synthesis (B), superoxide dismutase (SOD) activity (C) and glucose (Glu) concentrations (D) in the medium of each group. [a]Indicates significant difference *vs* Hep-N group; [b]Indicates significant difference *vs* homo-hepatocytes cultured by various concentrations of liver failure serum (Hep-F) group. Hep-N: Hepatocytes homo-cultured with normal serum; Co-N:Hepatocytes co-cultured with normal serum; Co-F: Liver failure serum.

Figure 3 Post-incubation influence of liver failure serum on hepatocyte metabolic functions. Concentrations of acetylcholine (CHE) activity (A), glutamine (Gln) synthesis (B), superoxide dismutase (SOD) activity (C) and glucose (Glu) concentrations (D) in the medium of each group. [a]Indicates significant difference *vs* hepatocytes homo-cultured with normal serum (Hep-N) group; [b]Indicates significant difference *vs* homo-hepatocytes cultured by various concentrations of liver failure serum (Hep-F) group. Co-N:Hepatocytes co-cultured with normal serum; Co-F: Liver failure serum.

Figure 4 Cytotoxic effects of liver failure serum on hepatocytes cultured alone *vs* co-cultured hepatocytes. A: Transmission electron microscopy (TEM) analysis of the homo-cultured hepatocytes (left panel) and hepatocytes co-cultured with mesenchymal stem cells (MSCs) (righ panel) in the presence of 60% of liver failure serum; B: Lactate dehydrogenase (LDH) release assay of hepatocytes was indicated in each group; C: Live/dead assay of homo-cultured hepatocytes (upper panel) and hepatocytes co-cultured with MSCs (lower panel) in the presence of 60% of liver failure serum. [a]Indicates significant difference *vs* Hep-N group; [b]Indicates significant difference *vs* homo-hepatocytes cultured by various concentrations of liver failure serum (Hep-F) group. Hep-N: Hepatocytes homo-cultured with normal serum; Co-N:Hepatocytes co-cultured with normal serum; Co-F: Liver failure serum.

Figure 5 Increased proliferation after incubation with liver failure serum by co-culturing with mesenchymal stem cells. The proliferating cell nuclear antigen (PCNA) levels of hepatocytes cutured alone in Hep-N and Hep-F groups were too low to be detected while a significant increase was observed in the co-cultured groups irrespective of liver serum insult (*P* < 0.05). Statistical analysis with regard to PCNA level showed no significant difference between Co-N and Co-F groups (*P* > 0.05). Hep-N: Hepatocytes homo-cultured with normal serum; Co-N:Hepatocytes co-cultured with normal serum; Co-F: Liver failure serum.

groups (P = 0.083) (Figure 2B). Gln synthesis in Hep-F group was significantly lower than that in Hep-N group (P = 0.033) (Figure 2B). Gln concentration in Co-F group was

significantly higher than in Hep-F group (P = 0.000) (Figure 2B). SOD activity in Hep-F group was significantly lower than that in Hep-N group (P = 0.000) (Figure 2C). There was no significant difference in the SOD activity between the Co-F group and Co-N group (P = 0.088) (Figure 2C). Furthermore, SOD activity in Co-F group was significantly increased compared with that in Hep-F group (18.15 ± 1.25 U/mL *vs* 13.49 ± 1.17 U/mL, P = 0.001) (Figure 2C). The concentration of Glu in the medium indirectly represented the Glu consumption by hepatocytes. The results showed that Glu in Hep-F group was significantly higher than that in the Hep-N group (P = 0.041) (Figure 2D), suggesting that liver failure serum delayed the glycometabolism of homo-hepatocytes. There was no significant difference of Glu between Co-F and Co-N groups (P = 0.926) (Figure 2D), suggesting that liver failure serum does not affect the glycometabolism of hepatocytes co-cultured with MSCs. Importantly, Glu concentration in Co-F group was significantly lower than that in Hep-F group (5.42 ± 0.91 *vs* 6.60 ± 1.28 mmol/L, P = 0.026), indicating that Glu consumption rate was improved in response to MSCs treatment.

Post-incubation influence of liver failure serum on hepatocyte metabolic functions

We further determined the effect on the hepatocyte metabolic functions after the second 24 h incubation with 10% FBS instead of human serum, which was defined as the post-incubation influence of liver failure serum on hepatocytes. As shown in Figure 3A, B and D, the pattern of CHE activity, Gln concentration and Glu content in the medium were similar to the effect of the first 24 h incubation with liver failure serum. Surprisingly, there was no significant difference of SOD activity in each group when human serum was changed into FBS ($P > 0.05$) (Figure 3C).

Cytotoxic effects of liver failure serum on homo-hepatocytes and co-cultured hepatocytes

TEM, dead/live assay and LDH leakage were used to determine the cytotoxic effects of liver failure serum on the homo-hepatocytes (Hep-F) and co-cultured hepatocytes (Co-F). Figure 4A displays quite a few occurrences of nuclear pyknosis, dilated endoplasmic reticulum, mitochondrial hydropic degeneration and large peroxisomes in the cytoplasm of hepatocytes in Hep-F group. On the contrary, hepatocytes co-cultured with MSCs maintained distinct membranes and cell ultrastructure, which was similar to that of hepatocytes *in vivo,* irrespective of presence or absence of liver failure serum (Figure 4A). Hepatocyte viability assay revealed that few hepatocytes were labeled with nonviable cell marker SYTOX (red nuclei) in coculture spheroids and a large population of cells, including hepatocytes and MSCs, was stained with viable cell marker calcein-AM (green cytoplasm) (Figure 4B, lower panel). In contrast, almost all hepatocytes scattering in full field showed a lower viability in Hep-F group (Figure 4B, upper panel). In addition, LDH activity in Hep-F group was significantly higher than that in Hep-N group ($P = 0.034$) (Figure 4C). In contrast, there was no significant difference in the LDH activity between Co-N and Co-F groups ($P = 0.340$) (Figure 4C), indicating that co-cultured hepatocytes did not response to liver failure serum. Finally, LDH activity in Co-F group was significantly decreased compared with that in Hep-F group ($P = 0.036$) (Figure 4C).

Increased proliferation of hepatocytes upon co-culturing with MSCs

Proliferating cell nuclear antigen (PCNA) level is one of the markers of cell proliferation. The PCNA of hepatocyte in Hep-N and Hep-F groups was not detected by Western blot analysis (Figure 5). A significant amount of PCNA was detected in the hepatocytes of Co-F and Co-N groups (Figure 5). Statistical analysis showed that there was no significant difference in the PCNA level between Co-N group and Co-F group ($P > 0.05$).

DISCUSSION

Of the estimated 112 million persons with chronic hepatitis B in China, 15%-40% will eventually develop liver complications including liver cirrhosis, chronic hepatic failure and hepatocellular carcinoma[19]. Ideal treatment is still not available for severe viral hepatitis. Chronic severe hepatitis could cause ACLF with a mortality rate of >70% if liver transplantation cannot be performed[20]. Therefore, more and more attention has been paid to delaying the progression of ACLF by using BAL devices or hepatocyte transplantation in China and other Asian countries[21-23]. Porcine hepatocytes have been serving as the most ideal cell source for both preclinical and clinical liver support due to their physiological similarities with human hepatocytes and their availability[24-25].

A wide range of endogenous toxic metabolites as well as cytokines accumulate in the circulation of patients with liver failure[9-10]. Serum from acute liver failure or FHF patients inhibited the growth, proliferation and metabolic functions of various hepatocytes, e.g, primary hepatocytes[11], Hep G2 cells[9,10] and HHY41 cells[12] by interfering RNA, DNA and protein synthesis and inducing apoptosis. However, recent studies argued that serum from adult patients with acute liver failure did not have detrimental effects on the overall cell metabolic activity, protein synthesis, and cytochrome P450 activity in the freshly isolated human hepatocytes[13]. One of the reasons for interpreting the controversial results of these studies is that several hepatotrophic substances, e.g., cytokines and growth factors are elevated in the sera of patients with liver failure[26,27]. Therefore, the effect of liver failure serum on the liver or hepatocytes is the net result of the balance between circulating stimulatory molecules and inhibitory compounds.

To date, the greatest challenge to the restoration of well-functioning liver cells *in vitro* lies in maintaining the short-term viability and facilitating the rapid phenotypic de-differentiation of primary hepatocytes in standard mono-layered culture[28]. The maintenance of cell phenotype is dependent on the cellular physiological microenvironment *in vivo,* which consists of multiple signals including paracrine cytokines and neighboring cells[29,30]. Recently, hepatocytes are co-cultured with a range of different cell types *in vitro* to mimic the liver-like microenvironment[31]. Our previous studies provided the first *in vitro* 3-D co-culture system in which porcine hepatocytes were cocultured with bone marrow MSCs. The morphology and functionality of the hepatocytes in this co-culturing system were well maintained and were superior to the hepatocyte homo-culture. In addition, the role of soluble factors derived from MSCs was confirmed as a vital component to facilitate hepatocyte homeostasis[16-18]. Therefore, studies are needed to determine whether such a robust co-culture system could maintain an ideal liver support functions *in vitro* and avoid the cytotoxicity of liver failure serum.

The pool of 18 liver failure serum samples induced a higher detachment rate, lower viability and decreased liver support functions of mono-layered hepatocytes, which is consistent with the main findings described previously[9,10]. In addition, presence of the post-incubation effect of liver failure serum suggested that some of the metabolic functions such as CHE activity and Gln concentration were still maintained at a lower level in hepatocyte homo-culture compared with the control group. In contrast, the newly developed 3-D hepatocyte co-culture system could tolerate the cytotoxicity of the serum from ACLF patients and

have a similar performance to that incubated with healthy human serum *in vitro*. These results demonstrated that co-culture system displayed a better advantage over the pure liver cells in hepatocyte-based therapy for end-stage liver diseases. Moreover, hepatocytes co-cultured with MSCs achieved a higher proliferation capacity despite of the presence of the liver failure serum.

Recent studies have shown that VEGF, also known as the vascular permeability factor, plays an essential role in liver regeneration[32-35]. It has been shown that expression of VEGF in both hepatocytes and non-parenchymal cells are increased during liver regeneration induced by partial hepatectomy[33,35]. Furthermore, exogenous VEGF administration after partial hepatectomy facilitates the proliferative activity in the injured liver[32,34]. In contrast, neutralization of VEGF significantly inhibits the proliferative activity in the liver during regeneration after partial hepatectomy[32]. Therefore, VEGF is not only an angiogenic factor but also plays a role in the survival of liver. On the other hand, the serum VEGF levels were increased in the patients with acute hepatitis compared with controls and other types of liver disease such as chronic hepatitis, fulminant hepatitis and cirrhosis[36]. In addition, serum VEGF in survivors of fulminant hepatitis was significantly increased in the recovery phase compared with the levels on admission. In the liver cirrhosis patients, serum VEGF levels were significantly lower than those of the control group, suggesting that serum VEGF level may be associated with hepatocyte regeneration grade[36]. More recently, Namisaki and coworkers reported that VEGF treatment could significantly reduce the mortality rate of acute severe liver injury and on-going acute hepatic failure in rats[37]. Thus, VEGF levels in serum may represent a predictor of clinical outcome for patients with hepatic failure[38]. In the present study, we compared the expression levels of some key chemokines related to liver regeneration in the liver failure serum with those in the healthy human serum. Our results revealed that HGF and TNF-α were remarkably elevated in response to ACLF while EGF and VEGF levels were significantly decreased, which may partially account for the inhibitory effect of liver failure serum on hepatocyte mono-layered culture rather than stimulatory role. Since multipotent MSCs are a stable source of VEGF-producing cells *in vivo* and *in vitro*[39,40], have the ability to trans-differentiate into hepatocyte-like cells under certain circumstances[41], and are immunosuppressive by modulating the immune function of the major cell populations involved in alloantigen recognition and elimination[42], our co-culture system may be a promising candidate in future cell-based therapy.

In conclusion, 3-D spheroid culture system by co-culturing primary hepatocytes with bone marrow MSCs can tolerate the cytotoxicity of ACLF serum and has a better performance in maintaining the function of hepatocytes. Hence, primary hepatocytes co-cultured with MSCs may be suitable for the application in clinical practice of BAL and hepatocyte transplantation.

COMMENTS

Background
Bioartificial livers (BAL) and hepatocyte transplantation are the cell-based therapies which served as a bridge to transplantation or liver regeneration via providing temporary hepatic support. However, none of the cell-based therapy currently available can be used as a well defined and practical option in clinical settings. This is primarily due to the accumulation of a wide range of putative toxic substances within the circulation of hepatic failure patients.

Research frontiers
Serum from acute liver failure or fulminant hepatic failure (FHF) patients inhibited the growth, proliferation and metabolic functions of various hepatocytes. The authors reported a new-brand BAL configuration for the development of a three-dimensional (3-D) porcine hepatocyte culture system by co-culturing with bone marrow mesenchymal stem cells (MSCs) *in vitro*. So it is necessary to investigate whether 3-D hepatocyte culture system could resist the cytotoxicity of circulating inhibitory factors in the serum or plasma from liver failure patients.

Innovations and breakthroughs
Although most of the studies concerning the effects of patients' plasma or serum on liver cells use monolayer-cultured hepatocytes or transformed cell lines, and direct contact exists between the patient's serum, plasma, or blood and the exogenous hepatocytes in the current cell-based therapy, 3-D hepatocyte culture system has not been investigated. This study focused on the *in vitro* effects of sera from patients with viral hepatitis B-induced acute-on-chronic liver failure (ACLF) in China on the metabolic functions and proliferation of 3-D hepatocytes spheroids by co-culturing with bone marrow MSCs.

Applications
The study found that 3-D spheroid culture system by co-culturing primary hepatocytes with bone marrow MSCs can tolerate the cytotoxicity of ACLF serum and has a better performance in maintaining the function of hepatocytes. It could be applied in clinical practice of BAL and hepatocyte transplantation.

Terminology
Three-dimensional (3-D) hepatocyte culture system is a culture system of porcine hepatocytes and bone marrow MSCs in a co-culture manner *in vitro*. Co-culture of hepatocytes with non-parenchymal cells is beneficial for optimizing cell functions via heterotypic interactions.

Peer review
This is an interesting study aimed to investigate whether the function of hepatocytes co-cultured with bone marrow mesenchymal stem cells could be maintained in the presence of serum from patients with acute-on-chronic liver failure.

Abstract

AIM: To determine the incidence of brain metastasis in a contemporary group of patients with carcinoma of the esophagus.

METHODS: Retrospective analysis of 53 patients with esophageal carcinoma who received radiotherapy as a component of treatment between 1998 and 2007, including patient and tumor characteristics, and subsequent diagnosis of brain metastasis. The association between the histological type of esophageal cancer and the incidence of brain metastasis was assessed using Fisher's exact test.

RESULTS: Forty-four of the fifty-three patients in this study had adenocarcinoma and nine had squamous cell carcinoma, ranging from stage ⅡA-ⅣB. Primary treatment was surgery with neoadjuvant chemoradiotherapy (trimodality therapy) in 19% of patients; chemoradiotherapy in 42%; and surgery and adjuvant radiotherapy in 7%. Twenty-five percent of patients in this study received palliative radiotherapy. The overall incidence of brain metastasis in this cohort was 13%. Adenocarcinoma was the primary tumor histology in all of the patients who developed brain metastasis, representing an incidence of 16% in this subgroup. No patients with squamous cell carcinoma received trimodality therapy. The association between histology and brain metastasis was not statistically significant.

CONCLUSION: The incidence of brain metastasis in this contemporary cohort of patients with esophageal carcinoma is higher than previously reported and was confined to those with adenocarcinoma.

Key words: Brain metastasis; Esophageal carcinoma

INTRODUCTION

The incidence of esophageal cancer has been increasing in the United States over the past thirty years[1], with an expected 16 470 cases and 14 530 deaths in 2009[2,3]. Underlying this increase is a steady rise in the incidence of adenocarcinoma histology, surpassing squamous cell between 1990 and the early 2000s as the most common histology in the United States[1,4-6].

Brain metastasis secondary to esophageal carcinoma

is considered to be a rare event, with a reported incidence of between 0.5% and 4.8%[4,7-13]. However, many of these studies included patients from the 1980s and 1990s when squamous cell was the predominant histology. In patients with non-small cell carcinoma of lung, the risk of brain metastasis is correlated with histological type, ranging from 40% to 50% in those with adenocarcinoma, *vs* 10% to 20% among those with squamous cell carcinomas[14-18]. Whether the incidence of brain metastasis in patients with esophageal carcinoma will increase as the predominant histology shifts from squamous cell to adenocarcinoma is unknown. Our recent clinical experience suggests that the incidence of brain metastasis in patients with esophageal carcinoma is higher than what has been reported. Therefore, a review of our database of patients with esophageal carcinoma at this community-based cancer center was undertaken to determine the incidence of brain metastasis in a contemporary group of patients with this disease. All of the patients received radiotherapy as a component of their treatment, but none had a diagnosis or suspicion of brain metastasis at the time of initial consultation.

MATERIALS AND METHODS

After obtaining Institutional Review Board approval, the medical records of all patients with a primary diagnosis of esophageal carcinoma between 1998 and 2007 treated in the Department of Radiotherapy at our center (Mayo Health System practice) were reviewed. Patient demographics, clinical characteristics, treatment modality, diagnosis of brain metastasis, and survival data were collected. All cases of brain metastases were diagnosed by radiographic imaging (CT or MRI scan). The association between the histology of esophageal cancer and the incidence of brain metastasis was assessed using the Fisher's exact test, with *P*-value of less than 0.05 considered to be statistically significant.

RESULTS

The clinical characteristics of fifty-three patients with a diagnosis of carcinoma of the esophagus are shown in Table 1. None of the patients had a diagnosis or suspicion of brain metastasis at the time of referral for radiotherapy evaluation. Forty-four patients had adenocarcinoma as the primary histology. Staging information was unavailable for three patients, and tumor grade was not available for twelve patients. Primary treatment modality is also shown in Table 1, with the majority (42%) receiving definitive chemoradiotherapy. No patients with squamous cell carcinoma underwent trimodality therapy. Thirteen patients with stage IVB disease received palliative radiation only. Forty-nine of the 53 patients have died. The median length of survival was 14 mo (range 3 to 56 mo) for squamous cell carcinoma patients and 13 mo (range 2 to 72 mo) for those with adenocarcinoma.

were subsequently diagnosed with brain metastases, all by radiographic imaging (CT or MRI scan). Characteristics of patients diagnosed with brain metastasis are shown in Table 2. Adenocarcinoma was the histology of the primary tumor in all seven patients, representing an incidence of 16% for the adenocarcinoma subgroup. The association between the histological type and brain metastasis was not statistically significant ($P = 0.24$). In six of these seven patients, the diagnosis of brain metastasis occurred within 11 mo of initial diagnosis of esophageal cancer.

DISCUSSION

This review identified a higher incidence of brain metastasis (13%) in a contemporary series of patients with carcinoma of the esophagus than has been previously reported[4,7-13]. The incidence of brain metastasis in those studies ranged from 0.5% to 4.8%. Information on the incidence of brain metastases by histology type is limited. Three studies from Japan reported the incidence of brain metastasis in patients diagnosed with esophageal cancer in the 1980s to early 2000s as ranging from 1.4%-1.5%[7,8,11]. Squamous cell carcinoma was the predominant histological type of esophageal cancer in Japan over that time period[7,11,19]. One of the studies concluded that although squamous cell was the primary tumor histology in over 95% of patients in Japan, the patients with brain metastasis "frequently exhibited other histologic types"[11].

Several studies in the United States also reported low incidence of brain metastasis in patients with esophageal cancer[1,4-6,10,13]. In a large series of patients from The University of Texas M.D. Anderson Cancer Center diagnosed with primary carcinoma of the esophagus between 1993 and 2001, adenocarcinoma was the predominant histology (68% of cases versus 25% with squamous cell carcinoma). The overall incidence of brain metastasis was 1.7% and the authors concluded that histology did "not appear to be a risk factor for the development of brain metastasis"[4]. However, Gabrielsen *et al*[13] reported a 3.6% incidence of brain metastasis in a review of 334 patients with esophageal carcinoma who underwent esophagectomy and concluded that there was a trend ($P = 0.16$) toward higher incidence of brain metastasis in those with adenocarcinoma. Although our results revealed the incidence of brain metastasis to be confined to those with adenocarcinoma, we could not demonstrate that histology was a significant risk factor for subsequent diagnosis of brain metastasis because of the small sample size, especially in the group with squamous cell carcinoma.

Rice and colleagues reported a correlation between adjuvant therapy and incidence of brain metastasis in a large series of patients with esophageal carcinoma from 1985 to 2002 who underwent esophagectomy with or without adjuvant therapy[10]. The overall incidence of brain metastasis was 3.8%; however, the rate at five years post treatment was 2.5% with surgery alone, and as high as 18.4% in patients who underwent surgery with both preoperative and postoperative therapy. Interestingly, all cases of brain metastasis occurred in patients with adenocarcinoma, con-

sistent with the pattern seen in our study. The incidence for those receiving multi-modality therapy was similar to the 16% observed for the adenocarcinoma group in our study. This finding deserves more investigation, including whether treatment type influenced the subsequent development of brain metastasis or if multi-modality therapy may have been a surrogate for advanced stage (although this was not supported in a matched-pair analysis in the above study) and/or adenocarcinoma histology.

In a population based study from the Mayo Clinic, the median survival of patients with adenocarcinoma of the esophagus improved from 8.5 to 11.7 mo between 1971 and 2000; however, this was not deemed to be a significant change[20] and is similar to the median length of survival of 13 mo in our study. Therefore, it is not clear that the higher rate of brain metastasis reported in this study can be explained by patients living significantly longer with modern therapy. The results observed in this study might reflect a difference in underlying tumor biology and metastatic potential for CNS involvement between the two primary histologies. This would be similar to the pattern seen in patients with non-small cell lung carcinoma, where the incidence of brain metastasis is at least two-fold higher in those with adenocarcinoma versus squamous cell carcinoma[14-18].

The relatively short interval between diagnosis of the primary tumor and development of brain metastases noted in our study (median 7 mo) is similar to the 5.6 mo reported by Weinberg *et al*[4]. Furthermore, in the study by Rice *et al*[10], twenty of the twenty-nine patients who developed brain metastasis did so within one year following esophagectomy. Based on these findings, close attention to neurological signs and symptoms, with consideration of brain imaging as clinically indicated, should be a component of initial and follow-up evaluations in patients with esophageal cancer, especially in those with adenocarcinoma.

Limitations of this study include the retrospective nature and the relatively small sample size, precluding the ability to demonstrate statistical correlation with histology or treatment modality. In addition, this review was limited to patients who received radiotherapy as a component of their treatment; therefore, it may not be representative of all patients with esophageal cancer. However, none of the patients in our study had a diagnosis or suspicion of brain metastasis at the time of referral for radiotherapy evaluation.

In conclusion, this study revealed a higher incidence of brain metastasis than previously reported in patients with esophageal cancer, and occurred exclusively in those with adenocarcinoma, possibly identifying a trend that may increase as the incidence of this particular histology continues to rise. However, other factors, including gender, stage, and treatment type, could not be thoroughly assessed. Further research, to include a larger sample size in a contemporary group of patients with esophageal carcinoma, is required to confirm the findings in this study and to better understand the possible association between histology, patient characteristics, and/or treatment modality and the development of brain metastasis.

ACKNOWLEDGMENTS

COMMENTS

Background
This is an original study analyzing the incidence of brain metastasis in patients with esophageal carcinoma. The study assessed whether the incidence is higher in a contemporary group of patients than previously reported.

Research frontiers
Previous studies have shown very low incidence of brain metastasis in patients with esophageal carcinoma when the primary histological type was squamous cell carcinoma. The predominant histology has shifted to adenocarcinoma; therefore, this study addressed the question of whether the incidence of brain metastasis is higher than when squamous cell was the predominant histology. This would be similar to the pattern seen in patients with non-small cell lung carcinoma, where the incidence of brain metastasis is two- to five-fold higher in patients with adenocarcinoma *versus* squamous cell carcinoma.

Innovation and breakthroughs
The authors reported a higher incidence of brain metastasis than previously reported and all patients with brain metastasis had adenocarcinoma. In addition, there was a relatively short interval between the diagnosis of the primary tumor and development of brain metastasis, similar to data reported by other studies.

Applications
The findings of this study highlight the need for attention to neurological signs and symptoms with consideration of brain imaging as clinically indicated, in patients with esophageal cancer, especially those with adenocarcinoma.

Peer review
This is an original study concerning the incidence of brain metastasis in patients with esophageal carcinoma. The topic is interesting, the number of cases is not negligible; the study is well described and provides indication for further researches. The references are updated.

Abstract

AIM: To investigate stapled transanal rectal resection (STARR) procedures as surgical techniques for obstructed defecation syndrome (ODS) by analyzing specimen evaluation, anorectal manometry, endoanal ultrasonography and clinical follow-up.

METHODS: From January to December 2007, we have treated 30 patients. Fifteen treated with double PPH-01 staplers and 15 treated using new CCS 30 contour. Resected specimen were measured with respect to average surface and volume. All patients have been evaluated at 24 mo with clinical examination, anorectal manometry and endoanal ultrasonography.

RESULTS: Average surface in the CCS 30 group was 54.5 cm^2 statistically different when compared to the STARR group (36.92 cm^2). The average volume in the CCS 30 group was 29.8 cc, while in the PPH-01 it was 23.8 cc and difference was statistically significant. The mean hospital stay in the CCS 30 group was 3.1 d, while in the PPH-01 group the median hospital stay was 3.4 d. As regards the long-term follow-up, an overall satisfactory rate of 83.3% (25/30) was achieved. Endoanal ultrasonography performed 1 year following surgery was considered normal in both of the studied groups. Mean resting pressure was higher than the preoperative value (67.2 mmHg in the STARR group and 65.7 mmHg in the CCS30 group *vs* 54.7 mmHg and 55.3 mmHg, respectively). Resting and squeezing pressures were lower in those patients not satisfied, but data are not statistically significant.

CONCLUSION: The STARR procedure with two PPH-01 is a safe surgical procedure to correct ODS. The new Contour CCS 30 could help to increase the amount of the resected tissue without differences in early complications, post-operative pain and in hospital stay compared to the STARR with two PPH-01 technique.

INTRODUCTION

The prevalence of constipation in adults ranges from 2% to 27% in North America, particularly over 65 years old and with a female predominance[1]. There are two major types of constipation: secondary constipation and primary functional constipation, which can be divided into slow transit constipation, constipation-predominant irritable bowel syndrome, and obstructed defecation. Approximately half of constipated patients suffer from obstructed defecation[1]. Obstructed defecation syndrome (ODS) is characterized by a cohort of symptoms including incomplete evacuation with painful effort, unsuccessful attempts with long period spent in bathroom, bleeding after defecation, use of perineal support and/or odd posture. ODS can also depend on intussusception of the rectal wall, extending into the anal canal, usually defined as internal prolapse. This condition is even frequently associated with rectocele[2]. Many different surgical techniques have been described in literature to correct ODS with important limitations and different patterns of post-operative complications[3]. The stapled transanal rectal resection (STARR) procedure is a surgical technique introduced to treat ODS due to rectocele and rectal intussusceptions and it has been demonstrated to be safe and effective[4,5]. Recently, a new device for the STARR procedure called the Curved Cutter Stapler 30 mm (CCS30) was developed by ETHICON ENDO-SURGERY Inc.® to correct ODS. The theoretical advantages of CCS30 include the ability to resect a single larger specimen and that it is more symmetrical than the other technique, with the avoidance of lateral "dog-ears".

The purpose of our study was to compare the specimen features (average volume and surface) obtained using the traditional two staplers technique (STARR) with Contour CCS 30 (Transtar), and to evaluate the early and late postoperative outcome. Moreover, we evaluated if a different resection (larger and more symmetric) may be associated with a higher complication rate or with differences in clinical, manometric and sonographic results at the 24 mo follow-up.

MATERIALS AND METHODS

Population under study and pre-operative assessment

From January to December 2007, 30 patients (all female; mean age 46.4 years old) suffering from ODS were treated in our department, 15 with double PPH-01 stapler and 15 with Contour CCS 30. All patients underwent a preoperative assessment mainly based on clinical evaluation, proctoscopy, defecography, anorectal manometry, and endoanal ultrasonography. A particular effort was made to investigate patient's obstetric and gynaecologist history, as well as previous anal or abdominal surgery. A colonoscopy was performed when malignant or inflammatory disease was suspected. Longo OD and Wexner scores were preoperatively filled in with all patients.

Inclusion criteria

Patients selected for surgery were those with: (1) failure of medical therapy (1.5 L/d of water, low-fiber diet, lactulose 10 g/d) with persistence of at least three of the following symptoms: feeling of incomplete evacuation, painful effort, unsuccessful attempts with long periods spent in bathroom, defecation with use of perineal support and/or odd posture, digital assistance, evacuation obtained only with use of enemas; and (2) at least two of the following findings at defecography: rectoanal intussusception extending 10 mm into the anal canal, rectocele deeper than 3 cm on straining or entrapping barium contrast after defecation. The presence of hemorrhoids was not a contraindication to the operation[3].

Exclusion criteria

Patients with non-relaxing puborectalis muscle at defecography, with synchronous genital prolapse, or cystocele requiring associated transvaginal operations, fecal incontinence, mental disorders, or general contraindications to surgery were excluded[3]. Patients with pelvic floor dyssynergia confirmed by clinical and instrumental evaluation were treated with pelvic floor training.

All patients gave informed, written consent. In the first phase, patients were operated on with STARR procedure (double PPH-01) while Contour Transtar was used as incoming technique in a second instance so that a total of 30 patients were enrolled in the present study, equally distributed according to the two techniques described (15 STARR with double PPH-01 and 15 Transtar with CCS 30). All surgical procedures were carried out in the lithotomy position by a single senior surgeon (GN). Preoperative enema and antibiotic prophylaxis with intravenous Metronidazole 500 mg were performed.

Spinal or general anaesthesia were both carried out and a particular effort was made to the muscle curarization in order to avoid, with a constant muscular relaxation, a sudden sphincter stretching during surgery.

Surgical techniques and specimen measurement

PPH-STARR was performed using two PPH 01-stapling devices (ETHICON Endosurgery, Cincinnatti, USA) as described elsewhere[3]. In addition, 2/0 vicryl sutures were used to oversew the staple line in order to reduce postoperative bleeding (Figure 1). For the Contour Transtar-procedure, a CCS-30 stapler kit (ETHICON Endosurgery, Cincinnati, USA) was used. Briefly, the procedure starts with gentle dilatation of the anus and insertion of the circular anal dilator (CAD), which is then fixed to the perineum with 4 sutures. The internal prolapse is verified by insertion and withdrawal of a gauze swab. Starting at the 2 o'clock position, a 2/0 Vicryl traction suture is placed at the apex of the prolapse. A further 4 traction sutures are then placed around the circumference of the prolapse. A final suture to mark the site and depth of the first stapler firing is placed at the 3 o'clock position. The Contour Transtar device is introduced into the rectum

Figure 1 Stapled transanal rectal resection with double PPH-01.

Figure 2 Stapled transanal rectal resection with contour CCS 30.

and the prolapse at the 3 o'clock position and pulled into the jaws using the previously placed traction suture and marking suture. The stapler is closed and, after checking the vagina for inadvertent incorporation of the vaginal mucosa, the first stapler firing is performed to produce a radial cut into the prolapse. After changing the stapler cartridge, the device is re-introduced into the rectum and sequential circumferential resection of the prolapse is performed using 4 to 5 separate stapler firings to complete the resection. In order to secure haemostasis, single 2/0 vicryl stitches were used to under-run the staple line. Finally an easy-flow-drainage is placed in the anus as an indicator of bleeding (Figure 2).

With concern to the specimen, it was opened and extended so that surface and volume could be measured.

The volume was measured using a controlled volume jar and obtained by variations in the volume of the jar.

Post-operative management and follow-up

Patients were treated with a standard protocol for pain control with intramuscular Ketorolac 30 mg and intravenous paracetamol 10 mg as a rescue dose. The post operative pain was evaluated with the Visual Analogical Scale (VAS) at the first and second day after the surgical procedure (twice a day).

All patients were prospectively evaluated after 7 d and 1 mo from the discharge. As regards long term follow-up, patients were asked to be clinically evaluated at 12 mo following surgery and all agreed. Moreover, they were all contacted and evaluated again 24 mo after surgery. Clini-

Table 1 Specimen and clinical data of the two groups under study

Compliance (%)		
Normal	4 (26.6)	4 (26.6)
Reduced	7 (50)	6 (40)
Increased	4 (26.6)	5 (33.3)

[1]Comparison is statistically significant ($P < 0.05$). STARR: Stapled transanal rectal resection.

cal examination and Longo OD/Wexner questionnaires were achieved as well as endoanal ultrasonography (Bruel and Kjaer 10 MHz 3-D rotating probe) and anorectal manometry.

Statistical analysis

All variables including demographic, clinical, operative and manometric findings were recorded and statistically analysed. Analyses were performed using the Statistical Package for the Social Sciences, SPSS 17.0 for Windows, XP, SPSS Inc., Chicago IL. Log-rank test was used to assess the difference between the groups. A *P* value less than 0.05 was considered significant.

RESULTS

The two groups under study (15 patients operated on with double PPH-01 and 15 patients with CCS 30) were homogeneous with respect to the demographic (mean age) and clinical data (obstetric/gynaecologist and general history; clinical examination). With regards to the resected specimen, average surface in the CCS 30 group was 54.5 cm² statistically different when compared to the STARR group (36.92 cm²). The average volume in the CCS 30 group was 29.8 cc, while in the PPH-01 it was 23.8 cc and difference was statistically significant as well (Table 1). With concern to post-operative pain during the first and second postoperative day, we found that in the CCS 30 group the VAS was 1.3 (range 0-4) and 1.1 (range 0-3) respectively, while in the group treated with two PPH-01 technique (STARR) the VAS was 2.55 (range 0-4) and 0.95 (range 0-3, 5). One month following surgery patients did not complain of pain anymore. The mean hospital stay was 3.1 d (range 2-5 d) in the CCS 30 group and 3.4 d (range 3-6 d) in the PPH-01 group (Table 1).

Only one complication, acute bleeding, occurred in the CCS 30 group (3.3%), promptly treated with surgery in order to control the bleeding. We have not recorded other perioperative complications such as rectal abscess, post-operative hematomas, tenesmus, or rectal strictures.

As regards the long-term follow-up, endoanal ultrasonography performed 1 year following surgery was con-

sidered normal in both of the studied groups. Above all, neither major damage nor sonographically demonstrable sphincter fragmentations were noticed in the endoanal exam performed at the follow-up. Urgency was complained by 5 patients (3 in the double PPH group and 2 in the Transtar one) and incontinence by 3 patients (2 in the double PPH group and 1 in the Transtar one), both resolved in some measure during the follow-up period with an overall satisfactory rate of 83.3% (25/30). In the study groups, the postoperative Longo and Wexner scores for ODS showed an improvement that was statistically significant with respect to the preoperative value.

Findings of anorectal manometry at the 1 year follow-up are showed in Table 2. In both groups of patients, the mean resting pressure is higher than the preoperative value (67.2 mmHg in the STARR group and 65.7 mmHg in the CCS30 group *vs* 54.7 mmHg and 55.3 mmHg respectively). Resting and squeezing pressures are lower in those patients not satisfied, but data are not statistically significant. Even if data are not statistically significant, postoperative rectal compliance seems to be lower in the STARR group than in the CCS group (Table 2).

DISCUSSION

Treatment of ODS is a widely debate topic, and the first consideration concerning the right indications of surgical procedure is to correct the ODS[6,7]. Defecography shows a rectocele or rectal intussusception in 81 and 35 percent of asymptomatic female respectively[8], therefore the presence of the rectocele and rectal intussusception are not an indication for surgery. In fact, only symptomatic patients with rectocele and rectal intussusception are suitable for a surgical treatment. For this reason, and according to the literature, we recommend a strict and careful selection of patients[3]. Moreover, we also believe that patients with pelvic floor dyssynergia, clearly demonstrated by clinical and instrumental evaluation, represent a particular population so that pelvic floor training should be considered the main therapeutic choice with respect to surgery.

The STARR procedure with two PPH-01 is a safe, well tolerated surgical procedure effectively restoring the anatomy and the function of the anorectum in patients with ODS due to rectocele and rectal intussusception, with a low rate of complication and a short hospital stay[9,10]. In the literature it is not clearly established which surgical technique is the most effective for the treatment of ODS[3]. In fact, no randomized trial has yet clearly demonstrated the best approach[3]. Moreover, in the era of healthcare cost management, it could be useful to underline that official prices of double PPH-01 and CCS 30 techniques are €800 and €1, 789 respectively. The new CCS 30 Contour has the advantage of a new semicircular head allowing the resection under direct vision into the anal canal. Moreover, it allows a more regulated specimen than using two PPH-01 and our data confirm this assessment in agreement with the international literature, as the amount of rectal resection can be easily regulated with regards to the depth of the rectal intussusception. Analyzing our data, we found a statistically significant difference in surface and volume between the two PPH-01 and CCS 30 Contour specimens. In accordance to the concept of a more regulated resection with CCS 30, the average surface and volume have turned out greater in the STARR group with this new device. Therefore, STARR with the CCS 30 Contour is a procedure that allows removal of a larger, more regular and more symmetrical specimen and, as a consequence, in a perfect cylinder compared with the 2 irregular specimens obtained by STARR with two PPH-01.

This data could provide an explanation for the reduced rectal compliance in the STARR group compared to the CCS30 group. In fact, the resection performed with the double PPH technique could result in an hourglass shape of the rectum, with a stricture at staple line level. On the contrary, the resection obtained with CCS30, performed with four or more firings, could results in a larger and softer staple line.

Although in the literature correlations between the amount of the prolapse removed and the functional improvement as well as between the functional failure and the insufficient removal of the prolapsed have not been demonstrated yet, we believe that Contour CCS 30 might increase the functional results of the STARR procedure even if our data and the short follow-up cannot support this theory yet.

Analyzing our data there are not significant differences between the CCS 30 Contour and the STARR with two PPH-01 groups concerning the hospital stay, postoperative VAS evaluation and, above all, we have not recorded any differences between the two groups concerning major early complications[11]. The literature reports 5% of post-operative bleeding following STARR with two PPH-01[6]. Although the average surface and volume of the resected specimen in STARR with CCS 30 group were larger compared to STARR with double PPH-01 group, in our experience complication rate is not increased. Actually the literature reports only one case of acute complications after STARR with CCS 30 contour; retroperitoneal and mediastinal emphysema treated with medical therapy[12].

In our study, incidences of fecal incontinence and urgency in both groups confirm the results of the international literature, but no significant alteration was found with regards to endoanal ultrasonography and anorectal manometry performed at the follow-up. In a recent study Renzi *et al*[13] report 2.9% of post-operative bleeding after STARR with CCS30 contour and our data confirmed these rates. Most authors report incontinence to flatus (IF) and urge to defecate (UD) that tends to resolve in few weeks[2]. Arroyo in a recent series of 104 patients, treated for ODS with a double PPH-01 STARR, reports an incidence of IF and UD at 1 mo of 22.1% and 26.9%, respectively[6]. In a published series of 90 patients, Boccasanta reports an IF incidence of 8.9% and 17.8% of UD 1 mo following surgery[2].

Some authors[3] tried to explain the incontinence advocating a sphincter or mucosal injury or an excessive anal dilation, but our findings with postoperative endoanal ultrasonography did not show any sphincter damage following surgery. According to Pechlivanides, IF and UD could be due to rectal wall edema and reduced rectal compliance[9]. Actually, in our experience, anorectal manometry at 1 year following surgery revealed a decreased rectal compliance, particularly in the STARR group with two PPH. On the other hand, an increased resting pressure is a common finding in these patients and might be a consequence of the lower rectal compliance as a compensatory mechanism. Our results are based on a short outcome and a small non-randomized population, so these theories should be further investigated on the basis of a longer follow-up.

In conclusion, in our experience STARR with Contour CCS 30 is a safe and feasible technique allowing the excision of a major amount of tissue without any increasing of the early complication rate or sphincter injuries, as demonstrated by the endoanal ultrasonography. Moreover, resected tissue after a Contour CCS 30 procedure is clearly more symmetric and larger in dimension, without any difference in post-operative pain and hospital stay compared to the STARR with two PPH-01 technique. On the other hand, in the current literature[14] a correlation between the amount of the prolapse removed and the functional improvement in patients with ODS has not been reported yet and so far it has not been demonstrated to have any correlation between functional failure and insufficient removal of the prolapse. Further studies should investigate longer clinical outcomes and allow us to evaluate if a larger rectal resection results in a functional improvement emphasizing the real advantages of CCS 30 with respect to STARR.

COMMENTS

Background
Obstructed defecation syndrome is a common disease, particularly in the female population, treated with two different stapled transanal rectal resection (STARR)

procedures.

Innovations and breakthroughs

Both STARR procedures are worldwide performed. All specimen data, manometric and sonographic evaluation should be considered with a clinical follow-up as well in the evaluation of these surgical procedures.

Peer review

The authors ought to be congratulated for a very well conducted study and for the large series of STARR procedures performed.

Abstract

AIM: To investigate the role of p53 antibodies (p53Abs), metallothioneins (MTs) and oxidative stress markers in the early detection of dysplasia in chronic ulcerative colitis (UC).

METHODS: The study included 30 UC patients, 15 without dysplasia (group Ⅱ) and 15 with dysplasia (group Ⅲ), in addition to 15 healthy volunteers (group Ⅰ, control subjects). The enzyme-linked immunosorbent assay technique was used to measure serum p53Abs and MTs, while advanced oxidation protein products (AOPPs), and reduced glutathione (GSH) levels were measured by spectrophotometric method in all subjects.

RESULTS: In group Ⅱ and group Ⅲ compared to group Ⅰ, there were significant increases in serum levels of AOPPs (145.94 ± 29.86 μmol/L and 192.21 ± 46.71 μmol/L *vs* 128.95 ± 3.06 μmol/L, $P < 0.002$ and $P <$ 0.001, respectively), MTs (8.18 ± 0.35 μg/mL and 9.20 ± 0.58 μg/mL *vs* 6.12 ± 0.25 μg/mL, $P < 0.05$ and $P < 0.05$, respectively), and p53Abs (20.19 ± 3.20 U/mL and 34.66 ± 1.34 U/mL *vs* 9.42 ± 1.64 U/mL, $P < 0.001$ and $P < 0.001$, respectively). There were significantly higher levels of AOPPs ($P < 0.05$) and p53Abs ($P < 0.001$) in UC patients with dysplasia compared to those without dysplasia, while MTs showed no significant difference between the 2 groups ($P > 0.096$). In contrast, GSH levels showed a significant decrease in both patients' groups (1.87 ± 0.02 μmol/mL and 1.37 ± 0.09 μmol/mL *vs* 2.49 ± 0.10 μmol/mL, $P < 0.05$ and $P < 0.05$ in groups Ⅱ and Ⅲ, respectively) compared with group Ⅰ, and the levels were significantly lower in group Ⅲ than group Ⅱ ($P < 0.05$). There was a positive correlation between AOPPs and both MTs ($r = 0.678$, $P < 0.001$) and p53Abs ($r = 0.547$, $P < 0.001$), and also between p53Abs and MTs ($r = 0.739$, $P < 0.001$). There was a negative correlation between AOPPs and GSH ($r = -0.385$, $P < 0.001$), and also between GSH and both MTs ($r = -0.662$, $P < 0.001$) and p53Abs ($r = -0.923$, $P < 0.001$).

CONCLUSION: Oxidative stress and oxidative cellular damage play an important role in the pathogenesis of chronic UC and the associated carcinogenetic process. p53Abs levels could help in early detection of dysplasia in these conditions.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease limited to the colon and affecting only mucosa and submucosa except in the most severe cases. Although the exact pathogenesis of UC remains unknown, various hypotheses have been put forward, and a number of factors are associated with its occurrence[1,2]. The development of dysplasia and cancer is one the most concerning complications of longstanding UC[3].

Both genetic and environmental factors contribute to the pathogenesis of colorectal cancer in UC. Oxidative stress also seems to be involved in the pathogenesis of UC because the inflammatory cells, neutrophils, and macrophages produce large amounts of reactive oxygen species (ROS)[2]. Oxidative stress in inflamed tissue can pave the way for malignant tumors, and it is a major pathogenetic factor in the well-established correlation between inflammatory diseases and cancer[4]. As it is difficult to detect UC-associated dysplasia endoscopically, the development of new diagnostic modalities at an early or precancerous stage is crucial to improve the prognosis of UC-associated neoplasia[5,6].

Advanced oxidation protein products (AOPPs) are new protein markers of oxidative stress with pro-inflammatory properties, which accumulate in many pathological conditions[7,8]. AOPPs are formed mainly as a consequence of the action of chlorinated compounds, leading to the formation of dityrosine residues and protein cross-linking[9,10]. Being the products of oxidative imbalance themselves, AOPPs further participate in the potentiation and perpetuation of both oxidative stress and inflammation[11].

Glutathione (GSH) and its related enzymes are essential enzymatic defense systems in the colonic mucosa that have many important functions, such as maintaining the reduced state of proteins and protecting the cells against ROS, drugs or heavy metal ions[12,13].

Metallothioneins (MTs) are a superfamily of small proteins that are present in virtually every living organism and have highly a conserved number and position of cysteine residues, enabling them to incorporate monovalent and divalent metal atoms and to reduce reactive oxygen and nitrogen species[14]. MTs are known to participate in fundamental cellular processes such as cell proliferation and apoptosis[15].

Altered genes may not only lead to a functional change that contributes to the appearance of a malignant phenotype, but may also generate molecules that will induce humoral or cell-mediated specific immune responses[16]. p53 is the most striking tumor suppressor gene. Mutations of the p53 gene are the most frequently reported somatic gene alterations in human cancer, leading to accumula-tion of p53 gene products in tumor cells that can initiate an immune response with generation of circulating anti-p53 antibodies (p53Abs)[17,18]. The earlier observation of p53Abs in sera of patients with lung, liver, colon, and breast cancer[17,19] not only raised the question of the relationship between p53 gene mutation, p53 accumulation, and the anti-p53 humoral response, but also opened the way to the development of new markers for cancer diagnosis[16].

