Abstract

The need for interval appendicectomy (I.A) after successful conservative management of appendiceal mass has recently been questioned. Furthermore, emergency appendicectomy for appendiceal mass is increasingly performed with equal success and safety to that performed in non-mass forming acute appendicitis. There is an increasing volume of evidence -although mostly retrospective- that if traditional conservative management is adopted, there is no need for routine I.A except for a small number of patients who continue to develop recurrent symptoms. On the other hand, the routine adoption of emergency laparoscopic appendicectomy (LA) in patients presenting with appendiceal mass obviates the need for a second admission and an operation for I.A with a considerable complication rate. It also abolishes misdiagnoses and deals promptly with any unexpected ileo-cecal pathology. Moreover, it may prove to be more cost-effective than conservative treatment even without I.A due to a much shorter hospital stay and a shorter period of intravenous antibiotic administration. If emergency LA is to become the standard of care for appendiceal mass, I.A will certainly become 'something' of the past.

INTRODUCTION

Acute appendicitis is the most common surgical emergency which may be complicated by the development of an appendiceal mass in 2%-10% of cases[1]. This mass results from a walled-off appendiceal perforation and represents a wide pathological spectrum ranging from an inflammatory mass that consists of the inflamed appendix, some adjacent viscera and the greater omentum (a phlegmon) to a periappendiceal abscess[2]. Ultrasonography has been advocated as the diagnostic modality of choice, revealing the diagnosis in 70% of cases, however, contrast-enhanced computerized tomography (CT) scanning is far superior[1]. The standard treatment which was introduced by Ochsner in 1901 advocating a conservative regimen (nil by mouth, intravenous antibiotics, bed rest and watchful observation) has proved popular over the years and has been shown to be safe and effective[1]. It allows the acute inflammatory process to subside in more than 80% of cases before interval appendicectomy (I.A) is performed some 8-12 wk later. However, some management issues of appendiceal mass such as the need for I.A after successful conservative treatment, and emergency appendicectomy for a 'hot' appendix

mass have recently surfaced with no general consensus or agreement on the appropriate line of management.

THE CONTROVERSY OVER INTERVAL APPENDICECTOMY

A recent questionnaire study of 67 surgeons in the Mid Trent region of England showed no agreed consensus on the management of appendiceal mass[3]. One of the controversial management issues is the need for I.A after successful conservative treatment. A survey of 663 surgeons in North America revealed that I.A is routinely performed by 86% of the surveyed surgeons[4]. The most cited reason is the risk of recurrent appendicitis which is reported to occur in 21%-37% of cases[4,5]. Another questionnaire survey of 90 consultant general surgeons in England (response rate: 78%) revealed that 53% of surgeons perform I.A routinely some 6-8 wk after resolution of the mass; mainly because of concerns about symptom recurrence[6]. However, the study from Mid Trent region, U.K showed that more than 75% of surveyed surgeons do so[3]. Moreover, the specialist registrars are less likely to offer patients routine I.A after successful conservative management than their consultants ($P < 0.05$)[3] which may reflect a change in the attitude of younger surgeons towards I.A.

The argument of recurrent appendicitis has been questioned as it occurs in less than 20% of cases and the risk becomes minimal after the first 2 years of the initial episode[3,7]. Hence, more than 80% of patients with appendiceal mass can be spared the morbidity of a surgical intervention that has questionable validity. Moreover, a recent large retrospective population-based cohort study of 1012 patients treated initially with conservative therapy showed that only 39 (5%) patients developed recurrent symptoms after a median follow-up of 4 years with male sex having a slight influence on recurrence[4]. Hence, it may be concluded that I.A after initial successful conservative treatment is not justified[4].

THE ARGUMENTS AGAINST I.A

A prospective non-randomized study of 48 I.A specimens, showed 37 (77%) appendices to have a patent lumen, while only 11 (23%) showed fibrosis and obliteration of appendicular lumen and symptom recurrence approaching 40%[5]. This fact has led some authors to advocate routine I.A. However, this means subjecting many patients to unnecessary I.A which necessitates a second admission and is not entirely free of complications; the reported complication rate of I.A is 12%-23%[1,8,9]. It seems that the driving force behind I.A after successful conservative treatment is the fear of symptom recurrence. Many other studies, however, have confirmed a low recurrence which is highest during the first 2 years of the initial inflammation[3,7]. A recent prospective randomized controlled trial (RCT) showed that patients treated conservatively without I.A had the shortest hospital stay and duration of work-days lost, and only 10% of patients developed recurrent appendicitis during a median follow-up period of more than 33.5 mo[10]. This overwhelming evidence from a well conducted RCT and the fact that the histological examination of 30% of the I.A specimens were found to be normal with no evidence of previous inflammation[1] argues strongly against routine I.A after the successful conservative treatment of an appendix mass.

Moreover, 83% of patients presenting with appendix mass did not require any intervention over a mean follow-up of 15.5 mo[11]. Therefore, I.A should not be the rule in every patient presenting with appendiceal mass. Karaca *et al*[12] demonstrated complete disappearance of the mass on repeat ultrasonography and normal appendix on barium enema in 10 out of 11 children with appendiceal mass who were treated conservatively with triple antibiotics for a week. None of these patients developed recurrent appendicitis during the follow-up period of 1-7 years, confirming that conservative treatment is feasible with no need for I.A[12]. However, a week of intravenous triple antibiotics in hospital[12,13] and repeated ultrasonography[12] is certainly not cost-effective. This cost needs to be compared with the cost of emergency laparoscopic appendicectomy (LA) for appendix mass. In term of costs, routine I.A is indeed not cost-effective as it involves another admission and an operation which is not free of complications; it increases the cost per patient by 38% compared with a more selective approach (follow-up and appendectomy only if recurrence occurs)[14].

Furthermore, only very few (20%) patients benefit from prevention of recurrent symptoms if I.A is performed after 6-12 wk and the complication rates for appendicectomy performed before or after recurrence of symptoms were equal at 10%[15].

HIDDEN PATHOLOGY

If I.A is not performed after successful conservative treatment, the fear of missing hidden pathologies such as cecal cancer, Crohn's disease and ileo-cecal tuberculosis masquerading as an appendiceal mass becomes an important issue. In a recent retrospective review of 106 patients, 17 (10.3%) patients had their diagnosis changed during follow-up; 5 patients (3%) were found to have colon cancer[15]. It is therefore essential to perform some follow up investigations to exclude the presence of such hidden pathologies. It is advocated to perform barium enema or colonoscopy after the acute episode has subsided in patients who have been treated conservatively[15], especially if aged more than 40 years[7,12]. However, there is no general consensus as to the right time to perform such an investigation. Timing is important as incompletely resolved appendix mass may mimic cecal carcinoma on barium enema and may give false positive results. A CT scan or CT colonography augmented -when indicated- by colonoscopy is far superior in excluding cecal pathology. It is believed that such investigations can be performed safely 4-6 wk after the acute episode[16].

IS I.A "SOMETHING" OF THE PAST?

Is I.A 'something' of the past? The short answer is no, as

delayed appendicectomy is needed for patients with recurrent symptoms and those with a patent or chronically inflamed appendix[17]. The problem of how to determine the patency of the appendix and chronicity of the inflammation still remains in patients presenting with appendiceal mass who have settled on conservative treatment[16]. This may be done by performing barium enema on all patients treated conservatively and only those with patent appendices may be offered LA. However, this may prove impractical, costly and may increase the workload of any radiology department. Contrast-enhanced CT scanning is another modality that may help in this regard as it may strongly suggest the presence of underlying neoplasm in the majority of patients with secondary appendicitis[18].

EMERGENCY SURGERY FOR APPENDIX MASS IN THE LAPAROSCOPIC ERA

Fear of the increased risk of intraabdominal abscesses[19] after performing LA in complicated appendicitis has recently been dismissed[20]. The successful adoption of laparoscopic I.A after successful conservative treatment is reported without perioperative morbidity[21,22] and the percentage of I.As which are performed laparoscopically has increased in recent years from 30% to 85%[22]. The operating time and complication rates did not differ from those of open I.A, but the hospital stay was much shorter in favor of the interval laparoscopic method[20,22-25].

Is there a role for LA in the emergency intervention for appendiceal mass? The answer is yes. Senapati *et al*[21] reported experience with emergency LA in patients with appendiceal mass in comparison with LA for non-mass-forming appendicitis. It was found that early emergency LA for appendiceal mass is feasible and safe; moreover, its operative time and hospital stay are comparable to those of LA performed for non-mass forming appendicitis[]. However, the proper timing for emergency surgery needs further substantiation.

Another major advantage of emergency surgery is that it obviates the need for a second hospital admission, avoids misdiagnoses and promptly deals with any unexpected ileocecal pathology that masquerades as an appendiceal mass. Furthermore, LA can be offered safely and successfully in the interval setting after successful conservative treatment for those with recurrent symptoms [20,22-25].

THE NEED FOR RCTS

The majority of -if not all- studies on I.A after conservative treatment of appendiceal mass are retrospective. The need for prospective randomized controlled multi-institutional trials is essential to scientifically compare emergency surgery for appendiceal mass with conservative management without I.A[26]. Such trials are needed to establish the safety of emergency open *vs* laparoscopic appendicectomy for appendix mass and to establish the safety of omitting I.A in those treated conservatively with successful outcomes. Such studies should look into various cost issues and the possible differences -if any- in the management of appendiceal masses in various age groups (pediatric *vs* adults) and different sexes (males *vs* females)[26]. The question of "golden hours" for emergency LA for 'hot' appendix masses -similar to that identified for emergency laparoscopic cholecystectomy for acute cholecystitis- needs to be answered. The possibility of increased infertility in females with appendiceal masses treated conservatively should also be studied to determine if emergency surgery is more beneficial in affected females in order to make a stronger argument for emergency management, at least, in females.

CONCLUSION

Based on the above, it seems that I.A can be safely omitted after exclusion of other ilo-cecal pathologies. This avoids a second hospital admission and a surgical procedure which is associated with a 10%-20% complication rate. I.A will still be reserved for patients with recurrent symptoms and can be performed safely by laparoscopic means. Emergency laparoscopic appendicectomy is emerging as a new safe treatment modality for the appendiceal mass, and may prove to be more cost-effective than conservative treatment even without I.A as it is associated with a much shorter hospital stay and obviates the need for long intravenous antibiotic therapy. It further obviates the need for I.A; the centre of controversy. If emergency LA becomes the standard of care, I.A will certainly become 'something' of the past.

Abstract

The physiologic and pathologic cellular and molecular changes occurring with age in the human colon affect both the inflammatory process leading to mucosal injury and the regenerative capacity of the epithelium. On the one hand, age-related telomere shortening and inflamm-ageing may lead to the development of colonic inflammation, which results in epithelial damage. On the other hand, the altered migration and function of regenerative stem cells, the age-related methylation of mucosal healing-associated genes, together with the alterations of growth factor signaling with age, may be involved in delayed mucosal regeneration. The connections of these alterations to the process of ageing are not fully known. The understanding and custom-tailored modification of these mechanisms are of great clinical importance with regard to disease prevention and modern therapeutic strategies. Here, we aim to summarize the age-related microscopic and molecular changes of the human colon, as well as their role in altered mucosal healing.

Key words: Colon; Mucosal repair; Ageing; Colorectal cancer; Telomere shortening; DNA methylation

INTRODUCTION

With the possible exception of stem cells and tumor cells, ageing is a nearly universal process that, through functional decline, leads to cell death and, eventually, death of the organism. The age-related molecular changes taking place in the human colon have not been exactly determined; moreover, the results of animal tests and human studies are sometimes contradictory.

Researchers have identified a variety of changes in colonic and rectal function associated with ageing. The total number of colonic myenteric neurons decreases with age in rats and in children, particularly during the first 4 years of life[1,2]. While noting an increase in the surface area of myenteric ganglia with age, Hanani *et al*[3] found that the proportion of ganglia with cavities and other structural abnormalities increases with age. Furthermore, a positive association between age and collagen content within myenteric ganglia has also been identified[2]. These changes in colonic innervation may have an impact on colonic motility[4-9].

As far as colonic epithelium is concerned, its renewal takes 4-5 d in humans[10]. The regulated balance of epithelial proliferation and apoptosis allows normal epithelial regeneration. Any deviation in epithelial cell kinetics may result in a loss of not only structural but also functional integrity. The imbalance of colonic epithelial renewal may lead to either ulcer or carcinoma development of the colonic mucosa.

The effect of ageing on colonic epithelial regeneration is not fully understood. In rat colon, crypt epithelial proliferation and apoptosis were found to be the most active in the 3rd week of life[11], which was thought to

be in connection with the development of the gastrointestinal tract. The results of Xiao *et al*[12] are, however, contradictory; the number of proliferative epithelial cells was higher, while the rate of apoptosis was lower in older rats. The epithelial expression of the anti-apoptotic Bcl protein and of the pro-apoptotic Bak protein was also in accord with ageing: the former was high, while the latter was low in older rats. This phenomenon may explain the survival of genetically defective cells, hence the increasing incidence of colorectal cancer in the elderly. The age-related rise in cell proliferation is thought to be in part the result of enhanced transition from G1 to S phase as well as stimulated progression through the S phase of the cell cycle[13,14]. Inconsistencies in results may be due to different sampling locations and different ages of the animals, together with the effects of errors in sample proceedings, immunohistochemical methods and data evaluation[15].

Inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease, are one of the major causes of epithelial destruction in the colon. It was recently demonstrated that the perceived differences seen in clinical practice between adults and children with UC are largely due to a decrease in histologic features of colitis in children less than 10 years of age[16]. As children approach adulthood, the degree of inflammation and microscopic architectural distortion seen becomes similar to that found in adults. Interestingly, in rectal biopsies of UC, no differences were found amongst all age groups.

Although the understanding of age-related physiological and pathological processes is of great clinical importance, data about the effect of ageing on the induction of mucosal inflammation and the age-related alterations of mucosal healing are scarce in scientific literature.

THE EFFECT OF AGEING ON INFLAMMATION INDUCTION

Telomere shortening and telomerase activity

Telomeres protect the ends of the chromosomes from end-to-end fusions, degradation and recombination. Telomere length decreases with age in most human tissues, including colon[17], and it has been hypothesized that short telomeres might partially explain the connection between cancer and ageing[18]. Telomeres shorten approximately 100 base pairs in each cell division because of their incomplete replication[19] and also as a consequence of oxidative damage[20]. When telomeres become critically short, and in the absence of efficient DNA repair mechanisms, anaphase bridges are formed during mitosis as a result of end-to-end chromosome fusions, which initiates breakage-fusion-bridge cycles. These cycles facilitate the accumulation of genetic changes and chromosomal instability; hence cells need to acquire mechanisms of telomere maintenance, which usually consist of telomerase reactivation. Telomerase prevents further accumulation of chromosomal instability and confers unlimited replicative potential to the cell[21]. It has been previously demonstrated that in UC, colorectal cancer progression is associated with shorter colonocyte telomeres, chromosomal instability and anaphase bridges[22]. It has also been observed that age-related telomere shortening is accelerated in UC[23]. It seems that there is a minimal viable length of colonocyte telomeres, consistent with data from both human cell lines[24] and a telomerase-deficient mouse model[25]. After reaching this critical length, colonocytes defective for DNA damage checkpoints can continue to proliferate but with increased chromosomal instability. Together with alterations in p53 and p16, which are frequent in the non-neoplastic epithelium of UC[10,26,27], this could be a common pathway of tumor progression in this chronic inflammatory disease.

Interestingly, decreased telomerase activity was observed not just in the non-neoplastic epithelium of severely active UC, but also in the non-affected normal mucosa[28,29]. This result suggests that telomerase deficiency may contribute to the pathogenesis of the disease. Moreover, the elevated epithelial telomerase expression found in mildly active UC[30] may help survival and immortalization of the genetically defective epithelial cells in long-standing, chronic inflammation, and thus create the basis for subsequent pathological cell proliferation.

Alterations of immune response

Ageing is associated with a progressive dysregulation of immune response. During ageing, adaptive immunity significantly declines, a phenomenon called immunosenescence, whereas innate immunity seems to be activated, which induces a characteristic pro-inflammatory profile. The latter is called inflamm-ageing[31,32].

Recently, a new subset of CD4+ T cells has been identified. The Th17 cells are distinct from the Th1 and Th2 cells, and secrete interleukin 17 (IL-17) and IL-22[33,34]. IL-17 has been shown to be a primary mediator in several autoimmune and inflammatory diseases, including IBD[35]. Ouyang *et al*[36] demonstrated that the induction of Th17 cytokines is significantly elevated in both aged humans and mice. In addition, they found that memory T cells are an important cell type for the induction of IL-17, and that the transfer of CD4+CD45Rbhi cells from aged mice induced more severe colitis in recombination-activating gene 1-deficient mice compared to cells from young mice. Their results suggest that ageing promotes an intrinsic predisposition towards the pathological Th17 immune response, which may explain the second peak (between 50-80 years of age) in the incidence of IBD which occurs in humans.

Ageing also results in alterations in the function of Toll-like receptors (TLRs), which have an important role in the pathogenesis of IBD[37]. Recent studies have begun to elucidate the consequences of ageing on TLR function in human cohorts and add to existing findings established in animal models. In general, these studies show that human TLR function is impaired in the context of ageing, and in addition there is evidence for inappropriate persistence of TLR activation in specific systems[38-41].

It has been shown in a mouse model that ageing and TLR2 deficiency have significant effects on the levels of pro-inflammatory cytokines, such as IL-10 and IFN-γ,

which could potentially provide a microenvironment that favors the development of more severe colitis following epithelial damage[42]. It has also been reported that the level of trefoil factor 3 (TFF3), an important colonic protective and repair factor, decreases over time in mice, and is negatively regulated by TLR2 signaling[42]. Cytokines such as TNF and IL-1β negatively regulate TFF3 expression in an epithelial cell line by activation of NF-κB, which has been demonstrated to negatively regulate the transcription of TFF3[43,44]. These interactions among ageing-associated changes, TLR deficiency and TFF3 regulation may be of particular relevance in understanding the development of chronic intestinal inflammation and mucosal injury in the elderly.

Several TLR polymorphisms are also involved in the course of IBD[45-47], although it seems likely that large-scale population studies will be needed to clarify the role of key TLR polymorphisms in ageing-related alterations of IBD pathogenesis.

THE EFFECT OF AGEING ON COLONIC MUCOSAL HEALING

Stem cells

The luminal border of the colonic wall is lined by an epithelial monolayer which has several functions, such as water and electrolyte absorption, and it is also a barrier against luminal pathogens[48,49]. Due to the high turnover of shedding epithelial cells, their continuous replacement from the local stem cell pool is required even in healthy colon. Stem cells are located at the basal part of crypts; their progeny migrate towards the luminal surface and undergo terminal differentiation to secretory (Paneth, enteroendocrine and goblet cells) and absorptive (epithelial) cells[48-50]. In the case of tissue injury, such as in IBD or graft-versus-host disease (GVHD), the capacity of intestinal stem cells is not sufficient for the perfect tissue repair, hence the homing of bone marrow-derived multipotent cells is also essential for mucosal regeneration[48,51,52]. It is well known that circulating hematopoietic stem cells (HSCs) play an important role not just in hematopoietic homeostasis, but in the regeneration of solid-organ tissue, which has been certified by several studies[53]. Stem cells are long-lived cells; therefore, they can sustain several genetic and epigenetic changes during cellular senescence. There is evidence both for and against stem cell ageing, and publications are not in agreement with regard to quality and quantity alterations of stem cells in the course of ageing[54].

HSCs in older mice have decreased per-cell repopulating activity, self-renewal and homing abilities, myeloid skewing of differentiation, and increased apoptosis related to stress[55]. It was recently reported that the cyclin-dependent kinase inhibitor p16INK4a, the level of which was previously noted to increase in other cell types with age, accumulates and modulates specific age-associated HSC functions[56]. Notably, in the absence of p16INK4a, HSC repopulating defects and apoptosis were mitigated, improving the stress tolerance of cells and the survival of animals in successive transplants, in a stem-cell-autonomous tissue regeneration model. As p16INK4a is involved in colorectal carcinogenesis[57], it may be supposed to have a specific role in the regulation of the behavior of migrating stem cells of the human colon as well.

Stem cells are in close connection with their niche by means of mechanical and/or chemical processes. Based on the results of bone marrow transplantation studies, one can assume that stem cell function and life span depend on the recipient's age, since increased post-transplant autoimmunity has been observed in the case of older recipients[54]. The age-related decrease of regenerative stem cell capacity, however, needs to be further studied.

The balance of cell proliferation and death ensures adequate epithelial regeneration. Although colonic epithelial stem cells can be distinguished from other epithelial cells only by morphology, several cellular markers may help the identification of both normal and cancer stem cells of the intestinal tract[58-60].

The effect of ageing on colonic epithelial regeneration and crypt-base stem cell function has come to the frontline of discovery recently. In a mouse model, a few apoptotic cells were seen around the stem cell position and this frequency did not alter with age. However, the apoptotic index within crypts was nearly twice as high in older mice after low dose gamma-irradiation and the number of surviving crypts decreased significantly faster after increasing the dose of irradiation; moreover, in the post-irradiation period the crypt regeneration was much slower in older animals[61]. It was shown that clonogenic cells are more radiosensitive in old mice, and that the growth of surviving crypts after injury was delayed in old mice even though the number of resident clonogenic cells were higher in older colonic crypts[62].

Methylation

In non-cancerous colonic mucosa, repeated injuries are likely to induce adaptive methylation changes that enable efficient wound healing and act against cancer development. The methylation-variable sites that are located in promoter or noncoding neutral regions have demonstrated gradual methylation changes associated with the ageing or long-term adaptation process[63]. The presence of transitional-CpG sites between the unmethylated promoters and nearby densely methylated retroelements has been proposed, in order to describe the complexity of variable methylation in gene control regions[64,65]. The transitional-CpG sites at the margin of the CpG islands and at the non-island CpG sites around the transcription start sites have been found to be either under- or over-methylated in a tissue-specific manner as well as to be methylated to various degrees in the same tissue type[65]. This result suggests that the methylation-variable sites nearest to the transcription start sites may serve as epigenetic markers for adaptive DNA methylation. The methylation-variable site of a strongly expressed tissue-specific gene can influence the expression of the nearby gene as well as its related genes. Therefore, the methylation-variable sites of the key colon-specific genes are expected to participate in both the dis-

crete mucosal adaptation and the interactive changes of methylation patterns that lead to mucosal alterations. In the stomach, recent evidence suggests that mucosal injury induces adaptive changes in DNA methylation[66]. The ulcer-healing genes, such as trefoil factor 1 and 2, (TFF1, -2), cadherin 1 (CDH1), and peroxisome proliferator-activated receptor gamma (PPARG), were found to be concurrently methylated with other genes depending on the presence or absence of CpG islands in the normal mucosa of healthy individuals, while both the TFF2 and PPARG genes were frequently undermethylated in gastric ulcer patients.

Age-related methylation loci, such as estrogen receptor 1 (ESR1) and myogenic differentiation 1 (MYOD1), have also been highlighted[67-69]. These loci showed age-dependent methylation in normal colon mucosa, and this type of methylation is considered to serve as a functional link between ageing and cancer, possibly by deregulating the growth and differentiation of normal colonic epithelial cells and predisposing them to tumorous transformation. In addition, methylation of ESR1 in colon epithelium occurs more frequently in patients with UC who have neoplasia than in UC patients without neoplasia[70].

Differences in methylation levels of age-related methylation loci between the proximal and distal colon have also been described[71]. This phenomenon may have an impact not just in colorectal carcinogenesis, but in the understanding of the pathogenesis of UC.

Growth factor receptors

Gastrointestinal mucosal cell proliferation is known to be under the regulation of a number of nutritional and hormonal factors. It was reported that an age-related rise in gastric and colonic mucosal cell proliferation is accompanied by a marked rise in expression and activation of several tyrosine kinases, including epithelial growth factor receptor (EGFR)[72-74]. The age-related rise in EGFR activation in the mucosa of the gastrointestinal tract is not fully understood, but some recent data suggest this could be partly the result of loss of EGFR-related peptide (ERRP), a "negative regulator"[75]. It was recently reported that in Fischer-344 rats, ageing is associated with increased activation of EGFR in the colonic mucosa, as evidenced by a 30%-35% increase in the levels of tyrosine phosphorylated EGFR in the proximal and distal colon of aged (20-22 mo old) compared to young (4-6 mo old) rats. In contrast, the levels of ERRP in both regions of the colon of aged rats were decreased by 50%-60%, compared to their younger counterparts[76]. Expression of ERRP was also found to be high in benign human colon, stomach and pancreas, but low in the respective invasive adenocarcinomas[77,78].

Age-related decrease of EGFR signaling in cells of ectodermal origin has additionally been described[79]. This may cause delayed mucosal healing in the case of older individuals.

Hepatocyte-derived growth factor (HGF) is mainly produced by mesenchymal cells and acts on cells of epithelial origin which express the HGF receptor C-met (HGFR). The HGF-HGFR system is important in gut homeostasis, and has a crucial role in gastrointestinal wound healing[30]. Furthermore, this system has morphogenetic effects, and it also regulates the formation of epithelial tubular and gland structures[30,80]. It was demonstrated that the production of HGF by fibroblasts increased sharply after about 70% completion of their lifespan in culture, which is regulated at the transcriptional level[80]. The expression of HGFR may decrease with ageing as well[81], which may have consequences on tissue repair.

Revealing age-related alterations in the expression of growth factor receptors involved in colonic mucosal repair, and the better understanding of alterations in receptor signaling, may result in new therapeutic targets of colonic mucosal damage.

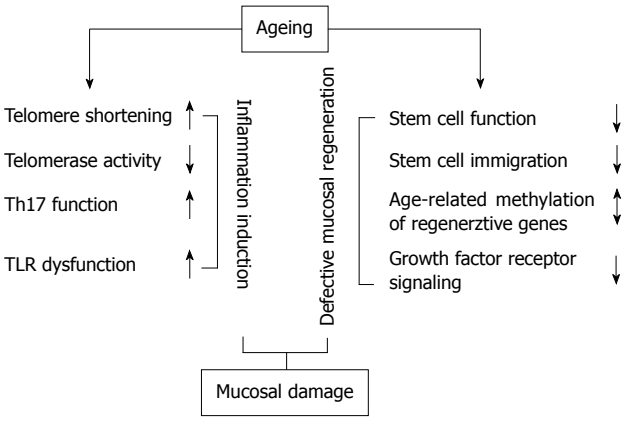

Figure 1 The effect of ageing on factors resulting in colonic mucosal damage.

CONCLUSION

There are numerous signs of ageing in the human gastrointestinal tract, including the colon (Figure 1). Beyond macro- and microscopic alterations, some of these can be detected at the genetic, gene expression and/or epigenetic level. The connection between ageing and colonic mucosal regeneration has been reported by several studies, and their results may provide an insight into physiologic and pathologic mucosal healing in the context of ageing. An understanding of the influence of these age-related mechanisms may help to develop new therapeutic strategies for chronic inflammatory bowel diseases accompanied by mucosal damage.

Abstract

Squamous cell carcinoma of the anus (SCCA) is a common cancer in the human immunodeficiency virus (HIV)-infected population, and its incidence continues to increase in male homosexuals. Combined chemoradiation with mitomycin C and 5-fluorouracil was poorly tolerated by severely immunocompromised patients in the early 1990s. In the era of highly active antiretroviral therapy (HAART), however, recent data indicate that: (1) most HIV patients with anal cancer can tolerate standard chemotherapy regimens; and (2) this approach is associated with survival rates similar to those of HIV-negative patients. However, HIV-positive patients with SCCA are much younger, more likely to develop local tumor recurrence, and ultimately die from anal cancer than immune competent patients. Taken together, these findings suggest that anal cancer is an often fatal neoplasia in middle-aged HIV-positive male homosexuals. In this population, SCCA is an opportunistic disease resulting in patients with suboptimal immune function from persistent infection and prolonged exposition to oncogenic human papillomaviruses (HPVs). Large-scale cancer-prevention strategies (routine anuscopy and anal papanicolaou testing) should be implemented in this population. In addition, definitive eradication of oncogenic HPVs within the anogenital mucosa of high-risk individuals might require a proactive approach with repeated vaccination.

INTRODUCTION

As human immunodeficiency virus (HIV)-infected individuals continue to benefit from highly active antiretroviral therapy (HAART), their risk of dying from neoplasia, including non-AIDS-defining cancers (NADC) is increased[1]. The incidence of squamous cell carcinoma of the anus (SCCA) is not only higher in the HIV-positive population, but continues to increase in the United States[2] (Figure 1). In Australia, anal cancer is now the third most common cancer in the HIV-infected population[3]. SCCA is a sexually transmitted disease clinically related to infection with oncogenic human papillomaviruses (HPV 16-18)[4,5]. Long before the AIDS epidemics, the pivotal role of immune suppression in anal carcinogenesis was highlighted by the high incidence of these tumors in solid organ transplant

patients, irrespective of sexual practice[6,7]. In a large French HIV cohort study, the risk of anal cancer increased with the time during which the CD4 count was < 200 cells/microL and viral load was > 100 000 copies/mL[8]. Thus, both compromised immune function and HPV infection play a role in the development of anal intra-epithelial neoplasia (AIN), the precursor lesion of invasive SCCA.

On a therapeutic standpoint, SCCA has served as a paradigm for the successful application of chemoradiation to solid tumors[9]. Since 1974, it is admitted that: (1) A majority of anal cancers can be cured with chemoradiation therapy (CRT), using 5-fluorouracil (5-FU) and mitomycin C (MMC); and (2) Surgical excision should be restricted to patients who fail to respond to CRT[10,11]. While treatment protocols have remained virtually unchanged during the past three decades, the patients who benefit from this approach nowadays are very different from those who were treated in the 70 s and 80 s. In the 1990s, CRT was poorly tolerated by HIV-positive patients[12,13]. Today, in the Western world, up to 50% of patients with SCCA are relatively young (40-60 years) male homosexuals under HAART[14]. The aim of this paper is to review the clinical data pertaining to clinical outcome of anal cancer in HIV-positive individuals before and after the introduction of HAART.

MANAGEMENT AND OUTCOME OF SCCA IN HIV-NEGATIVE PATIENTS

Combined chemoradiation with MMC and 5-FU is poorly tolerated by immunocompromised patients, and is associated with considerable toxicity in immune competent patients. Many HIV-negative patients with SCCA require radiotherapy breaks and/or chemotherapy dose reduction. In the Memorial Sloan-Kettering Cancer Center series, > 40% (all HIV negative) of patients needed chemotherapy dose reduction of at least one agent, and 77% had at least one radiotherapy break[15]. Data from four prospective randomized trials in HIV-negative patients[16-19] also indicate: (1) a male: female ratio of 1:2; (2) a median age > 60 years; (3) a local failure rate of 30%; and (4) a 3-year overall survival rate of 70%-75% (Table 1).

A closer analysis of data reveals, however, that HIV-negative individuals with SCCA represent a relatively old population of patients who rarely succumb to anal cancer. In the UKCCCR trial[16], 54% of deaths in the chemoradiation group were due to co-morbid conditions or second malignancies, and thus were not related to SCCA. In the RTOG trial[18], out of 146 HIV-negative patients who were treated with MMC-based chemoradiation, there were 32 deaths, but only 15 (46%) were attributed to anal cancer progression. In the MD Anderson Cancer Center series, out of 167 (161 HIV-negative) patients, there were 42 deaths, and only 21 (50%) were due to anal cancer[20]. In summary, 5-year overall survival of HIV-negative patients with SCCA who undergo MMC-based chemoradiation is close to 70%, but > 50% of deaths are unrelated to anal cancer. In accordance with the initial experience of Norman Nigro reported 30 years ago[21], these data indicate that SCCA in this population has limited metastatic potential and is ultimately responsible for the death of < 20% of patients.

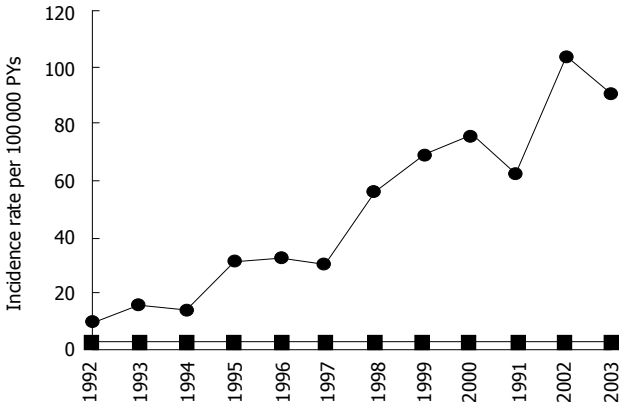

Figure 1 Annual incidence rates of anal cancer among HIV-infected persons (circles) and the general population (squares), USA 1992-2003.

MANAGEMENT AND OUTCOME OF SCCA IN HIV-POSITIVE PATIENTS IN THE HIV ERA (1982-1995)

In the pre-HAART era, HIV-positive individuals demonstrated poor tolerance to MMC-based chemoradiation protocols for anal cancer. Nonetheless, it was recommended that HIV-positive patients with CD4+ > 200/mm^3 should be treated with the standard chemoradiation regimen, whenever possible[22]. In at least seven small series[23-29], clinicians were struck by the fact that HIV-positive and HIV-negative SCCA patients differed by age (40-45 years *vs* 60-65 years), male gender (90%-95% *vs* 35%-40%), and homosexuality. Thus, the experience of treating HIV-positive patients with anal cancer prior to the development of HAART was essentially witnessing the emergence of a high-risk population (Table 2).

Many of these young homosexuals would eventually die of AIDS, with or without evidence of residual anal cancer - but the latter was rarely considered the primary cause of death at a time when median survival with a diagnosis of AIDS was only 17 mo[30]. In the series from Kaiser Permanente Medical Center in Los Angeles[25], after a median follow-up of 38 mo, half of patients were alive and disease-free, while the other half had died from complications of AIDS. Results in terms of local recurrence were disappointing, but many patients did not receive standard chemotherapy for fear of significant hematologic toxicity. Nonetheless, acute toxicity was quite frequent (> 50%), and local tumor recurrence rates were elevated (40%-50%). In addition, Kim *et al*[23] were the first to note that: (1) HIV-positive patients were more likely to die from SCCA than HIV-negative patients, who often succumbed to other, cancer-unrelated causes; and (2) the median time to cancer-related death in HIV-positive individuals was 1.4 years *vs* 5.3 years for HIV-negative patients. Since AIN progresses more quickly towards SCCA in HIV-positive patients, it was logical to hypothesize that

the molecular biology of anal cancer might differ between the two groups[31,32].

MANAGEMENT AND OUTCOME OF SCCA IN HIV-POSITIVE PATIENTS IN THE HAART ERA (1996-)

HAART does neither prevent the development of AIN, nor the progression of AIN towards SCCA[33,34]. The rising incidence of anal cancer in the HIV-positive population during 1996-2004 is well documented[35]. HAART certainly had a positive impact on patients' ability to tolerate chemo-radiation treatment; accordingly, many radiologists strongly caution against scaling back treatment of anal cancer in HIV-positive individuals[36]. This is also motivated by the recent recognition that SCCA is the greatest threat to these patients' lives. We have summarized, in Table 3, the results of eleven studies published since 2004, which evaluated the outcome of HIV-positive patients with SCCA in the HAART era[37-47]. With two exceptions[40,42], these small series are underpowered, and inadequate to detect survival differences between HIV-positive and HIV-negative individuals.

In the Veterans Affairs study[40], the authors concluded that in the HAART era, survival of SCCA is equivalent between HIV-positive and HIV-negative patients (overall 4-year survival 66% *vs* 62%). However, the age distribution of both groups was quite different; among HIV-positive individuals, patients aged 45-49 represented the largest percentage, whereas among HIV-negative individuals the largest percentage of patients was greater than age 75 (Figure 2). In other words, two populations with an age difference greater than 20 years have the same survival, which strongly suggests that SSCA-related mortality was higher in the HIV-positive group. This hypothesis is supported by the multicenter series reported by Oehler-Jänne *et al*[42]: five-year overall survival was similar in both groups (61% *vs* 65%), but HIV-positive individuals had a 4-fold higher risk of locoregional tumor recurrence (62% *vs* 13%), and the majority of them, unlike HIV-negative individuals with SCCA, died of anal cancer. In summary, and in the

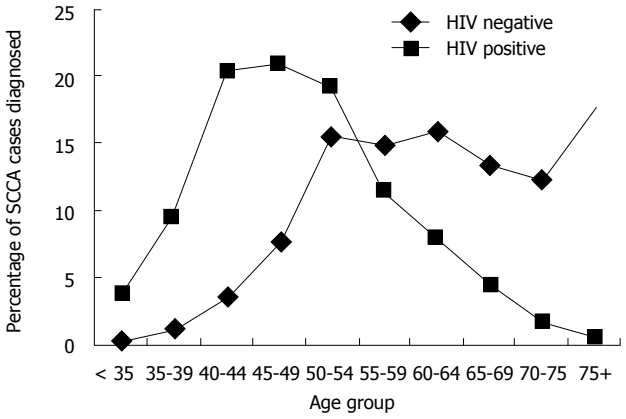

Figure 2 Percentage of anal cancer diagnosed among us veterans by age group (1998-2004). HIV: Human immunodeficiency virus.

HAART era, HIV-individuals with SCCA carry a 50% risk of local relapse and a 33% risk of dying from anal cancer.

CONCLUSION

In some countries, anal cancer is now the third most common cancer in HIV-infected individuals and its incidence continues to increase, despite (or because of) the use of HAART. It is a disease of relatively young male homosexuals, who should be considered candidates for chemoradiation, using standard doses of MMC and 5-FU, as well as pelvic irradiation. There is, however, evidence that HIV-positive patients experience a higher rate of locoregional tumor recurrence and are more likely to die from anal cancer than their HIV-negative counterparts; this explains why both HIV-positive and HIV-negative groups have similar survival, despite a > 20 years difference in age. HIV-positive male homosexuals under HAART are protected from opportunistic infections, but have an increased risk of developing, and eventually succumbing to anal cancer.

SCCA was not a frequent cause of death in HIV-positive patients before 1997-1998, and this affirmation stands true in 2010 for elderly HIV-negative patients. In contrast, for middle-aged male homosexuals under HAART, SCCA is an often fatal, opportunistic cancer which results from the combination of two factors: (1) persistent immune deficiency; and (2) persistent infection with oncogenic HPVs in the anal canal. Cancer-prevention strategies should be implemented in this population: male homosexuals should undergo routine anuscopy and an anal Papanicolaou test to detect and treat precursor lesions of SCCA. This approach, if successful, might hopefully mimic in male homosexuals, the dramatic improvement observed for cancer of the uterine cervix in women. Complete eradication of oncogenic HPVs in the anogenital mucosa might also require a proactive vaccination program for high-risk individuals[48,49]. This approach could also serve an important public health purpose, reducing the pool of susceptible individuals and contributing to the control of re-emerging HPV infection.

Abstract

AIM: To evaluate the effect of RNA interference (RNAi) mediated silence of signal transduction and activation of transcription (STAT)3 on the growth of human pancreatic cancer cells both *in vitro* and *in vivo*.

METHODS: STAT3 specific shRNA was used to silence the expression of STAT3 in pancreatic cancer cell line SW1990. The anti-growth effects of RNAi against STAT3 were studied *in vitro* and in experimental cancer xenografts in nude mice. The potential pathways involved in STAT3 signaling were detected using reverse transcription polymerase chain reaction and western blotting.

RESULTS: The expression of the STAT3 was inhibited using RNAi in SW1990 cells. RNAi against STAT3 inhibited cell proliferation, induced cell apoptosis and significantly reduced the levels of CyclinD1 and Bcl-xL when compared with parental and control vector-transfected cells. *In vivo* experiments showed that RNAi against STAT3 inhibited the tumorigenicity of SW1990 cells and significantly suppressed tumor growth when it was directly injected into tumors.

CONCLUSION: STAT3 signaling pathway plays an important role in the progression of pancreatic cancer, and silence of *STAT3* gene using RNAi technique may be a novel therapeutic option for treatment of pancreatic cancer.

INTRODUCTION

Pancreatic cancer is one of the most lethal solid malignancies and its overall 5-year survival is less than 5%. It represents one of the leading causes of cancer deaths in industrialized countries despite advances in medical and surgical modalities[1,2]. Up till now, surgical resection still remains the only treatment for pancreatic cancer[3,4]. However, because of the aggressiveness of this disease, most patients

have had local or metastatic spread by the time of diagnosis, and surgical resection is possible in only a few patients. Even among patients undergoing a potentially curative resection, the long-term prognosis remains poor due to early recurrence and metastasis[5]. Unfortunately, effective systemic therapy capable of reversing its aggressiveness is unavailable and the specific molecular regulatory pathways involved in pancreatic cancer initiation and progression have not been fully identified[6,7]. Targeting the currently known signaling pathways, however, may lead to effective treatment for pancreatic cancer.

STAT3, a member of the signal transduction and activation of transcription (STAT) family, is a key cytoplasmic transcription factor activated by tyrosine kinase growth and cytokine receptors. Once tyrosine is phosphorylated, two STAT3 monomers form a dimer through reciprocal phosphotyrosine-SH2 interactions, and translocate to the nucleus where they bind to STAT3-specific DNA-response elements of target genes, and induce gene transcription[8,9]. Elevated activity of STAT3 has been found frequently in a wide variety of human tumors including pancreatic cancer[10-13] and STAT3 participates in the occurrence and development of cancers by promoting cell proliferation, inhibiting cell apoptosis, inducing immune escape, and promoting angiogenesis and metastasis[14,15].

STAT3 signaling pathway may represent a new molecular target for novel therapeutic approaches for human cancers. Several reports showed that blocking of STAT3 expression in human cancer cells suppresses proliferation *in vitro* and tumorigenicity *in vivo*. Antisense oligonucleotides and decoy oligonucleotides[16,17], tyrosine kinase inhibitors[18,19], dominant negative STAT3 protein[20], drug-like non-peptide small molecules[21], and RNA interference (RNAi)[22,23] can target STAT3 signaling pathways. Among them, RNAi is the most popular one.

RNAi is a phenomenon of gene silencing, resulting from specific degradation of homologous mRNA mediated by small interfering RNA (siRNA) produced through degradation of double-stranded RNA (dsRNA)[24,25]. Gene silencing involving RNAi requires the processing of long double-stranded RNA (dsRNA) into 19- to 21-nt RNAs, which is called small interfering RNA (siRNA). This process is mediated by Dicer, a type of endonuclease. Subsequently, the siRNA molecules are incorporated into the RNA-induced silencing complex (RISC). The active complexes recognize and cleave the homologous mRNAs, thus selectively inhibiting the expression of the target gene[26,27]. Currently, a prompt and highly-effective method has been developed in RNAi technique to inhibit the expression of specific genes, and has been widely applied in the research of viral diseases, genetic diseases and malignant tumors[28].

The present study was designed to evaluate the use of RNAi to knockdown STAT3 expression and activation, and their effects on human pancreatic cancer cell growth both *in vitro* and *in vivo*. The phenotypic growth changes resulting from the reduction of STAT3 expression were observed both *in vitro* and *in vivo*. We found that knockdown of STAT3 gene by RNAi significantly suppressed the expression of CyclinD1 and Bcl-xL, both of which were accompanied with marked inhibition of tumor cell growth *in vitro* and *in vivo*. Our results demonstrate that STAT3 signaling pathway plays an important role in the progression of pancreatic cancer and that knockdown of STAT3 gene using RNAi technique may be a novel therapeutic option for treatment of pancreatic cancer.

MATERIALS AND METHODS

Cell lines and culture conditions

Human pancreatic cancer cell line SW1990 and PANC-1 were purchased from American Type Culture Collection (Manassas, USA). They were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum, 100 units/ml penicillin, and 100 μg/mL streptomycin in a humidified incubator with an atmosphere of 5% CO_2 and 95% air at 37℃.

In our previous studies, three coding regions corresponding to nucleotides 1819-1837, 1025-1043 and 237-255 of STAT3 sequence in the GenBank (NM003150) were selected to form siRNA target sequences. Three primer pairs were synthesized: one pair encoding nucleotides sites 1819-1837 (CTGCTAAGATTCAGTGAAA) followed by a 9 base "loop" (TTCAAGAGA) and the inverted repeat (STAT3-siRNA-1), the second one encoding nucleotides sites 1025-1043 (GCGTCCAGTTCACTACTAA) also followed by the loop and the inverted repeat (STAT3-siRNA-2), and the third one encoding nucleotides 237-255 (TCAGCACAATCTACGAAGA) again followed by the loop and the inverted repeat (STAT3-siRNA-3). We then constructed three STAT3 specific shRNA expression vectors (pRNAT-STAT3-siRNA-Ⅰ, Ⅱ, Ⅲ) and found that pRNAT-STAT3 siRNA-Ⅱ had the most obvious gene silencing effect. We also constructed scrambled siRNA expression vector as a negative control (pRNAT-Con). We established stable SW1990 pRNAT-Con transfectants (SW1990-Con) and SW1990 STAT3-RNAi transfectants (SW1990-RNAi) and found that stable transfection of pRNAT-STAT3-siRNA-Ⅱ vector silenced STAT3 expression. The stably transfected cells were used for subsequent studies[29].

Immunohistochemical detection of STAT3 in pancreatic tissues

Primary pancreatic tumors were found in 71 patients suffering from pancreatic cancer. Informed consent was obtained for the use of tissues in this study from all the patients, who underwent surgical treatment at Affiliated First People's Hospital of Shanghai Jiao Tong University. Ten normal pancreatic tissues were collected through regular multi-organ donor procedures. Paraffin wax samples from the 71 cases of primary pancreatic tumors and 10 with normal pancreatic tissues were cut into 4-μm-thick slices. These slices were dewaxed and the endogenous peroxidase activity was quenched after incubation in methanol con-

taining 3% hydrogen peroxide for 10 min. The histologic sections were incubated with a rabbit anti-human STAT3 polyclonal antibody (Cell Signal, USA) or rabbit polyclonal IgG controls (Vector Laboratories, USA) in blocking buffer overnight at 4℃. The sections were then rinsed in PBS (containing 0.5% bovine serum albumin and 0.1% Tween-20) and incubated for 30 min with biotinylated goat anti-rabbit IgG (ABC staining kit, Santa Cruz, USA) diluted according to the manufacturer's protocol. Next, a solution of avidin-conjugated horseradish peroxidase (ABC staining kit) was applied for 30 min, according to the manufacturer's instructions. Peroxidase activity was developed in 0.5% (vol/vol) 3,3'-diaminobenzidine hydrochloride (DAB, Sigma, USA) in PBS containing 0.03% (vol/vol) hydrogen peroxide for 2 min. Sections were counterstained with Harris' hematoxylin and mounted in gelatin (Sigma, USA). The criteria for immunohistochemical assay are as follows: positive cells contained brown particle staining in the nucleus or cytoplasm. Samples with < 5% positive cells were designated as negative (-); samples stained slightly (5%-25% positive) were designated as (+); samples stained moderately (25%-50% positive) as (++), and stained deeply (> 50 % positive) as (+++).

Cell proliferation assay and anchorage-independent growth assay

To quantify cell proliferation, SW1990 cells and stably transfected cells (SW1990-Con, SW1990-RNAi) were seeded in a 96-well plate at a concentration of 5×10^3 /well (100 μL/well). Eight parallel wells were assigned to each group. Then 20 μL/well of 5 mg/mL MTT (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) was added at 24 h, 48 h and 72 h after seeding and the cells were nurtured for another 4 h. The supernatant was removed and the product converted from MTT was dissolved by adding 150 μL/well dimethyl sulfoxide (DMSO) and shaking for 10 min. Optical density (OD) readings were obtained at 490 nm. The cell growth rate was represented by the relative ratio of OD490 at 24, 48 and 72 h, to OD490 at 0 h, respectively. The growth curve was drawn according to the cell growth rate. A soft agar colony formation assay was used to assess the anchorage-independent growth ability of cells. Specifically, SW1990, SW1990-Con and SW1990-RNAi cells were plated on a 0.6% agarose base in six-well plates (1.0×10^3 per well) in 1 mL DMEM medium containing 10% fetal bovine serum and 0.3% agarose. Colonies > 100 μm were counted 14 d after plating.

Cell apoptosis assay

Cell apoptosis was assessed by apoptosis kit (Roche, USA), according to the manufacturer's protocol. Briefly, SW1990 cells, and stably transfected cells SW1990-Con and SW1990-RNAi were collected to make single cell suspensions (5×10^6 cells). And 20 μL fluorescence-tagged Annexin-V and 20 μL pyridine iodinate (PI) were added into 1 mL incubation buffer to prepare the marking liquor. Cells were washed once by PBS and centrifuged at 500 × *g* at 4℃ for 5 min. The supernatant was discarded. The cell deposition was resuspended with 100 μL marking liquor and placed in dark at normal temperature for 10-15 min. Flow cytometric analysis showed that Annexin-V^+/PI cells were early apoptotic cells, while Annexin-V^+/PI^+ cells were late apoptotic and dead cells.

Cell cycle assay

SW1990 cells and stably transfected cells, SW1990-Con and SW1990-RNAi , were collected and fixed. After incubation in RNase A for 30 min at 37℃, the cells were stained with PI. Flow cytometric analysis was done using a FACScan instrument (Becton Dickinson, Mountain view, CA) and CellQuest software

Animals

Male athymic BALB/c nude mice were obtained from the Animal Center of Chinese Academy of Sciences (Shanghai, China) and housed in laminar flow cabinets under specific pathogen-free conditions. The mice were used when they were 6-8 wk old. The use of animals in this study complies with the Guide for the Care and Use of Laboratory Animals (NIH publication No. 86-23, revised 1985) and the current Chinese regulations and standards on the use of laboratory animals.

In vivo tumorigenicity assay

Male athymic BALB/c nude mice (6-8 wk old) were housed in laminar flow cabinets under specific pathogen-free conditions. SW1990, SW1990-Con and SW1990-RNAi cells were injected into the right flank of mice with a total volume of 100 μL (1.0×10^7 cells). The tumor-bearing mice were sacrificed 35 d after inoculation and the tumors were taken and weighed.

Gene therapy studies

SW1990 cells were injected into the right flank of BALB/c nude mice with a total volume of 100 μL (1.0×10^7 cells). Tumors were allowed to grow *in vivo* for 2 weeks, reaching an average size of 5 mm in diameter. The animals were divided randomly into three groups (six mice per group): (1) PBS buffer alone (mock), (2) pRNAT-Con (20 μg/mouse), and (3) pRNAT-STAT3-siRNA-Ⅱ (20 μg/mouse). The samples were diluted in 50 μL PBS buffer and injected percutaneously into the tumor using a syringe with a 27-gauge needle. Immediately after injection, tumors were pulsed with an electroporation generator. This process was repeated on day 21. Tumor sizes were measured every 5 d. Tumor masses (in cubic millimeter) were calculated as $a \times b^2 \times 0.52$ (a represents the length, b represents the width)[30]. The tumor-bearing mice were sacrificed on day 35, and the tumors treated with either pRNAT-Con or pRNAT-STAT3-siRNA-Ⅱ were taken, weighed and sectioned for STAT3 immunostaining with rabbit anti-human STAT3 polyclonal antibody (Cell Signal, USA) as before.

Reverse transcription polymerase chain reaction (RT-PCR)

Total RNA extraction from tumor cells was performed with Trizol Reagent (Life Technologies, USA). Two μg of total RNA was reverse-transcribed with the First Strand

cDNA Synthesis Kit (Promega, USA) to synthesize cDNA samples. Subsequently, 2 μL cDNA product was subjected to PCR amplification with Taq DNA polymerase (Sangon, China) on a thermal cycler using the following primers. The oligo-nucleotide primers for STAT3 were constructed using a software "Primer Premier 5.0". The oligo-nucleotide primers for Bcl-xL, Cyclin D1 and β-actin were constructed based on the published sequence. The PCR primers used to detect each factor were as follows: Bcl-xL, sense strand 5'-CCCAGAAAGGATACAGCTGG-3', antisense strand 5'- GCGATCCGACTC ACCAATAC-3', with a product length of 448 bp[31]; Cyclin D1, sense strand 5'- GAGACCATCCCCCTGACGGC-3', antisense strand 5'-TCTTCCTCCTCCTCGGCGGC-3', with a product length of 485 bp[31]; β-actin, sense strand 5'-ATCTGGCACCACACCTTCTACAATGAGCTGCG-3', antisense strand 5'-CGTCATACTCCTGCTTGCTGATCCACATCTGC-3', with a product length of 838 bp[32]. The PCR conditions were: one cycle of denaturing at 94℃ for 5 min, followed by 30 cycles of 94℃ for 1 min, 60℃ for 1 min and 72℃ for 1 min, before a final extension at 72℃ for 10 min. The PCR products were loaded onto 2% agarose gels and visualized with ethidium bromide under UV light. This experiment was performed three times and a representative data was shown.

Western blotting

Whole-cell protein extracts and nuclear protein extracts from tumor cells were prepared with RIPA Lysis Buffer (Santa Cruz, USA) and Nuclear Extract Kit (Active Motif, USA), according to the manufacturer's instructions, respectively. Protein concentrations were determined using a Bio-Rad assay kit (Bio-Rad, USA). Lysates containing 100 μg protein were mixed with loading-buffer with 5% β-mercaptoethanol, and heated for 5 min at 100℃. Samples were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto nitrocellulose membranes by semi-dry blotting. Membranes were incubated in blocking buffer (1 × TBS, 0.1% Tween 20, and 5% non-fat dry milk) for 1 h at room temperature, followed by hybridization with anti-p-STAT3 [tyr-705] antibody (Cell signal, USA, 1:1000 dilution), anti-STAT3 antibody (Cell signal, USA, 1:1000 dilution), anti-Bcl-xL antibody (Cell signal, USA, 1:1000 dilution), anti-CyclinD1 antibody (Cell signal, USA, 1:000 dilution) or anti-β-actin antibody (Labvision, USA, 1:100 dilution) at 4℃ overnight. After three washes in TBS/0.1% Tween 20, the membranes were hybridizated with a horseradish peroxidase-conjugated secondary antibody rabbit IgG (Santa Cruz, USA, 1:5000 dilution) for 1 h at room temperature. After three washes in TBS/0.1% Tween 20, signals were detected by chemiluminescence using the Western blotting Luminol Reagent (Santa Cruz, USA). The same experiment was performed three times and a representative data was shown.