The aim of this study was to investigate the role of p53Abs, MTs and some oxidative stress markers in the early detection of dysplasia in chronic UC patients.

MATERIALS AND METHODS

The study included 45 subjects in 3 groups. Group I (control group) comprised 15 healthy volunteers (8 male, 7 female), aged 40.3 ± 14.6 years. Group II comprised 15 UC patients (9 male, 6 female), aged 52.9 ± 17.8 years without colonic dysplasia. Group III comprised 15 UC patients (7 male, 8 female), aged 65.5 ± 11.2 years with mild to moderate degrees of dysplasia.

Patients were selected from the inpatients and outpatients of the Tropical Medicine Department of Tanta University Hospital, Egypt. Written consent was obtained from every investigated subject. Disease duration was calculated from the date of diagnosis of UC, taken from the medical records.

Patients with autoimmune disease, any malignant tumor, and/or chronic liver diseases and those with concurrent infections, previous surgery, chemotherapy or who had undergone colorectal surgery and those with nutritional support were excluded from the study. The diagnosis of UC was based upon a clinical history of diarrhea and/or rectal bleeding for 6 wk or more, typical radiological and endoscopic findings, and characteristic microscopic changes on biopsy specimens.

Colonic biopsy samples

All patients underwent colonic biopsy sampling during surveillance colonoscopy, which was performed according to established American Gastroenterological Association guidelines for UC surveillance colonoscopy[20]. An aliquot of the colon sample was immediately fixed in formalin for the histopathological evaluation which was performed by the pathologist in a blinded fashion throughout the study. Dysplasia was diagnosed in line with classification proposed by the Inflammatory Bowel Disease Dysplasia Morphology Study Group[21]. At the time of the endoscopic procedure, blood samples were taken from each subject under complete aseptic conditions, and the sera obtained by centrifugation were stored at -80℃ until the time of use.

Measurements

All groups were subjected to the following: (1) A thorough medical history-taking, full clinical examination and

routine laboratory investigations including complete blood picture and serum albumin, and lipid profile including serum total cholesterol, triglycerides, LDL-cholesterol and HDL-cholesterol; (2) Estimation of serum AOPP level: determination of AOPPs based on spectrophotometric detection according to Witko-Sarsat *et al*[9] (1998). Briefly, 200 μL of serum (diluted 1:5 with phosphate-buffered saline (PBS), 200 μL of chloramin T (0-100 μmol/L) for calibration and 200 μL of PBS as blank were applied on a microtiter plate; 10 μL of 1.16 mol/L potassium iodide and 20 μL of acetic acid were added to each well and absorbance at 340 nm was measured immediately. The concentration of AOPPs was expressed as μmol/L chloramine T equivalents units; (3) Spectrophotometric determination of serum GSH level: the method is based on the reduction of 5.5'-dithiobis-(2-nitrobenzoic acid) by GSH to produce a yellow compound. The reduced chromogen is directly proportional to GSH concentration and its absorbance was measured at 405 nm using a commercial kit (Biodiagnostic, Egypt)[22]; (4) Estimation of serum metallothionein level: MTs in the serum were measured by an enzyme-linked immunosorbent assay (ELISA) kit (Ray Biotech, Inc) after acid (1 mol/L HCl) and heat (100℃, 10 min) treatment to eliminate the co-existent antibody-reactive protein according to Cousins[23] (1991); and (5) Assay of serum p53Abs: p53Abs were detected by a commercially available ELISA kit (Quantkine) kit supplied by Clinilab according to Kirsch *et al*[24] (1998). Cut-off absorbance value was calculated according to the manufacturer's instructions (cut-off = 26.3). Therefore, we judged samples to be positive for serum when the p53Abs level was higher than 26.3 U/mL.

Statistical analysis

Statistical analysis was performed using SPSS for Windows 10.0. One way analysis of variance was used to compare groups and Tukey's test was used to determine the significance between 2 groups. The Pearson correlation coefficient (r) was used to identify a correlation between different parameters.

RESULTS

The demographics and biochemical characteristics in all studied groups are shown in Table 1.

Serum AOPP levels were significantly increased in UC groups II and III compared with the control group ($P < 0.002$ and $P < 0.001$, respectively), with significantly higher levels in patients with dysplasia than in those without dysplasia ($P < 0.001$). GSH serum levels were significantly reduced in groups II and III compared with controls ($P < 0.05$ and $P < 0.05$, respectively), with significantly lower levels in patients with dysplasia than in those without dysplasia ($P < 0.05$). MT serum levels were significantly increased in groups II and III compared with controls ($P < 0.05$ and $P < 0.05$, respectively), with no significant difference between the UC groups ($P >$

DISCUSSION

Chronic UC is associated with an increased risk of developing colorectal cancer. The risk of developing cancer, or its precursor lesion, dysplasia, increases exponentially with the duration of the disease[6]. For early detection of UC-associated colorectal cancer, surveillance colonoscopy is recommended in UC patients at high risk. However, poor acceptability by patients reduces its effectiveness. In addition, it is difficult to detect UC-associated dysplasia endoscopically; therefore, a suitable marker for selecting patients at high risk is needed[4]. Accordingly, this study aimed to investigate the value of AOPPs, GSH, MTs and p53Abs levels for the early detection of dysplasia in chronic UC patients.

The activities of phagocytic leukocytes are greatly increased in the colons of UC patients resulting in enhanced generation of pro-oxidant molecules that have been known to play an important role in the initiation and promotion of multi-step carcinogenesis through specific gene alterations, genetic instability and aberrant methylation[25-27]. Indices of oxidative damage are widely used as markers of oxidative stress. AOPPs are new protein markers of oxidative stress with pro-inflammatory properties, accumulated in many pathological conditions[11,13]. In the present study, serum AOPP levels were significantly increased in UC patients, with significantly higher levels in UC patients with dysplasia than in those without dysplasia. Our results are in agreement with other previous studies which showed an increased formation of AOPPs in inflammatory bowel disease[28,29], and those which showed that colorectal cancer is associated with oxidative stress with increased AOPP levels[30-32].

The epithelium of the colon contains multiple antioxidant systems, including antioxidant enzymes and low-molecular-weight antioxidant molecules such as GSH[33]. GSH and enzymes associated with it play crucial role in cell defense against ROS, which are implicated in various types of cancer[34,35]. In the present study, the significant decrease in GSH level in UC patients with significantly lower levels in patients with dysplasia are in accordance

with previous studies, which showed depletion of the GSH system in UC patients, leading to increased susceptibility towards toxic or carcinogenic compounds[13]. The significant decrease in GSH level in UC patients may result from an increased turnover of GSH to prevent oxidative damage in these patients. The lower levels of GSH in patients with dysplasia may still favor an overproduction of free radicals which in turn may induce damage to the cell membrane and cellular molecules (DNA, RNA) leading to neoplasia[34,35].

The thiol-rich protein MT plays a major role in detoxification of toxic metals and in protection against oxidative damage. In normal tissues, MT expression is usually undetectable, except in certain types of cells such as myoepithelial, renal and thyroid epithelial cells. It has been observed that the large bowel epithelial cells express MT in up to 40% of patients with UC, and a correlation has been found between the degree of MT expression and severity of inflammation[36].

Our study showed a significant increase in MT levels in both groups of UC patients, but a non significant difference between them. This finding is in agreement with the studies of Brüwer *et al*[36] and Waeytens *et al*[37], who found an increased expression of MT in epithelial cells of the intestinal mucosa in inflammatory bowel disease patients. The increased MT concentration in UC patients suggests induction of MT synthesis in response to the potential harmful effects of ROS and nitrogen intermediates produced during the inflammatory response. The generated ROS may activate MT expression through multiple pathways, including directly by stimulating an antioxidant response element and specific metal response elements in the promoter region as well as indirectly by events associated with second-messenger protein kinase pathways[17,18].

Several lines of evidence indicated that many types of tumors have high concentrations of MT and this may play a role in various carcinogenic processes. Also high levels of MT expression have been reported in initiation, progression, and metastasis of cancer[14].

MT overexpression may represent an important early step in the development of colorectal carcinoma in UC patients and those with low grade dysplasia[38]. It has been hypothesized that mutation-induced metallothionein overexpression may interfere with the function of zinc finger DNA binding transcription factors involved in the control of the expression of a wide range of genes regulating cell proliferation and apoptosis, such as p53, and conferring a growth advantage on the mutated cells[39].

The p53 gene mutations seem to be an early event in cancerous change in UC patients[25]. These mutations lead to inactivation of the p53 protein, and cellular accumulation in the nucleus which can initiate an immune response with generation of circulating p53Abs. These p53Abs reflect a humoral response that occurs early in tumor development. Previous studies reported high diagnostic sensitivity and specificity of p53Abs in patients with various types of cancers[40].

In the present study serum p53Abs showed significantly increased levels in both groups of UC patients, with significantly higher levels in patients with dysplasia. The widely accepted hypothesis for increased serum p53Abs is as follows; a point mutation of the p53 gene is associated with overexpression of p53 protein. Overexpressed mutant p53 is considered a nonself protein, triggering the immunocompetent cells and secretion of p53Abs[40]. The type and location of p53 gene mutations may impact on the generation of p53Abs. Most of these mutations lead to the synthesis of a stable protein which accumulates in tumor cells and may be important for the development of the immune response[40]. It has also been suggested that mutations in exons 5 and 6 (coding for mutant protein that binds to heat shock protein 70) are immunogenic, while mutations in exons 7 and 8 are not related to the generation of p53Abs[41]. Our results are in line with the study of Cioffi *et al*[15], 2004 who suggested that assessment of serum p53Abs is an indirect marker for p53 gene mutations, and the abnormally high p53 protein levels could be considered to have a potential for use as a complementary test to improve surveillance program performance in UC patients. Normally p53 comes into action when DNA is damaged and arrests the cell cycle so as to allow repair. In the case of failure of repair, p53 directs the cell to apoptosis; therefore, p53 mutation leads to uncontrolled proliferation of cells[42].

Using a cut-off value ($\geqslant$ 26 U/mL), we demonstrated that p53Abs were present in 40.0% of UC patients with dysplasia and in 13.3% without dysplasia. Further investigations on a large scale are needed to better define the sensitivity, specificity, positive and negative predictive values of p53 alterations in patients with UC with and without dysplasia.

In conclusion, oxidative stress and oxidative cellular damage play an important role in the pathogenesis of chronic UC and the associated carcinogenetic process. p53Ab levels could help in early detection of dysplasia in UC patients.

COMMENTS

Background
Patients with longstanding ulcerative colitis (UC) have an increased risk of developing dysplasia and colorectal cancer. This risk appears to be related to the cumulative effect of chronic inflammation and correlates directly with the extent and duration of disease. Earlier colonoscopy screening and surveillance for detecting mucosal dysplasia is important to select colorectal cancer-prone individuals for prophylactic colectomy but, to date, this has not been translated into a positive survival benefit. p53 antibodies (p53Abs), metallothioneins (MTs) and some oxidative stress markers may aid in the early detection of dysplasia in chronic UC patients and could be used as complementary tests to improve surveillance program.

Research frontiers
Despite several acknowledged limitations, periodic surveillance colonoscopy continues to be used to diagnose dysplasia and colorectal cancer complications of longstanding UC. Investigating the role of p53Abs, MTs and some oxidative stress markers may open the way to the development of new cancer diagnosis.

Innovations and breakthroughs
The present study revealed that the decreased serum protective antioxidant glutathione (GSH) level associated with an increased production of oxygen free

radicals results in protein oxidation and hence advanced oxidation protein products (AOPPs) with subsequent increase of MTs leading to p53 instability and the development of high levels of p53Abs in longstanding UC, that may precede and accompany dysplasia. These data are in line with previous studies and call for wider research on the associations in UC.

Applications

AOPPs, GSH and MTs are associated with dysplastic changes in chronic UC. p53Ab levels could be used as a complementary test in a surveillance program. Further investigations on large scale populations are needed to compare their sensitivity, specificity, positive and negative predictive values, in addition to, alterations of the p53 tumor suppressor gene, which occurs early in patients with UC and may precede dysplasia.

Terminology

p53: the *p53* gene is the tumor suppressor gene whose abnormalities are the most frequently reported gene alterations in human cancer. MTs: a superfamily of small proteins with a highly conserved number of cysteine residues and they reduce reactive oxygen and nitrogen species. GSH: essential enzymatic defense system in the colonic mucosa. AOPPs are protein markers of oxidative stress with pro-inflammatory properties.

Peer review

This is an excellent study which is based on the early detection of serological biomarkers in order to predict the risk of developing colorectal cancer in individuals with UC.

Abstract

AIM: To assess the clinical role of monoclonal immunoscintigraphy for the detection of metastasis and recurrence of colorectal cancer.

METHODS: Monoclonal immunoscintigraphy was performed in patients operated on for colorectal adenocarcinoma suspected of local recurrence and metastatic disease. The results were compared with conventional diagnostics.

RESULTS: Immunoscintigraphic investigation was done in 53 patients. Tumor recurrence occurred in 38 patients, and was confirmed by other diagnostic modalities in 35. In 15 patients, immunoscintigraphic findings were negative, and confirmed in 14 with other diagnostic methods. Comparative analysis confirmed good correlation of immunoscintigraphic findings and the results of conventional diagnostics and the level of tumor marker carcinoembryonic antigen. Statistical analysis of parameters of radiopharmaceutical groups imacis, indimacis and oncoscint presented homogenous characteristics all of three radiopharmaceuticals. The analysis of immunoscintigraphic target focus was clearly improved using tomography.

CONCLUSION: Immunoscintigraphy is highly specific and has a good predictive value in local recurrence of colorectal cancer.

Monoclonal immunoscintigraphy for detection of metastasis and recurrence of colorectal cancer. *World J Gastroenterol* 2011; 17(19): 2424-2430 Available from:

INTRODUCTION

Radiolabeled monoclonal antibodies (mAbs) against tumor-associated antigens enable imaging of primary tumors of the gastrointestinal system, and their metastases and/or recurrence, with high sensitivity and specificity. Whole body immunoscintigraphy and/or single photon emission computed tomography (SPECT) are accessible imaging methods focusing on specific type of tumors. Nuclear medicine imaging enables determination of the pathophysiological and biochemical parameters of the viable tumor tissue, including metabolic changes as well as the presence of specific proteins/receptors on the surface of the tumor cells. Positron emission tomography (PET) is the best method for imaging metabolic changes based on increased rate of tumor glycolysis and/or protein metabolism. Dual modality hybrid imaging techniques PET/CT enable precise morphological and anatomical localization.

Radio-immunoguided surgery has been introduced as a method of more accurate detection of tumor extension and enables radical resection. Radioimmunotherapy with mAbs as postoperative adjuvant treatment is currently been investigated[1].

The aim of the present study was to evaluate the clinical reliability of immunoscintigraphy for detection of metastasis and recurrence of colorectal carcinoma, using three different radiopharmaceuticals.

MATERIALS AND METHODS

Methodology

Imacis 1 contains a cocktail of (111 MBq ^{131}I) mAb 19-9 F (ab') 2 and mAb anti CEA F (ab') 2. It is labeled with ^{131}I. Its half-life of 8 d and β-minus emission leads to significant radiation exposure of the patient. In addition, its high energy (364 KeV) makes it less than optimal for imaging, necessitating special collimation for contemporary gamma cameras. The two other radiopharmaceuticals used in this study were labeled with ^{111}In. Indimacis 19-9 contains 19-9 F(ab')2/DTPA fragments of mAbs. It is a pure γ emitting isotope with a physical half life of 67 h, an abundance of photon emissions at 173 and 247 keV, while Oncoscint CR 103 is an immunoconjugate produced by site-specific modification of the mAb B72.3, which is a murine immunoglobulin that is able to recognize high molecular weight glycoprotein (TAG-72) expressed by a majority of adenocarcinomas[2-6].

Imacis 1 was administered by slow injection for approximately 30 min. Potassium iodide (600 mg/d) was administered orally for 10 d (starting 24 h before injection) to block the uptake of free iodine into the thyroid gland. Imaging was carried out after 96-120 h. Planar images (6 min/image or at least 200 000 counts over the whole field of view) including anterior and posterior projections of the thorax, abdomen and pelvis, were taken using large field-of-view cameras, fitted with parallel hole high energy collimators. Indimacis 19-9 at a dose of 185 MBq was administered by slow infusion of 100 mL 0.9% sodium chloride over 30 min. Anterior and posterior spot views of the abdomen, pelvis and/or chest (500 000 counts/view) were obtained 24 h and 48 h following the infusion. SPECT of abdominal and pelvic regions, including 360° rotating orbit, sampling every 6° with an 40-s acquisition per stop, using a 128 × 128 or 64 × 640 word matrix was carried out. Reconstruction was performed using Butterworth filter, order 6-10. Oncoscint CR 103 at a dose of 185-200 MBq was administered by slow injection for approximately 5 min, following the same acquisition protocol as above. To achieve more precise localization of the pathological lesions, as well as to increase target-to-background ratio, the dual isotope acquisition and subsequent subtraction of the obtained images were carried out. Thus, images of the vascular system (^{99m}Tc-red blood cells), liver and spleen (^{99m}Tc-sulfur colloid) or kidney (^{99m}Tc-DTPA) are obtained and used for subtraction. Scintigraphy was performed with a ROTA/Orbiter scintillation camera and Micro Delta computer.

Patients

The selection of patients was based upon complete diagnostic records [anamnestic data, physical examination, blood analysis, ultrasonography, contrast radiography, rectoscopy/colonoscopy, CT, magnetic resonance imaging (MRI), tumor marker assay] and clinical follow-up of at least 6 mo. The investigation was performed whenever there was a rise in serum levels of tumor markers [carcinoembryonic antigen (CEA) and carbohydrate antigen (CA 19-9)], and metastasis or recurrence could not be located according to clinical, radiological (chest X-rays), sonographic or endoscopic findings.

In all the patients, tumor marker (CEA and CA 19-9) blood levels were estimated every month in the same laboratory. Blood samples for tumor marker estimation were taken from the cubital vein of the patients and stored at -20℃ until analysis. Physiological values of CEA were considered up to 7 U/L, while for CA 19-9, they were up to 33 U/mL. Fifteen patients were treated with Imacis 1, 18 with Indimacis 19-9, and 20 with Oncoscint CR 103.

Statistical analysis

The study data were analyzed in program R version 2.8.1. Tables and graphs were created in Microsoft Office Excel 2007. For statistical analysis of inter-rater agreement of samples with normal distribution, the following graphs were used: Normal Q-Q plot, histogram, and Kolmogorov-Smirnov's and Shapiro-Wilk's tests. In order to test the differences between parameters based on their nature, we used Kruskal-Wallis's test, exact Wilcoxon's rank sum test and Fisher's exact test. The value of $\alpha = 0.05$ was accepted as statistically significant. In case of multiple testing of the same set of data, Bonferoni's correction was used ($\alpha_1 = 0.05/\beta = 0.0167$). For the inter-rater agreement of significant parameters, Cohen's κ coefficient test was used.

Type 0- no disease; 1- liver metastases; 2- recurrence; in colonoscopy and rectoscopy: 1- recurrence; 2-stricture and polyposis; 3- liver metastases and recurrence; 4- peritoneal carcinosis. CEA: Carcinoembryonic antigen; NA: Not Analyzed; US: Ultrasound; CT: Computed tomography; MR: Magnetic resonance; SPECT: Single photon emission computed tomography. Oncoscint CR 20: Indium In 111 satumomab pendetide; CA 19-9: Carbohydrate antigen 19-9.

RESULTS

Analysis of general parameters in three radiopharmaceutical groups-homogeneity

Data from various patients were statistically analyzed using Fisher's exact test in a study group consisting of 53 patients investigated with three radiopharmaceuticals. Analyzed parameters were: age, sex, surgical treatment, pathological verification and diagnostic examination findings. These analyses showed the homogeneity between the three different radiopharmaceuticals (Table 1).

Tumor marker CEA

With Kruskal-Wallis's test, levels of tumor markers CEA and CA 19-9 were analyzed in 53 patients. CA 19-9 level in the Indimacis 19-9 group was lower than in the other two groups, but it was still elevated. CEA level was elevated in all patients, but was significantly lower in those without pathological findings, and elevated in those with metastatic disease and/or recurrence (Table 2).

Complementary diagnostics

The findings of the complementary diagnostic methods

Table 2 Median carcinoembryonic antigen in types of immunoscintigraphy

Type of disease	n	CEA median
0	14	5
1	8	16.25
2	10	9.45
3	9	10
4	1	40

Type 0-no disease; 1-liver metastases; 2-recurrence; 3-liver metastases and recurrence; 4-peritoneal carcinosis. CEA: Carcinoembryonic antigen.

Table 3 Comparison of Cohen's κ coefficient for immunoscintigraphy and other diagnostic methods

Method	n	κ

Figure 3 Immunoscintigraphy, planar, anterior view. Accumulation of radiopharmaceutical (Oncoscint) in peritoneal carcinosis.

Figure 1 Immunoscintigraphy, planar, anterior view. Accumulation of radiopharmaceutical (IMACIS 1) in metastatic tumor of the right lower part of the liver (arrow).

Target background ratio

In 28 patients with positive immunoscintigraphic findings (both Indimacis 19-9 and Oncoscint), target/background (tg/bg) ratio was analyzed. Higher tg/bg ratio was found in metastatic foci with Indimacis 19-9 (Table 4). Further analysis of SPECT tg/bg ratio and planar tg/bg ratio points out the advantages of SPECT acquisition in immunoscintigraphic detection of metastases (exact Wilcoxon's rank sum test: planar images W = 169, $P = 0.0005$ and SPECT images W = 174.5, $P = 0.0001$).

DISCUSSION

The analyses showed homogeneity between the groups for the three different radiopharmaceuticals. CEA and CA 19-9 were analyzed in 53 patients. The CA 19-9 level was lower in the Indimacis 19-9 group compared with the other two groups, but it was still elevated. Tumor marker CEA was elevated in all patients, but significantly lower in those without pathological findings, and elevated in those with metastatic disease and/or recurrence. Thus, we can conclude that both parameters are valuable for evaluation and follow-up of disease.

The findings of the complementary diagnostic methods and immunoscintigraphy were analyzed and whole body immunoscintigraphy was superior in correlation

and immunoscintigraphy were analyzed with Cohen's κ coefficient for the statistical analysis of inter-rater agreement: ultrasonography, slight; rectoscopy, substantial; colonoscopy, moderate; CT, fair; and MRI, substantial (Table 3). Whole body immunoscintigraphy was superior in correlation with complementary diagnostic methods for the detection of pelvic and extrahepatic metastases. Tumor recurrence occurred in 38 patients, and was confirmed by other diagnostic modalities in 35. In three patients, immunoscintigraphic findings were false positive, because hepatic metastases were not confirmed by other imaging modalities. This can be explained by the local inflammation after liver surgery. Thus, sensitivity of the method was 97%, specificity 82%, positive predictive value 92%, negative predictive value 93%, and accuracy 92% (Figures 1-3).

with complementary diagnostic methods for the detection of pelvic and extrahepatic metastases.

Tumor recurrence occurred in 38 patients, and was confirmed by other diagnostic modalities in 35 (Figures 1-3). In three patients, immunoscintigraphic findings were false positive due to local inflammation after liver surgery. In 15 patients, findings were negative, which were confirmed in 14 patients using other diagnostic methods, and one patient had a false-negative result, which was a small lesion in the rectal lumen (1 cm) that was confirmed by rectoscopy. Thus, sensitivity of the method was 97%, specificity 82%, positive predictive value 92%, negative predictive value 93%, and accuracy 92%.

A higher tg/bg ratio was found for metastatic foci with Indimacis 19-9. Further analysis pointed out the advantages of SPECT acquisition for immunoscintigraphic detection of metastases.

In most of the investigated cases, immunoscintigraphy was complementary to other imaging methods and significantly influenced the patient management. The most appropriate applications of this method should be the detection of recurrence, assessment of viability, as well as follow-up of disease progression and regression after therapy. Its diagnostic role is complementary to the radiological methods, which show limitations such as viability assessment after surgery, radio- and chemotherapy (CT, MRI), as well as when contrast radiography and colonoscopy cannot be performed (patients with colostomas and strictures), or when recurrence has an extraluminal position. However, other morphological methods (CT, ultrasonography, MRI) are superior for detection of liver metastases, while immunoscintigraphy is more sensitive and specific for the discovery of recurrences of colorectal carcinoma.

With regard to the false-negative findings for small intraluminal tumors, we conclude that for intraluminal tumors, endoscopic methods such as rectoscopy are the methods of choice. Apart from localization, the disadvantage of immunoscintigraphy is low spatial resolution of gamma cameras, which can lead to overlooking of small lesions (1 cm). These disadvantages can be overcome by using new generation gamma cameras with increased resolution as well as fusion images with CT and MRI, and especially hybrid systems. Thus, the recent introduction of a hybrid imaging device that contains a low-dose CT system and a gamma camera (SPECT/CT) on a single gantry has enabled the sequential acquisition of the two imaging modalities, with subsequent merging of data into a composite image display. These hybrid studies have led to a revolution in the field of imaging, with highly accurate localization of tumor sites, assessment of invasion into surrounding tissues, and characterization of their functional status[7-9]. In the absence of SPECT/CT systems, tomography (SPECT) for a better distinction of the tumor is highly recommended. Further improvement in the detection of small tumor recurrences with immunoscintigraphy, using radioimmunoguided surgery (RIGS) and intraoperative detection of tumor deposits using special gamma probe systems, after i.v. application of radiopharmaceuticals, is discussed later.

Table 4 Target/background ratio (mean and SD) in planar and single photon emission computed tomography immunoscintigraphic foci

	Planar	SPECT	*n*
Indimacis 19-9 mean (SD)			
Recurrence	1.2	3.5	1/13
Metastasis	2.03 (0.44)	3.04 (0.8)	13/13
Oncoscint mean (SD)			
Recurrence	1.6 (0.24)	2.15 (0.29)	4/5
Metastasis	1.45 (0.26)	1.84 (0.28)	15/15

SPECT: Single photon emission computed tomography.

For accurate diagnosis, it is necessary to estimate tg/bg ratio, especially for the detection of liver metastases (subtraction method is highly recommended), and non-specific uptake of the radiopharmaceuticals in organs due to metabolism and excretion (liver and kidneys), and tissues mainly due to local inflammation. In our patients, false-positive findings can be attributed to the accumulation of radiopharmaceuticals in inflammation. We must emphasize that in all three false-positive patients, tg/bg ratio was on the lower edge of values for positive findings, which means lower than in tumor tissue, but the difference was not obvious and it was not easy to make a clear cut-off. All three patients underwent liver surgery during 6 mo before our investigation, which caused local inflammation with increased accumulation of radiopharmaceuticals. This means that, to prevent false-positive findings, the time of investigation should be longer after surgery, or repeated after 1 or 2 mo, with the expectation of obtaining lower values in non-specific accumulation and higher values in the case of tumor tissue, with obligatory quantification, i.e. estimation of tg/bg ratio[10,11]. Although the antibodies are tumor specific, there is a certain non-specific accumulation in tissues, due to increased vascularization and local inflammation because specific radioimmunotherapy has never been employed widely[12]. Also, as in previously described methods recommended for detection of false-negative cases, apart from physiological methods (immunoscintigraphy with SPECT), additional morphological investigation is recommended, such as hybrid SPECT/CT imaging, in order to distinguish accumulation in the unchanged, inflamed tumor tissue from newly developed tumor formation. Furthermore, even tumor marker/antigen (CEA, CA19-9) levels can be moderately increased due to local inflammation, which results in binding with specific radiolabeled antibodies[13,14]. This also confirms the importance of follow-up in unclear cases. However, even with the above-mentioned limitations, accuracy of the method is very high.

The results from the literature mainly correspond to ours. Thus, some authors have confirmed the significance of the method for detection of recurrence, but have not confirmed its validity for detection of liver metastases[15,16], whereas many[17-19] have emphasized the significance of tomography. However, on the contrary, some investigations[20-22] have found immunoscintigraphy inferior to other imaging methods, especially for the detection of lymph node metastases and for planning adequate surgical

approaches for recurrent colorectal carcinoma.

Our previous results, as well as those of other authors[23-29] have pointed out the particular application of these antibodies for disease staging, and detection of local recurrence and extra-hepatic metastases in colorectal carcinoma, and that they have an important role in the therapeutic decision making process. The clinical value of PET and immunoscintigraphy with ^{131}I or ^{111}In anti-CEA mAb for diagnosis of recurrent colorectal cancer has been confirmed by Ito *et al*[30], who have concluded that PET/CT reflects more accurately the biological character of tumors, but cannot provide the specificity of immunoscintigraphy that enables us to distinguish patients for antibody-based therapy. The superior value of PET with fluorodeoxyglucose for detection of distant metastases (liver, bone, and lung) and lymph node involvement has been estimated in comparison to ^{99m}Tc-labeled anti-CEA Fab for detection of recurrence of colorectal carcinoma[31]. Immunoscintigraphy is superior for detection of local recurrent colorectal cancer, whereas PET is better for detection of distal metastases[32].

RIGS[33] enables localization of small tumor deposits. Roveda *et al*[34] have performed immunoscintigraphy with ^{131}I or ^{111}In anti-CEA and 19.9 mAb using a gamma probe, and have found it particularly useful for endoscopic study of the pelvis after anterior resection, which is difficult to achieve by other diagnostic procedures. Both immunoscintigraphy and RIGS enable a more accurate diagnosis according to Hladic *et al*[35]. Florio *et al*[36] have found positive intraoperative gamma probe detection, although negative for immunoscintigraphy. RIGS applied in primary colorectal cancer enables the detection of occult lymph node metastases[37].

In summary, imaging methods (CT, US, MRI) have an advantage for detection of liver metastases, whereas immunoscinitgraphy is more specific for the assessment of recurrence of abdominal tumors. Thus, immunoscintigraphy should be applied in patients with suspected local recurrence and inconclusive results of routine diagnostic workup.

COMMENTS

Background
Considering that some tumors produce characteristic antigens, scintigraphy with monoclonal antibodies to these antigens seems to be a very promising method for detection. The aim of this study was to evaluate the clinical reliability of immunoscintigraphy for the detection of metastasis and recurrence of colorectal carcinoma, using three different radiopharmaceuticals.

Research frontiers
The results demonstrate that immunoscintigraphy is an accurate method for the detection of cancer recurrence. Together with single photon emission computed tomography (SPECT)/CT and radioimmunoguided surgery, it could have potential for selection of patients for immunotherapy or, in the future, radioimmunotherapy.

Innovations and breakthroughs
Imaging methods (CT, ultrasonography, magnetic resonance imaging) have advantages for detection of liver metastases, whereas immunoscintigraphy is more specific for the assessment of recurrence of abdominal tumors.

Applications
Immunoscintigraphy should be used in patients with suspected local recurrence and inconclusive results from routine diagnostic workup.

Terminology
Monoclonal immunoscintigraphy is scintigraphy with radiolabeled monoclonal antibodies on tumor markers/antigens.

Peer review
The research article by Artiko and his team deals with the usefulness of immnunoscintigraphy for the detection of metastases and the recurrence of colorectal cancer. The results indicate that immunoscintigraphy is reliable and has a specific advantage for the detection of tumor recurrence, and can also be useful for suspected local recurrence. There was a good correlation between immunoscintigraphic evaluation and the results of conventional diagnostic methods.

Abstract

AIM: To assess the long-term outcome of endoscopic hemorrhoid ligation (EHL) for the treatment of symptomatic internal hemorrhoids.

METHODS: A total of 759 consecutive patients (415 males and 344 females) were enrolled. Clinical presentations were rectal bleeding (593 patients) and mucosal prolapse (166 patients). All patients received EHL at outpatient clinics. Hemorrhoid severity was classified by Goligher's grading. The mean follow-up period was 55.4 mo (range, 45-92 mo).

RESULTS: The number of band ligations averaged 2.35 in the first session for bleeding and 2.69 for prolapsed patients. Bleeding was controlled in 587 (98.0%) patients, while prolapse was reduced in 137 (82.5%) patients. After treatment, 93 patients experienced anal pain and 48 patients had mild bleeding. Patient subjective satisfaction was 93.6%. Repeat treatment or surgery was performed if symptoms were not relieved in the first session. In the bleeding group, the recurrence rate was 3.7% (22 patients) at 1 year, and 6.6% and 13.0% at 2 and 5 years. In the prolapsed group, the recurrence rate was 3.0%, 9.6% and 16.9% at 1, 2 and 5 years, respectively.

CONCLUSION: EHL is an easy and well-tolerated procedure for the treatment of symptomatic internal hemorrhoids, with good long-term results.

INTRODUCTION

Hemorrhoids are the most prevalent anorectal disorder among adults, and over 90% of patients undergoing sigmoidoscopy or colonoscopy are found to have hemorrhoids of varying degrees. Hemorrhoids are defined as internal or external based on whether they are located above or below the dentate line. Internal hemorrhoids can be classified into 4 grades using the Goligher system[1]: Grade 1, hemorrhoids with bleeding; Grade 2, hemorrhoids with bleeding and protrusion, with spontaneous reduction; Grade 3, hemorrhoids with bleeding and protrusion that require manual reduction; and Grade 4, prolapsed hemorrhoids that cannot be replaced. Nonoperative management is considered for

patients with symptoms (anal bleeding or rectal prolapse) and grades 1, 2, and 3 internal hemorrhoids. Treatments include local injection therapy, anal divulsion, elastic band ligation, cryotherapy, infrared and laser photocoagulation, direct application of electrical current, and bipolar coagulation[2,3]. Based on the results of a meta-analysis, MacRae and McLeod[4] concluded that rubber band ligation should be recommended for Grades 1 to 3 internal hemorrhoids, and that patients treated by this method were less likely to require additional therapies than those treated with local injection therapy or infrared coagulation.

Since first introduced in the United States in 1951, rubber band ligation has become the mainstay of treatment for bleeding and prolapsing internal hemorrhoids, and is now a well-established, safe, and effective technique[5-7]. It has been shown to be substantially better than medication alone in terms of outcome, and is not associated with significant morbidity[8]. Conventional band ligation is performed with rigid anoscopic devices with limited maneuverability and a narrow field of view, and no ability to document treatment photographically[4]. These drawbacks can be overcome by using a video-endoscopic system that provides a detailed image of the operative field as well as photographic capability[9]. Our previous studies showed a good result of endoscopic hemorrhoid ligation (EHL) in patients with symptomatic internal hemorrhoids at initial therapy and one year after treatment[10,11]. The aim of this study was to further assess the long-term outcome and efficacy of EHL for treatment of symptomatic internal hemorrhoids.

MATERIALS AND METHODS

From November 2000 to October 2004, 759 consecutive patients with symptomatic internal hemorrhoids were treated with EHL and enrolled in this study prospectively. All the procedures were performed by the same endoscopist who has more than 10 years of endoscopic surgery experience. Before EHL, the endoscopist needs to identify the dentate line, and then EHL is easy to perform without learning curve. The whole procedure takes about 2-3 min, and compared to the traditional technique by anosocpe, EHL offers good view and also recordable for the trainee to learn the procedure.

There are 415 male and 344 female patients with a mean age of 54.2 years (range, 18-92 years). Rectal bleeding or prolapse was the major patient complaints. Sixty-eight patients were cirrhotic and 36 patients were uremia.

All patients underwent flexible sigmoidoscopy after fleet enema 1pc or colonoscopy after standard colonic preparation with polyethylene glycol 2000 mL or sodium phosphate 90 mL in splitting doses to exclude other causes of rectal bleeding. Patients were excluded if polyps or evidence of malignancy was found at colonoscopy. All patients gave informed consent for the ligation procedure. Patients were not asked to discontinue the use of aspirin or other non-steroid anti-inflammatory drugs (NSAID) before the procedures. The contraindications of EHL were the same as traditional band ligation, such as throm-

Figure 1 Endoscopic view of internal hemorrhoid, 2-5 mm above the dentate line, ligated with a rubber band.

bosed hemorrhoids, anal fistula or peri-anal abscess.

After the initial endoscopic examination, patients were treated if Grade 2 or greater internal hemorrhoids were present. As with esophageal variceal ligation, a transparent plastic endoscopic ligation cap (Sumitomo Co., Tokyo, Japan) was attached to the top of a diagnostic upper gastrointestinal (GI) endoscope (GIF-XQ230; Olympus Optical Co, Ltd, Tokyo, Japan). The dentate line then was identified, and ligation was performed 2-5 mm above the dentate line (Figure 1). The hemorrhoid was suctioned into the cap with the tip of the endoscope in the anal canal, and a single elastic band was released. If further ligation was required, another rubber band was placed on the cap. All ligations were performed in an outpatient setting without any premedications such as sedatives or analgesics.

Safety data were recorded and all adverse events were documented. After first treatment session, patients were asked to complete a questionnaire to evaluate the subjective satisfaction, which was classified as excellent, good, fair or poor. Patients were seen 1 wk after the procedure and then monthly and sigmoidoscopy after fleet enema 1pc was performed at all visits. In all cases, hemorrhoid severity and recurrent symptoms were assessed yearly after the ligation session. Failure of treatment was defined as persisted symptoms beginning 1 mo after ligation. Recurrent bleeding was defined as anal bleeding with two separate bowel movements or massive bleeding that required further treatment after one month of ligation. Recurrent prolapse was defined as recurrent prolapse symptoms that were troublesome to patient lasting more than 2 mo after initial successful treatment and requiring further treatment.

Student t test was used for analysis and P value less than 0.05 defined as statistically significant.

RESULTS

All patients were treated with one session initially, and were followed regularly. The mean follow-up period was 55.4 mo (range, 45-92 mo). Overall patient satisfaction was 93.6% after the first treatment session.

Rectal bleeding was the chief complaint of 593 patients: 146 had anemia (hemoglobin < 12 g/dL) due to

Figure 2 Pre-treatment showed grade 4 hemorrhoids.

Figure 3 After ligation, grade 4 hemorrhoids showed spontaneous reduction.

Table 1 Severity of hemorrhoids in the prolapsed group before and after the first endoscopic ligation session

		Before treatment		After treatment
Goligher grade	IV	23	IV	7
			III	16
	III	130	III	22
			II	93
			I	15
	II	13	I	13

hemorrhoid bleeding; 273 experienced intermittent dripping of blood from the anal area; and 174 noted blood intermittently on toilet tissue. Rectal bleeding was controlled in 587 patients (98.0%). The average number of band ligations performed in the first session for rectal bleeding was 2.35. There were 6 patients in whom symptoms were not controlled in the first session, and received a second treatment session. Bleeding in these patients was controlled after second session, thus, all of the patients had their symptoms controlled. The recurrence rate was 3.7% at 1 year (22 patients), 6.6% at 2 years, and 13.0% at 5 years.

Rectal prolapse requiring manual reduction was the major complaint of 166 of the 759 patients, 131 of whom also had intermittent mild rectal bleeding. The severity of hemorrhoid prolapse was classified by Goligher's grading. Most patients (82.5%, 137/166) had their hemorrhoids reduced by at least one grade in the first session (Table 1). Figures 2 and 3 showed improvement of pre- and post-treatment of ligation for Grade 4 hemorrhoids. The average number of band ligations performed in the first session was 2.69. For failed control of symptoms in the first session, 4 patients received further surgical hemorrhoidectomy due to thrombosed hemorrhoids and perianal abscess, while 21 patients received the second session of whom 17 had their symptom controlled. Three patients received a third EHL session and 2 patients showed improvement while the other received a hemorrhoidectomy for poor response to EHL. Five patients in the prolapsed group were lost to follow-up. The recurrence rate at 1 year was 3.0% (5 patients), at 2 years was 9.6%, and at 5 years was 16.9% (Figure 4).

The symptom control rate was higher in the bleed-

ing group than in the prolapsed group (98.0% *vs* 82.5%, respectively; $P = 0.043$). A total of 93 patients (12.3%) experienced mild anal pain or tenesmus sensation 1-3 days after treatment, which was relieved by oral mefenamic acid. There were 48 patients (6.3%) who had mild bleeding 1-14 d after ligation (mild bleeding means some blood noted in tissue papers), and most of them were treated by injection of 1-3 mL diluted solution of epinephrine (1:100 000) in divided doses directly into the wound. Two cirrhotic patients had experienced massive bleeding due to post-ligation ulcers (Figure 5) and required blood transfusion. Bleeding was controlled with local injection of epinephrine. No EHL-related mortality was observed.

The patients' subjective satisfaction was 93.6% (excellent or good response) after the first treatment session. The mean follow-up period was 55.4 mo (range, 45-92 mo). The percentage of symptom free patients during follow-up period is shown in Figure 6.

DISCUSSION

Rubber band ligation has been used to treat internal hemorrhoids since Blaisdale introduced a ligation device in 1951. This device is used via an anoscope to grasp hemorrhoid tissue with small prongs and an elastic band is applied. The hemorrhoid and its redundant mucosal tissues become thrombosed and slough off, usually within 5-7 d. One notable advantage of band ligation is the production of submucosal scarring that prevents subsequent development of new hemorrhoid tissue. Rubber band ligation is technically simple and can be used in the outpatient setting without local anesthesia. The reported success rate varies between 69% and 97%, depending on the degree of internal hemorrhoids, the ligation technique, and the duration of follow-up[8]. Serious complications, such as life-threatening massive bleeding[12,13] and sepsis are extremely rare, but should not be discounted[14,15]. Dickey and Garrett[16] found that hemorrhoid banding using video-endoscopic anoscopy and a single-handed ligator compared favorably with traditional hemorrhoid banding by anoscopy. This video-endoscopic technique may be preferred in the office setting.

There are other several non-operative methods for management of internal hemorrhoids, such as sclerothera-

Figure 4 Outcomes of the 759 patients undergoing endoscopic hemorrhoid ligation. EHL: Endoscopic hemorrhoid ligation.

Figure 5 Ulcer formation after ligation.

Figure 6 Five-year follow-up for the symptom-free percentage of bleeding and prolapsed patients.

py, cryotherapy, direct-current electrotherapy and infrared photocoagulation. MacRae et al performed a meta-analysis covering 23 studies that compared rubber band ligation, sclerotherapy, hemorrhoidectomy, infrared photocoagulation, and manual dilation of the anus for patients with Grade 1-3 hemorrhoids[17]. They found that rubber band ligation was more effective than sclerotherapy, less likely to require additional therapy than either infrared photocoagulation or sclerotherapy, and more likely to cause pain.

Stiegmann and Goff[18] first proposed elastic band ligation for the treatment of esophageal and gastric varices using a device attached to the tip of a video-endoscope to deploy the bands. Endoscopic band ligation of esophageal varices now is preferred to sclerotherapy because of equivalent efficacy, ease of use, and relatively fewer complications[19,20]. The application of the same device and technique to eradicate internal hemorrhoids is a logical extension of this established procedure. Trowers *et al*[9] reported preliminary experience with endoscopic hemorrhoid ligation in 1997 in which 95% of internal hemorrhoids were reduced by more than one grade after treatment. Berkelhammer and Moosvi[21] used retroflexed endoscopic band ligation to treat bleeding internal hemorrhoids. Excellent results were achieved in 80% of patients with Grade 2 hemorrhoids. In

addition, the results with treatment of patients with Grade 2 hemorrhoids were more likely to be excellent compared with those for patients with Grade 3 hemorrhoids.

There are two different endoscopic hemorrhoid ligation devices, a smaller one that is attached to gastroscope just as variceal ligators, and a larger one with a greater diameter cap used with a colonoscope. Our previous study showed that these two devices provided similar good results for the treatment of symptomatic internal hemorrhoids[10]. A later study in which the variceal ligation device was used with a gastroscope showed good initial and one-year results with more than 90% of hemorrhoids reduced by at least one grade[11].

In this study, we used the gastroscope for hemorrhoid ligation and found that 82.5% (137/166) of patients had their hemorrhoids reduced by at least one grade in the first session, with 93.6% subjective satisfaction. In addition, more than 80% of patients had sustained results. The symptom control rate was better in bleeding group other than prolapsed group. Bleeding hemorrhoids were easily identified by endoscopic view, while the prolapsed loosen hemorrhoid tissue might need more bands ligated to induce adequate submucosal fibrosis which would make the prolapsed tissue fixed in rectum. Only minor complications occurred such as mild anal bleeding and pain, and only 5 patients required further surgical interventions. Two cirrhotic patients had experienced massive bleeding due to post-ligation ulcers but the bleeding was controlled with local injection of epinephrine solution. Because cirrhotic or uremia patients were risky for bleeding tendency, these patients were at a higher risk for operation, EHL provided an alternative therapy for hemorrhoids of these patients and the risk was low compared with operation. The greatest advantage of EHL is that it can be performed repeatedly if needed. Patients who failed in symptom control after their first EHL session treatment received further treatment sessions, and most patients had good results. After successful treatment, the one-year recurrent rate was 3.7% in bleeding group and 3.0% in prolapsed group and the five-year recurrent rate was 13.0% in bleeding group and 16.9% in prolapsed group.

In conclusion, endoscopic hemorrhoid ligation is an important progress in the treatment of symptomatic internal hemorrhoids. Endoscopic hemorrhoid ligation is simple, safe, and effective. Multiple bands can be applied in one session, and further bands can be applied in subsequent sessions if a single session fails to completely eradicate the internal hemorrhoids. The treatment success rate is high, and the long-term recurrence rate is low.

COMMENTS

Background
Previous studies showed a good result of endoscopic hemorrhoid ligation (EHL) in patients with symptomatic internal hemorrhoids at initial therapy and one year after treatment.

Research frontiers
The aim of this study was to further assess the long-term outcome and efficacy of EHL for treatment of symptomatic internal hemorrhoids.