STAT3: Signal transduction and activation of transcription 3.

RESULTS

STAT3 and p-STAT3 are overexpressed in pancreatic cancer cell lines and pancreatic cancer tissues

To determine whether STAT3 and p-STAT3 are overexpressed in pancreatic cancer tissues, we compared the level of STAT3 and p-STAT3 expression in normal pancreatic tissues with that in the pancreatic cancer tissue and pancreatic cancer cell lines (PANC-1 and SW1990) using immunohistochemical and Western blot analyses with an anti-STAT3 antibody and anti-p-STAT3 antibody. Both approaches showed that STAT3 and p-STAT3 were overexpressed in cancer tissues and pancreatic cancer cell lines (Figure 1). STAT3 and p-STAT3 protein levels were measured by Western blotting. Quantitative evaluation of the relative expression of STAT3 revealed that this protein was overexpressed by an average of 2.8-fold in the 71 primary pancreatic tumors compared with normal pancreatic tissues. As summarized in Table 1, the STAT3 levels were significantly different ($P < 0.05$) between the pancreatic tumor specimens and normal pancreatic specimens. Immunohistochemical analyses also showed that pancreatic cancer specimens had a high density staining for p-STAT3.

RNAi targeting STAT3 inhibits SW1990 cell proliferation and anchorage-independent growth ability

To determine whether inhibition of STAT3 affects cell proliferation and metabolic activity of parental SW1990 cells, SW1990-Con cells and SW1990-RNAi cells were determined at 24, 48 and 72 h by the MTT assay. The cell proliferation was reduced significantly after treatment with pRNAT-STAT3-siRNA-Ⅱ ($P < 0.05$) as compared with that of parental SW1990 or SW1990-Con cells (Figure 2A). Furthermore, pRNAT-STAT3-siRNA-II reduced SW1990 cell colony formation by 72.6% ($P < 0.05$, Figure 2B).

RNAi targeting STAT3 arrests SW1990 cells at G_0/G_1 phase and increases SW1990 cells apoptosis

To analyze the mechanisms by which pRNAT-STAT3-siRNA-Ⅱ inhibits cell proliferation, the cell cycle and cell apoptosis of SW1990 cells as well as stably transfected cells SW1990-Con and SW1990-RNAi, were analyzed by flow cytometry. As shown in Table 2, the percentage of cells at G_0/G_1 phase was increased from 38.76% (parental

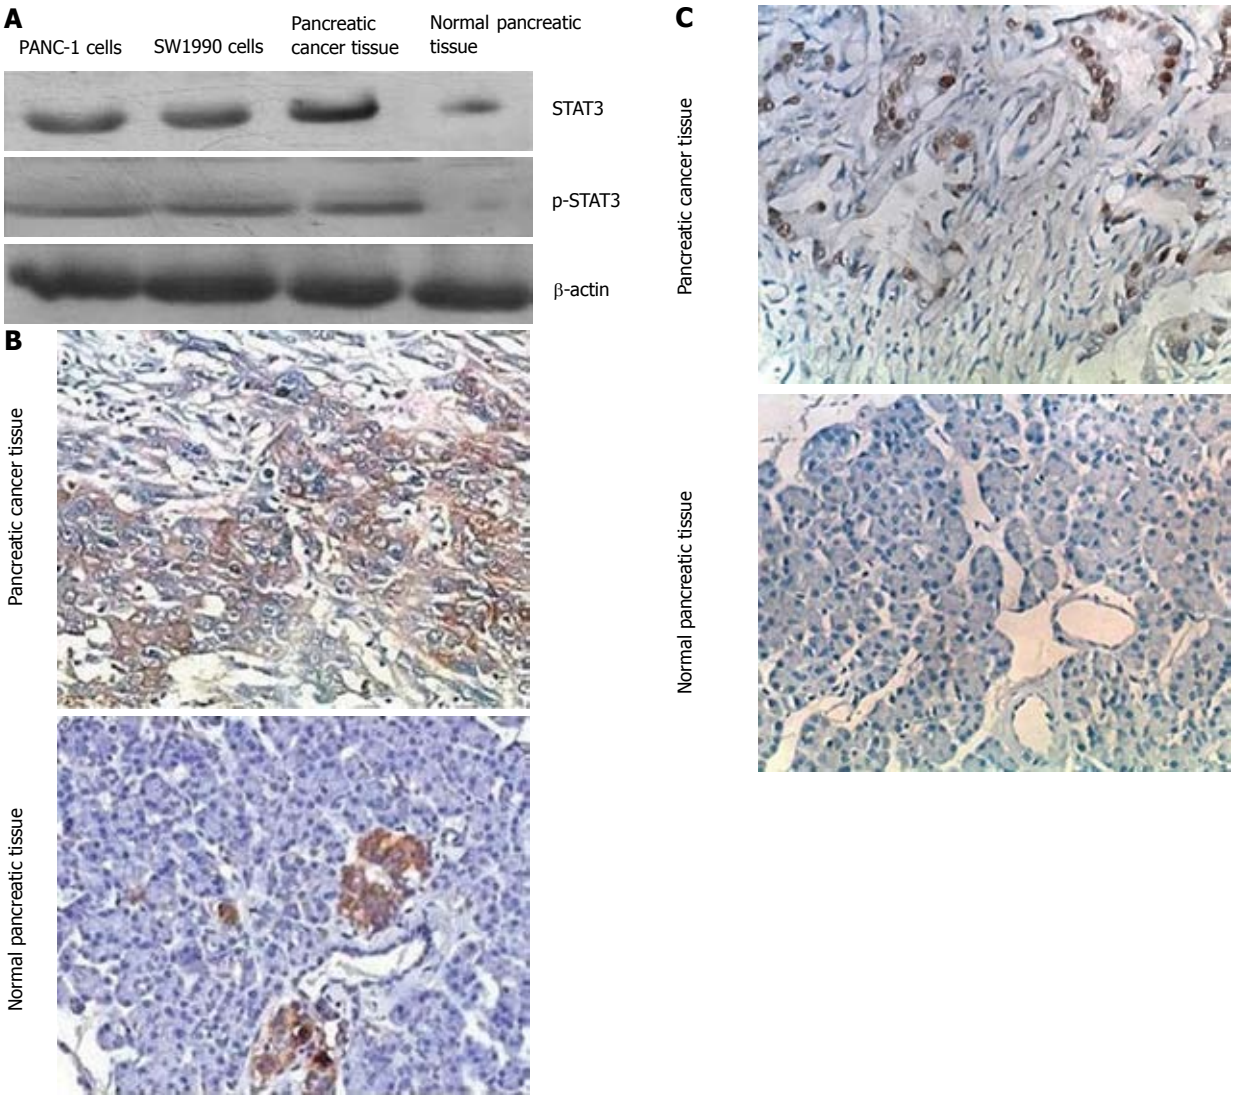

Figure 1 Signal transduction and activation of transcription 3 expression in human pancreatic cancer cells. STAT3: Signal transduction and activation of transcription 3.

Table 2 Effects of silence of signal transduction and activation of transcription 3 gene on cell cycle of pancreatic cancer cells (mean ± SD, %)

Group	G_0/G_1	S	G_2/M
SW1990	38.76 ± 4.64	29.47 ± 3.52	31.76 ± 4.05
SW1990-Con	40.12 ± 5.12	26.53 ± 3.15	33.34 ± 4.39
SW1990-RNAi	65.39 ± 5.83[a]	9.88 ± 2.98[a]	24.73 ± 2.97

[a]$P < 0.05$ *vs* control. SW1990-Con: SW1990 pRNAT-Con transfectants; SW1990-RNAi: SW1990 STAT3-RNAi transfectants.

SW1990) to 65.39% (SW1990-RNAi) and the S-phase cells were decreased from 29.47% (parental SW1990) to 9.88% (SW1990-RNAi). Figure 3 also indicates that the difference was not statistically significant in the rates of the early apoptotic cells and the late apoptotic cells between SW1990 cells and SW1990-Con cells, while these rates in SW1990-RNAi cells increased significantly ($P < 0.05$) as compared with parental SW1990 or SW1990-Con cells. These data showed that silencing of STAT3 can arrest cells at G_0/G_1 phase and increase cell apoptosis.

RNAi targeting STAT3 inhibits tumorigenicity in vivo

The tumorigenicity of SW1990 cells was examined after silencing of STAT3 *in vivo*. All mice developed tumors from parental SW1990 cells or pRNAT-Con-infected SW1990 cells (control) without significant difference in tumor weight. In contrast, only three of six mice developed tumors from pRNAT-STAT3-siRNA-Ⅱ-infected SW1990 cells and the tumors were significantly smaller than those of the control mice (Figure 4). These results suggest that STAT3 plays an important role in tumorigenicity.

RNAi targeting STAT3 inhibits tumor growth in vivo

We further investigated the possibility of using STAT3

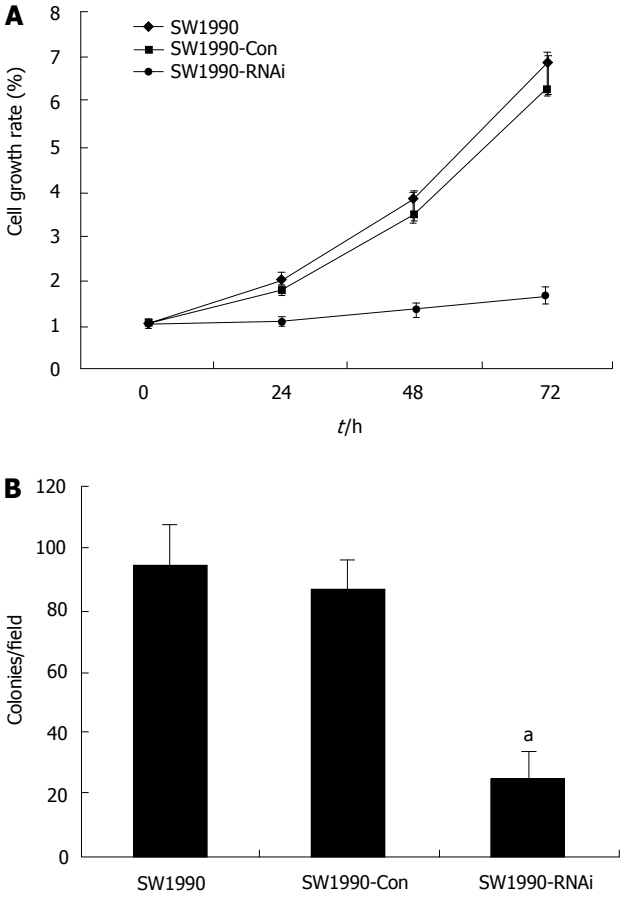

Figure 2 Effects of silence of signal transduction and activation of transcription 3 gene on cell proliferation and anchorage-independent growth of pancreatic cancer cells. A: Cell growth curve of pancreatic cancer cells. SW1990 cells and stably-transfected cells (SW1990-Con and SW1990-RNAi) were subjected to MTT assay as described in materials and methods. Cell proliferation of SW1990-RNAi cells was significantly reduced compared with parental SW1990 and SW1990-Con cells; B: Cell colony formation in soft agar of pancreatic cancer cells. SW1990 cells and stably-transfected cells (SW1990-Con and SW1990-RNAi) were subjected to colony formation assay as described in materials and methods. as a target gene for pancreatic cancer therapy in the nude mouse tumor xenograft model. Mice were transplanted s.c. with 1.0×10^7 SW1990 cells in the right flank. By day 14, palpable tumors had grown at the sites of injection. These mice were divided into three groups with six mice in each group and injected intratumorally with either PBS buffer alone (mock), pRNAT-Con, or pRNAT-STAT3-siRNA-Ⅱ. This process was repeated on day 21. Animals were sacrificed on day 35. As shown in Figure 5A, the mean tumor size of mice treated with PBS buffer control (mock) was 1349.36 ± 164.41 mm^3 on day 35; the mean tumor size in mice treated with pRNAT-Con was 1288.59 ± 129.26 mm^3 and that of the group treated with pRNAT-STAT3-siRNA-Ⅱ was 335.81 ± 55.74 mm^3. The difference was not statistically significant in tumor size between the mock group and pRNAT-Con group ($P > 0.05$). The group treated with pRNAT-STAT3-siRNA-Ⅱ showed marked tumor growth suppression compared with the pRNAT-Con ($P < 0.05$). STAT3 expression was significantly reduced after RNAT-STAT3-siRNA-Ⅱ treatment (Figure 5B and C). These results suggested that silencing STAT3 has a therapeutic potential for pancreatic cancer.

RNAi targeting STAT3 suppresses Bcl-xL and CyclinD1 expression in SW1990 cells

STAT3 activation contributes to oncogenesis through regulation of its target genes. To determine the effect of STAT3 downregulation on growth-related target gene expression, we assayed the expression of CyclinD1 and Bcl-xL by RT-PCR, both of which were directly involved in tumor cell proliferation and apoptosis. As shown in Figure 6A, the expression of CyclinD1 and Bcl-xL mRNAs in SW1990 cells was significantly inhibited after STAT3 silencing. The densitometric analyses revealed that the relative CyclinD1 expression in SW1990-RNAi cells was reduced to 52% compared with that of the parental SW1990 cells. And Bcl-xL relative expression in SW1990-RNAi cells was reduced to 39% of that of parental SW1990 cells. A similar inhibitory effect on protein levels is shown in Figure 6B, which demonstrated that the expression of CyclinD1 and Bcl-xL proteins in SW1990 cells was also significantly inhibited after STAT3 silencing. These results indicated that silencing of STAT3 gene suppressed CyclinD1 and Bcl-xL expression.

DISCUSSION

Pancreatic adenocarcinoma remains a widespread disease and difficult to be treated. Surgical resection can only cure a few cases, and most patients are not suitable for the surgical resection, and conventional chemotherapy and radiation

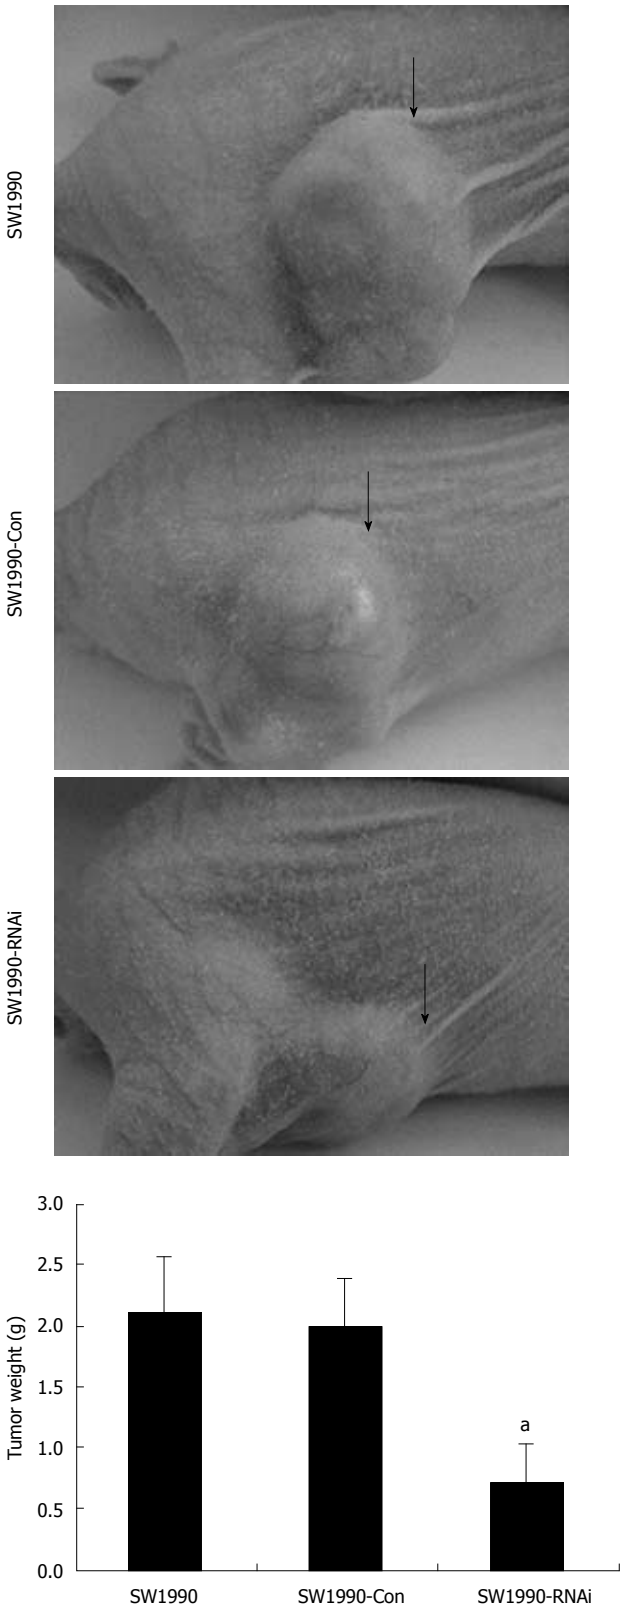

Figure 4 Effects of silence of signal transduction and activation of transcription 3 gene on tumorigenicity *in vivo*. *In vivo* assay was done as described in materials and methods. Six weeks after injection, tumors were harvested and analyzed. Tumors from pRNAT-STAT3-siRNA-Ⅱ–infected SW1990 cells were significantly smaller than those of control mice. Columns: mean (n = 6); Bars: SD. $^{a}P < 0.05$ *vs* control. SW1990-Con: SW1990 pRNAT-Con transfectants; SW1990-RNAi: SW1990 STAT3-RNAi transfectants.

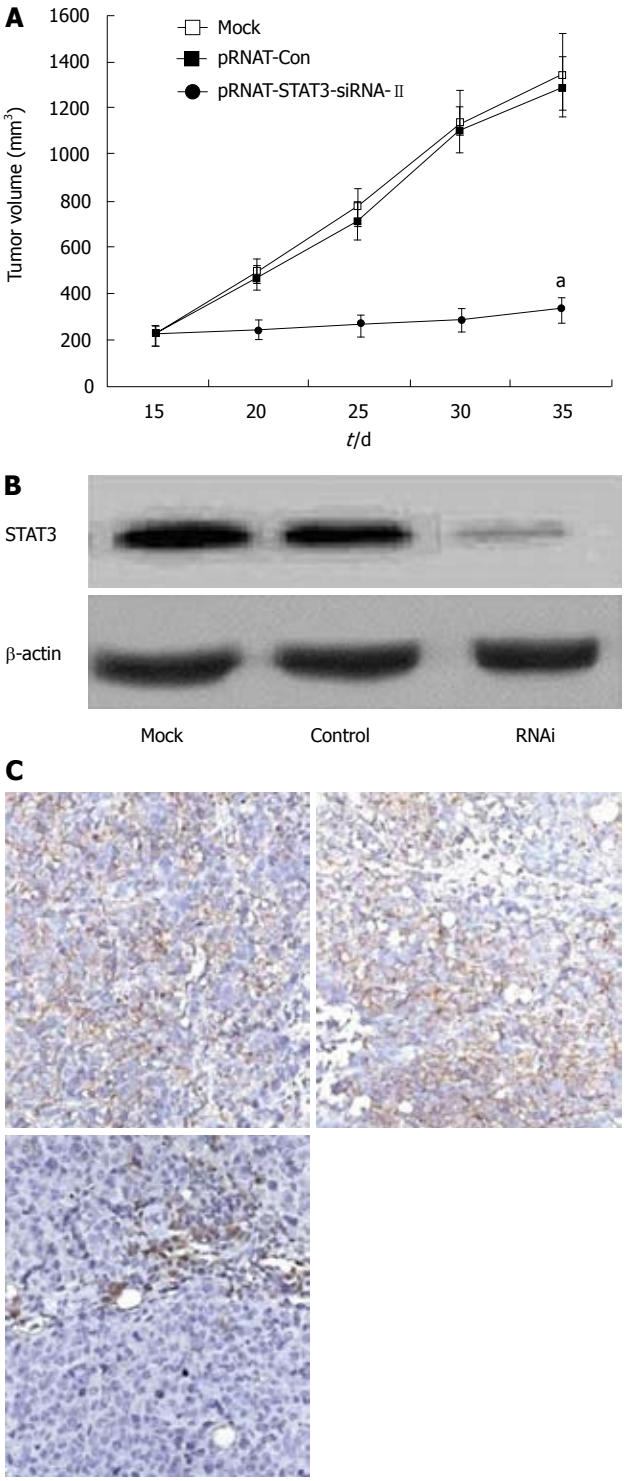

Figure 5 Effects of silence of signal transduction and activation of transcription 3 gene on tumor growth *in vivo*. A: Tumor growth curve after injection with mock, pRNAT-Con, and pRNAT-STAT3-siRNA-Ⅱ cells. Intratumoral electroinjection of pRNAT-STAT3-siRNA-Ⅱ resulted in significant inhibition of tumor growth; Points: mean (n = 6); bars: SD. $^{a}P < 0.05$ *vs* control; B: STAT3 expression of the tumors after injection with mock, pRNAT-Con, and pRNAT-STAT3-siRNA-Ⅱ cells was analyzed by Western blotting. In pRNAT-STAT3-siRNA-Ⅱ–treated tumors, STAT3 expression was significantly reduced. β-actin expression served as a control for equivalent protein loading; C: Tumor sections obtained from mock-, pRNAT-Con-, and pRNAT-STAT3-siRNA-Ⅱ cells –injected tumors were immunostained using anti-STAT3 antibody. In pRNAT-STAT3-siRNA-Ⅱ–treated tumors, STAT3 expression was significantly reduced.

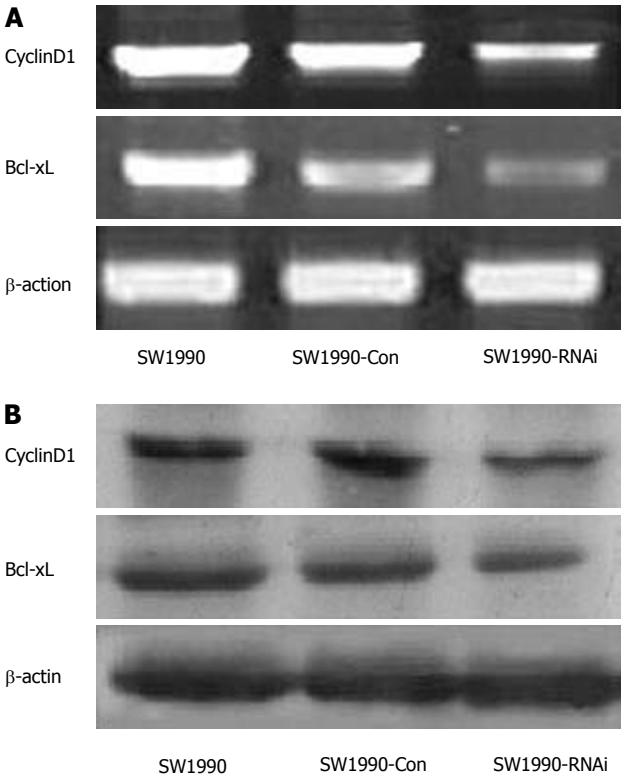

Figure 6 Effects of silence of signal transduction and activation of transcription 3 gene on the expression of CyclinD1 and Bcl-xL. A: Reverse transcription polymerase chain reaction analysis. The RNA samples (2 μg in each) extracted from SW1990 cells, SW1990 cells transfected with a control vector (SW1990-Con), and SW1990 cells transfected with STAT3-RNAi (SW1990-RNAi) were subjected to RT-PCR for CyclinD1, Bcl-xL and β-actin mRNAs. RT-PCR for β-actin was performed in parallel to show an equal amount of total RNA in the sample; B: Western blotting analysis. Whole protein extracts (100 μg in each) were prepared from SW1990 cells, SW1990-Con, and SW1990-RNAi. The expression of CyclinD1 protein was determined by Western blotting with an anti-CyclinD1 antibody. The expression of Bcl-xL protein was determined by Western blotting analysis with an anti-Bcl-xL antibody. The β-actin expression levels were determined as a control for equivalent protein loading. Results shown represent one of the three experiments.

remain largely ineffective. Thus, pancreatic adenocarcinoma represents one of the leading causes of cancer deaths in industrialized countries. With the expectation of increasing therapeutic efficacy, gene therapy is being investigated as a new treatment modality[33]. STAT3 has been considered a very promising target molecule for cancer therapy because it plays a pivotal role in tumorigenesis by cell cycle progression, apoptosis, angiogenesis, metastasis and tumor cell evasion of the immune system[14,15]. Strong evidence has proved that aberrant Stat3 signaling may play an important role in the development and progression of pancreatic adenocarcinoma. We also demonstrated that increasing STAT3 activation in pancreatic adenocarcinoma and blocking Stat3 activation by AG490 (a JAK-specific inhibitor) resulted in suppression of pancreatic cancer growth and invasion *in vitro*[34,35]. Collectively, these findings indicate that targeting STAT3 signaling may represent a novel approach to treat pancreatic adenocarcinoma.

RNAi represents a promising new experimental tool for the analysis of gene function and has become a key gene therapy technique in mammalian systems. Compared with traditional gene therapy, RNAi possesses the advantages of an exquisite precision and high efficacy in down-regulating gene expression[36,37].

In the present study, we used shRNAs targeting STAT3 to silence the expression of STAT3 in human pancreatic cancer cells SW1990. We successfully constructed the recombinant plasmid pRNAT-STAT3-RNAi-II and employed the recombinant plasmid to generate SW1990-RNAi cell line, which showed a significantly decreased STAT3 expression. Attenuation of STAT3 changed the growth behavior of human SW1990 cells both *in vitro* and *in vivo*. MTT assay and soft agar colony formation assay revealed that STAT3 silencing by RNAi inhibited SW1990 cell proliferation and anchorage-independent growth ability. Flow cytometry revealed that RNAi targeting STAT3 arrested SW1990 cells at G_0/G_1 phase and increased SW1990 cell apoptosis. Moreover, *in vivo* study showed that STAT3 silencing inhibited tumorigenecity and tumor growth of SW1990 cells in nude mouse tumor xenograft model.

The inhibitory mechanism in the tumor growth after STAT3 silencing with RNAi is considered as down-regulation of genes related with cell proliferation and apoptosis. CyclinD1 is believed to play a key role in the cell proliferation through promoting cell cycle[38] and overexpression of cyclin D1 was reported to correlate with poor prognosis in pancreatic cancer[39]. Recently, some studies have found that STAT3 signaling directly regulates CyclinD1 expression, tumor proliferation and growth and proved that CyclinD1 is a target gene of STAT3[40]. Our previous study found that inhibition of STAT3 signal with AG490 could inhibit growth of pancreatic cancer cells and decrease CyclinD1 expression[34]. This study also showed that the silencing of STAT3 markedly reduced the mRNA and protein expression of CyclinD1 in SW1990 cells.

Besides persistent proliferation, phenotypes of anti-apoptosis are also required for cancer cells to grow well *in vivo*. Bcl-xL, an anti-apoptotic gene of the BCL-2 family, is associated with poor survival and prognosis of pancreatic cancer patients[41]. Increased expression of Bcl-xL is dependent on the constitutively activated STAT3, and Bcl-xL has been proved to be a target gene of STAT3. Blocking STAT3 signal in human tumor cells has been shown to downregulate Bcl-xL expression and induce tumor-cell apoptosis[42]. As shown in our previous study, inhibition of STAT3 signal with AG490 could retard the growth of pancreatic cancer cells and decrease Bcl-xL expression[34]. This study also found that the silencing of STAT3 with RNAi significantly decreased the mRNA and protein expression of Bcl-xL in SW1990 cells.

In conclusion, the present study indicates that siRNA targeting STAT3 mRNA *via* a plasmid based system effectively sustains the silencing of STAT3 gene expression in SW1990 cells. The impaired STAT3 expression results in reduced SW1990 cell growth both *in vitro* and *in vivo* due to the the downregulation of the expression of CyclinD1 and Bcl-xL. Targeting STAT3 activation by RNAi may be a potential therapeutic strategy in the treatment of pancreatic adenocarcinoma.

COMMENTS

Background

signal transduction and activation of transcription (STAT)3 is a central cytoplasmic transcription factor. Uncontrolled activation of STAT3 plays a critical role in cell survival and proliferation during oncogenesis. The authors evaluated the effect of RNA interference (RNAi) mediated silence of STAT3 on the growth of human pancreatic cancer cells both *in vitro* and *in vivo*.

Research frontiers

Activated STAT3 has been shown to promote tumor cell proliferation, metastasis, and angiogenesis by regulating associated genes. The authors determined whether the STAT3 signaling pathway regulates the growth of pancreatic cancer cells, and found that silencing of STAT3 with RNAi may offer a novel strategy for pancreatic cancer intervention.

Innovations and breakthroughs

The expression of the STAT3 was inhibited using RNAi in SW1990 cells. RNAi against STAT3 inhibited cell proliferation, induced cell apoptosis and significantly reduced the levels of CyclinD1 and Bcl-xL. *In vivo* experiments showed that RNAi against STAT3 inhibited the tumorigenicity of SW1990 cells and significantly suppressed tumor growth.

Applications

The present study indicates that siRNA targeting STAT3 mRNA *via* a plasmid based system effectively sustains the silence of *STAT3* gene expression in SW1990 cells. The impaired STAT3 expression results in reduced SW1990 cell growth both *in vitro* and *in vivo*. Therefore, targeting STAT3 activation by RNAi may be a more effective approach in the treatment of pancreatic cancer.

Terminology

STAT3 is a key cytoplasmic transcription factor activated by tyrosine kinase growth factor and cytokine receptors. Once tyrosine is phosphorylated, two STAT3 monomers form a dimer through reciprocal phosphotyrosine-SH2 interactions, and translocate to the nucleus where they bind to STAT3-specific DNA-response elements of target genes, and induce gene transcription. It has been demonstrated that STAT3 participates in the occurrence and development of cancers.

Peer review

In this study, the authors evaluate the effect of RNAi mediated silence of STAT3 on the growth of human pancreatic cancer cells. They showed that RNAi for STAT3 not only inhibited cell proliferation and induced cell apoptosis *in vitro* but also suppressed pancreatic tumor growth *in vivo*. As the authors stated, the present study suggested the possibility that silence of *STAT3* gene using RNAi may be a novel therapeutic option for treatment of pancreatic cancer. Overall, the manuscript is well written.

Abstract

AIM: To investigate whether cisplatin (DDP) enhances the anti-tumor activity of cytokine- induced killer (CIK) cells in a murine colon adenocarcinoma model.

METHODS: Tumor size and weight served as indicators of therapeutic response. Immunohistochemistry was performed to observe intratumoral lymphocyte infiltration and tumor microvessel density. Changes in the percentage of regulatory T (Treg) cells within the spleens of tumor-bearing mice preconditioned with DDP were monitored using flow cytometry.

RESULTS: A marked T cell-dependent, synergistic anti-tumor effect of the combined therapy was observed (1968 ± 491 mm^3 *vs* 3872 ± 216 mm^3; $P = 0.003$). Preconditioning chemotherapy with DDP augmented the infiltration of CD3+ T lymphocytes into the tumor mass and reduced the percentage of both intratumoral and splenic Treg cells.

CONCLUSION: Preconditioning with DDP markedly enhances the efficacy of adoptively transferred CIK cells, providing a potential clinical modality for the treatment of patients with colorectal cancer.

Key words: Colorectal cancer; Preconditioning chemotherapy; Cytokine-induced killer cells; Regulatory T cells; Immunomodulation

Cisplatin pretreatment enhances anti-tumor activity of cytokine-induced killer cells. *World J Gastroenterol* 2011; 17(25): 3002-3011 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i25/3002.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i25.3002

INTRODUCTION

Colorectal cancer is one of the most common malignancies in the world[1]. Despite advances in surgery, chemotherapy and radiotherapy, the prognosis of the patients with advanced colorectal cancer remains poor[2,3]. Therefore, new and effective treatment modalities, such as immunotherapy, are urgently needed.

Cytokine-induced killer (CIK) cells are *ex vivo*-expanded T lymphocytes that share phenotypic and functional properties with both natural killer (NK) and T cells[4]. CIK therapy is a promising approach for the treatment of a broad array of malignant hematopoietic diseases and solid tumors[4-8]. However, clinical trials in CIK therapy did not show any noticeable improvement in cure rates or long-term survival[6-8], suggesting that the treatment needs to be refined to maximize its efficacy.

Recent advances in molecular immunology have un-

masked the crucial mechanisms that inhibit anti-tumor immune responses *in vivo*. In particular, regulatory T (Treg) cells, which are a distinct lymphocyte lineage that inhibits both adaptive and innate immunity[9], have received a great deal of attention. Treg cells can also hinder the anti-tumor activity of CIK cells[10,11]. Thus, strategies aimed at depleting Treg cells may increase the efficacy of CIK cells.

A number of studies have shown that some chemotherapeutic agents, in addition to their direct cytotoxic effects on tumor cells, possess the ability to modulate anti-tumor immune responses[12,13]. Cisplatin (DDP) is one of the conventional anticancer agents endowed with immunomodulating features. It can sensitize tumor cells to lysis by NKG2D-expressing lymphocytes by up-regulating the expression of the NKG2D ligand (NKG2DL) on tumor cells[14]. It may also increase the vulnerability of tumor cells to Fas ligand (FasL)-positive immune effectors by increasing Fas expression on the targets[15]. However, there have been no studies characterizing the potential suppressive effects of DDP on Treg cells.

In this study, to investigate whether DDP can enhance the anti-tumor activity of CIK cells, we used a combined therapy consisting of pretreatment with DDP followed by adoptive CIK therapy in a murine colon adenocarcinoma model. A marked T cell-dependent synergistic anti-tumor effect was observed. Preconditioning chemotherapy with DDP also increased the infiltration of $CD3^+$ T lymphocytes into the tumor mass and reduced the percentage of both intratumoral and splenic Treg cells, suggesting a potential mechanism underlying the immunostimulatory capacity of DDP. These results provide an immunological rationale for the combined chemoimmunotherapy and suggest a potential clinical modality for the treatment of patients with colorectal cancer.

MATERIALS AND METHODS

Animals

BALB/c wild type (WT) and BALB/c nu/nu male mice were purchased from the Chinese Academy of Military Medical Sciences (Beijing, China), and those at 6-8 wk of age were used for the experiment. All mice were maintained at controlled temperature and humidity, with a 12 h light-dark cycle, and sterile food and water *ad libitum*. The animal studies were conducted in accordance with the Animal Experiment Guidelines of the Ethics Committee of Jingling Hospital.

Tumor cells

Murine CT-26 colon adenocarcinoma cells were obtained from the Shanghai Institute of Biochemistry and Cell Biology (Shanghai, China) and maintained in cRPMI-1640 (Hyclone, Waltham, MA, USA) supplemented with 10% fetal calf serum, 100 U/mL penicillin and 100 μg/mL streptomycin at 37℃ in a humidified atmosphere of 5% CO_2.

Generation of Cytokine-induced killer cells

Murine CIK cells were obtained as previously described[16]. Briefly, spleen single cell suspensions were prepared from BALB/c WT mice and enriched for lymphocytes by Ficoll-Hypaque (Beijing Chemical Reagents Company, Beijing, China) density gradient centrifugation. Cells were then resuspended in cRPMI-1640 medium supplemented with 1000 U/mL interferon γ (PEPROTECH, Rocky Hill, NJ, USA) on the first day of culture. After 24 h, interleukin-2 (PEPROTECH, Rocky Hill, NJ, USA) and an anti-CD3 antibody (eBioscience, San Diego, CA, USA) were added at 500 U/mL and 50 ng/mL, respectively. Thereafter, cRPMI-1640 supplemented with interleukin-2 (300 U/mL) was added every other day for two weeks and to generate CIK cells.

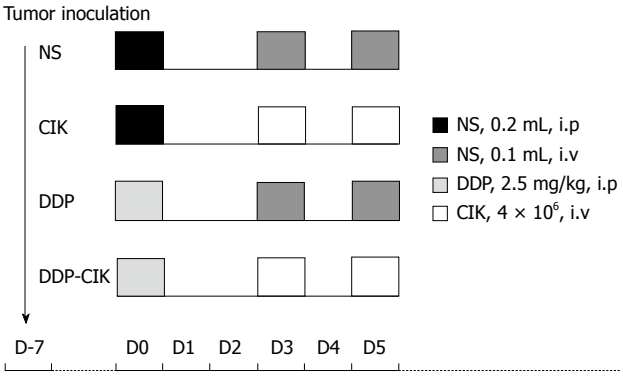

Figure 1 Treatment scheme. BALB/c WT or BALB/c nu/nu mice were injected s.c with 1 × 10^6 CT-26 cells on Day 7 and were treated with the respective regimens according to the treatment scheme. Group cytokine-induced killer cells (CIK) received two i.v infusions of 4 × 10^6 CIK cells at a 1-d interval; Group cisplatin (DDP) was treated with DDP (2.5 mg/kg, i.p); Group DDP-CIK was given preconditioning DDP followed by infusions of CIK cells 3 d later; Group normal saline (NS) was treated with normal saline as control.

In vivo experimental design

CT-26 cells (1 × 10^6/100 mL phosphate buffered saline) were subcutaneously inoculated into the right flank of BALB/c WT and BALB/c nu/nu mice. When tumors became approximately 5 mm in mean diameter, animals were randomly divided into four groups, five in each group, and subjected to the corresponding treatment. The preconditioning chemotherapy used in this study was a single intraperitoneal injection of 2.5 mg/kg DDP; and adoptive immunotherapy consisted of two intravenous transfusions of CIK cells at a 1-d interval (4 × 10^6 cells per dose in a total volume of 100 mL). The treatment scheme of each group is shown in Figure 1 and the detailed grouping was as follows: (1) Group normal saline (NS), treated with normal saline; (2) Group CIK, treated with CIK cells alone; (3) Group DDP, treated with DDP alone; and (4) Group DDP-CIK, preconditioned with DDP followed by transfusion of CIK cells. The tumor size (mm) was measured every other day using a caliper and tumor volume was calculated as: 0.5 × length × $width^2$.

Immunohistochemical analysis

Twenty days after the treatment, the tumor mass was excised, fixed in 10% formalin, embedded in paraffin and sectioned at 3 μm for histological and immunohistochemical

studies. Anti-CD3 (1:500, rat monoclonal, Abcom, Cambridge, MA, USA), anti-FoxP3 (1:1000, rabbit polyclonal, Abcom, Cambridge, MA, USA) and anti-CD31 antibodies (1:100, rat polyclonal, Abcom, Cambridge, MA, USA) were used for immunostaining. All procedures were carried out according to the manufacturer's instructions. Images of the sections were acquired using an Olympus BX-60 microscope to determine the $CD3^+$, $FoxP3^+$ or $CD31^+$ cell density. The number of positive cells was counted in 10 independent fields (0.16 mm^2 at ×400 magnification) within each section by two independent observers.

Flow cytometry

Spleen single cell suspensions were prepared from untreated or DDP-pretreated tumor-bearing mice at the indicated time points and enriched for lymphocytes using Ficoll-Hypaque density gradient centrifugation. A mouse regulatory T cell staining kit (eBioscience, San Diego, CA, USA) was used to determine the percentage of Treg cells. All operations were performed according to the manufacturer's instructions. Phenotypic analysis of splenocytes was performed using a FACSCalibur (BD Biosciences, San Jose, CA, USA). Splenic lymphocytes were gated by plotting forward *vs* side scatter and then by the expression of CD4 and CD25. $CD4^+CD25^{hi}$ T cells were further analyzed for expression of FoxP3. Ten thousands gated events were collected and analyzed using CellQuest software (BD Biosciences, San Jose, CA, USA). The following conjugated antibodies were used: PE-conjugated anti-FoxP3, FITC-conjugated anti-CD4, APC-conjugated anti-CD25, and isotype-matched controls (eBioscience, San Diego, CA, USA).

Statistical analysis

Differences between groups were compared using ANOVA, and LSD was used for multiple mean comparisons. A P value < 0.05 was considered significant. Statistical analysis was conducted using SPSS software v13.0 (SPSS Inc., Chicago, Illinois, USA).

RESULTS

DDP pretreatment and CIK therapy synergistically inhibits tumor growth in BALB/c WT mice

To investigate whether DDP pretreatment enhanced the anti-tumor activity of CIK therapy, CT-26 carcinoma-bearing BALB/c WT mice were injected i.p. with DDP and then i.v. with CIK cells. Tumor size change was monitored every other day throughout experiment (Figure 2A, left panel). On Day 19, the tumor mass was isolated (Figure 2B, left panel). Treatment with either DDP or CIK cells alone inhibited tumor growth compared with the NS control (Figure 2, left panel). However, a significantly greater inhibition of tumor growth was observed after the combined therapy in terms of tumor volume (Figure 2C, left panel) and tumor weight (Figure 2D, Left panel) compared with that seen in the single regimen or the NS control.

T cells are required for synergistic anti-tumor effect of the combined therapy

Previous studies showed that an intact immune system is essential for the immunostimulatory anti-tumor effects of chemotherapeutic agents[17,18]. To examine the mechanisms by which DDP treatment increased the efficacy of CIK therapy, the combined treatment protocol (DDP pretreatment plus CIK therapy) was also evaluated in a CT-26 carcinoma-bearing nude mouse model (Figure 2, right panel). With no treatment, the intrinsic tumor growth pattern in nude mice was similar to that in WT mice (Figure 3). In the therapeutic setting, tumor volume was monitored every other day (Figure 2A, right panel) up until Day 19, when the tumor mass was isolated (Figure 2B, right panel). DDP treatment efficiently inhibited tumor growth in WT mice (Figure 2, left panel) but showed only minor inhibitory effects on tumor growth in nude mice (Figure 2, right panel). In addition, CIK therapy alone did not inhibit tumor growth (Figure 2, right panel) when compared with the NS control. Moreover, no synergy between DDP treatment and CIK therapy was observed in the nude mice (Figure 2, right panel).

DDP enhances accumulation of $CD3^+$ T lymphocytes within tumor mass

Since the synergistic anti-tumor effects of the combined therapy rely on the presence of T lymphocytes, we analyzed the intra-tumoral accumulation of lymphocytes. Tumor tissues from all the experimental groups were removed on Day 19 and CD3 was used as a specific marker for counting T lymphocytes (Figure 4A). Tumor tissues from untreated hosts were infiltrated by a small number of $CD3^+$ T lymphocytes, and DDP or CIK treatment alone only slightly increased the density of intratumoral $CD3^+$ T lymphocytes, but this was not significant. In contrast, DDP pretreatment combined with CIK therapy reversed this phenomenon, significantly enhancing the influx of $CD3^+$ T lymphocytes into the tumor parenchyma (Figure 4B). This was consistent with the marked retardation of tumor growth seen in the combined treatment group.

DDP reduces percentage of Treg cells in tumor microenvironment

Because some chemotherapeutic agents selectively eliminate Treg cells[19,20], we tested whether DDP possessed this Treg-reducing immunostimulatory effect. We examined the changes in intra-tumoral Treg cell numbers in mice treated with CIK, DDP or combination therapy on Day 19. Nuclear transcription factor forkhead box protein P3 (FoxP3), the most specific Treg cell marker identified to date, was used to label Treg cells infiltrating the tumor (Figure 4C). The number of Treg cells, as assessed by the density of intra-tumoral $FoxP3^+$ cells, was not significantly different among the four groups (Figure 4D). However, due to the degree of lymphocyte infiltration into the tumor mass, it may be not accurate to determine the actual level of intra-

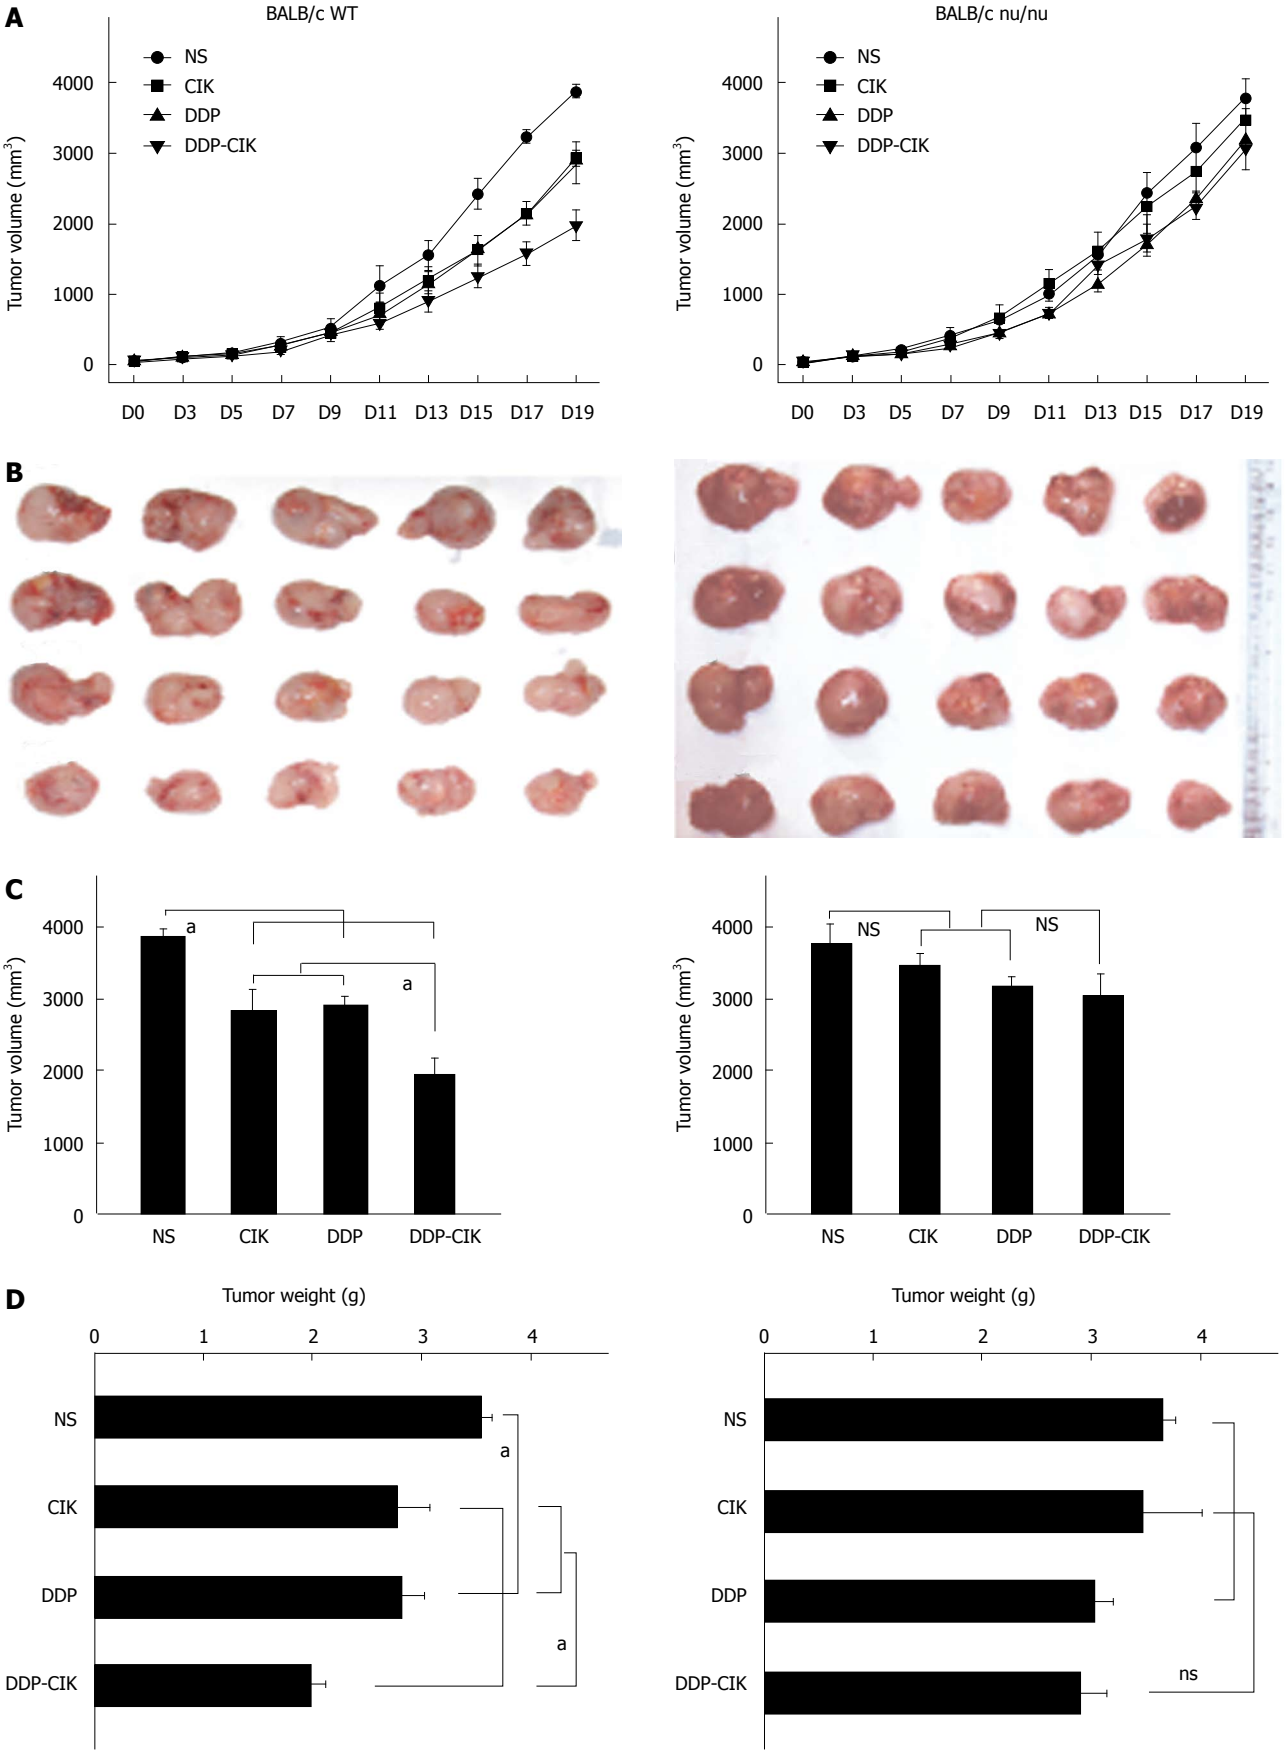

Figure 2 Anti-tumor effect of cisplatin and cytokine-induced killer cells therapy in BALB/c WT and nude mice. BALB/c WT and BALB/C nu/nu mice were inoculated s.c. with 1 × 10^6 CT-26 cells on Day 7 and treated according to the treatment scheme. Tumor size was monitored every other day (A). On Day 19, the tumors were isolated (B), and tumor volume (C) and weight (D) were measured. The results for BALB/c WT mice are shown in the left panel of each figure, while the results for nude mice are shown in the right panel. Points and columns : mean tumor volume or weight (n = 5); Bars: SE. $^aP < 0.05$.

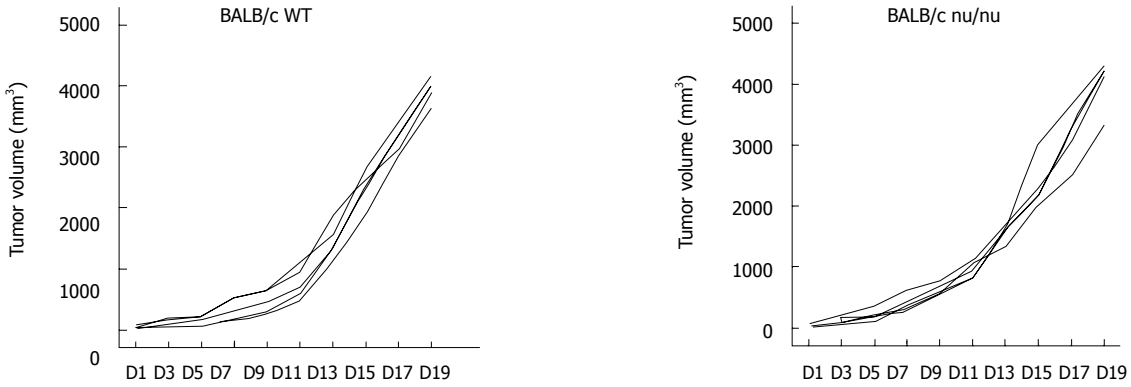

Figure 3 Intrinsic tumor growth pattern of CT-26 carcinomas in untreated BALB/c WT and nude mice. BALB/c WT (wild type) and BALB/c nu/nu mice were inoculated s.c with 1 × 10^6 CT-26 cells on Day 7 and tumor size was monitored every other day. The inherent growth patterns in both strains of mice are shown. Each line represents tumor growth in a single mouse.

tumoral Treg cells using the absolute number of $FoxP3^+$ cells. Therefore, two consecutive sections from each tumor sample were prepared and stained for CD3 and FoxP3, respectively. The percentage of Treg cells, represented as the ratio of $FoxP3^+$ lymphocytes to $CD3^+$ lymphocytes, was calculated to determine the adjusted level of Treg cells within the tumor microenvironment. We found that the percentage of intratumoral Treg cells in Group DDP and Group DDP-CIK was significantly reduced compared with that in Group NS and Group CIK (Figure 4E). This suggests that the systemic administration of DDP locally reduced the percentage of Treg cells in the tumor mass.

DDP reduces percentage of Treg cells in spleens of tumor-bearing mice

To profile the kinetics of Treg accumulation in the spleens of CT-26 carcinoma-bearing mice after DDP treatment, splenic lymphocytes were obtained at various time points and analyzed by flow cytometry. In tumor-free mice, the percentage of Treg cells in spleen was approximately 2% (data not shown). In the absence of intervention, the level of Treg cells in the tumor-bearing hosts increased in line with increasing tumor burden (Figure 5A and B). After DDP administration, the percentage of Treg cells declined at all time points compared with that in untreated mice (Figure 5A and B), suggesting that DDP significantly reduced the percentage of splenic Treg cells. We monitored the duration of Treg depletion induced by DDP, and found that the nadir was around Day 3 after treatment. Treg cell numbers then rebounded and expanded, following the pattern of tumor growth (Figure 5A and B). However, the number of Treg cells in tumor-bearing mice receiving DDP treatment was consistently lower than that in untreated mice throughout the period of observation.

Tumor microvessel density is not affected by DDP treatment

Chemotherapeutic agents have been shown to exert toxic effects on the endothelium of the growing vasculature[21]. Therefore, we tested whether, in addition to its action on the immune system, DDP possessed antiangiogenic effects. To this end, we compared the tumor microvasculature in all the experimental groups by determining microvessel density (MVD). The MVD within the tumor tissues was estimated from tumor sections stained with an antibody to CD31 (Figure 6A) and quantified as described in Materials and Methods. We found that the MVD was comparable among all four groups (Figure 6B), suggesting that DDP had no toxic effect on the tumor microvasculature in this model.

DISCUSSION

Immunosuppression is a significant obstacle to the generation of effective anti-tumor immunity. During tumor progression, tumor cells foster a tolerant and resistant microenvironment by employing various immunosuppressive mechanisms[22]. It is now clear that successful cancer immunotherapy will be achieved only after the removal of immunity-hampering barriers. Previous studies showed that preconditioning a host with immunomodulating chemotherapy can effectively augment the anti-tumor effects of adoptively transferred effectors[23]. In the present study, DDP pretreatment in combination with adoptive CIK therapy was tested in a murine model of colon adenocarcinoma. Our data showed a marked synergy between DDP chemotherapy and CIK immunotherapy in treating established CT-26 carcinomas in immunocompetent mice, suggesting that a single dose of DDP was sufficient to "groom" the immune system, eventually enhancing the efficacy of subsequent CIK therapy.

A number of murine tumor models show that eradication of tumors requires T cells[17,18,24]. In accordance with these studies, the synergic anti-tumor effect in our study was not evident in the BALB/c nu/nu mice which lack T cells, implying that T lymphocytes were the effectors in our model of anti-tumor therapeutic synergy. The natural growth pattern of CT-26 carcinomas in untreated nude mice was similar with that in immune replete WT mice, suggesting that "default" endogenous immunity was not able to prevent the growth of tumors, or to eradicate established tumors. Furthermore, DDP treatment efficiently

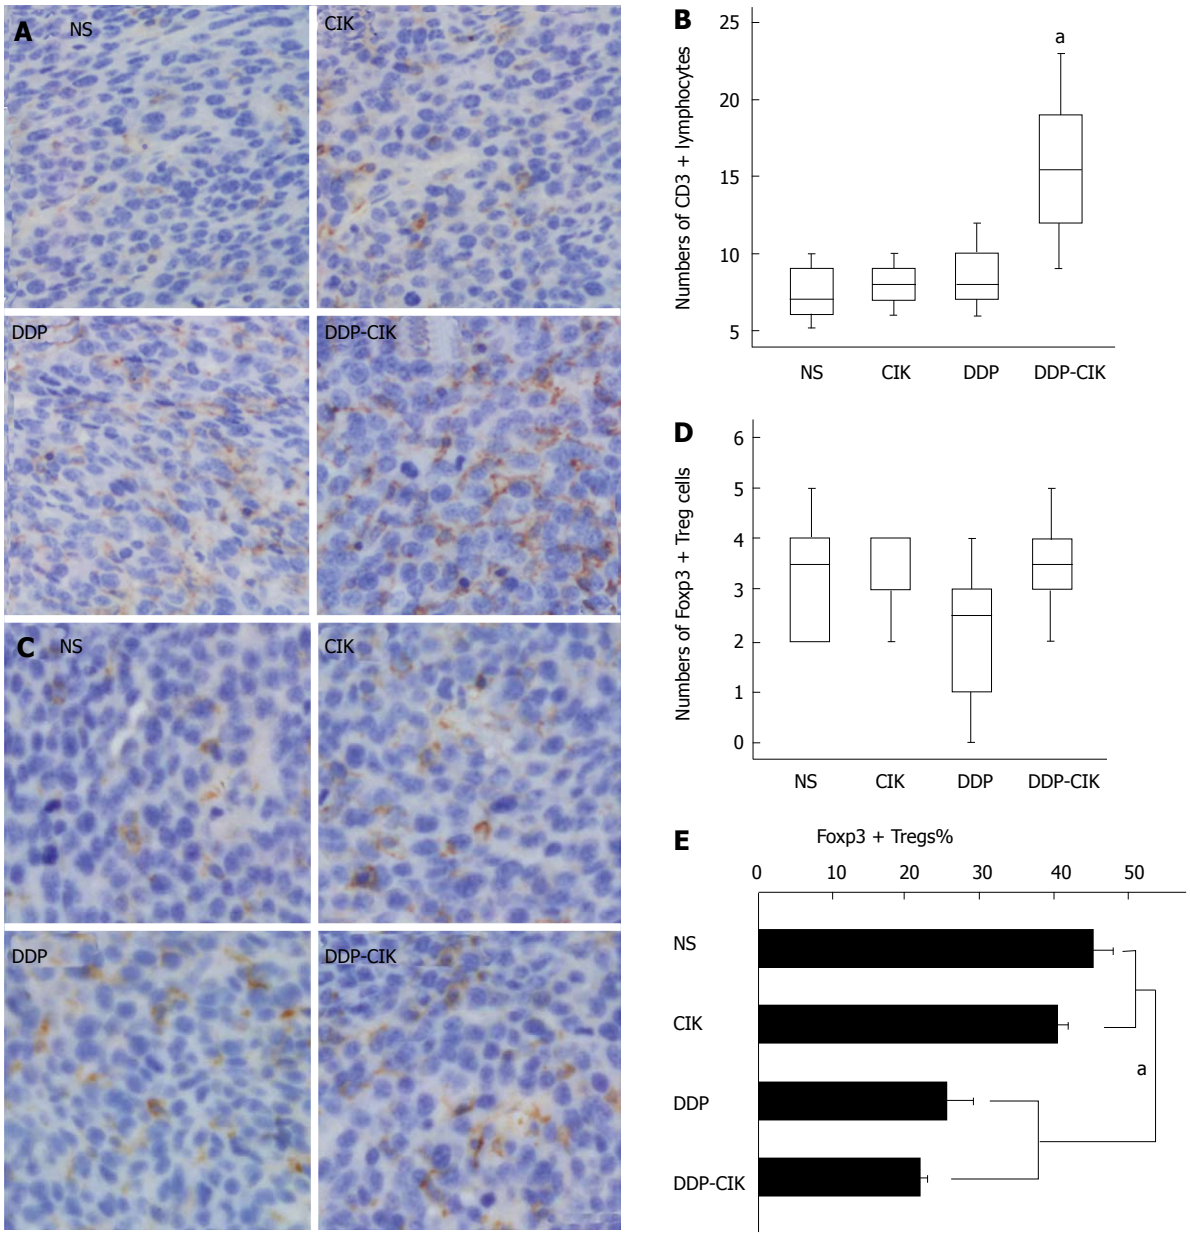

Figure 4 Intratumoral infiltration of lymphocytes after combined therapy. BALB/c WT mice were injected s.c. with 1 × 10^6 CT-26 cells and the treatment protocols were initiated 7 d later. On Day 19, consecutive tumor sections were prepared and analyzed by CD3 (A) and FoxP3 (C) staining. Ten individual fields (0.16 mm^2) surrounding the apoptotic area (× 400 magnification) were chosen to count the number of intratumoral $CD3^+$ T lymphocytes (B), and to determine the absolute number (D), and percentage (E) of FoxP3 + Treg cells. Experimental groups consisted of five mice per group. Representative sections from all groups are shown. Scale bar: 25 μm. Lines: median; Boxes:75% percentile; Bars (B, D) : SD. Columns : Mean Treg percentage; Bars (E): SE. $^aP < 0.05$. NS: Normal saline; CIK: Cytokine-induced killer cells; DDP: Cisplatin.

inhibited the growth of CT-26 carcinomas in WT mice, but failed to induce tumor growth retardation in the absence of T lymphocytes. This is in line with previous findings suggesting that inhibition of tumor growth by chemotherapeutic agents is strictly dependent on T cells[17,18,24]. Based on these results, we proposed that most of the anti-tumor effect seen in DDP could be attributed to its immunostimulating capacity, rather than to any direct cytotoxicity against tumor cells. Similarly, the efficacy of CIK therapy was observed only in immune-replete hosts, implying that endogenous T lymphocytes participate in the fight against tumor cells by assisting, or co-operating with, exogenously infused CIK cells. Therefore, in T lymphocyte-deficient nude mice, neither DDP pretreatment nor CIK therapy could induce tumor shrinkage. Moreover, preconditioning with DDP lost its capacity to enhance the effect of CIK therapy in the nude mouse model, and the synergy seen with combination therapy was abrogated. We speculate that endogenous T lymphocytes comprise both pro-tumor and anti-tumor subpopulations. The anti-tumor subpopulation collaborates with CIK cells to inhibit tumor growth, and is essential for the effect of CIK therapy. Also, the protumor subgroup is suppressed by DDP, whereas the anti-tumor subgroup is stimulated by DDP, leading to DDP-induced

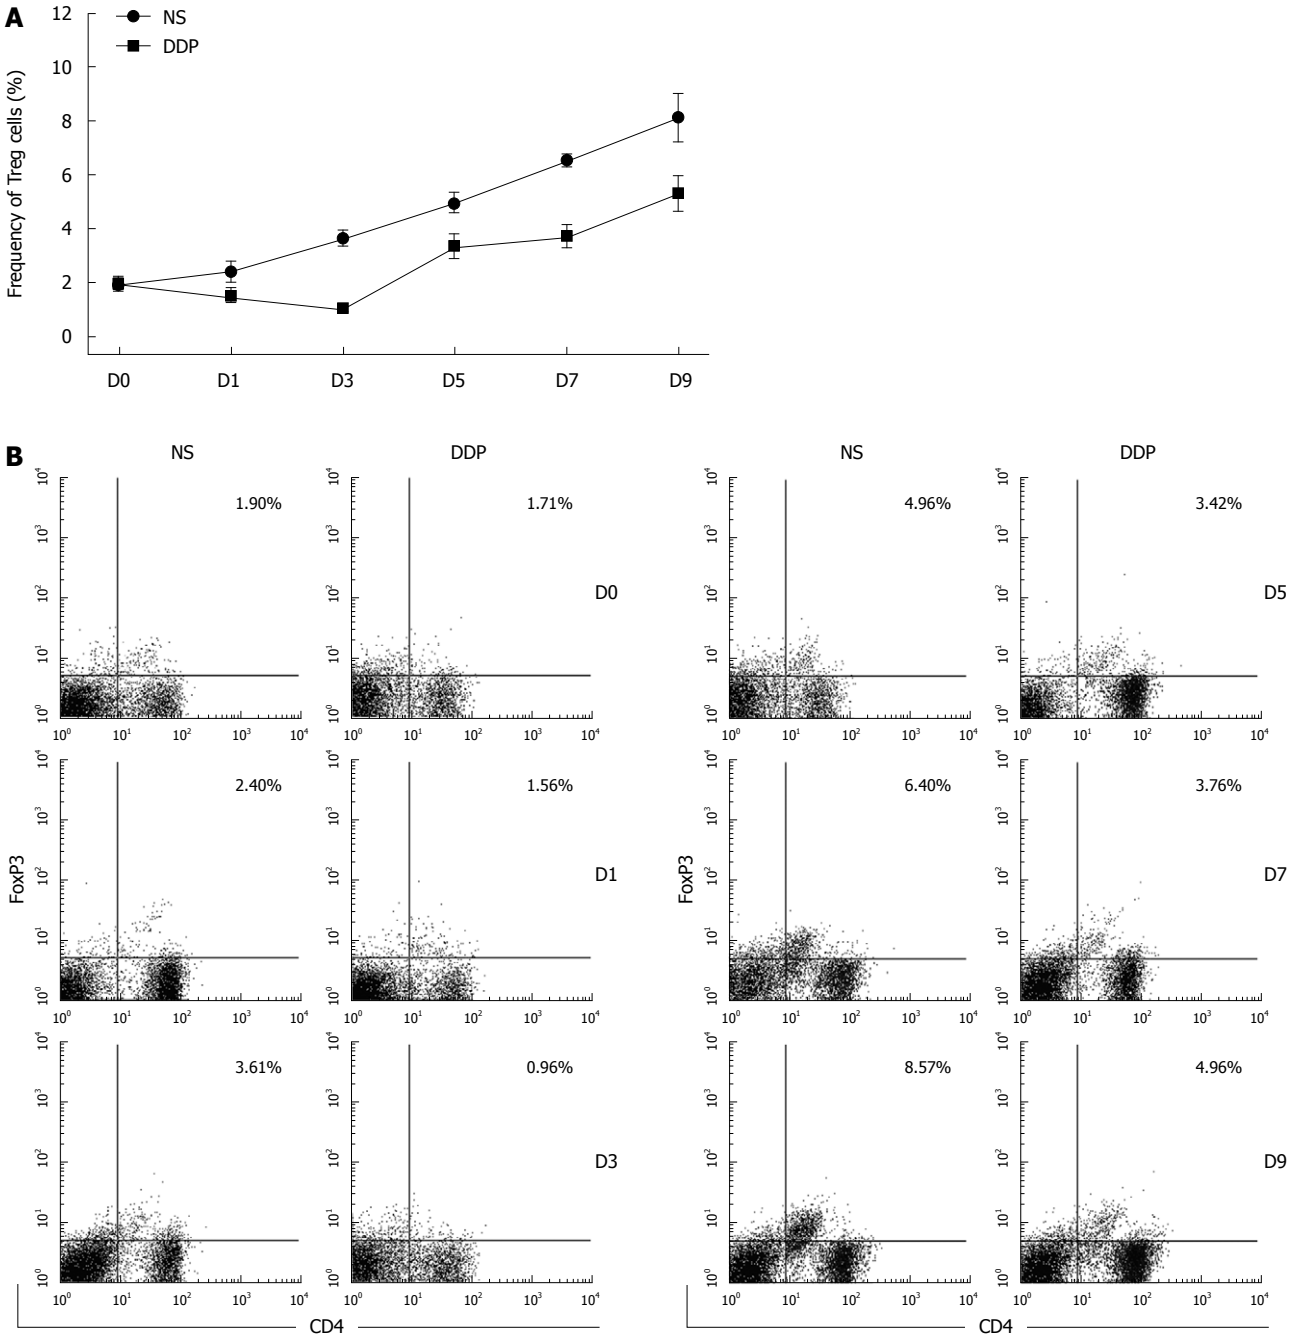

Figure 5 Dynamic changes in the percentage of splenic Tregs after cisplatin (DDP) administration. BALB/c WT mice were injected s.c. with 1 × 10^6 CT-26 cells 7 d before treatment. The tumor-bearing mice were treated with DDP (2.5 mg/kg, i.p., D0) and the spleen single cell suspensions prepared to analyze the Treg percentage by flow cytometry at the indicated post-treatment time points (A). Typical data from a representative experiment are shown (B). Points: mean Treg cell percentage (n = 3); Bars: SD. All experiments were performed twice with similar results. NS: Normal saline; DDP: Cisplatin.

suppression of tumor growth and increased CIK efficacy.

Because of the important effector role played by T lymphocytes in anti-tumor therapeutic synergy, the intratumoral accumulation of T lymphocytes was observed. Our data showed that, compared with the NS control and single therapy alone, the combination therapy significantly augmented the number of $CD3^+$ T lymphocytes infiltrating into the tumor mass, which correlated well with the inhibition of tumor growth.

However, as mentioned above, T lymphocytes comprise both protumor and antitumor subpopulations. Of the protumor subpopulations, Treg cells were mainly involved in tumor-induced immunosuppression. Treg cells are $CD4^+CD25^+$ T lymphocytes with the ability to suppress anti-tumor immune response. These cells accumulate in the peripheral blood, lymph node and tumors in many human cancers and animal tumor models[25]. Elimination of Treg cells *in vivo* using cytotoxic agents or antibodies enhances anti-tumor responses and results in tumor regression[26]. In this study, we determined the percentage of Treg cells in the local tumor microenvironment and found that DDP decreased the percentage of intratumoral Treg

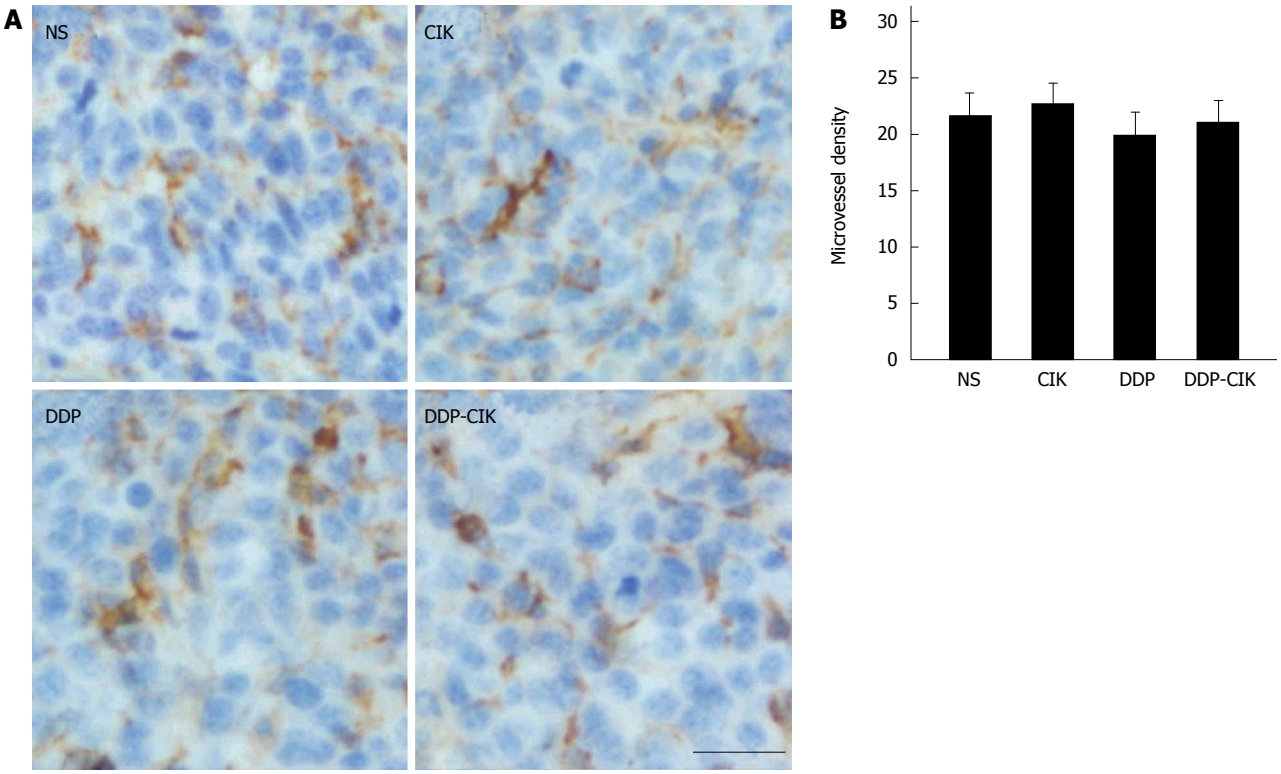

Figure 6 Tumor microvessel density after combination therapy. BALB/c WT mice were injected s.c. with 1 × 10^6 CT-26 cells and the treatment protocols were initiated 7 d later. On day 19, tumor sections were prepared and analyzed by CD31 staining (A). Ten individual fields (0.16 mm^2) at × 400 magnification were chosen to assess the tumor microvessel density (B). The experimental groups consisted of five mice per group. Representative sections from all groups are shown. Scale bars: 25 μm; Columns: mean microvessel number; Bars: SE.

cells. Based on these results, we propose that the DDP-induced reduction in the percentage of Treg cells could enable the development of an anti-tumor immune response, leading to the retardation of tumor growth.

We also examined the longitudinal changes in the percentage of splenic Treg cells in tumor-bearing mice after DDP treatment. It is noteworthy that, of the several cell types within the spleen, Treg cells were preferentially targeted by DDP. We found that the percentage of splenic Treg cells in pretreated tumor-bearing mice was reduced at all time points compared with that in untreated tumor-bearing hosts, implying that, besides its immunomodulating effect, DDP may also ameliorate systemic immunosuppressive factors by depleting splenic Treg cells. Regarding the DDP-induced dynamic changes in the number of Treg cells, the nadir was around Day 3 after treatment. Interestingly, the time points we chose for the transfer of CIK cells in the combined schedule were Days 3 and 5 after treatment, when the percentage of Treg cells was relatively low. Nevertheless, the percentage of Treg cells seemed to rebound and rise quickly on Day 5 after treatment. Therefore, CIK cells infused on Day 5 may have encountered a more "hostile" environment and were unable to exert their anti-tumor effects. Further studies are needed to determine the optimal schedule for combined therapy which triggers the maximal synergistic anti-tumor effects.

In addition to the immunosuppressive factors *in vivo*, angiogenesis, a pivotal process in tumor growth and metastasis, also plays a role in the failure of cellular immunotherapy. Angiogenesis suppresses the expression of the endothelial cell (EC) adhesion molecules involved in leukocyte adhesion to blood vessel walls, and that inhibition of angiogenesis may increase leukocyte-vessel wall interactions and the subsequent infiltration of lymphocytes into the tumor mass[27]. Some chemotherapeutic agents are characterized by their antiangiogenic effect when administered at small doses on a frequent schedule (sometimes referred to as metronomic chemotherapy). Metronomic administration of DDP showed toxic effects on the tumor microvasculature[28]. However, in this study, a single dose of DDP was used as the pretreatment therapy and we did not observe any antiangiogenic effect, ruling out any putative anti-angiogenic effect of DDP in this model.

In conclusion, our data showed that DDP pretreatment acted synergistically with CIK therapy to efficiently inhibit tumor growth in a murine colon adenocarcinoma model. This anti-tumor synergy was T lymphocyte-dependent. Preconditioning with DDP enhanced the infiltration of $CD3^+$ T lymphocytes into the tumors and reduced the percentage of both intratumoral and splenic Treg cells, revealing a potential mechanism underlying the immunostimulatory effects of DDP. In summary, the results of this study provide a potential combination regimen incorporating preconditioning chemotherapy and adoptive CIK therapy for the treatment of colon cancer.

COMMENTS

Background

Immune suppression constitutes a large obstacle to hinder the generation of effective anti-tumor immunity. It now becomes clear that successful cancer immunotherapy can be achieved only after the removing of immunity-hampering barriers. A number of studies have shown that preconditioning a host with immunomodulating chemotherapy can effectively augment the anti-tumor efficacy of adoptively transferred effectors.

Research frontiers

Regulatory T (Treg) cells, a distinct lymphocyte lineage inhibiting both adaptive and innate immunity, were mainly involved in tumor-induced immunosuppression. Elimination of Treg cells *in vivo* using agents targeting Treg cells such as cytotoxic agents or antibodies have been shown to enhance the anti-tumor responses, resulting in tumor regression.

Innovations and breakthroughs

To our knowledge, this is the first study to evaluate the potential synergy between Cisplatin (DDP) pretreatment and subsequent adoptive cytokine-induced killer cells (CIK) therapy in treatment of colon cancer. A dramatic T cell-dependent synergistic anti-tumor effect of the combination therapy was revealed in the model established in this study. Preconditioning chemotherapy with DDP could augment the infiltration of $CD3^+$ T lymphocytes into the tumor and diminish the percentages of both intratumoral and splenic Treg cells, thus improving the anti-tumor effect of CIK therapy.

Applications

This is a potential combination regimen incorporating the preconditioning chemotherapy to the adoptive CIK therapy for the patients with colorectal cancer.

Terminology

Preconditioning chemotherapy: Chemotherapy administered at a special dose and time point to modulate the host immune environment, thus providing a better ground for the subsequent adoptive cell therapy.

Peer review

How did the authors come upon the timeline for preconditioning and timing of sacrifice? Especially with the curves demonstrated in Figure 3, are we catching this too early? In Figure 3, it still appears that the slope of all of the curves continues to go up. As such, is this an initial impediment to grow more slowly but the end result is no difference? This is especially in light of the clinical trials that demonstrate no improvement in cure rate or long-term survival.

Abstract

AIM: To determine in obese children with nonalcoholic fatty liver disease (NAFLD) the accuracy of magnetic resonance imaging (MRI) in assessing liver fat concentration.

METHODS: A case-control study was performed. Cases were 25 obese children with biopsy-proven NAFLD. Controls were 25 obese children matched for age and gender, without NAFLD at ultrasonography and with normal levels of aminotransferases and insulin. Hepatic fat fraction (HFF) by MRI was obtained using a modification of the Dixon method.

RESULTS: HFF ranged from 2% to 44% [mean, 19.0% (95% CI, 15.1-27.4)] in children with NAFLD, while in the controls this value ranged from 0.08% to 4.69% [2.0% (1.3-2.5), $P < 0.0001$]. HFF was highly correlated with histological steatosis ($r = 0.883$, $P < 0.0001$) in the NAFLD children. According to the histological grade of steatosis, the mean HFF was 8.7% (95% CI, 6.0-11.6) for mild, 21.6% (15.3-27.0) for moderate, and 39.7% (34.4-45.0) for severe fatty liver infiltration. With a cutoff of 4.85%, HFF had a sensitivity of 95.8% for the diagnosis of histological steatosis $\geq$ 5%. All control children had HFF lower than 4.85%; thus, the specificity was 100%. After 12 mo, children with weight loss displayed a significant decrease in HFF.

CONCLUSION: MRI is an accurate methodology for liver fat quantification in pediatric NAFLD.

INTRODUCTION

Over the last two decades, the rise in the prevalence rates of overweight and obesity probably explains the emergence of nonalcoholic fatty liver disease (NAFLD) as the

leading cause of liver disease in the pediatric population worldwide[1,2]. NAFLD comprises a disease spectrum ranging from simple steatosis to nonalcoholic steatohepatitis (NASH), progressive to cirrhosis. It is a likely common cause of cryptogenic cirrhosis[3]. There is currently no specific biochemical or serological test for fatty liver and the diagnosis can be established accurately only by liver biopsy. The invasive nature of liver biopsy means that it cannot be used to screen large numbers of subjects at risk, or be performed repeatedly to measure fat changes following treatment. Therefore, availability of an accurate non-invasive tool to assess the presence and severity of liver fat will have important clinical implications in children.

To date, several imaging techniques are used to detect hepatic steatosis: ultrasonography (US), computed tomography (CT), proton magnetic resonance spectroscopy (MRS), and magnetic resonance imaging (MRI)[4-7]. Ultrasonography is a low-cost, widely used technique for the qualitative assessment of steatosis. However, it cannot provide reliable quantitative data, and its sensitivity is reduced in morbidly obese subjects and in those with small amounts of fatty liver infiltration. CT is accurate in the semiquantitative diagnosis of macrovesicular steatosis of 30% or greater; in addition, its use for monitoring treatment response is somewhat limited due to exposure to ionizing radiation. MRS is currently considered the most accurate non-invasive technique for detecting fat quantities as low as 0.5%. However, MRS demonstrates some limitations in that it is too time consuming for routine clinical practice, and requires a skilled operator to correctly perform the examination, process the data, and interpret the results. Because of these limitations, MRS still lacks general availability in current clinical practice for assessment and monitoring of hepatic steatosis. Unlike MRS, MRI is easy to perform and interpret, and, therefore, may be more suitable for widespread use. In adult patients several investigations have demonstrated a good correlation between the severity of hepatic steatosis on MRI and liver biopsy[8-11]. However, to the best of our knowledge, no studies to date have validated MRI with liver histology in the pediatric population. Thus, the purpose of the present study was to determine in a cohort of obese children with biopsy-proven NAFLD the accuracy of MRI for the detection and quantitative assessment of liver steatosis, and to correlate results with clinical, metabolic and histologic findings. We also sought to assess the usefulness of MRI for the evaluation of liver fat changes after a 1-year lifestyle intervention.

MATERIALS AND METHODS

Study design and patients

Twenty-five obese children and adolescents, 16 males and 9 females, aged 7-16 years, with suspected NAFLD ("cases") were recruited for study participation at the Department of Pediatrics, Sapienza University of Rome. Controls were 25 obese children matched for age, gender and pubertal stage, without ultrasound evidence of fatty liver and with normal levels of aminotransferases, as well as of insulin. All participants were of Caucasian ethnicity. The study was approved by the Institutional Review Board, and written consent was obtained from the parents or guardians of the children.

NAFLD diagnosis

NAFLD was suspected if the patients had elevated serum alanine aminotransferase (ALT) either persistently or intermittently, associated with diffusely hyperechogenic liver at ultrasound examination, and hyperinsulinism. Secondary causes of steatosis, including alcohol consumption, total parenteral nutrition, and the use of hepatotoxic medications, were excluded in all cases. In all patients, hepatic virus infections (hepatitis A-E and G, cytomegalovirus, and Epstein-Barr virus), autoimmune hepatitis, metabolic liver disease, α-1-antitrypsin deficiency, cystic fibrosis, Wilson's disease, and celiac disease were ruled out with appropriate tests. The final diagnosis of NAFLD was reached by liver biopsy.

Liver biopsy

The clinical indication for biopsy was either to assess the presence of NASH and degree of fibrosis or other likely independent or competing liver diseases. Percutaneous needle liver biopsy was performed with an 18-gauge needle, under general anaesthesia and ultrasound guidance. In all patients, in order to obtain an adequate sample, biopsy specimens were obtained twice at two different sites in the right hepatic lobe. Liver specimens that were at least 1.5 cm in length and contained at least 10-11 complete portal tracts were considered adequate for histological assessment. Sections were stained with hematoxylin-eosin, periodic acid Schiff, periodic acid Schiff-digested, iron stain, and Masson trichrome reagents. Biopsy specimens were evaluated for the following, using the NASH Clinical Research Network criteria[12]: steatosis [grade 0 (< 5% macrovesicular fat), grade 1 (mild = 5%-33%), grade 2 (moderate = 34%-66%), and grade 3 (severe ≥ 66%)], portal inflammation (0-2), lobular inflammation (0-3), ballooning degeneration (0-2), and fibrosis (stage 0 to 4).

Clinical and laboratory investigations

All study participants underwent physical examination including measurements of weight, standing height, body mass index (BMI), waist circumference (WC), determination of the stage of puberty, as well as systolic blood pressure (BP) and diastolic BP as previously reported in detail[13]. The degree of obesity was quantified by Cole's least mean square method, which normalizes the skewed distribution of BMI and expresses BMI as an SD score[14]. Blood samples were taken from each subject, after an overnight fast, for estimation of glucose, insulin, total and high density lipoprotein (HDL) cholesterol, triglycerides, ALT, aspartate aminotransferase (AST), and γ-glutamyl transferase (GGT).

Insulin concentrations were measured on a COBAS 6000 immunometric analyzer (Roche Diagnostics) by an electrochemiluminescent method. The remaining analytes were measured on a COBAS INTEGRA 800 analyzer (Roche Diagnostics). Insulin resistance (IR) was determined

by a homeostasis model assessment of insulin resistance (HOMA-IR). Scores were calculated as the product of the fasting serum insulin level (μU/mL) and the fasting serum glucose level (mmol/L), divided by 22.5.

MRI technique for hepatic fat quantification

NAFLD patients underwent MRI before liver biopsy and within a short-time interval [mean (SD) 3.1 (2.1) d; range, 1-7]. In controls, MRI was performed within 1 wk of clinical, laboratory and sonographic assessment. Hepatic MRI was performed with a 1.5-T magnet (Magnetom Avanto, Siemens Medical Systems, Erlangen, Germany) equipped with a phased-array surface coil and a spine array coil. Image acquisition was performed in the axial plane during an end-expiratory breath-hold using a sensitivity encoding (SENSE) technique, to reduce the overall acquisition time to approximately 15 s. We used the two-point Dixon method as modified by Fishbein *et al*[15]. The method is based on phase-shift imaging in which hepatic fat fraction (HFF) is calculated from the signal difference between the vectors resulting from in-phase (IP) and out-of-phase (OP) signals.

The multi-breath-hold T1-weighted dual gradient-echo sequence parameters were as follows: repetition time of 174 ms, echo time of 2.1 ms for OP images and 4.9 ms for IP images; flip angle, 70°; section thickness, 5 mm; matrix size, 256 × 182; field of view, 35 cm × 40 cm. Pixel signal intensities (SI) from IP and OP images were obtained from selected regions of interest (ROIs). The SI values both in the liver and the spleen were recorded for the IP and OP images by means of 1 cm^2 circular ROIs. At three different sections (above, at the level of, and below the transverse fissure of the liver), three different ROIs were drawn (2 in the right hepatic lobe; 1 in the left hepatic lobe), totaling nine ROIs. ROI selection within the liver parenchyma was performed taking care to avoid areas with vessels, motion artefacts, and partial volume effects. ROIs were placed at anatomically matched locations on paired images by using a co-registration tool available on the picture archiving and communication system workstation. The SI of the spleen was similarly measured and a mean SI was calculated from three ROIs selected at the corresponding liver levels. The standard deviation of the SI measurements within each ROI was kept to less than 10%. Liver fat was quantified as the percentage of relative SI loss of the liver on OP images, with the following formula: $[(SI_{in}-SI_{out})/2 \times SI_{in}] \times 100$ where SI is average liver signal intensity divided by the average spleen SI, SI_{in} and SI_{out} are signal intensity of IP and OP images, respectively. The SI of the spleen was used as a denominator in the formula to adjust for the lack of an objective SI scale at MRI[16,17]. MR imaging results were interpreted by an experienced radiologist who was blinded to clinical, laboratory, and histologic findings.

To assess reproducibility of MRI technique, measurements were performed again in 8 study subjects who agreed to a longer examination time. Standard deviations of the differences between measurements were less than 2% in HFF.

Follow-up

All 25 NAFLD children were offered the chance to take part in a 12-mo intervention program. This program consisted of physical exercise and nutrition education for the individual and his or her family. Diet was hypocaloric (25-30 calories/kg per day), consisting of carbohydrate (50%-60%), fat (23%-30%), and protein (15%-20%); fatty acid composition was two-thirds saturated, and one-third unsaturated; the ω6/ω3 ratio was 4:1 as recommended by the Italian Recommended Dietary Allowances. The diet regimen was prescribed with a recommendation to engage in a moderate daily exercise program (60 min/d at least 5 d a week).

Follow-up medical examinations (including assessment of changes in anthropometric characteristics) and laboratory measurements (including serum glucose, insulin, ALT, AST, GGT, total cholesterol, HDL cholesterol, and triglycerides) were performed at 6 and 12 mo of the intervention program. MRI was repeated at 12 mo. The NAFLD children were divided into those with and without substantial weight loss during the 1-year intervention. Substantial weight loss was defined as a decrease in the SDS-BMI $\geqslant$ 0.5. This division was used because in previous studies an improvement of cardiovascular risk factors and insulin resistance was only detectable if SDS-BMI decreased $\geqslant$ 0.5[18,19].

Statistical analysis

Statistical analyses were performed using the SPSS package. Data are expressed either as frequencies or as arithmetic means or geometric means with 95% confidence intervals (CI). The measured insulin, total cholesterol, HDL cholesterol, triglycerides and HOMA-IR values were distributed with a long tail to the right (positive skew), but their logarithms were approximately normally distributed. Thus, their mean values with 95% CI are reported as geometric means. Pearson correlations and linear regression analysis were used to analyse the relationship between HFF and the histological degree of steatosis as well as clinical variables. We also performed receiver operating characteristic (ROC) curve analysis to determine the best cut-off values for MRI to predict any grade, moderate, and severe hepatic steatosis. The area under the curve (AUC) was used to assess the accuracy of MRI. Values for sensitivity, specificity, and the optimum discriminative values were also obtained. We considered false-positive and false-negative results to be equally important, and thus values were chosen that maximized sensitivity plus specificity.

Pairwise comparisons were performed using paired *t* test or Wilcoxon's rank sum test, as appropriate. A *P* value of less than 0.05 was considered to be statistically significant.

RESULTS

Clinical and laboratory features of study population

The clinical and laboratory characteristics of cases and controls are summarized in Table 1. Obese children with NAFLD had higher BMI, BMI-SDS, WC, systolic and diastolic BP, triglycerides, insulin, and HOMA-IR values than the control group. Furthermore, compared to controls,

Table 1 Clinical and laboratory characteristics of children with and without nonalcoholic fatty liver disease

Characteristics	NAFLD (n = 25)	No NAFLD (n = 25)
BMI, kg/m^2	28.4 (26.4-30.3)[a]	25.6 (24.4-26.8)
BMI-Standard deviation score	2.20 (2.02-2.30)[a]	2.01 (1.92-2.17)
Waist circumference, cm	96.9 (91.8-102.1)[b]	85.2 (80.3-89.0)
Systolic BP, mmHg	117 (112-122)[b]	107 (105-109)
Diastolic BP, mmHg	70 (67-74)[b]	68 (65-70)
Aspartate aminotransferase, U/L	45 (33-58)[c]	24 (20-28)
Alanine aminotransferase, U/L	73 (55-91)[c]	21 (18-25)
γ-glutamyl transferase, U/L	31 (23-39)[c]	13 (12-14)
Total cholesterol, mg/dL	162 (143-181)	168 (146-190)
HDL cholesterol, mg/dL	42 (38-49)	40 (37-43)
Triglycerides, mg/dL	161 (115-207)[b]	112 (61-134)
Glucose, mmol/L	4.89 (4.69-5.10)	4.88 (4.77-5.02)
Insulin, μU/mL	31.2 (21.9-40.6)[a]	20.1 (16.2-24.1)
HOMA-IR values	4.27 (3.40-5.10)[a]	3.45 (2.97-4.01)
Hepatic fat fraction, %	19.0 (15.1-27.4)[c]	2.0 (1.3-2.5)

Results are expressed as n (%), mean (95% CI), or geometric mean (95% CI) for log-transformed variables. [a]$P < 0.05$, [b]$P < 0.01$, [c]$P < 0.0001$. BMI: Body mass index; NAFLD: Nonalcoholic fatty liver disease; BP: Blood pressure; HDL: High density lipoprotein; HOMA-IR: Homeostasis model assessment of insulin resistance.

Table 2 Features of the liver biopsies of the 25 children with nonalcoholic fatty liver disease

	Grade or stage	n	%
Steatosis	0	-	-
	1	9	36.0
	2	9	36.0
	3	7	28.0
	Total	25	100
Lobular Inflammation	0	-	-
	1	15	60.0
	2	9	36.0
	3	1	4.0
	Total	25	100
Portal inflammation	0	4	16.0
	1	20	80.0
	2	1	4.0
	Total	25	100
Ballooning	0	9	36.0
	1	12	48.0
	2	4	16.0

Fibrosis	0	7	28.0
	1	8	32.0
	2	9	36.0
	3	1	4.0
	4	-	-
	Total	25	100

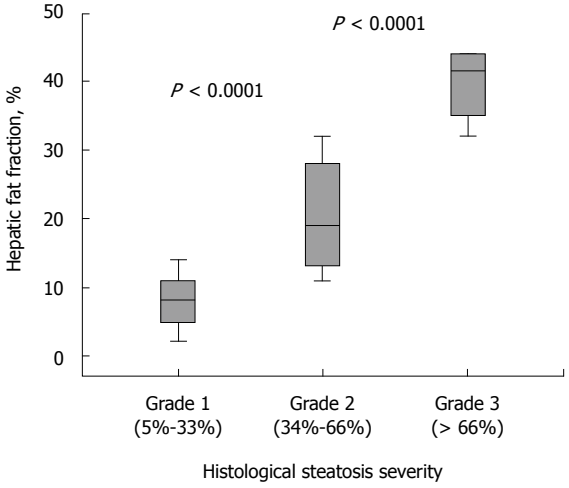

Figure 1 Magnetic resonance imaging hepatic fat fraction according to the histopathological results (grade of steatosis). Boxplots give the median value (black), 25th and 75th percentiles (lower and upper limits of the box), and lower and upper adjacent values (whiskers).

NAFLD children had significantly higher concentrations of ALT and AST, as well as of GGT. HFF ranged from 2% to 44% [mean, 19% (95% CI, 15.1 to 27.4)] in children with NAFLD, while in the control group this value ranged from 0.08% to 4.69% [2.0% (95% CI, 1.3 to 2.5), $P < 0.0001$].

Histological findings in children with NAFLD

All 25 cases fulfilled the histopathological requirements; that is, the length of liver specimens was on average 1.9 ± 0.2 cm, and included 14 ± 2 complete portal tracts. Macrovesicular steatosis was present in all cases and combined with microvesicular in 15% of cases. The amount of steatosis ranged from 10% to 95% with a mean of 42.6% (95% CI, 31.3 to 54.0) steatotic hepatocytes. The distribution of steatosis across the cohort was mild in 36%, moderate in 36%, and severe in 28% of subjects. Lobular inflammation was present in all patients, and it was of mild to moderate grade in 96% of patients. Sixty-four percent of children had ballooning of the hepatocytes that was in most cases of grade 1. Mild, more than mild, and no portal inflammation were found in 80%, 4%, and 16% of biopsies, respectively. Some degree of fibrosis was present in 72% of patients. Thirty-two percent showed stage 1 fibrosis, whereas 36% of biopsy specimens revealed stage 2 fibrosis (Table 2). Stage 3 fibrosis was present in 4%. No patient had hepatic iron deposit.

MRI and histological measurement of steatosis

HFF was highly correlated with histological steatosis over-

all ($r = 0.883$; $P < 0.0001$). According to the histological grade of steatosis, the mean HFF was 8.7% (95% CI, 6.0 to 11.6) for mild, 21.6% (95% CI, 15.3 to 27.0) for moderate, and 39.7% (95% CI, 34.4 to 45.0) for severe fatty liver infiltration. MRI imaging could differentiate between mild and moderate steatosis ($P < 0.001$), and between moderate and severe steatosis ($P < 0.001$) (Figure 1). Linear regression analysis was performed to determine the influence of the stage of fibrosis as well as of the degree of inflammation on the relationship between MRI and histological assessment of steatosis. Fibrosis was found to have no statistically significant influence [unstandardized coefficient, 1.10 (95% CI, 2.25 to 4.45); $P = 0.503$] on the estimates of HFF. Similarly, inflammation had no impact on the accuracy of MRI for the assessment of steatosis.

Accuracy of MRI for the diagnosis of steatosis

The accuracy of MRI for the diagnosis of mild, moderate, and severe steatosis is shown in Table 3. At the diagnostic threshold of 4.85% for HFF, MRI had a 95.8% sensitivity for diagnosing "any" grade of steatosis. There was only one child with histological steatosis of grade 1 who had HFF of 2%. A threshold of 9.0% for HFF was the best cutoff for the diagnosis of moderate to severe steatosis (sensitivity, 100%). A cutoff value of 19.0% for HFF was indicative of severe steatosis (sensitivity, 100%). All control children had HFF lower than 4.85% (specificity, 100%).

Relationship between MRI and variables

Among clinical and laboratory data, HFF was significantly associated with SDS-BMI ($r = 0.486$, $P < 0.01$), WC ($r = 0.406$, $P < 0.01$), triglycerides ($r = 0.374$, $P < 0.05$), insulin ($r = 0.290$, $P < 0.05$), and HOMA-IR values ($r = 0.349$, $P < 0.05$) in the whole study population. When the NAFLD group was analysed separately, HFF remained significantly associated with insulin ($r = 0.425$, $P < 0.05$), and HOMA-IR values ($r = 0.506$, $P < 0.05$).

Follow-up

After 12 mo, eleven NAFLD children demonstrated a substantial weight loss [mean SDS-BMI change: -0.88 (95% CI, -0.57 to -1.19)]. In these children, HFF [mean change: -13.1% (95% CI, -9 to -19); $P < 0.05$)], systolic BP [mean change: -8 mmHg (95% CI, -5 to -14); $P < 0.05$), ALT [mean change: -45 U/L (95% CI, - 37 to -70); $P < 0.05$), AST [mean change: -27 U/L (95% CI, -18 to -37); $P < 0.05$), triglycerides [mean change: -56 mg/dL (95% CI, -32 to -60); $P < 0.05$), and HOMA-IR values [mean change: -3.2 (95% CI, -2.0 to -5.8); $P < 0.05$)] decreased significantly. In contrast, in the 14 NAFLD children without substantial weight loss [mean SDS-BMI change: -0.10 (95% CI, -0.01 to -0.19), there was no significant change in HFF [mean change: -3.0% (95% CI, -0.3 to -5.0); $P = 0.48$] as well as in clinical and laboratory parameters.

DISCUSSION

Liver fat accumulation is becoming a common complication in pediatric obesity[1,2]. Biopsy remains the criterion standard to accurately determine, in a semiquantitative manner, the amount of fatty liver infiltration. Furthermore, liver biopsy is able to evaluate lesions associated with steatosis, such as fibrosis and inflammation, and thus, to evaluate the stage and grade of the disease. However, we cannot perform liver biopsy as a screening method to detect NAFLD in the general pediatric population. Therefore, a reliable, non-invasive method of screening NAFLD would represent a major advance in clinical hepatology.

Several non-invasive imaging techniques have been advocated as diagnostic tests. Standard MRI, MRS, and CT may not be feasible for children because of their long scan time, reliance on compliance of the patient, and ionizing radiation. Signal intensity loss on opposed-phase gradient-echo T1-weighted MR images frequently is regarded as an accurate method of detection and quantification of liver fat[8,20,21]. By using gradient-echo chemical shift imaging (Dixon method), MRI can be performed either as readily available T1-weighted dual echo, triple echo, multiecho, or multi interference. We chose to use the T1-weighted dual-echo MRI because of its simplicity.

In the adult population, a close relationship has been observed between the percentage of steatosis estimated by histology and dual-echo chemical shift imaging[8,11,21]. However, a major point to underline is that HFF appears to be influenced greatly by fat morphology[8]. Lipid is accumulated within the liver as a response to various disease states and may be deposited in a macrovesicular, microvesicular, or mixed steatosis pattern. In a group of 38 patients undergoing liver biopsy for a variety of liver diseases (including hepatitis C, NAFLD, methotrexate monitoring, chronic hepatitis of unknown etiology, cryptogenic cirrhosis, primary biliary cirrhosis, autoimmune hepatitis), Fishbein *et al*[8] showed that fast-MRI correlated better with macrovesicular steatosis ($r = 0.92$, $P < 0.001$) than with mixed steatosis ($r = 0.60$, $P < 0.05$). In NAFLD, a disorder associated with severe macrovesicular steatosis, fat fraction was higher than other liver disorders associated with lesser degrees of fatty infiltration, including hepatitis C. Similarly, in a very recent study including 46 patients undergoing liver resection, van Werven *et al*[21] showed that T1-weighted dual-echo MR imaging was strongly correlated with histopathologic steatosis assessment ($r = 0.85$, $P < 0.001$). In the 23 patients with macrovesicular steatosis greater than 5%, dual-echo MR imaging showed an even stronger correlation with histopathologic examination ($r = 0.92$, $P < 0.001$) than in the overall group.

In the pediatric population, the 2-point Dixon method

Table 3 Diagnostic accuracy of magnetic resonance imaging

Steatotic hepatocytes	⩾ 5%	> 33%	> 66%
Cutoff	4.85	9	19
AUC	0.98 (95% CI, 0.98-1.0)	1	1
Sensitivity (%)	95.8	100	100
Specificity (%)	100	100	100

AUC: Area under the curve.

as modified by Fishbein is an accepted technique for measuring hepatic fat content[22-24]. It can also be helpful in identifying fat regression or progression in children, and it has been found useful in differentiating increased liver echogenicity due to simple steatosis from that related to glycogen storage disease[25,26]. However, no previous studies in children have used the degree of hepatic steatosis at histologic analysis as the reference standard. In normal liver, lipid accounts for approximately 5% total wet weight[22]. Initial studies determining liver fat in children by fast-MRI defined as abnormal a threshold value for HFF greater than 2 SD above mean hepatic fat content of healthy adult volunteers[15] or lean, nondiabetic (mean age 21.6 ± 8.2 years) subjects[27]. Recent studies have validated the modified 2-point Dixon method against MRS in obese and lean adolescents who were at increased risk of having or developing hepatic steatosis, and found a very strong correlation between the two methods (r = 0.954, $P < 0.001$)[23,24]. In a cohort of 28 (mean age, 15.9 ± 5.3 years) obese and lean subjects, Kim *et al*[23] demonstrated that a 2-point Dixon HFF cutoff of 3.6% provided a good sensitivity (80%) and specificity (87%) compared to MRS reference. Our present results obtained in a homogeneous population indicate that the modified 2-point Dixon method may be a good alternative to biopsy for quantifying liver fat content in obese youngsters with NAFLD and for assessing the relation between HFF and metabolic outcomes in these patients. The clinical efficacy of fast-MRI has been previously demonstrated. Burgert *et al*[27] showed that obese children with a high HFF were significantly more insulin resistant, compared with those with a low HFF, and had higher triglycerides and lower adiponectin levels, even after adjustment for BMI-z scores, race/ethnicity, gender, and age. Furthermore, obese children with a high HFF had a significantly greater prevalence of the metabolic syndrome, after controlling for the above confounders. More recently, D'Adamo *et al*[28] suggested that the severity of fatty liver, as determined by the modified 2-point Dixon method, plays a central role in the insulin resistant state in obese adolescents, independently of visceral fat and intramyocellular lipid content. Using the disposition index, an estimate of β-cell function weighted by insulin sensitivity, the authors found this was reduced by 30% in children with fatty liver, thus increasing susceptibility to type 2 diabetes. We also previously showed that the increasing severity of MRI fat accumulation was strongly related to fasting hyperinsulinemia and insulin resistance after correction for confounding variables such as SD score-BMI, sex, age and pubertal status[29]. The present results obtained in obese youths with biopsy-proven NAFLD not only corroborate the clinical efficacy of the modified 2-point Dixon method, but also highlight the potential application of this method for tracking longitudinal changes in liver fat content in patients under targeted lifestyle intervention or medical therapy. In concordance with our longitudinal findings, fast-MRI has also been found to identify longitudinal liver fat changes in adults during pioglitazone treatment for biopsy-proven NAFLD and in obese children and adolescents after a 1-year nutrition-behavior intervention[25,30].

Fibrosis and inflammation may be present in patients with hepatic steatosis. In adult patients with heterogeneity of underlying pathologies including NAFLD, Fishbein *et al*[8] showed that hepatic MRI, based upon chemical shift imaging, is not influenced by the presence of fibrosis and was able to accurately quantify the hepatic fat content in the patients who also had significant hepatic fibrosis. Our present results confirm and expand on the findings of the above report. In fact, we found that in our obese children with NAFLD, neither inflammation nor fibrosis had an influence on the estimates of steatosis.

Our study has some limitations. Firstly, our results were obtained in a selected population of children with and without NAFLD. Therefore, one could argue that by doing so we would maximize the differences between cases and controls. If we had included patients from the general pediatric population, the results would have been more conclusive. However, obtaining hepatic biopsy for research purposes in such patients would not be feasible or ethical. Secondly, another restriction is that we did not perform MRI measurements at exactly the same locations in the liver that were used for histopathologic assessment. This could affect the results we reported in diagnostic performance. However, we obtained large-wedge liver biopsy specimens which provided accurate data. Lastly, we used a T1-weighted dual-echo chemical shift MRI method to study hepatic steatosis. No corrections for T1, T2*, or fat spectral complexity were made, and consequently only MR signal intensities were evaluated. Recent studies have indicated that T1-weighting (flip angle) and T2-weighting (iron deposition) may interfere with accurate fat quantification[16,31]. However, in the study by van Werven *et al*[21], a strong correlation between T1-weighted dual gradient-echo MR imaging and histopathologic results was demonstrated in the absence of any correction for T1, T2*, or fat spectral complexity. In that study as well as in ours, the mean signal intensity decay of 12 and 9 ROIs throughout the liver was measured, respectively. The T2 correction is important in cases where iron overload problems might lead to T2 changes. As liver iron deposition is a common secondary feature of many chronic liver diseases, signal intensity loss on in-phase gradient-echo MR images caused by the presence of liver iron is a potential pitfall in the determination of liver fat percentage at opposed-phase MR imaging in chronic liver diseases[16]. Thus the T2* correction is very important in cases where iron overload might lead to T2 changes, but none of our young patients with NAFLD had histological evidence of iron accumulation, consistent with a previous report of adult patients with NAFLD who were seen at a referral center without a special interest in disorders of iron storage[32]. In that report, significant iron histological accumulation was not observed in the majority of patients with NAFLD or its various subtypes.

In conclusion, this study with histopathologic validation shows that the modified Dixon method provides high diagnostic and fat-grading accuracy in obese children with NAFLD. Even if the small number of patients included in our study must be taken into account, the results ob-

tained are highly encouraging and may provide a basis for stimulating further studies which would include a larger number of children.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) has been increasing over the past three decades, both in children and adolescents, presenting a worldwide problem. NAFLD is characterized by lipid accumulation in the liver, and it represents a disease spectrum that ranges from simple hepatic steatosis to steatohepatitis, and eventually to cirrhosis and liver failure.

Research frontiers

Currently, liver biopsy is considered the gold standard to accurately determine, in a semiquantitative manner, the amount of fatty liver infiltration. However, the authors cannot perform liver biopsy as a screening method to detect NAFLD in the general pediatric population. This is an invasive procedure with the potential of complications, being also prone to sampling error and interobserver variability. Consequently, there is a need in children for non-invasive, safe diagnostic tools to detect and quantify hepatic steatosis as well as to identify hepatic fat regression or accumulation over time.

Innovations and breakthroughs

To date, several imaging techniques are used to detect hepatic steatosis. Ultrasonography is a low-cost, widely used technique for the qualitative assessment of steatosis in children. However, it cannot provide reliable quantitative data, and its sensitivity is reduced in subjects with small amounts of fatty liver infiltration. Standard magnetic resonance imaging (MRI), proton magnetic resonance spectroscopy, and computed tomography may not be feasible for children because of their long scan time, reliance on compliance of the patient, and ionizing radiation. In the pediatric population, among the MRI methods, the 2-point Dixon method as modified by Fishbein is an accepted technique for measuring hepatic fat content. It can also be helpful in identifying fat regression or progression in children, and it has been found useful in differentiating increased liver echogenicity due to simple steatosis from that related to glycogen storage disease. However, no previous studies in children have used the degree of hepatic steatosis at histologic analysis as the reference standard.