Innovations and breakthroughs
Endoscopic hemorrhoid ligation is an important advance in the treatment of symptomatic internal hemorrhoids. Endoscopic hemorrhoid ligation is simple, safe, and effective. Multiple bands can be applied in one session, and further bands can be applied in subsequent sessions if a single session fails to completely eradicate the internal hemorrhoids. The treatment success rate is high, and the long-term recurrence rate is low.

Applications
EHL is an easy and well-tolerated procedure for the treatment of symptomatic internal hemorrhoids, with good long-term results.

Terminology
EHL means endoscopic hemorrhoidal ligation, which is a new device of rubber band ligation for the treatment of symptomatic internal hemorrhoids.

Peer review
This is a well written and comprehensive report characterizing a substantive cohort in endoscopic hemorrhoidal ligation for the treatment of symptomatic internal hemorrhoids.

Abstract

AIM: To evaluate the concomitant effects of appendectomy and oral tolerance on colitis.

METHODS: Delayed-type hypersensitivity (DTH) was investigated at a 7-d interval after ovalbumin (OVA) administration and immunization under normal and colitis conditions in appendectomized or sham-operated mice. Pathological scores for the colon were graded after ingestion of colon-extracted protein (CEP) and induction of dextran sulfate sodium (DSS) colitis in appendectomized or sham-operated mice. Thereafter, Th1 and Th2 in Peyer's patches and spleen lymphocytes were detected in CEP-treated and bovine serum albumin (BSA)-treated control mice.

RESULTS: In appendectomized mice, DTH was not inhibited at day 7 after OVA administration and at the initial phase of DSS colitis, whereas it was inhibited at day 14 and day 21. However, in sham-operated mice, it was inhibited during the whole procedure and the onset of DSS colitis. The protective role of CEP against DSS colitis was present in sham-operated mice, with predominant improvement of colonic pathological changes, while vanished in the appendectomized mice. A shift from Th1 to Th2 in Peyer's patches resulted from a decrease of Th1 cells with the ingestion of CEP. Compared with BSA in the sham-operated group, no predominant changes were observed in the appendectomized mice.

CONCLUSION: Appendectomy interferes with the protective role of CEP in DSS colitis via a shift from Th2 to Th1 during oral tolerance induction.

INTRODUCTION

Ulcerative colitis (UC) is one of the major inflammatory bowel diseases (IBDs), and is a chronic inflammatory disorder of the intestine. Multiple factors cause the initiation and pathogenesis of this disorder, including genetic polymorphisms, environmental factors, and immune responses[1]. Studies on mucosal immunological disturbance help greatly understand the course of UC, and establish better therapeutic strategies.

Oral tolerance is one of the major features in gut immunology, and refers to the active non-response to dietary antigens and commensal enteric bacteria or substances administered orally[2,3]. IBD results from environmental trigging agents that act on suspected hosts to cause uncontrolled immune reactions in the gut, and is considered to be a consequence of the breakdown of normal mucosal tolerance[4]. Oral tolerance has been confirmed to be a therapy for a variety of autoimmune diseases including IBD[5].

As a part of the intestine, the appendix has long been considered as a deteriorated organ, until epidemiological research revealed that patients who have had an appendectomy have a lower incidence of UC than those with an intact appendix[6]. Furthermore, appendectomy shows a protective effect on colitis in TCR-$\alpha^{-/-}$ mice and trinitrobenzene sulfonic acid (TNBS)-induced murine colitis[7-9]. These results suggest that appendectomy is a protective factor against UC[10].

Although appendectomy and oral tolerance have been shown to have a potential role in intestine immunology, the combined effect of appendectomy and oral tolerance in the normal gut immune environment and in colitis is still unclear. In this study, the combined effect of appendectomy and oral tolerance was evaluated in mice.

MATERIALS AND METHODS

Mice
Male BALB/c mice, 4-5 wk old, were purchased from Vital River (Beijing, China). Mice were kept under special pathogen-free conditions with free access to food and water, unless required by the experimental protocol. Every six mouse was allocated to the treatment or control group. The study protocol was approved by the Ethics Committee of Zhejiang University School of Medicine.

Reagents
Ovalbumin (OVA; chicken egg albumin, grade V), complete Freund's adjuvant (CFA), bovine serum albumin (BSA), phorbol myristate acetate (PMA) and ionomycin were purchased from Sigma-Aldrich (St Louis, MO, USA). Dextran sulfate sodium (DSS) was purchased from MP Biomedicals (USA). Antibodies including CD3ε, CD4, CD8α, CD69, interferon (IFN)-γ and interleukin (IL)-4, either conjugated with PE, FITC, PE-cy5 or APC, or their corresponding controls in flow cytometry were purchased from Becton Dickinson Biosciences (USA). RPMI 1640 was purchased from Invitrogen (USA) and Percoll from Amersham Bioscience (USA).

Surgical procedure
BALB/c mice were anesthetized with ketamine hydrochloride under sterile conditions. For all surgical interventions, mice underwent a standardized procedure, starting with a midline laparotomy, followed by mobilization and exteriorization of the appendix. In mice that were subjected to appendectomy, division of the appendix was performed between two ligatures that were placed proximal to the border of the cecum and appendix. The cecal stump was irrigated with saline. In all groups, the abdominal wall was closed in two layers, using a running suture technique. Mice were monitored during the immediate recovery phase after anesthesia, and were assessed daily throughout the recovery period of 1 wk.

Oral tolerance induction
Intragastric administration of 250 μg OVA or colon-extracted protein (CEP) for five times (both were controlled by BSA) was applied in each group, followed by subcutaneous injection of 200 μg OVA in 200 μL 50% CFA.

Delayed-type hypersensitivity and evaluation
For delayed-type hypersensitivity (DTH) test, all mice were injected subcutaneously in the right rear footpad with 25 μL physiological saline that contained 100 μg OVA. After 24 h, the increase in footpad thickness was measured using a helicocaliper, and controlled by the normal left footpad that was treated with the same volume of PBS[11].

Colitis induction and evaluation
DSS colitis was induced by feeding 5% (w/v) DSS diluted in water for 7 d, during which, disease activity index was calculated daily according to body weight, stool consistency, and the occult blood test[12]. Mice were all sacrificed 7 d after treatment with DSS for pathological examination of the descending colon and flow cytometric detection.

Microscopic examination of the colon was performed in a blinded fashion on formalin-fixed tissue sections that were stained with hematoxylin and eosin, as previously described[13]. The sections were classified as 0-3 to evaluate the amount and depth of inflammation, and 0-4 to evaluate the amount of crypt damage or regeneration. These pathological changes were also quantified as the percentage of involvement by the disease process: 1, 1%-25%; 2, 26%-50%; 3, 51%-75%; and 4, 76%-100%. Each section was then scored for each feature separately by establishing the product of the grade for that feature and the percentage involvement (0-12 for inflammation and extent, and 0-16 for regeneration and crypt damage).

CEP preparation
CEP was prepared as described previously[14]. The colon was sampled at 7 d after DSS treatment, minced on ice, and centrifuged for 20 min at 15 000 × *g*. Protein concentration was measured after supernatant collection and filtration for sterilization.

Experimental design and procedure
The experiment procedure is shown schematically in Figure 1. The combined effects of appendectomy and OVA-induced oral tolerance were tested under conditions of normal gut immune status and DSS colitis. Oral

Figure 1 Experimental design and procedure. OVA: Ovalbumin; BSA: Bovine serum albumin; DTH: Delayed-type hypersensitivity; DSS: Dextran sulfate sodium; *qod*: Every other day; *sc*: Subcutaneous injection; CEP: Colonextracted.protein

tolerance was produced in mice by repeated intragastric administration of OVA at day 7 after appendectomy or sham operation, followed by 200 g OVA injected subcutaneously on day 18. DTH assessment was performed on days 25, 32 and 39 (7, 14 and 21 d after OVA immunization). To observe the effect of appendectomy on OVA oral tolerance in colitis, on day 26, a group of mice was challenged with 5% DSS, and DTH assessment was performed at the beginning and end points.

To observe the combined effect of appendectomy and CEP on protection of colitis, another group of mice was challenged with 5% DSS on day 18, and pathological assessment and lymphocyte analysis were performed at the end points.

Cell preparation and cytokine analysis
For lymphocyte isolation of SPL and PPL[15], spleen or Peyer's patch was removed, minced, passed through a nylon strainer, and counted after staining with trypan blue. Th1 and Th2 cells were separated by IFN-γ and IL-4 staining. Lymphocytes were cultured at 37℃ for 6 h in medium that contained ionomycin (500 ng/mL), PMA (5 ng/mL) and GolgiStop.

Statistical analysis
All data are presented as mean ± SD. Paired *t* test was used throughout the experiment, except that the statistical significance of the pathological differences was evaluated by non-parametric Wilcoxon rank sum test. $P < 0.05$ was defined as statistical significance.

RESULTS

Appendectomy postponed oral tolerance response
To assess the establishment of oral tolerance and verify the role of appendectomy, both the appendectomized and the sham-operated mice were injected subcutaneously with 200 g OVA. DTH was scored by measuring the thickness of the footpad at days 7, 14 and 21 after OVA injection (Figure 2).

Compared with the BSA-treated mice, the footpad thickness in the OVA-treated mice increased less significantly at days 14 and 21 in the appendectomized and sham-operated mice. However, on day 7, there was no difference in footpad thickness between the OVA- and BSA-treated appendectomized mice, but there was an obvious difference in the sham-operated mice. This suggests that appendectomy postponed the oral tolerance response.

Appendectomy suppressed oral tolerance in DSS-induced colitis
To evaluate whether appendectomy had an impact on oral tolerance in DSS-induced colitis, appendectomized and sham-operated mice were treated with 5% DSS at day 26 after OVA or BSA ingestion and OVA injection. The immune response was assessed by DTH at days 1 and 7 after DSS treatment (Figure 3).

In the appendectomized mice, DTH assessment showed no difference between OVA and BSA ingestion. In the group of sham-operated mice, although the OVA-ingested mice showed slighter immunoresponse than that of BSA-ingested mice on the first day, we could not observe the difference of immunoresponse between OVA- and BSA-ingested mice group. This was consistent with previous results and suggested that appendectomy did not enhance the oral tolerance protection in colitis. Furthermore, OVA treatment showed no protective effect against colitis both in the appendectomized and the sham-operated mice after 7 d, and the index of footpad thickness showed no significant difference. Taken together, these results suggested that OVA-induced oral tolerance was only present in sham-operated mice, and appendectomy suppressed oral tolerance in DSS-induced colitis.

Appendectomy eliminated the protective role of CEP against DSS colitis
It is possible that the non-protection of OVA-induced oral tolerance to DSS colitis resulted from the fact that OVA is not a specific oral tolerance antigen to DSS colitis. Therefore, we replaced OVA with CEP in the appendectomized and the sham-operated mice on day 8. After repeated intragastric administration of CEP or BSA, for five times on day 10, the mice were challenged with 5% DSS. Murine DSS colitis was characterized by destruction of the basic structure of colonic villi and almost total cast of epithelium, with the disappearance of crypts and massive infiltration of lymphocytes. In the appendectomized mice, CEP- and BSA-treated groups showed similar histological features, with massive lymphocytes infiltration, loss of goblet cells, crypt damage, mucosal ulceration, and accompanying submucosal edema (Figures 4 and 5). In the sham-operated mice, the CEP-treated group showed less amelioration of colonic inflammation compared with the BSA-treated control group. Pathological score showed that, in sham-operated mice, ingestion of CEP resulted in mild pathological changes in the descending colon, with a significantly lower

Figure 2 Delayed-type hypersensitivity was scored at days 7, 14 and 21 after ovalbumin injection in appendectomized and sham-operated mice. [a]$P < 0.05$ *vs* bovine serum albumin (BSA) control mice in appendectomized or sham-operated groups. OVA: Ovalbumin.

[a]$P < 0.05$ *vs* bovine serum albumin (BSA) control mice in sham-operated group. DSS: Dextran sulfate sodium; OVA: Ovalbumin.

Figure 4 Histological findings in colon-extracted protein- or bovine serum albumin-treated mice in appendectomized (A and B) and sham-operated (C and D) groups. In the appendectomy group, there were similar histological features, massive lymphocyte infiltration, loss of goblet cells, crypt damage, mucosal ulceration, and accompanying submucosal edema, whereas in sham-operated mice, there was less amelioration of colonic inflammation. CEP: Colon-extracted protein; BSA: Bovine serum albumin.

Figure 5 Blinded histological assessment of colitis at day 7 after treatment with 5% dextran sulfate sodium in appendectomized and sham-operated mice with colon-extracted protein or bovine serum albumin ingestion, based on the validated scoring system. [a]$P < 0.05$ *vs* bovine serum albumin (BSA)-treated mice in sham-operated group. CEP: Colon-extracted protein.

pathological score compared with the BSA controls. However, in the appendectomized mice, no significant difference was observed between the CEP- and BSA-treated groups. Our results suggested that appendectomy eliminated the protective role of CEP against DSS colitis.

Inhibition of the protective role of CEP against DSS colitis by appendectomy was associated with Th1/Th2 in PPL

We investigated the possible role of Th1 and Th2 in the difference of CEP protection against DSS colitis between the appendectomized the sham-operated mice (Figures 6

and 7). Th1 and Th2 of PPL and SPL were isolated at the end of colitis and stained with antibodies to IFN-γ and IL-4. The ratio of Th1/Th2 in SPL showed no significant difference between appendectomized and sham-operated mice. However, in PPL, Th1 decreased predominantly after ingestion of CEP in the sham-operated mice compared with BSA control mice, which resulted in the same trend change in Th1/Th2 ratio. Meanwhile, this situation was not observed in Th2 cells. With regard to the appendectomized mice, the number of Th1 and Th2 and their ratio did not change significantly.

Figure 6 Th1, Th2 and the ratio of Th1/Th2 in spleen lymphocytes at day 7 after treatment with 5% dextran sulfate sodium in appendectomized and sham-operated mice with colon-extracted protein or bovine serum albumin ingestion. CEP: Colon-extracted protein; BSA: Bovine serum albumin.

Figure 7 Th1, Th2 and the ratio of Th1/Th2 in Peyer's patch lymphocytes at day 7 after treatment with 5% dextran sulfate sodium in appendectomized and sham-operated mice with colon-extracted protein or bovine serum albumin ingestion. [a]$P < 0.05$ *vs* bovine serum albumin (BSA)-treated mice in the sham-operated group. CEP: Colon-extracted protein.

DISCUSSION

UC is a chronic relapsing inflammatory disorder of the large intestine. Results from experimental and clinical studies have indicated that there are multifactors in initiation and pathogenesis of this disorder, involving interactions among genetic, environmental, and immune factors[16]. Studies on mucosal immunological disturbance help greatly to understand the course of UC and might be useful to establish better therapeutic strategies. Among the immunotherapeutic options for UC, there are two phenomena that differ from other anti-cytokine strategies. One is the relationship between appendectomy and UC, and the other is the application of oral tolerance.

Appendicular lymphoid tissue, together with Peyer's patches, intestinal intraepithelial and lamina propria lymphocytes, and mesenteric lymph nodes, has been considered as one component of the gut-associated lymphatic tissue (GALT). Several studies have suggested an inverse association between appendectomy and UC[17,18]. UC with prior appendectomy is associated with a milder disease, as defined by the lesser requirement for immuno-suppression or colectomy for severe colitis[19]. A meta-analysis has reported a strong and consistent inverse association between appendectomy and the development of UC[20]. Further support for the involvement of the appendix in IBD is provided by the observation that appendectomy prevents the development of spontaneous experimental colitis in T-cell receptor α mutant mice[7]. However, things seem to be more complicated in humans. Histopathological findings that show the skip lesion of inflammation in the appendix in UC patients suggest that inflammation at one site in the large intestine of predisposed individuals might trigger UC at distant sites. Okazaki *et al*[21] have reported a case with a positive response of UC to appendectomy, with improved colonoscopic and microscopic findings. Several studies have shown inadequate and obscure effects on UC, including a cohort study in Denmark that has proved that appendectomy has no beneficial effect on admission rates in patients with UC[22]. If we disregard those studies with poor or inadequately described methods, the evidence still supports an inverse association between appendectomy, particularly at a young age, and later risk of UC[17]. All the problems might come from the fact that the specific immunological changes after appendectomy remain poorly defined.

Oral tolerance is one of the main features in GALT. It can be described as a state of specific immunological unresponsiveness to antigens that are capable of inducing a protective or injurious immune response under other circumstances. Neurath *et al*[23] have reported that induction of oral tolerance could be beneficial to mural TNBS colitis, *via* the mediation of transforming growth factor β, suppressor lymphocytes, or suppression of humoral immunity[24,25]. Kraus *et al*[26] have confirmed a defect in oral tolerance in patients with IBD, with keyhole limpet hemocyanin, which implies that disturbance of gut tolerance is present in IBD. Good results have been obtained from a double-blind clinical trial for the treatment of Crohn's disease by oral administration of Alequel, a mixture of autologous CEP, although the patients included might not be sufficient to achieve statistically significant results, but they still showed a good tendency[27].

Thus, appendectomy and oral tolerance were both involved in the disturbance of gut immunity in IBD. Their relationship and corresponding mechanism has not been clearly defined. Our study assessed the contribution of the appendix during oral tolerance induction by OVA in the normal or inflammatory gut environment. Our results clearly demonstrated that appendectomy postponed the occurrence of oral tolerance under normal and inflammatory conditions. At the same time, the protective role of CEP against mural DSS colitis could be inhibited when appendectomy was performed.

Concerning the effect of appendectomy on the traditional oral tolerance model induced by OVA feeding, our data from the normal gut immune status are in agreement with those from DSS colitis. The appendiceal lymphoid tissue is predominantly composed of CD4+ T-helper cells and B lymphocytes. Although the exact function of the appendix is undetermined, it is potentially involved in antigen sampling from the gut lumen and induces mucosal immunological responses as a part of the GALT, together with Peyer's patches. Therefore, it is possible that the suppressive effect on oral tolerance is transient in normal mice, as indicated by the fact that DTH reactions were re-inhibited after 2-3 wk in the appendectomized mice. At the onset of DSS colitis, the inhibition of oral tolerance is still predominant, with no significant inhibition of DTH reaction in the appendectomized mice. No difference was noticed at the end of colitis in IBD, because no inhibition of DTH with the defect in oral tolerance was observed[26]. Clearly, the appendix is involved in oral tolerance, at least at the early inductive stage, but to maintain oral tolerance, it seems not to be as important as Peyer's patches, which have a similar histological composition and may have compensatory effects.

For the clinical application of oral tolerance in IBD, the effectiveness of oral administration of CEP has been demonstrated in a series of rodent experiments[14,28,29]. TNBS colitis, which features Th1 oversensitivity, is the main model involved in the proof of protection from oral tolerance. The fact that it functions well in DSS colitis implies that oral tolerance could be an innovative strategy for immunotherapy of IBD. While as the appendix may be involved, the protective role of oral tolerance could be indistinctive in the appendectomized mice which shows the possibility of limited application in patients with appendix removed. Therefore, if oral tolerance is to work effectively, whether the appendix remains intact should be confirmed, as well as the dose to ensure a better response. Although we demonstrated the correlation between appendectomy and oral tolerance in UC, the mechanisms that mediate the protection afforded by appendectomy or oral tolerance, and their relationship, are still under investigation.

Mucosal immune dysfunction has been frequently proposed as a key factor in the development of IBD. Studies in animals or humans with IBD imply an abnor-

mal intestinal mucosal barrier function, overproduction of Th1 or Th2 cytokines, and uncontrolled activation of CD4[+] T cells by components of colonic bacteria as contributing factors to the pathogenesis of UC[30]. The Th1/Th2 paradigm has been shown to be crucial for oral tolerance to maintain the immune homeostasis in the gut, and at the same time, its disequilibrium correlates with occurrence of IBD[31,32]. Another strong proof of the participation of the Th1/Th2 paradigm in IBD is a series of studies on the effect of worm infection, which can induce a predominant Th2 immune response. Epidemiological research has demonstrated a high prevalence rate of IBD and low worm infection rate in developed countries, while the opposite results have been obtained in developing countries[33]. Worm infection can even be therapeutic for colitis in IL-10 knockout mice or TNBS colitis with a deviation in the Th1/Th2 balance[34,35]. The question remains whether Th1/Th2 is involved in the effect of the appendix on oral tolerance induced by CEP administration in DSS colitis.

A variety of experimental models, including the DSS model, have been developed to investigate mechanisms involved in the pathogenesis of IBD[36]. Oral administration of DSS to mice can cause acute or chronic colitis with similar histopathology as human UC, and has proven to be valuable for the assessment of cause and effect relationships between specific treatment and colitis. However, the specific pathogenic mechanisms that underlie DSS colitis remain elusive. DSS-mediated colonic injury is thought to result from mucosal damage, followed by the upregulation of Th1 and Th2 cytokines, as well as other pro-inflammatory mediators[37]. We investigated the Th1/Th2 ratio and the secretion of IFN-γ and IL-4 from SPL and PPL in appendectomized or control mice after CEP ingestion and DSS colitis. The deviation from Th1 to Th2 disappeared, together with improvement of colonic pathology in PPL caused by CEP induction in the appendectomized mice, whereas in sham-operated mice, there was a predominant Th1 to Th2 deviation that resulted from Th1 inhibition caused by CEP ingestion compared with BSA. This implies a crucial role for the appendix in the development of mucosal oral tolerance, and this could be via the deviation of Th1/Th2 in PPL. With regard to the complexity of the immune network in GALT, our results suggest that the appendix is involved in the initial phase of the immune response, which is complied with the histologic composition. The continued changes remain to be further investigated.

In summary, the appendix gives us an approach to investigate gastrointestinal immunology. We studied the effect of appendectomy on CEP-induced tolerance to DSS colitis and its relationship with the Th1/Th2 paradigm. Our results imply that the appendix plays a role in maintenance of oral tolerance induced by CEP in DSS colitis, and this function could be related to the deviation from Th1 to Th2 in PPL. These results provide a new insight into the pathogenesis of IBD, and perhaps more efficient use of appendectomy or oral tolerance as a therapeutic tool.

COMMENTS

Background
Oral tolerance refers to the active non-response to dietary antigens and commensal enteric bacteria or substances administered orally. Inflammatory bowel disease (IBD) results from environmental trigging agents acting on suspected hosts to cause uncontrolled immune reactions in the gut. Oral tolerance has been validated to be therapeutic in a variety of autoimmune diseases including IBD. Appendectomy showed a protective effect against colitis. However, the combined effect of appendectomy and oral tolerance in the normal gut immune environment and colitis is still unclear.

Research frontiers
Studies on mucosal immunology disturbance help greatly to understand the course of ulcerative colitis, and may be useful to establish better therapeutic strategies.

Innovations and breakthroughs
The combined effect of appendectomy and oral tolerance was evaluated by challenge in dextran sulfate sodium (DSS) colitis with oral tolerance induction, with or without appendectomy.

Applications
The result is novel and offers great potential for understanding the role of the appendix in the maintenance of immune homeostasis during oral tolerance in the gut. Appendectomy interferes with the protective role of colonic extracted protein against DSS colitis, *via* a shift from Th2 to Th1 during oral tolerance induction. The appendix might play a role in the maintenance of immune homeostasis during oral tolerance in the gut.

Terminology
Oral tolerance: oral tolerance is one of the major features in gut immunology, and refers to the active non-response to dietary antigens and commensal enteric bacteria or substances administered orally. It has been confirmed to be a therapy for a variety of autoimmune diseases including IBD.

Peer review
This study investigated the effect of appendectomy on oral tolerance protection against DSS-induced murine colitis. The results are novel and offer great potential for understanding the role of the appendix in the maintenance of immune homeostasis during oral tolerance in the gut. The study was performed in a detailed and convincing manner. The results are interesting.

Abstract

Small bowel tumors and Crohn's disease are common causes of small bowel obstruction. Early stage neoplasms can easily be mistaken for Crohn's disease. Therefore, thorough work-ups including imaging studies and endoscopic evaluation with biopsies are critical for accurate diagnosis. Here we report a case of an otherwise healthy female with progressive onset of multiple, recurrent obstructive symptoms secondary to terminal ileal narrowing who was referred for management of steroid-dependent Crohn's disease. After thorough evaluation, the diagnosis was revised to myeloid granulocytic sarcoma involving the terminal ileum. In this case, a delay in diagnosis can be detrimental for prognosis, as myeloid granulocytic sarcoma is highly predictive of underlying acute myeloid leukemia and needs urgent referral for chemotherapy and/or resection.

INTRODUCTION

Small bowel tumors are uncommon and represent 1%-2% of all gastrointestinal (GI) neoplasms[1-3]. The most common locations are in order: (1) ileum; (2) duodenum; and (3) jejunum. Two large population studies reviewing small intestinal cancers reported the most common histologic types and respective subtypes were: (1) neuroendocrine (39%)/carcinoid (90%); (2) carcinoma (31%)/adenocarcinoma (69%); (3) lymphoma (18%)/large B cell (50%); and (4) sarcoma (10%)/GI stromal tumor (57%)[4,5]. Myeloid sarcoma of the small intestine is unique and rare, with only 3 of 10 945 cases reported in a recent SEER (Surveillance, Epidemiology and End Results) population study[5]. Patients often present with abdominal pain, obstruction, GI bleeding, or an abdominal mass. For patients with underlying Crohn's disease, these symptoms can often mimic an active flare. Here we report a case of a steroid-dependent patient who was referred to our tertiary disease center. After endoscopy and workup, a rare case of myeloid granulocytic sarcoma of the ileum was diagnosed in an otherwise healthy, non-leukemic patient.

Figure 2 Colonoscopy image of erythematous, ulcerated, lumpy mucosa of the terminal ileum.

CASE REPORT

A 39-year-old female with no significant past medical history, presented with a 5-mo history of nausea, vomiting, non-bloody water diarrhea, and right lower quadrant crampy abdominal pain, resulting in multiple, recurrent small bowel obstructions. Her initial hospitalization and diagnostic workup gave a preliminary diagnosis of Crohn's disease based on computerized tomography (CT) findings of a thick walled terminal ileum. She responded immediately to bowel rest and steroid therapy, and was then discharged home on a 6-wk taper regimen, and started on mesalamine (Pentasa) 4 g/d. However, she had recurrent obstructive symptoms when weaned below 10 mg prednisone daily resulting in another Emergency Department visit and a repeat course of oral prednisone. In the subsequent 2 mo, she was hospitalized twice more for recurrent small bowel obstruction, each time after attempts to wean off oral steroid therapy. She remained steroid-dependent despite mesalamine (Pentasa) 4 g/d and a trial of budesonide 9 mg/d. Previous NSAID use was limited to one regular strength ibuprofen per day for menstrual cramps. She associated symptoms of nausea, vomiting, bloating, and oral ulcers with increased stress.

Laboratory tests were unremarkable including inflammatory markers (erythrocyte sedimentation rate 9, C-reactive protein < 0.07) and inflammatory bowel disease (IBD)-7 serology panel, ASCA (anti-*S. cerevisiae* antibody) IgA < 12 EU/mL, ASCA IgG < 12 EU/mL, anti-OMPC (outer membrane protein C of *E. Coli*) IgA 3.9 EU/mL, anti-CBir1 3.8, and pANCA (perinuclear anti-neutrophil cyto-

plasmic antibody) < 12.1. Initial colonoscopy and ileoscopy were unremarkable with normal biopsies. Wireless capsule enteroscopy showed inflammation in the proximal ileum.

The patient was referred to our IBD center for management of steroid-dependent Crohn's disease. We reviewed her wireless capsule study and noted additional findings that included ulcerated lumpy mucosa from the distal jejunum to proximal ileum (Figure 1), suggestive of neoplastic changes. Colonoscopy using a pediatric colonoscope showed normal colonic mucosa and ileocecal valve, but there was erythematous, ulcerated, lumpy mucosa for at least 20 cm into the terminal ileum (Figure 2). We could not advance the pediatric colonoscope further due to ileal narrowing. Ileal biopsies showed an extramedullary myeloid cell tumor (granulocytic sarcoma) with immunologic characterization consistent with myeloid lineage (myeloperoxidase positive) with co-expression of CD34, lysozyme, CD15 and CD68. Biopsies were negative for B-cell markers (CD20, CD79a, PAX-5) and T-cell markers (CD2, CD3, CD4, CD5, CD7, and CD8) (Figure 3). Other work-ups included positron emission tomography/CT that showed increased activity of the thickened bowel in the mid-anterior right quadrant, normal bone marrow aspirate, normal peripheral blood smear and flow cytometry, and fluorescent *in situ* hybridization (FISH) cytogenetics were negative for inv(16) and t(8;21) gene fusion. She underwent standard chemotherapy for acute myeloid leukemia (AML) followed by resection of the ileum and is currently disease free for 2 years.

DISCUSSION

Clinical presentation of a small bowel neoplasm can be nonspecific and often mimics active Crohn's disease. Here we demonstrate a case of a presumed Crohn's flare concealing an underlying small bowel malignancy. We also report a rare case of a sporadic isolated extramedullary myeloid cell tumor of the terminal ileum.

Myeloid sarcoma occurs in about 2 per 1 000 000 adults and 0.7 per 1 000 000 children[6]. Myeloid granulocytic sarcoma can present as an isolated tumor (67%) or as multiple lesions involving a variety of anatomic locations: skin, bone/spine, lymph nodes[7,8]. The GI tract was reported to

Figure 3 Biopsies from the terminal ileum showing extramedullary myeloid cell tumor (granulocytic sarcoma). A: 40 x magnification; B: 200 x magnification; C: 400 x magnification.

be involved in 4 of 61 (7%) cases[9] with the small intestine being the most frequent site (10%-11%)[7,9]. In a series of 20 cases of granulocytic sarcoma of the small intestine, 17 were localized; 11 of 17 involved the ileum, 12 were in non-leukemic patients, and one occurred during a myeloid leukemia blast crisis. Eight of 12 aleukemic cases progressed to AML within a mean of 10.8 mo[8]. Another report found 90% of aleukemic patients with granulocytic sarcoma progressed to AML within 10.5-11 mo[10].

Isolated myeloid infiltrative small bowel tumors are often mistaken for non-Hodgkin lymphoma or diffuse large B cell lymphoma[11]. Other considerations which must be ruled out include lymphoproliferative disorders and poorly differentiated carcinoma in adults, and melanoma, neuroblastoma, rhabdosarcoma, Ewing sarcoma, and medulloblastoma, in children[12]. Thus, accurate diagnosis of granulocytic sarcoma by histochemical and immunoperoxidase staining, cytogenetic, FISH, or flow cytometry is critical[8].

Cytogenetic abnormalities often reported in aleukemic cases of isolated GI tract granulocytic sarcoma are inversion of p16 and/or t(8; 21) fusion gene[8]. Here we report a case of isolated granulocytic sarcoma of the ileum in an aleukemic patient without inv(16) or t(8; 21) and with no clinical manifestations of a leukemic disorder at diagnosis.

New diagnosis of granulocytic sarcoma in a non-leukemic patient often predicts onset of AML and a potential blast crisis within 1 year. In a case series, 4 of 7 sporadic intestinal granulocytic sarcoma developed AML within an average of 8 mo (range, 4-21 mo)[13]. Another report found a median time of 9 mo for isolated granulocytic sarcoma to develop AML with median survival of 22 mo[14].

The prognosis of isolated myeloid sarcoma is vari-

able but is better if diagnosed early[8,15,16]. The prognosis is poor once there is infiltration of the GI tract with leukemic cells[17]. Systemic chemotherapy, especially AML type induction chemotherapy can delay the time to develop AML and prolong the survival period[7,9,14,18,19]. Yamauchi *et al*[7] showed a longer non-leukemic period after diagnosis of granulocytic sarcoma (median 12 mo) in patients treated with systemic chemotherapy (median 3-6 mo). In a series of 74 cases of primary granulocytic sarcoma without transformation to AML within 1 mo of diagnosis, 58% who received chemotherapy were disease-free for up to 11 mo, and 19% for up to 2 years compared with 5% who did not receive chemotherapy[8]. Surgical intervention or radiotherapy has not been proven to influence survival but may be indicated for symptomatic complications of tumors such as obstruction or perforation[14]. Nevertheless, a management plan with the goal of complete eradication and remission of leukemia and its respective potential needs to be made on an individualized basis.

In summary, intestinal granulocytic sarcoma is rare but should be part of the differential diagnosis for any sporadic small bowel mass of unknown origin, especially in the non-leukemic patient. An early and accurate diagnosis predicts the best outcome and survival. Granulocytic sarcoma is often a precursor to a diagnosis of AML needing urgent systemic chemotherapy and/or any combination of surgical resection, radiotherapy, or stem cell transplantation. Incomplete workup and presumptive diagnosis of Crohn's disease for the initial manifestation of an ileal narrowing or obstruction can easily delay the diagnosis of malignant neoplasms which require urgent intervention and treatment.

Abstract

The therapeutic options for hepatocellular carcinoma (HCC) have been so far rather inadequate. Sorafenib has shown an overall survival benefit and has become the new standard of care for advanced HCC. Nevertheless, in clinical practice, some patients are discontinuing this drug because of side effects, and misinterpretation of radiographic response may contribute to this. We highlight the importance of prolonged sorafenib administration, even at reduced dose, and of qualitative and careful radiographic evaluation. We observed two partial and two complete responses, one histologically confirmed, with progression-free survival ranging from 12 to 62 mo. Three of the responses were achieved following substantial dose reductions, and a gradual change in lesion density preceded or paralleled tumor shrinkage, as seen by computed tomography. This report supports the feasibility of dose adjustments to allow prolonged administration of sorafenib, and highlights the need for new imaging criteria for a more appropriate characterization of response in HCC.

INTRODUCTION

Therapeutic options for advanced hepatocellular carcinoma (HCC) have been so far inadequate[1-5]. Recent progress in molecular biology has allowed identification of new therapeutic targets, including vascular endothelial growth factor (VEGF), which is overexpressed and related to progression-free survival (PFS) and overall survival (OS) in HCC[6,7]. Sorafenib, an oral multi-kinase inhibitor, blocks tumor cell proliferation and angiogenesis by

targeting RAF, VEGF receptors, platelet-derived growth factor receptor β, c-KIT and FLT3 signaling pathways[8].

Efficacy and safety of sorafenib have been demonstrated by phase Ⅱ/Ⅲ trials, which have proven that 400 mg bid sorafenib significantly prolongs OS, reduces the risk of death by 31%, and increases the time to radiological progression[9-11]. Consequently, sorafenib has become the standard of care for patients with advanced HCC.

We present four cases of unresectable, systemic-treatment-naïve HCC, enrolled in phase Ⅱ (HOPE) and Ⅲ (SHARP) trials at the Department of Medical Oncology and Hematology of the Istituto Clinico Humanitas in Rozzano (Milan, Italy), who obtained long-lasting objective responses. All patients were diagnosed by histology and computed tomography (CT) or magnetic resonance imaging (MRI). Their peculiar responses and the personalized management of side effects provide suggestions to optimize the use of sorafenib in the management of HCC patients.

CASE REPORT

Patient 1

In December 2002, a 61-year-old caucasian man was examined by MRI, which showed a single 110 mm × 140 mm hepatic lesion and thrombosis of the main and right branches of the portal and superior mesenteric veins. The patient was Child-Pugh class A, Eastern Cooperative Oncology Group (ECOG) performance status (PS) 0, with α fetoprotein (AFP) of 10 ng/mL. Sorafenib treatment was started in January 2003. In February 2003, grade 2 diarrhea was controlled with loperamide. In April 2003, the lesion measured 70 mm × 66 mm; grade 3 diarrhea appeared and resolved in July 2003, after a 3-d pause from sorafenib and daily loperamide. In December 2003, persistent grade 2/3 diarrhea reappeared, and resolved after a 50% reduction in sorafenib dose. In January 2004, treatment was discontinued due to progressive disease: a new lesion appeared at the edge of the previous one. From March 2003 to January 2004, AFP values progressively increased from 20 to 218 ng/mL. The patient achieved a 70% objective response according to World Health Organization (WHO) criteria, and 12 mo PFS. The patient died in June 2005.

Patient 2

A 63-year-old caucasian man was diagnosed with hepatitis B and C virus-related cirrhosis in 1983, and with HCC in November 2002. In February 2003, at baseline, a 20 mm × 25 mm lesion in hepatic segment Ⅳ and a non-clearly definable lesion in segment Ⅱ were visible. Gynecomastia, moderate thrombosis and erythema were managed, since March 2003, with periodical treatment pauses. In September 2003, sorafenib dose was reduced by 50% (400 mg/d) due to persistent grade 2 diarrhea. A minor response was detected in May 2004, and the lesion in segment Ⅳ reduced to 15 mm × 15 mm (55%) in July 2004; the lesion in segment Ⅱ lost density and became undetectable on subsequent scans. In August 2005, after 30 mo on therapy, HCC disease progression was observed as an increase in the number of tumor lesions and an increase in the diameter of existing lesions. We observed progression in the liver and not at other sites. Thereafter, the patient was lost to follow-up and died in April 2008.

Patient 3

A 70-year-old caucasian man with hepatitis C virus (HCV)-related cirrhosis, with a good PS, was diagnosed in July 2002 with vascular-invading HCC. In January 2003, at baseline, a single hepatic lesion measured 60 mm × 50 mm and AFP was 15 ng/mL. In June 2003, a 50% reduction in sorafenib dose was required due to paresthesia and cramps in the hands and feet. From July to November 2003, the lesion gradually reached 35 mm × 35 mm. At that time, the area originally covered by the lesion ranged from a denser portion, which surrounded the persistent tumor, to a less dense area, towards the normal liver. In October 2004, the lesion was barely visible. In October 2005, a complete response was achieved. AFP slightly decreased throughout the study, stabilizing at 12 ng/mL. In January 2008, after PFS of 60 mo, a new 10-mm lesion was detected in segment Ⅷ, outside the area previously involved. The patient was treated with two chemoembolizations and he is in complete response as of July 2010.

Patient 4

A 69-year-old caucasian man who had HCV-related cirrhosis since 1987 was diagnosed with HCC in May 2005. At baseline, in June 2005, the patient presented with three hepatic lesions, thrombosis of the portal vein main branch, Child-Pugh class A and ECOG PS 0. After 10 d on sorafenib, treatment was stopped for 1 mo due to grade 3 hand-foot skin reaction, and restarted at 50% of the dose. In September 2005, a partial response was observed, and the density of the only remaining lesion was reduced. In October 2005, the treatment was paused for 9 d due to grade 3 hand-foot skin reaction. At resolution, treatment was restarted at a dose of 400 mg every other day. In May 2007, the lesion was radiographically unchanged, was biopsied and proven disease free. As of July 2010, 62 mo from enrollment, the patient, still on the reduced dose regimen, maintains a complete response (Figure 1).

DISCUSSION

Sorafenib is the only effective systemic therapy for the treatment of HCC, but side effects lead to treatment discontinuation in some patients. Nowadays, HCC is treated by hepatologists or oncologists. The former may be less accustomed to the typical side effects of anticancer drugs, and the latter may not be keen to manage problems related to underlying liver cirrhosis. This report proves the importance of a multidisciplinary approach in the management of advanced HCC patients.

The described cases highlight how, in case of sorafenib-related side effects, reductions and pauses in the admin-

Figure 1 Patient 4 - arterial phase computed tomography scans. A: Pre-sorafenib, the 25-mm lesion in segment Ⅷ was biopsied, and measured > 100 HU. B: Partial response, tumor necrosis and intra-lesional HU of 40-70 after 4 mo on sorafenib. C: After 40 mo on sorafenib, the necrotic area measured < 40 HU intra-lesionally, and was disease-free at histological examination. The arrows show the liver lesion.

istered dose can allow long-term treatments. Efficacy of conventional cytotoxic agents is strictly related to the administered dose. With new targeted agents, length of treatment, rather than dose intensity, may be fundamental for tumor control. The winning strategy may lie in managing side effects, and tailoring the anticancer regimen to the characteristics of the patients, rather than discontinuing treatment at the appearance of signs of intolerance. Unfortunately, data on drug blood levels that are needed to achieve and maintain target inhibition are inadequate. The multi-target nature of sorafenib is one additional challenge, which means that various factors play a role in the activity of this agent[6-8].

In three of the four reported cases, objective responses were achieved following substantial dose reductions. In patient 2, partial response was observed at month 16 of the study (7 mo at full dose and 9 at half dose). In patient 3, sorafenib dose was reduced by 50% during the month 6 on treatment; an objective response was seen in month 8 of therapy, and a complete response was achieved after a total of 34 mo on study. In patient 4, sorafenib dose was reduced by 50% after just 10 d of therapy, and 20 d later, a partial response was observed. One month later, dose was further reduced to 25%, and complete response was documented after 24 mo on study. The lesson appears clear: the recommended sorafenib dose is 400 mg bid; when needed, dose reductions, by limiting side effects, offer a better quality of life and can allow long-term administration and achievement/maintenance of tumor control.

The radiological features of responding lesions are another issue worthy of attention. When assessing the efficacy of targeted therapies by imaging, a gradual change in tumor density and blood flow may be observed before tumor shrinkage. However, the uncommon radiological patterns can lead to late recognition of responses, or worse, to misleading evaluations. Indeed, in two of the reported cases (patients 3 and 4), lesions seemed unchanged and, at first sight, had been considered active. On the contrary, these lesions were responding and being substituted by residual scars (in patient 4, this was confirmed by liver biopsy). This issue deserves serious con-

sideration and calls for new, more appropriate methods of appraisal. With targeted therapies, traditional methods of quantitative evaluation, such as WHO criteria or Response Evaluation Criteria in Solid Tumors, may not be optimal, and the need for qualitative standardized measurements becomes more pressing[9,12-14]. Although positron emission tomography is not reliable for evaluation of HCC, Hounsfield unit (HU) density scale for CT scan imaging, and signal patterns for MRI can be used to measure tumor necrosis. Combination of these methods with dimensional measurements allows more precise characterization of sorafenib responses in this disease[13,14]. In our experience, a lesion density reduction to 40 HU on CT scan can be considered indicative of tumor necrosis.

An additional mean of response evaluation may be provided by analysis of blood samples. At present, there is no agreement on specific biomarkers of response to sorafenib. We analyzed routine laboratory tests and did not identify any correlation in our patients, however, we did not search for alternative signals such as markers of inflammation and oxidative stress. The recommendations that derive from the reported cases are to tailor dose and schedule, to administer the drug until progressive disease is observed, and to evaluate critically dimensional and density changes in tumor lesions. Anticancer drugs have evolved in recent years, and so should the way physicians view tumor treatment strategies. Although this calls for more personalized treatment plans, agreement on standardized and more appropriate assessment techniques will allow more conscious decision making in the treatment of advanced HCC patients[13,14].

Abstract

Glucocorticosteroids have been used as the only treatment for a long time which significantly reduced the mortality of the patients with severe alcoholic hepatitis. The efficacy of transplantation has been recently addressed in a pilot study. The result seems promising but needs larger multicenter trials.

TO THE EDITOR

Amini and Runyon conclude that "the routine use of glucocorticoids for severe alcoholic hepatitis (SAH) poses significant risk with equivocal benefit"[1]. They refer to a 2008 Cochrane review but did not cite the authors' results that "Glucocorticosteroids significantly reduced the mortality of the patients with Maddrey's score of at least 32 or hepatic encephalopathy and with low-bias risk in a group of trials".

They also did not cite a recent review in a major journal which concluded that "Five patients need to be treated with corticosteroids to prevent one death"[2]. A more recent meta-analysis of individual patient data (221 allocated to corticosteroids *vs* 197 controls) confirms that corticosteroids significantly improve the 28-d survival in patients with SAH[3].

The conclusion "Histologic diagnosis of alcoholic hepatitis rules out the possibility of liver transplantation" is exaggerated according to the current literature. A teenager who develops liver failure after a deliberate overdose of paracetamol, or after contracting hepatitis B through irresponsible behaviour, has open access to liver transplantation[4]. Alcoholic patients must not be discriminated: after the transplantation, appropriate support measures must be taken with the alcohol services in the patient's locality. The efficacy of transplantation has been addressed in a study of 18 patients with SAH. Non-responders to steroids were identified by a Lille score: the 6-mo survival was 83% (compared with 44% in case-matched control) and none of the patients relapsed in the first year[5]. The result seems promising but needs larger multicenter trials.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUC-

TIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself.

File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. [a]$P < 0.05$, [b]$P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, [c]$P < 0.05$ and [d]$P < 0.01$ are used. A third series of P values can be expressed as [e]$P < 0.05$ and [f]$P < 0.01$. Other notes in tables or under illustrations should be expressed as [1]F, [2]F, [3]F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Fax: +86-10-85381893

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ABOUT COVER

Aziz-Seible RS, Casey CA. Fibronectin: Functional character and role in alcoholic liver disease.
World J Gastroenterol 2011; 17(20): 2482-2499
http://www.wjgnet.com/1007-9327/full/v17/i20/2482.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

An annual topic highlight: Alcohol and Liver, 2011, covers the important and new aspects of pathogenesis of alcoholic liver diseases (ALD). It includes broad topics ranging from the exacerbation of ALD by infectious (viral) agents (hepatitis C virus and human immunodeficiency virus) to the influence of alcohol on liver fibrogenesis, lipid rafts, autophagy and other aspects. This issue is recommended for both basic scientists and clinicians who are involved in alcoholic liver research.

Key words: Liver; Alcohol; Autophagy; Fibrogenesis; Immune cells; Lipid rafts; Mouse models; Hepatitis C; Human immunodeficiency virus

This annual topic highlight is the fourth issue of reviews devoted to alcoholic liver diseases (ALD) pathogenesis and treatment. It is one of the most respectful annual series of reviews in alcohol research, and now it has an established audience as well as the contributing authors, who are the leading specialists in alcohol studies, including experts from National Institute on Alcohol Abuse and Alcoholism. Here, we cover new aspects of alcohol research that were not addressed in our previous issues. Because alcohol exposure induces epigenetic changes in liver cells, two articles of this Topic Highlight[1,2] focused on the epigenetic regulation in ALD. Another two articles[3,4] addressed the mechanisms of pro-fibrotic changes in ALD. Several articles[5-7] summarized the available animal models for studying HCV infection based on "second-hit" effects of infections in ALD progression. In addition, other important aspects of ALD pathobiology, such as the role of lipid rafts, microRNAs, MSGT1, hepatic stellate cells and innate immunity and the proteasome inhibitor for ALD treatment are included in this issue[8-12].