Applications

The authors' present results obtained in a homogeneous population with NAFLD indicate that the dual-echo MRI may be a good alternative to biopsy for quantifying fat liver content in obese youngsters and for assessing the relation between hepatic fat fraction and metabolic outcomes in these patients. Furthermore, the authors' results highlight the potential application of this method for tracking longitudinal changes in liver fat content in patients under targeted lifestyle intervention or medical therapy.

Terminology

This study with histopathologic validation shows that the dual-echo MRI provides high diagnostic and fat-grading accuracy in obese children with NAFLD. MRI is easy to perform and interpret, and, therefore, may be suitable for widespread use.

Peer review

Dr. Lucia Pacifico and colleagues quantified the amount of liver fat in pediatric NAFLD by using T1-weighted dual-echo MRI, and assessed the validation of MRI quantification by comparing liver biopsy specimens. The noninvasive quantification method with high sensitivity and specificity is very important to assess the degree of fat accumulation in the liver, specifically in uncooperative or high-risk patients for invasive procedures. This study arouses interest for readers and provides an important clue to evaluate the degree of NAFLD or the improvement of the disease in the treatment or follow-up observation.

Abstract

AIM: To evaluate the prevalence of upper gastrointestinal symptoms and their association with clinical and functional characteristics in elderly outpatients.

METHODS: The study involved 3238 outpatients ⩾ 60 years consecutively enrolled by 107 general practitioners. Information on social, behavioral and demographic characteristics, function in the activities of daily living (ADL), co-morbidities and drug use were collected by a structured interview. Upper gastrointestinal symptom data were collected by the 15-items upper gastro-intestinal symptom questionnaire for the elderly, a validated diagnostic tool which includes the following five symptom clusters: (1) abdominal pain syndrome; (2) reflux syndrome; (3) indigestion syndrome; (4) bleeding; and (5) non-specific symptoms. Presence and severity of gastrointestinal symptoms were analyzed through a logistic regression model.

RESULTS: 3100 subjects were included in the final analysis. The overall prevalence of upper gastrointestinal symptoms was 43.0%, i.e. cluster (1) 13.9%, (2) 21.9%, (3) 30.2%, (4) 1.2%, and (5) 4.5%. Upper gastrointestinal symptoms were more frequently reported by females ($P < 0.0001$), with high number of co-morbidities ($P < 0.0001$), who were taking higher number of drugs ($P < 0.0001$) and needed assistance in the ADL. Logistic regression analysis demonstrated that female sex (OR = 1.39, 95% CI: 1.17-1.64), disability in the ADL (OR = 1.47, 95% CI: 1.12-1.93), smoking habit (OR = 1.29, 95% CI: 1.00-1.65), and body mass index (OR = 1.06, 95% CI: 1.04-1.08), as well as the presence of upper (OR = 3.01, 95% CI: 2.52-3.60) and lower gastroenterological diseases (OR = 2.25, 95%CI: 1.70-2.97), psychiatric (OR = 1.60, 95% CI: 1.28-2.01) and respiratory diseases (OR = 1.25, 95% CI: 1.01-1.54) were significantly associated with the presence of upper gastrointestinal symptoms.

CONCLUSION: Functional and clinical characteristics are associated with upper gastrointestinal symptoms. A multidimensional comprehensive evaluation may be useful when approaching upper gastrointestinal symptoms in older subjects.

Key words: Upper gastrointestinal symptoms; Elderly; Upper gastro-intestinal symptom questionnaire for the elderly; Gastroesophageal reflux disease; Disability

INTRODUCTION

Epidemiological and clinical studies suggest that the prevalence of upper gastrointestinal diseases is particularly high in older subjects[1]. Nevertheless, in older patients the clinical identification of upper gastrointestinal diseases on the basis of the presence of symptoms is very difficult and sometimes misleading. It has been reported that older patients with upper gastrointestinal diseases, such as reflux esophagitis[2] or peptic ulcer disease[3], may report a low prevalence of typical or specific symptoms, several patients recounting only nonspecific or no symptoms at all; thus the presence of nonspecific symptoms has been reported as one of the most important reasons for late diagnoses or even severe complications in elderly patients[4,5]. Conversely, many older subjects report upper gastrointestinal symptoms without a clear relationship with well defined disorders of the upper gastrointestinal tract[6]. Indeed, several clinical and functional conditions may influence the symptom perception and referral to doctor, especially in older people[7]. However, very few studies have been performed on the potential association of upper gastrointestinal symptoms and clinical and functional conditions in old age.

Recently, a diagnostic questionnaire, i.e. upper gastro-intestinal symptom questionnaire for the elderly (UGISQUE), was developed and validated in two independent populations of elderly patients who underwent an upper gastrointestinal endoscopy[8]. The UGISQUE included 15 items grouped into five symptom clusters that comprehensively explore both specific and nonspecific symptoms of the upper gastrointestinal tract in older subjects. The findings of this study suggested the concept that the use of a comprehensive diagnostic tool specifically developed for elderly patients may be useful in reducing misleading and under-recognized diagnoses of upper gastrointestinal diseases.

The aim of this study was to evaluate the prevalence of upper gastrointestinal symptoms and their association with clinical and functional characteristics in a large population of elderly outpatients referred to their general practitioner (GP) by using the UGISQUE.

MATERIALS AND METHODS

Study population

The study was conducted according to the Declaration of Helsinki and the guidelines for Good Clinical Practice. Written informed consent was obtained from the patients or from relatives prior to participation in the study.

The study was carried out by 107 GPs and involved elderly outpatients, in the frame of the IPOD project (Identification of symPtOms to Detect GERD and NERD). In the period between April and October 2007, 3238 patients were screened for enrollment, based on the following inclusion criteria: (1) age $\geqslant$ 60 years; (2) ability to provide an informed consent; and (3) willingness to participate to the study. Exclusion criteria were: (1) a cognitive impairment of grade moderate to severe as evaluated by a short portable mental status questionnaire (SPMSQ)[9] score $\leqslant$ 7; and (2) presence of neoplasm at late stages.

Data collection

Data were obtained by a structured interview of patients and were confirmed by the GP's medical records. General practitioners included all patients seen during a 1-wk period (5 working days) who agreed to participate in the study. All subjects aged 65 years and over who consulted their GP for a medical problem during this 2-wk period were included in the study. Elderly patients who were visited in their home or in nursing homes were not included.

The interview was carried out by skilled GPs. A Computer Assisted Personal Interview (CAPI) instrument followed the interview step by step in collecting and recording the demographic, functional and clinical data as well as the information on drug use and gastrointestinal symptoms. Computerized records were e-mailed to the statistics reference center for evaluation.

Measurements

Information on socio-demographic characteristics (age, gender, marital status, education), body mass index (BMI; body weight/height^2), smoking status, alcohol consumption, coffee use, functional status, comorbidity and drug consumption were collected by a structured interview.

Functional status was evaluated by the Barthel Index[10], which defines the level of dependence/independence of eight daily personal care activities (Activities of Daily Living, ADL), including bathing, eating, personal hygiene, dressing, toilet use, transfer, bladder and bowel control.

The cumulative illness rating scale (CIRS)[11] was used to ascertain presence and severity (5-point ordinal scale, score 1-5) of pathology in each of 13 systems, including cardiac, vascular, respiratory, eye-ear-nose-throat, upper and lower gastroenteric disease, hepatic, renal, genito-urinal, musculo-skeletal, skin disorder, nervous system, endocrine-metabolic and psychiatric behavioral problems. In this study we have considered only the comorbidity assessed as the number of concomitant diseases from moderate to severe levels (grade from 3 to 5). Medication use was defined according to the anatomical therapeutics chemical classification (ATC) code system[12] and the number of drugs used by patients was recorded. Patients were defined as drug users if they took a medication of any drug included in the ATC classification code system.

The UGISQUE questionnaire

The UGISQUE (Table 1) includes 15 items for the description of upper gastrointestinal symptoms divided into five symptom clusters: (1) abdominal pain syndrome [1. stomach ache/pain, 2. hunger pains in stomach or belly];

Table 1 Upper gastroIntestinal symptom questionnaire for the elderly

UGISQUE		Symptoms in the last week	Questions	Response scale[1]			
				0	1	2	3
Abdominal pain syndrome	1	Stomach ache or pain	Has he had pain or discomfort in the upper abdomen or the stomach?				
	2	Hunger pains in stomach or belly	Has he had hunger pains? (an empty, hollow feeling in the stomach and the need to eat between meals)				
Reflux syndrome	3	Heartburn	Has he suffered from heartburn? (a nagging, burning sensation in the upper chest or retrosternal region)				
	4	Acid reflux	Has he had acid regurgitation? (a sudden regurgitation of stomach acid content to the esophagus)				
Indigestion syndrome	5	Nausea	Has he suffered from nausea? (a feeling of discomfort in the stomach that can lead to vomiting)				
	6	Rumbling in the stomach	Has he had rumbling stomach? (i.e. growling, bubbling or gurgling sounds)				
	7	Bloated stomach	Has he suffered from bloating? (i.e. a fullness feeling correlated to gas build-up)				
	8	Burping	Has he suffered from burping? (i.e. bringing up excessive air followed by a sense of relief)				
Bleeding	9	Hematemesis	Has he had hematemesis? (vomiting blood) or melena (black stools)				
	10	Melena					
	11	Anemia	Loss of at least 3 g/dL of hemoglobin in the last 3 mo				
Non-specific symptoms	12	Anorexia	Has he suffered from anorexia? (a loss of appetite or interest in food)				
	13	Weight loss	Has he had a weight loss? (involuntary weight loss in the last 3 mo)				
	14	Vomiting	Has he suffered from vomiting? (involuntary, forceful expulsion of gastric content through the mouth)				
	15	Dysphagia	Has he had dysphagia? (sensation of difficulty in passing the food bolus through the esophagus)				

[1]Response scale: (0) absent = no symptoms are reported by patient; (1) mild = awareness of symptoms, but they are easily tolerated; (2) moderate = symptoms interfering with the normal activities; (3) severe = symptoms that induced inability to perform normal activities or symptoms requiring medical attention. UGISQUE: Upper gastroIntestinal symptom questionnaire for the elderly.

(2) reflux syndrome [3. heartburn, 4. acid reflux]; (3) indigestion syndrome [5. nausea, 6. rumbling in the stomach (i.e. vibrations or noise in the stomach), 7. bloated stomach (i.e. swelling in the stomach), 8. burping (i.e. bringing up air or gas through the mouth)]; (4) bleeding [9. hematemesis, 10. melena, 11. anemia]; (5) non-specific symptoms [12. anorexia, 13. weight loss, 14. vomiting, 15. dysphagia].

The UGISQUE includes a response scale with four grades: (0) absent = no symptoms are reported by patient; (1) mild = awareness of symptoms, but they are easily tolerated; (2) moderate = symptoms interfering with the normal activities; and (3) severe = symptoms that induce inability to perform normal activities or symptoms requiring health intervention. Symptomatic patients were defined as those patients who reported moderate or severe discomfort in at least one item. The recall period for symptom assessment was the last week before the interview.

Further details of the UGISQUE methods have been reported elsewhere[8].

Statistical analysis

Subjects were classified according to the absence/presence of UGISQUE symptoms into two groups. Associations between the two groups of subjects and demographic and clinical characteristics were investigated using the χ^2 test or the Fisher exact test for categorical variables. Group mean values were compared through the generalized linear model procedure, after testing for homoschedasticity with the Levene's test; Welch's Anova was considered in case of heteroschedasticity.

A logistic regression model was then developed. The variable on presence of UGISQUE symptoms was considered as the dependent variable, dichotomized into "no symptoms" *vs* "moderate/severe symptoms". As possible predictors, demographic (sex; age; marital status; education), clinical (comorbidities; drug use; BMI; smoking status; alcohol and coffee consumption) and functional (need of assistance in the ADL) characteristics were selected through a stepwise procedure. Relative risks and 95% confidence intervals were calculated to estimate the association of covariates with the dependent variable.

All statistical analyses were performed using SAS, version 9.1.3 package (Cary, SAS Institute).

RESULTS

During the study period 3238 patients were screened for enrollment; 138 patients were excluded because they did not have valid data on UGISQUE. Thus, complete data on 3100 patients were included in the present analysis: 1547 men, 1553 women; with a mean age of 72.2 ± 7.0 years, and an age range of 60-96 years.

Figure 1 shows the presence of gastrointestinal symptoms, according to the five UGISQUE clusters. The overall prevalence of upper gastrointestinal symptoms was 43.0% (1332 subjects out of 3100). In detail, 13.9% of subjects reported symptoms of abdominal pain, 21.9% reported symptoms of reflux syndrome, 30.2% of subjects reported symptoms of indigestion syndrome, 1.2% of subjects reported bleeding symptoms and 4.5% of subjects reported non-specific symptoms.

Table 2 reports the demographic and clinical characteristics of subjects, stratified by the two study groups. No significant differences were found between the two groups in mean age, education and in the prevalence of smoking habit, alcohol and coffee consumption. In symptomatic subjects, a significantly higher prevalence of women ($P <$

Table 2 Socio-demographic and clinical characteristics of patients divided by the presence of upper gastrointestinal symptoms according to the upper gastro-intestinal symptom questionnaire for the elderly clusters in elderly outpatients

	No symptoms (n = 1768)	Yes symptoms (n = 1332)	P-value
Sex (females, %)	45.8	55.8	< 0.0001
Age (yr, mean ± SD)	72.2 ± 7.0	72.2 ± 6.9	0.8635
Marital status (married, %)	68.3	64.2	0.0185
Education (none/primary school, %)	75.8	78.0	0.1503
Body mass index (kg/m^2, mean ± SD)	26.0 ± 3.6	26.6 ± 3.9	< 0.0001
Smoking status (current smoker, %)	11.2	13.0	0.1288
Alcohol consumption (%)	45.7	42.6	0.0957
Coffee consumption (%)	85.1	87.3	0.0743
Heart diseases (%)	29.3	33.2	0.0198
Hypertension (%)	63.2	65.3	0.2274
Vascular diseases (%)	13.6	16.6	0.0223
Respiratory diseases (%)	15.3	22.2	< 0.0001
Eye-ear-nose-throat diseases (%)	13.6	14.9	0.3103
Upper gastroenterological diseases (%)	20.0	44.8	< 0.0001
Lower gastroenterological diseases (%)	6.6	14.4	< 0.0001
Hepatic diseases (%)	5.6	8.1	0.0046
Kidney diseases (%)	4.5	5.0	0.4692
Genital-urinary diseases (%)	24.7	26.6	0.2434
Skeletal, muscle, skin diseases (%)	43.4	50.6	< 0.0001
Nervous system diseases (%)	5.3	6.5	0.1351
Endocrine-metabolic diseases (%)	22.5	22.0	0.7617
Psychiatric diseases (%)	12.6	21.6	< 0.0001
Number of comorbidities (mean ± SD)	2.8 ± 1.7	3.5 ± 1.9	< 0.0001
4 or more comorbidities (%)	28.7	45.3	< 0.0001
Drug consumption (%)	91.7	93.8	0.0285
Number of drugs (mean ± SD)	2.9 ± 1.6	3.3 ± 1.7	< 0.0001
3 or more drugs (%)	52.5	64.0	< 0.0001
Need of assistance in activities of daily living (%)	14.2	21.5	< 0.0001

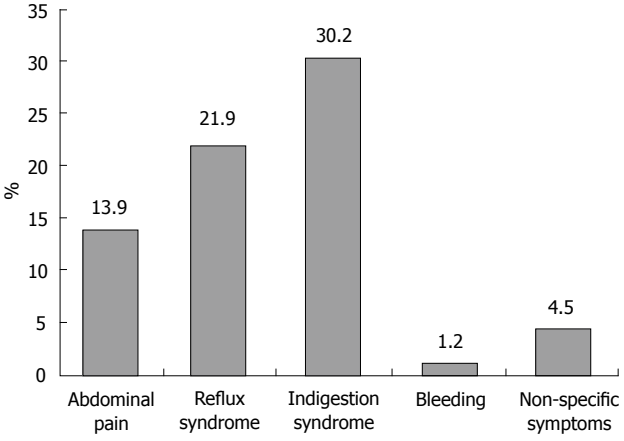

Figure 1 Prevalence of upper gastrointestinal symptoms according to the upper gastro-intestinal symptom questionnaire for the elderly score clusters.

0.0001) and unmarried subjects (P = 0.0185) was found compared to asymptomatic subjects. In the symptomatic group, a significantly higher prevalence of subjects who needed assistance in the ADL than in the asymptomatic subjects was observed (21.5% *vs* 14.2%, P < 0.0001). Moreover, symptomatic subjects had higher prevalence (P < 0.0001) and mean number (P < 0.0001) of concomitant diseases, higher prevalence of drug consumption (P = 0.0285) and higher mean number of drugs taken (P < 0.0001) than asymptomatic subjects.

As regards the concomitant diseases, 45.3% of symptomatic subjects reported 4 or more comorbidities, with respect to 28.7% among asymptomatic subjects (P < 0.0001). Moreover, higher prevalence rates of heart diseases, vascular, respiratory, upper and lower gastroenterological, hepatic, skeletal-muscle-skin and psychiatric diseases were observed in subjects who reported upper gastrointestinal symptoms than asymptomatic subjects.

Table 3 shows the results of a stepwise selection on a logistic regression model, with outcome as to the presence of upper gastrointestinal symptoms according to the UGISQUE clusters. Significant risk factors for upper gastrointestinal symptoms were female gender (OR = 1.39, 95% CI: 1.17-1.64), need of assistance in the ADL (OR = 1.47, 95% CI: 1.12-1.93), actual smoking (OR = 1.29, 95% CI: 1.00-1.65) and BMI (OR = 1.06, 95% CI: 1.04-1.08).

As expected, subjects with upper (OR = 3.01, 95% CI: 2.52-3.60) and lower gastrointestinal diseases (OR = 2.25, 95% CI: 1.70-2.97) were three and two times, respectively, more likely to report upper gastrointestinal symptoms. Moreover, the presence of psychiatric diseases (OR = 1.60, 95% CI: 1.28-2.01) and respiratory diseases (OR = 1.25, 95% CI: 1.01-1.54) were also significant predictors for upper gastrointestinal symptoms according to the UGISQUE clusters.

DISCUSSION

This study reports the results of a wide survey of the prevalence of upper gastrointestinal symptoms and their association with clinical and functional characteristics

Table 3 Risk factors for upper gastrointestinal symptoms according to upper gastro-intestinal symptom questionnaire for the elderly clusters in elderly outpatients

	Odds ratio	95% CI	*P*-value
Sex (female)	1.39	1.17-1.64	< 0.0001
Respiratory disease	1.25	1.01-1.54	0.0430
Upper gastroenterological diseases	3.01	2.52-3.60	< 0.0001
Lower gastroenterological diseases	2.25	1.70-2.97	< 0.0001
Psychiatric diseases	1.60	1.28-2.01	< 0.0001
Need of assistance in activities of daily living	1.47	1.12-1.93	0.0057
Smoking status (actual smoker)	1.29	1.00-1.65	0.0476

in a large population of elderly outpatients. The results showed that demographic, behavioral, functional and clinical characteristics of subjects were significantly associated with the presence of upper gastrointestinal symptoms in old age. These findings suggest that a comprehensive clinical and functional evaluation may be useful in approaching upper gastrointestinal symptoms in older subjects.

The mean age of the IPOD sample was not significantly different from the mean age of the Italian population who were 60-96 years old, as reported by ISTAT for 2006 (72.2 ± 7.0 years *vs* 72.1 ± 10.8 years, respectively; $t = 0.7204$, $P = 0.4713$) [13].

Co-morbidity data, assessed by the CIRS, shows a population that is affected by pathologies in 97.2% of cases, of whom 35.4% reported 4 or more comorbidities. In agreement with previous studies in geriatric populations[14,15], the most frequent diseases were hypertension (63.9%), bone and joint diseases (45.8%), heart diseases (30.7%) and diseases of the upper gastrointestinal tract (30.8%). The high prevalence of comorbidities also reflects the wide use of drugs found in this population. In fact, 92.1% of subjects took at least one drug, with 57.2% of the subjects taking 3 or more. This high prevalence of drug consumption is in agreement with other Italian[16,17] and American studies[18], that have reported drug use prevalence ranging from 90% to 96% in older outpatient populations.

In this study, the cognitive state of subjects was assessed to exclude people who were unable to respond appropriately to the UGISQUE questionnaire. Thus, by excluding subjects with moderate and/or severe cognitive impairment, only 17% of subjects included in the study reported needing assistance in one or more items of ADL. These findings are in agreement with previous data from the Italian national multicenter study of the SOFIA project[16].

In this study we used the UGISQUE, a recently developed questionnaire for the collection of upper gastrointestinal symptoms in elderly patients who underwent an upper gastrointestinal endoscopy. Findings from this study suggest that UGISQUE may also be a clinically useful diagnostic tool for evaluating upper gastrointestinal symptoms in elderly outpatients. Indeed, the survey demonstrates that more than 43% of subjects reported at least one symptom of the upper gastrointestinal tract, i.e. 13.9% of subjects reporting abdominal pain, 21.9% reflux symptoms, 30.2% indigestion symptoms, 1.2% bleeding symptoms and 4.5% non-specific symptoms of anemia (1%), dysphagia (2.7%) and vomiting (0.4%). The presence of this last cluster of symptoms seems to reflect a peculiarity of clinical presentation of the upper gastrointestinal disorders in elderly subjects, as previously reported in endoscopic studies carried out in older populations[2-5] and in agreement with previous data from Italy[19] and Europe[20,21].

Logistic regression demonstrated that female gender was a significant risk factor for reporting upper gastrointestinal symptoms; this finding is in agreement with previous studies performed in general populations[22]. Moreover, disability in the ADL was a significant predictor of upper gastrointestinal symptoms. All these findings confirm a previous study[16], performed in 5500 elderly outpatients, that reported a significantly higher prevalence of symptoms in females, patients who were taking a higher number of drugs, and those who had higher disability.

In agreement with previous studies that reported a significant association between high BMI value and gastrointestinal disorders in young populations[23-25], in this present study, for the first time, we also observed such an association between BMI and upper gastrointestinal symptoms in elderly people. Indeed, changes in gastroesophageal anatomy and physiology caused by obesity, including a diminished lower esophageal sphincter (LES) pressure, the development of a hiatal hernia, and increased intragastric pressure[26], may explain this association.

As expected, the presence of gastroenterological diseases was significantly associated with the risk of presenting upper gastrointestinal symptoms according to the UGISQUE clusters. Very interestingly, however, the presence of psychiatric disorders as well as respiratory diseases was also significantly associated with the presence of upper gastrointestinal symptoms in this population. While it has been reported that psychological distress, depression and anxiety may provoke symptoms of many organ systems, including upper gastrointestinal symptoms that prompt patients to consult a physician[27], at present, this seems to be the first study that has reported such an association in older subjects. This finding is in agreement with previous data reporting a significant association of upper gastrointestinal symptoms with the use of psycholeptic drugs (88% of which were benzodiazepines) in elderly outpatients[16] and supports the concept that subjects with anxiety syndromes and sleep disturbances

may have a greater frequency of functional gastrointestinal disorders, including abdominal pain and/or indigestion syndrome[28]. As regards the significant association between upper gastrointestinal symptoms and respiratory diseases, data do exist that suggest a pathophysiological[29] and clinical[30] link between upper gastrointestinal symptoms and respiratory diseases, especially asthma[31] and chronic obstructive pulmonary disease[32]. The data are in agreement also with a previous finding of a higher use of selective β_2 adrenoreceptor/adrenergic agonist drugs in older subjects with upper gastrointestinal symptoms than in asymptomatic subjects[16].

All these findings suggest that investigation of psychological and/or respiratory problems may be helpful for elderly patients with upper gastrointestinal symptoms.

In conclusion, demographic, functional and clinical characteristics of patients are significantly associated with the presence of upper gastrointestinal symptoms in old age. These findings suggest that a comprehensive clinical and functional evaluation may be useful in approaching upper gastrointestinal symptoms in older subjects.

COMMENTS

Background

Epidemiological and clinical studies suggest that the prevalence of upper gastrointestinal symptoms is particularly high in older age. However, very few studies have been performed on the potential association of upper gastrointestinal symptoms and clinical and functional conditions in old age. Recently, the upper gastroIntestinal symptom questionnaire for the elderly (UGISQUE) was developed and validated in different populations of elderly patients who underwent an upper gastrointestinal endoscopy.

Research frontiers

Gastrointestinal symptoms are widely diffused and frequently misdiagnosed in the elderly population. Their impact on clinical and functional conditions may influence the performance in the activities of daily living, therapeutic compliance, nutrition status, and finally, the quality of life. A multidimensional approach may improve clinical and functional evaluation of the older patient with gastrointestinal symptoms to better identify therapeutic and health care programs.

Innovations and breakthroughs

Specific functional and clinical characteristics, such as disability in the activities of daily living (ADL), body mass index and the presence of gastroenterological, psychiatric and respiratory diseases, are significantly associated with the presence of upper gastrointestinal symptoms in older patients. A comprehensive clinical and functional evaluation by means of diagnostic tools specific for older people (ADL, UGISQUE) may be useful in approaching upper gastrointestinal symptoms in older subjects

Applications

The functional and clinical definition of older patients with gastrointestinal symptoms could lead to better care in clinical practice. The UGISQUE is easy to administer and effective in predicting gastrointestinal disorders in older patients. Further prospective studies on the application of the UGISQUE for predicting gastrointestinal adverse drug reactions and other adverse outcomes, such as disability in the activities of daily living, are needed to evaluate the role of a multidimensional approach in improving the care of older patients.

Peer review

This cross-sectional study analyzed relationships of upper gastrointestinal symptoms and functional or clinical characteristics in elderly outpatients. This manuscript is well-written.

Abstract

AIM: To determine hepatitis C virus (HCV) seroprevalence and its genotypes, and to identify the factors associated with HCV infection.

METHODS: This cross-sectional study, conducted in two prisons (one male and one female) in the State of Sergipe, Brazil, comprised 422 subjects. All of the prisoners underwent a rapid test for the detection of HCV antibodies. Patients with a positive result were tested for anti-HCV by enzyme linked immunosorbent assay and for HCV RNA by qualitative polymerase chain reaction (PCR). The virus genotype was defined in every serum sample that presented positive for PCR-HCV. In order to determine the factors independently associated with positive serology for HCV, multivariate logistic regression was used.

RESULTS: HCV seroprevalence was 3.1%. Of the 13 subjects with positive anti-HCV, 11 had viremia confirmed by PCR. Of these, 90.9% had genotype 1. A total of 43 (10.2%) were injecting drug users, and HCV seroprevalence in this subgroup was 20.6%. The variable most strongly associated with positive serology for HCV was use of injecting drugs [odds ratio (OR), 23.3; 95% confidence interval (CI), 6.0-90.8]. Age over 30 years (OR, 5.5; 95%CI, 1.1-29.2), history of syphilis (OR, 9.8; 95%CI, 1.7-55.2) and history of household contact with HCV positive individual (OR, 14.1; 95%CI, 2.3-85.4) were also independently associated with HCV infection.

CONCLUSION: Most of the HCV transmissions result from parenteral exposure. However, there is evidence to suggest a role for sex and household contact with an infected subject in virus transmission.

INTRODUCTION

Hepatitis C virus (HCV) is one of the main causes not only of chronic viral hepatitis, but also of cirrhosis and end-stage liver disease in the world[1]. Hepatitis C, given its treatment costs, high morbidity and mortality, generates a significant burden in healthcare systems. According to the World Health Organization, there are over 170 million people with chronic hepatitis C and approximately 3 to 4 million new cases each year[2].

HCV seroprevalence in the general population has wide geographical variation. Studies performed in Brazil have shown an anti-HCV prevalence of 5.9% in the

Amazon region, 0.9% in the State of Rio de Janeiro and 0.34% in the State of Santa Catarina[3].

There are six HCV genotypes, with several subtypes. For each genotype, there is a different pattern of treatment response and, consequently, a distinct therapeutic approach[4,5]. There is a wide geographical variation when it comes to genotype distribution, so that genotypes 1, 2 and 3 are more frequent in Europe, the USA and Japan; genotype 4 in central Africa, Egypt and the Middle East; genotype 5 in South Africa; and genotype 6 in Asia. Brazil in general has a higher prevalence of genotype 1, followed by genotype 3[6].

Most HCV transmissions are due to parenteral exposure. It has been estimated that HCV is 10 times more infectious than HIV, per unit of blood, requiring less exposure to reach high prevalence[1]. Other routes have been described, such as sexual and vertical transmission, but these are less common than the parenteral one. Risk factors already proposed include use of injecting drugs (ID), tattoos, occupational blood exposure and hemodialysis[4,5]. It is important to highlight that HCV prevalence is higher in certain groups, such as prisoners[4]. Although these subjects represent only 0.8% of the American population, approximately 39% of the cases of chronic HCV infection have a history of imprisonment[7]. There are several international studies which determined hepatitis C prevalence in prisons, but studies in Latin America are scarce.

The following factors are related to higher prevalence of HCV in prisoners: duration of incarceration, use of ID, adverse socioeconomic situation and poor health care. Therefore, there is a potential public health issue, since the prison system works as a concentrator of hepatitis C subjects and a dissemination center of this infection. Risk behavior may precede imprisonment and continue afterwards[8,9].

A large number of HCV carriers are asymptomatic and remain undiagnosed for a long time, resulting in further complications, such as liver cirrhosis, liver failure and hepatocellular carcinoma. These asymptomatic patients also represent a natural reservoir of the disease, and a source of dissemination[2].

Prisons in the State of Sergipe, Brazil, do not currently screen for HCV and there are no statistics concerning HCV status of the prisoners incidentally diagnosed. Given the regional variation of HCV prevalence among prisoners, the lack of data in Sergipe and its importance in order to implement effective strategies to prevent HCV transmission, we conducted a study of the prevalence of HCV infection among prisoners, as well as HCV genotypes in viremic subjects, and factors associated with positive serology for HCV.

MATERIALS AND METHODS

Study population

This was a cross-sectional study performed in two prisons (one male and one female) in the State of Sergipe, Brazil. The study was conducted in the male prison in September 2009 and in the female one in February 2010. Subjects eligible for this study included all prisoners who agreed and signed the consent form.

Data collection

Structured and individual interviews were privately conducted. Before the interview, it was explained that any collected information would be kept confidential. Subjects' names were not collected. Each questionnaire received a code number, in order to allow further connection to its respective blood sample, and was formed by closed questions, including sociodemographic characteristics and risk behaviors, such as the ones involving drug use and sexual practices, before and during the imprisonment.

Blood sample collection

After the interviews, the subjects underwent a rapid test for the detection of HCV antibodies (kit HCV Rapid Test Bioeasy). Peripheral blood from those with a positive result in the rapid test was collected by a finger prick with a single use lancet. Then, six blood spots (two to confirm serology and four for molecular biology) were blotted onto high-quality filter paper (Schleicher & Scheull 903). For each circle, approximately three drops of blood were used. Afterwards, filter paper was left to dry at room temperature for 30 min or until the blood spot was completely dry. The material was kept in aluminum envelopes, along with a bag containing silica gel, and posted to Genoma Center. Only patients with positive anti-HCV had their results confirmed by qualitative polymerase chain reaction (PCR). Those with positive qualitative PCR had the HCV genotype determined.

Statistical analysis

Continuous variables are reported as mean ± SD, and analyzed using the Mann-Whitney *U* test. Categorical variables are presented as percentages and analyzed using Chi-square (χ^2) or Fisher's exact tests. $P < 0.05$ were considered to be statistically significant. In order to identify parameters independently associated with positive serology for anti-HCV, a logistic regression model was determined. Variables with $P < 0.1$ in univariate analysis were included in the multivariate analysis. Before indicating which variables would be inserted in the initial model, multicollinearity issues were solved. Backward selection of variables was performed, with entry and retention set at a significance level of 0.05. The discrimination capability of the final model was evaluated through the area under the ROC curve (AUC), and the goodness-of-fit of the logistic model was verified by the Hosmer-Lemeshow test ($P > 0.05$). Variables that continued in the model were tested for possible interaction among them. Each interaction (between two variables) was individually tested and then added to the final model if they showed statistical significance. Statistical analyses were performed using the Statistical Package for the Social Sciences, version 17 (Chicago, IL, USA).

This study was approved by the Research Ethics Committee of the Federal University of Sergipe in April 2009

(N° CAAE 0038.0.107.000-09). Prison authorities did not have access to any questionnaires or blood samples.

RESULTS

Prevalence and genotypes

Of 382 men, 303 (79%) agreed to participate in the research, and of 137 women, 119 (87%) participated. All included subjects underwent the rapid test for the detection of antibodies to HCV, but one of the subjects with a positive result for this test did not provide a blood sample for qualitative PCR. HCV seroprevalence was 3.1%. From the 13 subjects with positive anti-HCV, eleven had confirmed viremia by PCR. Of these, 10 (90.9%) had genotype 1 (Table 1).

HCV: Hepatitis C virus.

Subject characteristics

The mean age of the subjects was 32.7 (± 8.8) years, and the most frequent age group was 25-30 years (28.4%). A total of 303 (72%) were men (recruited in the State Penitentiary of Areia Branca); and 119 (28%) were women (recruited in the Female Penitentiary of Sergipe). Seventy-two (60.5%) women and 39 (12.8%) men had drug dealing or drug use as the reason for imprisonment. Many of the subjects were multiracial (38%) and single (39.6%). More than half of the population declared themselves as Catholics (56.4%) (Table 2).

Sexual practices and drug use

A total of 150 (35.5%) subjects reported previous sexually transmitted disease (STD), of which gonorrhea was the most frequently declared. Two hundred and forty-seven (58.5%) participants affirmed that they had paid or been paid for sex, and 109 (25.8%) rarely or never used condoms. Regarding drug use, 311 (73.7%) subjects had used illegal drugs, while 10.2% stated that they had used ID. Among ID users (IDU) (n = 43), 32.6% shared needles and syringes or other injecting equipment, 7% started injecting in prison and 11.6% continued injecting at the time of the interview. HCV seroprevalence among IDU was 20.6% (Table 3).

Univariate analysis

As shown in Tables 4 and 5, we studied the association between serologic HCV status and sexual practices, drug use, sociodemographic and behavioral characteristics. Positive serology for HCV was significantly associated with the following characteristics: previous imprisonment; household contact with a HCV carrier; history of tattooing, though there was no significance considering only tattooing inside prison; previous syphilis; and use of illegal drugs, including inhaled cocaine, marijuana and ID. However, use of crack was not associated with HCV infection. Moreover, those with positive anti-HCV presented significantly higher mean age, higher mean CAGE score and higher mean duration of use of inhaled cocaine, marijuana and ID. There was no significant association between HCV and marital status (data not shown), gender, ethnicity, religion and sexual orientation. Rarely or never having

HCV: Hepatitis C virus.

used a condom, and a history of paying or being paid for sex were not associated with a higher HCV seroprevalence. An association was not observed between STD and HCV, except for syphilis. Regarding partner characteristics, the only variable that was significantly associated with HCV was a positive anti-HCV partner. Both groups (positive and negative anti-HCV) had similar mean duration of imprisonment, mean number of sexual partners in the last year, mean age at the time of the first sexual intercourse, mean family income and average years of education.

Multivariate analysis

Multivariate logistic regression was performed using HCV status as the dependent variable. Among variables that presented collinearity issues (data not shown), the ones with greater clinical impact were chosen. Continuous variables were turned into dichotomous ones, using the receiver operating characteristic (ROC) curve to choose the cut-off point that presented the best discrimination capability. Table 6 shows the variables independently associated with positive serology for HCV, and the strongest

Table 6 Multivariate logistic regression of characteristics associated with positive serology for anti-hepatitis C virus

Characteristic	Crude odds ratio	Adjusted odds ratio	95%CI	*P*-value
Injecting drug user	24.8	23.3	6.0-90.8	0.0000
History of household contact with HCV carrier	10.2	14.1	2.3-85.4	0.004

Hosmer-Lemeshow test (P = 0.420). HCV: Hepatitis C virus; CI: Confidence interval.

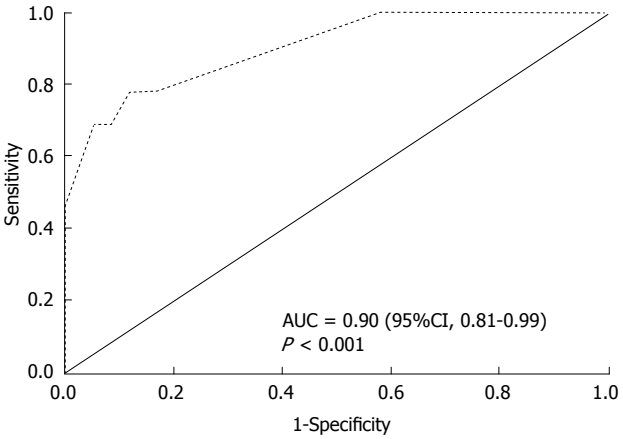

Figure 1 Multivariate model receiver operating characteristics curve. AUC: Area under the curve; CI: Confidence interval.

association verified was between positive serology for HCV and use of ID (OR, 23.3; 95% confidence interval (CI), 6.0-90.8). The chance of presenting with positive anti-HCV was 14 times higher among subjects that had lived with an HCV carrier compared with those without this history, even after adjusting for other variables, such as use of ID. Age over 30 years and previous syphilis were also independently associated with positive serology for HCV. None of the tested interactions was statistically significant (data not shown). The Hosmer-Lemeshow test had P = 0.420, so the final model was considered to be adequate. Moreover, the area under the ROC curve was 0.90 (95%CI, 0.81-0.99; $P < 0.001$), and the discrimination capability of the final model was considered to be good (Figure 1).

DISCUSSION

To our knowledge, this is the first study to determine HCV seroprevalence, and factors associated with this infection in inmates in Northeastern Brazil. HCV seroprevalence observed in this research was 3.1%, which is higher than that found in the general population (1.14%)[4]. Nevertheless, this percentage is below expectation, especially if we consider the following aspects: the prevalence among prisoners described in other regions of Brazil or even in other countries; the absence of damage control programs in the evaluated prisons; and higher prevalence is expected in an already imprisoned population[10]. In Brazil, the studies conducted by Guimarães *et al*[5], Burattini *et al*[8] and Coelho *et al*[11] verified positive serology for HCV in 41%, 34% and 9% of inmates, respectively. Catalan-Soares *et al*[12], in a study involving 63 prisoners, observed lower HCV seroprevalence (6.3%), but it was still twice that found in the present study. Moreover, Strazza *et al*[9], in a study in a Brazilian female prison, found an HCV seroprevalence of 16.2%. In the USA, in an incarcerated population, 16%-41% presented serological evidence of HCV infection, and approximately 12%-35% had chronic hepatitis C[7]. Experiences in Spain, England and France reported a prevalence of 48%, 30% and 30%, respectively[13].

It is important to point out that, depending on the studied region, even inside one country, HCV seroprevalence presents a wide variation. HCV seroprevalence seems to increase along with the proportion of IDU. Vescio *et al*[10], in a meta-analysis, concluded that the most important source of heterogeneity among studies is the different proportion of IDU in each population. In addition, according to the same study, HCV seroprevalence among IDU also has an important influence on this heterogeneity. In our research, 10.2% of the inmates declared that they had already used ID. This proportion varies from 3% to 69% throughout the world[10]. Perhaps the explanation for the proportion of IDU not being as high as expected in our population is linked to the low percentage of imprisonments motivated by drug dealing or drug use, and also to other social and cultural characteristics not assessed in the present investigation.

It has been reported that HCV-RNA may be detected in 40%-90% of subjects with positive anti-HCV[2]. In our population, there was a high proportion of positive HCV-RNA-84.6% of the inmates with positive anti-HCV-that is, subjects capable of infecting others. This information corroborates the hypothesis that prisoners are important carriers of HCV and a potential source of transmission[7,13], especially when many of them will return to society.

Genotyping of hepatitis C provides not only epidemiological data, but also information from the perspective of the therapeutic response. Treatment offers better results for genotypes 2 and 3[14]. Genotyping was performed in all 11 cases in which HCV-RNA was detected. We only identified genotypes 1 and 3, and genotype 1 was the most frequent (90.9%). Other studies also showed genotype 1 as the most frequent[14-18], but always with a higher frequency of genotype 3 when compared with that in the present study.

There was no significant difference in HCV seroprevalence with respect to gender. Previous results in the medical literature are conflicting, in spite of one meta-analysis demonstrating a discreet predominance of positive anti-HCV among women[10]. However, this meta-analysis did not consider confounding variables that could be respon-

sible for such an association. One proposed confounding factor is the higher proportion of women incarcerated for drug dealing or drug use[19]. Regarding ethnicity, previous studies showed that Caucasians had a higher chance of presenting positive for anti-HCV[20,21], but race did not influence the serological status in our population.

Age over 30 years was independently associated with positive serology for HCV, which was also observed in other studies[11,16,20]. This finding may be explained by a higher risk of exposure to HCV over the years. Guimarães *et al*[5] found a different result, in which younger subjects had a higher chance of infection, but this finding might represent a local peculiarity.

Self-reported use of drugs, including ID, has been shown to be both valid and reliable[22]. Despite statistical significance in univariate analysis, inhaled cocaine did not remain in the final model. In the medical literature, HCV transmission through sharing materials used for inhaling cocaine remain controversial[23]. Use of ID remained in the final model and it was the factor most strongly associated with positive serology for HCV. This finding is consistent with those of other studies[9-11,20,24-28] and supports the effectiveness of HCV parenteral transmission. Use of ID during imprisonment has been reported by 3%-28% of inmates[7]. In the present study, only a minority of IDU (11.6%) referred to injecting inside prison. As previously mentioned[10], difficulty in obtaining equipment for use of ID can lead to sharing, making HCV transmission easier. In our population, 32.6% declared that they shared needles, so a needle exchange program might be effective.

It has been demonstrated that HCV seroprevalence was three times higher in prisoners who had tattoos, when compared to those who did not[10]. In spite of observing an association between tattoos and HCV in univariate analysis, we did not identify an independent effect of this variable in HCV seroprevalence. In accordance with Hellard *et al*[29], in this study tattoos were strongly associated with use of drugs, presenting multicollinearity issues in multivariate analysis. However, it is important to point out that tattooing inside prison was not associated with positive anti-HCV, unlike previous findings[29]. Therefore, this might not be an important route of transmission in the studied population.

Other proposed routes of transmission do not seem to be relevant in the studied population. All of the subjects with positive anti-HCV denied a history of blood transfusion. Sharing personal care items and a history of getting wounded by a sharp weapon in a struggle occurred equally in prisoners in both groups-positive and negative anti-HCV.

It has been suggested that previous imprisonment would be associated with HCV infection[5]. Despite its significance in univariate analysis, this variable was not independently associated with a positive serology for HCV. Subjects with previous imprisonment, when compared to those without this background, had a higher proportion of IDU, and for this reason would present higher HCV seroprevalence. For IDU, imprisonment is a fairly common event, due to the illegality of their behavior or to crimes committed because of the high cost of drugs on the black market[30].

Sexual transmission of HCV is controversial[10]. Some authors consider this route of transmission ineffective[31,32], which is corroborated by the fact that use of condoms did not seem to protect the studied prisoners from HCV infection. An association between HCV and syphilis has been described[5,33,34] and we observed that a history of previous syphilis was independently associated with positive serology for HCV, even after adjustment for ID use and other confounding factors. Syphilis may be a marker of sexual promiscuity, but variables that evaluate this aspect, such as number of partners in the last year, other previous STD and having already paid or been paid for sex, were not associated with HCV infection. We suggest that HCV is not associated with STD in general, but with genital ulcers, inherent in syphilitic infection. As previously suggested[35], blood containing HCV would penetrate more effectively through injured genital skin. Other studies corroborate the hypothesis of genital ulcers influencing HCV transmission[23,35]. Therefore, in spite of not being the main route, sexual transmission seems to have a role in this population.

Some studies[25,35] stated that homosexuality would lead to a higher chance of HCV infection. This association was not confirmed in our study. All the subjects with positive anti-HCV denied homosexual practices. This finding demonstrates that perhaps the association found in other studies might be related to risk behaviors, instead of homosexuality itself, which is in accordance with Fox *et al*[26] and Mahfoud *et al*[15].

A previous partner infected by HCV and household contact with an HCV carrier were associated with positive serology for HCV. However, only household contact with an infected subject was retained in the final model. One possible explanation would be that, although both groups referred equally to sharing personal care items, household contact may lead to blood to blood contact by common use of such objects sporadically or in an unobserved manner.

Most HCV infections are acquired before imprisonment[10,36], but transmission inside prisons has been reported[22,37], which justifies implementation of prevention programs, especially in populations with a high proportion of susceptible subjects, such as the one in this study.

Our study has some limitations. This research included populations from two institutions, which makes external validity difficult for other populations in the world or even in other institutions in Northeastern Brazil. Some prisoners may not have answered some questions correctly, especially the ones concerning STD, chronological aspects and with legal implications, such as the use of ID inside prison. Strengths of the study include: a short period of data collection, showing the real HCV prevalence at that moment; interviews were conducted before test results were available, minimal ascertainment bias; and high sensitivity of the rapid test used, which avoids underestimation of HCV seroprevalence. It has been described that this test has both sensitivity and specificity close to 100%[38,39].

The data shown corroborate the hypothesis that, in the studied prisoners, parenteral HCV transmission is the main route. However, there is evidence to suggest a role for sex and household contact in HCV transmission. This study demonstrated low HCV seroprevalence, with a high proportion of subjects having genotype 1. The large number of susceptible individuals in the studied population, the poor response of genotype 1 to antiviral treatment and the progress of chronic infection make prevention programs more important. It has been shown that treatment is cost-effective[40], even in an imprisoned population[41]. Entering the prison system could be an opportunity to treat and break the transmission cycle. In addition, treatment adherence and side effects could be closely monitored.

Data on hepatitis C in Brazil are still scarce, so more epidemiological studies are necessary in order to guide and monitor prevention programs. We defend the offer of anti-HCV tests for those with a higher chance of infection, such as those with a previous history of syphilis, those aged over 30 years, IDU, or those who had lived with an HCV carrier, to improve the positive predictive value of the tests. This active research should be guided, if possible, by local studies. Even the ones not eligible for treatment may reduce transmission and progress to end-stage liver disease after receiving counseling.

COMMENTS

Background

Most studies have shown that hepatitis C virus (HCV) prevalence is higher in certain groups, such as prisoners. Duration of incarceration, use of injecting drugs, adverse socioeconomic situation and poor health care are related to higher prevalence of HCV in this population.

Research frontiers

There is a wide regional variation of HCV prevalence among prisoners and studies that aimed to determine HCV prevalence in prisoners in Latin America are scarce. Most HCV transmission results from parenteral exposure, but other routes have been described. Sexual transmission is still controversial. There is a potential public health issue, since the prison system works as a concentrator of hepatitis C and a dissemination center of this infection. Many HCV carriers are asymptomatic and represent a natural reservoir of the disease, and a source of dissemination

Innovations and breakthroughs

The data shown corroborate the hypothesis that parenteral transmission is the main route. There is evidence to suggest the role of sexual and household contact in HCV transmission. Household contact may lead to blood to blood contact, by common use of personal objects sporadically or in an unobserved manner. This study also demonstrated a low HCV seroprevalence, probably due to the low proportion of injecting drug users.

Applications

Since this study describes HCV prevalence in a regional prison, it may allow the development of strategies to guide and monitor prevention programs. Household contact with an infected subject must not be neglected, and, in the future, may be a risk factor to be considered in routine evaluation.

Peer review

The obtained results show that most of the HCV transmissions are due to parenteral exposure and that transmission through sex and household contact with an infected subject play an important role. The paper is well written and the results appear to be well described and critically discussed (also in consideration of other studies).

Abstract

AIM: To determine the incidence of peripheral fractures in patients with celiac disease (CD) and the effect of treatment on fracture risk.

METHODS: We compared the incidence and risk of peripheral fractures before and after diagnosis between a cohort of 265 patients who had been diagnosed with CD at least 5 years before study entry and a cohort of 530 age- and sex-matched controls who had been diagnosed with functional gastrointestinal disorders. Data were collected through in-person interviews with an investigator. The overall assessment window for patients was 9843 patient-years (2815 patient-years after diagnosis).

RESULTS: Compared with the control group, the CD cohort showed significantly higher incidence rate and risk of first peripheral fracture before diagnosis [adjusted hazard ratio (HR): 1.78, 95% CI: 1.23-2.56, $P < 0.002$] and in men (HR: 2.67, 95% CI: 1.37-5.22, $P < 0.004$). Fracture risk was significantly associated with the classic CD presentation with gastrointestinal symptoms ($P < 0.003$). In the time period after diagnosis, the risk of fractures was comparable between the CD cohort and controls in both sexes (HR: 1.08, 95% CI: 0.55-2.10 for women; HR: 1.57, 95% CI: 0.57-4.26 for men).

CONCLUSION: CD patients have higher prevalence of fractures in the peripheral skeleton before diagnosis. This is associated with male sex and classic clinical presentation. The fracture risk was reduced after the treatment.

Key words: Celiac disease; Fracture risk; Peripheral fractures; Gluten-free diet; Sex difference

INTRODUCTION

In the past two decades, the effect of celiac disease (CD) on bone health has been extensively studied[1]. Osteopenia or osteoporosis detected by bone mineral density measurements has been seen in > 50% of patients at the time of their diagnosis of CD[2-5]. Data have accumulated to show that low bone mineral density is more common in adults and is present even if patients have atypical or asymptomatic CD at the time of diagnosis[1,6-8]. The impact of CD treatment on bone density has received some attention but remains under-explored[6,9-13]. Few studies have evaluated the risk of fractures, a more relevant clinical endpoint than bone mineral density, in CD patients[1,14-21]. A recent systematic review with a meta-analysis that pooled 20 995 CD patients and 97 777 controls, from eight studies published between 2000 and 2007, concluded that CD patients have a 43% higher risk of fractures compared with people without CD [pooled odds ratio: 1.43, 95% CI: 1.15-1.78][22]. A more recent study, published after the systematic review, confirmed the significant association between CD and increased fracture risk[23]. It should be noted that available studies are limited by heterogeneity in study methodology, patient population, and potential biases; thus, results have varied widely[22]. Nevertheless, evidence suggests that physicians should carefully examine the bone health of patients with CD.

Current evidence is mixed on fracture risk in patients who are maintaining a gluten-free diet (GFD) to treat CD[24]. In a seminal study that we have conducted previously[14], we found a lower rate of any type of fractures among treated CD patients compared with untreated CD patients. However, three subsequent studies with different study designs have reported different findings[18,20,21,23]. All of these studies showed that the risk of fractures in diagnosed and treated CD patients was significantly higher than in healthy controls. A fifth study did not show any significant difference between patients, before and after diagnosis[16]. Moreover, a Swedish population-based study[21] recently has reported that the elevated risk of fractures among CD patients remains unchanged 20 years after diagnosis. These studies employed different methodologies, which makes it difficult to extrapolate their findings to the general CD patient population.

Theoretically, dietary treatment can improve patients' bone health and reduce the risk of falls, which in turn, may reduce the risk of fractures[1]. Given the equivocal evidence, a better understanding of the effect of GFD on patients' fracture risk is of clinical importance to physicians and patients. The present study aimed to assess the risk of fractures in a large cohort of CD patients and the effect of GFD on this risk.

MATERIALS AND METHODS

Patients and controls

A cohort of 265 adult patients (> 18 years old) with a diagnosis of CD and a cohort of 530 age- and sex-matched controls with functional gastrointestinal disorders were recruited at the gastroenterology units in four medical centers in Buenos Aires, Argentina from March 2007 to November 2009. The CD diagnosis was based on a combination of positive clinical findings (presence of symptoms or risk factors such as family history), characteristic CD enteropathy in duodenal biopsy at the time of diagnosis, positive CD-specific serology, and a positive clinical and/or histological response to a GFD. The presence of positive CD-related serological tests at diagnosis (anti-gliadin antibodies, anti-tissue transglutaminase antibodies and/or antiendomysium antibodies) was considered sufficient for a diagnosis of CD without follow-up assessments. Patients were enrolled in the study if their diagnosis of CD had been established at least 5 years prior to their entry to the study. Confirmation of the CD diagnosis was required at the time of enrollment irrespective of the patient's compliance with the GFD. We excluded 163 patients who were diagnosed with other disorders that could independently reduce bone health (e.g. uncontrolled thyroid dysfunction, rheumatoid arthritis, inflammatory bowel disease, diabetes), who took medications that may affect bone metabolism (e.g. steroids, calcium, vitamin D, alendronate, anticonvulsants, thyroid hormones, estrogen or androgen replacement), and who had complicated CD. Two controls subjects attending the same gastroenterology unit were enrolled for each CD patient in the study. These control subjects were selected if a definitive diagnosis of functional gastrointestinal disorder based on Rome Ⅲ criteria was confirmed by their medical records, and if they had the same age and sex as the enrolled CD patient.

Study design and data collection

Medical history related to CD and fractures was taken from the CD patient and control cohorts using a standard questionnaire through in-person interviews conducted by the investigators, who were experienced with CD. The interview included demographic information; age at which the patient began to experience CD-like symptoms such as diarrhea, weight loss and anemia; age at diagnosis of CD; gynecological and obstetric history; and fracture history, including the type and severity of trauma that produced the fracture and the site of the fracture. All study participants were further questioned about their smoking habits, long-term medications, and hormone replacement therapy. Participants were asked whether they had ever broken a bone and which bone they had fractured. All data reported at the time of the interview were checked with those reported in patient

records. If any discrepancy was detected, patients were contacted by telephone to confirm observations. If the discrepancy still persisted and no documentation of the event was available, the patient was excluded from the study. Trauma was considered as: (1) severe, if it involved a traffic accident, was sports-related, or caused by falling from a height; (2) moderate, if the fracture resulted from slipping or stumbling, or from a fall on level ground; and (3) mild, if minimal trauma was involved. Body weight was determined for all enrolled patients, and body mass index (BMI) was calculated.

CD patient adherence to GFD was estimated based on multiple assessments: (1) opinion of the patient's primary treating physician; (2) patient's self-report; and (3) a validated questionnaire[25]. The degree of adherence was characterized by one investigator as one of the following categories: (1) strict (adherence for > 90% of the time); (2) partial (50%-90% of the time); or (3) poor (< 50% of the time).

Each study unit tabulated data in a centralized Excel spread sheet. The data were periodically verified *via* comparison with patients' medical records and, if necessary, corrected by three investigators who were not involved in data collection. If discrepancies were noted for a study subject, the subject was contacted by the data reviewer and the most accurate information available was accepted as valid. Data on each year of diagnosis and clinical presentation of CD were confirmed by the patient's medical records. Based on the clinical presentation at the time of CD diagnosis, a patient was categorized as presenting with classic (predominantly gastrointestinal symptoms), atypical (extra-intestinal symptoms), or silent (asymptomatic cases detected through screening) CD. The periods before and after diagnosis for control subjects were categorized according to the index CD case.

Statistical analysis

Results are reported as median and range, mean and 95% CI, or mean and standard error of the mean ± SE as appropriate for the data distribution. In the statistical analysis, the time period "before diagnosis" for both populations was defined as the period from a patient's date of birth to 1 year after the date of diagnosis of CD in the index case. Conversely, the time period "after diagnosis" was defined as the period between 1 year after the diagnosis and the time of study enrollment. We included the first year after diagnosis as part of the "before diagnosis" period to minimize the potential residual effect produced by a long-term disease and slow recovery on GFD. It has previously been observed that the risk of complications may be elevated in the immediate period before and after CD diagnosis[26]. Time at risk of fractures for patients and controls was defined as the period between birth (before diagnosis) or diagnosis of CD (after diagnosis) and the time (age) of the first fracture or the enrollment in the study, whichever came first. The rate of factures was compared between the CD and control cohorts.

Comparisons between cohorts were performed using Student's *t* test or Mann-Whitney test. Multivariate linear regression analyses were performed. Data were also reported as incidence rate (IR), which represents the number of events/1000 subject-years at risk, and as the excess number of events (IR of CD patients minus IR of controls). Cox regression analysis was conducted to estimate and compare the risk of fractures between cohorts. Results were reported as hazard ratio (HR) and 95% CI. Separate analysis of fractures was performed by the before/after CD diagnosis period and by sex. The risk of fractures before diagnosis was also analyzed by clinical presentation (classic CD *vs* atypical/silent forms). The HR was adjusted for potential confounders, including age, age at diagnosis, BMI, smoking, and gynecological and obstetric history. The effect of GFD treatment on fracture risk was analyzed by the degree of compliance with the GFD. Statistical significance was defined as 95% CI not including 1.0.

RESULTS

Study sample characteristics

Table 1 summarizes the demographic and clinical characteristics of the CD and control cohorts. The sex and age distributions were well matched between the cohorts. Most subjects were female (84%). Among the CD patients, the median age at CD diagnosis was 30 years, and 65% of the cases were diagnosed at ⩽ 16 years of age.

CD patients had significantly lower BMI at study enrollment compared with controls ($P < 0.001$). Female CD patients and controls were comparable in age at menarche or menopause. The overall assessment period was 9843 patient-years for the CD cohort and 20160 person-years for the control cohort.

Table 2 presents CD patients' clinical characteristics and fracture history according to gender. Female patients were on average older at study entry and at CD diagnosis than male patients ($P < 0.04$ and $P < 0.003$, respectively). Male CD patients had significantly higher BMI at the time of enrolment ($P < 0.05$) and a greater proportion of time at risk after diagnosis (61% *vs* 37%). According to our assessment of patient adherence to GFD, 85 (38%), 48 (22%) and 90 (40%) female patients and 19 (45%), 7 (17%) and 16 (38%) of male patients were deemed as poor, partial, and strict adherents, respectively.

Rates of fractures in CD patients and controls

Overall, CD patients reported a significantly higher rate of having experienced at least one fracture (23%) compared with controls (15%) (Table 1). Twenty-eight percent of the CD patients with a history of fractures had more than one fracture, compared with only 12% of controls ($P < 0.04$). The mean number of fractures was 1.46 per CD patient and 1.13 per control subject ($P < 0.0001$). Multiple fractures appeared to be limited to a subset of cases. Ten of the 11 control subjects with multiple fractures had two; however, 17 CD patients with multiple fractures reported up to four different fractures in the pe-

ripheral skeleton. Compared with controls, CD patients had a lower median age at the time of the first fracture ($P < 0.05$). Cole's fracture was the most common site in the peripheral skeleton for CD patients, as well as controls (54% *vs* 42%, respectively); possibly because most cases and controls were < 50 years old. One CD patient and no controls reported hip fracture. Finally, compared with controls, more CD patients with fractures reported that the event was caused by mild trauma (29% *vs* 44%, respectively, $P < 0.05$). No differences were observed between cohorts in terms of moderate and severe/sport-related traumas.

Among CD patients, the rate of fractures was higher in male (59%) than female (26%) population ($P < 0.0001$) (Table 2). Male patients had the first fracture at an earlier age than females ($P < 0.04$). Mild trauma was the most common cause of first fracture in women (48% of cases with at least one fracture *vs* 37% in men) and a severe/sports injury was more common in men (32% *vs* 9.5% in women).

Hazard ratios (HRs) were adjusted by age at enrollment, age at diagnosis, body mass index (BMI), smoking habits and menopause. CD: Celiac disease; IR: Incidence rate.

Risk of fractures before diagnosis

As shown in Table 3, the risk of fractures in the peripheral skeleton before the diagnosis of CD was higher in the CD than in the control cohort. Compared with controls, the excess number of fractures estimated in the CD cohort was 3.03 per 1000 patients/year. Although the excess of fractures (1.49 events) in female CD patients was marginally higher than in the matched female controls, the excess number of fractures was significantly higher

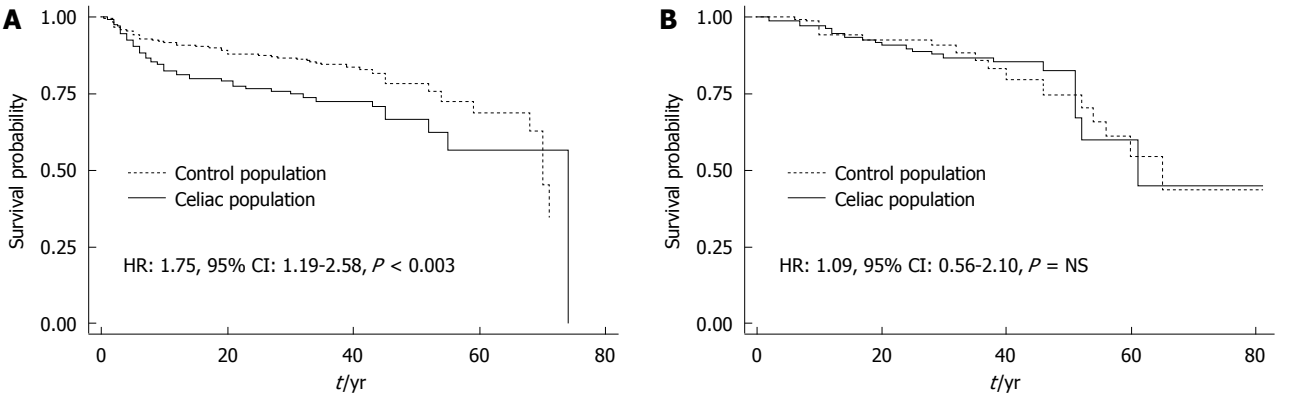

Figure 1 Kaplan-Meier curves of time to first fracture for patients according to clinical presentation in celiac disease patients and matched control population before the time of celiac disease diagnosis. A : Classic presentation celiac disease (CD) patients; B: Atypical/silent presentation CD patients. HR: Hazard ratio; NS: Not significant.

in male CD patients (19.15 events) than in male controls. The risk of fractures before diagnosis was linked to confounders such as age at study entry, age at CD diagnosis, smoking, menopause and BMI only in female patients (Table 3). However, none of these confounders individually modified the estimated risk above 10%. Among CD patients, fractures before CD diagnosis occurred at younger age in male than in female patients ($P < 0.04$) (Table 2).

Figure 1 depicts the survival curves of time to first fracture in CD patients by their clinical presentation at the time of CD diagnosis as compared with controls. The IR of fractures in the classic CD patients was almost twice that of their matched controls (10.14 *vs* 5.73 per 1000, respectively; HR 1.75, 95% CI: 1.19-2.58, $P < 0.003$). In contrast, the incidence of fractures in atypical/silent CD patients did not differ significantly from that of their matched controls (5.44 *vs* 5.84, respectively; HR: 1.09, 95% CI: 0.57-2.10, P = NS).

Risk of fractures after diagnosis and effect of GFD

Compared with the time period before diagnosis, the IR for the first peripheral fracture after CD diagnosis was comparable between the control and CD cohorts. After CD diagnosis, the IR of fractures for the CD cohort decreased from the pre-diagnosis period (-1.22 events per 1000 patients/year). Furthermore, compared with matched controls, all CD cases had an excess of fractures of 1.41 events (HR: 1.28, 95% CI: 0.74-2.21, P = NS) in the after-diagnosis period. Compared with the before-diagnosis period, female CD patients had a lower IR (-1.10 events) after diagnosis, and their risk of fractures was comparable to that of controls (excess of fractures in cases: 0.18 events) (P = NS) (Table 3). Male patients had a significant decrease in fractures from before to after CD diagnosis (-11.33 events/1000 patients per year). However, in the post-diagnosis period, male CD patients continued to have an excess number of fractures (8.19 events) compared with controls, which was not statistically significant (HR: 1.57, 95% CI: 0.57-4.26, P = NS). Female patients categorized as poorly adherent with the GFD (n = 90) had an IR very similar to the before-diagnosis IR (6.41 events/1000 patients per year). Although only one of 16 (7.2%) strictly adherent male patients had at least one fracture after diagnosis, seven of 19 (36.8%) poorly adherent male patients had a fracture. The small number of male patients prevented us from estimating their IR and fracture risk. Figure 2 shows the survival curve of time for first fracture for patients and matched control population before and after the diagnosis of CD according to gender.

DISCUSSION

Previous studies have demonstrated that CD patients have an increased risk of fractures in the peripheral skeleton. Whether this risk can be modified by a GFD is still unclear. Our seminal study has suggested that the prevalence of fractures decreases after initiation of a GFD[14]. However, this conclusion has been challenged by other studies[18,20,21,23]. Some authors have suggested that an early diagnosis and therapeutic intervention for CD before bone damage occurs is the only way to significantly lower the risk of fractures in CD patients.

The present study confirmed the increased risk of fractures overall among CD patients compared to controls with functional gastrointestinal disorders, and this increased risk was most prominent before their CD diagnosis. Additional supportive findings included the increased incidence of fractures produced by mild trauma events (for female cases) and a history of multiple fractures (up to four different events) seen in a subset of CD patients. The increased risk for female CD patients was more pronounced and statistically borderline when data were adjusted for potential confounders such as age at study entry, age at CD diagnosis, smoking, menopause, and BMI. Thus, older age, later diagnosis, cigarette smoking, and lower BMI were factors that contributed to the higher incidence of fractures in the peripheral skeleton. The effect of these confounders was not significant in male patients before CD diagnosis and in the overall patient cohort after CD diagnosis. Our study also con-

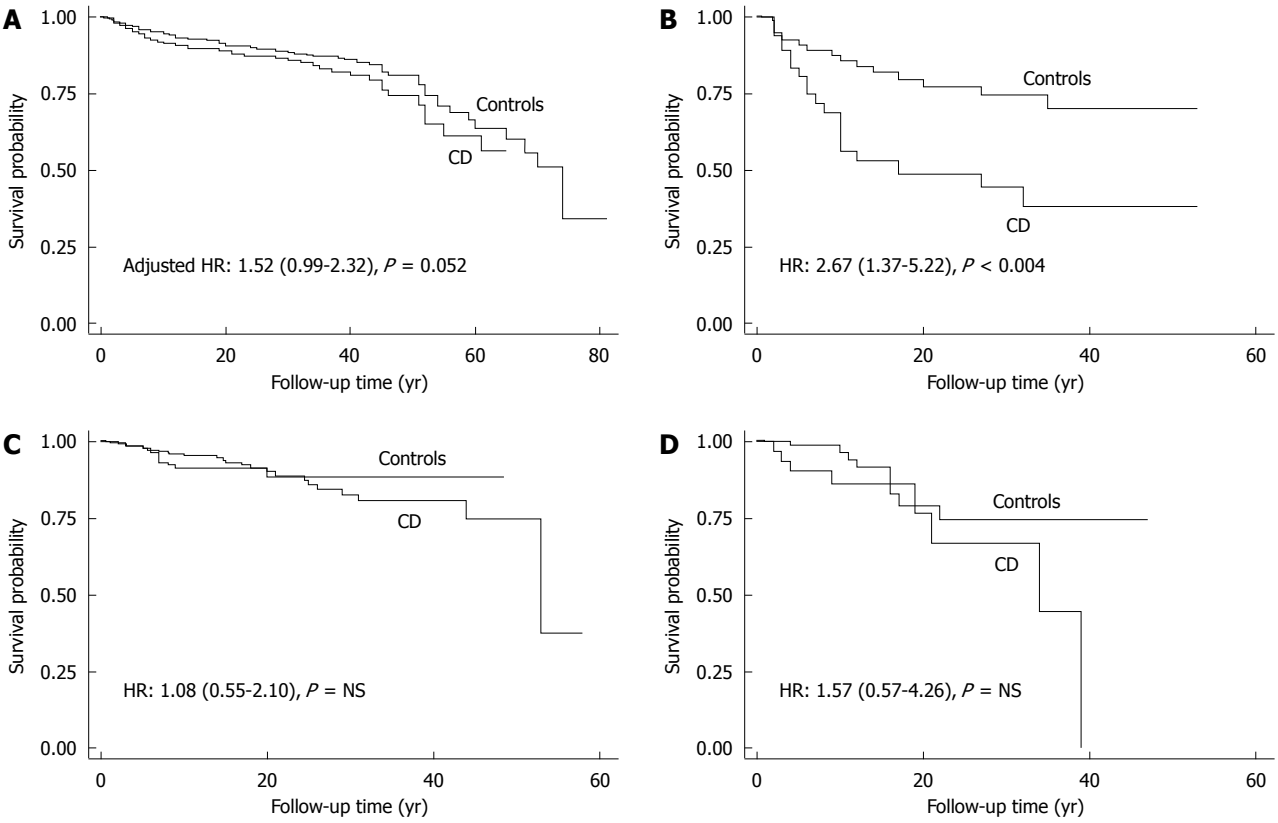

Figure 2 Kaplan-Meier curves showing time of first fracture according to gender in celiac disease population *versus* control group. A: Females before diagnosis; B: Males before diagnosis; C: Females after diagnosis; D: Males after diagnosis. CD: Celiac disease; HR: Hazard ratio; NS: Not significant.

firmed our previous observation that the increased risk of peripheral fractures before CD diagnosis was associated with the classic clinical presentation but not with atypical/silent forms.

Of note, the present study is believed to be the first to identify sex as a relevant risk factor for fracture risk in CD patients; especially before they are diagnosed. The fact that the IR in male controls was more than twice that in female controls indicates that males have a higher exposure to trauma, regardless of whether they have CD. Furthermore, the IR in male CD patients was more than fourfold higher than that in female CD patients, and almost threefold higher than that in matched male controls. In addition, male CD patients had their first fractures before diagnosis at a younger age than female CD patients. Our findings do not support the hypothesis that the increased IR in male CD patients is due to osteoporotic fractures (i.e. events caused by mild trauma).

Our present study also provides original evidence for the profound impact of treatment with GFD on the risk of fractures in the peripheral skeleton. The improvement in bone health was seen in both sexes. These findings are in line with previous evidence that has shown that gluten restriction can reverse the systemic and local physiological mechanisms in bone deterioration of CD patients[3,11-13,27]. Although normalization of bone mass is unlikely in adult CD patients, significant re-mineralization of axial and peripheral skeleton has been shown in several studies[3,6,10-13]. It should be noted that reducing the risk of fracture does not solely depend on increasing bone mass and mineral density[27-32]. Other risk factors, such as structural alteration of bones with impairment of the mechanical quality (stiffness of cortical bones), deterioration of protective factors from trauma (body mass, fat and muscle compartments), and neuromuscular dysfunction, also contribute to bone weakness in CD patients[28,30]. In this context, improving body mass and fat/muscle composition, nutritional status, and bone architecture through long-term GFD treatment may reduce the overall risk of fractures in CD patients. Our study provides further support to the clinical benefits of GFD. Although the conclusion is limited by sample size, our data suggest that greater adherence to a GFD may be beneficial in male as well as female patients.

The sex differences observed in the risk of fractures in CD patients have not been reported before and deserve further comment. A previous study on bone structure and strength in CD patients detected some sex differences in mineral and bone metabolism, localization of bone damage (predominantly cortical/subcortical bone mass of the radius), mechanical quality of bones, and changes induced by 1-year treatment with a GFD[27], which may be related to differences in the development of the male and female mammalian skeleton. At 1-year follow-up, gluten-free treatment appeared to correct only the metabolically induced disturbances, which were predominant in women. However, the current results suggest that long-term adherence to a GFD may significantly reduce fracture risk in male patients as well.

Although intriguing, the current study results were limited by a relatively small number of male patients; larger studies are needed to confirm these findings. Another limitation was that fractures were based on self-report and may have been subject to recall errors; however, the risk of failed recall is expected to be similar between patients and controls. Misclassification of the type of trauma may have biased the results toward a positive association between bone disorders and osteoporotic fractures in CD patients. However, this association is well-established in female patients and not corroborated in male patients; therefore, the conclusions are not likely to have been altered. The assessment of GFD adherence is difficult, particularly in retrospective analyses. Our assessment relied on patients' self-reports and detailed interviews conducted by expert physicians, and was characterized by an independent researcher unaware of other clinical information.

In conclusion, this cohort study confirms the increased risk of fractures in the peripheral skeleton in undiagnosed CD patients and an association of bone damage with the classic, but not the atypical/silent clinical presentation of CD. In addition, this study is believed to be the first to demonstrate a higher excess risk of fracture in male patients compared with female patients before CD diagnosis. Sex differences in the pathogenesis of bone weakness should be further explored. Finally, the study is also believed to be the first to recognize a beneficial effect of a GFD in reversing the elevated risk of fractures, and patients who adhere to long-term GFD can achieve a similar risk of fracture to those without CD, which provides a further argument for strict adherence to the diet to prevent complications of CD.

COMMENTS

Background

Reduced bone health is seen in > 50% of celiac disease (CD) patients at the time of diagnosis. Very few studies have evaluated the risk of fractures in CD patients. A recent systematic review and meta-analysis of eight studies, published between 2000 and 2007, concluded that CD patients had a 43% higher risk of fractures compared with people without the disorder.

Research frontiers

Although several studies have shown a positive effect of a gluten-free diet (GFD) on bone density and other bone-protective factors, the impact of treatment on the risk of fractures remains controversial. Some studies have suggested that the risk of fractures detected before diagnosis of CD remains elevated several years after diagnosis. In this study, the authors explored the incidence of fractures in the peripheral skeleton of CD patients before diagnosis and the effect of CD treatment on fracture risk.

Innovations and breakthroughs

This study confirms that, before diagnosis, CD patients have a significantly higher rate of fractures in the peripheral skeleton compared with controls with functional gastrointestinal disorders. In addition, the risk is associated with the classic presentation of CD (predominantly gastrointestinal symptoms). This study is believed to be the first to demonstrate that the increased incidence of fractures in CD patients is associated with male sex and that, with treatment GFD, the fracture risk becomes comparable to controls.

Applications

The study further supports the importance of adherence to a GFD to reduce the risk of bone complications in CD patients.

Peer review

The paper provides relevant and novel information, but some issues deserve discussion. I would strongly suggest to engage in a much more in depth discussion and speculation on their opposite findings in CD patients.

Abstract

AIM: To quantitatively investigate the effect of p16 hypermethylation on hepatocellular carcinoma (HCC) and hepatocirrhosis using a meta-analysis of available case-control studies.

METHODS: Previous studies have primarily evaluated the incidence of p16 hypermethylation in HCC and corresponding control groups, and compared the incidence of p16 hypermethylation in tumor tissues, pericancer liver tissues, normal liver tissues and non-tumor liver tissues with that in other diseases. Data regarding publication information, study characteristics, and incidence of p16 hypermethylation in both groups were collected from these studies and summarized.

RESULTS: Fifteen studies, including 744 cases of HCC and 645 non-tumor cases, were identified for meta-analysis. Statistically significant odds ratios (ORs) of p16 hypermethylation were obtained from tumor tissues and non-tumorous liver tissues of HCC patients (OR 7.04, 95% CI: 3.87%-12.78%, $P < 0.0001$), tumor tissues of HCC patients and healthy liver tissues of patients with other diseases (OR 12.17, 95% CI: 6.64%-22.31%, $P < 0.0001$), tumor tissues of HCC patients and liver tissues of patients with non-tumorous liver diseases (OR 6.82, 95% CI: 4.31%-10.79%, $P < 0.0001$), and cirrhotic liver tissues and non-cirrhotic liver tissues (OR 4.96, 95% CI: 1.45%-16.96%, $P = 0.01$). The pooled analysis showed significantly increased ORs of p16 hypermethylation (OR 6.98, 95% CI: 4.64%-10.49%, $P < 0.001$) from HCC tissues and cirrhotic tissues.

CONCLUSION: P16 hypermethylation induces the inactivation of p16 gene, plays an important role in hepatocarcinogenesis, and is associated with an increased risk of HCC and liver cirrhosis.

Key words: P16 hypermethylation; Hepatocellular carcinoma; Liver cirrhosis; Meta-analysis; Odds ratio

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major

causes of cancer death worldwide[1]. The HCC incidence is still increasing in developed countries although considerable progress has been made in diagnostic and therapeutic modalities[2]. The molecular genetics of HCC have recently been extensively characterized[3]. Among these molecular genetics, aberrant DNA cytosine methylation is one of the most consistent epigenetic changes in human cancers. Generally, the overall DNA methylation level is lower in cancer cells than in normal cells. However, some loci tend to show increased DNA methylation in cancer cells[4].

The *p16INK4A* gene is located on chromosome 9p21 and is one of the most frequently altered genes observed in various human neoplasms[4,5]. It is a cell cycle-related gene encoding a p16 protein that binds competitively to cyclin-dependent kinase 4 protein (Cdk4), thereby inhibiting the interaction of Cdk4 and cyclin D1 to stimulate passage through the G1 phase of the cell cycle[6]. The disruption of p16-mediated cell cycle control seems to play a role in hepatocarcinogenesis because inactivation of the *p16INK4A* gene resulting from methylation of the p16INK4A gene, has been reported in HCC[7].

Although previous reports indicated that inactivation of the *p16INK4A* gene is mainly induced by the methylation of the p16 gene, and it is one of the important genetic alterations in HCCs, the reported rates of p16 methylation in HCCs were remarkably diverse. Moreover, whether it is associated with the incidence of hepatocirrhosis is still unclear. The various results of these studies underpin the need for assessing the evidence of the relationship between p16 inactivation and HCC. Hence, we conducted a systematic review and meta-analysis to quantitatively evaluate the effects of p16 hypermethylation on the incidence of HCC.

MATERIALS AND METHODS

The meta-analysis was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses[8] and the recommendations of the Cochrane Collaboration[9].

Data source and search

To avoid publication bias, both published and unpublished studies, with an English or Chinese language restriction, were included, and several methods were used to identify all relevant studies. The databases screened were PubMed (1976 onward), EMBASE (1966 onward), Cochrane Library (no date restriction), Biological Abstracts (no date restriction), Science Citation Index (no date restriction), China National Knowledge Infrastructure (no date restriction), and the Chinese BioMedical Literature Database (no date restriction). Medical Subject Headings were used in the searching in both Chinese and English languages. The keywords used were p16 methylation, HCC and hepatocirrhosis. Relevant reviews and meta-analysis of the role of p16 methylation in the incidence of HCC and hepatocirrhosis were examined for potential inclusive studies. We also searched http://www.jamas.gr.jp and http://www.cdc.gov websites for studies completed but not yet published.

Study selection

The following studies were included in this meta-analysis: studies primarily evaluating the incidence of p16 hypermethylation in HCC and corresponding control groups, and comparing the incidence of p16 hypermethylation in tumor tissues, pericancer liver tissues, normal liver tissues, and non-tumor liver tissues with other identified diseases. The bibliographies of the search results were manually scanned and independently reviewed by two authors (Xie F and Zang JJ) to identify relevant studies that met the inclusion criteria (full text or abstract). If there was any disagreement between the two authors, it was settled by discussion with a third author (He J) until a consensus was reached. One author (Xu JF) contacted the authors of the article for missing data if necessary.

Data extraction

Data extraction was independently conducted by two reviewers (Xu JF and Qin YY) using a standardized approach. Data for publication information (year of publication and name of first author), study characteristics (sample size and distributions of age and sex), and rates of p16 hypermethylation were collected using standard data extraction forms. Point estimates for selected variables were extracted and checked by the other two reviewers (Xie F and Qin YY). Disagreement was adjudicated by a third reviewer (He J) after referring back to original articles.

Statistical analysis

Odds ratios (ORs) were used as a measure of the relationship between p16 hypermethylation and the risk of HCC for case-control studies and the corresponding 95% CIs. The pooled ORs were combined by the Mantel-Haenszel methods. When there were trials with no events in one or both arms, the Peto method was used[6,10].

An OR > 1 indicated a higher incidence of p16 methylation in HCC tissues than in corresponding controls. The percentage of variability across studies attributable to heterogeneity beyond chance was assessed by χ^2 test ($P < 0.1$) and I^2 statistics[11]. When there was no statistically significant heterogeneity, a pooled effect was calculated with a fixed-effects model; otherwise, a random-effects model was employed. We also assessed the probability of publication bias with funnel plots[12] and Egger's test[13]. A P value of less than 0.1 indicated statistically significant publication bias. In addition, we conducted a sensitivity analysis to evaluate whether the results were statistically affected. Statistical significance was defined as a two-tailed P value of 0.05. All statistical analyses were conducted with RevMan version 5 from the Cochrane Collaboration.

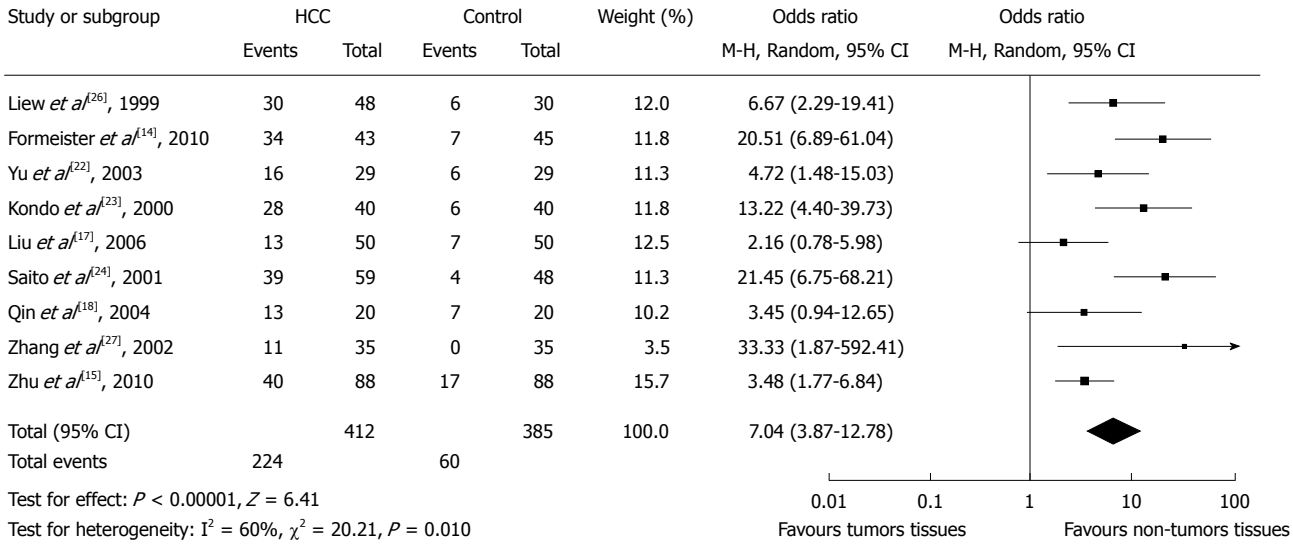

Figure 1 Pooled analysis of p16 hypermethylation in tumorous liver tissues and non-tumorous liver tissues of hepatocellular carcinoma patients. HCC: Hepatocellular carcinoma.

to the aforementioned search strategies and provided data regarding p16 hypermethylation in 744 cases of HCC tumor tissues and 645 cases of non-tumor tissues. Hypermethylation profile of tumorous and paired non-tumorous liver tissue samples from nine studies, HCC tumor tissues and normal tissues (normal liver tissues or blood samples) from five studies, and HCC tumor tissues and abnormal and non-tumorous tissues (dysplastic nodule, liver cirrhosis, and chronic hepatitis) from four studies was compared, respectively. Twelve eligible trials were conducted in Asia from 1999 to 2010, and the other three were conducted in the United States and Germany. Three of them were published in Chinese, and the others were published in English. The median sample size was 79 patients (range, 22-176). The median age of the study participants ranged from 48.5 to 66.2 years. All of the specimens in the 15 studies were surgically obtained from HCC patients or non-HCC patients who underwent liver surgery. The characteristics of the included studies are shown in Table 1.

P16 hypermethylation in tumorous liver tissues and non-tumorous liver tissues of HCC patients

Data for this comparison were available in nine studies which included 412 and specimens of HCC tissues and 385 non-tumorous pericancer tissues. Overall, 224 (54.5%) and 60 (15.6%) cases of p16 hypermethylation were observed in tumorous and non-tumorous tissues of HCC patients, respectively. The pooled analysis showed significantly increased ORs of HCC for p16 hypermethylation compared with controls (OR 7.04, 95% CI: 3.87%-12.78%, $P < 0.0001$). There was, however, evidence of heterogeneity across the studies (P for heterogeneity = 0.01, $I^2 = 60\%$, Figure 1). The heterogeneity

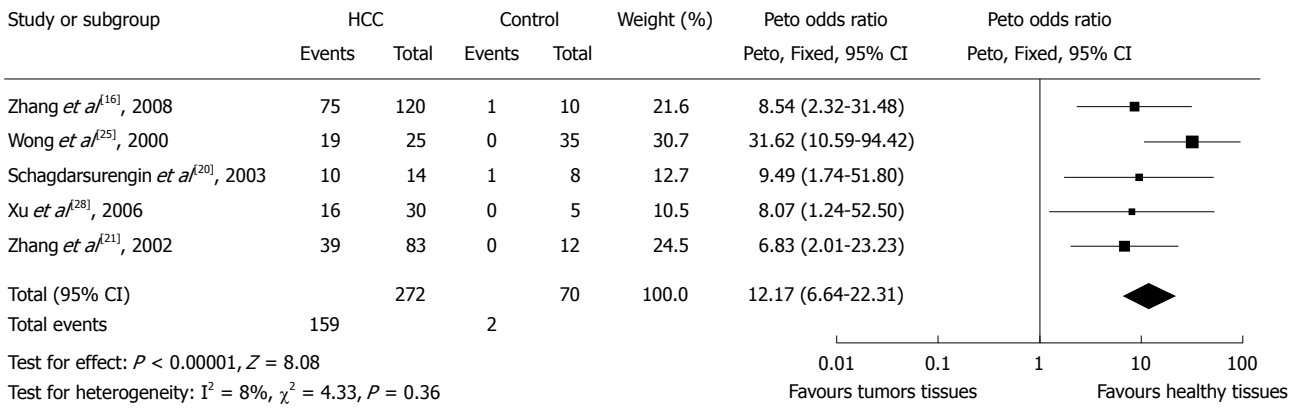

Figure 2 Pooled analysis of p16 hypermethylation in tumorous liver tissues of hepatocellular carcinoma patients and healthy liver tissues of patients with other diseases. HCC: Hepatocellular carcinoma.

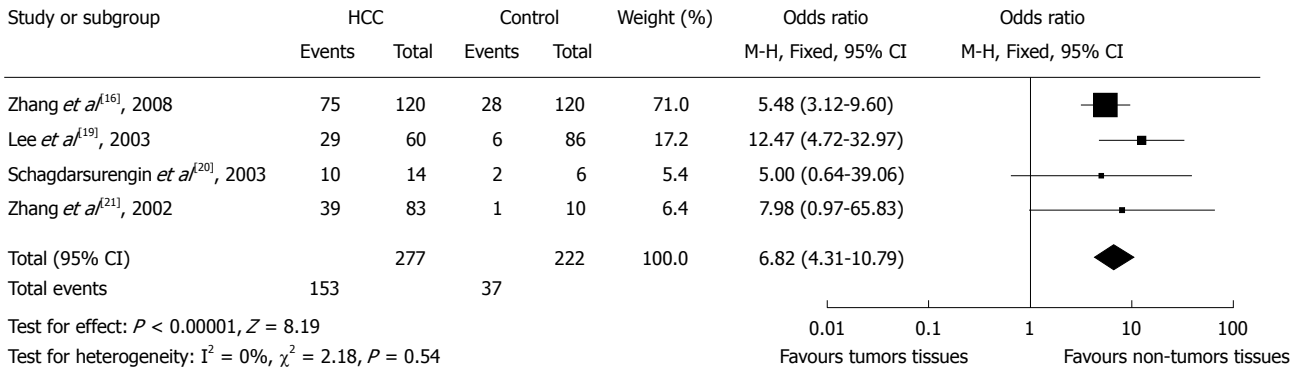

Figure 3 Pooled analysis of p16 hypermethylation in tumorous liver tissues of hepatocellular carcinoma patients and liver tissues of patients with non-tumorous liver diseases. HCC: Hepatocellular carcinoma.

was incorporated into the random-effects model. Funnel plots did not show any evidence of publication bias.

P16 hypermethylation in tumorous liver tissues of HCC patients and healthy liver tissues of patients with other diseases

Five studies calculated the OR of p16 hypermethylation in HCC patients and non-HCC healthy patients (Figure 2). There were 159 cases of methylated p16 genes among 272 (58.5%) HCC patients and 2 in 70 (2.9%) non-HCC patients, indicating an OR for p16 hypermethylation of 12.17 (95% CI: 6.64%-22.31%, $P < 0.0001$). There was no evidence of heterogeneity across the studies (P for heterogeneity = 0.36; $I^2 = 8\%$). Funnel plots did not show any evidence of publication bias.

P16 hypermethylation in tumorous liver tissues of HCC patients and liver tissues of patients with non-tumorous liver diseases

Four studies calculated the OR of p16 hypermethylation in liver tissues of HCC patients and those of patients with liver diseases (Figure 3). There were 153 cases of hypermethylated p16 genes in 277 (55.2%) HCC patients and 37 in 222 patients (16.7%) with liver diseases, indicating an OR for p16 hypermethylation of 6.82 (95% CI: 4.31%-10.79%, $P < 0.0001$). There was no evidence of heterogeneity across the studies (P for heterogeneity = 0.54; $I^2 = 0\%$). There was no evidence of publication bias in the funnel plots.

Among these studies, data on the comparison of p16 hypermethylation in HCC tissues and cirrhotic tissues were also extracted. Overall, 133 (60.7%) and 30 (15.9%) cases of p16 hypermethylation were observed in 219 HCC tissues and 189 cirrhotic tissues, respectively. The pooled analysis showed significantly increased OR (6.98, 95% CI: 4.64%-10.49%, $P < 0.001$, data not shown).

P16 hypermethylation in cirrhotic liver tissue and non-cirrhotic liver tissue

Five studies did this comparison, which included 185 specimens of cirrhotic tissues and 87 specimens of non-cirrhotic tissues. Overall, 42 (22.7%) and 8 (9.2%) cases of p16 hypermethylation were observed in cirrhotic tissues and non-cirrhotic tissues, respectively. The pooled analysis showed significantly increased OR of liver cirrhosis for p16 hypermethylation compared with matched controls (OR 4.96, 95% CI: 1.45%-16.96%, $P = 0.01$, Figure 4). There was no evidence of heterogeneity across the studies (P for heterogeneity = 0.74; $I^2 = 0\%$). There was no evidence of publication bias in the funnel plots.

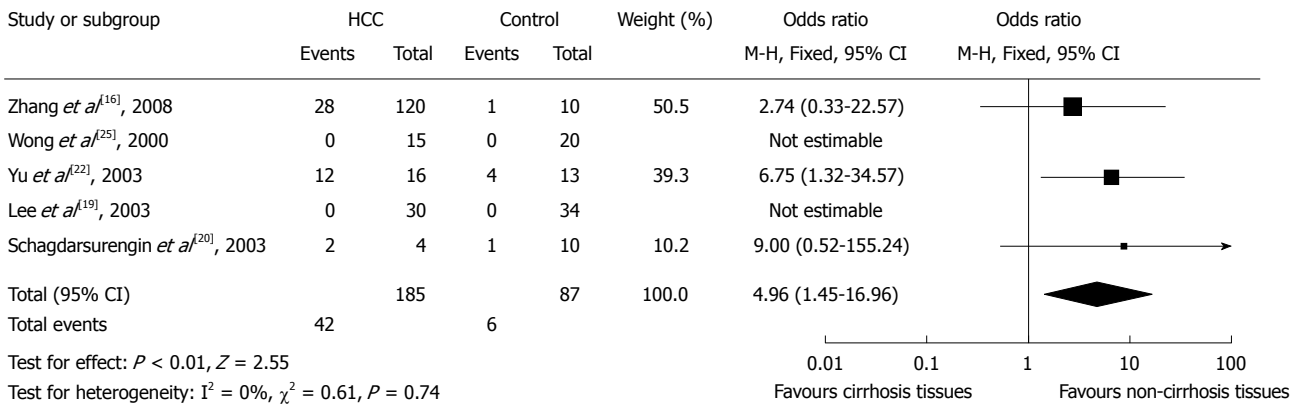

Figure 4 Pooled analysis of p16 hypermethylation in cirrhotic liver tissues and non-cirrhotic liver tissues. HCC: Hepatocellular carcinoma.

DISCUSSION

Gene-specific promoter alterations are common epigenetic aberrations found in human liver tumors; however, the epigenetic changes of p16 gene hypermethylation specific to the underlying disease etiology remains elusive. Based on 15 studies and a total of 744 cases of HCC tumor tissues and 645 cases of non-tumor tissues, this pooled analysis comprehensively assessed the relationship between p16 gene hypermethylation and the incidence of HCC or liver cirrhosis. Using the pooled crude ORs from the included studies, we found that p16 gene hypermethylation was associated with 6.16-, 12.17-, and 6.82-fold increased risks of HCC compared with non-tumorous tissues of HCC patients, healthy liver tissues of patients with other diseases, and liver tissues of patients with non-tumorous liver diseases, respectively. Moreover, a 4.96-fold increased risk of liver cirrhosis was also found when compared with non-cirrhotic tissues.

The relationship between p16 gene hypermethylation and the incidence of HCC has been verified by other studies that assessed p16 mRNA expression and its promoter CpG island methylation. Kaneto *et al*[29], using methylation-specific PCR and immunohistochemistry, detected methylation of the p16 promoter in HCC (72.6%, 16/22) and loss of expression in all methylation-positive HCCs. Roncalli *et al*[30] reported that methylation of the p16 promoter with complete loss of immunoreactivity occurred in 27 of 33 HCCs (82%). Our results, which were consistent with those of other reports, suggested that p16 gene methylation might play an important role in hepatocarcinogenesis and it might be the major mechanism of *p16* gene inactivation.

This review quantitatively assessed the relationship of p16 gene methylation between HCC tissues and non-HCC tissues using well-designed case control studies. To our knowledge, this has not been presented in other meta-analyses or reviews[31-33]. Consistent results were shown in sensitivity analyses, and no evidence of publication bias was found.

This study has several potential limitations. First, the possibility of information and selection biases and unidentified confounders cannot be completely excluded because all of the included studies were observational. Second, the searching strategy was restricted to articles published in English or Chinese. Articles with potentially high-quality data that were published in other languages were not included because of anticipated difficulties in obtaining accurate medical translation. Third, most studies included in this meta-analysis were conducted in Eastern Asia, where HCC more frequently occurs. Fourth, comparisons of p16 hypermethylation in cirrhotic non-tumorous liver tissues and normal tissues, chronic hepatitis tissues, or non-cirrhotic HCC tissues were involved in five of the included studies. However, there was no distinction between cirrhotic liver tissues with or without HCC. Thus, we could not perform comparisons under these circumstances. Hence, cautions should be taken when our findings are interpretated among the general populations.

In conclusion, we found that p16 hypermethylation was associated with an increased risk of HCC and liver cirrhosis. P16 hypermethylation, which induced the inactivation of the p16 gene, plays an important role in hepatocarcinogenesis.

COMMENTS

Background

The inactivation of the *p16INK4A* gene is one of the important genetic alterations in hepatocellular carcinoma (HCC), which is mainly induced by the hypermethylation of *p16* gene. However, the role of p16 hypermethylation in HCC or hepatocirrhosis is unclear. Hence, the authors performed a systematic review and meta-analysis to quantitatively evaluate the effects of p16 hypermethylation in the incidence of HCC and hepatocirrhosis.

Research frontiers

Inconsistent results have been reported on the effect of p16 hypermethylation on HCC or hepatocirrhosis and its corresponding controls, and the incidence of p16 hypermethylation.

Innovations and breakthroughs

This is the first systematic review and meta-analysis to investigate quantitatively the effect of p16 hypermethylation in HCC or hepatocirrhosis.

Applications

P16 hypermethylation induces the inactivation of *p16* gene and plays an important role in hepatocarcinogenesis, and it is associated with an increased risk of HCC and liver cirrhosis. Detection of p16 hypermethylation using a methylation-specific PCR is favorable for the differential diagnosis of HCC from liver cirrhosis.

Peer review

The authors aimed to quantitatively evaluate the effects of p16 hypermethyl-

ation on the incidence of HCC and hepatocirrhosis by systematic review and meta-analysis. The authors found that p16 hypermethylation was associated with an increased risk of HCC and liver cirrhosis. The article is well organized. The methods utilized were appropriate and they presented convincing evidence.

Abstract

AIM: To review safety, efficacy, and proper nursing care of double-balloon enteroscopy (DBE) in pediatric patients with small intestinal disease.

METHODS: Our study included 37 patients with abdominal pain, diarrhea, passage of blood in the stools, and other symptoms, who underwent DBE from December 2006 to July 2010. DBE was retrograde in 36 procedures, antegrade in six, and from both ends in five. The diagnostic significance and salient points in nursing care are discussed in this article.

RESULTS: At least one lesion was discovered in 28 out of 37 patients, which yielded a positive diagnosis in 75.7% of cases. Good bowel preparation and skilled nursing care not only shortened the procedure time, but could also alleviate patient discomfort and enhance the quality of examination. No serious procedure-related complications were observed in any cases.

CONCLUSION: DBE is a new modality of endoscopic procedure that improves the standard of diagnosis and treatment of small bowel diseases in children. Good nursing care is essential to the successful execution of the procedure.

Key words: Children; Double-balloon enteroscopy; Nursing care; Small intestinal disease

INTRODUCTION

Small intestinal diseases are not rare in children, but limitations in investigative approaches affect our understanding of pediatric small bowel disorders. The small intestine is deep-seated, up to 6 m long in adults, and has many turns and convolutions, which makes direct visualization through the traditional means of upper and lower gastrointestinal endoscopic procedures difficult. Sonde or push enteroscopes can examine the small intestine only up to 80-100 cm beyond the ligament of Treitz, thus, a full endoscopic examination of the small bowel has always been difficult.

Double-balloon enteroscopy (DBE) provides a significant advance in diagnosis and management of small intestinal diseases[1-5]. It also poses a challenge to the nursing profession. Nurses are responsible for assisting the endoscopist with completing the examination, minimizing the suffering of patients undergoing the procedure, and preventing the occurrence of complications during and after the examination. Our hospital acquired DBE equipment in 2006 and has achieved satisfactory results in its

application. Here, we report our experience using DBE in the management of small intestinal diseases, with an emphasis on indications and special aspects of nursing care.

MATERIALS AND METHODS

Ethics

This study was approved by the Institutional Ethics Committee of the Children's Hospital of Fudan University, Shanghai, China and informed consent was obtained from all patients and their parents.

Clinical data

During December 2006 to July 2010, we had 37 patients who underwent DBE, with 26 boys and 11 girls. Patient age ranged from 4 to 16 years, specifically: 4-8 years old, nine patients; 8-12 years old, nine patients; and 12-16 years old, 19 patients. Retrograde DBE was performed in 36 cases, antegrade DBE in six, and DBE from both ends in five. Demographic characteristics of the 37 children who underwent DBE examination are in Table 1. Procedures indicated included (Table 2): occult gastrointestinal bleeding, recurrent abdominal pain, chronic diarrhea, and hypoproteinemia. All patients underwent traditional investigations that included gastroscopy, colonoscopy, abdominal computer tomography (CT) or magnetic resonance imaging (MRI), and radioisotope scan for Meckel's diverticulum if symptom cause could not be identified.

Table 1 Demographic characteristics of 37 children who underwent double-balloon enteroscopy

Age group (yr)	*n*	Mean age (yr)	Male/female	Antegrade/retrograde/both
4.0-8.0	9	5.6	3/6	0/8/1
8.1-12.0	9	10.4	3/6	1/6/2
12.1-16.0	19	13.9	5/14	0/17/2

Table 2 Preliminary indication for double-balloon enteroscopy in 37 children

Preliminary indication	*n*
Occult gastrointestinal bleeding	12
Recurrent abdominal pain	10
Chronic diarrhea	13
Other	2

Methods of examination

DBE can be administered through the mouth (antegrade), or through the anus (retrograde). The route of insertion is determined by the clinical features and results of other ancillary examinations including CT/MRI scans, angiography, barium examination of the small bowel, and radioisotope scanning. The procedure is usually conducted in a fully equipped operating room with full anesthetic capabilities, with the anesthesiologist administering general anesthesia *via* an endotracheal tube. The lower ileum can usually be reached in the transoral, antegrade approach, whereas the upper jejunum can be reached *via* the transanal, retrograde approach. Sequential application of the antegrade and retrograde examinations can achieve full examination of the small intestine.

Pre-procedure nursing care

Psychological care: Psychological preparation of an adult patient undergoing DBE is very important. If patients are poorly prepared, an unsuccessful examination may result. For the pediatric patient, psychological preparation is equally or more important. Most of our patients undergoing DBE suffered from illnesses of long duration and had received gastroscopy, colonoscopy, and many other investigations without a definitive diagnosis. Moreover, because DBE requires a long procedural time, and most patients and parents demonstrated anxiety, a preprocedural routine that carefully detailed the aspects of the examination to the parents as well as patients was imperative. The aim, method, significance, and other details of the procedure were carefully explained, to gain confidence and cooperation before the examination.

Dietary and bowel preparation: We recommended a restrictive diet for the patients prior to the procedure. Two days before the examination, they were instructed to consume a low-residue, semi-liquid diet. A light laxative such as senna or lactulose was administered with adequate fluid. On the day of examination we usually gave, in addition to the laxative, an enema of 500-1000 mL of warm saline until clear fluid passed.

Others: Six hours before the procedure we carefully enquired if the patient had any contraindications. Any serious cardiological or pulmonary disorder and significant gastrointestinal blood loss was noted and evaluated for suitability to undergo the procedure. We routinely checked the liver and renal function, electrocardiogram, complete blood count and clotting factors preoperatively. Venous access, cardiac monitoring, oxygen saturation monitoring, and other routine monitoring procedures were set up for the anesthesiologist. Other facilities such as suction tubes, suction pump, oxygen supply, Ambu bag, and instruments and medications for resuscitation were also routinely checked to ensure patient safety.

Nursing care during the procedure

The double balloon endoscope is different from regular gastroscopy or colonoscopy, and is much longer and softer. The small intestine is long and convoluted, and situated deeper in the abdomen; hence, manipulation of the endoscope is difficult. The assistance of nursing personnel during the procedure is very important. Before the procedure, a small amount of water was added into the space between the overtube and the endoscope, as a lubricant to facilitate the pushing and pulling of the scope. K-Y Jelly (Johnson and Johnson Co.) was routinely used as a lubricant to reduce the friction between the mucosa and the endoscope. For antegrade DBE, the initial part of

the insertion of the endoscope was similar to that for routine gastroscopy. The endoscope was first introduced into the duodenum as far as the third part of the duodenum. Then, the balloon tip was inflated to anchor the tip of the endoscope at this part of the intestine. The overtube was slid to the most anterior position and the balloon inflated, anchoring it firmly to this part of the duodenum. The balloon at the tip of the endoscope was deflated and gradually inserted further into the small intestine beyond the ligament of Treitz. The balloon tip was again inflated and the overtube balloon was deflated. The overtube was slid to the anterior position and the entire endoscope, together with the overtube, was pulled out to shorten the inserted length, and pleated the small intestine onto the shaft of the endoscope. The entire procedure was repeated several times to increase the depth of insertion. For retrograde insertion, the endoscope was inserted into the anus, rectum, and sigmoid colon as in a regular colonoscopy examination. The balloons were inflated and deflated as previously described to facilitate the advance of the endoscope to the cecum. The overtube balloon was inflated to anchor it securely at the cecum, and the tip of the endoscope with its deflated balloon was inserted into the ileocecal valve. The endoscope was manipulated to have a safe length inside the ileum, and the balloon tip inflated. The overtube balloon was deflated and the overtube was slid carefully to the anterior position through the ileocecal valve. The overtube balloon was inflated again to allow secure anchoring at the terminal ileum. The endoscope balloon was deflated and the tip of the endoscope gradually advanced deeper into the small intestine. The process of inflation and deflation of the balloons and advancing of the endoscope were repeated to achieve deeper insertion of the endoscope into the small intestine, until it could go no further or the suspected lesion was reached.

During the procedure, nursing assistance was needed for maintaining the endoscope and overtube at the proper position during various phases of the procedure, and for inserting the overtube to the 1.55-m mark on the surface of the endoscope. When a pathological lesion was detected during the procedure, the endoscopic nurse assisted in obtaining biopsies, injection of dye, removal of polyps *via* diathermy snare, and other tasks. The procedure usually took more time than regular gastroscopy or colonoscopy, hence, the period of anesthesia was also longer. Patient vital signs were carefully monitored, and the condition of the abdomen closely observed. Excessive inflation of air can cause gross distension of the abdomen; in this case, the operator must be alerted and air removed from the intestinal lumen. In this series, we did not encounter any perforation or major bleeding after the procedure.

Post-procedural nursing care

After the examination, vital signs were closely monitored in the recovery room until the patient was fully conscious. For patients undergoing antegrade examination, the head was turned towards one side, and any secretion or vomit was cleared from the oral cavity and pharynx to prevent aspiration. When fully conscious, patients may complain of a slight headache or sore throat. This was thoroughly explained to patients and parents. The long procedure time and repeated insertion and withdrawal of the overtube can result in frictional injury to the pharynx that usually does not require special treatment. Management was usually supportive, including rinsing the mouth with chilled saline, which can be effective in soothing the oral and pharyngeal mucosa and reducing discomfort. For patients who underwent retrograde DBE, rectal bleeding can be a complication and was watched for; nursing care to the anus was also performed. The patients were usually kept nil by mouth for 6 h after the procedures until they were fully conscious. Feeding was initiated with a fluid diet, and after eating, patients were monitored for nausea, vomiting, and abdominal pain. Changes in level of consciousness, stool characteristics, and other symptoms were closely observed. Any deterioration was reported to the doctors responsible for the patient. The small intestine is very long, so after the procedure, gas tends to be retained in the intestine, which results in distension. Patients were encouraged to pass gas through the anus or by burping, and early ambulation also enhanced the passage of gas from the system.

Table 3 Endoscopic findings and diagnoses from double-balloon enteroscopy in 37 patients

Endoscopic findings or diagnoses	Cases (%)
Inflammatory bowel disease	13 (35.1)
Meckel's diverticulum	5 (13.5)
Ulcerations or erosions	4 (10.8)
Non-specific ileitis	2 (5.4)
Jejunal polyp	1 (2.7)
Amebiasis	1 (2.7)
Anaphylactoid purpura	1 (2.7)
Congenital small intestinal lymphangiectasia	1 (2.7)
Overall positive rate	28/37 (75.5)

Equipment cleansing and sterilizing after use

After the procedure, the enteroscope was immediately cleaned as a preliminary procedure, and then fully treated in the endoscope treatment room with water, enzyme, antiseptic and finally rinsing with 75% ethyl alcohol and water. The enteroscope was dried with air current and hung in the endoscope cabinet for future use.

RESULTS

Among the 37 cases, lesions were detected in 28 (75.5%) (Table 3). Lesions were mainly inflammatory bowel disease, Meckel's diverticulum, jejunal polyp, anaphylactoid purpura, and congenital small intestinal lymphangiectasia. Of 10 cases that were investigated for abdominal pain, no mucosal abnormality in the small intestine was detected in seven (positive rate of 30%), and these were probably cases of functional disorders that resulted in abdominal pain. In 10 of 12 patients with occult gastro-

intestinal bleeding, the bleeding source was found (positive rate of 83.3%). The positive rate for patients with suspected intestinal bleeding was higher than for patients with abdominal pain.

In all procedures, patients who underwent examinations had no complications during or after DBE, and the average procedure time was 101 ± 53.0 min (antegrade: 91 min; retrograde: 104 min).

DISCUSSION

Yamamoto *et al*[1], and May have been pioneers in applying DBE for clinical use. They generally regard DBE as a safe procedure and the appearance of bleeding or perforation are rare complications. Recent reports have confirmed the safety of DBE in pediatric patients[6,7]. A majority of patients may develop abdominal distension, mild abdominal pain or sore throat, but these symptoms are mostly self-limiting and resolve spontaneously without any specific treatment. In this study, no major complication resulted after the procedure, which confirmed that DBE is a relatively safe procedure in the pediatric age group.