This Topic Highlight provides an overview of the most modern literature/approaches in the alcohol research and is strongly recommended for gastroenterologists, hepatologists and scientists who work in this field.

Abstract

Alcoholic liver disease (ALD) is characterized by steatosis or fat deposition in the liver and inflammation, which leads to cirrhosis and hepatocellular carcinoma. Induction of target genes without involving changes in DNA sequence seems to contribute greatly to liver injury. Chromatin modifications including alterations in histones and DNA, as well as post-transcriptional changes collectively referred to as epigenetic effects are altered by alcohol. Recent studies have pointed to a significant role for epigenetic mechanisms at the nucleosomal level influencing gene expression and disease outcome in ALD. Specifically, epigenetic alterations by alcohol include histone modifications such as changes in acetylation and phosphorylation, hypomethylation of DNA, and alterations in miRNAs. These modifications can be induced by alcohol-induced oxidative stress that results in altered recruitment of transcriptional machinery and abnormal gene expression. Delineating these mechanisms in initiation and progression of ALD is becoming a major area of interest. This review summarizes key epigenetic mechanisms that are dysregulated by alcohol in the liver. Alterations by alcohol in histone and DNA modifications, enzymes related to histone acetylation such as histone acetyltransferases, histone deacetylases and sirtuins, and methylation enzymes such as DNA methyltransferases are discussed. Chromatin modifications and miRNA alterations that result in immune cell dysfunction contributing to inflammatory cytokine production in ALD is reviewed. Finally, the role of alcohol-mediated oxidative stress in epigenetic regulation in ALD is described. A better understanding of these mechanisms is crucial for designing novel epigenetic based therapies to ameliorate ALD.

INTRODUCTION

Chronic alcohol consumption has a significant impact on human health and is identified as a major risk factor for development of liver disease. Alcoholic liver disease (ALD) is one of the leading causes of liver disease mortality worldwide. Alcohol-related liver injury includes a spectrum of pathological conditions in the liver including steatosis, steatohepatitis, cirrhosis and hepatocellular carcinoma. Of the molecular mechanisms studied, epigenetic mechanisms altered by alcohol appear to play a significant role in development and progression of disease. These mechanisms have been identified in parenchymal and non-parenchymal cells in the liver and contribute to induction of fatty liver, inflammation, as well as hepatocyte

apoptosis and necrosis. In the past decade, a number of studies have reported epigenetic alterations by alcohol in the liver including histone modification, DNA and histone methylation derived from the methyl group donating system, S-adenosyl methionine (SAMe), miRNA as post-transcriptional modifiers, and chromatin remodeling enzymes responsible for epigenetic regulation such as histone acetyltransferases, histone deacetylases and DNA methyltransferases[1,2]. Defining an epigenetic imprint in alcohol-induced liver injury will provide new insights into pathophysiological mechanisms and open avenues for potential novel epigenetics-based therapeutics.

The goal of this concise article is to review alcohol-mediated epigenetic alterations, in parenchymal and non-parenchymal cells of the liver. Specifically, alcohol-mediated alterations in epigenetic enzymes, miRNAs as epigenetic modifiers, chromatin modifications affecting immune cell function in alcoholic liver, and the role of oxidative stress in chromatin remodeling that regulates alcohol-mediated gene expression in the liver are described.

THE EPIGENETIC CODE

The classical view defines epigenetics as heritable changes that affect gene expression without altering the DNA sequence. Epigenetic regulation of gene expression is facilitated through different mechanisms such as DNA methylation, histone modifications, and RNA-associated silencing by small non-coding RNAs. All these mechanisms are crucial for normal development, differentiation and tissue-specific gene expression. These three systems interact and stabilize one another and can initiate and sustain epigenetic silencing, thus determining heritable changes in gene expression. Alterations in one or more of these systems leads to inappropriate target gene expression or silencing that results in epigenetic regulation of human diseases such as cancer, autoimmune diseases, and age-related as well as neurological disorders[3,4]. Epigenetic abnormalities are diverse, tissue-specific and can occur due to various environmental factors such as toxins and drugs, including alcohol.

Epigenetic regulation of gene expression primarily works through modifying the secondary or tertiary structures of DNA (chromatin), which makes it more or less accessible to transcription. Chromatin is made up of repetitive structural units called nucleosomes. Nucleosomes are comprised of a histone octamer and the DNA that wraps around it. Histones are globular basic proteins that are subject to various covalent modifications that occur primarily on the N-terminal tail[5]. The histone octamer contains two molecules of each of the histones H2A, H2B, H3 and H4, around which the DNA wraps. Histone H1 the "linker histone" along with "linker DNA" physically connects the adjacent nucleosome core particles. Covalent histone modifications appear to act sequentially or in combination to form a recognizable code that is identified by specific proteins to regulate distinct downstream

Table 1 Histone modifications, enzymes and genes

Modifications	Enzymes	Target gene transcription
Acetylation		
H3	GNAT	Activating
H4	MYST	Activating
H3 and H4	CBP/p300	Activating
Deacetylation		
H3 and H4	HDACs 1-11	Silencing
Methylation		
H3K4	Set1	Activating
H3K36	Set2	Activating
H3K79	DoT1L	Activating
H3K27	EZH2	Silencing
H3K9	SUV39H1	Silencing
H4K20	SUV4-20H1	Silencing
Phosphorylation		
H3S10	RSK2	Silencing
Methylated CpG	DNMT1, DNMT3a-3b	Silencing

events such as transcriptional activation or repression[5]. Histones are subject to various post-translational modifications such as acetylation, methylation, phosphorylation, ubiquitinylation and sumoylation, all having an impact on gene transcription[5]. Histone acetylation is a transcription-activating modification that is achieved by addition of acetyl groups to lysine residues by enzymes called histone acetyltransferases (HATs). The major sites of acetylation in histone H3 are Lys4, Lys9, Lys14 and Lys28. Acetyl groups are removed by histone deacetylases (HDACs) and this is generally associated with loss of gene expression or silencing[6]. Mammalian HDACs have been classified into four classes. Class I HDACs (1, 2, 3 and 8) are found predominantly in the nucleus, whereas Class II HDACs (4 5, 6, 7, 9 and 10) shuttle between the nucleus and cytoplasm. Class I and Class II HDACs have tissue-specific expression profiles. HDACs 1, 2 and 3 are expressed in various immune cells[7]. Class III HDACs (SIRT1-SIRT7) form a distinct class of NAD-dependent enzymes, can be inhibited by nicotinamide, and are important in DNA repair and anti-apoptotic functions[8]. HDAC 11 possesses properties of Class I and II HDACs and is classified as Class IV. Table 1 illustrates the histone modifications and enzymes linked to the changes.

Histone methylation is catalyzed by histone methyltransferases at lysine and arginine residues on histone H3 and H4 and can be mono-, di- and tri-methylated. The major sites on histone H3 are Lys4, Lys9, Lys27, Lys36 and Lys79, whereas histone H4 is methylated on Lys20[5]. The methyl group donor is S-adenosyl methionine. The effects of alcohol exposure on SAMe-mediated epigenetic changes have been under investigation[9]. Arginine methylation is transcription-activating, and lysine methylation can cause either transcriptional activation or repression, depending on the lysine residue methylated. For instance, H3K9 can be acetylated as well as methylated and have opposite transcriptional consequences; H3AcK9 causes transcriptional activation whereas H3K9me (mono-, di- and tri-) leads to transcriptional repression. Thus, a

balance in H3K9 acetylation and methylation may be important in determining chromatin architecture and gene silencing or activation[5].

Histone phosphorylation is a transcription-activating modification achieved by kinases that catalyze the transfer of a phosphate group from ATP or GTP to the serine or threonine residue of histone H3. Besides phosphorylation, histone H1, H2A, H2B and H3 can be ubiquitinated at lysine residues that activate transcription. Sumoylation on the other hand occurs on lysine residues and is a transcriptionally repressive modification.

DNA methylation involves transfer of a methyl group to cytosine bases at the C5 position of CG dinucleotides, referred to as CpG dinucleotides, and may occur in clusters, known as CpG islands. By definition, CpG islands are genomic regions that are at least 200 base pairs long, with ≥ 50% GC content and ≥ 60% expected CpG ratio[10]. The methyl donor is SAMe and the enzyme involved is DNA methyltransferase (DNMT). Two groups of mammalian DNMTs, one that *de novo* methylates DNA, and the other that maintains the methylation status, are classified as four different types: DNMT 1, 2, 3A and 3B. Although DNMT 3A and 3B are *de novo* methylation enzymes[11], DNMT 1 maintains methylation status, whereas the function of DNMT 2 is not yet clear and it has weak methyltransferase activity. DNA methylation leads to transcriptional silencing due to chromatin condensation, increased recruitment of methylated CpG binding transcriptional repressor, and inhibition of DNA binding of transcriptional activators[11]. The unmethylated CpG islands are associated with transcriptionally active promoters, and how CpG islands remain unmethylated is still unclear[12].

Non-coding RNA (ncRNA) is another mechanism of epigenetic regulation and is driven by long or small ncRNAs. Long ncRNAs such as *Air*[13], *Kcnq1ot1*[14] and *H19*[15] exert their epigenetic effect by genomic imprinting, which involves DNA methylation. On the other hand, small ncRNAs such as miRNA affect translational repression of mRNA, mRNA degradation, DNA methylation, and chromatin modification[16]. miRNAs are short [~22 nucleotides(nt)] ncRNAs that regulate gene expression by binding to their cognate binding sites at the 3'-end of the target mRNA, and inhibiting their translation. miRNAs are transcribed from miRNA genes mostly by RNA polymerase II into long primary miRNA (pri-miRNA) transcripts that often contain thousands of nucleotides and form hairpins (stem loops). The pri-miRNA is processed in the nucleus by Drosha-DGCR8 complex to produce 70-80-nt precursor miRNA (pre-miRNA)[16]. Pre-miRNAs are transported from the nucleus to the cytoplasm by exportin-5 and Ran-GTP complex, where they are further processed into ~22-nt long miRNA/miRNA duplex by Dicer, a RNAse type III enzyme. One of the miRNA strands bind to the cognate binding site on the target mRNA with a ~2-nt mismatch, and it is binding of the RNA silencing complex at the 3' UTR of the target mRNA that represses its translation and results in gene silencing[16].

The crosstalk between various epigenetic mechanisms

described above can determine downstream chromatin remodeling and gene expression. Mechanisms such as histone acetylation and methylation, DNA methylation and ncRNA-mediated modifications, are acquired throughout life, and persist, and influence the ability to deal with environmental factors such as nutritional factors, toxicants and lifestyle-related factors including tobacco smoke, alcohol, chemical carcinogens, infectious agents and UV radiation, thus influencing the clinical outcomes of health and disease[17].

EPIGENETIC DYSREGULATION IN ALD

The emerging role of epigenetic regulation of gene expression by alcohol and its effect on organ injury comes from studies in the past decade[1,2]. Here, we review mechanisms related to histone modifications and DNA methylation induced by alcohol exposure in liver cells, which contribute to ALD.

Histone modifications: acetylation, phosphorylation and methylation

Multiple lines of evidence from *in vitro* and *in vivo* studies have established that alcohol induces epigenetic modifications in various organs including the gastrointestinal system, brain and liver[2]. In the liver, alcohol alters histone acetylation, methylation as well as phosphorylation. Selective acetylation of histone H3 at lys 9 (H3AcK9) has been observed in primary rat hepatocytes exposed to alcohol *in vitro*[18]. On the other hand, other lysine residues H3 lys14, lys18 and lys23 were not acetylated. In the liver, H3 acetylation was modulated by alcohol *via* increased HAT activity and HDAC inhibition[19].

The status of histone acetylation depends on the activity of HAT and HDAC[20]. In some instances, the balance of HAT/HDAC ratio determines the acetylation of histone residues and influences gene expression[21]. Alcohol exposure appears to alter HAT and HDAC activity in hepatocytes[19]. *In vitro* alcohol exposure of hepatic cells impairs HDAC6 function, which directly affects microtubule dynamics[22]. The mRNA expression of class III HDAC, sirtuin 1 (SIRT1) is reduced in alcohol-exposed hepatocytes[23]. Furthermore, an essential role for SIRT1 in mediating effects of alcohol on SREBP-1 and hepatic lipid metabolism in alcoholic fatty liver has been reported[24]. These results indicate that SIRT1 can be developed as a therapeutic target in ALD. Overall, alcohol seems to influence HATs and HDACs in hepatocytes. Studies are needed to determine the precise role of these altered enzyme activities in the context of ALD *in vivo*.

Similar to acetylation, phosphorylation of histones is crucial to chromatin modifications, and activates gene transcription downstream of cell signaling events[25]. Acute alcohol exposure modulates H3 phosphorylation at serine 10 and serine 28 in rat hepatocytes, and this is dependent on p38 mitogen-activated protein kinase activity but not extracellular signal-regulated kinase and C-Jun N-terminal

kinase[26]. Recent studies also have indicated that *in vivo* acute alcohol exposure induces H3 serine-10 and serine-28 phosphorylation which was transiently increased at 1 h, but decreased at 4 h after alcohol administration[27]. On the other hand, persistent H3K9 acetylation in the liver was observed at 4 h after acute alcohol exposure *in vivo*[27]. A relationship between acetylation and phosphorylation in context with gene activation has been examined[25]. For instance, cytokine-induced gene expression mediated by nuclear IKKα leading to nuclear factor (NF)-κB activation involves coupling of H3 phosphorylation at serine 10 and acetylation at lysine 14[28,29]. On the other hand, retinoic acid receptor-β and c-jun gene regulation is linked to phosphorylation of histone H3 and not acetylation, which indicates that these two epigenetic changes can occur independently[30-32]. Whether alcohol induces histone phosphorylation and acetylation synergistically or as independent pathways to regulate target gene expression in ALD remains to be investigated.

Specific methylated lysine residues on histones function as stable epigenetic marks that direct particular biological functions, ranging from transcriptional regulation to heterochromatin assembly[33]. Histone methyltransferases catalyze transfer of a methyl residue predominantly to H3 and H4 histones that impart biological functions such as transcription or epigenetic silencing[33]. Shukla *et al*[34] have shown differential methylation of H3 and H4 in rat hepatocytes exposed to alcohol *in vitro*. These studies have indicated that methylation at H3meLys9 is decreased and is associated with downregulation of genes such as Lsdh, whereas increased methylation of H3meLys4 is associated with upregulation of alcohol dehydrogenases (ADH1)[34]. Whether acute or chronic alcohol-mediated histone methylation serves as a stable genomic imprint that determines the transcriptional state of a gene contributing to disease is still unknown.

DNA methylation in ALD

Methylation of cytosine at C5 in the CpG dinucleotides silences transcription, whereas absence of methylation activates transcription. Although 80% of CpG dinucleotides are methylated, unmethylated CpG residues in promoter regions of constitutively active genes are referred to as CpG islands[35]. The predominant methyl donor, SAMe, which is important in DNA methylation, is depleted in alcoholic livers, which results in hyperhomocysteinemia that is commonly observed in patients with ALD[36]. Decreased SAMe in alcoholic livers also seems to affect DNA methylation. Rats fed an intragastric alcohol diet for 9 wk exhibited decreased methionine, SAMe, glutathione and loss of DNA methylation by 40%[37]. This DNA hypomethylation can lead to alteration in gene expression and chromatin structure, results in increased DNA damage and strand breaks[37,38], which predisposes cells to malignant degeneration[39]. An association between alcohol intake and hypomethylation of the O⁶-methylguanine DNA methyltransferase gene has been noted in context with hepatocellular carcinoma[40]. Studies also have shown that alcohol-metabolizing enzyme, ADH1,

is regulated by epigenetic mechanisms in hepatoma cells involving DNA hypomethylation[41]. In addition to direct effects of alcohol on DNA hypomethylation, direct effects of acetaldehyde on DNA methyltranferase[42] and methionine synthase[43,44] have been reported. Whether alcohol directly alters DNA methyltranferase activity and methionine synthase is yet unknown. Chronic alcohol consumption induces global DNA hypomethylation[45], whereas hypermethylation of DNA is observed in human peripheral blood cells after alcohol consumption in humans[46,47]. Alcohol-associated hypomethylation thus far is linked to decrease in SAMe, the methyl donor.

An interplay between histone acetylation and DNA methylation is involved in the process of gene transcription and/or silencing in diseased states[17]. For instance, hypermethylation of CpG islands in target gene promoters triggers deacetylation of local histones, whereas lower levels of histone acetylation seem to sensitize DNA to methylation. Although there is an intimate communication between these two epigenetic phenomena, it is still not clear whether there is any hierarchical order of these events. In chronic alcohol exposed livers, whether an interconnection exists between hyperacetylation of H3K9, loss of methylation of H3K9, and increased methylation of H3K4, along with global hypomethylation of DNA is unknown. Studies undertaken to identify the interplay of epigenetic events will provide new insights into mechanisms of ALD.

miRNAs AS EPIGENETIC MODULATORS IN ALD

The role of miRNAs as epigenetic modulators is apparent from its regulation of gene expression at the post-transcriptional level. miRNAs elicit degradation of target mRNA or hinder translational mechanisms such as initiation, elongation, degradation or segregation of mRNA into P bodies for translational inhibition[48-50]. The importance of miRNAs in liver diseases such as viral hepatitis, alcoholic fatty liver disease and non-alcoholic fatty liver disease (NAFLD), fibrosis, and hepatocellular carcinoma has recently been recognized[51]. Studies have shown that alcohol exposure regulates miRNAs that control post-transcriptional events and influence gene expression that are important in ALD[52]. miRNAs have been linked to lipid metabolism and inflammation in steatohepatitis[53-56]. Dolganiuc *et al*[52] have shown that alcohol feeding increases and decreases ~1% of known miRNA, whereas methionine/choline-deficient diet upregulates 3% and reduces 1% of known miRNAs. Common to ALD and NAFLD, miR-705 and miR-122 are increased with both diets. However, miR-182, miR-183 and miR-199a-3p are increased in NAFLD and decreased in ALD mouse models. The functional relevance of miRNAs in ALD and NAFLD remains to be determined. Using hepatocyte cultures, recent studies have shown that ~11 miRNAs are altered in hepatic lipid droplets[57]. MiR-181d is the most efficacious inhibitor and reduces lipid droplets by 60%, which confirms its role in cellular synthesis of triglycerides

and cholesterol esters[57]. More recent studies have shown that chronic alcohol induces miRNA-155 in liver macrophages[58]. Chronic alcohol exposure also alters miRNAs that affect intestinal permeability[59]. Alcohol intake results in induction of miR-212, which in turn downregulates tight junction protein zonula occludens 1[59]. miRNA-212 is also higher in colon biopsy samples of patients with ALD, which confirms the pathophysiological significance of miRNA-212 in altering intestinal permeability during ALD. The role of miRNAs as epigenetic modulators of gene expression and silencing is becoming evident in ALD. An improved understanding of miRNAs and subsequent post-transcriptional regulatory mechanisms will be of importance in advancing their application as diagnostic or prognostic markers, as well as therapeutic targets in ALD.

EPIGENETICS AND INFLAMMATION IN ALD

The first report on aberrations in the epigenetic code in an inflammatory disease condition such as rheumatoid arthritis was reported in 1990[60]. Anti-inflammatory effects of HDAC inhibitors used in a number of experimental models of inflammatory diseases have confirmed a role for epigenetics in immune function[61-63]. Epigenetic regulatory mechanisms are central to the immune response, allowing an appropriate gene expression pattern in immune cells[64,65]. Environmentally regulated or endogenously mediated epigenetic alterations contribute to environment-host interactions in various forms of inflammatory diseases[66].

Innate immune responses and macrophage function play a central role in ALD[67,68]. Epigenetic modifications that influence inflammatory responses have been reported in macrophages[69] during lipopolysaccharide (LPS) tolerance. This phenomenon is dependent on histone acetylation and H3K4 methylation, as well as chromatin remodeling enzymes such as SW1/SNF[70]. Acute alcohol exposure decreases LPS induced proinflammatory responses in human monocytes[71,72]. Whether acute alcohol mediates histone modifications and recruitment of nucleosome remodeling enzymes at the promoters of the cytokine genes is yet to be determined.

The transcription factor NF-κB is a master regulator of proinflammatory responses in macrophages and monocytes[73,74]. It is the organization of the chromatin structure that controls the kinetics of NF-κB recruitment to target gene promoters that represents a focal point in mediation of transcription cooperativity (Figure 1). Acute and chronic alcohol exposure modulates NF-κB DNA binding that regulates expression of proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β and IL-6[68,75]. A tailored immune response that is regulated by NF-κB *via* interaction with HATs and HDACs elicits epigenetic modifications[76]. For instance, HDAC-1 is known to form a complex with NF-κBp50 homodimers to repress gene transcription[77]. On the other hand, inflammatory stimuli such as LPS can induce phospho-

Figure 1 Epigenetic regulation of gene expression *via* histone modification. Under normal conditions, activation of histone deacetylases (HDACs) inhibits acetylation (Ac) of histones, which results in chromatin packaging, restriction of DNA accessibility for transcription, and controlled target gene expression. During alcohol exposure, histone modifications mediated by histone acetyltransferases (HATs) influence elevated transcription of target genes, due to chromatin accessibility, which leads to increased DNA occupancy of transcription factors such as nuclear factor-κB (p50/p65), co-activators and transcriptional complexes, and elevated target gene expression.

acetylation of histone H3 (K9/S10) at a subset of cytokine and chemokine gene promoters for increased NF-κB recruitment[29,78,79]. Reductions in H3 Lys9 methylation, along with increased H3/H4 acetylation are strongly correlated with RNA polymerase II recruitment, which results in transcription of NF-κB-inducible inflammatory genes[79]. Whether alcohol exposure affects epigenetic mechanisms to prolong or reduce DNA binding of NF-κB to the cytokine gene promoters in monocytes and macrophages is not yet known. Another environmental agent, cigarette smoke induces post-translational modification of phospho-deacetylases, HDAC2 and SIRT1, acetylation of p65-NF-κB and phosphoacetylation of histone H3 that leads to chromatin rearrangement and sustained proinflammatory gene transcription[80,81]. It is likely that chronic alcohol exposure modulates HDAC2 and SIRT1 in immune cells to regulate epigenetic events that promote prolonged proinflammatory responses in ALD.

In macrophages stimulated with viruses or bacteria, miRNA-155 is the only increased miRNA induced by both stimulants[82,83]. miRNA-155 regulates TNF-α production positively by enhancing its translation[84]. Bala *et al*[58] recently reported that chronic alcohol induces miRNA-155 in an NF-κB-dependent manner that increases mRNA stability and TNF-α expression in ALD. miR-146 is predominantly expressed in T regulatory and Th1 cells[85] and is upregulated in toll-like-receptor-stimulated macrophages in an NF-κB-dependent manner. miR-146 targets IRAK-1 and TRAF6 genes and is unaffected by chronic alcohol exposure in liver immune cells[58]. Overall, these findings suggest that miRNAs are capable of regulating alcohol-induced innate immune cell function and thus determining cellular memory *via* miRNA-mediated epigenetic modulation.

ALCOHOL, OXIDATIVE STRESS AND CHROMATIN REMODELING

Oxidative stress regulates chromatin remodeling by alteration of histone acetylation and deacetylation events *via* HAT/HDAC activity[86,87]. Acute and chronic alcohol exposure increases reactive oxygen species (ROS) production and lowers antioxidant levels that enhance oxidative stress in the liver[88]. Metabolism of alcohol through alcohol dehydrogenase and microsomal cytochrome P450 2E1 leads to enhanced production of ROS in the liver[88]. Acetylation of histone H3 by alcohol in rat hepatocytes is mediated by ROS[89]. Inhibition of NADPH-oxidase-mediated ROS results in decreased H3AcK9, whereas ROS inducers directly increase alcohol-induced acetylation of H3K9, along with induction of ADH1 mRNA expression[89]. A redox-sensitive class III HDAC molecule, SIRT1, is also decreased in alcohol-exposed rat hepatocytes and livers of alcohol-fed rats[24]. Whether alcohol-induced ROS[90] play an important role in modulation of SIRT1 to regulate steatosis remains to be determined. In addition to alcohol, acetaldehyde and acetate, which are products of alcohol metabolism, cause acetylation of H3K9. Pyrazole, an inhibitor of alcohol dehydrogenase and methyl cyanamide, an inhibitor of aldehyde dehydrogenase, both reduce H3K9 acetylation, which indicates that alcohol and its metabolites can trigger acetylation of histone residues. Similar to *in vitro* observations, *in vivo* acute alcohol exposure in rats also shows that H3K9 acetylation is significantly increased in the liver[91]. Studies have shown that H3K9 acetylation in hepatocytes due to alcohol exposure correlates with transcriptional increase in alcohol dehydrogenase (ADH1)[19]. It is likely that alcohol-induced acetylation is required for activation of alcohol-metabolizing enzymes, which induce oxidative stress. This, in turn, induces acetylation that creates an amplifying "autocrine loop" between alcohol metabolism and epigenetic events. Future studies to determine the precise role of alcohol-mediated oxidative stress in chromatin modifications in hepatocytes and liver macrophages will identify new pathophysiological mechanisms and epigenetic targets of gene expression in ALD.

Stress-induced heat shock transcription factor (HSF)1 plays an important role as a transcriptional repressor of proinflammatory cytokine genes[92,93]. Recent studies have suggested that HSF1 serves as a master regulator of global acetylation in normal cells, whereas, in stressed cells, HSF1 interacts with HDAC1 and HDAC2, which induce histone deacetylation and chromatin remodeling[94]. Studies from our laboratory have shown that alcohol exposure induces HSF1 DNA binding activity in monocytes and macrophages[95]. Whether alcohol-induced HSF1 induces chromatin reorganization that affects proinflammatory cytokine production is being investigated. Another key stress-induced molecule, heat shock protein (hsp)90, is characterized as an epigenetic "gatekeeper" that interfaces with the environment and may finally determine whether certain epigenetic markers succeed in downstream phenotypic expression[96-98]. Chronic alcohol exposure upregulates hsp90 expression in liver macrophages[95]. It is likely that hsp90 facilitates an alcohol-mediated "epigenetic code" in the liver. Studies to delineate epigenetic effects of alcohol-induced hsp90 on gene transcription in liver macrophages and hepatocytes are awaited.

Hydroxyl radicals generated by oxidative stress interfere with the ability of DNA to function as a substrate for DNMT, which results in global hypomethylation[99,100]. Recent studies have provided evidence for the role of endoplasmic reticulum stress pathways and epigenetic gene regulation[101]. It is likely that alcohol-mediated oxidative stress regulates epigenetic markers in ALD.

CONCLUSION

The interplay of epigenetic mechanisms and their influence on gene transcription in ALD is evolving. Epigenetic alterations associated with acute and chronic alcohol exposure of hepatocytes and immune cells in relation to ALD is discussed in this review. Studies thus far have shown that alcohol exposure, probably *via* oxidative stress, exhibits differential regulation of acetylation, phosphorylation and methylation of histones that regulate chromatin remodeling and gene expression. The effects of alcohol on DNA methylation in hepatocytes and miRNA regulation have been elucidated. An integrative approach of the various mechanisms that lead to genomic imprinting during alcohol exposure will identify novel pathways in the alcoholic liver and support epigenetic therapeutic interventions.

Abstract

Alcoholism is a major health problem in the United States and worldwide, and alcohol remains the single most significant cause of liver-related diseases and deaths. Alcohol is known to influence nutritional status at many levels including nutrient intake, absorption, utilization, and excretion, and can lead to many nutritional disturbances and deficiencies. Nutrients can dramatically affect gene expression and alcohol-induced nutrient imbalance may be a major contributor to pathogenic gene expression in alcohol-induced liver disease (ALD). There is growing interest regarding epigenetic changes, including histone modifications that regulate gene expression during disease pathogenesis. Notably, modifications of core histones in the nucleosome regulate chromatin structure and DNA methylation, and control gene transcription. This review highlights the role of nutrient disturbances brought about during alcohol metabolism and their impact on epigenetic histone modifications that may contribute to ALD. The review is focused on four critical metabolites, namely, acetate, S-adenosylmethionine, nicotinamide adenine dinucleotide and zinc that are particularly relevant to alcohol metabolism and ALD.

INTRODUCTION

Alcoholism is a growing health problem worldwide. In the United States, alcoholism is a major cause of liver-related disease and deaths. Recent statistics reveal 52% of US adults to be "current regular" drinkers (Summary Health Statistics for U.S. Adults: National Health Interview Survey, 2009) and the death rate for alcohol-

induced causes to be on the rise (National Vital Statistics Reports, May 2010). As a result, alcohol-induced liver disease (ALD) continues to be studied, with the objectives of elucidating the underlying mechanisms and discovering potential therapeutic targets.

ALD consists of the spectrum of pathological changes including fatty liver, alcoholic hepatitis and alcoholic cirrhosis. The clinical manifestations of these changes and the pathogenesis of this disease have been extensively studied and described. There is a growing body of evidence supporting the involvement of epigenetic mechanisms in response to environmental inputs in the development of human disease. Accordingly, in recent years, there has been increasing interest in understanding the role of epigenetic mechanisms in the initiation and/or progression of ALD.

Nutrient fluctuations can impact transcriptional activity and expression of selective genes by modulating epigenetic parameters including histone modifications, DNA methylation, and nucleosome positioning. In ALD, especially in chronic alcoholics, the combined effect of alcohol metabolism and compromised nutrition causes major nutrient disturbances that are likely to influence epigenetic mechanisms, gene expression and disease pathogenesis. Covalent modifications of the amino termini of the core histones in nucleosomes play a key role in regulating chromatin structure as well as DNA methylation status. This review interrelates alcohol-mediated nutrient disturbances and consequent histone modifications that may have a contributory role in ALD (Figure 1). Specifically, the review is focused on fluctuations in four critical metabolites, namely, acetate, S-adenosylmethionine (SAM, also known as SAMe or AdoMet), nicotinamide adenine dinucleotide (NAD⁺) and zinc that are relevant to alcohol metabolism and ALD.

ALCOHOL AND ACETATE

The principal route of ethanol oxidation is through the enzyme liver alcohol dehydrogenase, which converts alcohol to aldehyde with the reduction of NAD^+ to NADH[1]. Acetaldehyde is then further oxidized by acetaldehyde dehydrogenase to acetate. The other major route of oxidation is through the microsomal ethanol oxidizing system (MEOS), in which the chief enzyme catalyzing alcohol oxidation is the cytochrome P450 mixed-function oxidase isoenzyme CYP2E1[1]. This route is engaged when alcohol is ingested in large quantities or in chronic alcoholics, who upregulate CYP2E1 expression. Thus, the end-product of both pathways of ethanol metabolism in the liver is free acetate[1]. This free acetate is then incorporated into acetyl-coenzyme A (acetyl-coA), by the catalytic action of the cytosolic and mitochondrial enzymes acetyl-coA synthetases[2]. Acetyl-coA is the substrate for histone acetylation, in addition to being utilized in the Krebs cycle, fatty acid synthesis and acetylation of other proteins[3].

Alcohol increases acetate production
Ethanol consumption has been shown to increase blood acetate levels significantly in several studies, dating back to

Figure 1 Nutrient disturbances, a potential link between alcohol metabolism and histone modifications in alcohol-induced liver disease. SAM: S-adenosylmethionine; NAD⁺: Nicotinamide adenine dinucleotide; HAT: Histone acetyltransferase; HDAC: Histone deacetylase; ALD: Alcohol-induced liver disease.

the 1980s. Short-term ethanol administration in humans led to a sustained steady state concentration of 0.4 to 0.6 mmol acetate within 2 to 5 h following ingestion in a study consisting of healthy male and female volunteers[4]. Although this phenomenon was also seen in alcoholics, there were variations in the kinetics of acetate production, with chronic alcoholics eliminating alcohol faster and producing more acetate[5,6]. Acetate levels were significantly higher both in the hepatic vein (1.79 and 1.15 mmol) and peripherally (0.91 and 0.52 mmol) in alcoholics than in non-alcoholics respectively[6]. In another study employing an enzymic acetate detection method, acetate concentration in peripheral human blood increased to about 20 times the normal level with ethanol consumption, whereas neither fasting nor the intake of a fatty meal significantly influenced acetate concentration[7].

Acetate and histone modifications
Amongst the various modifications documented at the tails of histone proteins in humans, acetylation and methylation are the best characterized[8]. Generally, acetylation at the lysine residues of histones depicts a transcriptionally permissive state, allowing opening up of the chromatin structure and access to transcriptional machinery[8]. Hyperacetylation of histones has been observed after alcohol administration in both, cell culture and animal studies[9-13]. In a 2003 study by Park *et al*[12], ethanol increased acetylation at lysine 9 on histone 3 (H3K9Ac) in a dose- and time-dependent manner in isolated rat hepatocytes. There was a remarkable 8-fold increase in the amount of H3K9Ac at 24 h by 100 mmol ethanol without an increase in histone 3 protein expression[12]. Also, inhibition of the metabolism of ethanol to acetate largely abolished this effect, suggesting that production of the ethanol metabolite, acetate, was critical to the process of acetylation[12]. Similar experiments in rat hepatic stellate cells (HSCs) demonstrated an increase in H3K9Ac levels with

no changes at lysines 14 or 18[9]. An *in vivo* study of the effect of acute ethanol (binge drinking) in rats concluded that the ethanol-induced increase in H3K9Ac was largely restricted to the liver, lung and spleen, with the liver showing a maximal increase of ~6-fold in a 12 h period[10].

An increase in the acetylation of histones in response to ethanol may be brought about by an orchestration of events that (1) increase the substrate for the reaction, acetyl-coA, (2) and/or modulate the enzymes controlling histone acetylation (HATs, HDACs). A study by Shukla's group in 2005 demonstrated that ethanol increased histone 3 acetylation at lysine 9 by specifically modulating HAT(s) targeting lysine 9 in rat hepatocytes[13]. However, it was not determined whether ethanol induced this effect by increasing transcriptional expression of HAT(s) or by specifically augmenting their activity. Accordingly, H3K9Ac and HAT activity was also increased by acetate in these cells, again indicating it as the likely mediator of ethanol-induced histone acetylation[13]. Interestingly, signaling pathway analysis showed that mitogen-activated protein kinase kinase (MEK) and c-Jun N-terminal kinase (JNK) inhibitors reduced ethanol-induced acetylation without affecting ethanol-induced HAT activity. This suggests a role for MEK and JNK in histone 3 acetylation induced by ethanol; however, the mitogen-activated protein kinase (MAPK) cascades may influence histone 3 acetylation without involving HAT activity. In similar experiments, acetate-induced acetylation was not affected by MEK or JNK inhibitors further indicating that the MAPK pathway was not downstream of acetate in the process of acetylation. The precise role of MAPKs in ethanol-induced histone acetylation needs further investigation[13]. Another study in which rats were fed ethanol intragastrically demonstrated that levels of P300, a histone acetyltransferase, increased corresponding to the peaks in urinary alcohol levels, and this correlated with an increase in histone 3 acetylation at lysine 9[14].

A recent study by Day's group very elegantly demonstrated that the formation of acetate from alcohol is key to the process of alcohol-induced inflammatory gene expression by promoter histone acetylation in acute alcoholic hepatitis[15]. Treatment of Monomac6 cells (human macrophage cell line modeling Kupffer cell responses in ethanol) with ethanol increased global H3 and H4 acetylation and reduced HDAC activity significantly. Ethanol also induced the expression of acetyl-coA synthetases (ACSS1 and 2), the enzymes required for conversion of acetate to acetyl-coA, the substrate for acetylation reactions. Corresponding to this effect, increased acetylation was observed at the promoters of inflammatory cytokines IL-6 and tumor necrosis factor (TNF)-α, with an increase in their mRNA expression. Notably, when these experiments were performed using acetate, these effects could be reproduced. What underscores the critical role of acetate in these ethanol-induced effects is that inhibition of ethanol metabolism to acetate using 4-methylpyrazole (4-MP) completely abrogated the effects and histone acetylation remained at baseline[15]. This confirms that acetate is indeed, the mediator of alcohol-induced histone acetylation.

Although there are no published reports regarding the

Figure 2 S-adenosylmethionine metabolism in alcohol-induced liver disease. Effects of alcohol are indicated by dotted arrows; a: Methionine adenosyltransferase; b: Enzymes involved in transmethylation reactions; c: S-adenosylhomocysteine (SAH) hydrolase; d: Cystathionine-β-synthase; e: Betaine homecysteine methyltransferase; f: Methionine synthase; g: glutamate-cysteine synthetase; h: Glutathione (GSH) synthetase. SAM: S-adenosylmethionine; THF: Tetrahydrofolate.

exact mechanisms by which acetate formed by ethanol metabolism may affect histone acetylation, some hypotheses have been suggested. Acetate may increase HAT activity simply by increasing substrate availability for the reaction. Since acetate is also the product of deacetylation reaction, free acetate may cause feedback inhibition of HDACs[15]. It should also be noted that most of the studies done with regard to ethanol-induced acetylation measure global acetylation and studies focusing on specific genes affected by alcohol metabolism are only beginning to be performed. One such gene examined in hepatocytes is ADH1 (Class 1 alcohol dehydrogenase)[13], while TNFα and IL-6 have been examined in Monomac6 cells[15] in response to alcohol. Also of interest are the findings that alcohol seems to have an effect on the acetylation at certain lysine residue, such as lysine 9 on H3 (H3K9), but not others (H3K14, H3K18)[9,12]. Further research is required to explore the significance and relevance of these findings.

ALCOHOL AND SAM

SAM is the one of the most widely used cofactors in nature, probably second only to ATP[16]. The liver is the main source of SAM in humans, and is also largely the site where SAM is metabolized by methyltransferases to S-adenosylhomocysteine (SAH)[17,18] (Figure 2). SAH is a potent inhibitor of all methyltransferases, and needs to be promptly eliminated by the body by a reaction catalyzed by SAH hydrolase[19]. SAM is an essential molecule that is vital to numerous cellular processes and is the principal biological methyl donor required for methylation of histones; as also other proteins, DNA, RNA, biogenic amines and phospholipids. It gives away its high energy methyl group to methyltransferases in transmethylation reactions, and thus, plays a central role in the epigenetic regulation of genes that are controlled by histone or DNA methylation[19]. The ratio of SAM to SAH is a critical determinant of the efficiency of transmethylation reactions and hence this ratio is referred to as the cellular

methylation potential[20]. SAM dependent methyltransferases is a broad class of enzymes that contains over a hundred genes[21,22]. Besides, SAM also contributes to gene regulation by methylation of non-histone proteins such as tumor suppressor p53, transcriptional factor TAF10 and the receptor for angiogenic factor VEGF, VEGFR1[23].

Alcohol causes SAM deficiency

SAM deficiency in alcohol-induced liver disease was first described in the early 1980s[24]. Hepatic MAT activity was found to be subnormal in alcohol-dependent individuals, blocking the conversion of methionine to SAM and resulting in hypermethioninemia[25-27]. Alcohol-dependent individuals often display glutathione (GSH) deficiency because GSH synthesis requires SAM[27,28]. Hepatic SAM depletion in response to chronic alcohol consumption has been studied both in humans and in animal models. SAM deficiency has been associated with hepatitis in humans[29], and different stages of alcohol-induced liver injury in rats[30], baboons[31] and micropigs[32].

Ethanol may deplete hepatic SAM by more than one mechanism (Figure 2). Ethanol administration reduces hepatic MAT activity by the oxidation or nitrosylation of the cysteine residue at position 121 and this may be affected by the reactive oxygen and nitrogen species generated during ethanol metabolism[33,34]. MAT activity has also been shown to be reduced due to decreased gene expression of MAT1 (liver specific MAT) in alcoholic hepatitis patients[29] and ethanol-fed micropigs[35]. In another study in rats, chronic ethanol administration decreased SAM levels and glutathione concentration without affecting MAT and it was proposed that SAM consumption was increased to fuel glutathione synthesis[36]. In addition to increased consumption, SAM deficiency may occur because its synthesis may be inhibited by the unavailability of methionine, the endogenous precursor of SAM. Chronic ethanol administration can influence methionine synthesis by decreasing methionine synthase (MS) activity, and the hepatic levels of folate and betaine[35,37-39]. Thus, alcohol consumption can affect aspects of SAM production and metabolism at multiple levels to result in hepatic SAM deficiency in ALD.

SAM and histone modifications

Unlike histone acetylation, which is generally a transcriptionally permissive modification, histone methylation is known to exhibit differential effects that depend on the position of the particular residue that is modified. Methylation of the lysine at position 9 on H3 (H3K9) is a silencing event[40,41], and opposes the transcription-activating acetylation (H3K9Ac) of the same residue. On the other hand, methylation of lysine 4 on H3 (H3K4) activates transcription, and trimethylation at this residue (H3K4Me3) is strongly correlated with active transcription[42]. Also, in contrast to histone acetylation, histone methylation appears to be a more permanent mark and is relatively irreversible[43,44].

The effect of ethanol on histone and DNA methylation has been studied in cell culture and animal studies[9,10,45,46]. However, in comparison to histone acetylation,

studies involving methylation changes with ethanol are only beginning to be documented. Pal-Bhadra *et al*[45] examined the effect of ethanol on H3 methylation in primary rat hepatocytes, and reported contrasting methylation patterns at H3K9 and H3K4 following ethanol treatment. H3K9 dimethylation was decreased whereas H3K4 dimethylation was increased. Further analysis showed that K9 methylation was associated with the promoters of ethanol-downregulated genes [L-serine dehydratase (Lsdh) and Cytochrome P450 2C11 (CYP2C11)] and K4 methylation with those of ethanol-upregulated genes [Alcohol dehydrogenase-1 (Adh-1) and Glutathione S-transferase Yc2 (GST-Yc2)] in these cells[45]. In earlier studies in rat liver and rat hepatic stellate cells, ethanol had been shown to increase acetylation at H3K9 with little, if any, change in methylation at the same residue[9,10]. In another recent study using a chronic rat model for ethanol (intragastric feeding model), a significant increase was noted in dimethyl histone 3 lysine 4 (H3K4Me2). Trimethylation of histone 3 lysine 27 (H3K27Me3), a transcriptionally silencing modification, also increased significantly after chronic ethanol feeding[46]. Similarly, the effect of SAM treatment on histone methylation[47,48] and gene expression[49] has been documented in some studies. When SAM was administered along with ethanol intragastrically to rats for a month (chronic model), SAM remarkably attenuated the ethanol-induced liver injury[48]. Histone 3 trimethylation at lysine 27 (H3K27Me3) was significantly increased with SAM treatment, irrespective of ethanol feeding. SAM also prevented most of the changes in gene expression caused by ethanol feeding. Since H3K27 trimethylation correlates with gene repression, it was postulated that SAM stabilized global gene expression and prevented the blood alcohol level (BAL) cycle through this epigenetic modification[48]. Other experiments in RAW and Kupffer cells show that SAM can inhibit the LPS-stimulated expression of pro-inflammatory genes such as TNF-α and i-NOS at the transcriptional level. In these studies, it was found that LPS increased the trimethylation of H3K4 at the promoters of these genes, and treatment with SAM reversed this effect[47]. Overall, research thus far indicates that SAM deficiency may be an important mediator of histone modifications in ethanol-induced liver disease.

ALCOHOL AND NAD⁺

The ubiquitous biological molecule, NAD$^+$, was first discovered in 1906, and since then, has been widely studied for its ever-expanding repertoire of cellular functions. NAD$^+$ is best known for its role in oxidation-reduction reactions in cell metabolism[50]. NAD$^+$ is also the precursor of the important second messenger cyclic ADP-ribose[51], and more recently, has been found to be absolutely essential for the protein deacetylase activity of sirtuins[52,53]. Sirtuins or Sir2 proteins are a class of histone deacetylases and in addition to their role in gene transcription, are also involved in the regulation of ageing and metabolic processes[54]. Thus, from being a coenzyme in redox reactions, NAD$^+$ has come a long way, now being called

a critical metabolic regulator of transcription, longevity, calorie-restriction mediated life-span extension and several age-associated diseases, including diabetes, cancer and Alzheimer's disease[55].

Alcohol depletes NAD⁺

Alcohol metabolism utilizes NAD^+ at the very initial steps of breakdown[1]. NAD^+ is used up both when alcohol dehydrogenase converts alcohol to acetaldehyde and when acetaldehyde dehydrogenase further converts it to acetate. In both these reactions, NAD^+ is reduced to NADH. Several acute effects of ethanol are caused by the reduction of the NAD^+/NADH ratio in the liver, as a consequence of ethanol metabolism. An increased NAD^+/NADH ratio in the liver disrupts fatty acid oxidation and can induce ketogenesis, lactic acidosis, hyperuricemia and hypoglycemia[56]. Even after conversion of ethanol to acetate, NAD^+ continues to be consumed. Acetate forms acetyl-coA, which reduces NAD^+ to NADH once it enters the Krebs cycle. Chronic ethanol consumption also recruits the CYP2E1 pathway for metabolism, which adds to the imbalance in the hepatic redox state by reducing NAD^+ and increasing hydroxyl radicals[57]. The oxidative stress and reactive oxygen species (ROS) caused by ethanol consumption are only aggravated by the poor nutritional status in chronic alcoholics, and play a major part in depleting NAD^+ and advancing liver injury[58].