In our series of 37 patients who underwent a total of 42 DBE procedures, the positive rate was 75.5%, and the preliminary indication for DBE examination was occult gastrointestinal bleeding. In 12 patients with intestinal hemorrhage, five were diagnosed with Meckel's diverticulum, and in these, conventional diagnostic methods including ^{99m}Tc scaning, did not yield a definitive diagnosis. Meckel's diverticulum is usually located 50-100 cm from the ileocecal valve, therefore, it is out of the range of conventional endoscopic procedures. If Meckel's diverticulum is highly suspected, but ^{99m}Tc scanning is negative, DBE examination may be considered. In the present study, the positive rate for patients with suspected intestinal bleeding was higher than for patients with abdominal pain.

In our study, 15 patients underwent DBE examination for suspected Crohn's disease, and diagnosis was confirmed in 13. Characteristic changes were found in all 13 patients, such as aphthous ulcers, intestine stenosis and discontinuity inflammatory lesions. Lesions of Crohn's disease are beyond the reach of traditional colonoscopy, therefore, DBE examination may be a good choice for patients with suspected Crohn's disease. Our research demonstrated that DBE has high diagnostic value for Crohn's disease.

DBE is a reliable procedure for the investigation of small intestinal pathology, and its safety and reliability have been reported in various clinical studies[8-11]. In the present study, a significant 75.5% of patients had a positive diagnosis after examination, which was comparable to other centers, both in China and internationally[12-14]. Videoendoscopy is superior to other modalities of investigation for the diagnosis and management of gastrointestinal disorders. DBE, as a successor to traditional gastroscopy and colonoscopy, is a major advance in gastrointestinal endoscopy[15-18]. Through cycles of insertion, anchoring and pulling, the small intestine can be shortened by telescoping it onto the shaft of the endoscope, which enables examination of regions beyond the reach of the endoscope length. Compared to the maximum depth of insertion of a traditional enteroscope, which is 80-100 cm from the ligament of Treitz, DBE can be inserted much farther. Normally, the mid-ileum can be reached, and the terminal ileum can be reached in some patients. The double balloon endoscope provides a wide visual field and images of high clarity and definition. Moreover, similar to a regular gastroscope or colonoscope, with DBE, it is possible to insufflate air, aspirate, and perform biopsies and therapeutic procedures when necessary. It is now considered a gold standard for the diagnosis and management of small intestinal diseases that cannot be replaced with other means.

After 42 DBE procedures, we made the following observations from a nursing perspective. To assist endoscopists with performing DBE and to minimize the suffering of sick children, the endoscopic nurse should: (1) meticulously examine the instrument before the procedure, paying special attention to the installation of the endoscope balloon to ensure that it is functioning properly and free from leakage; (2) provide psychological support and intestinal preparation; (3) closely monitor the vital signs, and fully cooperate with the endoscopist during the procedure, to control the insertion and withdrawal of the endoscope and overtube, and occasionally introduce water or lubricant to the space between the endoscope shaft and overtube, to reduce friction; (4) be aware of markings on the endoscopic shaft to prevent damage to the endoscopic balloon; and (5) ensure that after the procedure, the child fasts for 6 h before a fluid diet is introduced. The child can usually be fed normally on the second day.

In conclusion, in adults, DBE is a well-established procedure that is used in many countries. Its application in the pediatric age group is relatively recent; hence, few reports are available on this topic. This study investigated the nursing perspective in cases conducted in our hospital under intravenous or general anesthesia. We conclude that DBE is a safe and reliable procedure in the pediatric age group, with few complications and little suffering. High quality nursing care and good coordination with the endoscopists are essential to the successful conduction and completion of the procedure. We look forward to conducting a prospective study on patients undergoing DBE, preferably with a large sample size. We hope that, as nurses, we can better collaborate with physicians, so that procedure time can be shortened and patient suffering can be minimized.

The authors would like to thank the team members of Professor Huang for their helpful discussion and critical reading of the manuscript.

COMMENTS

Background

Technical challenges have obstructed the diagnosis and treatment of small intestinal disease. The small intestine is long, tortuous, far from both ends of

the digestive tract, and unfixed in position. An innovative form of enteroscopy, double-balloon enteroscopy (DBE), allows full-length visualization, biopsy, and endoscopic treatment of previously inaccessible lesions. The diagnostic and therapeutic benefits of DBE have been well documented in the adult population. To date, little has been published to evaluate the safety and efficacy of DBE in pediatric patients and the impact of nursing on this procedure, which has its own unique set of indications, limitations, and potential complications.

Research frontiers

DBE constitutes a new procedure for digestive endoscopy that makes direct visualization of the entire small bowel possible, with the simultaneous ability to take biopsy specimens and carry out endoscopic interventions. However, more studies are needed to evaluate the diagnostic value of DBE in children with suspected small intestinal disease, and determine the role of appropriate nursing care in reducing the incidence of complications, shortening the examination, and improving the lesion-detection rate.

Innovations and breakthroughs

Publications on pediatric DBE operation and nursing care are limited. In this report, a descriptive, qualitative study was conducted on 37 pediatric patients who underwent 42 DBE examinations for suspected small intestinal diseases. The clinical significance and salient points for nursing are summarized.

Applications

In this study, the pre-procedural, intraprocedural, and post-procedural nursing care were described in detail. In addition, the points of nursing care for pediatric patients undergoing DBE are summarized, which may offer a reference strategy for future DBE operations.

Terminology

Antegrade DBE is administered through the mouth, whereas retrograde DBE is inserted through the anus. The route of insertion is determined by the clinical features and results of other ancillary examinations. If the suspected lesion is low in the intestinal, retrograde DBE should be chosen.

Peer review

In this paper, the authors review the safety, clinical efficacy and nursing care of DBE in children. This topic is interesting in the pediatric age group but before publication, the authors should discuss the indications for pediatric DBE in more detail.

Abstract

AIM: To examine the epidemiologic and clinical characteristics of hepatitis B virus (HBV) related liver failure in patients in China.

METHODS: This study was conducted with a retrospective design to examine 1066 patients with HBV-related liver failure in the southwest of China.

RESULTS: There were more male than female patients. Young and middle-aged people comprised most of the patients. Farmers and laborers comprised the largest proportion (63.09%). Han Chinese accounted for 98.12%, while minority ethnic groups only accounted for 0.88% of patients. A total of 43.47% patients had a family history of HBV-related liver failure and 56.66% patients had a history of drinking alcohol. A total of 42.59% patients with HBV-related liver failure had definite causes. With regard to the clinical manifestation of HBV-related liver failure, the symptoms were: hypodynamia, anorexia and abdominal distension. Total bilirubin (TBIL) and alanine aminotransferase (ALT) levels were altered in 46.23% of patients with evident damage of the liver. Univariate logistic regression analysis showed that the patients' prognoses were correlated with ALT, aspartate aminotransferase, albumin, TBIL, prothrombin activity (PTA), and alpha-fetoprotein levels, and drinking alcohol, ascites, hepatorenal syndrome, infection and $\geqslant$ 2 complications. Multifactor logistic regression analysis showed that the activity of thrombinogen and the number of complications were related to the prognosis.

CONCLUSION: Alcohol influences the patients' prognosis and condition. PTA and complications are independent factors that can be used for estimating the prognosis of HBV-related liver failure.

Key words: Hepatitis B virus related liver failure; Chronic hepatitis B; Epidemiology; Prognosis

INTRODUCTION

Hepatitis B virus (HBV) infection is a severe threat of public health worldwide. Two billion people have been infected with HBV out of a total population of 6 billion, including chronic HBV infection in 350 million people[1,2]. One million people have died of liver disease related to HBV, 75% of which are distributed in the Asian-Pacific area[3]. China has a high occurrence of HBV infection. A survey of national epidemiology announced in April 2008 by the Ministry of Health showed that 93 million people in China have been infected with HBV.

The features of HBV-related liver failure include a lot of complications in patients, difficulty of treatment and a high fatality rate. Therefore, a large sample investigation about the natural history and the clinical process of HBV-related liver failure are required. This study analyzed the epidemiologic and clinical characteristics of HBV-related liver failure, based on a sample of 1066 cases in the southwest region of China.

MATERIALS AND METHODS

Case selection

All the 1066 cases were chosen from inpatients of the General Infectious Disease Institute of Southwest Hospital, the Third Military Medical University of China PLA, from February 2003 to December 2009. The patients were mostly from Chongqing and Sichuan, including the southwest regions in Guizhou and Yunnan.

The selection criteria included: (1) patients with chronic hepatitis B; (2) serum total bilirubin (TBIL) ≥ 171 μmol/L, prothrombin activity (PTA) ≤ 40% and complete data. The exclusion criteria were: (1) liver transplantated patients; (2) a short time of hospitalization (< 72 h); (3) patients with missing clinical and laboratory data; and (4) patients with associated tumors and other major diseases.

Methods

Epidemiologic survey: A questionnaire was given to the patients, which required information such as age, sex, ethnic group, career, family history, history of drinking alcohol, inducement of HBV-related failure, symptoms, physical signs, laboratory examinations, and complications. Questions that were not properly answered were not included in the statistical analysis. The daily alcohol intake (g) is equal to: alcohol intake × 0.8 × spirit (%), which was classified into low, medium, and high degrees (Table 1).

Laboratory examinations: Serum biochemical tests of alanine aminotransferase (ALT), AST, total bilirubin and albumin levels were measured by a Hitachi 7060 full-automatic chemical analyzer. α-fetoprotein (AFP), hepatitis B surface antigen (HbsAg), hepatitis B core antibody (HbcAb), hepatitis B e antigen (HbeAg) and hepatitis B e antibody (HbeAb) were measured using a German Roche Elecsys 2010 full-automatic electrochemiluminescence analyzer.

Serum HBV DNA was measured by a PE5700 instrument (ABI) and the reagent kits were from Cloning Biological High-tech Co., Ltd. (Shanghai, China). HBV DNA ≥ 1000 copy/mL (3.0 logl0) was positive.

Statistical analysis

SAS V8.0 statistical software was used for analysis. Data were shown as means ± SD. Potential factors that may have influenced the prognosis were examined by logistic analysis. $P < 0.05$ indicates statistical significance.

RESULTS

Epidemiology

Among the 1066 patients with HBV-related liver failure, there were 901 males (84.52%) and 165 females (15.48%), with a male: female ratio of 5.46:1.

The mean age was 39.76 ± 11.69 years (range, 12-75 years). The highest morbidity was in the age group of 30-39 years (31.71%, Table 2). The age group with the second highest morbidity was between 40 and 49 years (28.61%), followed by 20-29 years (18.01%), 50-59 years (14.26%), > 60 years (6.19%) and < 20 years (1.22%) (Table 2).

With regard to the occupation structure of the patients with HBV-related liver failure, farmers comprised the highest proportion , followed by laborers, cadres, teachers, students, businessmen, drivers, doctors, nurses and a painter and a policeman (Table 2).

A total of 1046 (98.12%) patients belonged to the Han ethnic group, followed by the Tujia minority ethnic group (1.50%), the Miao minority ethnic group (0.28%), and the Gelao minority ethnic group (0.09%) (Table 2).

Family history and history of alcohol drinking

A total of 463 patients (43.47%) had a family history of HBV-related liver failure and 56.66% of patients had a history of drinking alcohol. Two hundred patients seldom drank alcohol (18.76%), 171 patients drank alcohol lightly

Table 3 Inducement of chronic hepatitis B into severe hepatitis/liver failure

Inducement	*n* (cases)	Percentage (%)

Edema	126	12.27

(16.04%), 108 patients drank alcohol moderately (10.13%) and 125 patients drank alcohol heavily (11.73%).

Inducement of chronic hepatitis B into severe hepatitis/liver failure

The incidence rate of HBV-related liver failure was highest in the presence of other contagious viruses that infect the liver. Among 192 cases (18.01%), 109 cases were also infected by HDV (Table 3). The second highest cause of inducement of disease was drinking alcohol, followed by fatigue and other infections. Over half of the patients had no ascertainable cause of disease. In those patients in whom the cause of disease was known, most only had 1 factor that induced the disease. None of the patients had more than 3 types of inducement of disease.

Clinical manifestations

On admission, the patients' main clinical manifestations were hypodynamia, loss of appetite and abdominal distension (Table 4).

Table 5 Laboratory data in patients with hepatitis B virus related liver failure

Laboratory indexes	Mean
ALT (IU/L)	272.51 ± 541.51
AST (IU/L)	262.13 ± 440.55
Glutamyltranspeptidase (IU/L)	91.24 ± 55.74
Alkaline phosphatase (IU/L)	187.41 ± 96.01
ALB (g/L)	32.08 ± 7.95
TBIL (μmol/L)	396.56 ± 190.52
Direct bilirubin (μmol/L)	234.48 ± 100.75
PTA (%)	15.62 ± 12.98
Glucose (mmol/L)	5.35 ± 3.86
Blood urea nitrogen (mmol/L)	59.45 ± 970.09
Creatinine (μmol/L)	204.40 ± 613.78
AFP (ng/mL)	191.26 ± 221.36
HBV DNA (copies/mL)	$4.3 \pm 8.8 \times 10^7$

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALB: Albumin; TBIL: Total bilirubin; PTA: Prothrombin activity; AFP: α-fetoprotein; HBV: Hepatitis B virus.

Table 6 Complications in patients with hepatitis B virus related liver failure

Complications	*n* (cases)	Percentage (%)
Ascites	509	47.83
Hepatic encephalopathy	506	47.48
Ⅰ level	34	3.86
Ⅱ level	178	20.23
Ⅲ level	122	13.86
Ⅳ level	172	19.55
Hernia of brain	29	2.72
Hydrocephalus	78	7.32
Hemorrhage of digestive tract	234	21.95
Hepatorenal syndrome	210	19.70
Spontaneous bacterial peritonitis	103	9.66
Infection	417	39.12
Electrolyte imbalance	141	13.23

Laboratory examinations

The laboratory data of the patients are shown in Table 5. A total of 11.54% (123 cases) of the cases were HBeAg positive, 22.52% (240 cases) were HBeAb positive, 78.30% (834 cases) were HBV DNA positive, and the mean value was $4.3 \pm 8.8 \times 10^7$copies/mL.

Complications

The most common complications were ascites, hepatic encephalopathy, and infection. Hemorrhage of the digestive tract and electrolyte imbalance were the next most common complications (Table 6).

Prognosis

The patients were divided into 2 groups: the improved group and the deteriorated group (including exacerbation and death). The description "improved" was used

to define those patients who were able to be discharged from hospital because clinical symptoms improved and liver function recovered. The description of "deteriorated" was defined as patients who died or deteriorated when they were voluntarily discharged from the hospital, except for those who died or further deteriorated because of other diseases or accidents. Three hundred and forty-five cases improved (34.36%) and 721 cases were deteriorated (67.64%) (369 cases died and 352 cases were exacerbated). The rate of death due to the disease was 34.62%.

Logistic single factor regression analysis

Logistic regression analysis was performed for 42 factors that might have influenced the prognosis, using prognosis (improvement and unsuccessfully treated) as the dependent variable. The result showed that the patients' prognoses were related to ALT, AST, ALB, TBIL, PTA, and AFP levels, and drinking alcohol, ascites, hepatorenal syndrome, infection and $\geqslant 2$ complications.

Logistic multifactor regression analysis

Logistic multifactor regression analysis was performed for prognostic factors that were screened out by single factor regression analysis. We found that PTA ($P = 0.03$) and the number of complications ($P = 0.01$) were independently related to the prognosis of HBV-related liver failure.

DISCUSSION

In China, the main transmission route of HBV is vertical transmission and the secondary way is by blood products. Among the patients in our study, there were more males than females, while the number of males with HBV-related liver failure is increasing. With regard to profession, farmers and laborers comprised the largest proportion at 63.09%, with farmers occupying even larger proportion than laborers. The cause of the illness might be related to people's life style and working environment, inaccurate comprehension of the disease due to poor medical conditions and minimal schooling, and missing the best time for treatment because of not visiting a doctor in time. Among the ethnic groups, the Han accounted for 98.12% of patients, while minority ethnic groups only accounted for 0.88%. This finding could be because economic conditions are better and the population of the Han is higher compared with the ethnic minorities in the southwest of China. The result of single factor analysis showed that the patients' prognosis was not related to sex, age, occupation and ethnic groups.

The recurrence and aggravation of chronic HBV are due to various inducements during the long repetitive chronic process. Based on our data analysis, illness conditions deteriorated in 42.59% of patients in whom the cause of disease was known. The main factors responsible for inducing the illness were as follows: superinfection with other contagious viruses that infected the liver, drinking alcohol, fatigue and being complicated with other infections. With regard to superinfection with other contagious viruses that infect the liver, internationally, it is regarded that HGV virus infection does not cause liver failure, but it is rather found in patients co-infected with HBV. In China, drinking alcohol is common because of the rich "alcohol culture" and gradually enriched material conditions. Young and middle-aged people are busy with work and are under great social pressure. These factors, which have resulted in a trend for a lower average age for HBV-related liver failure, are the reasons for inducing and exacerbating the illness. Infection was found to be another cause of HBV-related liver failure, with 10 cases having liver failure due to an unclean diet history. Eight of these 10 cases had diarrhea and the patients may have been complicated with gastrointestinal infection. If the inducement of HBV-related liver failure is fatigue, it is related to damage of the patient's immune system. In 57.41% of patients, their illness deteriorated and there did not appear to be any definite cause of HBV-related liver failure. This may be related to several factors such as social environment, job competition, mental stress and emotional factors. In summary, infection (including being complicated with other hepatitis virus infections and other infections) is the biggest inducement of the disease, which is similar to the findings in other reports[4,5]. In addition, the factor of alcohol further increased the possibility of HBV-related liver failure.

Our data showed that the characteristics of severe hepatitis in the southwest of China are similar to acute liver failure and acute-on-chronic liver failure abroad, and these included acute onset, inducement for initiating or worsening of the disease, superinfection by hepatitis B and D viruses, and being complicated by infection and fatigue. Clinical manifestations of HBV-related liver failure involve two main types: alimentary tract symptoms, such as yellowing of the skin and sclera, hypodynamia, anorexia, abdominal distension, and physical signs of hepatitis such as liver palms, hepatic face, and spider nevus. Some of the patients did not have encephalopathy at the early stage of the disease, and this occurred after hospitalization. Some of the patients had ascites as the main clinical manifestation at admission, and most of them had secondary onset of hepatic encephalopathy. The prognosis of patients with hepatic encephalopathy greater than stage II was worse.

According to the laboratory data, liver function indicated damage to the liver and PTA was decreased. In the early stage of the disease, ALT and AST levels were increased. TBIL was also increased. The results of single factor analysis showed that patients' prognoses were related to ALT, AST, ALB, TBIL, PTA and AFP levels, which is consistent with other studies in China and in other countries[6-8]. Multifactor logistic regression analysis showed that PTA was independently related to the prognosis. PTA is the most important biochemical index used to determine the aggravation of chronic hepatitis B[9]. The lower the level of PTA, the higher the rates of hemorrhage and fatality[9]. The prognosis is bad if PTA is < 30%, and if this

is the case, the majority of patients die[9]. The quantity of serum bilirubin reflects the degree of damage to liver cells. TBIL appeared to be related to HBV-related liver failure, but multifactor analysis showed that TBIL was not a factor that affected the prognosis. It is generally acknowledged that the higher the level of AFP, the better the prognosis of patients with liver failure. The US Acute Liver Failure Study Group has shown that a 1-fold higher level of AFP is not related to a good prognosis; however, patients' prognoses are relatively good when AFP levels are increased 3 days after hospitalization[10].

HBV-related liver failure/severe hepatitis B is a serious disease. The incidence rate of complications is high. It is critical to prevent complications to improve the survival rate[11]. Our study results showed that 70.73% of patients had up to several complications. A total of 48.78% of patients had 2 or more complications. The type, quantity and the degree of severity of complications are important factors that can influence the outcome of HBV-related liver failure/severe hepatitis B. In our study, single factor analysis showed that the patients' prognoses were related to ascites, hepatorenal syndrome, infection and $\geqslant$ 2 complications. Multifactor analysis showed that the number of complications was an independent risk factor of HBV-related liver failure. In the USA and European countries, the first manifestation of hepatic failure is often hepatic encephalopathy. However, according to our data, ascites is the main manifestation in China. Infection is usually the earliest complication occurring in the midterm stage of the disease. Our data showed that infection was a complication that occurred in the early stage of HBV-related liver failure. Infection was related to the prognosis and it also aggravated the disease. Previous studies have shown that 60% to 80% of liver failure patients have secondary bacterial or fungal infection[12-17]. Riordan and Williams demonstrated that approximately 80% of patients with severe HBV are complicated with infection, which is difficultly controlled[18]. Because of the complexity of the pathogenesis of liver failure, the present system for estimating the prognosis cannot predict the results, although there is a great deal of patients' data available.

Liver failure is severe liver damage caused by various factors, which cause obstruction or decompensation of function, such as composition, detoxification, drainage and biotransformation[19]. Various clinical syndromes can appear, including the obstruction of coagulation mechanisms, icterus, hepatic encephalopathy and ascites[19]. According to the speed of pathological development, histology of liver failure and the patient's condition, liver failure can be classified into 3 types: acute liver failure (ALF), acute-on-chronic liver failure (ACLF) and chronic liver failure (CLF)[19,20]. According to morbid physiology, liver failure is mainly divided into two types that separately result in necrosis caused by the inflammation of liver cells and the decompensation of liver cells. ALF belongs to the type of liver failure that results in necrosis caused by inflammation of liver cells[19]. ACLF and CLF belong to the type of liver failure with decompensation of liver cells[19]. Patients with ALF have symptoms such as abnormal cruor (usually an international normalized ratio $\geqslant$ 1.5), a change in consciousness to varying degrees (encephalopathy), and the duration of disease is less than 26 wk[21,22]. Patients with ACLF have acute decompensation on the basis of chronic liver disease (TBIL $\geqslant$ 171 μmol/L)[23]. Patients with CLF have chronic decompensation of liver function (TBIL < 171 μmol/L) caused by a decrease in liver function on the basis of the final phase of hepatism[19]. According to the diagnostic standard discussed above[19-23], in our study, 654 cases had ACLF, 296 cases had CLF, and 116 cases had ALF.

The term "liver failure" is used in European countries and the USA because it is associated with function, whereas it is called severe chronic hepatitis in China and Japan because it is associated with inflammation. Hepatitis virus that appears to be acute liver failure is called severe hepatitis[24]. The main difference between the terms "liver failure" used in the USA and European countries and "severe hepatitis" used in China is whether to include hepatic encephalopathy in the diagnosis. Some patients with liver failure do not have hepatic encephalopathy[25]. Severe damage of the liver may develop into liver failure before hepatic encephalopathy occurs.

Although there are differences, liver failure has been divided into ALF, including the acute and sub-acute types, and CLF, including the chronic acute and chronic decompensated types, and this point of view gradually becomes consistent among international academic communities. Because of the large amount of etiologies of liver failure, physicians use a combination of clinical diagnoses (e.g. chronic severe hepatitis) and morbid physiology diagnoses (e.g. CLF). Liver decompensation is the main manifestation of chronic liver failure. Patients with this disease may not have hepatic encephalopathy, but patients with acute liver failure must have hepatic encephalopathy[26-30].

In conclusion, the morbidity of chronic HBV is steadily increasing. Once chronic HBV develops into HBV-related liver failure/chronic severe hepatitis, the liver is seriously damaged with complex symptoms, it develops rapidly, it has many complications, it is difficult to treat and it has a high death rate. We advise patients with hepatitis to enhance self-protection and prevent bad life-style habits, so that they can be diagnosed in the early stage and be cured in a timely manner with positive results and treatment of complications, so as to ultimately reduce the death rate.

COMMENTS

Background

Hepatitis B virus (HBV) infection becomes a severe threat for public health worldwide. The features of HBV-related liver failure include: a serious condition of the patients, a high incidence of complications, difficulty of treatment and a high fatality rate. Large-sample studies are needed to determine the natural history and clinical process of HBV-related liver failure.

Research frontiers

This study investigated the inducement of liver failure/severe hepatitis B and the independent risk factors associated with its prognosis.

Innovations and breakthroughs

This study explored the inducement and prognosis of hepatitis B virus related liver failure as well as the diagnostic classification of liver failure.

Applications

This study is useful in clinical management and prognosis prediction of hepatitis B virus related liver failure.

Terminology

HBV-related liver failure/chronic severe hepatitis: HBV-related liver failure refers to patients with liver failure caused by chronic hepatitis B virus (HBV) infection. Liver failure is severe liver damage caused by various factors, which cause obstruction or decompensation of function, such as composition, detoxification, drainage and biotransformation. Chronic severe hepatitis refers to patients with evidence of chronic liver disease that leads to acute decompensation of liver function.

Abstract

AIM: To determine the effects of duodenogastric juice pH on the development of esophageal adenocarcinoma (EAC).

METHODS: An animal model of duodenogastroesophageal reflux was established using Sprague-Dawley (SD) rats undergoing esophagoduodenostomy (ED). The development of EAC was investigated in rats exposed to duodenogastric juice of different pH. The rats were divided into three groups: low-pH group (group A), high-pH group (group B) and a sham-operated group as a control (group C) (n = 30 rats in each group). The incidence of esophagitis, Barrett's esophagus (BE), intestinal metaplasia with dysplasia and EAC was observed 40 wk after the treatment.

RESULTS: The incidence rate of esophagitis, BE, intestinal metaplasia with dysplasia and EAC was higher in groups A and B compared with the control group after 40 wk ($P < 0.01$), being 96% and 100% ($P > 0.05$), 88% and 82.4% ($P > 0.05$), 20% and 52.1% ($P < 0.05$), and 8% and 39% ($P < 0.05$), respectively.

CONCLUSION: Non-acidic refluxate increases the occurrence of intestinal metaplasia with dysplasia and EAC while the low-pH gastric juice exerts a protective effect in the presence of duodenal juice. The non-acid reflux is particularly important in the progression from BE to cancer. Therefore, control of duodenal reflux may be an important prophylaxis for EAC.

Key words: Esophageal reflux; Esophageal adenocarcinoma; pH-metry; Pathogenesis

Role of pH refluxate pH in duodenogastroesophageal reflux-induced esophageal adenocarcinoma. *World J Gastroenterol* 2011; 17(25): 3060-3065 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i25/3060.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i25.3060

INTRODUCTION

The incidence rate of esophageal adenocarcinoma (EAC) has been increasing more rapidly than that of other malignancies[1]. This rapid increase may be related to the increasing occurrence of gastroesophageal reflux disease (GERD) and Barrett's esophagus (BE)[2,3]. BE is the main risk factor and an acquired condition for these tumors[4]. Gastric acid has been regarded as the major risk factor for GERD, and acid suppression is the first-line treatment[5]. However, the role of the gastric acid in the development

of GERD remains controversial.

Gastric juice refluxing into the esophagus contains gastric, biliary and pancreatic secretions that have refluxed into the stomach from the duodenum. Early studies showed that reflux of combined duodenal and gastric juices into the esophagus caused severe esophagitis[6], and reflux of duodenal juice alone resulted in a similar degree of esophageal injury[7]. It has been shown[8-12] that esophageal exposure to duodenal juice is a key factor in the genesis of BE and EAC. Some researchers have suggested that the obvious increase in the incidence of EAC might be related to the acid suppression[13]. However, to dynamically monitor the duodenal juices and clarify the role of duodenal juice reflux in the pathologic process has attracted much attention. Some studies have confirmed that duodenal juice reflux could induce BE and EAC in rats[10].

Improved animal models are therefore needed to examine the role of non-acidic reflux in EAC induced by duodenal juice reflux in the absence of exogenous carcinogens. The aim of this study was to investigate the roles of gastric and duodenal juices in the genesis of EAC in a rat model.

MATERIALS AND METHODS

Experimental animal

Ninety 8-wk-old Sprague-Dawley (SD) rats weighing 200-250 g were purchased from the Experimental Animal Center of Xi'an Jiao Tong University. The male pairing female rats were randomly divided into three groups, each with 30 rats.

Animal model

A rat model of duodenogastroesophageal reflux, with different pH values of reflux contents, was established in accordance with the method of Zhang *et al*[14]. Surgical diversion of duodenal secretions into the esophagus in the experimental group was induced by end-to-side esophagoduodenostomy (ED). The rats were divided into a low-pH group (group A) and a high-pH group (group B), with 30 rats in each group. A sham-operated group (group C, n = 30) was used as a control group (Figure 1).The esophagus was separated from the posterior vagal trunk and left gastric vessels, tied with silk at the gastroesophageal junction, and dissected 2 mm proximal to the tie. The anterior vagus nerve was protected from damage when the esophagus was cut with 16 interrupted stitches of 7-0 polypropylene. The purpose of the anastomosis was to induce the reflux of both gastric and duodenal juices into the esophagus. In group A, the anterolateral wall of the duodenum at the distal end 1 cm from the pylorus was opened longitudinally, and anastomosed with the cut end of the esophagus. In group B, the anterolateral wall of the duodenum at the distal end 2 cm from the pylorus was opened longitudinally and anastomosed with the cut end of the esophagus. In group C, the lower esophagus and the first portion of the duodenum were dissociated. Surgery was performed after an acclimatization period of 4 d. Rats were kept in hanging cages under a 12 h light-dark cycle at a temperature of 21℃ and a humidity of 60%. Water and standard chow were provided ad libitum. Food was discontinued the evening before surgery, and water was discontinued on the morning of surgery. Rats were anesthetized with an intramuscular injection of xylazine hydrochloride (18 mg/kg) and ketamine (72 mg/kg), with further doses administered intraperitoneally during surgery, as required. Before closure, 0.5-1.5 mL of 0.9% sodium chloride was instilled into the peritoneal cavity. Water was permitted when the rats awoke, and chow was provided the next day. The rats were housed in cages at 22-25℃ with free access to standard rat pellet food and water for 40 wk. Rats were treated following the guidelines for the care and use of laboratory animals of the National Animal Welfare Committee.

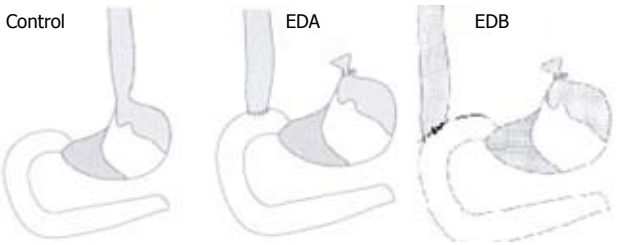

Figure 1 Animal model establishment. Esphagoduodenostomy group A (EDA) for duodeno-gastro-esophageal reflux of low pH value and esphagoduodenostomy group B (EDB) for high pH value respectively, and control for the sham operation group.

Intraluminal pH was measured using a pH glass electrode of Digitrapper MK Portable pH Monitor(Sweden Medtronic Synectics Company, Stockholm, Sweden). It was positioned in the distal end of the esophagus, the forestomach, the opisthogaster and the duodenum 1 and 2 cm from the pylorus in the process of esophagoduodenostomy. It was also measured after rats were killed 40 wk after operation.

Tissues and specimens

Rats were killed 40 wk after operation. The esophagus was opened longitudinally and gross pathologic changes were observed. Esophagitis, BE and EAC were differentiated, and samples of the three abnormal tissues (0.2 × 0.2 cm^2) were removed, and fixed in formalin. Paraffin sections were stained with hematoxylin-eosin and observed under a light microscope.

Statistical analysis

The incidence rates of esophagitis, BE and EAC between the groups were analyzed and compared using χ^2 tests with SPSS software, and differences in numerical data were compared between groups using t test. The level of significance was set at $P < 0.05$.

RESULTS

The number of the surviving rats in the three groups was 25, 23 and 29, respectively. The overall mortality was 14.4%.

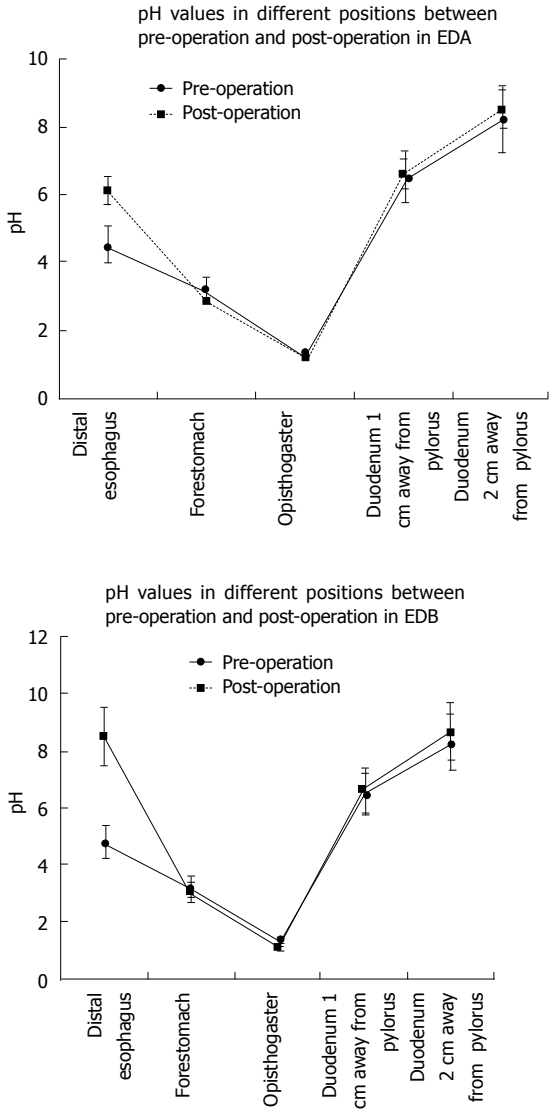

Figure 2 pH in different positions of esophagus, stomach and duodenum.

pH values in different parts of esophagus, stomach and duodenum

The pH values increased from the proventriculus down to the duodenum 2 cm away from the pylorus ($P < 0.05$), (Figure 2). The preoperative pHs at the distal end of the esophagus in groups A and B were significantly lower than the postoperative values ($P < 0.05$).

Postoperative pH values in the distal esophagus in groups A and B

The pH value in the distal esophagus in group A, in which the duodenum was cut 1 cm from the pylorus, was 6.14 ± 0.36, which was significantly lower than that in group B (8.27 ± 0.46, $P < 0.01$). There was no significant difference in preoperative pH values in the distal esophagus between the two groups ($P = 0.12$).

Gross observations

In the sham-operated group, the esophageal wall was thin, with a smooth mucosa, and the esophageal lumen was

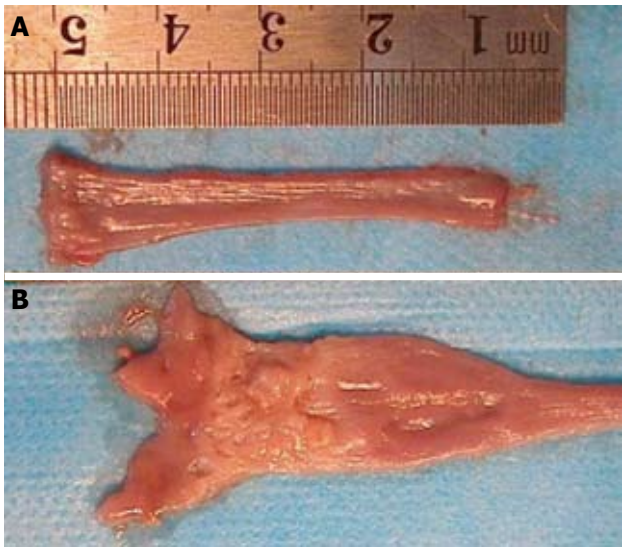

Figure 3 Gross specimens of the sham operated-group(shown in picture A) and animal model group(shown in picture B).

uniform in size along its length. Blood vessels were visible below the mucous membrane, and congestive inflammation was occasionally visible in the distal esophagus. In most animals in both groups, the lumen of the middle and the lower parts of the esophagus was dilated. Esophagitis appeared as mucosal hyperplasia, with a thickened, rough surface with small and large kernels in longitudinal rows, becoming less pronounced from the distal to the proximal end. Hyperemia, edema, mild erosion and indistinct blood vessels below the mucous membrane were visible at the proximal end. BE occurred mostly in the distal esophagus at the stoma between the esophagus and duodenum, and appeared as an unclear boundary between the esophagus and the duodenal mucosa. The esophagus was inflamed at the proximal end, smooth and velvet-like, with a clear boundary from the duodenum. The area of BE generally extended for about 0.5-2 cm, with chronic proliferation and inflammation at the proximal end of the esophageal mucosa. Small sheets of BE pathology were seen in some cases of esophagitis. The upper esophagus was normal in BE, and all esophageal adenocarcinomas (EACs) developed near the proximal end of the stoma in BE, with nodular hyperplasia, ulcer and fish-like appearance. The esophagus at the upper end of the tumor was obstructed, with obvious dilation and changes in the features of BE. The hyperplasia was reduced at the proximal end of the obstruction, and appeared as congestion of 1-2 mm and presented edema changes (Figure 3).

Histologic characteristics

Normal esophageal epithelium appeared as stratified squamous epithelium, with neat rows, some showing keratinization. Esophagitis appeared as hyperplasia of the scaly epithelial basal cells, excessive keratinization and papillomatosis, visible neutrophilic granulocytes, infiltrated lympho-epithelioid cells, mucosal erosion and edema of the submucosa in the mucosa and the lower layers of the mucosa. BE

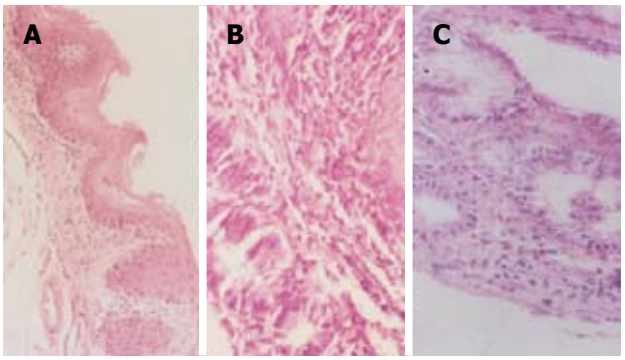

Figure 4 The changes of the esophagus mucosa in the sham operated group and the animal model groups under the light microscope (200 ×). A: Normal esophagus in the sham operated group; B: Esophagitis and barrett esophagus in the model group; C: Intestinal metaplasia with dysplasia and esophageal adenocarcinoma in the model group.

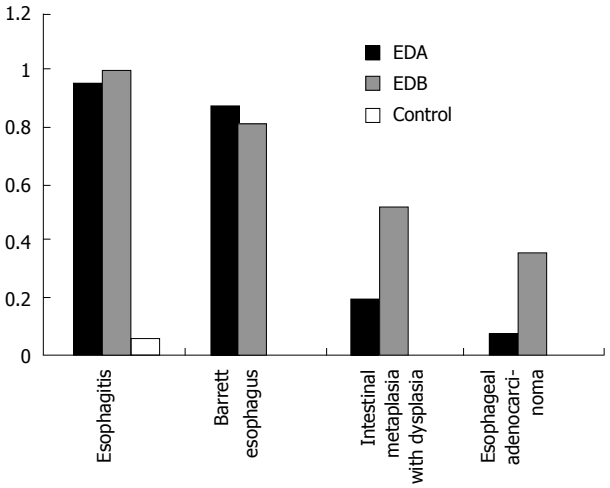

Figure 5 The incidence rates of diseases of esophagitis, Barrett esophagus, intestinal metaplasia with dysplasia and esophageal adenocarcinoma 40 wk after operation. The incidence of esophagitis, barrett esophagus, intestinal metaplasia with dysplasia and esophageal adenocarcinoma 40 wk after operation in the sham, operated group (Control), esophagoduodenostomy group A (EDA) and esophagoduodenostomy group B (EDB) group.

showed replacement of the squamous mucosa with simple columnar epithelium. Intestinal metaplasia with dysplasia showed replacement of the mucosa with simple columnar epithelium, changes in the size and shape of hyperplastic cells, with large, hyperchromatic nuclei and increased nucleoplasm, irregular arrangement of the cells, disappearance of cell polarity, and irregular shape and arrangement of the glandular cells. However, these changes were not characteristic of cancer and no obviously abnormal cells could be seen and no pathologic invasion to the basilar membrane. EAC showed severe intestinal metaplasia with dysplasia, pathologic invasion to the basilar membrane, and some to the blood or lymphatic vessels (Figure 4).

Incidence rates of esophagitis, BE, intestinal metaplasia with dysplasia, and EAC

The incidence rate of esophagitis in groups A and B 40 wk after the treatment was 96% and 100%, respectively (χ^2 = 0.930, P = 0.330). The equivalent incidence rate of BE was 88% and 82.4%, respectively χ^2 =0.280, P = 0.60), and of intestinal metaplasia with dysplasia was 20% and 52.1%, respectively (χ^2 = 5.420, P = 0.02). The incidence rate of EAC was 8% and 39% in the two groups, respectively (χ^2 = 6.570, P = 0.01). All these rates were significantly higher than in the sham-operated control group (P < 0.001) (Figure 5).

DISCUSSION

GERD occurs when the contents of the stomach and duodenum are regurgitated into the esophagus, causing pathologic lesions of the mucosa, and pathologic changes in the esophagus[15]. Gastroesophageal reflux can result in the development of EAC. The incidence rate of EAC has increased significantly in recent years, more rapidly than that of other tumors[16], and the annual increase in the incidence rate of GERD reflects the increasing incidence rate of EAC. Clinical epidemiological studies have shown that gastroesophageal reflux correlates closely with EAC[17].

The mechanism that gastroesophageal reflux induces EAC has been the subject of numerous studies[18], and a recent research has shown that reflux of both gastric and duodenal juices can damage the esophageal mucosa[19]. However, the contributions of the specific components of gastroesophageal reflux to the development of EAC remains unclear[20]. The current study used an animal model, in which the pH values of the duodenogastric reflux could be varied, to investigate the effects of gastric acid and duodenal juice on the EAC induced by gastroesophageal reflux, with the aim of identifying the specific responsible factors.

Gastric acid is believed to be an important contributory factor in reflux esophagitis[10,21]. However, recent studies suggest that the role of other refluxes in the morbidity of gastroesophageal reflux cannot be ignored[22]. With the development of biliary monitoring technology, the effects of duodenogastric reflux can be better understood. The duodenal contents include bile, pancreatic juice, and intestinal juice, of which cholic acid, trypsin and hemolytic lecithin could damage the esophageal mucosa[23,24]. Exposure to acid and duodenal contents for a prolonged period would lead to the damage of the esophageal mucosa, the development of BE, and even EAC. Animal experiments have shown that bile can damage the esophageal mucosa[9]. Cholic acid synergizes with gastric acid, and could damage the esophageal mucosa by increasing the acidic environment, thus reinforcing the damaging effects of acid and pepsase, instead of being destroyed by acid after combining cholic acid and trypsin[25].

An animal model was established in this study to investigate the duodenogastric reflux of contents with different pH values, their damage to the esophageal mucosa and their effects on the development of BE and EAC. The pH value of the duodenogastric reflux 2 cm away from the pylorus was significantly higher than that 1 cm away (P < 0.05). This difference was related to the relative proportions of sodium bicarbonate secreted by the pancreas and gastric acid secreted by the stomach. The pH values dif-

fered depending on the position in the esophagus relative to the anastomosis of the esophagus and duodenum; the pH value 2 cm away from the pylorus was higher than that 1 cm away from the pylorus ($P < 0.01$).

These results confirm that the esophagus was stimulated by the contents of the stomach and duodenum with different pH values; a higher pH indicated a higher proportion of duodenal juice, while a lower pH indicated a higher proportion of gastric juice.

Esophagitis, BE, intestinal metaplasia with dysplasia and EAC developed in both the treated groups after 40 wk. The incidence rates of intestinal metaplasia with dysplasia and EAC were higher in the high-pH group, compared with the low-pH group ($P < 0.01$). There were no significant differences in the incidence rate of esophagitis or BE.

The results of this study showed that the reflux of gastric juice and duodenal contents could induce EAC in rats. More acidic duodenogastric reflux was associated with lower incidence rate of intestinal metaplasia with dysplasia and EAC, compared with more basic duodenogastric reflux. These results suggest that duodenal juice reflux increases the incidence rate of intestinal metaplasia with dysplasia and EAC, thus playing an important role in the pathogenesis of EAC, while gastric juice regurgitation had an opposite effect. The results imply that non-acid reflux is particularly important in the progression from BE to cancer. Therefore, control of duodenal reflux may be an important prophylaxis of the EAC.

COMMENTS

Background

The incidence rate of esophageal adenocarcinoma (EAC) is rising faster than that of any other cancers. Clinical epidemiological studies have shown that gastroesophageal reflux correlates closely with EAC. However, the relationship between the specific reflux components and the induction of EAC remains unclear.

Research frontiers

Gastroesophageal reflux can cause EAC, and the mechanisms have been the subject of extensive research. The specific gastroesophageal reflux components responsible for EAC remain largely unknown. In this study, the authors demonstrated that non-acidic reflux increases the incidence rates of intestinal metaplasia with dysplasia and EAC, while acidic reflux had an opposite effect.

Innovations and breakthroughs

Recent reports have highlighted the importance of duodenal juice in the pathogenesis of EAC. The duodenum contains bile, pancreatic juice, and intestinal juice, of which cholic acid, trypsin and hemolytic lecithin could damage the esophageal mucosa. This is the first study to report a relationship between the pH of the duodenogastric refluxate and the incidence of EAC. The results of this study therefore suggest that duodenal juice plays an important role in the pathogenesis of EAC and gastric juice had an opposite effect.

Applications

Better understanding of the roles of the specific esophageal reflux components in the pathogenesis of EAC may represent a future strategy for the prevention of EAC.

Peer review

The article is original and well-thought. The topic of the research is important, as it would add to the body of evidence regarding the role of alkaline reflux in esophageal carcinoma. The manuscript is clearly laid out and well written. The methodology/design is suitable to answer the questions posed.

Abstract

There are four types of gastric carcinoid tumors, classified according to their histology and malignant potential. Only a few cases of carcinoid tumors in patients infected with *Helicobacter pylori* (*H. pylori*) have been reported so far. We report a patient infected with *H. pylori* presenting with a small solitary gastric carcinoid tumor with very low proliferative rate and normal gastrin levels. The tumor was endoscopically removed and the patient received an eradication therapy against *H. pylori*. No signs of metastatic disease have been found so far during more than 3 year of follow-up. Infection with *H. pylori* may cause chronic gastritis with normal or elevated gastrin levels, leading to the development of gastric carcinoids by mechanisms unrelated to gastrin. Enterochromaffin-like cell tumors related to a chronic *H. pylori* infection may be considered as a distinct type of gastric carcinoid tumors.

Key words: Gastric carcinoids; Gastrin; Gastritis; *Helicobacter pylori*

INTRODUCTION

Gastric carcinoids are rare neuroendocrine tumors of the stomach that arise from the enterochromaffin-like (ECL) cells[1]. Initially, three types of gastric carcinoids were reported[2,3]. The first two types, which are multiple, are related to high gastrin levels; type Ⅰ arise in patients with autoimmune chronic atrophic gastritis type A and type Ⅱ occur in patients with the Zollinger-Ellison Syndrome. Type Ⅲ is a solitary tumor with no known correlation to gastrin production. More recently a highly aggressive variant has been described, named type Ⅳ gastric carcinoid tumor[1].

Helicobacter pylori (*H. pylori*) has been reported to cause chronic atrophic gastritis[4] and alteration of the gastric secretion[5]. Chronic gastritis caused by *H. pylori* can be a risk factor for gastric cancer[4], but the occurrence of ECL cell tumors in the stomach of patients infected with *H. pylori* is rare[6]. We here present a patient infected with *H. pylori* presenting with a solitary gastric carcinoid tumor.

CASE REPORT

A 60-yr-old woman from Sweden had been suffering from abdominal pain for several years and flushing since 2003. She had no family history for MEN I, Zollinger-Ellison syndrome or autoimmune gastritis. Gastroscopy in May 2006 due to oral lichen showed a polyp-like lesion in the

gastric body near the cardia. Microscopic examination showed a neuroendocrine tumor positive for chromogranin A, VMAT-2 and synaptophysin, and with serotonin positivity in the majority of the cells. Ki67 was positive in < 1% of the tumor cells (Figure 1). The tumor was considered to be a type Ⅲ ECL-oma. Inflammation and *H. pylori* were present in the gastric mucosa (Figure 2). The patient was referred to our Department and a new gastroscopy in September 2006 showed inflammation in the antrum, corpus and fundus, atrophy in the antrum and corpus, and ECL-cell hyperplasia in the corpus, where a polyp considered as ECL-oma of type Ⅰ was found. Gastroscopy in November 2006 showed gastritis and positivity for *H. pylori* but no ECL hyperplasia. Gastric pH was 3.5. The patient had normal urinary histamine metabolites, normal U-5'HIAA, normal fasting serum gastrin and normal plasma chromogranin A and B. She received eradication treatment against *H. pylori*. A gastroscopy in February 2007 showed chronic inflammation without atrophy in the mucosa. There was a 0.5 cm polyp in the upper corpus surrounded by ECL hyperplasia. The tumor cells were positive for chromogranin A and VMAT 2, but negative for serotonin. Ki67 was < 1%. The tumor was considered to be a type Ⅲ ECL-oma due to lack of mucosal atrophy. The patient underwent an endoscopic mucosal resection of the polyp in April 2007. The pathology report showed a 7 mm ECL cell carcinoid with 5 mm depth that did not invade the muscularis propria. The tumor cells were positive for chromogranin A, synaptophysin and VMAT-2 but negative for gastrin and serotonin; Ki67 was < 1%. The tumor was considered as a type Ⅲ ECL-oma. A gastroscopy in September 2007 showed inflammation in the antrum with focal metaplasia but no signs of *H. pylori*, and another gastroscopy in December 2008 showed no inflammation or atrophy. The patient has not had any signs of metastatic disease in the liver or elsewhere. Repeated CT scans and ultrasounds, as well as an octreoscan in 2006 and a 5-HTP PET scan in January 2008, have been negative. Urinary 5-HIAA, plasma chromogranin A and B and serum gastrin and pancreatic polypeptide have been normal at all control visits. She has no evidence of pernicious anemia and thyroid hormone levels have been normal. At the latest control visit in January 2010, gastroscopy was macro- and microscopically normal. Staining for *H. pylori* was negative.

DISCUSSION

We report a patient with normal gastrin levels presenting with a small solitary gastric carcinoid with very low proliferative rate and without evidence of metastatic disease during more than 3 years of follow-up. The normal gastrin levels suggest that the carcinoid tumor was not type Ⅰ or Ⅱ. The absence of metastatic disease and the small dimension of the polyp, together with the low proliferative rate, indicate that it was not a type Ⅲ carcinoid. The patient was infected with *H. pylori* and had signs of chronic gastritis, gastric atrophy and ECL cell hyperplasia, which resolved after eradication of the *Helicobacter* infection. There have been no recurrences after the eradication treatment and endoscopic polypectomy. Although careful interpretation is needed, a causal relationship seems plausible. It is well known that chronic acid suppression may induce ECL cell proliferation[7]. However, our patient did not receive any proton pump inhibitors or other acid suppressive therapy, neither before the development of the carcinoid tumor nor during the follow-up period. It has previously been shown that longstanding *H. pylori* infection causes chronic inflammation of the gastric mucosa in animals[8]. A long-term *H. pylori* infection is also associated with atrophy of the gastric mucosa, and atrophy is a

risk factor for malignancy[4]. *H. pylori*-induced gastritis may play an important role in the development of gastric adenocarcinoma in humans[4] and animal models[9]. Development of gastric carcinoid tumors in subjects infected with *H. pylori* is believed to be rare[6], but has been described in animals[9-11] and, more rarely, in humans. Five humans infected with *H. pylori* without atrophic gastritis or Zollinger-Ellison syndrome who developed gastric carcinoids have been reported in Japan[12]. In Europe, Solcia reported four cases[13] of gastric carcinoids in *H. pylori*-infected humans, of whom all had chronic atrophic gastritis type A. Infection with *H. pylori* was, however, found to be much more common in patients with early gastric carcinomas than in carcinoid patients[13]. *H. pylori* thus seems more likely to cause neoplasms with higher malignant potential than the indolent carcinoids. Since the chronic gastritis in our patient resolved and no tumor recurrences have occurred after eradication treatment, it is nevertheless possible that her gastric carcinoid was actually caused by *H. pylori*-induced chronic gastritis.

H. pylori may affect the acid secretion of the parietal cells by causing mucosal inflammation[14]. Gastric acid secretion depends on the localization and the degree of the inflammation[14]. Acute infection with *H. pylori* results in hypochlorhydria, whereas chronic infection can cause either hypo- or hyperchlorhydria, depending on the distribution of the infection and the degree of corpus gastritis[5]. Recent studies suggest that inflammatory cytokines, produced in response to the bacteria, can play a role in the perturbations in acid and gastrin secretion induced by *H. pylori* [5]. Gastrin is associated with enterochromaffin-like (ECL) cell proliferation and is a factor implicated in the pathogenesis of ECL-cell tumors type Ⅰ and Ⅱ[3]. The patients in Japan with *H. pylori*-associated gastric carcinoids mentioned above all had high gastrin levels. Our patient, however, developed ECL-cell hyperplasia and a gastric carcinoid tumor despite normal gastrin levels. This observation suggests that *H. pylori* may facilitate gastric ECL cell proliferation by other mechanisms, independent of gastrin hypersecretion. The mucosal inflammation induced by *H. pylori* has been shown to cause excessive apoptosis, which in turn leads to proliferation[15,16]. Lipopolysaccharides also appear to influence tumor ECL cell proliferation[16,17]. Another factor involved in ECL cell proliferation is REG protein, which may be produced by *H. pylori* infection[18].

In conclusion, we postulate that *H. pylori* may lead to chronic gastritis, with normal or elevated gastrin levels, and cause the development of gastric carcinoids by mechanisms unrelated to gastrin. ECL cell tumors related to a chronic *H. pylori* infection may be considered as a distinct type of gastric carcinoid tumors, as they seem to have distinct histopathological, pathogenetic and clinical characteristics compared to the other types of gastric carcinoids.