NAD⁺ and histone modifications

The NAD^+/NADH ratio in the liver likely plays a major role in the regulation of histone modifications and thus, gene transcription/silencing[59]. Histone deacetylases are categorized into three main classes, and class Ⅲ HDACs or sirtuins (SIRT), are activated only in the presence of NAD^+. In sirtuin-mediated deacetylase reactions, NAD^+ is hydrolyzed into nicotinamide and accepts the acetate moiety, O-acetyl-ribose. The nicotinamide formed is a potent inhibitor of sirtuin HDAC activity. Thus, the histone deacetylase activity of sirtuins is intricately controlled by NAD^+ metabolism, requiring NAD^+ for catalysis and being inhibited by nicotinamide. Ethanol, as discussed earlier, increases histone acetylation in the liver. The mechanisms underlying this effect of ethanol are not well characterized; however, there are reports of increased HAT activity[10] and/or decreased HDAC activity[11]. It may then be postulated that ethanol-induced inhibition of HDACs is due to the depletion of NAD^+ caused during its metabolism. Ethanol has already been shown to inhibit sirtuin expression and activity in other studies in the liver[60,61]. Chronic administration of ethanol in mice reduced hepatic SIRT1 protein levels and significantly inhibited its deacetylase activity in a recent study by You *et al*[61]. In an earlier report, ethanol was shown to increase SREBP-1c (Sterol regulatory binding protein-1c) lysine acetylation and transcriptional activity in rat H4IIEC3 cells, and this effect was at least in part, mediated by SIRT1 inhibition[62]. Results from another study reaffirm the link between ethanol consumption and SIRT1 reduction, and in this study ethanol reduced hepatic SIRT1 mRNA expression to half its baseline levels[60]. In addition, independent studies have shown that oxidative stress can inhibit HDACs[63-66].

In light of these findings, it can be hypothesized that the interplay between NAD^+ levels, reactive intermediates and oxidative stress will impact histone modifications and gene expression in ALD.

ALCOHOL AND ZINC

Zinc is an essential trace element and is vital in carbohydrate and protein metabolism, glucose control, wound healing, the immune system, digestion, fertility, and growth[67-69]. Zinc plays an important role in controlling gene expression, antioxidant defense and DNA repair. Abundant changes in gene expression in dietary zinc deficiency have been profiled in several tissues, including the liver[70,71], although the mechanisms have not been investigated. Zinc is an essential cofactor for over 300 enzymes; of particular relevance to this review are the zinc-requiring enzymes, namely (1) histone deacetylases (HDACs) that catalyze the removal of an acetyl group from lysines on histones protein tails, thereby increasing the accessibility of nucleosomal DNA and resulting in transcriptionally active chromatin; and (2) histone demethylases that demethylate Lys residues on histones and modulate gene expression.

Alcohol causes zinc deficiency

Zinc deficiency is often observed in chronic alcoholics and approximately 30%-50% of alcoholics are thought to have low zinc status[67,69], possibly due to decreases in intestinal absorption, increased urinary excretion and/or inadequate dietary zinc intake. Clinical studies have demonstrated that zinc concentrations in both serum and liver were significantly reduced in patients with alcoholic steatosis, hepatitis, and cirrhosis[72-75]. Indeed, zinc insufficiency is one of the most commonly observed nutritional manifestations of alcoholic liver disease[76]. Zinc depletion in the liver has also been documented in animal models of ethanol-induced liver injury[77-82]. Investigations of zinc metabolism in alcoholics has demonstrated that ethanol consumption leads to increased Zn excretion in urine[83] and decreased Zn absorption from intestine[84,85]; the latter is also seen in a chronic ethanol feeding animal model[86].

Zinc and histone modifications

While class Ⅲ HDACs require the cofactor NAD^+ for their deacetylase function, the class Ⅰ, Ⅱ and Ⅳ HDACs are structurally distinct and require zinc for their deacetylase function[87]. A suboptimal zinc concentration, as is observed in alcoholic individuals, is highly likely to significantly decrease the activity of HDACs, leading to altered gene expression. Indeed, the alcohol-induced decrease in HDAC activity observed by others[88] and us [unpublished results] may be attributed, at least in part, to lowered zinc levels. A direct effect of zinc on epigenetic histone changes was demonstrated in a recent study using chromatin immunoprecipitation assays, wherein zinc treatment rapidly decreased Lys4-trimethylated and Lys9-acetylated histone H3 in the metallothionein1 (MT1) promoter and

decreased total histone H3. Also, the micrococcal nuclease sensitivity of the MT1 promoter was also increased by zinc, suggesting that the chromatin structure in the MT1 promoter may be disrupted by zinc-induced nucleosome removal[89]. Another *in vitro* study showed that p21 transcription was downregulated by lowered zinc in HepG2 cells[90]. Zinc deficiency led to a reduction in acetylated histone-H4 on the p21 promoter resulting in reduced p21 promoter accessibility, which contributed to the decrease in p21 promoter activity and the downregulation of p21 mRNA and protein expression in zinc-depleted HepG-2cells. Specifically, the amounts of acetylated histone-4 associated with the proximal and distal p21 promoter regions were decreased in severe zinc-deficient (73% and 64%, respectively) and mild zinc deficient (82% and 77%, respectively) cells compared with zinc-normal (100% and 100%, respectively)[90].

A recently discovered histone lysine demethylase, LSD2, was shown to not only contain a CW-type zinc finger motif, but also to bind zinc with 3:1 molar ratio (zinc: protein), suggesting that zinc maybe important for its activity[91]. Also, a zinc finger motif located at the end of the conventionally defined JmjC domain of histone demethylases, such as jumonji-type JMJD2A, is thought to be essential for enzymatic function[92]. Changes in zinc status as seen with chronic alcohol consumption are expected to cause dramatic alterations in gene expression, leading to phenotypic changes. In addition to direct epigenetic effects, zinc deficiency is also known to reduce the utilization of methyl groups from SAM in rat liver, resulting in genomic DNA hypomethylation and histone hypomethylation[93,94]. This occurs due to the fact that the enzyme betaine-homocysteine S-methyltransferase (BMHT) is a zinc metalloenzyme[95]. Overall, we believe that alcohol consumption-induced zinc deficiency may greatly impact gene expression *via* direct and indirect epigenetic histone modifications and modulation of chromatin structure and gene expression.

In addition to the nutritional alterations mentioned in this review, alcohol is known to cause disturbances in other nutrients, which may also play a role in the epigenetic changes effected by alcohol. Alcohol has also been shown to influence other histone modifications, such as glycation[96] and phosphorylation[97]. The significance of these modifications in relation to gene expression is, however, not clear.

CONCLUSION

Alcohol metabolism is inextricably connected to the regulation of key nutrient metabolites in the liver. There is a growing body of literature suggesting a role for the complex interplay between alcohol-induced nutrient changes, histone modifications and gene expression. It is becoming widely accepted that specific aberrant patterns of histone modifications play a fundamental role in chromatin structure and function contributing to the development of disease processes. Epigenetic histone modifications provide a plausible link between alcohol-mediated nutrient altera-

tions and pathogenic gene expression. However, in ALD, the precise contribution of histone modifications in the alteration of expression of specific genes remains largely unknown. Clearly more advances are needed and will be witnessed in this area that will enhance our knowledge about the epigenetic mechanisms underpinning ALD pathogenesis and lead to the development of relevant therapeutic strategies.

Abstract

Alcoholic liver disease (ALD) is a leading cause of liver disease and liver-related deaths globally, particularly in developed nations. Liver fibrosis is a consequence of ALD and other chronic liver insults, which can progress to cirrhosis and hepatocellular carcinoma if left untreated. Liver fibrosis is characterized by accumulation of excess extracellular matrix components, including type I collagen, which disrupts liver microcirculation and leads to injury. To date, there is no therapy for the treatment of liver fibrosis; thus treatments that either prevent the accumulation of type I collagen or hasten its degradation are desirable. The focus of this review is to examine the regulation of type I collagen in fibrogenic cells of the liver and to discuss current advances in therapeutics to eliminate excessive collagen deposition.

INTRODUCTION

Liver fibrosis is an exacerbation of the generic wound-healing process of the liver and is defined by excess synthesis and deposition of extracellular matrix (ECM) components, of which type I collagen predominates[1]. Accumulation of ECM in the sub-endothelial space of Disse can disrupt liver microcirculation, leading to damage and death of parenchymal cells[2]. Liver fibrosis is a common sequela for a variety of insults, such as viral infection, industrial solvent exposure, autoimmunity, cholestasis, inborn errors of metabolism, and ethanol abuse.

In a setting of chronic fibrogenic stimulus, myofibroblast-like cells produce large quantities of ECM components. Extensive investigation has revealed several cell types that are potential myofibroblast precursors, including the hepatic stellate cell (HSC). HSCs are star-shaped, vitamin A-storing cells residing within the subendothelial space of Disse[3]. In fibrosis HSCs lose their vitamin A stores, transdifferentiate to a proliferative, myofibroblast-like cell, and produce or secrete excess ECM components[4]. Though considered the predominant source of ECM in hepatic fibrosis, other cell populations have been identified as sources of collagen and other ECM components. Portal fibroblasts and bone marrow-derived myofibroblast precursors have also been implicated as sources of ECM in fibrosis. Evidence also suggests that hepatocytes may undergo epithelial to mesenchymal transition to produce ECM, at least *in vitro*[5-7].

Globally, viral hepatitis is the leading risk factor for hepatic fibrosis; however, in highly developed nations chronic, high ethanol consumption is the principal risk factor for developing fibrosis. Nonalcoholic steatohepatitis (NASH) has also been identified as a growing cause of fibrosis[8]. Untreated, liver fibrosis is a major contributor of morbidity and mortality, as unresolved fibrosis may progress to cirrhosis and result in organ failure or progression to hepatocellular carcinoma (HCC). Despite increased understanding of fibrogenesis, there remains a dearth of effective anti-fibrotic treatments. This review will focus on type I collagen expression in fibrosis in alcoholic liver disease (ALD) and therapeutic strategies to limit or reverse its accumulation.

REGULATION OF TYPE I COLLAGEN

Excess ECM deposition in liver fibrosis can largely be attributed to members of three families of proteins - collagens, in particular types I, III and IV; proteoglycans, such as fibronectin, laminin, and hyaluronic acid; and glycoproteins, including heparin, chondroitin sulfates, and biglycan. Although multiple ECM components are dramatically upregulated in hepatic fibrosis, type I collagen is the most abundant protein in the body and has been extensively characterized, making it an attractive target for the development of anti-fibrotic therapies.

Collagens are synthesized as a triple helix from three polypeptide α chains composed of continuous Glycine (Gly)-X-Y peptide repeats[9]. Glycine is essential in the first position as its side chain is the only one small enough to fit within the center of the coiled-coil triple helix[10]. Proline is frequently found in the X position and hydroxyproline in the Y position[11]. These amino acids limit rotation of the triple helical structure and their placement on the surface facilitates self-assembly and polymerization of collagen molecules through charge-charge and hydrophobic interactions[9].

In normal tissues, collagens are secreted into the ECM and help maintain the integrity of tissue by interacting with cell surfaces, with other ECM components, and with growth and differentiation factors[12]. Type I collagen is an important component in the wound-healing process and is found in large quantities in scar tissue associated with a variety of pathological conditions[13,14]. In the liver, chronic damage stimulates activation of HSCs and other myofibroblast precursors, resulting in a phenotypic change towards excessive production and secretion of ECM products, particularly type I collagen.

Transcriptional regulation of procollagens

Synthesis of type I collagen is initiated by expression of the *col1a1* and *col1a2* genes, giving rise to α1(I) and α2(I) procollagen mRNAs, respectively. Levels of these gene products can be regulated at both the transcriptional and post-transcriptional level. Despite being located on different chromosomes, expression of these two genes are coordinately regulated in a tissue-specific manner giving rise to α1(I) and α2(I) procollagen mRNA products in a 2:1 ratio, respectively[15]. Numerous regulatory elements have been identified in the promoter and first intron of *col1a1* and *col1a2* that regulate expression of procollagen mRNA messages through interactions with transcription factors.

In ALD, ethanol consumption results in mediators that influence the expression of type I collagen. Metabolism of ethanol by alcohol dehydrogenase (ADH) and cytochrome P450 2E1 (CYP2E1) generates acetaldehyde and reactive oxygen species (ROS)[16]. Acetaldehyde treatment of HSCs increases binding of a kruppel-like transcription factor (KLF), basic transcription element binding protein (BTEB) to a region between -1484 and -1476 in the *col1a1* promoter in a *c-jun* N-terminal kinase (JNK)-dependent manner, enhancing α1(I) procollagen mRNA levels[17,18]. Other KLFs, such as Sp1 and KLF6, have also been shown to upregulate transcription of procollagen mRNAs[19].

Transforming growth factor-β (TGF-β) has been described as the most potent fibrogenic cytokine for HSCs and is thus a common target for anti-fibrotic therapy[1]. TGF-β expression is upregulated in fibrosis and is secreted by HSCs and other cell types, such as Kupffer cells. Stimulation with TGF-β activates Smad signaling, which can upregulate procollagen expression *via* formation of a heterotrimeric complex of Smad2, 3, and 4, where Smad7 is inhibitory. TGF-β can also stimulate enhanced procollagen expression through the generation of intracellular H_2O_2 and subsequent activation of p38-mitogen activated protein kinase[1].

Nuclear factor κB (NFκB) is commonly associated with liver fibrosis, including ALD. Although NFκB is not required for the activation of HSCs, an increase in the p65/p50 heterodimer, with concomitant decrease in the NFκB inhibitory protein, IκBα, promotes survival of activated HSCs[20,21]. Overexpression of NFκB in activated HSCs, however, has been shown to inhibit α1(I) and α2(I) procollagen mRNA expression in culture-activated HSCs[22,23]. It is unclear, however, whether this observation occurs *in vivo*.

Post-transcriptional regulation of procollagen mRNAs

Upon activation of HSCs and other myofibroblast precursors, there is a > 50-fold increase in α1(I) procollagen mRNA levels, with a concomitant increase in message half-life from 1.5 to 24 h[24]. Although fibrogenic stimuli, such as chronic ethanol consumption, increase the transcription rate of procollagen mRNAs, the major contributing factors associated with this increase are post-transcriptional. The α1(I) procollagen mRNA possesses regulatory elements within both the 3' and 5' untranslated regions (UTRs), which influence the stability and translation of the message.

Heterogenous ribonucleoprotein particles (hnRNPs) are a family of RNA-binding proteins that have a variety of functions, including prevention of mRNA folding, transporting, association with the splicing apparatus, and mRNA stability. αCP is an hnRNP that has demonstrated

binding to the 3' UTR of several messages, including α-globin[25]. αCP binds to a C-rich segment of the 3' UTR of α1(I) procollagen mRNA located downstream of the stop codon, stabilizing the message and preventing degradation[24,26]. Though expressed in both quiescent and activated HSCs, αCP only has binding activity in activated HSCs. Furthermore, the cellular localization of αCP varies in HSCs, with αCP localized in the nucleus of quiescent HSCs and in both the nucleus and cytoplasm of activated HSCs, suggesting a yet to be identified post-translational event regulating the localization of αCP[27].

A well-conserved 5' stem-loop structure has been described in the message of collagen mRNAs, including α1(I) procollagen mRNA, comprising the translation initiation codon[28,29]. Mutation of this 5' stem-loop structure revealed improperly assembled procollagen I, as demonstrated by pepsin-sensitivity and diminished intermolecular disulfide bond formation[30]. Recent work has revealed La ribonucleoprotein domain family member 6 (LARP6) as a sequence-specific 5' stem-loop binding protein of α1(I) procollagen mRNAs[30]. Reporter experiments in the same study revealed that deletion of the 5' stem-loop or LARP6 resulted in diffuse accumulation of the reporter throughout the endoplasmic reticulum (ER), in contrast to the focal areas of translation associated with proper assembly of procollagens[31]. Further investigations by the same group demonstrated that LARP6 interacts with non-muscle myosins, and disruption of this interaction results in increased intracellular degradation of procollagen polypeptides and a preference towards α1(I) homotrimers[32]. Emergence of LARP6 as a collagen-specific regulator of translation may present a new therapeutic target for modulating excessive collagen synthesis in fibrogenic conditions like alcoholic fibrosis and cirrhosis.

Post-translational modifications of procollagen polypeptides

Most proteins begin folding at the N-terminus prior to completion of translation and translocation. For type I collagen, however, folding is initiated at the C-terminus following co-translational translocation into the ER[33]. Several proteins play an important role in facilitating the proper folding and trafficking of α chains into triple helix procollagen molecules. The 78-kDa glucose-regulated protein (Grp78) recognizes hydrophobic residues on polypeptide chains to help maintain solubility and may also bind the C-propeptide[34]. Protein disulfide isomerase (PDI) also plays a role in triple helix formation by catalyzing disulfide bonds between C-propeptide domains of the three α chains[35,36]. PDI also acts as a β-subunit for prolyl 4-hydroxylase (P4H) by keeping the catalytic α-subunits in a soluble state[37]. Further stabilization of the triple helix is accomplished through hydroxylation of select proline residues (typically in the Y position) by the P4H enzyme, which in turn facilitates hydrogen bonding and the formation of water bridges within and between collagen chains[38,39]. A 47-kDa heat shock protein (Hsp47) is a collagen-specific chaperone that also plays an important role in collagen trafficking[40]. Although the exact role of Hsp47 has not been clearly defined, studies utilizing Hsp47-/- mice showed they are embryonically lethal at day 11.5[41]. After procollagens traverse the Golgi apparatus and are secreted into the extracellular space, the C- and N-prodomains are cleaved by C- and N-peptidases, respectively[42]. This process decreases the concentration required for fibril formation and results in the self-assembly of collagens into fibrils[43].

THERAPEUTIC TARGETING OF TYPE I COLLAGEN

Removal (or suppression) of the underlying pathology is considered the most effective way to reverse liver fibrosis; however, removal of the causative agent is not always feasible. In ALD, patients often fail to comply with abstention programs and many patients do not respond well to casual treatments, or present with advanced fibrosis and/or cirrhosis. Thus, there is a need to identify and develop anti-fibrotic agents that can retard, or even reverse, liver fibrosis. To date there is no well-regarded or frequently used anti-fibrotic therapy in clinical practice.

Therapeutic strategies for established liver fibrosis can target type I collagen accumulation by employing one or more strategies: (1) decrease the secretion of type I collagen by disrupting either its transcription or assembly; or (2) stimulating fibrinolysis of type I collagen that has accumulated extracellularly. Therapies to reduce the pool of fibrogenic myofibroblasts are also a therapeutic strategy; however, these approaches are beyond the scope of the current review.

Antioxidants

Liver fibrosis caused by ALD has a well-established link with oxidative stress. Metabolism of ethanol by ADH and CYP2E1 generate ROS and acetaldehyde, leading to a variety of cellular defects including depletion of reduced glutathione (GSH), the main intracellular antioxidant, lipid peroxidation, acetaldehyde-protein adducts, and proteasome inhibition[44-46]. Oxidative stress from Kupffer cell activation or from damaged hepatocytes can promote HSC activation and procollagen mRNA expression. These findings led investigators to evaluate a variety of antioxidants as a way to limit production of type I collagen and other matrix components, with mixed results.

S-adenosyl-L-methionine (SAMe) is the principal biological methyl donor and is a precursor to GSH, thus it has received interest as a potential treatment for liver diseases. Liver fibrosis has been shown to be attenuated by SAMe administration in several animal models of fibrosis, including a rat model of ALD[47-49]. *In vitro* experiments reported that SAMe inhibits both basal and TGF-β-stimulated type I collagen expression in activated HSCs[50,51]. Additionally, studies by our group indicate that SAMe can enhance polyubiquitination of type I collagen, possibly suggesting a novel mechanism to prevent secretion of collagen (Thompson

et al 2011 DOI:10.1111/j.1478-3231.2011.02512.x). SAMe supplementation prevented oxidative stress and lipid per-oxidation in ethanol- and ethanol plus LPS-fed animals as evidenced by normal GSH:oxidized glutathione (GSSG) ratio and diminished levels of 4-hydroxynonenal, respectively[47]. Despite attractive results *in vitro* and with animal models, SAMe has shown mixed results in modulating liver disease in human trials. A comprehensive review by Rambaldi *et al* revealed no clear benefit by SAMe in most trials analyzed; however, a well-designed study by Mato *et al* reported that SAMe administration could delay the need for hepatic transplantation in alcoholic cirrhotics[52,53]. However, the combination of SAMe with other antioxidants, such as dilinoleoylphosphatidylcholine (DLPC), has attenuated liver injury in a NASH model and *in vitro* studies reported decreased collagen and TIMP-1 expression in HSCs[54-56].

Turmeric has been used for centuries in Indian Ayurvedic medicine to treat a variety of ailments. Curcumin is a polyphenolic compound and the principal curcuminoid in turmeric. Curcumin in part owes its antioxidant properties to stimulation of nuclear factor erythroid-2-related factor 2 (nrf2), a transcription factor that binds several intracellular oxidant genes and enhances their transcription, including genes associated with production of glutathione[57,58]. In rodent models of cirrhosis, curcumin is reported to be protective; however, differences were noted depending on the model used. Curcumin can prevent thioacetamide (TAA)-induced cirrhosis, but no effect by curcumin was seen on established cirrhosis[59]. On the other hand, using bile duct-ligation (BDL) and carbon tetrachloride (CCl_4) models of established cirrhosis, curcumin improved liver histology and diminished collagen accumulation[59]. Studies utilizing curcumin on activated stellate cells revealed enhanced expression of peroxisome proliferator-activated receptor-γ (PPAR-γ), disruption of TGF-β signaling, and diminution of collagen expression[60,61]. Additionally, curcumin has been demonstrated to improve alcohol-induced liver injury through prevention of oxidative stress and inflammation *via* downregulation of NF-κB[62-64].

Another antioxidant that has received attention as a potential therapy for hepatic fibrosis is resveratrol, a phytoalexin (a class of antibiotics produced in plants) naturally found in grapes and commercially in red wine. Resveratrol exhibits anti-inflammatory properties, anti-oxidant effects, and modulates metabolism of lipids[65]. In a CCl_4-mediated model of fibrosis, resveratrol prevented fibrosis with concomitant inhibition of NF-κB translocation and attenuation of TGF-β production[66]. Inhibition of NF-κB by resveratrol was also reported *in vitro* along with a decrease in pro-inflammatory cytokine production[67,68]. In a rat model of alcoholic liver injury, resveratrol blocked increased oxidative stress, as measured by malondialdehyde, through upregulation of superoxide dismutase, glutathione peroxidase, and catalase[69]. Resveratrol has also been shown to alleviate alcohol-induced fatty liver disease in mice through promotion of sirtuin 1 and AMP-activated

kinase[70]. There is, however, a lack of human studies examining the efficacy of resveratrol as a treatment for liver disease.

Silibinin is an active flavinoligand derived from milk thistle, which has been used for several millennia as a treatment for a variety of liver disorders. Silibinin has demonstrated anti-proliferative, anti-fibrogenic, and anti-cancer properties with *in vivo* animal models and can inhibit TGF-β-induced collagen secretion in a human HSC cell line[71,72]. In addition to direct antioxidant properties, silibinin can inhibit CYP2E1 expression in the setting of chronic alcohol consumption, suggesting decreased ROS production in alcoholics[73]. Despite encouraging results in animal studies, enthusiasm for its use in humans to treat chronic liver disorders is limited by questionable success in clinical trials. A review of 13 randomized clinical trials revealed silibinin had no effect on mortality, liver histology, or liver-related complications, but there was a significant decline in liver-related mortality; however, others found no decrease in liver-related mortality in trials that were deemed to be of high quality[74].

MicroRNAs

MicroRNAs (miRNA) belong to a class of small non-coding RNAs involved with post-transcriptional regulation of gene expression, termed RNA interference (RNAi). These sequences are typically 18-25 nucleotides and are generated by processing of full-length primary transcript miRNAs, termed pri-miRNA, through enzymatic cleavage by RNase Ⅲ Drosha, generating pre-miRNAs. Subsequent transport to the cytosol permits additional processing by dicer to produce double-stranded miRNAs. One strand is loaded into the silencing complex and translation is disrupted by imperfect binding of the miRNA and elements within the 3'-UTR of target transcripts[75].

miRNAs have demonstrated roles in most biological events, including proliferation, differentiation, cell-fate determination, apoptosis, and signal transduction. Disregulation of miRNAs has been implicated in a number of disease states, including cancer and fibrogenesis in a number of solid organs including liver[76]. Comparisons of miRNA expression between quiescent and activated HSCs revealed several miRNAs that may be involved in liver fibrosis and are thus attractive candidates for targeting. Expression of miR-27a and miR-27b were shown to increase during activation of rat HSCs. Inhibition of these miRNAs reverted activated HSCs back to a quiescent state that was associated with an increase in retinyl ester storage and decreased proliferation[77]. Studies by Guo *et al*[78] suggested that miR-15b and miR-16 reduce Bcl-2 and increase caspase signaling, promoting apoptosis of activated HSCs. Overexpression of miR-150 and miR-194 in human LX-2 cells (a human activated HSC line) resulted in decreased expression of α-SMA and type I collagen, possibly through inhibition of c-myb and rac 1[79].

MiRNAs that specifically target collagen production have also been identified in a variety of tissues, including liver. Accumulating evidence implicates the miR-29-

family in the regulation of type I collagen expression in several disease states[80,81]. Examination of miR-29-family members in two models of liver fibrosis revealed down-regulation of miR-29a, b, and c with associated increases in type I collagen expression. Cell-specific expression from isolated primary liver cells revealed high expression of miR-29b in HSCs, which was lost upon culture-activation[82]. *In vitro* experiments aimed to determine a mechanism revealed that TGF-β treatment downregulated miR-29b expression with a concomitant increase in type I collagen expression. Another striking observation was that miR-29a serum levels are downregulated in human fibrotic patients compared to healthy patients; the degree of fibrosis and cirrhosis correlated with the extent of miR-29a suppression, suggesting that miR-29a may be a novel serum marker of liver fibrosis in humans[82].

Small interfering RNA therapy

Small interfering RNAs (siRNA), like miRNAs, are a class of double-stranded RNA molecules 20-25 nucleotides in length that participate in the RNAi pathway and have received considerable attention as a therapeutic strategy for a variety of conditions. Several barriers exist to effective siRNA therapies in hepatic fibrosis, including targeting delivery to the intended liver cell(s) to avoid systemic consequences and overcoming the physical barriers that occur in fibrosis that limit exchange, including the loss of endothelial cell fenestration and accumulation of ECM components in the space of Disse.

Efforts to target TGF-β, the most potent pro-fibrotic cytokine, has led to the development of siRNAs that can inhibit TGF-β mRNA expression in a rat HSC cell line[83]. These siRNAs have been conjugated with galactosylated poly(ethylene glycol)(Gal-PEG) or mannose 6-phosphate poly(ethylene glycol)(M6P-PEG) and targeted to HCC (HepG2) and HSC (HSC-T6) cell lines, respectively[84]. M6P-PEG targets to HSCs *via* M6P/insulin-like growth factor-Ⅱ receptor-mediated endocytosis and Gal-PEG targets to hepatocytes *via* asialoglycoprotein receptor-mediated endocytosis[84]. Though specific targeting produced favorable results *in vitro* these strategies have yet to be validated *in vivo*.

A novel approach to deliver siRNAs against Hsp47 has recently been reported utilizing two models of liver fibrosis; CCl₄ and BDL, and a lethal model of dimethylnitrosamine (DMN)-induced cirrhosis. Investigators conjugated vitamin A to liposomes carrying siRNAs targeting gp46, a homolog of Hsp47, which rapidly resolved fibrosis and prolonged survival in DMN-induced cirrhosis[85]. Evaluation of radiolabeled vitamin A-coupled liposomes showed uptake predominantly in livers, demonstrating organ specificity. These data represent an exciting advance in siRNA-mediated treatment of fibrosis and demonstrate that targeting of collagen production, not just the underlying pathology, can be an effective anti-fibrotic strategy. However, further studies to assess the functional consequences of Hsp47 disruption need to be conducted, as the investigators revealed that Hsp47 repression stimulated collagenase activity[85].

Inhibitors of chaperone proteins

A novel approach to targeting type I collagen secretion is inhibiting the activity of one or more chaperone proteins associated with the numerous post-translational modifications procollagens undergo prior to secretion. As described in the previous section, one such approach utilized siRNA against Hsp47 to abolish fibrosis in two animal models[85]. However, systemic administration of inhibitors to collagen chaperones poses systemic risks, particularly in tissues with high normal expression of type I collagen, like skin and bone.

One such approach to prevent systemic consequences centered on the design of a pro-drug inhibitor of prolyl 4-hydroxylase, HOE 077, which would be converted to the active form by liver cytochrome P450 activity to pyridine-2,4-dicarboxylate (2,4-PDCA). Use of this drug attenuated liver fibrosis and collagen accumulation induced by CCl₄ administration[86]. However, *in vitro* mechanistic studies reported that HOE 077 prevented activation of HSCs as opposed to type I collagen production[87].

Hsp47 is an attractive target for the generation of small inhibitors, as type I collagen is the only reported target for this chaperone. Several inhibitors of Hsp47 have been reported; however, their efficacy in inhibiting collagen production by mediators of fibrosis, or in animal models, has yet to be demonstrated[88].

Matrix metalloproteinases

Regulation of the ECM is accomplished in part by a diverse family of calcium- and zinc-dependant endopeptidases called MMPs. There are 25 identified unique members of the MMPs, of which 24 are found in mammals, and they are capable of degrading a variety of matrix components. MMPs can be divided into five categories: interstitial collagenases, gelatinases, stromelysins, membrane-type collagenases, and a metalloelastase (MMP-12), although there is some overlap in function between these groups.

In liver, the main interstitial collagenases are MMP-1 in humans, and MMP-8 and MMP-13 in rodents. MMP-3 (stromelysin-1) is another interstitial collagenase expressed in liver; however, it exhibits weak proteolytic activity towards ECM components[89]. Liver fibrosis results from an imbalance between fibrinogenesis and fibrinolysis, with an increase in tissue inhibitors of metalloproteinases (TIMPs) primarily responsible for this imbalance. Four TIMPs have been identified (TIMP-1, TIMP-2, TIMP-3, and TIMP-4), each consisting of 184-194 amino acids. TIMPs inhibit MMPs by directly binding to the catalytic domain of MMPs in a 1:1 stoichiometric ratio. TIMPs have been shown to inhibit the activity of each MMP, though with varying efficiency[90]. Besides the well-established direct role of TIMPs as inhibitors of MMPs, TIMP-1 is capable of indirect inhibition of HSC apoptosis[91]. Furthermore, reduction of TIMP-1 levels is associated with increased hepatocyte proliferation *via* degradation of fibrotic ECM to permit hepatocyte expansion and liberation of ECM-bound hepatocyte growth factor[92]. Thus, therapeutic strategies to improve fibrinolysis can focus either on in-

creasing the pool of active MMPs or reducing the expression of TIMPs.

Attempts to enhance the expression of fibrinolytic MMPs have been carried out in various animal models of fibrosis. Infection with an adenovirus carrying human MMP-1 gene attenuated fibrosis with concomitant decrease in α-SMA positive cells in a rat TAA model[93]. An adenoviral delivery strategy was also utilized to stimulate human MMP-8 expression to abrogate fibrosis in rats treated with CCl4 or subjected to BDL[94].

A similar approach was taken to inhibit expression of TIMP-1 in HSCs, utilizing an siRNA against TIMP-1 packaged in an adeno-associated virus (AAV) vector. AAV vectors have the ability to infect dividing and non-dividing cells, to incorporate into the genome at a specific site (AAVS1) in human chromosome 19 for sustained expression, and are non-immunogenic[95]. TIMP-1 expression was suppressed for > 12 wk, suggesting AVV-delivered siRNA against TIMP-1 has the potential for long-term efficacy. The study also reported concomitant increases in MMP-13 expression, the rodent equivalent to MMP-1 in humans; however, the investigators did not assess MMP-13 activity by zymography and have not investigated the efficacy of this system *in vivo*[96].

MMPs and their inhibitors clearly play an important role in the development, progression, and resolution of hepatic fibrosis. However, the context of MMP and TIMP expression must be considered when developing therapeutic strategies to target their activity. In early stages of hepatic fibrosis, MMPs appear to play a deleterious role, whereas in the resolution of fibrosis, MMP activity is critical to reduce the scar and achieve restoration of the normal liver architecture. Additional work to evaluate their effectiveness in treating hepatic fibrosis should be conducted.

CONCLUSION

Liver fibrosis is a complex disease that represents a common pathology for a variety of liver insults, including ALD. Sustained fibrogenesis can be linked to an exacerbation of the wound-healing process and results in the accumulation of ECM products, which can impair oxygen and nutrient delivery, stimulate proliferation of fibrogenic cells and result in injury. To date, there are no established therapies for liver fibrosis outside removal of the causative agent. Type I collagen is the most abundant component of the extracellular scar in liver fibrosis and is an attractive target for anti-fibrotic therapies.

Therapies to limit pro-fibrotic mediators, such antioxidants to scavenge ROS, have produced promising results *in vitro* and with animal models of fibrosis; however, antioxidants have failed to consistently reduce fibrosis in human trials. This discrepancy is not understood, and therefore, attention should be made to developing new therapeutics. Regardless of the etiology, it is widely accepted that other factors (e.g. genetic and environmental) contribute to the development and progression of fibro-

sis, thus a therapeutic target directed towards the culprit of fibrosis (collagen) might be a more successful and comprehensive therapy. Attempts to reduce accumulated type I collagen through MMP-mediated fibrinolysis has generated attractive results in animal models; however, their efficacy has yet to be tested in human trials. Additionally, further work to refine targeting and delivery of MMP-based therapies needs to be performed, as non-specific delivery of MMPs could have unintended consequences in other collagen-rich tissues.

Recent work in targeted delivery of siRNAs against the collagen-specific chaperone Hsp47 represents exciting proof-of-concept therapy of tissue-directed suppression of type I collagen, potentially reducing deleterious effects of systemic type I collagen inhibition. Despite this promising finding, additional studies to determine the efficacy and safety of this approach in humans need to be conducted. Continued investigation into the molecular mechanisms of type I collagen production and secretion in fibrogenic mediators should be performed to produce new targets for anti-fibrotic therapy.

Abstract

Fibronectins are adhesive glycoproteins that can be found in tissue matrices and circulating in various fluids of the body. The variable composition of fibronectin molecules facilitates a diversity of interactions with cell surface receptors that suggest a role for these proteins beyond the structural considerations of the extracellular matrix. These interactions implicate fibronectin in the regulation of mechanisms that also determine cell behavior and activity. The two major forms, plasma fibronectin (pFn) and cellular fibronectin (cFn), exist as balanced amounts under normal physiological conditions. However, during injury and/or disease, tissue and circulating levels of cFn become disproportionately elevated. The accumulating cFn, in addition to being a consequence of prolonged tissue damage, may in fact stimulate cellular events that promote further damage. In this review, we summarize what is known regarding such interactions between fibronectin and cells that may influence the biological response to injury. We elaborate on the effects of cFn in the liver, specifically under a condition of chronic alcohol-induced injury. Studies have revealed that chronic alcohol consumption stimulates excess production of cFn by sinusoidal endothelial cells and hepatic stellate cells while impairing its clearance by other cell types resulting in the build up of this glycoprotein throughout the liver and its consequent increased availability to influence cellular activity that could promote the development of alcoholic liver disease. We describe recent findings by our laboratory that support a plausible role for cFn in the promotion of liver injury under a condition of chronic alcohol abuse and the implications of cFn stimulation on the pathogenesis of alcoholic liver disease. These findings suggest an effect of cFn in regulating cell behavior in the alcohol-injured liver that is worth further characterizing not only to gain a more comprehensive understanding of the role this reactive glycoprotein plays in the progression of injury but also for the insight further studies could provide towards the development of novel therapies for alcoholic liver disease.

INTRODUCTION

Fibronectins are ubiquitous, multifunctional, high-molecular weight glycoproteins that have been implicated in a wide array of fundamental biological processes specific to their structure and distribution in the body. These proteins have been the subject of extensive study for over 60 years yet their physiological roles remain to be completely defined. Most reports emphasize their critical participation in biological phenomena involving the modulation of components in the extracellular environment. However, there is a growing body of evidence that reveals fibronectins may also be directly involved in regulating cellular behavior, particularly in injured tissue and under pathological circumstances.

HISTORY

Two classes of fibronectin exist *in vivo*, each discovered through widely different research initiatives. Plasma fibronectin (pFn), which is found primarily as a soluble dimer circulating in various body fluids, was first identified as "cold-insoluble globulin" during post World War Ⅱ studies on the fractionation of human blood plasma[1]. Twenty-five years later, the search for tumor markers led to the discovery of cellular fibronectin (cFn) described then as the "large external transformation sensitive (LETS) protein" or "galactoprotein", and later determined to also be the "surface fibroblast antigen"[2-4]. This fibronectin is found predominantly as an insoluble, multimeric, fibrillar constituent of extracellular matrices. Separate biochemical and cell biological analyses of these two glycoprotein types drew similar conclusions that eventually led to the convergence of such studies and the realization that these molecules are, in fact, related[5-7]. The common term of "fibronectin" was agreed upon to define these similar proteins, but it was only after detailed genetic and structural analyses could be made that this similarity was truly understood[8].

During a marked collaborative period, several other research groups became aware that their glycoproteins of interest, originating from sources other than plasma and fibroblasts, resembled fibronectin in character. It was revealed that these proteins were, in fact, variants of fibronectin, as it appeared they all derive from the same complex gene. This gene consists of more than 45 distinct coding (exons) and non-coding (introns) nucleotide sequences, which can be transcribed from a single promoter into alternatively spliced messenger RNAs that account for the multiple isoforms of fibronectin found in human tissue[9-11].

STRUCTURE

Generally, the functional protein is composed of two similar, but not always identical subunits of 220 to 250 kDa that are joined by disulphide bonds at the carboxyl-termini to create the characteristic fibronectin dimer. Greater than 90% of the structure of each fibronectin monomer is

Figure 1 Domain structure and interaction sites of fibronectin. Fibronectin is a dimer comprised of two subunits which are covalently joined by two disulfide bridges near the COOH-terminus. Each subunit consists of three types of homologous structural domains called Ⅰ, Ⅱ, and Ⅲ. Recognition sequences, integrin binding sites, cryptic sites and interactive regions of the molecule are labeled.

defined by variable combinations of three different types of homologous repeating domains termed Types Ⅰ, Ⅱ and Ⅲ that are linked by short peptide segments (Figure 1)[8]. There are twelve Type Ⅰ (~40 amino acid residues) and two Type Ⅱ (~60 amino acid residues) homologous repeats in each fibronectin sequence that are individually folded to form sheets of β-strands stabilized by disulphide bonds. Type Ⅲ repeats (~90 amino acid residues) of which there are fifteen to seventeen per sequence flanked by Type Ⅰ and Type Ⅱ regions, are similarly organized into overlapping β-sheets. However, these modules lack disulphide bridges, thus have greater conformational latitude. Type Ⅰ and Type Ⅱ modules are each encoded by a single exon, while Type Ⅲ modules are coded for by 2 exons each with the exception of extra domains A and B (denoted EIIIA, EDA or EDI and EIIIB, EDB or EDII respectively) and the ninth Type Ⅲ domain (Ⅲ-9). Rather, these particular domains are each encoded by single exons of somewhat extended lengths[8-11].

Considerable molecular subunit diversity results from the complex splicing of the fibronectin primary transcript at three specific sites that code for the Type Ⅲ domains, EIIIA, EIIIB, and a region of the molecule towards the

carboxyl-terminus that links Type Ⅲ units, Ⅲ-14 and Ⅲ-15, referred to as the Type Ⅲ connecting segment (ⅢCS) or variable (V) domain[8]. Patterns of inclusion or exclusion of the sequences of these three alternatively spliced domains confer variability among species that express fibronectin[8, 11]. In fact, variations between the two biological forms of this glycoprotein are also largely attributed to differential splicing of pre-mRNA. Neither subunit of the pFn dimer contains the EIIIA and EIIIB sequences and only one of these subunits has a V-region. Alternatively, cFn contains variable proportions of all three domains[8,11]. Furthermore, the V-domain undergoes a more intricate tissue-specific splicing mechanism that results in its sequence being either entirely included or excluded, or only variable parts of it being present in the molecule. In humans, such splicing patterns generate five V-region variants. Altogether, these mechanisms can potentially produce greater than twenty human subtypes, which can be assembled to form a diverse array of fibronectin heterodimers. Such varied composition, particularly for cFn, is likely associated with a diverse array of functions.

Further structural complexity is established through post-translational modifications of the fibronectin molecule. Though both phosphorylation and sulfation have been observed, these modifications do not appear to account for significant differences among isoforms[12]. However, analyses have revealed considerable variation in the glycosylation profiles of fibronectin molecules derived from different sources[8,13]. All forms of fibronectin contain significant amounts of carbohydrate (5%-10%) that are predominantly in the form of biantennary asparagine-linked side chains that reside mostly among Type Ⅲ repeats. Some heterogeneity, with regard to the number and size of these carbohydrate side chains, is present among individual fibronectin polypeptide units. Studies have shown that domains with carbohydrate moieties are resistant to proteolysis and that glycosylation contributes to the conformational stability of the fibronectin molecule[14]. Interestingly, cFn variants have greater carbohydrate content than pFn which may serve to protect the function of cFn molecules in areas of active proteolysis and tissue remodeling where they are normally found. Additional evidence suggests that glycosylation may be involved in modulating the binding affinity of fibronectin to other matrix, as well as, cell-surface proteins[15]. Rotundo *et al*[16] revealed that the composition of the carbohydrate side chain determines whether fibronectin associates with a receptor on the surface of liver parenchymal cells that is involved in the clearance of endogenous glycoproteins from circulation. The presence of terminal galactose residues on the carbohydrate side chains of cFn make it a natural ligand for this receptor, termed the Ashwell or asialoglycoprotein receptor (ASGP-R), however, the fully sialylated chains of pFn are not recognized[16,17]. Approximately 80%-85% of the terminal carbohydrates of cFn are not capped by sialic acid[8].

Typically, the absence of sialic acid caps on its carbohydrate chains suggests that a protein is defective either as a result of normal catabolic mechanisms or pathogen induced sialidase activity[18]. These proteins may be harmful and induce a defensive response from the body if they are not rapidly removed. Perhaps cFn, as a naturally occurring desialylated glycoprotein, is intended to provoke a similar response from tissues that generate it in excess locally particularly during conditions of disease and disrepair.

FUNCTIONAL INTERACTIONS AND CHARACTER

The complex structure of fibronectins, their extensive presence in various tissues and fluids of the body, and their conserved expression across species, suggest that these molecules are important to fundamental biological processes. This is conclusively demonstrated by the lethality of *FN* gene inactivation during early murine embryonic development[19]. A greater understanding of this fundamental position can be obtained through a closer examination of its molecular architecture.

Fibronectin's functional properties are mapped by specific domains of modular repeats along the molecule itself[8,20,21]. Polypeptide regions linking these globular domains are particularly susceptible to proteolysis, thus are readily cleaved to form fibronectin fragments of defined structural and functional character. Analyses of these fragments have led to the identification of distinct interacting sites along the fibronectin molecule that provide some insight into the physiological role of this glycoprotein (Figure 1)[8,20,21].

The domain represented by the amino-terminal fragment of fibronectin is composed of type I homologous repeats that can bind to a variety of substrates including matrix heparin and cell-surface heparan sulfate proteoglycans, glycosphingolipids found in membranes of central nervous system tissues, as well as to bacteria[22]. Of particular relevance is this domain's strong affinity for fibrin, an insoluble plasma protein essential to blood clotting, to which fibronectin can be covalently stabilized *via* factor ⅩⅢa transglutaminase-catalyzed cross-linking[23]. This cross-linking mechanism can also facilitate other fibronectin interactions with asymmetric acetylcholinesterase and *Staphylococcus aureus*[24,25]. Thrombospondin, present in tissue matrices and implicated in platelet aggregation, also binds to fibronectin at its amino-terminal domain[26]. These interactions suggest the participation of fibronectin in such events as cell adhesion, blood clotting, as well as pathogen recognition and/or clearance.

Immediately adjacent to the amino-terminal domain is the highly glycosylated collagen/gelatin binding site of the fibronectin molecule[8,20,21]. Fibronectin has demonstrated variable affinity for the various types of collagen in their native forms, however, it also adheres quite effectively to the unfolded regions of the denatured collagen triple helix[27]. Under physiological conditions, it appears that Type I collagen, which is found at elevated levels in the matrices of injured tissue, is in an unfolded state thus could readily interact with fibronectin[28]. The same domain that adheres to collagen can also bind to the C1q component of the

complement system, facilitating fibronectin's involvement in the clearance of immune complexes and cellular debris during the body's defense response[29].

Situated at the carboxyl-terminal region of fibronectin is the molecule's major heparin binding domain[30]. It comprises Type Ⅲ repeats along with a variable segment that is determined by the tissue of origin. Nearest to the interchain disulphide bonds is a region consisting entirely of Type Ⅰ modules that contains the molecule's second fibrin binding site. However, this domain does not exhibit the diverse interactions of its amino-terminal counterpart and plays a more minor role in fibronectin-fibrin binding[30].

Clearly, the structure-function relationships of the terminal regions of fibronectin are well defined and reflect similar substrate affinities and functional character. Conversely, the central, more variable region of the fibronectin molecule remains more obscure. This central region is made up entirely of Type Ⅲ homologous repeats that include the alternatively spliced EIIIA and EIIIB sequences positioned between repeats 11 and 12, and 7 and 8, respectively[8-10]. The heightened susceptibility of this section of the molecule to protease activity precludes it from the extensive fragmentation analysis that has been used to characterize the amino- and carboxyl-termini. Rather, the functional character of this large area of fibronectin must be determined through alternative analytical means. Accordingly, primary sequence data analysis has revealed the presence of a plausible DNA and heparin binding site adjacent to the collagen binding domain at the amino end of the central region; while the extra domains, EIIIA and EIIIB, have been implicated in a variety of roles based largely on *in vitro* analyses of their increased presence in fibronectin, particularly, under certain conditions of injury and disease[31-34].

Unlike the isoforms found in embryonic tissue, fibronectin molecules from healthy adult tissues include very low levels of EIIIA and EIIIB[35,36]. However, the variants with EIIIA and EIIIB will re-appear in abundance during such processes as wound repair and tissue regeneration[32,37]. Elevated levels of EIIIA and EIIIB fibronectin isoforms are also present under the pathological conditions of fibrosis and tumorigenesis[32,34,38]. Studies on malignant and benign remodeling activity in bone, as well as in human gingival tissue, show an increased presence of these extra domain containing forms of fibronectin[39,40]. In addition, these variants are also considered to be important mediators of the extensive interactions between participating cells and their environment during vascular morphogenesis[31]. Apparently, the EIIIA and EIIIB domains confer a role for fibronectin molecules containing them in processes that involve elaborate tissue modification and re-organization.

Interestingly, each fibronectin splice variant appears to be expressed in a tissue- and cell-specific manner, triggered by different stimuli at variable times. These distinctions have been demonstrated in studies on bone fracture repair that reveal a diffused expression pattern for EIIIA-containing fibronectin throughout the connective tissue that accumulates in the fracture gap during the granulation phase of healing, while the EIIIB-containing isoform remains localized in osteoblastic cells at the periphery of the newly differentiating tissue. Similarly, during the early stages of hepatic fibrosis, sinusoidal cells are the predominant source of EIIIA enriched fibronectin, which may be involved in the activation of hepatic stellate cells that subsequently produce the EIIIB inclusive fibronectin protein[32]. Additional evidence of such temporally and spatially distinct functions for EIIIA and EIIIB fibronectin splice variants can also be found in studies on chondrogenesis, renal fibrosis and various forms of lung cancer[41-43]. These observations suggest that the expression and function of fibronectin molecules with EIIIA and EIIIB segments may be regulated by specifically coordinated independent mechanisms that facilitate the transformative systems in various adult tissues.

More defined roles for the EIIIA and EIIIB domains have been identified in such events as matrix assembly, cell adhesion, migration and differentiation, as well as in cell cycle progression and mitogenic signal transduction, which are all relevant for tissue alteration, proliferation and development[42-45]. According to these *in vitro* studies both the EIIIA and the EIIIB domains appear to have equally essential, though different, roles in the aforementioned processes.

However, recent studies using genetically engineered mice seem to suggest a more critical function for EIIIA than EIIIB *in vivo*. Strains incapable of expressing EIIIA-containing fibronectin proteins have significantly shorter lifespans than their control counterparts[46]. Though these EIIIA knock-out mice exhibit wound healing defects, altered behavior and impaired motor coordination, they also develop fewer and smaller atherosclerotic lesions and appear to be protected from progressive fibrosis after bleomycin-induced lung tissue damage[34,46-48]. However, the *in vivo* function of the EIIIB domain remains obscure. No distinct phenotype has been observed in EIIIB knock-out mouse models aside from the impaired ability of extracted fibroblasts to form a significant pericellular matrix[44,49]. Nevertheless, this domain is highly conserved among vertebrates, thus it must have some biological importance. Perhaps the EIIIB domain plays a compensatory role in the absence of EIIIA during certain developmental processes, as mice devoid of EIIIA grow normally while the EIIIA and EIIIB double knock-out mice have lethal defects[19,46]. The EIIIB domain may have a significant function during the body's response to stress brought on by injury and disease, as these are the conditions under which the extra domain-inclusive fibronectin isoforms are upregulated.

Located in the tenth Type Ⅲ module (Ⅲ-10), on an exposed loop in the central region of the fibronectin molecule is a three-amino acid consensus sequence, Arg-Gly-Asp (RGD), that has been identified as the main site of cellular attachment to fibronectin[8,50]. Adjacent to this site, in the ninth Type Ⅲ module (Ⅲ-9) exists a Pro-His-Ser-Arg-Asn (PHSRN) sequence that acts synergistically to enhance the binding affinity of cells to the Ⅲ-10 RGD sequence[51]. These repeats, critical to cell-fibronectin con-

tact, lie in a region between the two alternatively spliced EIIIA and EIIIB domains. Several studies suggest that the inclusion or exclusion of these extra domains may affect the conformation of the fibronectin molecule in that region which, in turn, determines the interactions of the RGD and PHSRN sites with specific receptors on the surfaces of nearby cells[52,53]. These interactions can trigger a cascade of distinct intracellular signals that translate into a multitude of different responses.

The receptors largely responsible for mediating these fibronectin-induced effects belong to a family of heterodimeric transmembrane glycoprotein complexes known as integrins[54]. Each integrin is comprised of two non-covalently associated α- and β-subunits that link the fibronectin-rich extracellular matrix with the cytoskeleton of the cell[55]. Structural studies have revealed that residues along the fibronectin molecule, external to specific integrin binding sites, play a critical role in optimizing the specificity and stability of this receptor-ligand assemblage[56]. Moreover, binding affinity is determined not only by the external configuration of the fibronectin ligand, but also by internal mechanisms that modulate the condition of the receptors themselves. Certain intracellular events can affect the association of the integrin α and β cytoplasmic tails, thus also, the activation state and the affinity of the receptor for specific ligands[57]. As such, integrins can function both as sensors (inside-out signaling) determining the presence of fibronectin, then mediating cell attachment and matrix assembly; and upon ligation with fibronectin, they can function as effectors (outside-in signaling) promoting ligand-induced biochemical processes[58].

To date, a dozen members of the integrin family have been shown to interact with fibronectin[50,59]. Not surprisingly, the major cell-binding III-10 RGD sequence on the fibronectin molecule is a key integrin-recognition motif and critical binding site for several of these cell surface receptors[8,50]. Of these integrin heterodimers, the prototype fibronectin receptor, α5β1, binds with greatest specificity. It is widely expressed, and likely serves as the major mediator of fibronectin-cell interactions in most tissues. Binding of α5β1 to the RGD motif is optimized through its association with the PHSRN synergy sequence on the adjacent III-9 repeat[51]. This sequence is also recognized by the platelet integrin αIIbβ3[60].

Other regions of fibronectin, besides repeats III-9 and III-10, have also been reported to interact with integrins. The α5β1 receptor exhibits a low affinity attachment to the N-terminal region of fibronectin, specifically to an Asn-Gly-Arg (NGR) sequence in the fifth Type I module (I-5) that has been converted through deamidation and isomerization to an isoAsp-Gly-Arg (isoDGR) sequence[61]. Though deamidated proteins typically undergo loss of function, this modification on the fibronectin molecule may bring about a gain of function. Studies have shown that the isoDGR sequence is also a high affinity binding site for the αvβ3 integrin, which is involved in regulating endothelial adhesion and blood vessel formation[61]. Protein deamidation is also linked to aggregate formation through a process resembling matrix assembly, thus the

isoDGR sequence may be involved in fibronectin fibrillogenesis[62]. Tissue accumulation of proteins with atypical aspartyl residues is often observed during injury and disease[63,64]. Though unconfirmed, it seems likely that the prevalent form of fibronectin under such conditions would also contain a modified I-5 repeat.

Alternative splicing of the fibronectin primary transcript results in the production of structurally diverse molecules with very specific configurations and binding capabilities. The arrangement of alternatively spliced domains determines the level of exposure and accessibility of binding sites in involved regions of the protein[52,53,65]. However, the existence of internal integrin recognition sequences suggests that, in addition to structural considerations, these domains can also directly influence fibronectin's effect on cell behavior. The alternatively spliced Type III connecting segment (IIICS) of the fibronectin carboxyl-terminal region contains two active binding sequences, Leu-Asp-Val (LDV, residues 1-25) and Arg-Glu-Asp-Val (REDV, residues 90-109), that interact with the leukocyte integrin receptors, α4β1 and α4β7[66-68]. The sequence, Glu-Asp-Gly-Ile-His-Glu-Leu (EDGIHEL) in the EIIIA domain is recognized by integrins α9β1 and α4β1 during cell adhesion and wound healing[69]. Structural analyses have revealed the presence of a conserved Ala-Gly-Glu-Gly-Ile-Pro (AGEGIP) sequence on the EIIIB beta strand CC' loop (links beta strands C and C') that is part of an acidic groove created by the interface of the EIIIB domain with the adjacent eighth type III module (III-8)[52]. However, the specific binding partners for this site are yet to be identified. It is apparent that each variation in the splicing pattern of these alternate domains would produce distinct combinations of binding sites that would have a differential influence on cell behavior when engaged by the appropriate receptor.

Proteoglycan receptors, such as the integral membrane syndecan-1, -2 and -4, as well as, glycosyl-phosphatidylinositol (GPI)-anchored proteoglycans such as glypican-1, have been linked to the fibronectin mediated processes of cell adhesion, cytoskeletal organization and matrix assembly[70,71]. These proteins can link directly to fibronectin through their covalently attached flexible glycosaminoglycan (GAG) chains of heparan sulfate (HS) or chondroitin sulfate (CS). Although proteoglycans are capable of affecting cell behavior directly by independently engaging relevant intracellular pathways, most reports suggest that these receptors are more likely to be involved in complementary functions that support the activities of other fibronectin receptors, specifically integrins, that are considered to have a more significant role in certain cellular events[72,73]. The spatial arrangement of the respective binding sites for each receptor along the fibronectin molecule facilitates their cooperative regulation of the adhesive functions of the cell that influence movement and morphology, as well as, pericellular fibronectin fibril assembly[72-75]. Alternatively, the proximity of these binding sites could also allow for direct regulatory interactions between the different receptors themselves. Additional receptor collaboration may involve the strategic recruitment of distant fibronectin molecules, detected by the extended ectodo-

mains of the proteoglycan receptors, for closer positioning to the cell surface where more efficient integrin binding can occur. Cooperative mechanisms may also include the transduction of signals by activated proteoglycans to effect an appropriate distribution of integrins and influence their consequent function. A synergistic convergence of such signals could occur, which would reinforce a particular effect, as illustrated by the fibronectin-induced activation of both α5β1 and syndecan-4 to promote cell adhesion and matrix contraction in the unstable environment of a wound during tissue repair[73]. Evidently, the functional regulation of fibronectin-mediated cellular processes entails some degree of coordinated activity between participating proteoglycan and integrin receptors, however, the actual mechanisms behind these interactions remain obscure.

Considering the number of receptors from the integrin family itself, that are reported to interact with fibronectin and the diversity of such interactions, it is expected that cross-regulation between activated integrins must also occur to ensure appropriate receptor cooperation or antagonism. Examination of the complex sequence of events that lead to the directional migration of a cell along a fibronectin fibrillar matrix, has revealed a pattern of spatially and temporally-regulated binding and alternate signaling by the α5β1 and αvβ3 integrin receptors, both of which recognize the same fibronectin domain[76]. Though not considered to be a fibronectin-specific receptor under normal conditions due to its indiscriminate adhesion to a variety of ECM molecules, the neutrophil receptor, αMβ2, during the cellular response to inflammation, binds with greater than normal avidity to fibronectin to effectively hinder directed migration[77]. Coordinated communication between α5β1 that facilitates chemotaxis, and αMβ2 must take place to ensure the effective translocation of the neutrophil to the site of injury where its presence is secured by additional interactions between αMβ2 and the fibronectin-enriched matrix so that it may effect the appropriate defensive response. The adhesive properties of the cell are further enhanced by the collaborative signaling of α5β1 and α4β1, each of which binds to different sites along the fibronectin molecule and interacts differentially with the provisional matrix that forms with granulation tissue during wound healing and repair[73]. Clearly, effective regulation of these fibronectin-integrin mediated physiological processes involves some coordinated crosstalk between the respective signaling pathways.

Each event induced by a particular set or sequence of interactions with fibronectin is not only dependent upon cooperative receptor activity but also upon synchronous availability and accessibility of respective ligand binding sites. When fibronectin is first secreted into the interstitial space of tissues, it exists as a soluble dimer whose compact form, stabilized by intramolecular forces, conceals many of these ligand binding sites and regions of significant adhesive character[78]. Though this closed conformation under physiological conditions is programmed by fibronectin's inherent structure, environmental factors can effect changes to its shape that expose these otherwise embedded sites, to potential binding partners[79]. It

is thought that upon ligation to integrins and other cell surface receptors, particularly α5β1, which recognizes the already accessible RGD loop, a cooperative unfolding and elongation of the respective arms of the dimer is initiated which then expose these sites to binding by key receptors involved in fibronectin fibrillogenesis[80]. Gradual extension of this originally tightly-folded molecule is largely attributed to cell-traction forces that are induced by cytoskeleton-dependent events and transmitted through adherent receptors[81,82]. The globular structure of individual Type III modules is disrupted, revealing intradomain binding sites that readily interact with their counterparts on other dissociated fibronectin molecules to launch progressive self-association that can lead to fibrillar matrix assembly[83,84]. These uncharacterized hidden or cryptic sites, as they are termed, are only activated when exposed by conformational changes that counter the native configuration of fibronectin. This suggests that these sites are involved in functional interactions, other than self recognition, particular to modifications in the extracellular environment that challenge normal physiological conditions.

As previously mentioned, the native fibronectin molecule is vulnerable to proteolysis, particularly along the unfolded polypeptide links between the compact domains. Cell-derived tensile forces increase the incidence of unfolding, thus create more unprotected regions that can be acted upon by endogenous proteases. Fibronectin is a known substrate of numerous different proteases, particularly the aggrecanases such as ADAM (A Disintegrin And Metalloproteinase)-8 and ADAM-TS (with Thrombospondin Motifs)-4, as well as matrix metalloproteases (MMPs) such as the gelatinases, MMP-2 and -9, the metalloelastase, MMP-12 and the membrane-type (MT)1-MMP. Interestingly, studies reveal that fibronectin itself induces the release and activity of several of these proteases, likely as a homeostatic response during ECM maintenance, that is regulated in part by its association with integrins and membrane-anchored MMPs[85,86]. Ongoing studies have revealed the presence of numerous specific cleavage sites or neoepitopes along the molecule that suggests the proteolytic degradation of fibronectin is not an arbitrary process and may have some functional value[87]. Random mechanical fragmentation, however, does also occur, especially among the less resilient Type I and Type II domains that have more restricted conformations.

The fibronectin fragments that result from these proteolytic events would have distinct folding patterns from their intact forms on the native molecule, therefore variably exposed binding sites. These peptides are, consequently, able to interface with dissimilar binding partners than the intact molecule thus they may act quite differently. In fact, certain fibronectin fragments have been associated with bioactivities that are quite disparate from those of the parent molecule and likely serve a regulatory role[73]. Many studies report a similar competence between fragments and native fibronectin to modulate protease activity, while other reports reveal that such proteolytic potential exists in the fibronectin fragments themselves[88,89]. These fibro-

nectin-derived proteases or fibronectinases are capable of autodigestion but otherwise remain cryptic in nature, as no associated physiological role nor other mechanism has yet been identified. Other fragments can exhibit chemotactic activity, promote apoptosis, regulate anabolic and catabolic processes or induce the release of nitric oxide and cytokines[90-92]. Analyses of these fibronectin fragments and their specific functions can reveal distinct interactions that may provide further insight into the physiological role of the native protein itself. Studies of endogenous fragments that contain the EIIIA domain, for example, have revealed a unique interaction with Toll-like receptor (TLR)-4 that stimulates the release of proinflammatory cytokines[92]. These data suggest that fibronectin isoforms containing this alternatively-spliced domain may have a role in the physiological response to inflammation in injured tissue.

Fibronectin also adheres to a variety of different signaling molecules and regulates their distribution and access to other binding partners and cells[93,94]. Tumor necrosis factor (TNF)-α, upon release from activated cells at the site of inflammation, can complex with the amino terminal domains of fibronectin in the surrounding matrix[93]. This interaction confines this proinflammatory cytokine near to its source thus ensuring its availability to further stimulate cells in the region to release proteases as part of the defense response[95]. Fibronectin may also be involved in presenting a growth factor to its cognate receptor in a manner that will enhance a desired physiological effect. This is demonstrated when hepatocyte growth factor (HGF) or vascular endothelial growth factor (VEGF) attaches to fibronectin with a specific juxtapositioning that promotes the coordinated interaction and costimulation of the respective growth factor receptor and the fibronectin-binding α5β1 integrin, to amplify the proliferation and migration of endothelial cells[94]. Though fibronectin does not interact directly with transforming growth factor (TGF)-β, but with the latent TGF-β binding proteins (LT-BPs) to which the TGF-β-confined small latent complex (SLC) is covalently bound, it is able to sequester TGF-β, and regulate its activation by proteases and matrix remodeling forces[96,97].

The detection of additional binding partners is ongoing, as is the recognition, with each associated function, that fibronectin is more than a mere component of biological scaffolds and conduits of cellular activity. It is a repository for both intrinsic ligands that can be proteolytically transformed into soluble signaling peptides, and extrinsic ligands that can be regulated through complex formation. Moreover, its pliable constitution hints at mechanotransducing capabilities. This glycoprotein has the potential to affect cell behavior in a myriad of different ways.

SIGNALING PROCESSES

The mechanisms by which fibronectin may affect signaling events, as indicated by the diversity in its interactions, are expected to be quite involved (Figure 2). The initiating influence on cell behavior may be conceived when the soluble fibronectin molecule is ligated by a cognate

receptor, likely an integrin heterodimer, and activates the first recognition-dependent sequence of molecular signals within the cell. Cytoskeletal restructuring and the consequent stimulation of certain intracellular complexes promote cell contractility which causes conformational changes in the attached molecule[80]. Intramolecular dissociation ensues and the compact dimer unfolds to expose additional binding sites and recognition sequences, which upon engagement, can trigger simultaneous cascades of signals that further influence cell behavior. Fibronectin self-association between attached and extended molecules, modulated again by cellular events such as receptor clustering, takes place to form an adhesive template upon which additional fibronectin molecules can also unfold. The progressive layering and interweaving of these elongated and stretched out fibronectin fibrils eventually results in the formation of a connective web between neighboring cells. Other matricellular components, recognizable to fibronectin can also be incorporated into this structure. The diversity and distribution of these elements can affect the character and signaling propensity of this fibronectin matrix that may now behave as a cohesive unit or solid-phase ligand. Nevertheless, individual interactions can impose changes to matrix ligand architecture that may create a flow of signals through interconnected molecules. Mechanical stress brought about by such extracellular perturbations can also alter the connectivity between ligand and receptor, and change the composition of signals being relayed[98]. Mechanotransduction is further regulated by the composition and density of this matrix ligand. A dense and correspondingly rigid matrix creates more exogenous tension which can affect such cellular activity as spreading and directed motility[99]. Protease release is also up-regulated in response to matrix rigidity. The resulting cleavage of fibronectin fibrils produces fragments with signaling properties that differ from the intact molecule. New interactions are formed that stimulate a different array of signal transduction pathways to evoke a differential cellular response. Other molecules, whose association with fibronectin have been compromised by proteolytic remodeling, are now also accessible to responsive cells[100]. All of these mechanisms by which fibronectin may influence cell behavior comprise a dynamic system that has complex spatially and temporally regulated components. Signaling pathways, though individually engaged, are part of a collective communication network between fibronectin and the cell.

Most of these pathways are thought to be driven by integrin-mediated signaling processes. Focal adhesion, stress fiber formation, and cell translocation are determined by integrin recruitment of focal adhesion kinases (FAK) with subsequent activation of the phosphatidylinositol 3-kinase (PI3K) signal transduction pathways[101,102]. However, recent studies have also implicated other receptors and associated pathways in the regulation of these events. It has been shown that cell adhesion and migration, as well as cytoskeleton reorganization are also determined by syndecan-2 and -4 mediate mechanisms that involve protein kinase C

Figure 2 Model for signaling processes mediated by fibronectin. A: Initial signals are mediated when soluble compact cellular fibronectin (cFn) binds a cognate receptor; B: This causes cFn to unfold and interact with other receptors inducing further signals; C: Receptor clustering and the formation of signaling complexes lead to the reorganization of the actin cytoskeleton which creates tensile forces, conveyed through the integrin receptors to further stretch cFn into fibrillar form. Exposed cryptic sites interact with other cFn fibrils in matrix assembly. Access to growth factors and other molecules is regulated by cFn binding. Heparan sulfate proteoglycans also bind to cFn and recruit distant molecules closer to the cell surface; D: All of these interactions create a cascade of different signals, some of which promote matrix protease release. Resulting cFn fragments activate additional intracellular signaling pathways. Thus, cFn can regulate cell behavior *via* numerous different mechanisms.

(PKC)-dependent activation of the small GTPase molecules, Rac, Cdc42 and Rho[71,72,103]. Fibronectin-induced

cell survival and proliferation are also regulated *via* the integrin-mediated FAK/PI3K pathway[104]. Other coordinat-

ed signals originating from a different set of fibronectin receptors may exist but have yet to be identified. Studies suggest that cytokine release and protease production that result from nuclear factor (NF)-κB activation or mitogen-activated protein kinases (MAPKs) signaling may also be mediated by toll-like receptors (TLRs) and MT-MMPs in addition to integrins, however, this needs to be further clarified[92,105]. Continued examination of the numerous interactions between fibronectin and cells, may reveal the identity of additional pathways and signaling mechanisms which would further our understanding of this multifaceted protein in its regulation of various cellular processes.

Clearly, the involvement of multiple ligand-receptor systems in fibronectin signaling requires intricate regulation and the appropriate integration of respective pathways to ensure optimal cellular activity. This elaborate network calls attention to the important role this glycoprotein plays in numerous biological processes. Disruption of these coordinated events could certainly have severe and deleterious consequences.

ROLE IN DISEASE

The aforementioned interactions and associated functions can generally be ascribed to both classes of fibronectin except where the alternatively spliced EIIIA and EIIIB domains are involved, as only the cellular forms of fibronectin contain these extra structures. Both pFn and cFn are secreted by cells as soluble globular proteins. Hepatocytes are the primary source of pFn, which is readily secreted into the bloodstream for distribution throughout the body. Cellular fibronectin, however, is produced locally in tissues, predominantly by resident fibroblasts and endothelial cells, to be deposited in the pericellular matrix. Nevertheless, it can also be taken up into the circulation. Conventionally, cFn is thought to be the main form of fibronectin found in the extracellular matrix of tissues, however, recent studies have determined that an almost equivalent fraction of matrix fibronectin is plasma-derived[106]. It appears that under normal physiological conditions, there is a balance of both types of fibronectin in intact tissues. It is not surprising then, to discover that unusually elevated levels of cFn are indicative of some underlying disturbance in the tissue of origin, which could very well have some pathological consequence.

Cellular fibronectin plays a critical role in tissue-specific morphogenesis and cellular differentiation during embryonic development[19]. These events recur in adult tissues during conditions that require regeneration or repair. Therefore, the accumulation of cFn at sites of injury and tissue perturbation where morphogenetic processes are again active is normal. Studies show that cFn regulates cell migration in damaged tissue, where it also stimulates fibroblast transitioning to its activated phenotype[73,107]. Other reports highlight the chemotactic activity of cFn and its regulation of growth factors during active wound repair[108]. Particularly convincing are data from knockout animal studies that reveal defective wound healing in cFn-deficient mice[46]. Clearly, this isoform is essential to the processes

of tissue repair. Therefore, conditions involving any form of tissue damage would be marked by an increase in cFn production and release, particularly by cells near the site of injury. Under normal regulation, these events would culminate in the restoration of tissue function and integrity and a reduction in cFn to physiological levels.

However, under certain circumstances cFn levels remain elevated. Fibronectin-mediated cellular activity persists and may even be amplified. Otherwise uninvolved or down-regulated signaling mechanisms, eventually, become activated. Accordingly, cellular behavior adjusts and the maintenance of normal physiological processes changes to the promotion of pathological ones.

A prominent feature of many disorders associated with elevated levels of cFn is the persistent production and deposition of extracellular matrix proteins in affected tissue. This build-up of scar tissue may have started innocently, as a regulated wound healing response to chronic injury. However, it eventually becomes a fibroproliferative process that progressively destroys tissue integrity. Such fibrotic damage has been observed in many organ systems, particularly hepatic, pulmonary and renal systems[109-111]. Though it has been suggested that fibrosis may be reversible, most conditions do not improve but gradually progress to organ failure.

The pathological implications of cFn accumulation are considerably complex and widespread, reflecting the multifunctional capacity of this protein to influence cell behavior. The effects of cFn manifest in a tissue specific manner that may be exacerbated by other underlying factors unique to each disorder. For example, the cFn-induced fibrotic response may be complicated by factors involving the source of chronic injury. These parallel yet interdependent effects need to be recognized in order to achieve a deeper understanding of the molecular basis for these conditions and the specific role that cFn may play in their progression.

ROLE IN LIVER DISEASE

In the normal liver, the most abundant matrix protein is plasma fibronectin. This is not surprising, considering it is originally synthesized by hepatocytes. It can be detected in the subendothelial space of Disse where it comprises a major part of the low-density matrix that connects hepatocytes with the endothelial cells that line the sinusoids[112]. Cellular fibronectin, however, is present at very low levels throughout the liver. It is localized primarily in the pericellular matrix that surrounds the cells but also exists as bundles connected to the microvilli of hepatocytes in the space of Disse[113].

Naturally, most studies on fibronectin that reference the liver focus on the plasma isoform and of these, only a small percentage deal with disease. Most of those reports deal with the effects of hepatic insufficiency on pFn production and physiological function. Very few address a potential role for fibronectin itself in the incidence of liver damage that creates conditions of insufficiency. Such liver damage may result from a range of potential pathogenic

mechanisms accounted for by autoimmune diseases (autoimmune hepatitis), genetic disorders (Alagille syndrome, alpha-1 antitrypsin deficiency, hemachromatosis, Wilson's disease), viral infection (hepatitis A, hepatitis B, hepatitis C), disorders of uncertain etiology (cancer, primary sclerosing cholangitis, non-alcoholic fatty liver disease) and those attributed to systemic disease (Reye's syndrome, Budd-Chiari syndrome) and toxic insult (alcoholic liver disease).

Many of these conditions have acute and chronic presentation. Under conditions of acute liver damage, wound healing would not be a prolonged process. It would entail a quick remodeling of the ECM to create a cFn-rich provisional matrix, which would be involved in modulating repair activity to restore liver integrity. The onset of this response would be marked by a sudden surge in fibronectin production, which would just as suddenly diminish once the repair is complete. However, under conditions of chronic liver damage, wound healing would no longer be a finite process. The initial surge in cFn production may likely persist.

Accordingly, studies concerning such conditions of sustained and chronic liver damage report a considerable increase in patient blood plasma levels of cFn[114]. Immunohistochemical and RT-PCR analyses also reveal elevated amounts of cFn and its mRNA in the tissue of diseased livers[115,116]. These findings confirm that cFn production does persist as a likely response to mechanisms perpetuating liver injury under such conditions of chronic disease. The only role cFn has been considered to have in the course of these events is as an indicator of the onset of progressive damage. As such, it has potential utility as a biomarker for chronic liver disease.

Currently, a liver biopsy is the only means by which clinicians can accurately determine the extent of liver damage in patients suffering from chronic disease. However, it is an invasive, painful and inherently risky procedure that does not always provide information that would lead to significant alterations in treatment, especially if severe liver damage was already a concern[117]. Therefore, the development of additional biomarker tests that could reduce the prevalence of unnecessary biopsies is of great interest. Much consideration has been given towards developing a means to incorporate cFn as a marker in this system. However, elevated levels of cFn are not specific to hepatic injury, as similar concentrations have also been detected in the plasma of patients with no known hepatic pathologies, but who suffer from some other tissue-related chronic disease[114]. This lack of specificity diminishes the utility of cFn as a diagnostic indicator of liver disease. Nevertheless, increasing cFn levels remain a reliable indicator of sustained tissue damage. Perhaps tests for cFn could be incorporated in a panel that includes tests for the more specific markers of hepatic damage, alanine aminotransferase (ALT) and gamma glutamyl transpeptidase (GGT), thus providing a means to determine whether a detected increase in cFn levels is, in fact, related to liver disease[118]. A ratio of ALT or GGT levels to cFn could also be instructive.

These efforts to determine a clinical application for cFn have led to further investigations of the pathophysiological events in chronic liver disease that result in its upregulated levels. It was previously believed that such upregulation was a response to injury and had no relevance to the progression of disease itself. However, recent studies suggest that cFn may participate in, and may even promote, the progression of injury that marks these chronic conditions.

Chronic injury of the liver may initially manifest as altered lipid metabolism that leads to the accumulation of fat deposits in hepatic cells. There is no evidence to date to suggest any cFn involvement in this process. However, as the injury persists, an inflammatory response is induced that could involve cFn-regulated wound healing activity. Studies that currently report a regulatory role for cFn during inflammation in the liver address acute rather than chronic injury conditions. Although studies from other systems suggest that cFn does affect the behavior of immune and inflammatory cells, thus may also be a potent mediator of the inflammatory response to chronic injury, further investigation is still required to confirm such a role for cFn in chronic liver disease[119,120].

In response to injury, hepatic sinusoidal endothelial cells (SECs) become activated and increase their production of cFn[32]. It has been suggested that this event occurs in the very early stages of damage, and could, in fact, be among the initial reactions to the detection of harmful stimuli. For example, the hepatitis B virus x antigen (HbxAg) has been shown to activate fibronectin gene expression in liver cells *via* an NF-κB-dependent mechanism[121]. The direct detection of HbxAg by SECs could, therefore, be an initiating event in the progression of hepatitis B-induced liver injury. The resulting upsurge in cFn production dramatically increases the total concentration of cFn in the liver to a level that is several-fold above normal[32].

Of particular interest, Jarnagin *et al*[32] showed that greater than 80% of the cFn produced by SECs during injury, 12-24 h after stimulation, contain the alternatively spliced EIIIA domain. As mentioned earlier in this text, the fibronectin EIIIA domain has been implicated in cell adhesion and pro-inflammatory cytokine production through its interaction with cell surface receptors, α9β1 and α4β1 integrins, and TLR-4[69,92]. Moreover, studies have also shown that cFn activates α5β1 signaling *via* the RGD motif in its major cell binding domain to upregulate the production of MMPs. These MMPs are involved in ECM remodeling events that can also produce cFn fragments, which can further stimulate cell behavior. Thus, it would not be too bold to suggest that cFn may be involved in regulating many of the cellular responses to injury in the liver.

In fact, activation of hepatic stellate cells (HSCs) during injury is mediated by cFn[32]. Studies reveal that HSCs will transition to their myofibroblastic phenotype *via* a TGF-β1 regulated mechanism induced by EIIIA cFn[122]. Further studies show that TGF-β1 up-regulates the expression of the fibronectin receptor, α5β1 in HSCs, making them more responsive to cFn thus reinforcing its effect[123].

Once activated, HSCs are involved in mediating most

of the ECM remodeling activity that leads to fibrotic damage in the liver. These cells are also the major source of matrix protein constituents in connective scar tissue that manifests during disease progression. HSCs also produce cFn in continually increasing amounts, but of a different composition than the cFn secreted by SECs. The cFn secreted by HSCs is also predominantly of the EIIIA variety, constituting 42% of the total, 7 d post-activation[32]. However, there is also a significant increase in the relative amount of cFn produced that contains the EIIIB domain (9% of the total after 7 d). The physiological significance of this increase in EIIIB variant levels and the regulatory relevance of timing its production during the advanced stages of chronic hepatic injury, are yet to be determined.

Each form of chronic liver disease may present with variable distinction between the stages of injury; however, should the incidence of damage continue along this general trajectory, fibrotic scarring will totally compromise organ function. Without a transplant, death is certain. It has become apparent that cFn has a functional role in this progression of liver injury, thus may warrant greater attention for its pathogenic nature than for any biomarker potential.

ALCOHOLIC LIVER DISEASE

As the body's major detoxifying organ, the liver is the primary site of alcohol metabolism, and is particularly susceptible to the detrimental effects of alcohol abuse. Though the association between liver injury and the excessive consumption of alcohol was established over 200 years ago, we are still unable to fully understand how such damage occurs, nor have we developed any thoroughly effective strategies to counter the progression of alcoholic liver disease (ALD).

ALD initially manifests as fatty liver (steatosis), a reversible condition characterized by increased fat deposition in the liver cells, which leads to hepatomegaly (enlarged liver) and can progress to alcoholic hepatitis, a more serious condition marked by inflammatory changes. Persistent damage prompts the development of scar tissue (fibrosis), which will eventually replace the functional tissue of the liver resulting in alcoholic cirrhosis, hepatic failure and death.

Evidence suggests that alcohol itself and its metabolites are direct hepatoxins that stimulate changes in the cells of the liver which result in a cascade of responses culminating in tissue damage[124-129]. The toxicity of alcohol is linked to its oxidation which is catalyzed mainly by the multi-variant cytosolic enzyme, alcohol dehydrogenase (ADH), to produce acetaldehyde, which is further processed in mitochondria to form acetate, most of which escapes to the blood[126,130]. Acetaldehyde binds reactive amino acid residues in proteins to form acetaldehyde-protein adducts which can impair secretion and enzymatic activity[128]. As the level of alcohol increases with ongoing consumption, microsomal enzymes, predominantly cytochrome p450 isozymes, as well as peroxisomal cata-

lase (minor pathway), become involved in metabolizing alcohol with the additional creation of reactive oxygen species (ROS) and hydroxyl radicals that provoke lipid peroxidation events and the release of further harmful metabolites[131,132].

The conversion of alcohol involves the reduction of a co-enzyme intermediate, nicotinamide adenine dinucleotide (NAD^+) to generate NADH which increases the $NADH/NAD^+$ ratio and redox state within cells. A highly reduced intracellular environment sustained by persistent metabolism of alcohol will greatly impair the cell's ability to function normally. Under these conditions, hepatic cells are rendered more vulnerable to damage from the reactive metabolites of alcohol whose concentrations are correspondingly increased[124,127-129].

Typically, these cells would respond to the increasing levels of such harmful byproducts by releasing factors that stimulate mechanisms of tissue defense and repair. However, such mechanisms are impaired in liver tissue that has been subject to prolonged insult by alcohol. Rather than countering the progression of injury, the cellular response reinforces it.

For example, SECs respond to increasing levels of harmful adduct modified proteins formed during alcohol metabolism by up-regulating their output of the EIIIA variant of cFn that is involved in tissue repair[132]. Under a condition of chronic alcohol metabolism, this process will persist, resulting in an elevation in the levels of cFn in the liver. Restoration of homeostatic levels of this glycoprotein will usually occur towards the end of a wound healing response to injury. In the liver, this turnover of cFn is mediated, in part, by the hepatocyte specific ASGP-R[17]. However, studies have shown that the cellular processes of this receptor, particularly those that involve protein trafficking, are particularly susceptible to the effects of alcohol[133-135]. Several alcohol-induced alterations in ASGP-R activity have been identified that contribute to impaired receptor-mediated uptake of its ligands[136,137], which could include cFn. This coupling of persistent production with ineffectual clearance would lead to a build-up of cFn in the alcohol-injured liver. This has been demonstrated in studies using a rat model of alcohol consumption. Significantly elevated levels of cFn were detected in the livers of animals subject to prolonged alcohol administration which correlated with the inability of the hepatocytes from these animals to adequately internalize and degrade cFn[138,139]. Though these observations have not yet been corroborated in human liver tissue, a blood plasma study found elevated levels of cFn in patients suffering from alcoholic cirrhosis which suggests that the hepatic levels of cFn were also high[114].

The functional character of cFn suggests that its accumulation would exacerbate the deleterious effects of sustained alcohol abuse on the liver. A clearer understanding of how this reactive glycoprotein influences the cellular events that promote injury may reveal new targets for the development of effective treatments for ALD.

To this purpose our lab employed a rat model that is

extensively used in alcohol research. Male Wistar rats were pair-fed a nutritionally adequate Lieber-DeCarli liquid diet that contained 6.4% alcohol by volume as 36% of total calories or an isocaloric control diet. Animals maintained on this diet exhibit morning (i.e. 9 am CST) blood alcohol levels of 100 to 150 mg/dL (21.7 to 32.6 mmol/L)[140]. These concentrations correspond to levels found among chronic drinkers in the human population. After twelve weeks of feeding, 60% more cFn was detected in livers of the alcohol-fed animals than from pair-fed controls. Furthermore, we found that the hepatocytes from these alcohol-fed animals exhibited a diminished capacity to degrade cFn that correlates with its accumulation. As the purpose of this study was to ascertain whether cFn contributes to the development of advanced liver injury, animals were fed for a shorter duration of 4-6 wk, sufficient for the development of the early stages of alcoholic liver injury but not prolonged enough for substantial cFn accumulation to have already taken place[138,139]. Moreover, the Lieber-DeCarli rodent model rarely ever sustains injury beyond fatty liver, thus it is an appropriate system to investigate whether cFn could provoke further inflammation and/or a fibrotic response when added exogenously to cultured cells isolated from the livers of alcohol-fed animals.

The pro-fibrogenic propensity of cFn has largely been attributed to its observed effects on HSC activation and proliferation[32]. Moreover, studies have shown that fibronectin fibrils have a particular affinity for collagen Type I molecules that are synthesized by activated HSCs and are major constituents of the connective tissue that forms during fibrosis. Formation of the matrix during the fibrotic response to injury requires a stable ECM layer of cFn[141]. These reports imply that the build-up of cFn in the liver of chronic consumers of alcohol would be sufficient to initiate fibrotic damage.

However, cFn has also been implicated in the recruitment and activation of other cell types besides HSCs during the wound healing response. These cells may be involved in the pro-inflammatory activity that precedes HSC activation and may even prime the conditions in the liver for an HSC response. Kupffer cells (KCs), as the resident macrophages of the liver, are the primary mediators of such inflammatory activity in response to alcohol-induced injury that occurs during the early onset of damage. Anchored at strategic intervals throughout the hepatic sinusoid, these macrophages sentinel portal flow entering the liver lobule for incongruous and harmful substances. Accordingly, they can detect early changes in the hepatic environment arising from alcohol-induced injury such as the increasing levels of cFn. In healthy tissue, Kupffer cells orchestrate defensive and reparative processes through their phagocytic activity and production of soluble signaling molecules. However, under a condition of chronic alcohol administration, excess cFn provokes a response in Kupffer cells that actually promotes rather than protects against further tissue damage[142].

Kupffer cells are the major source of TNF-α and IL-6 during the liver's homeostatic response to tissue damage.

Elevated levels of these pro-inflammatory cytokines are characteristically detected in the serum of patients with alcohol-induced liver injury. These cytokines stimulate autocrine and paracrine effects that result in the activation of other liver cell types during the injury process[143]. For example, both TNF-α and IL-6 are involved in the transition of HSCs to their myofibroblast-like phenotype. These cells in turn, accelerate the production of ECM proteins that heralds the fibrogenic response to injury[143].

Regions of the liver that first respond to the toxic effects of alcohol contain both cFn-enriched matrices and elevated numbers of KCs[144]. The behavior of KCs in these regions is likely influenced by the high concentration of cFn present. In fact, studies from our lab have shown that cFn has a profound effect on the KC secretion of TNF-α and IL-6, and therefore may be involved in promoting the KC-mediated activation of HSCs[142].

ECM remodeling poses a homeostatic challenge to cells that prompts the production of agents that can restore and maintain normal tissue architecture. MMPs and their inhibitors (TIMPs) are key agents that regulate this process. An imbalance in the relation of MMPs to TIMPs can lead to profound changes in the composition of the ECM such as is found in various pathological conditions including alcoholic fibrosis[113,145]. We believe that increasing levels of cFn, itself a constituent of the ECM, can prompt events leading to such imbalance in susceptible tissue.

Though HSCs are the most prolific source of factors that regulate the deposition of matrix components in the liver, during the early stages of fibrotic injury and prior to HSC activation KCs assume this role. Our studies have revealed that in response to increasing levels of cFn, cultured KCs from both control and alcohol-fed animals secrete significantly higher amounts of MMP-2 protein than their untreated counterparts. This increase in protease levels may be a regulatory response to excess cFn, a known substrate of MMP-2. However, we also found that the cells from alcohol-fed animals released significantly more of the associated inhibitor, TIMP-2, than matched control and untreated cells. Correspondingly, though the total MMP-2 secreted by the KCs from alcohol-fed animals was elevated, most of the enzyme detected was still in the less operational precursor form (pro-MMP-2)[142]. These results suggest that a higher degree of MMP-2 inhibition exists under a condition of alcohol administration. The consequent reduced degradative capacity of this protease could, in turn, contribute to the eventual build-up of ECM proteins characteristic of fibrotic injury.

These findings also imply that chronic alcohol consumption alters the homeostatic response of KCs to the build-up of proteins in the ECM. This may be another regulatory mechanism compromised by excessive alcohol metabolism that may contribute to the accumulation of cFn in the liver. The inhibition of matrix proteases is reinforced with each increase in cFn, creating a cycle that may later also facilitate the deposition of other matrix proteins involved in the fibrogenic process. Collectively, these studies suggest a role for cFn in Kupffer cell activation that

Figure 3 Schematic representation of the proposed model of ethanol-induced liver injury linking altered asialoglycoprotein receptor clearance of cellular fibronectin with hepatocyte and kupffer cell activation by the accumulating protein. The alcohol induced up regulation of cellular fibronectin (cFn) production by sinusoidal endothelial cells (SECs) and its impaired clearance by the hepatocyte-specific asialoglycoprotein receptor (ASGP-R) leads to the accumulation of cFn in the liver. Hepatocytes (HCs) and kupffer cells (KCs) are stimulated by cFn to produce the pro-inflammatory/pro-fibrogenic cytokines, tumor necrosis factor (TNF)-α and interleukin (IL)-6, which further activate hepatic stellate cell (HSCs) stimulating their transformation to the pro-fibrogenic phenotype. HCs and KCs are also stimulated to produce the matrix degrading enzyme, matrix metalloproteinase (MMP)-2 and its corresponding inhibitor, tissue inhibitor of metalloproteinase (TIMP)-2. Greater levels of TIMP-2 are secreted resulting in the inhibition of MMP-2 activity and subsequent build-up of the extracellular matrix (ECM), characteristic of the early onset of fibrotic liver damage. RME: Receptor mediated endocytosis.

contributes to the progression of alcohol-induced liver injury that may lead to fibrogenesis (Figure 3).

Hepatocytes are the chief functioning cells of the liver and key targets for mediators of injury. Accordingly, studies on the effects of various hepatoxins focus on disruptions to hepatocytic processes, such as alcohol-induced impairments to ASGP-RME as previously determined by our lab. As an extension of this work, we examined whether the consequent accumulated cFn would itself also be toxic to hepatocytes[138]. We found that elevated concentrations of cFn induced a significant increase in caspase-3 activity, a marker of apoptosis (programmed cell-death), in hepatocytes from alcohol-fed animals after a 20-h incubation.

It was also observed, in these same cells, a corresponding increase in the secretion of TNF-α and IL-6. This treatment with elevated, pathology-associated, concentrations of soluble cFn also stimulated cultured hepatocytes from both control and ethanol-fed animals to secrete significantly higher amounts of MMP-2. As pre-

viously mentioned, the activity of MMPs is dependent upon their balanced relationship with corresponding TIMPs. We also found that in the presence of elevated levels of cFn, cultured HCs from ethanol-fed animals secreted more TIMP-2 protein than their control and untreated counterparts. These cells, much like the KCs from ethanol fed animals, also release TIMP-2 in excess of MMP-2. Again, this disparity in the relative levels of these proteins would lead to an inhibition of MMP-2 activity which contributes to a reduction in matrix protein degradation and the subsequent build-up of the ECM.

The response by the hepatocytes to treatment with high concentrations of cFn was, however, not particularly robust relative to KCs, suggesting that the secretion of these factors may have a more localized purpose. For example, TNF-α, in particular, has been implicated in both the inflammatory and apoptotic responses of cells[146,147]. It is thus plausible that the observed increase in both the release of IL-6, and in the activity of caspase-3, may be attributed

to autocrine TNF-α signaling after cFn induction. However, as demonstrated by other ECM molecules, cFn may also influence cell death directly[148,149]. Moreover, MMP-2 and TIMP-2 produced by these hepatocytes in response to cFn treatment may be involved in the immediate degradation of the surrounding matrix, producing reactive fragments of cFn which would have only a localized effect on hepatocyte behavior[150]. It is plausible that the hepatocyte response to excess cFn affects hepatocytes alone and is not to be included as part of the collective signaling pool. Thus these findings also suggest that hepatocytes may be more involved in reinforcing their own demise during a condition of alcohol-induced injury than previously assumed (Figure 3). The specific mechanisms underlying these observed responses will, however, require further examination.

This seemingly unconventional response observed in hepatocytes could be explained by recent reports that suggest that these cells possess an inherent plasticity that makes them more susceptible to changes in the tissue microenvironment that could compromise pure epithelial character[151,152]. This plasticity is essential to the regenerative capacity of the liver that allows for recovery from sustained damage, which is an inevitable consequence of its function as a detoxifying organ. However, this poses a unique challenge for the researcher studying a specific aspect of hepatocyte behavior, as current isolation procedures and culture techniques can also alter the character of these cells. These findings should be further explored using new techniques involving 3D cultures and liver slices that are more representative of *in vivo* conditions[153,154].

CONCLUSION

Under normal conditions, cFn is an ostensibly innocuous and minor component of the ECM that is produced locally by tissues where it concentrates in the pericellular matrix that surrounds cells. It debuts as a critical factor for embryonic development, after which its levels greatly diminish, and are only re-established in adult tissue during events that involve regeneration or repair. However, its elevated presence has also been associated with various chronic disorders that are characterized by extensive tissue damage. These conditions create doubts as to whether cFn is truly a mediator of healing processes or an instigator of disrepair.

In healthy tissue, where physiological processes are appropriately regulated, cFn production is stimulated in response to signs of injury. Its upregulation provokes extreme activity that is essential for the repair of damaged tissue. Once tissue integrity has been restored cFn production is reduced to homeostatic levels and normal cFn turnover is restored. However, during a condition of relentless attack by agents that compromise tissue function, the regulatory mechanisms that restrict cFn activity become impaired. A condition of unbridled 'wound healing' develops that actually causes more tissue damage rather than repair.