Abstract

Hepatitis B (HBV) reactivation induced by chemotherapy is problem encountered recently in the management of malignant diseases. Chemotherapy-induced HBV reactivation may ultimately lead to terminal acute liver failure. Liver transplantation (LT) currently remains the only definitive treatment option for such cases, but is generally denied to patients suffering from malignancy. Here, the authors describe 2 cases of cancer-free and HBV graft re-infection-free survival after LT performed for terminal liver failure arising from HBV reactivation induced by chemotherapy for advanced stage lymphoma. These 2 cases, and some other reports in the literature, may suggest that patients suffering from hematologic malignancies and terminal liver disease can be considered for LT if the prognosis of their hematologic malignancy is good.

INTRODUCTION

Reactivation of a previous hepatitis B virus (HBV) infection is a known complication in patients undergoing chemotherapy or immunosuppressive treatment. Such reactivations have been observed in HB surface antigen (HBsAg) positive and negative subjects, with an incidence of 26% to 47%[1,2]. Although lamivudine prophylaxis is considered as the treatment of choice in such situations, in some cases it may not prevent reactivation of the underlying infection[3]. Chemotherapy-induced

HBV reactivation may then lead to terminal liver failure, with very limited treatment options, as life-saving liver transplantation (LT) is generally not performed in patients suffering from preexisting extrahepatic malignancies[4]. We report 2 cases of long-term cancer-free and HBV graft re-infection-free survival after LT for HBV reactivation induced by chemotherapy administered for advanced staged lymphoma.

CASE REPORTS

Case 1

A 49-year-old Caucasian male was diagnosed with advanced nodular sclerotic Hodgkin's lymphoma stage IIIb-IV in January 2006. In the following month, chemotherapy was initiated using 4 cycles of escalated BEACOPP regimen (bleomycin, etoposide, adriamycin, cyclophosphamide, oncovin, procarbazine, prednisone). After 3 cycles, blood analyses indicated an acute HBV infection (HBsAg+, anti-HBc+). Indeed, prior to chemotherapy, the patient had been an HBsAg carrier, a status he had failed to mention initially. Further blood tests confirmed the revised diagnosis of chronic HBV infection (anti-HBs-, anti-HBe+). His hepatic function was closely monitored and the last cycle of escalated BEACOPP was administered in April 2006. A follow-up positron emission tomography (PET) revealed significant lymphoma regression, after which the patient was switched to a baseline BEACOPP pattern, to minimize adverse effects.

One month later, after the first cycle of baseline BEACOPP chemotherapy, the patient was admitted to hospital with fatigue, anorexia, generalized edema and jaundice. Blood analysis showed significant alteration of liver function (aspartate aminotransferase: 505 IU/L, alanine aminotransferase: 300 IU/L, lactate dehydrogenase: 579 IU/L, T-bilirubin 45.9 mg/L), and further chemotherapy had to be postponed. Polymerase chain reaction for HBV-DNA was performed with positive results (HBV-DNA > 10 000 000 copies). Lamivudine therapy was then initiated. In June 2006 the patient presented with liver failure (MELD (Model for End-stage Liver Disease) score 35, Quick < 20%, Factor V < 20%, international normalized ratio > 5) and hepatic encephalopathy. Additional serology performed for other pathogens remained negative (human immunodeficiency virus, HCV, cytomegalovirus, Epstein-Barr virus, herpes simplex virus, toxoplasmosis), so that hepatic failure could only be attributed to the reactivation of the underlying HBV infection. He was then referred to our university hospital for LT evaluation, despite the fact that the last cycles of chemotherapy had not yet been administered. As the last PET showed no residual lymphoma activity, an emergency LT was performed. Immunosuppression was initialized using tacrolimus, mycophenolate mofetil and prednisone. Graft reinfection was prevented using anti-Hbs immunoglobulin injections and lamivudine. No further chemotherapy was administered. In the first 4 years of follow-up, regular computed tomography (CT) and PET scans did not show any evidence of lymphoma activity. Immunosuppressive treatment was gradually tapered as in other LT recipients. At 4-year follow-up, the patient was alive and well, cancer-free and HBV-free, on long-acting tacrolimus monotherapy and HBV prevention bi-therapy (lamivudine + anti-HBs immunoglobulin injections).

Case 2

A 53-year-old female originating from central Africa was diagnosed with big cell lymphoma type B of the stomach, with thoracic involvement in December 2006. Staged as IIIa, the patient underwent poly-chemotherapy using a R-ACVBP regimen (rituximab, doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisone). The last chemotherapy was administered in March 2007, and she was considered in full remission (negative PET, CT and gastroscopy). Despite her hepatitis B status (HBAg+, anti-HBc+, anti-HBs-, anti-HBe+) being known before chemotherapy initiation no preventive therapy was taken, and HBV reactivation was diagnosed in November 2007 (positive PCR). The patient immediately received lamivudine, which proved ineffective, resulting in terminal hepatic failure (MELD-score 29, Quick < 23%, Factor V < 30%) in March 2008. The patient was then referred for LT evaluation. An urgent LT has then been performed since stage 2 to 3 encephalopathy became apparent. Because of severe coagulopathy, hemostatis was difficult during the LT procedure, and splenectomy had to be performed at the same time. Pathology of the spleen did not reveal lymphoma. Graft HBV reinfection was prevented by anti-Hbs immunoglobulin injections and lamivudine, and initial immunosuppression consisted of tacrolimus, mycophenolate mofetil and prednisone, rapidly tapered. At 2-year follow-up, the patient was alive and well, and her immunosuppressive medication has been adjusted to long-acting tacrolimus monotherapy. She did not develop any sign of HBV or lymphoma recurrence.

DISCUSSION

This article reports 2 patients with lymphoma who underwent successful LT for chemotherapy-induced HBV reactivation. These cases demonstrate that life-saving LT should not be denied as an absolute contraindication in patients with lymphoma and chemotherapy-induced HBV reactivation. This concept confirms other reports suggesting that patients suffering from hematological diseases show low recurrence rates after LT[5,6]. These cases offer the opportunity to reconsider current LT limitations, particularly in those instances where transplantation would usually be denied. The authors consider that patients suffering from preexisting malignant diseases should not be excluded by default for this life-saving procedure, but that potential benefits and risks must be evaluated individually particularly in malignant lesions affecting a younger and fitter population. This

view was also recommended by the King's College Hospital group[7].

Reactivation of a previous HBV infection is an entity regularly encountered with chemotherapy. Cases of fatal fulminant or subacute HBV liver failure following chemotherapy for lymphoma have been reported[8-10]. This is particularly true in cases in which rituximab and corticosteroids are included in the protocol[1,2,8]. The pathophysiology remains to be determined, but reports suggest that immunosuppressants favor viral reproduction, and that a massive immunological reaction occurs as soon as normal immune system function is reestablished at the end of chemotherapy. This overwhelming immune response is the origin of hepatic acute cytolysis[1]. Reports suggest that every patient undergoing chemotherapy should be checked for previous HBV infection, and that HBV preventive treatment throughout the patient's chemotherapy should be performed in case of previous HBV infection. However, at the time of treatment of the 2 patients mentioned in this case report, lamivudine prophylaxis was not reimbursed by the Belgian health system so that it was administered only after reactivation had already occurred. Nonetheless in some cases, lamivudine prophylaxis may not prevent reactivation, and terminal or fulminant liver failure may occur[3]. Urgent LT is the only effective treatment[11,12] but is usually denied because of the underlying malignancy. To the best of the authors' knowledge, only a few cases of LT in this particular setting have been reported so far[5,8,13]. This suggests that patients suffering from hematologic diseases seem to constitute a subgroup in which the reoccurrence rate after LT seems to be low. These 2 cases do support these observations. To some extent these observations can be explained by the new treatment possibilities and the recent outcome improvements that have been made over the last few decades in the management of hematologic diseases. New chemotherapy regimens, as well as new methods (e.g. PET) to assess the efficiency of ongoing treatments, are being continuously developed, allowing tailored therapies for each patient, rendering this condition highly curable. Current studies suggest that an escalated BEACOPP regimen is the treatment of choice for advanced Hodgkin lymphoma, and has an overall chance of 96% to achieve full remission with a 5 year survival rate peaking at 92%[14-16]. Other complications such as veno-occlusive disease or graft-*versus*-host disease following bone marrow transplantation may also cause terminal liver failure in patients treated for hematologic malignancies. Though experience is limited, reports indicate that LT may also be a feasible and effective approach in such cases[17-19].

Recurrence of the underlying preexisting malignancy may occur after LT, promoted by the necessary immunosuppression and by a direct effect of calcineurin inhibitors[4,20]. However, in cancer patients with good prognosis, as in the 2 lymphoma patients described here, LT may be life-saving. In the absence of large studies, each patient should be assessed individually to evaluate if organ transplantation can be beneficial in terms of survival and quality of life. Further studies with longer follow-up are needed to establish prognostic factors to identify those patients in whom LT can be considered as an effective approach.

Abstract

Biliary cystic tumors, such as cystadenomas and cystadenocarcinomas, are rare cystic tumors of the liver, accounting for less than 5% of all intrahepatic cysts of biliary origin. Biliary cystadenomas have been known to occur predominantly in women (> 85%), and 38%-44% of biliary cystadenocarcinomas have occurred in males. We wrote this letter to comment on a brief article (*World J Gasteroenterol* 2011 January 21; 17(3): 361-365) regarding a case of intrahepatic biliary cystic neoplasm treated with surgery. The adenoma-carcinoma sequence is the possible mechanism of carcinogenesis. If the carcinogenesis of biliary cystadenocarcinoma occurs in the adenoma-carcinoma sequence, we believe that the male-to-female ratio of cystadenoma should be higher than the incidence rate that has been reported to date.

Key words: Biliary cystadenoma; Cystadenocarcinoma; Carcinogenesis; Incidence

TO THE EDITOR

Biliary cystic tumors, such as cystadenomas and cystadenocarcinomas, are rare cystic tumors of the liver, accounting for less than 5% of all intrahepatic cysts of biliary origin. Biliary cystadenomas have been known to occur predominantly in women (> 85%), and this almost exclusively female predominance suggests a strong hormonal influence. Emre *et al*[1]. reported nine patients with intrahepatic biliary cystic liver neoplasms, all of them were female. And 38%-44% of biliary cystadenocarcinomas occur in males with a higher mean age compared with cystadenomas[2].

In spite of the improvement in imaging techniques, the differential diagnosis of simple hepatic cysts and intrahepatic biliary cystadenoma is still problematic.[1] If the malignancy is suspected, surgery is recommended; if benign disease is suspected, many clinicians might misdiagnose cystadenomas as simple cysts and recommend observation and/or follow-up examinations rather than surgical treatment. Cases of biliary cystic neoplasm reported in the literature are diagnosed mostly based on pathologic findings after operation. Thus, we examined whether there may be a bias toward the gender-related incidence of biliary cystadenoma.

Between May 2004 and December 2009, 10 patients underwent surgery for intrahepatic biliary cystic neoplasm at Chonnam National University Hospital, Gwangju, Korea. Eight patients had biliary cystadenomas, and two had cystadenocarcinomas. The patients with cystadenomas consisted of five females (62.5%) and three males (37.5%). Both patients with cystadenocarcinomas were males. In our report, the female predilection of biliary cystadenoma is much weaker than in other reports[1,2].

The role of biliary cystadenoma in the pathogenesis of biliary cystadenocarcinoma is controversial. Transformation into a cystadenocarcinoma has been reported, although it is rare[3]. Thus, the adenoma-carcinoma sequence is a possible mechanism of carcinogenesis. Biliary cystadenomas have been known to occur predominantly in women. If the carcinogenesis of biliary cystadenocarcinoma occurs in the adenoma-carcinoma sequence, we believe that the male-to-female ratio of cystadenoma should be higher than the incidence rate that has been reported until now. The current knowledge and predictions about intrahepatic biliary cystic neoplasms are based on a limited number of case reports. The precise mechanisms of carcinogenesis remain unknown. Thus, accumulation of larger groups of patients and further examinations will be necessary to analyze the pathogenesis and incidence of intrahepatic biliary cystic neoplasms (cystadenomas and cystadenocarcinomas).

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Hepatocellular carcinoma (HCC) is among the most common cancer diseases worldwide. Arterial hypervascularisation is an essential step for HCC tumorigenesis and can be targeted by transarterial chemoembolization (TACE). This interventional method is the standard treatment for patients with intermediate stage HCC, but is also applied as "bridging" therapy for patients awaiting liver transplantation in many centers worldwide. Usually the devascularization effect induced by TACE is transient, consequently resulting in repeated cycles of TACE every 4-8 wk. Despite documented survival benefits, TACE can also induce the up-regulation of proangiogenic and growth factors, which might contribute to accelerated progression in patients with incomplete response. In 2007, sorafenib, a multi-tyrosine kinase and angiogenesis inhibitor, was approved as the first systemic treatment for advanced stage HCC. Other active targeted compounds, either inhibitors of angiogenesis and/or growth factors, are currently being investigated in numerous clinical trials. To overcome revascularisation or tumor progression under TACE treatment it seems therefore attractive to combine TACE with systemic targeted agents, which might theoretically block the effects of proangiogenic and growth factors. Over the last 12 mo, several retrospective or prospective cohort studies combining TACE and sorafenib have been published. Nevertheless, robust results of the efficacy and tolerability of such combination strategies as proven by randomized, controlled trials are awaited in the next two years.

Key words: Hepatocellular carcinoma; Sorafenib; Anti-angiogenesis; Transarterial chemoembolization

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is rising with a world-wide annual incidence above 600 000[1]. Treatment of HCC is challenging because HCC mainly occurs within liver cirrhosis[1], and therapy options and prognosis are determined by tumor biology as well as impaired liver function. Several clinical staging systems have been proposed[2]. However, the most commonly used in Western countries is the Barcelona Clinic Liver Cancer (BCLC) system[3,4]. According to this algorithm, treatment is stratified according to tumor stage, liver function, and performance status. Intermediate stage HCC (BCLC stage B) without options for surgical treatment or ablation is treated by transarterial chemoembolization (TACE). TACE has been shown to expand median survival from 16 to 19-20 mo[5,6]. In patients with advanced (BCLC stage C) and especially end-stage HCC (BCLC stage D), survival depends not only on progression of

tumor disease but depends incremental on accompanying liver dysfunction, also. Without intervention, survival of patients with advanced HCC rarely exceeds 6 mo, and median survival in patients with end-stage HCC (BCLC stage D, Okuda stage Ⅲ, performance status 3-4) is commonly below 3-4 mo[4,7-9]. According to the modified BCLC system, the dual kinase inhibitor sorafenib is considered the standard of care for patients with advanced HCC[10]. However, the survival benefit is limited to approximately 3 mo, whereas disease stabilization can be achieved in 27%-78% as shown in prospective trials[11-14].

Typically, HCC is a hypervascularized tumor with characteristic early arterial enhancement during dynamic imaging, which is the rational for TACE. By TACE, however, mainly central vessels of a tumor nodule are occluded, while progression may occur via neovascularization in the tumor periphery. In theory, this might be prevented or at least attenuated by concomitant systemic treatment with anti-angiogenic agents (Figure 1).

ANGIOGENESIS IN PATHOGENESIS OF HEPATOCELLULAR CARCINOMA

Chronic hepatitis and hepatic fibrogenesis are closely connected to angiogenesis[15]. Different cytokines, growth factors, and metalloproteinases are involved in these processes. Vascular endothelial growth factor (VEGF) was shown to be crucially involved in angiogenesis as well as fibrogenesis[15]. Despite other factors, hepatic tissue hypoxia seems to be a relevant trigger for angiogenesis in necroinflammatory liver disease, especially by induction of VEGF, resulting in increasing arterial contribution to hepatic perfusion[16,17]. At this stage, the majority of neo-vessels originate from the portal vein, supporting short-circuits between the portal vein system and the hepatic veins[16,18]. Despite the predominant occurrence of HCC in liver cirrhosis rather than in non-cirrhotic liver disease[1], it is still unknown whether HCC arises from hepatic stem cells or from hepatocytes *via* malignant transformation. The latter concept is supported by the observation that development of HCC from dysplastic nodules has been described[19,20]. Arterial hypervascularization seems to be pathognomonic for established HCC, and HCC nodules larger than 2 cm regularly show arterial enhancement[21,22]. Therefore, neovascularization seems to be crucial for HCC tumorigenesis.

Consistently, increased expression of angiopoietin-1/-2 mRNA in tumor tissue was reported, suggesting a critical role of neo-vascularisation for HCC pathogenesis[23]. Moreover, augmented expression of VEGF was found in HCC, and higher serum VEGF levels were associated with poor prognosis of patients with HCC[24-29]. In contrast, a recent study showed that neither VEGF-A nor VEGFR were up-regulated in HCC tissue, and angiotensin-1/-2 expression were only modestly changed[30]. Of note, sinusoidal capillarization suggesting vascular remodeling was observed within the same study[30]. These inconsistent data further highlight that tumor angiogenesis is a complex process and most likely heterogeneous. The angiopoietin/VEGF system seems to play an important role in angiogenesis of HCC, but other, yet incompletely understood pathways may also be involved.

THERAPEUTIC INHIBITION OF ANGIOGENESIS IN HEPATOCELLULAR CARCINOMA

Inhibition of angiogenesis is an established and successful treatment strategy in a variety of malignant diseases. The liver is predominantly supplied by the portal venous system, whereas HCC nodules are characterized by typical arterial hypervascularization. This accounts for the rationale for use of hypervascularization as a diagnostic criterion as well as development of angiogenesis inhibition treatment strategies. In the absence of targeted agents, embolization of arterial tumor vessels was established in the 1980s. Currently, TACE is commonly used in patients with HCC BCLC stage 0/A as bridging therapy until liver transplantation and as non-curative therapy in patients with HCC BCLC stage B and C[6].

Indeed, TACE may lead to reduction of tumor vascularization and viable tumor volume[6]. Recently, this has also been confirmed for a modified TACE technique using doxorubicin eluting beads (DEB)[31]. Furthermore, VEGF levels as a surrogate marker for angiogenesis were shown to correlate with therapeutic outcome after TACE. Pretreatment VEGF levels were significantly higher in patients not responding to TACE compared to patients with disease stabilization. Moreover, pretreatment VEGF serum levels > 240 pg/mL were an independent prognostic factor for survival[32].

It has been suggested that tumor progression after TACE may be caused by activation of angiogenesis due to TACE-induced hypoxemia[33]. Plasma VEGF levels were shown to increase shortly after TACE, reaching a peak value one day after TACE[34-37]. Additionally, increase of plasma VEGF levels after TACE was correlated with the development of metastasis and a reduced progression free survival[35,37]. Unfortunately, reliable biomarkers predicting response to TACE are missing. Nevertheless, a median survival of 35 mo has been reported in patients with complete tumor response[38]. In this study low VEGF levels were associated with a longer survival, while higher VEGF levels were detectable in patients without tumor response. Of note, prior TACE was reported to induce angiogenesis in surgical specimens, whereas patients who underwent surgery without prior TACE had no induction of angiogenesis[39]. Whether the use of DEB-TACE, which can induce higher rates of tumor response, also leads to upregulation of proangiogenic factors is under debate[40,41].

Sorafenib, the first systemically agent approved for HCC, is a multikinase inhibitor with activity against VEGFR2, PDGFR, c-Kit receptors, b-RAF, and p38[42], signal transduction pathways which seem to be involved in pathogenesis of HCC[43]. However, there are limita-

[1]Interim analysis; [2]20/50 patients received 2 cycles of transarterial chemoembolization (TACE), only, and 18 of these 20 patients achieved complete response compared to 2 patients with progressive disease. 30/50 patients received more than 2 cycles of TACE and achieved partial response or stable disease; [3]Primary objective of this prospective trial was evaluation of safety and tolerability of a continuous regimen of sorafenib combined with TACE; [4]According to 31 patients who received at least 1 cycle of TACE, 2/31 (6.5%) showed complete response, 15/31 (48.4%) showed partial response, and 11/31 (35.5%) showed stable disease. PFS, TTP, and OS are given for all 44 patients enrolled at time point of interim analysis; [5]Patients who completed DEB-TACE showed 100% objective tumor response and 100% partial response or stable disease according to EASL or RECIST criteria, respectively. DEB-TACE: (Drug eluting beads)-transarterial chemoembolization; NR: Not reported; DS: Disease stabilization (%); OS: Overall survival (mo); PFS/TTP: Progression free survival/time to progression (mo); PFS-6m: Progression free survival rate at 6 mo (%); RR: Response rate [complete + partial response (%)]; SIRT: Selective internal radio therapy.

STRATEGIES FOR COMBINATION OF TACE AND TARGETED AGENTS IN HCC

Combination of local and systemic inhibition of angiogenesis seems to be a consequential step to improve outcome in intermediate and advanced stage HCC[44]. Tolerability of combination therapy with sorafenib and conventional TACE as well as DEB-TACE was shown within different trials[45-49]. Currently, the combination of conventional TACE and sorafenib as well as combination of sorafenib and DEB-TACE (SPACE trial) is being evaluated in phase Ⅱ and Ⅲ trials[50]. Moreover, sorafenib was combined with selective internal radiation therapy within a multicenter phase Ⅱ study showing good efficacy in patients with advanced HCC but without extra-hepatic metastasis[45]. So far, no increased toxicity has been reported. The combination of brivanib, a dual VEGFR and fibroblast growth factor inhibitor[51], and TACE is currently evaluated within the multicenter phase Ⅲ BRISK TA Study.

Another interesting approach could be the inhibition of VEGF driven angiogenesis by targeting VEGF with siRNA as shown in a proof-of-concept study recently[52]. Furthermore, promising results were reported for other agents alone or in combination with TACE, e.g. tegafur/uracil, the multi-tyrosine kinase inhibitor TSU-68, sunitinib, erlotinib, and the VEGF antibody bevacizumab[53-57]. However, none of these agents is approved for HCC. Of these, bevacizumab is the currently most commonly clinical used VEGF inhibitor in a variety of malignant entities. However, despite encouraging results in earlier trials, even as single agent treatment, bleeding complications were reported in up to 11% of patients treated with bevacizumab[58]. For the combination of bevacizumab with TACE, severe bleeding and septic complications have been reported in 25% of patients, and the AVATACE-1 trial investigating TACE in combination with bevacizumab has been terminated due to safety concerns in the treatment arm, which does not justify a further clinical development of bevacizumab in this indication. This highlights that large phase Ⅲ trials are required for new agents in HCC, which seems challenging given the increasing number of phase Ⅰ and Ⅱ studies addressing HCC in the last years (Tables 1-3).

In summary, inhibition of angiogenesis in HCC seems a very promising approach for future treatment

of HCC. Multimodal approaches with combination of local and systemic therapy may further improve survival in intermediate and advanced stage HCC.

Abstract

Nonalcoholic fatty liver disease (NAFLD) encompasses a range of liver histology severity and outcomes in the absence of chronic alcohol use. The mildest form is simple steatosis in which triglycerides accumulate within hepatocytes. A more advanced form of NAFLD, nonalcoholic steatohepatitis, includes inflammation and liver cell injury, progressive to cryptogenic cirrhosis. NAFLD has become the most common cause of chronic liver disease in children and adolescents. The recent rise in the prevalence rates of overweight and obesity likely explains the NAFLD epidemic worldwide. NAFLD is strongly associated with abdominal obesity, type 2 diabetes, and dyslipidemia, and most patients have evidence of insulin resistance. Thus, NAFLD shares many features of the metabolic syndrome (MetS), a highly atherogenic condition, and this has stimulated interest in the possible role of NAFLD in the development of atherosclerosis. Accumulating evidence suggests that NAFLD is associated with a significantly greater overall mortality than in the general population, as well as with increased prevalence of cardiovascular disease (CVD), independently of classical atherosclerotic risk factors. Yet, several studies including the pediatric population have reported independent associations between NAFLD and impaired flow-mediated vasodilatation and increased carotid artery intimal medial thickness-two reliable markers of subclinical atherosclerosis-after adjusting for cardiovascular risk factors and MetS. Therefore, the rising prevalence of obesity-related MetS and NAFLD in childhood may lead to a parallel increase in adverse cardiovascular outcomes. In children, the cardiovascular system remains plastic and damage-reversible if early and appropriate interventions are established effectively. Therapeutic goals for NAFLD should address nutrition, physical activity, and avoidance of smoking to prevent not only end-stage liver disease but also CVD.

Key words: Nonalcoholic fatty liver disease; Metabolic syndrome; Cardiovascular risk; Children

INTRODUCTION

Over the last two decades, the rise in the prevalence rates of overweight and obesity may explain the emergence of nonalcoholic fatty liver disease (NAFLD) as the leading

cause of liver disease in pediatric populations worldwide[1]. NAFLD comprises a disease spectrum ranging from simple steatosis to steatohepatitis (NASH), with varying degrees of inflammation and fibrosis, progressing to end-stage liver disease with cirrhosis and hepatocellular carcinoma[2,3]. NAFLD affects from 2.6% to 9.8% of children and adolescents, and this figure increases up to 74% among obese individuals[4-8]. NAFLD is strongly associated with obesity, insulin resistance, hypertension, and dyslipidemia, and is now regarded as the liver manifestation of the metabolic syndrome (MetS)[9], a highly atherogenic condition. When compared to control subjects who do not have steatosis, patients with NAFLD have a higher prevalence of atherosclerosis, as shown by increased carotid wall intimal thickness, increased numbers of atherosclerotic plaques, and increased plasma markers of endothelial dysfunction, that are independent of obesity and other established risk factors[10-13]. Consistent with these observations natural history studies have reported that the increased age-related mortality observed in patients with NAFLD is attributable to cardiovascular as well as liver-related deaths[14-17].

Pathologic studies have shown that atherosclerosis is an early process beginning in childhood, with fatty streaks observed in the aorta and the coronary and carotid arteries in children and adolescents[18,19]. There is a positive correlation between the extent of early atherosclerotic lesions in the aorta and the coronary and carotid arteries and cardiovascular risk factors, including obesity, dyslipidemia, hypertension, and diabetes[20-22]. Yet the exposure to cardiovascular risk factors of children and adolescents is independently associated with an increased carotid atherosclerosis in early to middle adulthood[23,24]. Thus, the possible impact of NAFLD on cardiovascular disease (CVD) deserves particular attention in view of the implications for screening/surveillance strategies in the growing number of children and adolescents with NAFLD. In the present review, we examine the current evidence on the association between NAFLD and atherosclerosis in the pediatric population, discuss briefly the possible biological mechanisms linking NAFLD and early vascular changes, and address the approach to treatment of NAFLD to prevent not only end-stage liver disease but also CVD.

NAFLD AND THE METABOLIC SYNDROME

NAFLD is closely associated with abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance and impaired glucose tolerance, which are all features of the MetS. Approximately 90% of patients with NAFLD have at least one of the features of MetS, and about 33% meet the complete diagnosis, placing NAFLD as the hepatic representation of MetS[25]. The relationship of NAFLD with MetS features has been confirmed in adults in several studies[9,26-29]. Evidence for a relationship between MetS and NAFLD in children is also emerging[30-32]. The Korean National and Nutrition Examination Survey found that participants aged 10-19 years who presented with three or more risk factors for MetS, had an odds ratio (OR) of 6.2 (95% CI, 2.3-16.8) for an elevated serum alanine aminotransferase (ALT), which they used as an indicator of fatty liver[30]. A single center study from Italy reported MetS to be present in 65.8% of children (3-18 years) with biopsy-proven NAFLD and found grade of fibrosis to be the only histological feature significantly associated with MetS on univariate analysis[31]. A case-control study comparing 150 overweight children with biopsy-proven NAFLD to 150 age-, sex-, and obesity-matched children without evidence of NAFLD, found that, after adjustment for age, sex, race, ethnicity, and hyperinsulinemia, children with MetS had an OR of 5.0 (95% CI, 2.6-9.7) for NAFLD compared with children without MetS[32]. This is the most compelling data to support a significant relationship between NAFLD and MetS, not explicable merely by the coexistence of overweight or obesity in these two conditions, and lend support to the hypothesis that fat accumulation in the liver has an important role in the pathogenesis of other obesity-related comorbidities[33].

NAFLD AND CARDIOVASCULAR DISEASE

Increases in morbidity and mortality from CVD are probably among the most important clinical features associated with NAFLD[13]. Published studies have shown that mortality among patients with NAFLD is higher than that in the general population, mainly due to concomitant CVD and liver dysfunction[14-17]. Using the resources of the Rochester Epidemiology Project, Adams *et al*[14] conducted a population-based cohort study to examine the natural history of patients diagnosed with NAFLD on the basis of imaging studies (83%) or liver biopsy (17%). Mean (SD) follow-up was 7.6 (4.0) years culminating in 3192 persons/years follow-up. Death occurred in 12.6% of patients and was most commonly due to malignancy and ischemic heart disease, which were also the two most common causes of death in the Minnesota general population of the same age and sex. Liver disease was also an important contributor of death among patients with NAFLD, being the third most common cause and accounting for 13% of all deaths. In contrast, "chronic liver disease and cirrhosis" was the 13th leading cause of death among the Minnesota general population, accounting for less than 1% of all deaths[14]. This implies that the increased overall mortality rate among NAFLD patients compared with the general population was at least in part due to complications of NAFLD. In a cohort study involving 129 consecutively enrolled patients diagnosed with biopsy-proven NAFLD, Ekstedt *et al*[15] compared survival and causes of death with a matched reference population. Mean follow-up (SD) was 13.7 (1.3) years. Mortality was not increased in patients with steatosis. In contrast, survival of patients with NASH was significantly reduced. A comparison of the causes of death of patients with NASH with those of the corresponding reference population showed it was significantly more common for patients with NASH to die from liver-related causes (2.8% *vs* 0.2%) and from cardiovascular disease

(15.5% *vs* 7.5%). No significant differences in causes of death were found between non-NASH patients and the corresponding reference population[15]. In a cohort study involving 173 patients retrospectively identified as having a diagnosis of biopsy-proven NAFLD, Rafiq *et al*[16] showed that after a median follow-up of 18.5 years, patients with histologic NASH had significantly higher liver-related mortality than the non-NASH NAFLD cohort (17.5% *vs* 2.7%). The most common causes of death were coronary artery disease, malignancy, and liver-related death. In a very recent study involving a cohort of 118 subjects with NAFLD who underwent liver biopsy because of elevated liver enzymes, Söderberg *et al*[17] confirmed that, after a 28-year follow-up, overall survival was reduced in subjects with NASH, whereas bland steatosis with or without severe fibrosis was not associated with any increase in mortality risk in comparison with the general population. The main causes of death among patients with NAFLD were CVD, followed by extrahepatic cancers and hepatic diseases. All these data provide evidence of an increased risk for cardiovascular mortality in patients with NASH. However, most studies which examined the natural history of NAFLD were retrospective cohort studies with relatively small numbers of patients with histologically proven NAFLD who were seen at tertiary referral centers - features that limit the generalizability of the findings to a community-based practice where patients may have a milder disease. Indeed, among people with NAFLD, those who are referred to hepatologists may have a more advanced liver disease than those detected in the community or population based screening but are not referred. Therefore, the magnitude of mortality risk in NAFLD depends on the setting and method of ascertainment. Future longitudinal studies with larger and less selected cohorts of patients are needed to identify through reliable, noninvasive means the true impact of the wide spectrum of NAFLD in the general population on the long-term overall and cardiovascular mortality.

Data on the prognosis and clinical complications of NAFLD in children remain scant[3]. Although coronary artery disease and stroke usually occur in middle and late age, autopsy studies have shown that the atherosclerotic process in the vascular wall begins in childhood and is accelerated in the presence of risk factors[18-24]. Given the large number of children affected, it is imperative that we establish a better understanding of the natural history of pediatric NAFLD in terms of the progression of liver disease as well as its complications (including long-term cardiovascular risk profile). Feldstein *et al*[34] recently reported the first longitudinal study describing the long-term survival of children with NAFLD who underwent a follow-up of up to 20 years. That study demonstrated that NAFLD in children is a disease of progressive potential. Some children presented with cirrhosis, others progressed to advanced fibrosis or cirrhosis during follow-up, and some developed end-stage liver disease with the consequent need for liver transplantation. Feldstein *et al*[34] also showed that NAFLD in children is associated with significantly shorter long-term survival than the expected survival in the general population of the same age and sex. Children with NAFLD had a 13.8-fold higher risk of dying or requiring liver transplantation than the general population of the same age and sex. The recorded deaths were not liver-related.

Recent epidemiological studies in adult subjects have also demonstrated that NAFLD is associated with an increased risk of incident CVD that is independent of the risk conferred by traditional risk factors and components of the MetS[35-42]. Yet, several studies (including the pediatric population) have reported independent associations between NAFLD and impaired flow-mediated vasodilatation (FMD) and increased carotid-artery intimal medial thickness (cIMT) - two reliable markers of subclinical atherosclerosis - after adjusting for cardiovascular risk factors and MetS[10,12,43-47].

NAFLD AND MARKERS OF SUBCLINICAL ATHEROSCLEROSIS IN CHILDREN

The relation between obesity and atherosclerosis development has been evaluated in many pediatric studies[48], but few studies focused on the relation between NAFLD and atherosclerosis (Table 1)[32,47,49-56]. In an autopsy study involving 817 children (aged 2 to 19 years) who died of external causes (accident, homicide, suicide) from 1993 to 2003, Schwimmer *et al*[49] showed that the prevalence of atherosclerosis was increased by a factor of 2 among those with NAFLD. Atherosclerosis was assessed as absent, mild (aorta only), moderate (coronary artery streaks/plaques), or severe (coronary artery narrowing). Fatty liver was present in 15% of the children. For the entire cohort, mild atherosclerosis was present in 21% and moderate to severe atherosclerosis in 2%. Atherosclerosis was significantly more common in children with fatty liver than those without the disease (30% *vs* 19%, $P < 0.001$). Body mass index (BMI) was not independently correlated to the presence of atherosclerosis, but fatty liver status and BMI did interact significantly ($P < 0.01$). Consequently, for obese subjects the odds of having atherosclerosis was more than 6 times higher in children with fatty liver than those without[49].

Despite this, there are currently few data regarding the possible association between liver histopathologic changes and atherogenic risk in children[32,52,56]. In the Bogalusa heart study in children, investigators found that the extent to which the intimal surface was covered with atherosclerotic lesions was significantly associated with elevation of concentrations of total cholesterol (TC), low-density lipoprotein cholesterol (LDL-c), triglycerides (TG), and lower concentration of high-density lipoprotein cholesterol (HDL-c). Ratios of cholesterol ester-rich lipoprotein level (TC/HDL-c and LDL-c/HDL-c) are well-established predictors of C VD[57]. More recently, the TG/HDL-c ratio has been shown to be a strong predictor of MetS and CVD[58,59]. In a case-control study, Schwimmer *et al*[32] showed that children with a biopsy-proven NAFLD had a significantly higher fasting glucose, insulin, TC, LDL-c,

Table 1 Published studies on the association between nonalcoholic fatty liver disease and markers of atherosclerosis in the pediatric population

Authors	Study population and sample size (No.)	Diagnosis	Outcomes	Main results
Schwimmer *et al*[49]	Children (817) who died of external causes (accident, homicide, suicide) from 1993 to 2003. Fatty liver was present in 15% of the children	Autoptic liver biopsy	Atherosclerosis was assessed as absent, mild (aorta only), moderate (coronary artery streaks/plaques), or severe (coronary artery narrowing)	For the entire cohort, mild atherosclerosis was present in 21% and moderate to severe atherosclerosis in 2%. Atherosclerosis was significantly more common in children with fatty liver than those without the disease (30% *vs* 19%; $P < 0.001$)
Schwimmer *et al*[32]	Overweight children with (150) and without (150) NAFLD matched for gender, age, and severity of obesity	Liver biopsy	Prevalence of cardiovascular risk factors (abdominal obesity, dyslipidemia, hypertension, insulin resistance, and glucose abnormalities)	NAFLD was strongly associated with multiple cardiovascular risk factors independently of both BMI and hyperinsulinemia
Pacifico *et al*[50]	Obese children with (29) and without (33) NAFLD; Healthy lean children (30)	Liver ultrasound	cIMT	cIMT was significantly higher in obese children with NAFLD compared with obese children without NAFLD and control group. Yet, the severity of fatty liver was associated with cIMT independently of anthropometric and metabolic features
Demircioglu *et al*[51]	Obese children with mild (32), moderate-severe (22) NAFLD, and without NAFLD (26); Healthy lean subjects (30) matched for age and gender	Liver ultrasound	cIMT	cIMT measured at left sites of common carotid artery, carotid bulb, and internal carotid artery was significantly higher in obese children compared with controls. Moreover, there was an increase in the mean cIMT of each segment with the increase in steatosis grade
Kelishadi *et al*[54]	Obese adolescents with (25) and without (25) components of MetS; Normal weight adolescents with (25) and without (25) components of MetS	Liver ultrasound and elevated ALT	cIMT	cIMT was significantly associated with insulin resistance and NAFLD
Manco *et al*[52]	Overweight and obese children with (31) and without (49) NAFLD matched for gender, age, and BMI	Liver biopsy	cIMT	cIMT was similar in cases and controls on the right side but significantly higher on the left site. There was no association between cIMT and severity of steatosis as well as fibrosis, and NAFLD activity score
Caserta *et al*[53]	Randomly selected adolescents (642) of whom 30.5% and 13.5% were, respectively, overweigth and obese. Overall prevalence of NAFLD, 12.5%	Liver ultrasound	cIMT	NAFLD, BMI (or waist circumference) and systolic blood pressure were independently associated with increased cIMT
Nobili *et al*[56]	Children with NAFLD (118)	Liver biopsy	Atherogenic lipid profile (TG/HDL-c, TC/HDL-c, and LDL-c/HDL-c ratios)	The severity of liver injury was strongly associated with a more atherogenic lipid profile, independently of BMI, insulin resistance, and presence of MetS
Pacifico *et al*[47]	Obese children with (100) and without (150) NAFLD; Healthy lean children (150)	Liver ultrasound and elevated ALT	cIMT and FMD	Obese children had more functional and morphologic vascular changes than healthy lean controls, regardless of liver involvement. However, obese children with NAFLD had significantly decreased FMD response and increased cIMT compared to obese children without NAFLD independently of other cardiovascular risk factors and MetS
Weghuber *et al*[55]	Obese children with (14) and without (14) NAFLD	Proton MR spectroscopy	FMD	FMD was comparable between the two groups

NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; cIMT: Carotid intima-media thickness; TG: Triglycerides; HDL-c: High-density lipoprotein cholesterol; TC: Total cholesterol; LDL-c: Low--density lipoprotein cholesterol; ALT: Alanine aminotransferase; FMD: Flow mediated dilation; MetS: Metabolic syndrome; MR: Magnetic resonance.

TG, systolic and diastolic blood pressure than age-, sex-, and BMI-matched peers without NAFLD. These data confirm that fat accumulation in the liver may play a more important role than obesity itself in determining the risk for "weight-related" metabolic comorbidities[33]. Thus, the authors concluded that NAFLD may serve as a marker to stratify the cardiovascular risk of overweight and obese children and adolescents[32]. Furthermore, in a study involving 118 consecutive children with biopsy-proven NAFLD undergoing extensive metabolic profiling, Nobili and colleagues found that the NAFLD activity and fibrosis scores had a significant positive correlation with TG/HDL-c, TC/HDL-c, and LDL-c/HDL-c ratios[56]. After adjusting for potential confounders including BMI, homeostatic model assessment index, impaired glucose tolerance, and presence of MetS, both NAFLD activity

score and stage of fibrosis remained independent predictors of an atherogenic lipid profile. The lipid ratios were found to be markedly higher in children with established NASH compared with those patients with simple steatosis or borderline disease, indicating that severity of liver injury in children with NAFLD is strongly associated with increased atherogenic risk[56].

Recent improvements in imaging technology have identified early vascular changes that can be assessed by the use of ultrasonography. These early changes include impairment of FMD, arterial stiffness, and increased cIMT. The measurement of FMD and cIMT by high-resolution ultrasound is increasingly used for cardiovascular risk evaluation in young individuals with obesity, MetS or its components, and pre-diabetes[23,60,61]. Pacifico *et al*[50] first showed that the severity of ultrasonographically diagnosed NAFLD in obese children was significantly associated with carotid atherosclerosis, independently of anthropometric and metabolic features. Demircioglu *et al*[51], in a subsequent study, also found an association between ultrasonographically detected NAFLD and cIMT measured at sites of the common carotid artery, carotid bulb and internal carotid artery. In addition, there was an increase in the mean of cIMT of each segment with the increase in hepatosteatosis grade[51]. Kelishadi *et al*[54] also demonstrated that cIMT was significantly associated with insulin resistance and NAFLD, suggesting that the liver and the vessels share common mediators. This is in contrast to the case-control study by Manco *et al*[52] including a mixed population of overweight and mildly obese children of whom 31 had biopsy-proven NAFLD, whereas 49 had no ultrasound evidence of NAFLD and no abnormal levels of aminotransferases. Although cIMT was statistically significantly higher on the left side in NAFLD cases, the authors concluded that this difference was unlikely to be clinically relevant because of the substantial overlap of cIMT values between cases and controls. Also, there were no differences in the frequency of MetS components between the groups. Finally, there was no association between histologic severity of NAFLD and cIMT[52]. However, a recent study by Patton *et al*[30] showed the potential power of MetS as a prognostic indicator of disease severity in NAFLD. Of the MetS features, central obesity and insulin resistance were most consistently associated with NAFLD histology[30].

The association between NAFLD and carotid atherosclerosis has also been determined in a large, randomly selected adolescent population from Reggio Calabria, a town in southern Italy[53]. The authors found that NAFLD, BMI, waist circumference, and systolic blood pressure were independent markers of increased cIMT. Likewise, in a very recent study with a large sample size it has been shown that obese children with NAFLD have a significantly lower FMD response and increased cIMT compared to obese children without NAFLD independently of other cardiovascular risk factors and MetS, and that obese children exhibit more functional and morphologic vascular changes than healthy lean controls, regardless of liver involvement[47]. The larger number of subjects in that study may in part account for the associations the authors were able to identify between NAFLD and functional vascular changes, in contrast to the study by Weghuber *et al*[55]. in which a very small sample of obese children with and without NAFLD had a similar FMD response.

Although longitudinal studies are needed to clarify the extent to which pediatric NAFLD and its severity influence long-term cardiovascular outcomes in the general population, overall the above cross-sectional findings suggest that childhood NAFLD is associated with early atherosclerosis.

POSSIBLE BIOLOGICAL MECHANISMS LINKING NAFLD AND ACCELERATED ATHEROSCLEROSIS

The biologic mechanisms by which NAFLD contributes to accelerated atherosclerosis, independently of other risk factors, are still poorly understood. Increased visceral adipose tissue and insulin resistance are the undisputed major contributors to NAFLD, MetS, and atherosclerosis[9,62,63]. The adipose tissue inflammation with consequent release of multiple proinflammatory molecules is one of the earliest steps in the chain of events involved in the development of insulin resistance and atherosclerosis, in particular in obese and overweight persons[64-66]. While insulin resistance promotes fatty acid accumulation in the liver, the latter causes hepatic insulin resistance characterized by a lack of suppression of endogenous liver glucose production. Therefore, NAFLD might act as a stimulus for further increased whole-body insulin resistance and dyslipidemia (with a characteristic overproduction of triglyceride- and cholesterol-rich remnant particles), leading to accelerated atherosclerosis[33]. It is also conceivable that other atherogenic mechanisms could be involved in patients with NAFLD including enhanced oxidative stress and chronic, subclinical inflammation, which are thought to be causal factors in the progression from simple steatosis to more advanced forms of NAFLD[27-29,62]. Indeed, patients with NAFLD frequently have higher plasma markers of oxidative stress and inflammation, at least partially derived from the diseased liver, as well as decreased adiponectin concentrations, an adipose-secreted cytokine with antiatherogenic properties[11,67-69].

Recent research has suggested a role for increased fructose consumption as a risk factor for NAFLD[70,71]. Strong evidence exists that fructose consumption may promote hepatic de novo lipogenesis and intrahepatic lipids, inhibition of mitochondrial β-oxidation of long-chain fatty acids, triglyceride formation and steatosis[72]. In addition, compared to glucose consumption, sustained dietary fructose has been reported to significantly increase plasma concentrations of fasting small dense LDL-c, oxidized LDL-c, and postprandial remnant-like-particle-triglyceride and -cholesterol in overweight and obese subjects[73]. These changes may be associated with increased risk of CVD[74,75].

Finally, NAFLD could be linked to accelerated athero-

genesis through the presence of abnormal lipoprotein metabolism, especially during the post-prandial phase[76,77]. Apolipoprotein (APO) B is a large protein involved in the transport of triglycerides and cholesterol from the liver to peripheral tissues. Diminished synthesis of APO B, a rate-determining step in the very low density lipoproteins (VLDL) assembly, would impair the ability of the hepatocyte to export triglycerides and cholesterol esters. Impaired VLDL secretion would also result in increased levels of atherogenic triglyceride- and cholesterol-rich remnant particles. Recent studies have suggested a genetic basis for abnormal lipoprotein metabolism in patients with NAFLD. Two single-nucleotide polymorphisms in the gene encoding APOC3 may be associated with hypertriglyceridemia[78-80]. APOC3 variants C-482T and T-455C lead to increased plasma concentrations of APOC3, which in turn inhibit lipoprotein lipase and triglyceride clearance, thus conferring a predisposition to both fasting and postprandial hypertriglyceridemia due to an increase in chylomicron-remnant particles[81].

THERAPEUTIC APPROACH

The only accepted therapy for pediatric NAFLD is lifestyle modification with diet and physical exercise. The close association of NAFLD with MetS and obesity in children provides the rationale for the therapeutic role of weight reduction in the treatment of fatty liver disease. Fortunately, this approach may also be beneficial in improving cardiovascular risk profile.

Weight-loss oriented lifestyle interventions in the overweight pediatric population have been shown to increase glucose tolerance and improve the MetS risk factors[82]. In children with presumed NAFLD, several studies demonstrate a normalization of serum ALT associated with weight loss[5,83,84]. However, the relative efficacy of weight loss and degree of weight loss needed to induce histologic improvement in pediatric NAFLD is unknown. Studies in adults with NAFLD suggest that weight loss also leads to significant improvement in liver histology. In particular, a weight loss greater than 5% has been associated with significant improvement in liver histology[85]. There is only one clinical trial using liver histology as the primary end point in children and adolescents with NAFLD[83]. The study demonstrated that 2 years of lifestyle intervention with a diet tailored on individual caloric requirement and increased physical activity was associated with a mean weight loss of approximately 5 kg, resulting in a significant improvement in liver histology as well as in insulin resistance, serum levels of aminotransferases, and lipid levels. No information exists on recommending any type of diet. A low-carbohydrate diet has been shown to lead to a reduction in serum ALT and fatty liver content in adult patients[86]. A randomized controlled study in obese adolescents has demonstrated that a diet based on a reduced glycemic load is more effective than a low fat diet in achieving weight loss[87], but similar data are not available in children with NAFLD. Current data on the role of a low fructose diet in children with NAFLD are inconclusive[71]. A 6-month pilot study in children with NAFLD showed that a low fructose diet was associated with a significant decrease in oxidized LDL-c[88]. However, no effect on serum ALT concentrations was found. N-3 long-chain polyunsaturated fatty acids (LCPUFA) including eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have been reported to control some of the metabolic stigmata of obesity[89]. Dietary N-3 LCPUFA lower blood triglycerides and have anti-inflammatory as well as insulin-sensitizing effects[89]. A recent randomised clinical trial has shown that the supplementation of DHA improves liver steatosis and insulin sensitivity in children with NAFLD[90]. Their role in prevention of CVD is also emerging[91]. At this time, however, the available information is insufficient to derive dietary intake recommendations for EPA and DHA[92]. Finally, diet duration and amount of weight loss have not been definitively assessed in children[83,93,94].

A general consensus exists about the key role of physical activity and its synergic effect when combined to diet modifications. Increasing energy expenditure is an additional way to reducing daily calories. Liver biopsy has shown improvement of histologic features in children with NAFLD who were engaged in a moderate daily exercise program (45 min/d aerobic physical exercise) associated to dietary changes[83].

Owing to the likely role of insulin resistance and oxidative stress in the development and progression of NAFLD, most studies on pharmacological treatment have focused on the use of metformin or antioxidants. These drugs have been found to be effective in pilot studies[5]. Recently, in a multicenter, randomized, placebo-controlled clinical trial of treatment with metformin, vitamin E, or placebo for 96 wk in 173 nondiabetic children with histologically confirmed NAFLD, the Nonalcoholic Steatohepatitis Clinical Research Network found that compared with placebo, neither vitamin E nor metformin was associated with a sustained reduction in serum ALT[95,96]. Compared to placebo, vitamin E significantly improved hepatocellular ballooning and NAFLD activity score and, in the subset of children with NASH at baseline, significantly increased resolution of NASH. Metformin had no significant effect on any secondary histologic outcome[96]. Neither vitamin E nor metformin had significant effects on fibrosis, lobular inflammation, or portal inflammation scores. No significant differences in safety were reported between groups[96]. However, the likelihood that vitamin E would need to be taken indefinitely[97] underlines the importance of long-term prospective studies involving patients with NASH to assess the effect of vitamin E on liver-related and cardiovascular mortality[98].

Given the role of obesity in the pathogenesis of NAFLD, bariatric surgery has been proposed as a potential treatment strategy. In obese adult patients, bariatric surgery has been shown to induce weight loss, ameliorate cardiovascular risk factors, resolve hepatic steatosis and, in most studies, inflammation[99-101]. NASH was improved in the majority of affected patients and was intimately associ-

ated with insulin resistance over both the short and long term[101]. The issue of NAFLD and bariatric surgery in children is complex[71]. Though adolescents are increasingly undergoing surgical treatment of obesity, the guidelines for eligibility are not standardized[102]. In addition, children with a clinical diagnosis of NAFLD are different from those typically undergoing bariatric surgery[103]. Children with a clinical diagnosis of NAFLD tend to be younger and less obese than adolescents undergoing surgical treatment of obesity[103]. Although several studies report resolution or improvement of comorbidities after bariatric surgery in adolescents[104,105], liver outcome data are needed. In a series of 41 adolescents, Nadler *et al*[105] reported improvement in liver function enzymes 1 to 2 years after surgery.

CONCLUSION

The current body of evidence suggests that NAFLD is associated with a significantly greater overall mortality than in the general population, as well as with increased CVD prevalence, independently of classical atherosclerotic risk factors. These observations raise the possibility that NAFLD may be not only a marker but also an early mediator of atherosclerosis.

Children with NAFLD may also be at a higher risk for atherosclerosis. Therefore, the rising prevalence of obesity-related MetS and NAFLD in childhood may lead to a parallel increase in adverse cardiovascular outcomes. In children, the cardiovascular system remains plastic and damage-reversible if early and appropriate interventions are established effectively. Therapeutic goals for NAFLD should address nutrition, physical activity and avoidance of smoking to prevent not only end-stage liver disease but also CVD.

Abstract

Chronic inflammation is thought to be the leading cause of many human cancers including colorectal cancer (CRC). Accordingly, epidemiologic and clinical studies indicate that patients affected by ulcerative colitis and Crohn's disease, the two major forms of inflammatory bowel disease, have an increased risk of developing CRC. In recent years, the role of immune cells and their products have been shown to be pivotal in initiation and progression of colitis-associated CRC. On the other hand, activation of the immune system has been shown to cause dysplastic cell elimination and cancer suppression in other settings. Clinical and experimental data herein reviewed, while confirming chronic inflammation as a risk factor for colon carcinogenesis, do not completely rule out the possibility that under certain conditions the chronic activation of the mucosal immune system might protect from colonic dysplasia.

Key words: Colorectal cancer; Inflammation; T cells; Cytokines; Immunosurveillance

INTRODUCTION

Chronic inflammation is thought to be the leading cause of many human cancers including colorectal cancer (CRC). Ulcerative colitis (UC) and Crohn's disease (CD), the two major forms of inflammatory bowel disease (IBD), are associated with an increased risk of developing colitis-associated colorectal cancer (CAC). The risk of CRC in UC patients is 2% after 10 years, 8% after 20 years and 18% after 30 years of active disease[1]. Although more recently other studies have estimated a lower risk in this class of patients, the overall incidence rate ratio for developing CRC calculated in UC patients was found by Bernstein *et al*[2] to be 2.75 [95% confidence interval (95% CI), 1.91-3.97] compared to the general population.

While the relationship between UC and CRC is well established, the risk associated with CD has been unclear until recently. Indeed, the heterogeneous nature of CD which can involve any part of the gut in a non-continuous way, with many patients having no colonic involvement, makes it difficult to estimate the actual risk of developing CRC in these patients. A milestone Swedish study demonstrated a relative risk of CRC of 5.6 for CD patients with exclusive localization in the colon and 3.2 for patients with ileo-colitis[3]. In contrast, patients with exclusive ileal localization of the disease had no increased risk. A meta-analysis of CRC risk in CD revealed an overall relative risk of 2.5 (95% CI, 1.3-4.7)[4]. In the subset of patients with exclusive colonic

localization, the risk was 4.5 (95% CI, 1.3-14.9) while the risk in patients with ileal disease was not significantly increased. Interestingly, when comparing Crohn's colitis with UC of similar extent, the relative risk of developing CRC is similar between the two groups.

Several risk factors concur to determine the probability of developing CRC in single patients. The observation that the cumulative risk increases over the years indicates that disease duration does play a role[1,3]. In addition, the extension of the disease has been shown to increase the risk of CAC; this being 1.7 in patients with ulcerative proctitis, 2.8 in those with left-sided colitis and 14.8 in patients with extensive colitis[3]. Also, the severity of inflammation independently correlates with the risk of developing CAC[5]. The same independent risk factors have been linked to the risk of developing CRC in CD. In addition, in CD patients, perianal disease, bypasses and strictures might be sites of increased risk of neoplastic transformation[6-8].

Overall, these data indicate that chronic inflammation of the colon such as that observed during either UC or CD increases the risk of developing CRC. However, the mechanisms involved in this process are still poorly understood. The current opinion regarding the pathogenesis of IBD is that, in genetically susceptible individuals, there is an overreaction of the immune system toward antigens of the gut microbiota leading to chronic inflammation[9]. UC and CD are characterized by different immune responses. While UC is caused by an atypical T helper (Th)2-mediated immune response characterized by high levels of IL-5 (but not IL-4) and IL-13, in CD there is a prevalent activation of Th1 cells with high expression of TNF-α and IFN-γ[10-13]. More recently, a new subset of IL-17-producing T helper cells, the Th17 cells, has been shown to play a role in the pathogenesis of CD[14,15]. Finally, in addition to CD4+ T cells, CD8+ T cells, natural killer, natural killer T cells and regulatory T cells have also been implicated in the pathogenesis of IBD[16-18].