In the liver, chronic metabolism of alcohol leads to the build-up of harmful byproducts which cause the in-creased production of cFn by hepatic SECs, as well as its impaired clearance by the hepatocyte specific ASGP-R. Although the physiological relevance of the resulting accumulation of cFn in the liver parenchyma remains debatable, evidence suggests cFn is not a static component of the hepatic scaffold, but a dynamic mediator of cellular events that may promote the progression of liver damage associated with chronic alcohol abuse. This reactive glycoprotein stimulates specific cells in the liver to release pro-inflammatory and pro-fibrogenic factors which create further tissue damage and disrepair that lead to alcoholic fibrogenesis (Figure 3).

Despite the medical community's initiatives to educate and intervene, alcohol consumption rates world-wide continue to rise and with it the development of alcoholic liver disease with often fatal outcome. Currently, there are no effective measures to counter this epidemic. Therefore, the effects and underlying mechanisms of cFn-induced cell behavior in the alcohol-injured liver are worth further characterizing, not only to gain a more comprehensive understanding of the role this glycoprotein plays in the progression of alcohol-induced liver injury but also for any insight such investigation could provide towards the development of desperately needed novel therapies for alcoholic liver disease.

Abstract

Clinical observations have demonstrated that excessive chronic alcohol use negatively affects human immunodeficiency virus (HIV) infection and contributes to the liver manifestations of the disease, even in HIV mono-infection. HIV/hepatitis C virus (HCV) co-infection is associated with increased progression of HVC liver disease compared to HCV infection alone, and both of these are negatively affected by alcohol use. Recent data suggest that alcohol use and HIV infection have common targets that contribute to progression of liver disease. Both HIV infection and chronic alcohol use are associated with increased gut permeability and elevated plasma levels of lipopolysaccharide; a central activator of inflammatory responses. Both alcoholic liver disease and HIV infection result in non-specific activation of innate immunity, proinflammatory cytokine cascade upregulation, as well as impaired antigen presenting cell and dendritic cell functions. Finally, alcohol, HIV and antiretroviral therapy affect hepatocyte functions, which contributes to liver damage. The common targets of alcohol and HIV infection in liver disease are discussed in this mini-review.

INTRODUCTION

The life expectancy of patients infected with human immunodeficiency virus (HIV) has been prolonged, therefore, liver diseases have assumed far greater importance as a cause of morbidity and mortality in these patients. Antiretroviral therapy (ART) used by patients who have HIV infection is often hepatotoxic. In addition, patients who have HIV often are co-infected with hepatotropic viruses such as hepatitis B and C viruses; factors that are damaging to the liver. Furthermore, chronic alcohol consumption causes injury to the liver and may result in more rapid progression to cirrhosis, end-stage liver disease, and hepatocellular carcinoma in co-infected patients. This review addresses the interactions between these factors that result in furthering liver damage.

HIV, VIRAL HEPATITIS AND ALCOHOL USE - EPIDEMIOLOGY AND NATURAL HISTORY OF LIVER DISEASE

The natural history of HIV infection has drastically changed since the discovery of its clinical manifestation, AIDS in advanced disease[1-3]. HIV affects about 40 million people worldwide, with most of the infections in developing countries. As a blood-borne pathogen, HIV infection is transmitted *via* blood, sexual contact, and maternal-newborn transfer. HIV primarily infects immune cells and it replicates in T lymphocytes and monocytes[4-7]. HIV mono-infection results in minimal hepatitis, however, co-infection with hepatitis virus results in increased liver damage. Hepatitis B virus (HBV) infection affects 370 million people and it is estimated that an additional 170 million suffer from hepatitis C virus (HCV) infection[8-13]. Both HBV and HCV can lead to chronic hepatitis and as a result, progressive liver inflammation and fibrosis lead to cirrhosis and liver failure. An additional insult to the liver is excessive alcohol consumption that is an ongoing social and medical problem in people with and without HIV infection.

Several studies have found significant alcohol problems in HIV-infected individuals. In a primary care setting, physicians have reported that alcohol consumption is a common habit in patients initiating care for HIV disease[14-16]. Heavy drinking among people with HIV infection under medical care has been found to be almost double that of the general population[17]. It has also been shown that heavy alcohol consumption has a negative impact on CD4 cell count in HIV-infected persons who are not receiving ART[18].

The interaction of HIV and HCV infection has received increasing attention in recent years. It has been well documented that liver disease progression is accelerated in HIV/HCV co-infected patients compared with HIV or even HCV mono-infection[11,13,19]. Furthermore, chronic heavy alcohol consumption acts as an additional insult in all of these forms of chronic hepatitis. With the new era of highly active antiretroviral therapy (HAART) that provides sufficient control of HIV replication, it has become evident that, in HIV/HCV co-infected patients, progression of HCV infection causes more lethality than HIV infection itself[11,13,19].

Excessive alcohol consumption is associated with fatty liver, and if persistent, it can lead to alcoholic steatohepatitis, liver fibrosis and cirrhosis[20]. Clinical studies have demonstrated that excessive alcohol consumption in individuals with comorbid conditions such as chronic HCV or HBV infection accelerates liver damage and progression to liver cirrhosis. In a study of a large cohort of HIV-positive and negative US veterans, investigators have found a trend toward increased liver injury manifested as inflammation and fibrosis, in patients with hazardous or binge drinking[21]. The same study has shown that alcohol abuse and dependence significantly increase the risk of advanced fibrosis and cirrhosis in HIV-mono-infected patients, as well as in those with HIV/HCV co-infection[21]. A cross-sectional study has investigated the impact of alcohol on

Figure 1 Alcohol and human immunodeficiency virus in liver disease. There are multiple common sites of action of alcohol and human immunodeficiency virus (HIV) infection that contribute to the development of liver disease. These include modification of immune functions and inflammatory responses, functions of hepatocytes and intestinal permeability.

liver fibrosis using aspartate aminotransferase (AST)-to-platelet ratio index (APRI) as a measure of liver function, and has found significant liver disease with an APRI > 1.5. This study also has found that hazardous alcohol drinking is an independent, modifiable risk factor for fibrosis[21], and the same investigators have concluded that the problem of alcohol abuse is not adequately addressed by health care providers in patients with HIV positivity[21].

In HIV-infected patients, 17% of death was related to end-stage liver disease; of those, 75% of patients had HIV/HCV co-infection and 48% heavy alcohol use history[22]. Alcohol use in HIV-infected patients was also shown to be associated with decreased adherence to ART, and not surprisingly, reduced HIV suppression[23].

ALCOHOL AND HIV: COMMON TARGETS IN LIVER DISEASE

Although the pathological mechanisms of alcoholic liver disease are relatively well explored[24-26], the mechanisms by which HIV infection affects the liver remain somewhat elusive. Based on current knowledge, several elements in the pathological mechanisms of alcohol-induced liver disease can by exacerbated by HIV infection, which results in the potentiation of the individual negative effects. These major categories of mutual actions and modulating effects of both alcohol and HIV infection are on gut permeability and gut-liver homeostasis, immune functions and inflammation, and alterations in hepatocyte functions and survival (Figure 1).

Gut permeability and the role of lipopolysaccharide in HIV infection and alcoholic liver disease

The important role of gut-derived lipopolysaccharide (LPS) has been demonstrated in alcoholic liver disease in humans, as well as in animal models of chronic alcohol administration[27,28]. Gut-derived LPS has been shown to have a causative role in alcoholic liver injury as demonstrated by experiments in which gut sterilization with antibiotics prevented alcohol-induced liver damage[29]. This

was associated with increased intestinal permeability in rats[30]. Alcohol feeding in rats and mice increases serum endotoxin levels after 1-2 wk, and these increases remain after continued alcohol administration[31]. Studies in mice as well as *in vitro* have demonstrated that alcohol damages the intestinal epithelial barrier by downregulating tight junction proteins[32-34]. The importance of the gut-liver axis has been implicated in alcoholic liver diseases and in other etiologies of liver injury[27,28].

The novel finding, that HIV infection is associated with increased plasma endotoxin levels was first reported by Douek's group in 2006[35]. Plasma LPS was significantly increased in patients with chronic HIV infection, as well as in patients with AIDS compared to uninfected controls or to those with acute infection[35]. LPS in the serum is bound to lipoprotein binding protein (LBP) and soluble CD14 (sCD14) that modulate the biological availability of LPS. The same authors have found increased plasma sCD14 and LBP levels even in acute HIV infection, as well as in those with progressive HIV infection[35]. Subsequent studies have evaluated the effect of ART on plasma LPS levels and have found that patients with ART have a moderate decrease in plasma LPS levels[36]. This is also associated with an improvement in plasma tumor necrosis factor (TNF)α levels, which suggests attenuation of inflammatory cell activation[36-38]. The source of the increased plasma LPS in HIV infection is presumably the gut. It has been speculated that HIV infection in the intestinal epithelial and immune environment permits increased translocation of gut microbiota and their components such as LPS[39].

Increased serum LPS levels have been noted in patients with chronic HCV infection, even in the absence of advanced liver disease[40]. Furthermore, in patients with HCV and HIV co-infection, serum LPS levels are higher compared to those in patients with HIV infection alone[41].

The biological significance of the elevated serum or plasma LPS in HIV infection is yet to be fully understood. It is generally accepted that chronic LPS exposure of immune and inflammatory cells results in a non-specific inflammation that may "reset" thresholds for specific immune responses[42]. It is tempting to speculate that constant and repeated exposure of innate immune cells, particularly tissue macrophages (Kupffer cells) in the liver from the gut-derived LPS in the portal blood, could result in loss of LPS tolerance, which predisposes to increased inflammatory responses[43]. We have found loss of Toll-like receptor (TLR) tolerance in circulating monocytes of HCV-infected patients, and this is associated with increased production of proinflammatory signals including TNFα[40].

In alcoholic liver disease, there is a large body of evidence in support of increased sensitivity of Kupffer cells to LPS and proinflammatory cytokine activation[44,45] (Figure 2). Early studies have demonstrated that elimination of Kupffer cells with gadolinium chloride in rats ameliorates alcohol-induced liver damage and that LPS/CD14 receptor signaling is involved[44]. Recently, we have shown that deficiency in TLR4, the receptor for LPS, or deficiency in the TLR4 downstream signaling by interferon regulatory factor 3, are crucial for development of

Figure 2 **Alcohol-induced hepatocyte damage is amplified by human immunodeficiency virus infection.** The current model of alcohol-induced liver disease includes increased gut-derived lipopolysaccharide (LPS) entry into the liver where Kupffer cells are activated *via* LPS/Toll-like receptor (TLR) 4 and produce tumor necrosis factor (TNF)α. Human immunodeficiency virus (HIV) infection also increases gut-derived LPS levels in the circulating blood. Increased production of TNFα will act on alcohol-exposed hepatocytes to induce apoptosis. ROS: Reactive oxygen species.

alcohol-induced liver damage[31,46]. The combined effect of alcohol and HIV infection on LPS signaling in the liver awaits further investigation.

Inflammation and immune functions

Activation of the inflammatory cascade and increased proinflammatory cytokine production is a hallmark of both alcoholic steatohepatitis and chronic HIV infection[26,45]. The immunological consequences of such proinflammatory cascade activation are not fully understood. The clinical observations of increased susceptibility to infections in alcoholic steatohepatitis and chronic HIV infection demonstrate that, although non-specific proinflammatory activation is present, pathogen-specific innate immune responses are defective. Furthermore, antigen-specific immune responses as well as antigen presenting function of monocytes and dendritic cells are severely dampened by alcohol exposure, as well as in chronic HIV infection[47-49]. Our previous studies have demonstrated that acute alcohol consumption in humans inhibits the antigen presenting function in human monocyte-derived dendritic cells and monocytes *via* mechanisms that involve decreased interleukin (IL)-12 and co-stimulatory molecule expression and/or impaired dendritic cell differentiation/maturation[48-50]. The effects of prolonged alcohol also inhibit myeloid dendritic cell functions in humans as well as mouse models[51].

Defects in myeloid and plasmacytoid dendritic cell function have been extensively studied in HIV infection. It has been shown that HIV infection results in impaired differentiation and maturation of monocyte-derived dendritic cells in humans and that these dendritic cells have impaired antigen presentation capacity. Chronic HCV infection is also associated with decreased antigen presenting function of dendritic cells and HIV and HCV infection affect im-

mune responses[52,53]. Although the combined effects of alcohol exposure and HIV infection are yet to be evaluated on dendritic cell functions, we have previously demonstrated that alcohol treatment has an additive inhibitory effect on the already dampened accessory cell function in dendritic cells of HCV-infected patients[54]. This is associated with reduced expression of the T cell co-stimulatory molecules, CD80 and CD86, low IL-12 and increased IL-10 production[54]. The role of dendritic cells in HIV/HCV co-infection in relation to the liver disease needs further exploration. However, the importance of dendritic cells in liver tolerance and inflammation is emerging[42,43].

Hepatocyte function and cell death

There are multiple mechanisms by which alcohol, HIV infection and even ART could directly affect hepatocytes. As summarized in Table 1, reactive oxygen radical production, mitochondrial damage and steatosis can all be induced independently by alcohol, HIV or HCV infections alone or in combination with HAART[55]. However, these factors together will most likely cause combined damage in exposed hepatocytes. Some of the mechanisms involved include depletion of the intracellular glutathione stores by chronic alcohol and HIV infection that predisposes to increased reactive oxygen species (ROS) production and increased susceptibility to hepatocyte death[55]. In addition, alcohol, HCV, and HAART cause mitochondrial damage, fatty liver, and increased levels of proinflammatory cytokines, particularly, TNFα, which results in hepatocyte death. This mechanism has been investigated in alcoholic liver damage as well as in HIV infection, and HIV/HCV co-infection[55].

Although the introduction of HAART for HIV infection has resulted in a significant decrease in the mortality rate of AIDS, a sizable proportion of patients receiving HAART develop liver toxicity. For example, patients treated with the antiretroviral nucleoside reverse-transcriptase inhibitors (NRTIs) zidovudine, zalcitabine, didanosine and stavudine have been reported to develop hepatic steatosis[56,57]. Heavy alcohol consumption by HIV patients on HAART results in liver decompensation in about 2% of cases[58], and increases the risk of liver injury 5.8 times in 10% of patients receiving NRTI or non-NRTI regimens[55]. The enhanced liver toxicity due to alcohol, HCV,

and HAART could result from shared mechanisms such as fat accumulation and mitochondrial damage.

Fat accumulation and insulin resistance

Alcohol and HCV-induced fatty liver is well documented. Several mechanisms have been reported for alcohol-induced fatty liver including increased hepatic uptake of fatty acids and *de novo* lipogenesis, impaired peroxisome proliferator-activated receptor α signaling, reduced mitochondrial fatty acid oxidation and reduced secretion of triglycerides[59-61]. These effects could be attributed to reduced adiponectin secretion by the adipose tissue and elevated expression of TNFα[62-64].

Some AIDS patients develop HAART-associated lipodystrophy (LD). A study by Sutinen *et al*[65] has shown that, in comparison to HIV-negative subjects, HAART+LD patients show: (1) higher liver fat content (regardless of alcohol consumption); (2) for a given amount of liver fat, serum-free insulin concentration correlated with liver fat, which suggests that fat accumulation in the liver is crucial for development of insulin resistance; and (3) significantly lower leptin concentrations than the other two groups. Others have also demonstrated low plasma leptin concentrations in patients with HAART-associated LD[66]. Hypoleptinemia and subsequent insulin resistance could favor fatty liver accumulation in patients suffering from NRTI-induced lipoatrophy[67-69].

Although Sutinen and co-workers did not observe lactic acidosis, others have reported lactic acidosis and hepatic steatosis in some patients using HAART, which was attributed to mitochondrial toxicity induced by nucleoside analogs[70,71]. In addition, co-infection with HCV increases the risk for severe liver damage during HAART[72], and end-stage liver disease is the primary cause of death in HIV/HCV co-infected patients under HAART[73,74]. Seth[75] has reported that, in HIV co-infected patients, the HCV load is higher by an average of 0.5-1.0 log than the mono-infected patients due to immune depression. Studies on liver fibrosis show conflicting results. Although some studies have found that early HAART in HIV/HCV co-infected patients may slow liver fibrosis progression[76], others have found that HAART regimens including nevirapine accelerate liver fibrosis progression in HIV/HCV co-infected patients[77].

Mitochondrial damage

Alcohol and HCV can induce mitochondrial DNA (mtDNA) damage through the production of ROS and/or reactive metabolites. It has been reported that prolonged administration of antiretroviral NRTIs increases the risk of mitochondrial damage in the liver[78]. NRTIs can cause the accumulation of the oxidized base 8-hydroxydeoxyguanosine (8-OH-dG) in liver mtDNA[79,80]. In addition, NRTIs can cause mtDNA point mutations in some patients, which may result from interaction with mtDNA replication (*via* misreading of 8-OH-dG by DNA polymerase c) and/or impairment of polymerase c repair capacity[81]. It has been reported that NRTIs inhibit mtDNA replication by

undergoing phosphorylation as the cognate endogenous nucleosides, which are subsequently incorporated within the mitochondrial genome by DNA polymerase c[81].

CONCLUSION

Although increasing evidence suggests enhanced combined effects of alcohol and HIV infection on the liver with and without viral hepatitis, a number of questions remain unanswered. What are the interactions between alcohol use, HIV, HCV and HBV infections? Is the crosstalk between organs, such as the homeostasis between the liver and gut, affected by combined insults of alcohol, HIV and viral hepatitis? What is the effect of the cumulative effects of alcohol and HIV infection on cross-regulation between various cell types in the liver? How can new therapeutic targets be developed in the light of knowledge about the interactive effects of HIV and alcohol on the liver? All of these questions are pertinent to the status and defects observed in immune functions, gut permeability, Kupffer cell activation, hepatocyte function and liver fibrosis/stellate cell function in patients with HIV infection and excessive alcohol use and/or viral hepatitis.

Abstract

This review describes the principal pathways of macroautophagy (i.e. autophagy), microautophagy and chaperone-mediated autophagy as they are currently known to occur in mammalian cells. Because of its crucial role as an accessory digestive organ, the liver has a particularly robust autophagic activity that is sensitive to changes in plasma and dietary components. Ethanol consumption causes major changes in hepatic protein and lipid metabolism and both are regulated by autophagy, which is significantly affected by hepatic ethanol metabolism. Ethanol exposure enhances autophagosome formation in liver cells, but suppresses lysosome function. Excessive ethanol consumption synergizes with hepatitis C virus (HCV) to exacerbate liver injury, as alcohol-consuming HCV patients frequently have a longer course of infection and more severe manifestations of chronic hepatitis than abstinent HCV patients. Alcohol-elicited exacerbation of HCV infection pathogenesis is related to modulation by ethanol metabolism of HCV replication. Additionally, as part of this mechanism, autophagic proteins have been shown to regulate viral (HCV) replication and their intracellular accumulation. Because ethanol induces autophagosome expression, enhanced levels of autophagic proteins may enhance HCV infectivity in liver cells of alcoholics and heavy drinkers.

INTRODUCTION

Alcohol is known to exacerbate the pathogenesis of hepatitis C virus (HCV) infection and makes chronic hepatitis C patients less sensitive to antiviral treatment. Recent investigations indicate that autophagy is involved in the regulation of HCV replication and infectivity. Here, we provide basic information about the role of autophagy in liver and how ethanol modifies the autophagic response in liver cells. In addition, to underline a link between autophagy and viral replication, we review the data about HCV structure, replication cycle and autophagy in HCV-infected liver cells. Since alcohol consumption exacerbates HCV pathogenesis, we propose possible mechanisms that lead to liver failure in HCV-infected patients who drink

excessively, which may in part be regulated *via* autophagy-mediated accumulation of HCV in liver cells.

AUTOPHAGIC MACROMOLECULAR DIGESTION IN THE LIVER

Lysosomes and autophagy

In most tissues, the majority of intracellular proteins are degraded by the proteasome, an integral component of the ubiquitin-proteasome system (UPS)[1]. In tissues such as liver that respond quickly to the composition of the plasma, the lysosome has a large part in degrading extracellular proteins (e.g. obsolete plasma proteins) brought by endocytosis into the hepatocyte. Lysosomes also degrade the remaining fraction of intracellular proteins that are not proteasome substrates and break down complex lipids (e.g. triglycerides), complex carbohydrates (e.g. glycogen) and nucleic acids. All the latter hydrolytic steps are done by autophagy, which literally means "self eating"[2]. While autophagy always terminates by degrading macromolecular substrates in lysosomes, it can begin *via* one of three distinct cellular pathways. The most well-characterized process by which autophagy is defined is macroautophagy, the vacuolar sequestration by endoplasmic reticulum (ER) membranes of bulk portions of cytoplasm, forming a double membrane-enclosed body known as an autophagosome or autophagic vacuole (AV). The nascent AV, which contains both soluble constituents and particulate organelles, fuses with existing lysosomes to form a hydrolytic organelle called an autolysosome. Here, the sequestered substrates are hydrolyzed and the degradation products are released. Microautophagy, which is less well characterized than macroautophagy, is the uptake of smaller cytoplasmic particles by the lysosomal membrane followed by their degradation in the lysosome interior. Chaperone-mediated autophagy (CMA) is the uptake and degradation by lysosomes of single protein substrates that bear a KFERQ peptide motif. The latter is recognized by soluble chaperonins of which the most prominent is the heat shock constitutive protein 70 (HSC 70), which binds to and "directs" the protein substrate to lysosome-associated membrane proteins (LAMP). Most significant is LAMP-2A, which recognizes substrate chaperonin complexes and facilitates entry of the protein substrate into the lysosomal matrix for degradation. CMA was formerly considered a minor autophagic pathway, but recent findings indicate its heightened importance in liver cell maintenance and hepatic performance. CMA activity declines with age due to a gradual loss of LAMP-2A on the lysosome surface. Artificial restoration of this protein in aged LAMP-2A transgenic mice significantly improves liver function[3]. CMA also has a compensatory function when macroautophagy in liver cells declines after artificial knockdown of macroautophagy gene products[4].

Autophagy is important for liver cell survival, particularly in times of nutrient deprivation, when autophagy swiftly responds to fasting. The short half-life of autophagosomes (< 10 min)[5] indicates that the protein compo-

Figure 1 Molecular aspects of autophagosome formation. Reproduced with permission from[11].

nents required for their formation are readily available for recruitment. Like the proteasome, autophagy has a key housekeeping and backup function as it degrades misfolded, aggregated proteins that are resistant to proteasome-catalyzed degradation[6]. The importance of removing such aggregated proteins is clearly illustrated by the association of aggregate accumulation with disease pathogenesis. Patients with α-1-antitrypsin (A-1AT) deficiency are more susceptible to cirrhosis and liver cancer because of a propensity of the mutated, unsecreted A-1AT protein to aggregate within hepatocytes[7].

Mechanism of autophagy

Identification of the major autophagy genes in yeast[7-10] designated "Atg" has contributed significantly to our understanding of how autophagy proceeds in mammals. In all eukaryotic cells, nutrient deprivation is an inducer of autophagy. The mechanism of autophagy is described below in three steps and depicted in Figure 1.

Inititation of autophagosome formation: Inititation of autophagosome formation is regulated by the class Ⅲ phosphoinositol-3-kinase (PI-3K) which triggers an upstream signaling cascade to inhibit the activity of the mammalian target of rapamycin (mTOR), a major anabolic kinase and a potent suppressor of autophagy. Inhibition of mTOR triggers the autophagic response by activating Atg proteins. In mammals, a complex is formed among the serine/threonine-protein kinase, ULK1 (a homolog of the yeast Atg1), the focal adhesion kinase family interacting protein 200, (FIP200), Atg17-like protein and Atg13, to begin the process of AV nucleation[11]. Autophagosome (autophagic vacuole) formation begins when Beclin-1 (Atg6) forms a complex with Atg14. This subsequently

brings about formation of a double membrane vesicle that is likely derived from the ER[12]. Coordinated complexes of Atg proteins catalyze vacuole (vesicle) elongation, notably the Atg12 ubiquitin-like conjugation system, consisting of Atg 5, 12 and 16, catalyze cleavage of Atg8, the microtubule light chain-3 (LC3I), and its conjugation to phosphatidylethanolamine (PE) to form the autophagic marker, LC3 II. The latter subsequently localizes to the autophagosome membrane, while its unlipidated precursor, LC3I remains in the cytoplasm (Figure 1).

Docking and fusion of cargo-filled autophagosomes: Docking and fusion of cargo-filled autophagosomes with lysosomes follows autophagosome formation to form the hydrolytic autolysosome. Fusion is believed to be highly dependent upon the lysosomal membrane protein, LAMP-2.

Breakdown of the autolysosome contents occurs: The mechanism that triggers this hydrolysis is incompletely understood but it is likely that the collective action of lysosomal hydrolases brings about autolysosome dissolution.

Lysosomal proteolysis during ethanol consumption: Liver enlargement (hepatomegaly) is common in alcoholics and in alcohol-fed laboratory animals. The rise in hepatic protein and fat each accounts for half the net increase in liver mass[13]. The net protein gain very likely contributes to the more severe alcohol-induced liver pathologies, because some of the accumulated proteins are damaged by oxidants generated from ethanol metabolism, from mitochondrial leakage and from secondary reactions that enhance production of reactive species[14,15]. In early studies, we showed that ethanol-induced protein accumulation reflects slower degradation of long-lived proteins, which are generally degraded in lysosomes[16]. We later confirmed that ethanol feeding diminishes the proteolytic capacity of liver lysosomes[17]. This is due to a reduced capacity for their acidification[18] and lower contents of cathepsins B and L[19]. The latter deficiency results from disruption of cathepsin precursor trafficking to lysosomes[20], owing to declines in the ligand-binding activity, content, and synthesis rate of the mannose-6-phosphate receptor[21,22]. This protein recognizes and binds cathepsin precursors for placement into the lysosomal compartment[23].

Because lysosomes degrade the contents of autophagic vacuoles, we considered it likely that ethanol suppresses the initial stages of autophagy. Others demonstrated that livers of ethanol-fed rats exhibit volume densities of autophagosomes and autolysosomes substantially lower than controls[24]. Other lines of evidence support autophagic suppression, including ethanol-induced down-regulation of AMP kinase, a catabolic regulator[25] and ethanol-elicited disruption of cytoskeletal proteins[26] that are essential for delivery of AV cargo to lysosomes.

Ethanol effects on intracellular autophagosome content in vitro and ex vivo

Using the marker, LC3- II we quantified autophagosomes in recombinant HepG2 (VL-17A) cells which metabolize ethanol *via* ADH and CYP2E1. Parental HepG2 cells express neither enzyme[27]. Contrary to our expectations, exposure of VL17A cells to 25 or 100 mmol/L ethanol for 12 to 72 h enhanced autophagosome content over that of untreated cells. AV elevation by ethanol was blocked by simultaneous exposure to 4-methyl-pyrazole (4MP), an inhibitor of ethanol oxidation. Furthermore, exposure to ethanol of non-metabolizing HepG2 cells showed no differences from untreated controls in autophagosome content, to suggest that the initiation of autophagy depends on the generation of ethanol metabolites[28]. These results are consistent with those reported recently[29]. Interestingly, they contrast with another report[30] demonstrating that in CYP2E1-expressing E-47 (HepG2 recombinant) cells, ethanol exposure enhances steatosis but only slightly increases autophagy by 50%. In non-metabolizing C34 cells (similar to HepG2 cells) ethanol exposure causes a four-fold rise in autophagy but only a slight elevation of steatosis. The apparent disparity may be explained by differences in the duration of ethanol exposure (12 to 72 h reported here, compared with 120 h in the Wu *et al*[30] study) and the high degree of cellular steatosis, which is reciprocally regulated with autophagy in liver cells[31].

We further tested the autophagic response in control and ethanol-exposed precision-cut rat liver slices (PCLS)[32]. LC3 II levels in PCLS exposed to 50 mmol/L ethanol were increased two-fold over controls after 24 h of incubation. Simultaneous exposure to 4MP blocked this response[28].

***In vivo* studies:** After acute ethanol administration to mice, we observed a 35% enhancement in autophagosome content. This coincided with a decline in reduced glutathione (GSH) and a significant elevation in hepatic lipid peroxides, both indicators of oxidant stress. Chronic ethanol feeding to transgenic LC3-green fluorescent protein (GFP) mice caused a five-fold increase over controls of fluorescent puncta, indicating enhanced autophagosome formation. It is noteworthy that ethanol-fed mice in this study exhibited hepatomegaly and elevated liver protein over pair-fed controls[28] consistent with our previous findings in rats[16,33].

Summary

Our results are consistent with those recently published[29] but are inconsistent with our hypothesis that ethanol suppresses the autophagic pathway. An obvious paradox emerges from these recent findings in view of our previous work, showing slower protein degradation in livers of ethanol-fed animals because of a disruption of lysosome function and biogenesis[17-22]. An explanation for this disparity is that our recent investigations focused on autophagosome formation while our earlier studies emphasized lysosome function. We now postulate that ethanol metabolism enhances autophagosome formation while it disrupts the distal, degradative step of autolysosome formation. Previous work in alcohol/endotoxin-induced

pancreatitis, revealed that LAMP-2 protein is severely reduced in pancreata of ethanol-fed/endotoxin-treated rats. This alteration reduces autolysosome formation and subsequent degradation of autophagosome cargo[34]. We postulate that this also occurs in liver during ethanol metabolism. Finally, we do not know the exact mechanism by which ethanol metabolism induces autophagosome content but we surmise that acetaldehyde, the primary oxidation product of ethanol metabolism and/or other reactive species generated by reactions secondary to ethanol metabolism, is/are probably responsible for this activation. Further, chronic alcohol consumption causes oxidant stress, which enhances the unfolded protein response (UPR) in the ER[35]. Because AV membranes are derived from this organelle[12], ER stress could enhance the formation of autophagosomes during ethanol oxidation.

HCV, ETHANOL AND AUTOPHAGY

Ethanol-induced oxidative stress and HCV infection

HCV is a well-established second hit, which drives the progression of alcoholic liver disease. Worldwide, 170 million people (about 2.2% of the world's population) are infected with HCV, and in about 80% of cases, infection persists for many years. Chronic viral hepatitis provides the potential risk for cirrhotic liver disease and life-threatening complications of portal hypertension and hepatocellular carcinoma[36]. The ability of HCV proteins to induce oxidative stress *via* generation of reactive oxygen species (ROS) by mitochondrial electron transport complex I plays an important role in HCV infection pathogenesis. Therefore, ROS release results in decreased mitochondrial GSH and mitochondrial depolarization, which can be augmented by simultaneous ER oxidative stress[37-39]. Cytochrome P450 (including CYP2E1) is involved in evolution of hepatitis to HCV-associated hepatocarcinoma[40]. Furthermore, alcohol abuse associated with CYP2E1 activation strongly accelerates the progression of HCV infection by increasing fibrosis as well as the risk of death from cirrhosis in HCV patients. It is believed that immunosuppressive effects of alcohol impair viral clearance[41,42]. The main mechanisms of HCV infection development, including immune dysfunction, apoptosis, steatosis and hepatic iron overload, can be triggered by heavy alcohol consumption in HCV patients[43,44].

Hepatitis C virus and viral proteins

HCV, an enveloped virus of Flaviviridae family, has a positive-sense and single-stranded RNA. Its genome is 9.6 kb, encodes a polyprotein of 3010 amino acids and consists of a single open reading frame (ORF) flanked by untranslated regions[45]. The NH_2-terminal part of the polyprotein includes three structural proteins: core (capsid protein) and two envelope proteins, E1 and E2[46]. The polyprotein is processed by cellular and viral proteases into distinct structural and non-structural viral proteins. The COOH-terminal portion of the polyprotein consists of the non-structural (NS) proteins (p7, NS2, NS3, NS4A, NS4B, NS5A, NS5B) that form the replication complex for synthesis of viral RNA and regulate virion assembly[47-49]. The release of structural proteins from the nascent polyprotein is catalyzed by cellular proteases, while NS proteins are produced by viral proteases[50].

The HCV replication cycle

To initiate the viral life cycle, HCV binds to specific cell receptors on the hepatocyte surface and is internalized by clathrin-dependent endocytosis. Although the exact mechanism of HCV cell entry is unknown, it is believed to be a multi-step process involving at least the tetraspanin CD81[51], tight junction molecules, claudin 1 and occludin 1, as well as scavenger receptor SR-B1[52,53]. Since extracellular HCV also circulates bound to lipids and very-low-density lipoproteins (VLDLs)[54], the low density lipoprotein receptor may have a role in facilitating viral attachment. Initial capture of HCV particles by lipoprotein receptors is followed by interactions with SR-B1, CD81 and tight junction receptors leading to uptake and intracellular penetration of HCV *via* low-pH endosomes[55]. Most receptors for HCV entry are species specific, which prevents infection of mouse tissue with human virus, thereby limiting or preventing cross-species infections. After attachment to the receptors and penetration inside the cells, HCV viral and cellular membranes are fused at the acidic compartment and an HCV RNA is released into cytoplasm. Viral RNA replication requires the formation of a complex contacting NS proteins, replicating RNA and cellular membranes, and an enveloped HCV virion carrying a newly-synthesized viral genome is formed by budding into the ER lumen. After assembly of the viral particle on lipid droplets (LDs), HCV leaves the cells through a secretory (VLDL) pathway[56].

Association of HCV with lipid droplets

HCV core protein released from the polyprotein after host signal peptidase cleavage undergoes further maturation by proteolytic processing by signal peptidase[57,58]. *In vitro* expression of core protein is associated with ER membranes and the surface of LD[59]. The immature form of core protein cannot attach to LD. After maturation, core protein is directed from the ER to LD, and it attaches *via* a D2 domain, which includes a 55 amino acid protein containing two amphipathic α-helices (H I and H II) separated by a hydrophobic loop[60]. D2 is important for core protein stability and its subsequent associations with cell membranes. The neighboring core segment, D1, has important functions in RNA binding and protein-protein interactions[46]. LDs are directly involved in the production of infectious HCV particles[61]. They are surrounded by unique membranes called "membraneous web", allowing a high amount of plus- and minus-strand HCV RNA as well as NS proteins (NS5A) to attach to LD covered with HCV core protein. NS5A-core interactions require the serine phosphorylation toward the C-terminal end of NS5A and are essential for the association of replication complex to the periphery of LDs, which is a pre-requisite for infectious virion assembly[56]. Importantly, disruption of the core protein-LD association causes defects in HCV RNA and NS localization

and results in a loss of infectious viral particle assembly[61], demonstrating that core protein is responsible for recruitment of NS proteins to LD. Attachment of core protein to LDs leads their aggregation toward the periphery of the nucleus, suggesting that the core modifies the microtubule-dependent mobility of LDs; it also displaces adipocyte differentiation-related protein (ADRP), the major LD surface protein[62]. The modulation of the microtubule network by core protein is extremely important, as microtubule disruption reduces virus production. Thus, core protein changes the intracellular localization of LDs, securing the contacts between the sites of RNA synthesis and LDs. Due to core-NS5A protein-protein complex formation, these two proteins form a bridge between LDs and the sites of HCV RNA replication[46]. The targeting of the viral components to LDs establishes the link between assembly and release of HCV virions, VLDL production and apoprotein B lipidation[63].

HCV and autophagy

Some viruses, including HBV and HCV, subvert autophagy and use it to their own benefit. The link between autophagy and HCV replication is supported by several studies. Knockdown of autophagic proteins, beclin-1, Atg4B, Atg5 and Atg12 suppresses HCV replication at the onset of infection[64]. Specifically, Atg7 knockdown decreases the production of infectious viral particles without affecting HCV viral protein expression[65]. By inducing ER stress, HCV infection stimulates autophagosome formation regardless of HCV genotype[64,66]. Recently, we have shown that this autophagosome formation and specifically, LC3 lipidation can be further enhanced by exposure to ethanol of JFH1-infected ethanol-metabolizing hepatoma cells (unpublished observations). Nevertheless, a co-localization of LC3-Ⅱ protein in autophagosome and HCV proteins has not been found[65,67]. However, a recent study of Guevin *et al*[68] demonstrated a transient link between Atg5 and HCV NS5B (RNA-dependent RNA polymerase) protein at a very early stage of infection. This study was conducted in the frame of yeast two-hybrid analysis on the cells co-expressing Atg5 and NS5B. Interaction between these proteins is required for the onset of viral replication. Atg5 is indeed involved in other positive-strand RNA virus replications *via* formation of a double membrane vesicle[69]. This Atg5-NS5B interaction suggests that autophagy proteins play some additional, autophagy-unrelated role. Induction of autophagosome formation in HCV infection does not necessarily mean activation of autophagic protein degradation because HCV induces an incomplete autophagic response by impairing autolysosome function[66,70]. One of the possible reasons is either defective autophagosome-lysosome fusion or impaired postfusion proteolytic degradation of autophagosome contents induced by alkalization of lysosome due to HCV p7 protein[71]. The reduced capacity for lysosomal digestion may further prolong HCV survival.

HCV replication and ethanol

As revealed from numerous studies, exposure of liver cells to ethanol affects HCV replication. Zhang *et al*[72] demonstrated that ethanol produces a concentration-dependent increase in HCV replication and related that effect to the activation of NF-κB promoter. In addition, exposure of Huh7 cells and primary human hepatocytes to increasing concentrations of ethanol up-regulates intracellular and extracellular HCV RNA[73]. However, the role of ethanol metabolism in HCV replication is still controversial. Recent studies in full genomic and subgenomic HCV replicon cells have shown that alcohol increases HCV replication 4-fold in a CYP2E1-dependent manner and these effects are blocked by N-acetyl cysteine[74]. As demonstrated by Seronello *et al*[75], replication of both HCV genotypes 1b and 2a depends on lipid metabolism, is enhanced by acetaldehyde and requires elevated NADH/NAD+ ratio. On the other hand, extracellular and intracellular ROS suppress HCV replication. In addition, the effect of ethanol on HCV RNA replication in ethanol-metabolizing JFH1-infected Huh7.5 CYP2E1-expressing (RLW 2-9) cells depended on when ethanol was applied to the cells; application of ethanol before infection of cells with JFH1 enhanced HCV RNA replication, while exposure of RLW 2-9 cells to ethanol 3 d after infection suppressed HCV RNA levels[76].

The mechanisms by which ethanol interferes with or activates the HCV replication cycle are not clear. While the literature on viral entry develops rapidly, very little is known about how ethanol affects the expression of receptors for HCV entry. These effects may depend on the ability of cells to metabolize ethanol. Thus, by using ethanol non-metabolizing cells, it has been shown that the expression of CD81 is up-regulated on monocytes of HCV-infected alcohol-consuming patients[77], while ethanol exposure decreases claudin1 expression on alveolar epithelial cells[78]. Recently, we showed that ethanol exposure did not affect CD81, but enhanced claudin 1 expression on ethanol-metabolizing CYP2E1+ HCV replicon and JFH1-infected infected hepatoma cells[76,79]. Other mechanisms explaining the enhancement of HCV replication/expression by ethanol exposure to hepatocytes, including the regulation of autophagy, are under investigation.

HCV, fatty liver and autophagy

Expression of PPARα, a nuclear receptor that modulates the expression of oxidative enzymes and fatty acid import into mitochondria, is impaired by HCV[80]. HCV core protein reduces expression of PPARα as well as its transcriptional activity. In addition, HCV core protein activates fatty acid synthesis by affecting SREBP1c. Sterol response element-binding proteins (SREBPs) are transcription factors that are bound to ER and regulate the activity of enzymes that support cholesterol and fatty acid synthesis. Genes for these proteins are transcriptionally induced by HCV[81]. The phosphorylation and activation of these proteins *via* the MAP kinase or PI3-K-Akt pathways leads to induction of fatty acid synthase. Activation of SREBP1 by HCV core protein requires the participation of PA28γ, a nuclear protea-

some activator[82]. Lipid droplets accumulate fat and are the place of HCV full particle assembly[83]. Since lipid droplet content is regulated in part by autophagy[84] and autophagic degradation of the substrates (including lipids) is compromised by HCV and ethanol, this defect in autophagy may further promote fat deposition in the liver of HCV alcohol-consuming patients.

CONCLUSION

Autophagy is mediated by autophagosomes that "capture" autophagic substrates (proteins and lipids) and deliver them to the lysosome for further degradation. Ethanol up-regulates the upstream part of autophagy (autophagosome formation), but it suppresses lysosomal function, thereby negatively affecting protein degradation. By creating ER stress, HCV also enhances autophagosome formation; however, some HCV proteins (p7) interfere with normal lysosome function. In addition, autophagic proteins are involved in regulation of HCV replication. Autophagosome content hepatoma cells can be further increased by exposure to ethanol. The effects of ethanol on HCV replication are redox-dependent (require elevated NADH/NAD+ ratio). Thus, HCV- and alcohol-modified autophagy apparently plays a role in enhanced viral replication, intracellular virus accumulation and steatosis progression in HCV-infected alcohol-consuming patients.

Abstract

Chronic consumption of ethanol has a dramatic effect on the clinical outcome of patients with hepatitis C virus (HCV) infection, but the mechanism linking these two pathologies is unknown. Presently, *in vitro* systems are limited in their ability to study the interaction between a productive wild-type HCV infection and chronic ethanol exposure. Mouse models are potentially very useful in dissecting elements of the HCV-ethanol relationship. Experiments in mice that transgenically express HCV proteins are outlined, as are experiments for the generation of mice with chimeric human livers. The latter models appear to have the most promise for accurately modeling the effects of chronic ethanol intake in HCV-infected human livers.

INTRODUCTION

Chronic consumption of ethanol has a dramatic effect on the clinical outcome of patients with hepatitis C virus (HCV) infection. HCV-infected patients who also abuse alcohol have higher levels of HCV RNA[1], accelerated progression of fibrosis[1] and clinical disease[2,3], and an overall increased risk for development of hepatocellular carcinoma (HCC)[4,5]. Although both chronic alcohol use and HCV infection are individually injurious to the liver, when combined, their effects seem to be multiplied. Despite the well-known deleterious consequences of this combination, however, the mechanism that links these two pathologies remains obscure.

Complicating the study of HCV and ethanol is the fact that *in vitro* systems that support viral replication are based on the HCV strain JFH-1[6], a genotype 2a virus that caused an acute self-limited viral hepatitis in a young Japanese male[7]. Although unquestionably valuable in advancing the field of HCV biology, care must be taken in extrapolating results from this unique viral strain into wild-type strains in the community. Furthermore, the hepatoma-derived cell lines that are capable of supporting HCV replication, such as Huh-7, are inherently deficient in main ethanol-metabolizing enzymes such as CYP2E1 and alcohol dehydrogenase, although this has been overcome in part through the engineering of cell lines to metabolize ethanol and support HCV replication[8].

As pointed out by McCartney and Beard[9], progress

in this area has been significantly hampered by lack of a small animal model system. Species-restriction of HCV to humans and chimpanzees has impaired the ability to study HCV and ethanol use *in vivo*. Researchers have attempted to overcome this block through the development of transgenic strains of mice that express key portions of the HCV genome, and through the creation of mice with chimeric human livers. In this review, we explore the studies in transgenic systems, and examine humanized mouse models as potential platforms for HCV/ethanol studies.

TRANSGENIC MOUSE SYSTEMS

Transgenic mice that express portions of or the entire HCV genome have been created[10-12], and some strains have been used in experiments that have explored the relationship between ethanol administration and viral protein expression. In core-expressing mice exposed to 5% ethanol feeding for 3 wk, total reactive oxygen species were significantly elevated as compared to control animals[13]. In the absence of ethanol, these same mice showed activation of the mitogen-activated protein kinase pathway (which led to enhanced cellular proliferation signaling), which was significantly enhanced by the addition of 3 wk ethanol[14]. These murine experiments suggest that hepatocarcinogenesis mediated through the expression of HCV core protein is enhanced by medium-term administration of ethanol, and that this model system is appropriate for assessing the core protein/ethanol interaction.

In another series of experiments that have examined the HCV/ethanol relationship, core-expressing mice were subjected to chronic ethanol feeding (20% ethanol for 10 mo), and examined for effects on lipid oxidation and peroxidation, hepatic lipoprotein secretion or cytokine expression[15]. No interaction was seen between core expression and ethanol ingestion for lipid oxidation or secretion of lipoproteins, but an additive effect was seen on lipid peroxidation and a synergistic effect on expression of hepatic transforming growth factor-β and tumor necrosis factor-α. The latter effect mimics the accelerated fibrosis that is seen in HCV-infected patients who abuse alcohol, and supports the validity of a core-expressing transgenic mouse model for long-term experiments.

The interaction between NS5a expression and ethanol ingestion in carcinogenesis has been explored in an elegant study by Machida *et al*[16], who have used mice on a C57BL/6 background that transgenically expressed NS5a with either wild-type or knocked-out Toll-like receptor (TLR)4 expression. When fed ethanol by intragastric infusion for 4 wk, alcoholic steatohepatitis was significantly increased in NS5a-expressing mice compared with non-expressing controls; an effect that was largely ameliorated by TLR4 knockout. In a longer-term experiment, NS5a-expressing mice with or without TLR4 fed a control diet for 1 year showed no development of HCC, whereas, when they were fed a 3.5% ethanol Lieber–DeCarli diet for the same time, HCC developed in 23% of NS5a TLR4$^{+/+}$ mice but not in NS5a TLR4$^{-/-}$ mice.

These findings suggest that NS5a expression and ethanol ingestion affect hepatic inflammation and carcinogenesis, which are mediated through the TLR4 pathway. In similar experiments using 12-mo ethanol feeding in NS5a-expressing mice (wild-type TLR4), upregulation of oncogenic pathways such as RNA pol Ⅲ dependent transcription and TBP and Brf1 expression were induced in animals that were chronically fed alcohol[17]. Taken together, these studies support a role for chronic ethanol use enhancing inflammation and carcinogenesis in livers that express NS5a.

Although they are seemingly valid and useful for studying the interaction between virally expressed proteins and ethanol ingestion, it is important to stress that transgenic models are not models of infection, and the expression of viral proteins is not under the same controls as would be seen in naturally infected hepatocytes. Although some investigators have demonstrated that expression of viral proteins is similar to that seen in human tissue sections[16], the expression is indiscriminate in all hepatocytes, which differs from the variable regions of replication seen in human liver. Additionally, the intracellular location of expression might differ from that in wild-type infections. Transgenic models are undoubtedly useful, but cannot yet evaluate the interaction of ethanol and HCV within the context of a full viral reproductive cycle.

CHIMERIC MOUSE MODELS

Given the species-restriction of HCV and the general inability to infect and maintain primary human hepatocytes in culture reliably, researchers have turned to alternate approaches to develop a model that is capable of supporting HCV infection *in vivo*. The establishment of murine models that support engraftment and expansion of non-transformed human hepatocytes within the liver has led to the term "chimeric mice", which here refers to mice with livers that are composed of substantial numbers of human hepatocytes. Two separate models, the Alb-uPA and the FAH-deficient mouse, appear to be capable of sustained support of human liver cells, and demonstrate many properties that make them useful for the study of HCV and ethanol.

Alb-uPA model
The first success in this area was the development of the SCID/Alb-uPA mouse[18]. The Alb-uPA transgene is a tandem array of murine urokinase genes under the control of the albumin promoter, which target overexpression of urokinase to the murine liver *in utero* and after birth[19,20]. Expression of the transgene causes a bleeding diathesis and hepatic toxicity, and produces a chronic stimulus for regeneration to which the mouse is incapable of responding. After spontaneous somatic deletion of portions of the transgene[20], cells are no longer restrained by expression of the transgene, and rapidly proliferate to fill the liver with non-transgenic cells, which reverses the liver and bleeding defects. By transplanting either mouse or rat hepatocytes into the portal venous system (*via* the

spleen), rapid expansion of the transplanted cells leads to similar reversal of the Alb-uPA phenotype[21,22].

Mice from the Alb-uPA strain have been crossed with an immunodeficient strain (c.b17-SCID-bg) and the transgene bred to homozygosity. These mice can then be transplanted intrasplenically with human hepatocytes, and have been shown by multiple groups to be capable of supporting high levels (up to 90%) of human chimerism within the liver[18,23,24]. In mice with sufficient human chimerism (typically > 20%), after inoculation with HCV, infections are established at levels identical to those seen in infected humans, and the infected state persists to beyond 16 wk after inoculation, often to the life of the infected animal[18]. The virus can be serially passaged between mice, which confirms that fully formed and infectious particles are produced, and the mice are capable of being infected with virus passaged through cell culture. Infections have been successfully established using viral genotypes 1a, 1b, 2a, 3a, 4a, and 6. The system has been confirmed by multiple groups to model accurately entry, replication, packaging and release of infectious particles[25], respond to human interferon $\alpha 2\beta$[26,27], putative antiviral agents[27,28], and blockade of infection by passive immunization[29].

Important in the study of ethanol-HCV interactions is the similarity between chimeric mouse and normal human liver metabolism. Similarities in the genomic response to HCV infection between human and chimeric mouse livers have been demonstrated by Walters et al[30], which suggests that not only does the system support the viral life cycle, but it also models the normal human response. In a series of experiments by a Japanese group, it has been shown that chimeric mouse livers express a wide variety of mRNA for drug-metabolizing enzymes and transporters[31], and that the levels of protein expression of these enzymes are very similar to those from source human liver tissue[32]. The expression of specific cytochrome P450 enzymes has also been studied, and shown to be appropriately expressed and induced (CYP3A4[33]), and inhibited (CYP2D6[34]). Although there have been no published studies on the metabolism of ethanol in chimeric livers, generalizing from other enzymes systems, it would appear likely to be very similar to that in humans.

FAH-deficient model

An alternate model of repopulation has been developed based on mice rendered deficient in the tyrosine catabolic enzyme fumarylacetoacetate hydrolase (FAH)[35]. FAH mutant mice are protected by administration of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) in their water source, and develop liver disease when it is withdrawn, hence allowing for conditional expression of the phenotype. After withdrawal of NTBC, there is a stimulus for proliferation that can be exploited to expand a population of transplanted hepatocytes, similar to what happens in the Alb-uPA model. By crossing the FAH-deficient trait onto an immunodeficient background (Rag2/common γ-chain knockout), a strain of mice has been produced that is capable of supporting expansion of hu-

man hepatocyte grafts[36]. This model requires temporary introduction of the uPA gene *via* an adenoviral vector[37] to initiate engraftment. This model has the advantage of being useful for transplantation at any age (Alb-uPA mice are typically transplanted between days 7 and 28 of life), however, usable engraftment (serum human albumin level > 1 mg/mL) was achieved in only seven of 43 transplants (16%); somewhat lower than that seen in the Alb-uPA model. However, very high level engraftment has been achieved in some cases.

Chimeric FAH-deficient mice have been shown to express drug-metabolizing genes (CYP1A2, CYP3A4) at levels typical of adult human liver, and when hepatocytes have been isolated from chimeric livers and plated in temporary cultures, they have been found to be indistinguishable from primary human hepatocytes in standard drug metabolism assays[36]. In experiments by another group, these chimeric mice have been shown to be capable of supporting HCV infection, and of responding to standard antiviral therapies, including pegylated interferon (peg-IFN), peg-IFN plus ribavirin, and the cyclophilin inhibitor Debio 025[38]. Based on these experimental findings, it appears that chimeric FAH-deficient mice should also be appropriate for the modeling of HCV/ethanol interactions in the human liver.

Pilot studies of HCV and ethanol in Alb-uPA mice

We have conducted preliminary studies on the feasibility of using chimeric mice in the study of HCV/ethanol interactions, based on the Alb-uPA model. Potential concerns about tolerability of an ethanol regimen, as well as the ability to model the human response to ethanol exposure have been addressed by feeding a cohort of chimeric mice a diet including 20% ethanol in water for 5 wk. These mice tolerated the ethanol protocol with a slight decrease in weight and fluid consumption, as compared with mice on a control diet, and no evidence of increased mortality. At completion of ethanol feeding, liver samples from two of these mice were taken and analyzed by HPLC for glutathione (GSH) and SAM levels. These samples demonstrated a 40% decrease in SAM levels and an 83% decrease in GSH levels; both indicative of chronic ethanol toxicity on the livers. Studies of ethanol administration in HCV-infected mice are ongoing.

CONCLUSION

Based on the state of knowledge presently available, study of the complete interaction between ethanol and natural HCV infection will require the use of mouse models. Transgenic models have proven useful to study the relationship between ethanol exposure and viral protein expression, but have limitations in how accurately they can model HCV infections in humans. Studies based on chimeric mice appear to be the most promising, but have their own complexities which include technical challenges in establishing these models and the ability to extract the human response of a chimeric liver from within its murine

background. However, in well-engrafted mice, the overall response seems to mimic that of humans so closely that the murine background might not matter.

Abstract

Liver diseases are an increasingly common cause of morbidity and mortality; new approaches for investigation of mechanisms of liver diseases and identification of therapeutic targets are emergent. Lipid rafts (LRs) are specialized domains of cellular membranes that are enriched in saturated lipids; they are small, mobile, and are key components of cellular architecture, protein partition to cellular membranes, and signaling events. LRs have been identified in the membranes of all liver cells, parenchymal and non-parenchymal; more importantly, LRs are active participants in multiple physiological and pathological conditions in individual types of liver cells. This article aims to review experimental-based evidence with regard to LRs in the liver, from the perspective of the liver as a whole organ composed of a multitude of cell types. We have gathered up-to-date information related to the role of LRs in individual types of liver cells, in liver health and diseases, and identified the possibilities of LR-dependent therapeutic targets in liver diseases.

Key words: Hepatocytes; Stellate cells; Kupffer cells; Endothelial cells; Signaling; Therapeutic; Viral; Hepatitis C virus; Metabolism

INTRODUCTION

The liver is the largest parenchymal organ of the body and has a multitude of important and complex functions; among the most notable are the metabolism of fat, proteins, and carbohydrates, synthesis and secretion of bile, microelement recycling and detoxification of products resulting from body metabolism (bilirubin, ammonia, *etc.*) and from exogenous toxins (drugs, alcohol and environment)[1]. The liver is also an immune[2] and an endocrine[3,4] organ and functions as a blood capacitance reservoir[5,6]. To accomplish these many assignments, the liver accommodates a wide variety of cell types, including those that call liver "home", namely liver progenitor cells, hepatocytes, Kupffer cells (KCs), stellate cells (SCs) and the cellular components of vasculature, and those that use the liver as a temporary and/or terminal station, such as blood cells[1,7]. Liver diseases are the 10th leading cause of death and account for significant morbidity across the entire age and gender spectrum of the US population[8,9]. The mechanisms of liver diseases are extensively researched but not fully understood. More recently, research data have emerged proposing that some pathogenic mechanisms, such as inflammation, tissue death and regeneration, and organ remodeling, are shared across a large spectrum of liver diseases of distinct etiologies[10-14], with the suggestion that common denominators of cell structure or function may be involved. Here we have focused on a common denominator of the cellular structure, the lipid rafts (LRs), as players in liver physiology and pathology.

Cellular membranes separate each cell and define their entity. The main components of the cellular membrane are lipids and proteins[15]. Structurally, the membrane lipid molecules consist of a polar globular head and a straight non-polar hydrophobic backbone region. Each row of lipids aligns in a leaflet at the level of globular heads and hydrophobic areas of the leaflet attract similarly charged structures, such as the straight region of another lipid layer. Thus, the plasma membrane (PM) consists of two leaflets with the non-polar regions pointing inward and the polar heads pointing to the water rich-zones (intra- and extra-cellular spaces); architecturally this structure portrays a lipid bilayer[16] (Figure 1). Besides serving as warrant of cellular identity and integrity, the lipid bilayer assures that the membrane is flexible. At lower temperatures, the lipid bilayer forms a gel state and is tightly packed; as the temperature rises the bilayer favors tri-dimensional movement of the lipid molecules and the interior space between the two leaflets becomes more fluid. It is the gel/fluid exchange state that allows horizontal and vertical movement of lipids, and also of other components of the membrane[15-17]. Proteins are embedded into the lipid bilayer, either by spanning through, as transmembrane integral structures that could cross in a single- or multi-pass fashion, or as attached structures; the latter exist as peripheral proteins, attached to the membrane exclusively on either the extracellular or cytosolic face, or as glycosylphosphatidylinositol (GPI)-anchored proteins on the extracellular face of the membrane[18]. At the end of the 20th century, the LR hypothesis of cellular membrane function emerged: this proposed that certain regions of the lipid bilayer modify their chemical composition to become more rigid, thus allowing some membrane proteins to physically segregate depending on their interaction with the bilayer components and with other proteins[19,20]. This theory combined the biological knowledge about cellular activation and the biochemical knowledge about protein folding with biophysical approaches to the dynamic cellular membrane structure and attempted to answer the puzzling question about how proteins cluster and what contributes to signal transduction.

LRS: STRUCTURE, FUNCTIONS AND RESEARCH METHODOLOGY

LR structure and functions

LRs are areas of cellular membranes with a signature composition rich in sphingolipids and cholesterol phospholipids. Saturated fatty acids are preferentially enriched in the side chains of the membrane phospholipids, which allows closer packing and thus increased rigidity, more order, and less fluidity of the LRs compared to the surrounding membrane[15,19-21]. LRs act as a unique platform that aids co-localization of proteins involved in sensing (receptors), reacting (pores) and triggering/sustaining cell activation (intracellular signaling pathways) (Figure 1). Besides their structural signature, LRs exhibit two more unique characteristics: they are small, ranging from several to about

500 nm, and are dynamic, with a variable life span in the order of milliseconds (msec). It is not fully understood whether the LRs form and disintegrate constantly or maintain a longer lifespan when a cell is in its steady state, because a relatively constant number/composition of proteins can be identified in the LRs at this stage. However, once the cell is activated, the LRs undergo a radical change in composition by adding or eliminating certain proteins and thus accommodating the cellular needs for formation of signaling platform in a matter of msec. While they are well documented to be in the PM of the cells, it has been suggested that LRs can also reside in the intracellular structures, such as endoplasmic reticulum (ER), peroxisomes, mitochondria, and endosomes[22-26]; to date it is not clear whether such findings are truly due to LR presence in these intracellular compartments or if they are an artifact of LR isolation/investigation techniques. LRs are present throughout the entire evolutionary chain, from the viruses and bacteria[27] to mammals; the purpose of the LR in evolution is yet to be fully understood.

LR research methodology

Studying the LRs is challenging. With sizes ranging up to 500 nm in diameter, the LRs are beyond the resolution of optical microscopes. For this reason the overlay of one or more stains tagged to the proteins of interest revealing a significant co-localization with the coalesced LRs, labeled indirectly with a fluorescent choleratoxin B, is usually suggestive but never a definite indication of the LR localization of the studied proteins. In addition to being small, the rafts diffuse in msec across the cell membrane and thus require additional efforts for timely detection. The transmission electron microscope can analyze a 5-nanometer-thick cell membrane and captures short time frames; the more dynamic and short-lived rafts can only be observed with advanced imaging techniques such as atomic force microscopy (AFM)[28]. Fluorescence lifetime spectroscopy, including Förster resonance energy transfer (FRET), is becoming more accepted in the LR research field due to the fact that the capacity of energy transfer in FRET is about the size of the rafts and it occurs in the range of msec, thus covering both the size and the life span of the LR. Single point microscopic decay and fluorescence lifetime imaging microscopy are often used in combination with FRET for more comprehensive analysis of LR-related time-sensitive processes[29]. Flow cytometry analysis of LRs is emerging; however, it provides very limited resolution both for the size and for the timing of LR-localized events[30]. Fluorescence correlation and cross-correlation spectroscopy (FCS/FCCS) deliver information of fluorophore mobility and dynamics of lateral heterogeneity in the membrane and can be used in single or multiple colors[31]. Single particle tracking (SPT) can be employed to define the translational trajectory of very small particles, including quantum dots, to identify cluster size confinement based on intensity. The thinning out clusters while conserving stoichiometry of labeling (TOCCSL) technique is employed for

Figure 1 The theoretical model of lipid bilayer and lipid rafts in cellular membranes. GPI: Glycosylphosphatidylinositol; DRM: Detergent-resistant domain.

LR analysis because of its proficiency in discriminating between clusters and monomers[32]. The additional advantage of FRET, FCS/FCCS, SPT and TOCCSL is their high spatial/temporal resolution, and thus their ability to register rafts as they form and dissociate in time. Labeling of living cells with the fluorescent probe 6-acyl-2-dimethylaminonapthalene (Laurdan), which exhibits a 50-nm red shift as membranes undergo phase transition from gel to fluid due to altered water penetration into the lipid bilayer, followed by two-photon microscopy, is often used as another indirect method of LR visualization[33].

Translocation of proteins to or from the LRs is often analyzed by sucrose-density gradient fractionation of the membranes and subsequent Western blot analysis; LRs are defined by their insolubility in diverse nonionic detergents [thus named detergent-resistant domains (DRMs)] and by floating in the low-density sucrose fractions (interface between 5% and 30%) upon ultracentrifugation[34]. Diverse detergents can be employed, yielding diverse composition of DRMs[34-39]. Furthermore, some researchers construct step sucrose gradients and further sub-divide the DRMs into light and intermediately-light fractions, which may have distinct protein composition. It is still debatable as to how closely the DRMs represent the true identity of the LRs; however, this method yields consistent results and is the only one available that allows enrichment and analysis of large protein complexes at reasonable cost and using old-fashioned technology.

The functional assessment of the LRs *in vitro* is usually performed using reduction and enrichment approaches. Treatment with agents leading to cholesterol sequestra-

tion, including amphotericin, filipin or nystatin, inhibition of cholesterol synthesis using HMG-CoA reductase inhibitors, or cholesterol wash-out with mβCD, are among the well-accepted approaches to disrupt putative LRs; they are largely based on cholesterol manipulation[40,41]. Another method commonly utilized for LR destabilization is treatment with fumonisin B1, which removes sphingolipids[40]. The advantage of using mβCD over fumonisin B1 is based on the fact that the former acts rapidly, while the latter requires pretreatment of cells for about 72 h, which is longer than the time some polarized cells, including hepatocytes, can remain truly polarized in isolated cell culture[42]. Cholesterol replenishment and ceramide supplementation, which displaces cholesterol, are often employed to modulate the fluidity of the LRs and thus affect their function.

In vivo LR modulation has gained recent popularity based on findings that dietary lipids can modify lipid composition of cell membranes. In this context, multiple studies have attempted to establish how dietary factors or modulation of blood lipids, including cholesterol, affect LR-based signaling in various cell types[43,44]. Comprehensive experimental-based conclusions about the effects of dietary lipids in regulating LRs in non-liver systems and targeted evaluations of the liver in this regard are still awaited. Reliable methods of *in vivo* visualization of LRs also await development.

The significant difficulties in analysis of LRs in primary biological membranes have led to development of model systems. Diverse artificial membranes and models have been created over time, with different ranges of

spatial and temporal orders, diverse lipid and protein compositions, protein/lipid ratio or thickness of the lipid bilayer[45,46]. While helpful to elucidate the basics of the membrane function and structure, these models lack the combination of the proximity of the membrane with the cytoskeleton and regulatory/signaling proteins that are recruited in diverse ratios and in a time-dependent manner in natural biological membranes[45]; to date there is no comprehensive artificial model of LR-containing membranes.

COMPOSITION OF LIVER LRS

An extensive number of proteins have been identified as residing in LRs in the liver[36-39]. Depending on the method of raft isolation and protein analysis, it is currently estimated that at least 300 proteins reside in the LRs in the normal liver; these data include analysis of both human and rodent livers[36-39]. Bae et al[36] identified 196 proteins and pointed to a relatively large content of mitochondrial proteins in the rat liver membrane LRs. Zhang et al[38] reported 175 non-redundant gene products identified in mouse liver PM, isolated from mouse liver by floating in the sucrose density gradient upon ultracentrifugation, which largely resemble the DRM fraction enriched in LRs[23,34]. Zhang et al[38] also identified that about 50% of the LR-associated proteins were integral membrane proteins with one to seven transmembrane domains (TMDs), 40% represented enzymes, 12% were receptors and 9% were proteins with unknown function. He et al[39] identified 104 proteins in human liver membranes with about one third being of cytoskeletal affiliation, including proteins in fodrin-based meshworks, adhesion proteins involved in inter-cellular junctions, focal adhesions, desmosomes, hemidesmosomes and tight junctions, proteins that regulate F-actin dynamics, and motor proteins; most of these proteins usually affiliate with LRs in other cell types. Mazzone et al[37] pointed to the differential protein identity from the apical and basolateral LRs of the PM in normal rat hepatocytes. These data indicate a great diversity in the types of proteins affiliated with LRs in the liver (Figure 2) and indirectly suggest the importance of the LRs in the liver.

The analysis of the composition/function of LRs in the liver performed so far has involved whole liver and does not take into account that liver, as a whole, accommodates a wide variety of cell types. Nevertheless, fractioning of LRs from the whole liver has revealed novel information and thus spearheaded the interest in the field and targeted focused investigations towards specific liver cell populations.

LRS IN RESIDENT LIVER CELLS

LRs in hepatocytes
LRs aid polarized sorting and trafficking of apical proteins in both directed and trans-cytotic pathways in hepatocytes: Two structurally and functionally distinct PM

Liver lipid rafts:

Are present in all liver cells, resident and non-resident, parenchimal and non-parenchimal
Are enriched in cholesterol
Contain about 300 proteins
According to proteomic analysis, the proteins identified in liver lipid rafts belong to several intracellular compartments including:

- ● Mitochondria
- ● Microsome
- ● Membrane
- ● Unknown/others

Figure 2 Estimation of the protein origins identified in the liver lipid rafts. Adapted, in part, from Bae et al[36], with permission.

domains, i.e. the apical and basolateral domains, determine the tri-dimensional architecture of the hepatocyte as true polarized cells; these domains are separated by the tight junctions. While the molecular signature of apical and basolateral domains is relatively well known, the maintenance of such identity requires sophisticated protein sorting and trafficking, the mechanisms of which are yet to be fully defined. Specific membrane-sorting signals have identified many involved proteins[47]. For example, GPI-membrane anchor and TMD target the proteins to the membrane[48]. Moreover, Tyr- and diLeu-based amino acid motifs, which are recognized by distinct molecular subunits of adaptor complexes, seem to direct the proteins to the basolateral membrane[49].

Two membrane-sorting pathways are known: direct and indirect. Unlike many polarized cells, hepatocytes employ both pathways to guide their proteins to the desired location. In "direct" pathway of membrane targeting, the newly synthesized proteins are primarily sorted in the trans-Golgi network (TGN) and then delivered directly to the membrane; this pathway serves both apical or basolateral membrane domains without advantaging either of them[50]. Membrane multispanning ATP-binding cassette (ABC) transporters, multidrug resistance protein 1 (MDR1), and P-glycoprotein, to name a few, employ the direct sorting mechanism in hepatocytes[51]. In "indirect" pathway, the new protein cargo travels from the TGN to the basolateral surface, from where it is endocytosed and subsequently transported to the opposite apical surface of the membrane, as reviewed by Nelson et al[52]. This laborious, energy-inefficient and very lengthy process is also called the trans-cytotic pathway and its purpose is not fully understood. The GPI-linked proteins and those with a single TMD preferentially employ the indirect pathway for apical trafficking[53].

Until recently, the factors that directed the proteins into direct *vs* indirect pathways of membrane-sorting were largely unknown. Nyasae et al[54] reported that cholesterol and glycosphingolipids are required for delivery from basolateral early endosomes to the subapical compartment.

Slimane *et al*[55] identified that the protein structure and its lipophilic characteristics sort the differential apical *vs* basolateral targeting of the proteins in a sphingolipid/cholesterol-enriched LRs-dependent manner. These authors also reported that the liver apical proteins that contain multiple membrane-spanning domains are selectively incorporated into lipid microdomains in the TGN and are then transported directly to the apical membrane[55]. However, direct apical sorting is not solely driven by incorporation into LRs *per se*[55]. Conversely, proteins that have only one TMD or tether to the membrane using their GPI anchor are also sorted to the LRs in TNG; they travel first to the basolateral membrane, where LR-based mechanisms are again key in their delivery to the subapical compartment and further exposure on apical membrane. Slimane *et al*[55] additionally suggested that lipid composition of the LRs is also critical for protein sorting. Thus LRs play a key role in both direct and indirect membrane targeting of the proteins and act as sorting platform for directing the proteins *via* one pathway or another.

LRs in hepatocyte polarity: Hepatocytes are classical polarized cells; the adequate function of the liver as an organ is ensured by the spatial setting and by maintenance of hepatocyte polarity. The complex polarity of the hepatocyte is characterized by the existence of several basolateral and apical poles per cell. The complex mechanisms of establishment and maintenance of hepatocyte polarity are not fully understood; however, a role for calcium waves has been proposed. In hepatocytes the Ca^{2+} waves are polarized, thus occurring in an apical-to-basal fashion[56]. The polarity of the Ca^{2+} signal is largely due to the increased density of inositol 1,4,5-trisphosphate receptor (InsP3R) in the pericanalicular region; redistribution of InsP3R from the apical to the basolateral region is associated with concomitant slowing of the onset and speed of Ca^{2+} waves in hepatocytes[57]. The pericanalicular accumulation of InsP3Rs in not exclusive to hepatocytes, as it is also observed in other types of polarized cells such as pancreatic acinar cells, cholangiocytes, salivary acinar and duct cells[58]. The pericanalicular area has been named the "trigger zone," because it defines the subcellular region that triggers the formation of Ca^{2+} waves[59,60]. The pericanalicular area is rich in LRs and it is also a preferred localization of InsP3Rs; most importantly, recruitment of InsP3Rs to this area is highly dependent upon the presence of intact LRs[57]. Similar to InsP3R redistribution, LR disruption by cholesterol depletion substantially slows Ca^{2+} waves in hepatocytes[57]. The expression of apical InsP3Rs is decreased or absent in cholangiocytes from patients with primary biliary cirrhosis, sclerosing cholangitis, common bile duct obstruction, and biliary atresia, suggesting that InsP3Rs deficit and/or misplacement may represent a final common pathway for the development of cholestatic disorders[61]. Given the key role of LRs in housing the InsP3Rs on the apical hepatocyte membrane, it is easy to envision a role for LRs and/or hepatocyte

de-polarization in cholestatic disorders; this area remains open for investigation.

LRs as signaling platforms: The hepatocyte PM houses a wide variety of proteins that function as sensors, receptors, and/or transporters; these proteins allow the hepatocyte to react to a rapidly changing extracellular environment and accommodate the needs of homeostasis. Among the best researched hepatocyte receptors for which the intracellular signaling pathways are well defined and the ties to LRs are well established are hepatocyte growth factor (HGF) receptor (HGFR), epidermal growth factor (EGF) receptor (EGFR), angiotensin Ⅱ type 1 (AT₁R) and insulin receptor (IR) receptors.

The HGFR, also called c-Met, is activated by HGF and triggers hepatocyte proliferation, morphogenesis and survival. Defects of HGFR are a cause of hepatocellular carcinoma[62]. The HGFR is a heterodimer that exhibits tyrosine kinase activity and associates with a multiprotein complex to trigger downstream signal systems, including src, Grb2/SOS, PI3 kinase, Gab1 and focal adhesion kinase; the adequate function of these adaptors/signal transducers is largely dependent on LRs[63,64]. To date, it is not clear if the HGFR itself is localized in the LRs. However, HGF promotes HGFR association with CD44 and recruitment of this multi-protein receptor complex into caveolin-enriched LR microdomains[65]. The LR-dependent HGF/HGFR signal plays a role in several pathologic processes, including protection from lipopolysaccharide-induced vascular hyper-permeability[65]; its role in hepatocyte function remains to be clarified.

EGF binds to the EGFR and regulates hepatocyte growth both *in vivo* and in primary culture. EGFR signaling activates a group of signal transducers and activators of transcription, which increase the transcription of a characteristic set of early growth response genes thus leading to hepatic DNA replication[66]. In normal adult liver, EGFR expression is low, whereas EGF is virtually nondetectable. In contrast, in advanced cirrhosis, a continuous EGFR synthesis is accompanied by EGF expression that is localized to hepatocytes and proliferative bile epithelium[67,68]. EGF treatment is followed by rapid ubiquitination of the EGFR in hepatocytes[69] and plays a key role in trafficking of the EGFR between early and late endosomal compartments[70]. Ubiquitinated EGFR is internalized almost exclusively *via* a non-clathrin LR-dependent route[70]. In this context, EGFRs recruited to LRs in response to EGF derive almost exclusively from endosomes[24]. EGFRs in early endosomes are more tyrosine phosphorylated than those in late endosomes, indicating that EGFR might be partially dephosphorylated in an LR-dependent manner before accessing the late compartment; however, once localized, the EGFRs in endosomal LRs are relatively resistant to dephosphorylation[24]. Some of the kinase receptors that are internalized through caveolin-containing LRs have a high probability of being directed to the degradative pathway rather than having a function in signaling[70]. To this extent, the EGFR is no

exception: the EGF-engaged EGFRs that are localized in LRs are more tyrosine phosphorylated than EGFRs in whole endosomes. Endosomal LRs recruit highly Tyr-phosphorylated EGFR along with various signaling proteins, including Grb-2, Shc, and c-Src, indicating a likely role for this compartment in signal transduction[24]. According to Teis et al[25], targeting of the MP1-ERK1/2 complex to late endosomes during EGF-mediated ERK activation depends on the adaptor protein; further, p14-MP1-ERK1/2 complex formation is needed for EGF-induced ERK activation at later stages of this process. Thus, it seems plausible that intracellular LRs target the ubiquitinated PY-EGFR/Grb2/Shc complex to the cytoplasmic face of the late endosomes for specific activation of ERK1/2. If this theory holds true, the ubiquitinated EGFRs should be later sorted into the intraluminal vesicles of late endosomes before their degradation or may be recycled back to the PM. This hypothesis was in part confirmed by data from Balbis et al[24] and by Lai et al[26], thus placing the LRs among the key players in ensuring efficient EGF/EGFR function. The possibility that this LR-dependent mechanism can be exploited is valid, because some of the widely-used drugs can be employed for this purpose. For example, heparin can suppress LR-mediated signaling and ligand-independent EGF receptor activation[71]. The detailed role of LR-mediated EGF/EGFR function in liver diseases remains to be determined.

Angiotensin Ⅱ (AT) engages and initiates angiotensin AT_1 receptor (AT_1) signaling which is involved in cell growth and mitogenesis[72]. At least in C9 liver cells, Ang Ⅱ-stimulation involves LR-mediated activation of ERK1/2[73]. Furthermore, Yin et al[74] reported that in angiotensin-stimulated C9 cells the cholesterol-rich LR domains mediate the actions of early upstream signaling molecules such as Src kinases and intracellular Ca^{2+} and that LR resident caveolin-1 has a scaffolding role in this process. Angiotensin causes caveolin-1 phosphorylation that is in turn regulated by intracellular Ca^{2+} and Src, thus indicating reciprocal interactions between LRs, caveolin-1, Src kinases, and intracellular Ca^{2+} through the AT_1[74].

Insulin is an anabolic hormone with a role in carbohydrate and lipid metabolism and cell growth. The IR is a transmembrane tyrosine kinase that binds insulin with its two extracellular α-subunits and transmits signals via its two β-subunits that contain the tyrosine kinase domain; the receptor is activated by autophosphorylations. LRs ensure the initial steps of IR activation[24,75,76]. IR β subunits require palmitoylation for proper function[75]; however, regardless of its palmitoylation status, the unoccupied IR has low affinity to LRs[76]. In adipose or muscle tissue, IR needs to partner with caveolin-1 for function. In the liver, the autophosphorylation of the insulin engaged-IR still takes place in the LRs but can occur with[24] or without[76] caveolin participation. In the latter context, glycophospholipid clustering inhibits IR phosphorylation and IR is excluded from the LRs when the latter are more rigid[76]. These results suggest that LRs offer an additional

level of control over IR function in the liver and support the hope that manipulation of LRs could modulate IR activity and thus liver metabolism.

LR role in bile formation/secretion: Bile production is one of the basic functions and an organ-specific signature of the liver. ABC transporters are located in the canalicular membrane of hepatocytes and are critical players in bile formation and detoxification. ABC is a family that includes P-glycoprotein (MDR1) for organic cations; MDR2 for phosphatidylcholine translocation; P-glycoprotein-related protein acting as bile salt export pump; and MRP2 (or cMOAT) for non-bile acid organic anions[51]. ABC transporters are located in LRs of the hepatocyte cellular membrane and mediate the transport of the majority of lipids secreted into the bile[77].

The canalicular PM is constantly exposed to bile acids, which act as detergents. Once secreted into bile canaliculi, bile salts extract phosphatidylcholine from the outer leaflet of the cellular membrane and incorporate it into mixed micelles. The bile preferentially extracts phosphatidylcholine; the latter constitutes only about 35% of canalicular phospholipids in the context of a relative abundance of sphingomyelin, thus the bile threatens the well-being of healthy cells. During evolution, a protective mechanism was developed in all bile-exposed cells to prevent self-solubilization with own bile by means of expressing a combination of distinct LRs that have unique lipid composition and protein content. Ismair et al[35] reported the existence of at least two such LR entities on the canalicular side of the hepatocyte PM. One of these is rich in caveolin-1, contains the majority of canalicular cholesterol and phospholipids, portions of the marker enzymes APN and DDPIV, and a large portion of all known ABC transporters including ABCG5, BSEP, MRP2, MDR2, and MDR1; this LR is Lubrol-soluble. In contrast, Triton-soluble LRs are associated with reggie-1/2 proteins and sphingomyelin; they contain a minor fraction of canalicular cholesterol, APN, DDPIV and MDR1/2 ABC transporters[35]. The exact purpose of such differential expression of ABC transporters in distinct LRs is not fully understood; furthermore, their distribution in LRs in steady-state vs activated state is largely unknown. However, several liver diseases are linked to ABC defects; for example, recessively inherited hepatobiliary phenotype is related to mutations in ABC transporter genes; defects in ABCB11 and MDR3 lead to familial intrahepatic cholestasis types 2 and 3, respectively; Dubin Johnson syndrome is associated with defects in MRP2 produced, and sitosterolemia with defects in ABCG5 or ABCG8[51]. It is also known that an altered secretory process of biliary cholesterol is associated with elevated hepatic cholesterol levels[78], thus suggesting the possibility that low membrane fluidity due to stabilization with cholesterol could provide an additional layer of control of ABC transporter function. It remains to be investigated whether the increased rigidity of LRs, which occurs when cholesterol content in the cell increases[15,16], may supplement the impairment of bile se-

cretion in real-life liver diseases in addition to functional impairment of ABC transporters *per se*.

LRs in KCs/monocytes

KCs are active immune players and participants in a wide variety of liver diseases. The role of the LR in KCs is currently unknown, in part due to the scarcity of primary KCs and difficulties with their isolation. However, taking into account that KCs are tissue macrophages (Mf), several key findings about the role of LR in other types of tissue Mf could be extrapolated to KCs.

Inflammation occurs in a diverse array of liver diseases and is highly dependent on Mf. In Mf, the key molecules involved in pathogen recognition from exogenous danger signals either reside (CD14) or are recruited [Toll-like receptor (TLR)2, TLR4] to the LRs upon ligand engagement[79,80]; the function of pathogen recognition is thus highly dependent on LRs and suggests that LR modulation may be a candidate for managing the macrophages. Indeed, exposure to acute alcohol renders Mf temporarily insensitive to TLR4/CD14 ligands in a LR-dependent manner[81,82]. Similar to alcohol, selective modulation of fat content in LRs by macrophage-specific ABC transporter A1 also dampens inflammation by reducing MyD88-dependent TLRs trafficking to LRs[83]. Furthermore, peritoneal macrophages from dyslipidemic mice are primed for more robust TLR responses, reflecting increased LRs and increased TLR4 expression[84]. In the same dyslipidemic mice, the Mf from the lung airspace, in which cholesterol is maintained as constant during dyslipidemia, have normal responses and normal composition of LRs[84]. It is important to note that LRs also drive the Mf response to endogenous danger signals, such as those coming from dead cells. In this context, necrotic but not apoptotic cells co-localize with LRs within engulfing Mf. Interestingly, necrotic cell-induced secretion of tumor necrosis factor (TNF)-α and interleukin (IL)-1β by Mf is susceptible to LR destruction, suggesting a role for LRs in the signaling of necrosis-driven inflammatory response[85].

Related to the role of liver in the iron cycle, the ability of Mf to capture/store iron is highly dependent on the LRs. Expression of the iron exporter ferroportin at the PM of Mf is enhanced by iron loading and is decreased by hepcidin[86]. Macrophage ferroportin is preferentially located in caveolin/flotillin 1-enriched LRs; iron overload strongly increases the presence of ferroportin in the LRs, while LR destruction decreases hepcidin activity on macrophage ferroportin[86]. Collectively, these data support the idea that LRs participate in several key Mf functions that are key for liver homeostasis.

LRs in SCs

The SCs store retinol and are the main cellular source of collagen and other extracellular matrix substances in normal as well as fibrotic livers. The LR composition, and their distribution and function in primary SCs are largely unknown, mainly due to limited numbers of SCs isolated from the normal liver and extreme technical difficulties

of their isolation from the fibrotic liver. Andrade *et al*[87] employed the murine hepatic SC line GRX, which expresses the myofibroblast phenotype at baseline and can be induced *in vitro* to display the fat-storing phenotype (lipocytes), to show that total ganglioside content and GM2 synthase activity were lower in myofibroblasts compared to lipocytes. Both SC phenotypes presented similar content of gangliosides GM2, GM1, and GD1a, as well as their precursor GM3. Sphingomyelin and all the gangliosides were expressed as doublets; their ratio is increased in retinol-induced lipocytes due to increased content of long-chain fatty acids[87]. Taken together, these results indicated that myofibroblasts and lipocytes can use distinct ceramide pools for sphingolipid synthesis. Differential ganglioside expression and presence of long-chain saturated fatty acids suggested that these components could participate in the formation of LRs with specific functions in the two phenotypes of GRX-SCs[87].

Anandamide (AEA) is an amide of arachidonic acid and ethanolamine with endogenous endocannabinoid function that engages cannabinoid and other yet unknown receptors, and exerts a variety of physiological and pharmacological effects in chronic liver diseases[87]. Yang *et al*[88] employed the hepatic SC line T6 and reported that moderate AEA amounts inhibited hepatic SC proliferation and high-dose AEA caused hepatic SC death; cell death was necrotic rather than apoptotic and occurred independently of cannabinoid receptors. More importantly, AEA-mediated death in hepatic SCs was dependent on the cholesterol content of the membrane LRs, the fatty acid composition of the membrane, and the function of PI3K/protein kinase B signaling pathway[87]. These data gave support to speculations that AEA may be a potential antifibrogenic drug in the treatment of liver fibrosis in a LR-dependent manner.

Sonic hedgehog (Shh) is an embryonic morphogen that is key in cell proliferation, differentiation, and morphological patterning during embryogenesis; the Shh signaling pathway also promotes maintenance of adult stem cells and is involved in tumorigenesis[89]. In the hepatic SC line HSC8B, Shh physically interacts with caveolin-1 within the LRs in the Golgi apparatus to form large protein complexes that are packaged as large punctuate structures (transport vesicles) and transported to the PM in an LR-dependent manner[90]. Collectively these data suggest that LR manipulation can have a significant impact on liver SCs.

LRs in endothelial cells

Liver sinusoidal endothelial cells (ECs) isolate and protect the hepatocytes from passing blood and play an important role in hepatic microcirculation. Microvascular exchange in the liver is governed by fenestrations in sinusoidal ECs and is key to proper liver function. One of the basic properties of liver endothelium is the fact that there is no basal lamina, thus allowing free passage of macromolecules up to medium-sized chylomicrons[91]. The fenestrae are surrounded by a dense ring of actin,

whereas the sieve plates are formed by microtubules; both number and size of fenestrae can be regulated by a variety of processes that will impact on hepatic function. For example, loss of fenestrae or sinusoidal capillarization occurs in alcoholic liver disease (ALD) and cirrhosis, respectively[91,92]. While the details in the liver are unknown, in other vascular systems the ECs are heavily governed by the functionality of their LRs. Disruption of LRs in ECs causes loss of cell viability and altered cell morphology, including loss of fenestration[93,94]. LRs govern the function of EGFR, multi-drug resistance P-glycoprotein, and adhesion molecules in ECs, and are critical to a sound EC-gated vascular barrier, at least at the blood/brain interface[95-98]. LRs also house the NADPH oxidase components gp91, p22phox, and p47phox; several pro-inflammatory cytokines, such as TNF-α, employ a LR-dependent mechanism to trigger oxidative stress and eNOS production in ECs[99].

LRs in cholangiocytes

Cholangiocytes outline the intrahepatic bile ducts; they are of epithelial origin, share their common hepatoblast progenitor with the hepatocytes and, similar to them, are polarized cells[100]. The cholangiocytes function as regulators of ductal bile secretion; in addition, they absorb and secrete water, organic anions, organic cations, lipids, and electrolytes[101]. Cholangiocytes interact with the immune cells and are potent cytokine producers, thus playing a role in liver immune responses[100,101]. Several research groups have recently reported that polarized primary rat cholangiocytes express LRs[102,103]. McWilliams identified that Shank2E, which is an ankyrin repeat-rich multidomain scaffolder, is localized in the LRs of the apical surface of the cholangiocytes[103]. LRs not only host but are also vital for the function of Shank proteins, which involves coordination of the targeted delivery of the proteins to the apical membrane in actin-containing cytoskeleton-dependent fashion[103]. These novel findings point to the role of LRs in cholangiocyte function.

LRs in non-resident liver immune cells (dendritic cells, natural killer cells, lymphocytes)

At any given time healthy liver accommodates a wide variety of non-resident immune cells, including dendritic cells (DCs), natural killer (NK) cells and lymphocytes; selective recruitment and retention of certain immune populations occurs during diverse liver diseases and these cells play a critical role in development and resolution of liver inflammation, remodeling and injury[2]. All immune cells have LRs as components of their cellular membranes; more importantly, LRs participate in some of the key functions of the immune cells.

DCs recognize, engulf, process and present antigens to other immune cells while producing a wide array of immune-modulating factors, including cytokines, chemokines, and metabolites, to control the immune responses. LRs provide the signaling platforms for a variety of DC receptors, including TLRs, major histocompatibility complex molecules, and co-stimulatory molecules; disruption

of LRs significantly impairs the functional capacity of DCs[104-106]. More recently, Wang et al[107] reported that high-density lipoprotein (HDL) promotes reverse cholesterol transport and is protective against dyslipidemia and atherosclerosis. Further, they reported that HDL and apolipoprotein A-I promoted tolerance and inhibited immune responses by inhibiting the ability of antigen presenting cells, and DCs in particular, to stimulate T cells in a cholesterol-dependent manner[107]. HDL-induced cholesterol efflux from cells alters their LR structure, which in turn activates the TNF-α converting enzyme ADAM17-dependent processing of transmembrane substrates[108]. These findings suggest that LRs may play a role in HDL-induced DC impairment and further regulate the inflammatory processes; these authors also suggested that modulation of LRs in DCs could provide a desirable approach to inducing immune tolerance[108].

NK cells link innate and adaptive immunity via the production of cytokines and have the ability to kill/lyse infected non-malignant and tumor cells. Unlike other immune cells, NKs are activated and inhibited by separate sets of receptors which ensure their rapid initiation and prompt silencing to promote immune response without autoimmune reactions. LRs are implicated in both activating and limiting steps of NK function. Upon CD2 cross-linking or target cell binding, the NK-activating receptors aggregate in the LRs, which further leads to the formation of complexes of LAT with PI3K and PLC-γ1 which are essential for the NK lytic mechanisms[109]. Moreover, NK cell cytotoxicity was found to be closely related to total plasma cholesterol concentration in humans[110]. Further, colocalization of the IL-12 receptor and FcγRIIIa to LRs leads to activation of ERK and enhanced production of interferon-γ by NKs[111]. Engagement of inhibitory receptors by HLA class I on target cells blocks phosphorylation of 2B4 receptor which is found exclusively in LRs. CD94/NKG2A is an ITIM-containing inhibitory receptor expressed by NK cells that recognizes HLA-E; the engagement of this receptor prevents NK cell activation by disruption of the actin network and exclusion of LRs from the point of contact with its ligand. The latter structure is an inhibitory NK cell immunological synapse (iNKIS) and is key to NK function. Thus, targeted LR exclusion from the iNKIS is an active process that aims to maintain LRs outside the inhibitory synapse[112,113]. These data suggest that LRs are actively engaged in dousing the NK activity. However, the DCs and NK cells work closely together; in the reverse order of events, activation of resting NK cells by mature DCs is important at the initiation phases of immune responses; more importantly, DC/NK cross-talk is dependent on CX3CL1, intact cytoskeleton and LRs[114].

Lymphocytes are classified into T and B cells, and further differentiated in diverse subpopulations depending on their abilities to produce certain cytokines or antibodies, respectively.

In T-lymphocytes, LRs are implicated in signaling from the T-cell antigen receptor (TCR) and in localization and function of proteins recruited/activated downstream

from the receptor. Statins (inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A reductase) block cholesterol biosynthesis and reduce the pathogenesis of classical T-cell-inducing damage in experimental autoimmune encephalomyelitis by interfering with leukocyte recruitment, transmigration through vascular barriers and their adhesion, and ultimately limiting T-cell activation, as reviewed by Weber et al[115]. Polyunsaturated fatty acids (PUFAs) intercalate and thus remodel LRs; treatment of TCR-stimulated T-lymphocytes with PUFAs leads to miss-localization of LR-anchored TCR adaptor LAT, reduction in LAT tyrosine phosphorylation and low IL-2 production[116]. PUFAs inhibit the formation of the immune synapse[117]; it remains to be determined if this is due to isolated effects of PUFA on LRs of T cells, on DCs, or on both. Exposure of T cells to sialidases, which are able to hydrolyze the non-reducing terminal sialic acid linkage, led to control of LR-associated glycosphingolipid content and influenced activation in T-lymphocytes. Furthermore, sialidase inhibitor oseltamivir (Tamiflu) down-regulated the expression of LR-resident GM1 on the surface of T-cells and reduced cytokine production in activated T-cells[118,119]. These results suggest that LR-dependent modulation of T cells has translational potential.

In B lymphocytes, B-cell depleting anti-CD20 antibodies, namely rituximab, induced translocation of CD20 to the membrane LR fraction and triggered cell apoptosis; this process was prevented by LR disruption[120,121]. While the detailed mechanisms of such LR-mediated cytotoxicity of malignant B cells is not well understood, it is known that in normal B cells, trafficking of internalized Ag/B-cell receptor (BCR) complexes to intracellular Ag-processing compartments is driven by ubiquitination of the cytoplasmic domain of the BCR. The ubiquitinated Ag/BCR complexes are formed via a signaling-dependent mechanism and restricted to PM LRs[122]; the signaling from BCR is initiated only when the LR localization is accomplished. At this stage, Bright, which is a B-cell-restricted factor, forms complexes with Bruton's tyrosine kinase (Btk) and its substrate transcription initiation factor-I (TFII-I), and acts to activate immunoglobulin heavy chain gene transcription in the nucleus[123]. In resting B cells, palmitoylated pool of Bright is diverted to LRs where it associates with signalosome components. After BCR ligation, Bright transiently interacts with sumoylation enzymes, blocks calcium flux and interferes with phosphorylation of Btk and TFII-I; Bright is then excluded from LRs as a Sumo-I-modified form. The remaining LR-associated Bright contributes to the signaling threshold of B cells: the sensitivity to BCR stimulation decreases as the levels of Bright increase[123]. Thus, LRs play a key role in governing B cell function.

IMPLICATIONS OF LRS IN LIVER DISEASES

Bacterial and viral diseases

Role of LRs in bacterial infections involving liver: Lis-teria monocytogenes (LM) causes severe liver disease in children, pregnant women and in immunocompromised individuals. LM proteins internalin and InIB bind E-cad-herin (E-CAD) and HGFR, respectively; engagement of E-CAD and HGFR are sufficient for LM invasion into the host hepatocyte[124]. More importantly, intact host LRs are needed to complete the E-CAD/HGFR-mediated entry of LM[124,125].