Given the role played by these cell subsets and by the cytokines they express in the induction and maintenance of gut inflammation, their role has also been investigated in the pathogenesis of CAC. Here we review some of the recent data that implicate immune cells and inflammatory cytokines in the pathogenesis of CAC.

INFLAMMATION AND TUMOR INITIATION: A DOUBLE-EDGED SWORD

Chronic inflammation is thought to induce dysplasia by inducing DNA modifications in intestinal epithelial cells. Indeed, chronic accumulation of activated immune cells such as neutrophils, macrophages and dendritic cells is accompanied by the release of oxygen and nitrogen reactive species, which are known to induce genomic mutations[19,20]. Moreover, chronic inflammation is associated with DNA methylation and histone modification[21-23]. All these processes have been associated with the altered expression of genes involved in carcinogenesis such as *p53, APC, K-ras* and *Bcl-2*[24]. Once initiated, dysplastic cells are subjected to the effect of cell-derived growth factors and cytokines which contribute to tumor growth. However, lines of evidence have also indicated that, under certain conditions, immune cell subsets and cytokines fight to maintain dysplastic cells in check thus preventing tumor progression. A change in the immune response and/or an adaptation to the selective pressure of the immune system, referred to as immune-editing, at a certain point will select dysplastic cell clones able to grow sustained by the presence of growth factors and proinflammatory cytokines released in the surrounding microenvironment, thus changing the role of the immune system from a negative regulator of tumor growth to cancer promoter[25]. Although most of the data sustaining this mechanism derive from models of sporadic cancer, it is possible that a similar alteration of the balance between immune system and dysplastic cells might also occur during long-standing intestinal inflammation.

CD4+ T cells and colitis-associated carcinogenesis

Whether T cells are required for the development of colitis-associated CRC is an open question. In the azoxymethane/dextran sulphate sodium (AOM/DSS) experimental model of CAC, RAG1-deficient mice that do not have B and T cells did not develop tumors even in the presence of colitis[26]. These results indicate that lymphocytes are required to promote tumor growth in the context of colitis. However, it is worth considering that an enhanced activity of natural killer (NK) cells, which are still present in RAG1-/- mice, might be responsible for tumor protection in these mice. Indeed, depletion of suppressive subsets of T cells (i.e. regulatory T cells) has been shown to increase NK cell activity and tumor rejection[27-29]. Experiments with RAG1-/-//γ-chain-/- double knockout mice which lack B, T and NK cells would help to address this issue.

With regard to T helper cell subsets, the role of Th1 and Th2 cells in CAC has been shown by Osawa *et al*[30]. The authors compared CAC development in IL4-/- and IFN-γ-/- deficient mice which have a biased Th2 and Th1 immune response, respectively. Interestingly, Th1-biased IFN-γ-/- mice developed more tumors than wild type. Since in these mice there was high expression of IL-4 and IL-5, the authors concluded that Th2-derived cytokines promote tumor growth. Indeed, a Th2 response has been correlated with progression of experimental and human sporadic CRC[31,32] while a Th1 response has been associated with a better prognosis[33]. Moreover, the Th2-related cytokines IL-4 and IL-13 have been shown to induce the upregulation of activation-induced cytidine deaminase (AID), an enzyme involved in DNA mutation in epithelial cells *in vitro*[34]. Accordingly, AID levels are highly expressed in tumor samples from UC patients. The higher susceptibility to develop CAC shown by IFN-γ-/- mice might be related to a decreased immunosurveillance[34]. Indeed, IFN-γ has been shown to be involved in the activation of cytotoxic T cells and NK cells which play a central role in the antitumor immune response[35,36].

The initial observation that UC patients have a higher risk of CAC in comparison to CD fits well with the con-

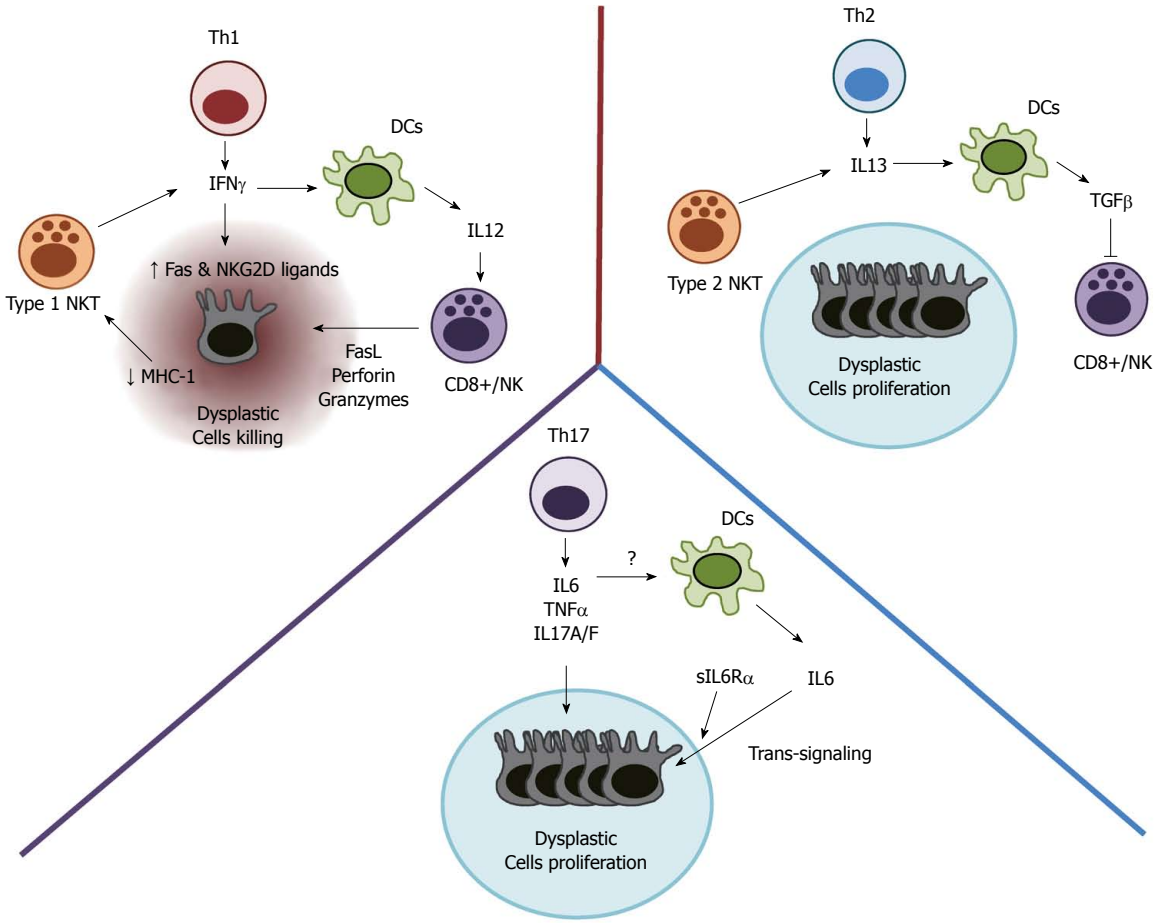

Figure 1 Different T helper-mediated immune responses might be associated with distinct effects on dysplastic cell survival. While Th2 and Th17 immune responses might promote dysplastic cell proliferation and tumor growth, Th1 cells could induce cell death thus preventing tumor progression. Th: T helper; NK: Natural killer; NKT: Natural killer T cells; IL: Interleukin; TGF-β: Transforming growth factor-β; DC: Dendritic cells; MHC: Major histocompatibility complex; Fas: Tumor necrosis factor receptor superfamily, member 6; NKG2D: Killer cell lectin-like receptor subfamily K, member 1; TNF-α: Tumor necrosis factor-α; sIL6R-α: Soluble IL-6 receptor-α.

cept that the Th2 immune response, observed in UC, promotes cancer development while the CD-associated Th1 response is protective. However, as mentioned above, the initially observed lower incidence of CAC in CD in comparison to UC is considered to be due to the methodological approach used in these studies. An alternative explanation for this apparent contradiction could derive from recent advances in the pathogenesis of CD. CD has been long thought to be a Th1-mediated immune disease. This concept derives from initial studies on the role of IL-12, a cytokine involved in the differentiation of Th1 cells[13,37]. In these studies, neutralization of p40, a subunit of IL-12, was effective in preventing gut inflammation both in experimental models and in humans[38-40]. However, we now know that p40 is shared by another cytokine, IL-23, which is a heterodimer composed of p40 and p19. IL-23 has been shown to be involved in the maintenance of Th17 cells, a novel class of T helper cells[41]. Accumulating evidence suggests that Th17 cells might play a role in the pathogenesis of CD. Gain of function polymorphisms of the IL-23 receptor gene are associated with CD[42]. IL-23 p19-/- mice are less susceptible to colitis in comparison with IL-12 p35-/- mice which do not express IL-12[43]. Mice deficient in receptor-related organ receptor (ROR)γ t, the lineage commitment transcription factor of Th17 cells, are resistant to inflammation in different models of colitis[44]. Most of the proinflammatory effect of Th17 has been attributed to the expression of IL-17. IL-17 is known to induce the expression of proinflammatory factors such as TNF-α, IL-6, IL1, iNOS, metalloproteinases and chemokines, which also play a role in CAC[45]. Finally, IL-23 expression is increased in several types of human cancer including CRC[46], and IL-23 p19-/- mice are demonstrated to be more resistant to tumor development[47]. Overall, these data suggest that tumor-promoting Th17 cells rather than Th1 cells might sustain inflammation in CD, thus explaining the increased risk of CAC in CD patients (Figure 1).

Cytotoxic T cells

CD8+ T cells, NK and natural killer T (NKT) cells have been shown to play a role in cancer immunity. Their role, initially limited to the capacity to kill dysplastic target cells, has been recently extended demonstrating a more complex contribution to the antitumor immune response.

A central role in cancer immunosurveillance is attrib-

uted to CD8+ cytotoxic T cells. After presentation of tumor-related antigens by antigen-presenting cells, CD8+ T cells become activated and release different cytotoxic molecules responsible for target cell killing. Activated CD8+ T cells express high levels of IFN-γ and FasL[48]. While FasL, a membrane bound molecule, induces apoptosis by interacting with Fas expressed on the surface of dysplastic cells[49], IFN-γ has been shown to enhance the expression of Fas in colorectal cancer cell lines thus enhancing the killing process[50]. Perforin, granzyme A and granzyme B are also expressed by CD8+ T cells and their effect on target cells is to induce a permeabilization of the cell membrane and cell death[51,52].

NK cells are large granular lymphocytes with both cytotoxicity against tumor and cytokine-producing effector function. NK cells are involved in the rejection of *in vivo* implanted tumors in a manner dependent on the presence or absence of signals on the target cells. The lack of MHC class I expression on the surface of target cells or the upregulation of NKG2D ligands can determine NK cells activation[53-55]. NKG2D ligands are expressed at various levels in CRC cell lines and the expression of one of them, MICA, was associated with a better prognosis in CRC patients[56]. Once activated, NK cells express high levels of IFN-γ, perforin and granzymes which induce apoptosis in target cells. Interestingly, IL-21, a cytokine highly expressed in both UC and CD, has been shown to activate NK cells[57]. However, whether IL-21-induced activation of NK cells plays a role in anti-tumor immunity is still unclear[58-60].

In contrast to NK cells, which lack the T cell receptor (TCR), NKT cells express a limited variety of TCRs. Although NKT cells have NK-like cytolytic activity, they are considered regulators of the immune response, being able to express both Th1- and Th2-related cytokines. In tumor immunity, NKT cells have been considered as both enhancers and suppressors of the anti-tumor activity. A subset of NKT cells (type I NKT), characterized by the expression of V-α-14-Jα-18 TCR-α chain, has been shown to enhance tumor immunity by IFN-γ expression and NK cell activation[61,62]. Moreover, IFN-γ indirectly promotes the activation of CD8+ T cells by inducing the expression of IL-12 in antigen-presenting cells[63]. Tumor infiltration by type I NKT cells in CRC patients has been positively correlated with the disease-free survival[64]. In contrast to type I NKT cells, type Ⅱ NKT cells, which do not express the V-α-14-Jα-18 TCR-α chain, have been associated with suppression of antitumor immunity. Type Ⅱ NKT cells express IL-13, which has been shown to induce the expression of the immunosuppressive cytokine TGF-β in myeloid cells[56,65]. Interestingly, the selective activation of type Ⅱ NKT cells enhanced CT26 cell growth in a mouse model of CRC metastasis[66]. In UC, activation of type Ⅱ NK cells and expression of IL-13 characterize the "atypical" Th2 immune response observed in these patients[11]. It is tempting to speculate that activation of type Ⅱ NKT cells in UC might contribute to CAC development by selectively dampening the antitumor immune response while sustaining mucosal inflammation and cancer development.

Innate immune cells

The role of innate immune cells in sporadic CRC progression has started to be unveiled (For review, see Mantovani *et al*[67]). However, whether these cells are also important in the development of CAC is still unclear.

The role of innate immunity in the development of CAC is suggested by recent findings that Toll-like receptors (TLRs) are important in inflammation and CAC. TLRs form a family of membrane-bound receptors expressed by cells of different lineages such as epithelial cells, macrophages and dendritic cells. TLRs "sense" the presence of bacterial compound present in the extracellular space. The interaction between the microbiota and the intestinal mucosa through TLRs is required to maintain intestinal homeostasis. Recent genetic studies suggest that polymorphisms in the genes encoding TLRs are associated with increased risk of IBD and disease extension[68,69]. Moreover, TLR4 is demonstrated as being upregulated in intestinal epithelial cells of patients with active IBD[70]. With regard to CAC, it was shown that intestinal bacteria are required for tumor development in models of CAC. Furthermore, deficiency of MyD88, a molecule involved in TLR intracellular signaling, significantly exacerbated chemically-induced colitis[71] and reduced tumor number and size in sporadic and colitis-associated CRC models[72,73].

CAC: the role of cytokines and chemokines

As mentioned above, immune cells actively contribute to CAC by expressing soluble factors (e.g. cytokines and chemokines) and the role of some of these has been extensively investigated.

IL-6

IL-6 is a multifunctional cytokine important for immune responses, cell survival, apoptosis, and proliferation. IL-6 has been linked to IBD pathogenesis. Atreya *et al*[74] have demonstrated that IL-6 expression in the mucosa of IBD-affected patients induces T cell resistance to apoptosis, thus contributing to chronic inflammation. Accordingly, a correlation between IL-6 levels and the clinical activity of IBD has been demonstrated[75,76]. With regard to CAC, IL-6 expressed during colitis was shown to promote tumor growth in mice[26]. In this model, selective inhibition of the TGF-β signaling in T cells was associated with an enhanced expression of IL-6. In turn, IL-6 trans-signaling, mediated by the interaction of IL-6 and the soluble form of the IL-6 receptor α (sIL-6α) with the gp130 receptor expressed on the surface of dysplastic cells, enhanced tumor cell proliferation. Moreover, in a similar model, Grivennikov *et al*[77] demonstrated that IL-6 expressed by lamina propria myeloid cells protects normal and transformed epithelial cells from apoptosis in a STAT-3-dependent manner, demonstrating the critical oncogenic function of this cytokine-activated transcription factor. Recently, higher expression of IL-6 and STAT3 was observed in both patients with active UC and those who had progressed to CAC, compared with patients with inactive disease or control patients[78]. In the same study, patients with either inactive or active UC, compared with

control individuals, showed increased expression of suppressor of cytokine signaling 3 (SOCS3), which limits the ability of IL-6 to activate STAT3. On the other hand, the expression of SOCS3 was decreased in patients with UC who had progressed to CRC. In the AOM/DSS mouse model of CAC, IEC-specific SOCS3 gene disruption led to increased size, number and load of colonic tumors and this was associated with increased STAT3 and nuclear factor-κB (NF-κB) activation in colon[79].

TNF-α

Tumor necrosis factor (TNF)-α is a pivotal cytokine in the pathogenesis of IBD and anti-TNF-α monoclonal antibody (MAb) therapy is routinely used in UC and CD patients[80]. Although TNF-α has been classically considered as an anticancer agent, it is currently recognized that chronically elevated TNF-α in tissues may promote tumor growth, invasion and metastasis[81]. Indeed, mice deficient for the p55 TNF-α receptor subunit were protected from tumor development in the AOM/DSS model of CAC[82]. Moreover, in the same study, repetitive anti-TNF-α treatment not only suppressed colitis in mice but also prevented CAC.

The effect of TNF-α signaling in CAC is mostly due to the intracellular activation of NF-κB. NF-κB is a pleiotropic transcription factor with a key role in innate and adaptive immunity and is required for the expression of various proinflammatory factors[83]. In addition to its critical function in inflammation, NF-κB activation can support carcinogenesis by increasing cell proliferation and angiogenesis, inhibiting cell death, and promoting cell invasion and metastasis[84]. Greten *et al*[85] have shown that blocking NF-κB activation in the intestinal epithelium dramatically reduced the incidence of CAC, and this was associated with enhanced epithelial cell apoptosis during early tumor development. Interestingly, no reduction of intestinal inflammation was observed in these mice, thus indicating that prosurvival signals provided by NF-κB in epithelial cells play a role in CAC initiation independent of the inflammation severity.

IL-10

IL-10 is an immunomodulatory cytokine and its main biological function is to limit and terminate inflammatory responses. Experimental data indicate that IL-10 might play a role in the pathogenesis of IBD and CAC. Indeed, patients carrying mutations of IL-10 receptor that abrogate IL-10 signaling develop more aggressive disease. Moreover, IL-10-deficient mice spontaneously develop colitis[86] and CAC[87] when infected with certain enteric bacteria such as *H. hepaticus*. In this model, colitis and CAC could be prevented by administering exogenous IL-10, thus indicating that IL-10 is pivotal in the control of inflammation and inflammation-related cancer in the gut. Analogous to IL-6, IL-10 activates STAT3 in target cells. However, the final effect is inhibition of NF-κB activation[88,89] and reduction of the expression of proinflammatory cytokines such as TNF-α, IL-6 and IL-12[90]. IL-10 has also been shown to act as an antiangiogenic factor[91].

A source of IL-10 is represented by regulatory T cells (Tregs), a class of immunosuppressive T cells. Interestingly, in a model of sporadic CRC, Erdman *et al*[92] showed that the transfer of wild type Tregs, but not IL-10-/- Tregs, in CRC-susceptible $Apc^{min-/+}$ mice prevented the development of adenomas and induced rapid tumor regression. These data suggest that, besides its role as a negative controller of the immune system, IL-10 might directly suppress the growth of transformed epithelial cells. Accordingly, Tregs transfer was associated with induction of epithelial cell apoptosis and downregulation of Cox-2, a molecule involved in dysplastic cell survival and proliferation.

TGF-β

Another important immunosuppressive cytokine is transforming growth factor (TGF)-β. TGF-β tightly controls the activation of the immune system and the inhibition of TGF-β signaling causes autoimmune diseases involving several organs including the gut. Moreover, the inhibition of TGF-β signaling operated by the intracellular inhibitory molecule Smad7 in gut lamina propria cells has been shown to contribute to chronic gut inflammation observed in IBD[90].

TGF-β plays an important role in epithelial cell differentiation and growth arrest. Accordingly, TGF-β signaling is found to be altered in sporadic CRC[93]. In contrast, the role of TGF-β in CAC is still unclear. Using a T cell-specific dominant negative TGF-β receptor II transgenic mouse, Becker *et al*[26] demonstrated that TGF-β signaling-mediated negative control of IL-6 expression in T cells is required to inhibit dysplastic epithelial cell proliferation. Conversely, IL-6 has been shown to inhibit TGF-β signaling by inducing Smad7 expression[94]. Smad3 is a key intracellular mediator of the anti-inflammatory and immunosuppressive activity of TGF-β in the colon. Accordingly, Smad3-deficient mice develop CAC that is dependent on the presence of enteric bacteria[95]. Despite the role of TGF-β as immunosuppressant and inhibitor of dysplastic cell growth, TGF-β signaling acts, under certain conditions, as a tumor promoter. Indeed, TGF-β-induced suppression of tumor-specific CD8+ T cells might favor tumor growth and progression[96].

Chemokines

Chemokines and their receptors play an integral role in IBD by regulating the accumulation of immune cells at the site of intestinal inflammation[97].

Monocyte chemoattractant protein 1 (MCP-1, CCL2), a member of the CCβ family of chemokines, is a known chemotactic factor regulating the recruitment of monocytes/macrophages and other inflammatory cells to sites of inflammation *via* activation of the CCR2 receptor[98]. The expression of MCP-1 is increased in the mucosa of patients with IBD[99]. Popivanova *et al*[100], using a model of CAC, showed that CCL2 blockade reduces the infiltration of COX-2-expressing F4/80-positive cells and suppresses COX-2 expression by infiltrating macrophages, resulting in retardation of cancer progression.

The role of chemokines in CAC is further supported by recent studies on chemokine decoy receptor D6. D6, like all decoy receptors, does not induce a conventional intracellular signal but mediates high-affinity ligand binding and efficient ligand degradation. D6 expression is increased in patients with IBD and with CAC compared with healthy subjects. In the AOM/DSS model of CAC, D6-deficient mice showed increased expression of chemokines and higher accumulation of inflammatory cells in comparison to the wild type, resulting in the development of more severe colitis and higher incidence of CAC[101].

CONCLUSION

Clinical and experimental data indicate that chronic inflammation increases the risk of developing CAC, acting at different stages of the carcinogenesis process. The constant release of free radicals is known to be genotoxic leading to the dysregulation of important oncogenes and onco-suppressors. Moreover, it is also known that the release of cytokines such as IL-6 and TNF-α during chronic colitis can promote tumor growth and that low expression of immunosuppressive cytokines such as TGF-β and IL-10 can exacerbate this process. However, it is also clear that what we call macroscopically chronic inflammation may be the result of very different kinds of immune responses and their impact on CAC development is still unclear.

Many lines of evidence indicate that IFN-γ expressed by Th1 cells protects from tumorigenesis in different experimental models. Indeed, IFN-γ is critical in the activation of cytotoxic cells and antitumor activity. Moreover, IFN-γ renders dysplastic cells more susceptible to cell-mediated cytotoxicity. In contrast, Th2- and Th17-mediated immune responses in the gut seem to promote CAC development. Therefore, it is tempting to speculate that different Th-driven "chronic inflammations" of the gut could be associated with different risk of CAC (Figure 2). If this concept will turn out to be true, not only generic immunosuppressive therapy but also modulation of the ongoing intestinal immune response could be considered as an approach in the prevention of CAC in IBD patients.

In clinical practice, many anti-inflammatory drugs and immune-modulators are routinely used in the therapy of IBD. Their efficacy is based on the capacity to reduce clinical manifestations related to disease and to reduce the *in situ* macroscopic/microscopic inflammation. However, in most of the cases little is known about their impact on the immune response at a molecular level and the consequent effect on colon carcinogenesis. An exception is represented by 5-ASA. Clinical data indicate that the long term use of 5-ASA might prevent CAC in UC patients, acting as an anti-inflammatory agent and interfering with cancer cell growth[102]. However, whether 5-ASA might act in part by modulating the activity of the immune system, sustaining immunosurveillance, has not yet been investigated. The impact of other anti-inflammatory drugs and immune-modulators on UC-related colon carcinogenesis, and their capacity to improve or dampen the immunosurveillance against dysplastic cells, are still unknown. The long term evaluation of patients undergoing different therapeutic regimens will help address this issue.

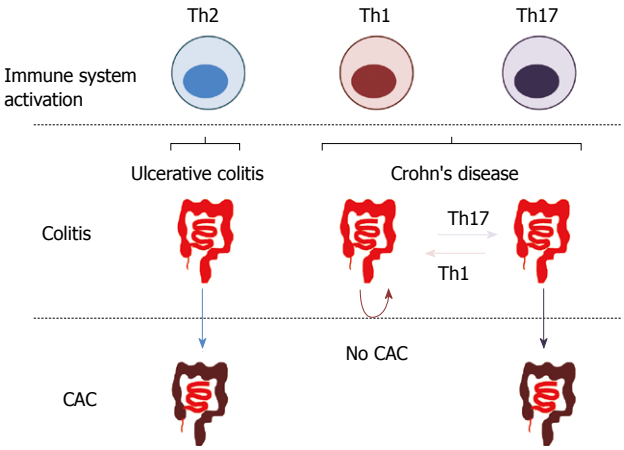

Figure 2 Hypothetical relationship between inflammatory bowel disease and colitis associated colorectal cancer. The T helper (Th)2 immune response characterizing ulcerative colitis determines an elevated risk of developing colitis associated colorectal cancer (CAC). In Crohn's disease, while a Th17-mediated immune response could cause inflammation and enhance CAC risk, the shift towards a Th1-mediated colitis could lower the incidence of CAC.

Abstract

Liver transplantation is considered as the most effective treatment for end-stage liver disease. However, serious complications still exist, particularly in two aspects: ischemia and subsequent reperfusion of the liver, causing postoperative hepatic dysfunction and even failure; and acute and chronic graft rejections, affecting the allograft survival. Heme oxygenase (HO), a stress-response protein, is believed to exert a protective function on both the development of ischemia-reperfusion injury (IRI) and graft rejection. In this review of current researches on allograft protection, we focused on the HO-1. We conjecture that HO-1 may link these two main factors affecting the prognosis of liver transplantations. In this review, the following aspects were emphasized: the basic biological functions of HO-1, its roles in IRI and allograft rejection, as well as methods to induce HO-1 and the prospects of a therapeutic application of HO-1 in liver transplantation.

Key words: Liver transplantation; Heme oxygenase-1; Allograft rejection; Ischemia/reperfusion injury

Peer reviewer: Yasuhiko Sugawara, MD, Artificial Organ and Transplantation Division, Department of Surgery, Graduate School of Medicine University of Tokyo, Tokyo, Japan

INTRODUCTION

Transplantation remains the main therapeutic option for patients with end-stage liver disease. Thanks to the clinical use of immunosuppressants, acute rejections have been brought under substantial control. However, the adverse effects of these drugs, such as the development of blood hypertension, hyperlipidemia, diabetes, renal failure, and *de novo* tumors in transplanted patients, are significant, increasing the postoperative mortality. The severe side effects of the immunosuppressants limit their success in attenuating acute rejection. In addition, surgery and preservation of the allografts result in a cascade of ischemia-reperfusion injury (IRI) in the transplantation, for which there are still no effective therapeutic interventions. Consequently, the strategies to simultaneously attenuate IRI and induce donor-specific tolerance would considerably improve the quality of life and survival of the transplant recipients.

The liver, an immunologically privileged organ, bears inherent tolerogenic properties in the event of orthotopic

liver transplantation (OLT). Liver allografts could be established and maintained even without immunosuppressants[1]. In humans, liver transplants can also confer protection on other organ grafts stemming from the same donor[2]. Based on the aforementioned characteristics of the liver, it seems more feasible to induce a donor-specific tolerance in liver transplantations than in the case of transplantations of other solid organs.

More attentions have been paid to heme oxygenase (HO)-1 because of its cytoprotective, antioxidant, maintaining microcirculation, modulating the cell cycle and anti-inflammatory functions[3]. In the process of a liver transplantation, many cell types, including Kupffer cells, endothelial cells, and dendritic cells (DCs), can induce an HO-1 overexpression to prevent IRI and rejections[4-6]. Since HO-1 seems to be involved in both processes, it may act as a linkage between IRI and rejection in liver transplantation in order to induce donor-specific tolerance.

BASIC BIOLOGICAL FUNCTIONS OF HO-1 AND ITS BYPRODUCTS

HOs are rate-limiting enzymes in the heme catabolism. The heme catabolism by HO-1 produces carbon monoxide (CO), free iron, and biliverdin that is subsequently converted to bilirubin by biliverdin reductase[7]. Three HO isozymes have been identified: HO-1, HO-2 and HO-3. HO-1 is an inducible enzyme, while the other two are expressed constitutively[8].

HO-1 is a bona fide 32-kDa stress protein (Hsp32), variously manifested in endothelial, epithelial, smooth muscle and other cell types. HO-1 plays a protective role in many disease models *via* its anti-inflammatory, anti-apoptotic, and anti-proliferative actions[3]. Three products of the heme metabolism are considered to be beneficial due to their immunomodulatory, anti-apoptotic, and vasoactive properties.

CO, despite its potential toxicity, has recently caused a great interest because of its function as a signaling molecule with vasodilatory effects mediated by cGMP, and its antiapoptotic and anti-inflammatory effects[9,10]. CO can travel freely throughout intracellular and extracellular compartments and exert a wide spectrum of modulating physiological effects on multi-systems[11].

Bilirubin, a byproduct, is found to exert a beneficial influence on many diseases, including atherosclerosis, inflammatory, autoimmune, degenerative diseases, and cancer, in which it serves as a highly lipophilic antioxidant[12]. It can slightly reduce ethanol-induced lipid peroxidative injury by decreasing MDA content[9]. In addition, Takamiya *et al*[13] have demonstrated that HO-1 stabilizes mast cells (MCs) in order to exercise an anti-inflammatory action through bilirubin.

Furthermore, Fe, the third product, despite its cytotoxic pro-oxidant effects, induces an over-expression of ferritin, which in turn has strong antioxidant effects through the depletion of free iron and also by other less characterized effects that result in the induction of tolerogenic dentritic cells[14].

HO-1 ATTENUATES LIVER IRI IN LIVER TRANSPLANTATION

IRI is a continual process that culminates in hepatocellular injury. Clinically, it remains a major obstacle to liver transplantation and can lead to hepatic dysfunction and even post-transplantation failure. As a result, the mechanisms and prevention of cellular injury during hepatic ischemia and subsequent reperfusion needs to be elucidated[15].

Kupffer cells, the resident macrophage population within the liver, play key roles in IRI. They are activated after reperfusion by various stimuli in an autocrine fashion by Toll-like receptor 4 signaling[16], or by complement activation[17,18]. After being activated, they release inflammatory cytokines and free radicals, such as reactive oxygen species (ROS), tumor necrosis factor α (TNFα), interleukin 1 (IL-1), nitric oxide (NO), thromboxanes, and leukotrienes[19], and recruit neutrophils to the liver. TNF and IL-1 can also recruit and activate CD4+T-lymphocytes which maintain Kupffer cell activation by secretion of the granulocyte stimulating factors or interferon (IFN)-γ[20,21]. Of all the hepatic cells, the nonparenchymal sinusoidal endothelial cells (SECs) are most susceptible to IRI[22]. SECs are activated by tissue anoxia that disturbs the intracellular energy metabolism and enzyme function, leading to their apoptosis. These cause marked microcirculatory disturbances, leukocyte and platelet adhesion, diminished blood flow and continuation of the ischemic process, resulting in massive hepatic necrosis[23]. Thus, the inhibition of SEC apoptosis may be a useful therapeutic strategy to reduce the risk of ischemia injury in liver preservation. Yue *et al*[5] have found that the apoptosis of SECs was attenuated after the TAT-HO-1 was transducted into the liver, which may be associated with an increased expression of Bcl-2 and a reduced expression of Bax.

It is well known that it is of critical importance to attenuate IRI in liver transplantation. Both HO-1 and its products of degradation play a role in attenuating IRI (Figure 1). The findings that $Hmox^{-}/^{-}$ animals are more susceptible to IRI injury than the $Hmox^{-}/^{+}$ and $Hmox^{+}/^{+}$ animals indicate that HO-1 may play a potent protective role in IRI[24]. A further study has shown that donor livers with an enhanced HO-1 expression lowered the serum ALT/AST levels of the recipient, alleviated allograft injury, and suppressed cytokine release[4]. Luke Devey described a mechanism that HO-1 could drive macrophage differentiation down an "anti-inflammatory" pathway[24]. Therefore, preconditioning the donor liver, especially its Kupffer cells with a strong induction of HO-1, plays a potential protective role. Kupffer cells are not only the main factor associated with liver IRI, but also a major site of expression of the hepatic HO-1. Based on these findings, we can assume that HO-1 in Kupffer cells is

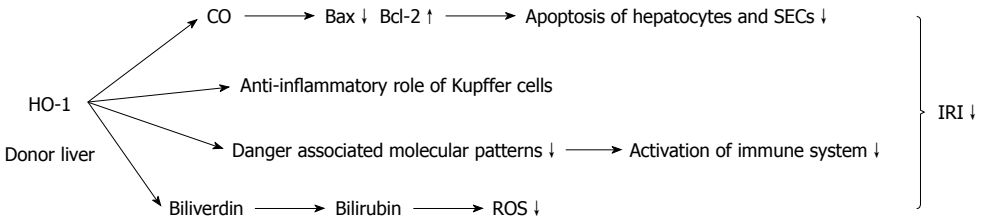

Figure 1 Function of heme oxygenase 1 and its degradation product in ischemia and reperfusion injury during liver transplantation. HO-1: Heme oxygenase 1; CO: Carbon monoxide; SEC: Sinusoidal endothelial cell; ROS: Reactive oxygen species; IRI: Ischemia-reperfusion injury.

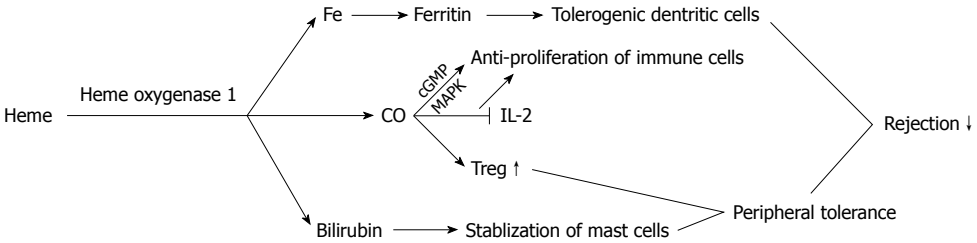

Figure 2 Function of heme oxygenase 1 degradation product to reduce rejection. CO: Carbon monoxide; Treg: Regulatory T cells; IL: Interleukin.

induced exclusively to exert a protective function in the event of IRI. Additionally, HO-1 can modulate each stage of the immune activation pathway such as limiting the production of damage-associated molecular patterns, modulating T cell activation, and enhancing immunological tolerance[25].

As previously described, CO mediates a cytoprotective and anti-inflammatory effect in I/R related oxidative injury. It significantly reduces the messenger RNA (mRNA) levels of the proapoptotic Bax, while it upregulates the anti-apoptotic Bcl-2. Bax and Bcl-2 are both found to be expressed in hepatocytes and SECs at the sinusoidal space. Therefore, CO reduces the IRI-mediated apoptosis through an overexpression of Bcl-2 and diminished Bax expression. This protective role of CO is mediated by an activation of the soluble guanylyl cyclase, as demonstrated by the fact that 1H-(1,2,4)oxadiazole (4,3-α) quinoxaline-1-one (ODQ; a soluble guanylyl cyclase inhibitor), completely reversed its beneficial effect[26].

The oxidation of bilirubin by ROS results in the conversion of bilirubin to biliverdin, the latter being a precursor of bilirubin in the heme degradation that is recycled to bilirubin in mammals by biliverdin reductase. This recycling process between bilirubin and biliverdin is believed to be behind one of the explanations for bilirubin's powerful antioxidant effects in the redox cycle[27]. However, the exact mechanism of the protective role of HO-1 remains to be fully explained.

Contrary to the aforementioned protective role of HO-1 against oxidant-induced injury and the induction of HO-1 as an adaptive response against oxidative damage, Froh *et al*[28] reported that a cobalt protoporphyrin (CoPP)-induced HO-1 over-expression increases liver injury, as demonstrated by an over-expression of hepatic ALT, aggravation of cell necrosis, and fibrosis. They suggested that high levels of HO-1 may sensitize cells to oxidative stress due to an accumulation of free divalent iron, thereby increasing oxidative injury. Since Kupffer cells are the main source of HO-1 in the liver, an increased expression of HO-1 may also aggravate the activation of Kupffer cells, thus increasing the formation of inflammatory and fibrogenic mediators. The controversial role of the HO-1 expression in human liver allografts of either cytoprotection or increased cytotoxicity ought to be investigated in more detail in the future.

HO-1 REDUCES REJECTIONS IN LIVER TRANSPLANTATION

The spontaneous graft tolerance of the liver is an active process which depends upon the transfer of donor leukocytes in the liver. Migration within the recipient's lymphoid system results in an early immune activation of recipient lymphocytes, with their subsequent deletion from exhaustion. Regulatory T cells and antigen presenting cells (APCs) are both involved in inducing donor-specific tolerance.

One highly significant tolerance inducing mechanism is the suppression of allogeneic responsiveness by regulatory T cells. Regulatory T cells (Tregs) are a subset of T lymphocytes that play a core role in immunological suppression and the termination of immune responses. Deficiency or dysfunction of these cells may lead to autoimmunity or an aggravated pathogen-induced inflammation[29]. The end-products of HO-1 degradation do not have much organ specificity to reduce rejection (Figure 2). CO could provide one mechanism by which the regulatory capacity of Tregs is generated. CO has been shown to have broad anti-proliferative effects in human CD4+T cells[30]. Generally, CO is thought to perform those anti-proliferative actions by modulating the activity of guanylate cyclase to increase the cellular cGMP

levels, and through the MAPK (mitogen activated protein kinase) pathway. More specifically, CO was also shown to block the production of IL-2, a principal cytokine responsible for T cell proliferation[31]. CO, functioning as a nonspecific suppressor, also fits with the observation that Treg cells are capable of suppressing the proliferation of various immune cell types without major histocompatibility complex restriction and in a non-Ag-specific manner.

Recently, the existence of interactions between Tregs and MCs has been demonstrated[32]. The secretion of immunosuppressive mediators, such as transforming growth factor β, forms the basis of the pivotal role of MCs in inducing allograft tolerance. IL-9 is the functional link by which activated Tregs recruit and activate MCs to mediate regional immune suppression. This is demonstrated by the fact that by neutralizing IL-9, allograft rejection in tolerant mice is greatly accelerated[33]. However, the degranulation of intragraft or systemic MCs causes the loss of Tregs and MCs from the graft, and impairs Treg function. As a result, rejection occurs in the established tolerant allograft[34]. Therefore, it seems important to stabilize the MCs in order to sustain allograft tolerance. As described above, the liver more easily induces tolerance than other organs. Although MCs are not abundant in the liver, an inhibition of MC degranulation seems important, because of the hepatic immunological privilege. Takamiya *et al*[13] illustrated that an overexpression of HO-1 suppresses compound 48/80-, IgE-induced MC degranulation through bilirubin. Yasui *et al*[35] demonstrated that the upregulation of HO-1 within the MCs also inhibits their cytokine production associated with a selective suppression of the DNA-binding activity of the AP-1 transcription factors. As a result, to induce HO-1 within MCs may be another target to affect Tregs. On the other hand, because MCs are involved in the fibrosis of chronic rejection, inhibiting MC degranulation and cytokine production may control the progression of chronic rejection. Whether the HO-1 overexpression of the donor's or the recipient's MCs is more important, needs to be ascertained.

It is well known that the Treg functions depend on the activity of APCs, and the HO-1 of APCs may also influence the Tregs. George *et al*[36] have demonstrated that lack of HO-1 in the APCs significantly impairs the suppressive function of Treg cells on effector T cells, which indicated the importance of HO-1 within APCs. APCs are involved in initiating rejection and can also be mediated to induce tolerance. Perfusion of donor liver with HO-1 inducers will up-regulate HO-1 expression of many cells in the liver, including hepatic dentritic cells. This pathway contains some mechanism for HO-1 to reduce both acute and chronic rejections (Figure 3). There are two recognition patterns associated with organ transplantation rejection: direct and indirect recognition induced by donor and recipient APCs, DCs are the main APCs in the liver, the only cell type that can activate naïve CD4+T cells. Hepatic DCs differ from those in other organs, because they are less immunostimulatory in response to diverse antigens. Some data have also shown that compared with splenic and blood DCs, freshly isolated mouse liver DCs express lower levels of Toll-like receptor 4 mRNA and are less able to activate allogeneic T cells, or polarize naïve T cells toward Th1 responses to LPS[37]. Immature DCs (imDCs) lack the capability of presenting alloantigen to alloreactive T cells because of a low expression of costimulatory molecules[38]. As it is shown, imDCs express HO-1, but apparently reduce or lose the ability of expression as they become mature[39]. There is expanding evidence that donor hepatic imDCs can downregulate immune responses, thus inducing and maintaining peripheral T-cell tolerance[39]. Furthermore, it has been hypothesized that the presence of large numbers of imDCs within the donor liver that circulate and repopulate the recipient contribute to microchimerism, another mechanism associated with donor-specific tolerance[40]. However, in the event of an acute liver transplant rejection, when the imDCs undergo maturation upon alloantigen stimulation, they induce an acute rejection through direct recognition. Consequently, keeping DCs in their immature state is crucial in order to induce an antigen-specific tolerance in liver transplantation.

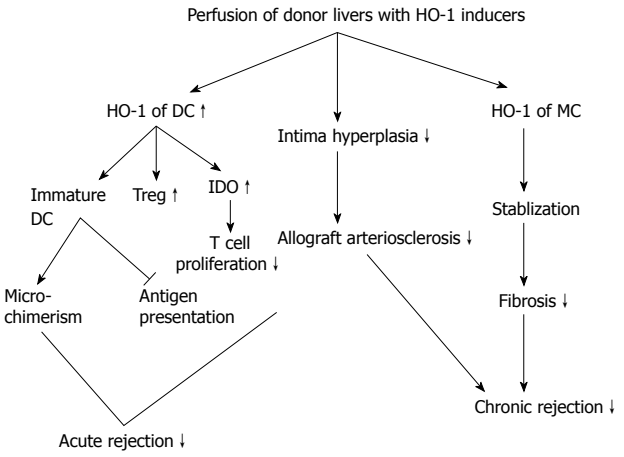

Figure 3 Perfusion of donor liver with heme oxygenase 1 inducers could reduce rejections through many pathways. HO-1: Heme oxygenase 1; DC: Dendritic cell; Treg: Regulatory T cells; IDO: Indoleamine 2,3-dioxygenase; MC: Mast cell.

Many studies have supported the idea that an induction of HO-1 or its products can inhibit DC maturation. Chauveau *et al*[39] have proven that the induction of HO-1 directs DC refractory to an LPS-induced maturation. Recent studies have also demonstrated that an HO-1 overexpression inhibits the secretion of cytokines critical for DC maturation, such as IL-12[41]. Indoleamine 2,3-dioxygenase (IDO) is a further mechanism associated with the immunosuppressive activity of imDCs, whereby IDO can inhibit T cell proliferation through tryptophan degradation, and induce Tregs as well[42,43]. An upregulation of HO-1 resulted in an IDO overexpression through CO[6]. The above-mentioned information all demonstrates that by inducing HO-1, the development of DCs could be directed selectively toward a tolerogenic DC type. In chron-

Table 1 Upregulation of heme oxygenase-1 in donor liver to alleviate ischemia-reperfusion injury and rejection

Effective product	Targets	Results	Ref.
HO-1	KC	Preventing IRI	[4]
HO-1	Attenuating apoptosis of SEC	Alleviating IRI	[5]
HO-1	Inhibiting DC maturation	Reducing rejection	[6]
HO-1	Anti-inflammatory differentiation of KC	Preventing IRI	[24]
HO-1	Modulating oxidative stress and proinflammatory mediators	Alleviating IRI	[30]
CO	Suppressing T cell proliferation	Reducing rejection	[31]
HO-1	Microchimerism	Inducing allograft tolerance	[41]
CO	Inhibiting TLR-induced DC maturation	Reducing rejection	[42]
HO-1	Suppressing intragraft infiltration of KC and neutrophils, preventing proinflammatory cytokine and chemokine expression	Alleviating IRI	[50]
HO-1	Inducing Treg	Inducing allograft tolerance	[56]
Biliverdin	Decreasing P-selectin, ICAM-1, iNOS and IL-6	Alleviating IRI	[60]

HO-1: Heme oxygenase 1; CO: Carbon monoxide; KC: Kupffer cell; SEC: Sinusoidal endothelial cell; DC: Dendritic cell; TLR: Toll-like receptor; Treg: Regulatory T cells; ICAM-1: Intercellular adhesion molecule-1; iNOS: Inducible nitric oxide synthase; IL: Interleukin; IRI: Ischemia-reperfusion injury.

ic rejection, graft arterial vasculature remodels after the transplantation. Chronic graft dysfunction is characterized by the development of intimal hyperplasia and narrowing of the vessel lumen[44]. Cheng *et al*[45] have found that a loss of HO-1 in DCs or *HO-1* gene silencing by small interfering RNA upregulated the MHCII expression through CIITA-driven transcriptional regulation and transcription 1 (STAT1) phosphorylation. They have also illustrated that an inhibition of HO-1 in DCs aggravated the development of transplant arteriosclerosis by increasing intimal hyperplasia, and by activating a CD4(+) T cell allograft response mediated by an MHCII upregulation. Therefore, we conclude that the activity of HO-1 is an important regulatory mechanism affecting multiple levels of the immune response to induce tolerance. Elucidating its effects on specific immune cells will aid the development of therapeutic strategies for a variety of inflammatory disorders, including autoimmune diseases and transplant rejection.

UP-REGULATION OF HO-1 AS POTENTIAL THERAPY ON GRAFT PROTECTION IN LIVER TRANSPLANTATION

Based on the aforementioned information, we can conclude that HO-1 plays a potential protective role in both IRI and graft rejection, whereby HO-1 may act as a link between these two events (Table 1). Thus, by upregulating HO-1 within the donor liver allograft, a preconditioned pre-transplantation hepatic status can be provided that may uphold allograft survival and normal function for a long time.

HO-1 is highly inducible by a variety of stimuli including heme, NO, cadmium, growth factors, and hyperoxia. These diverse stimuli act *via* a similarly broad range of signaling pathways. The nuclear factor (NF)-κB and activator proteins-1 and -2 lie in the promoter region of HO-1.The transcription factor NF-E2-related factor-2 is recognized as the key mediator of HO-1 induction and the protective functions of HO-1, as seen in experimental models both *in vivo* and *in vitro*[46]. Due to the potential toxicity of the conventional HO-1 inducers, such as hemin and CoPP, a number of new strategies, including protein transduction, traditional Chinese medicine, adenoviral transduction and others, have attracted substantial interest as potential HO-1 inducers[5,47,48].

Protoporphyrines are prototypic HO-1 inducers *in vitro*. Depending on the metal atom of the porphyrines, the enzymatic HO-1 function is activated (e.g. iron or cobalt atom). However, since porphyrines are heavy metals, their clinical usage has many limitations.

Simvastatin, clinically used as a lipid-lowering drug, is another inducer of HO-1. Lee *et al*[49] have shown that the protective effect of statins on vessels is produced by HO-1. Uchiyama *et al*[50] further demonstrated that simvastatin increases the HO-1 expression by inducing a nuclear translocation of the heat shock factor 1 in vascular endothelial cells. However, there are still several unresolved problems. Simvastatin is administered orally in clinical applications. Uchiyama *et al*[50], however, induced HO-1 by an intraperitoneal injection of a high-dose of simvastatin in their experiments. In view of its potential for a clinical application, a pilot study is necessary to evaluate whether simvastatin administered orally also induces HO-1.

In recent years, traditional Chinese herbal medicine has become popular in inducing HO-1. Sinomenine, a pure alkaloid extracted from the Chinese medical plant *Sinomenium acutum*, has been investigated for its protective effect on hepatic cells affected by an overexpression of HO-1 to attenuate IRI[5]. *Isodon Serra* (*I. Serra*) is another Chinese medicinal herb that has been found to possess the capacity to induce HO-1. It is a perennial herb that has been used widely for the treatment of arthritis, enteritis, jaundice, hepatitis, lepromatous leprosy, ascariasis and acute cholecystitis[51]. Moreover, it has been used in China to treat esophageal cancer. It has an anti-proliferative effect on melanoma cells and many other kinds of malignant cells[52,53]. However, our studies focused on other functions, besides its anti-tumorigenic activities[54,55]. Matsushima *et al*[56] have proven that crassin acetate, a

coral-derived cembrane diterpenoid, can effectively induce HO-1 mRNA/protein expression and HO-1 enzymatic activity in DCs. Nodosin and Oridonin, extracts obtained from *I. Serra*, also belong to a type of diterpenoid. Our previous studies elucidated that Oridonin has an immunosuppressive effect by regulating the cell mitosis cycle and modulating the signal mechanisms of four cytokines (IL-2, IFN-γ, IL-12 and TNFα)[54]. Oridonin, a potent HO-1 inducer, is a promising immunosuppressive drug. Hu *et al*[55] have shown that Oridonin upregulated the HO-1 expression at both the transcriptional and translational levels, and accordingly promoted HO-1 activity *in vitro* in their experiments. However, the exact mechanisms of our findings remain to be further investigated. Nodosin, another *I. serra* extract, also induces HO-1. We used a Nodosin solution *in vitro* to perfuse the isolated liver, while lactic Ringer's solution was used as control. The results showed that the expression of HO-1 in both the mRNA and the protein is higher in the perfused group than in the control group[57]. The potential role of *I. Serra* extract in the upregulation of HO-1 suggested that it is a novel nontoxic drug candidate for liver allograft protection. More models and methods used for the study of *I. Serra* extracts need to be defined in the future investigations. We believe that in the near future, the full pharmacological activity and detailed mechanisms of *I. Serra* will be further described.

FUTURE PROSPECTS

In a clinical setting, however, the inducible HO-1 system still has several limitations. The different effects of HO-1, which are neither exclusively cytoprotective nor exclusively cytotoxic, should be further investigated. The HO-1 induced cytoprotection might be restricted to a narrow threshold of overexpression. Besides, there are no available reagents that can specifically induce HO-1. Therefore, the unintended effects of treatment with non-specific HO-1 inducers would likely present a disadvantage[10]. Although an adenoviral-based HO-1 gene transfer has been attempted *in vivo*, the efficiency of viral transfection is organ dependent. CO may represent a candidate for the treatment of transplanted patients against IRI. However, its therapeutic window must be carefully considered, because the inhalation of high levels can be toxic or even be lethal. Biliverdin and reduced bilirubin may also represent possible candidates for clinical application. We have recently demonstrated that biliverdin had a protective effect in stringent rat liver models of IRI, as evidenced by an improved portal blood flow/bile production and a reduction in hepatocellular damage. It also improved the survival rate in a syngeneic rat OLT model after prolonged cold ischemia[58]. However, because bilirubin in excess can cause neurotoxicity and can act as a lytic agent binding to erythrocyte membranes, the therapeutic window of biliverdin must be examined in detail prior to its clinical use.

From the above, the question arises if HO-1 or its products can be used clinically. Although CO is toxic, beneficial results can be obtained with relatively low doses for appropriate length of time. In rodents, the administration of biliverdin or bilirubin in the first few weeks of life did not reveal much toxicity. Recent evidence indicates that they are not only non-toxic at physiological concentrations in normal cells, they may also have important anti-oxidant, anti-inflammatory, or anti-apoptotic properties[59,60].

Based on this review, which reveals that HO-1 is associated with both processes of IRI and acute rejection, we can conclude that the preconditioning of the donor liver with an upregulation of HO-1 not only attenuates IRI, but also reduces rejection after liver transplantation. HO-1, therefore, seems to stand out as a potential key therapeutic target to maintain graft function and improve the recipients' prognosis in liver transplantation. However, due to its limitations, the therapeutic role of HO-1 must undergo further critical analysis.

Abstract

AIM: To evaluate the influence of preoperative FOLFOX chemotherapy on CCL20/CCR6 expression in liver metastases of stage Ⅳ colorectal cancer (CRC) patients.

METHODS: Using Real Time-PCR, enzyme-linked immunosorbent assay, Western Blots and immunohistochemistry, we have analyzed the expression of CCL20, CCR6 and proliferation marker Ki-67 in colorectal liver metastasis (CRLM) specimens from stage Ⅳ CRC patients who received preoperative FOLFOX chemotherapy (n = 53) and in patients who did not receive FOLFOX chemotherapy prior to liver surgery (n = 29).

RESULTS: Of the 53 patients who received FOLFOX, time to liver surgery was ⩽ 1 mo in 14 patients, ⩽ 1 year in 22 patients and > 1 year in 17 patients, respectively. In addition, we investigated the proliferation rate of CRC cells in liver metastases in the different patient groups. Both CCL20 and CCR6 mRNA and protein expression levels were significantly increased in patients who received preoperative FOLFOX chemotherapy ⩽ 12 mo before liver surgery (P < 0.001) in comparison to patients who did not undergo FOLFOX treatment. Further, proliferation of CRLM cells as measured by Ki-67 was increased in patients who underwent FOLFOX treatment. CCL20 and CCR6 expression levels were significantly increased in CRLM patients who had undergone preoperative FOLFOX chemotherapy.

CONCLUSION: This chemokine/receptor up-regulation could lead to increased proliferation/migration through an autocrine mechanism which might be used by surviving metastatic cells to escape cell death caused by FOLFOX.

Key words: FOLFOX chemotherapy; CCL20/CCR6 expression; Colorectal liver metastases; Proliferation

INTRODUCTION

Colorectal cancer (CRC) constitutes one of the most common causes of cancer death in the western world. CRC is also a tumor with a high propensity for metastatic spread, mostly to liver and lungs. Liver metastases develop in approximately 50% of CRC patients at some point in the course of their disease and worsen the prognosis for patient survival dramatically[1,2]. To date, long-term survival of patients with colorectal liver metastases (CRLM) can only be achieved by surgical resection. However, in cases where metastases are considered unresectable, chemotherapy is the treatment of choice, although 5-year survival with chemotherapy alone is very poor. Thus, surgical treatment of resectable liver metastases has become the standard treatment[3].

However, surgical resection can only be successful when liver metastases can be thoroughly resected and provided there is no other non-resectable distant metastasis. Moreover, the primary tumor needs to be resectable. Since all these criteria are often not fulfilled, cancer recrudescence occurs in 45% to 75% of CRLM patients within the first five years after primary tumor resection[3,4]. For these reasons, adjuvant chemotherapy has been evaluated in patients with resectable CRLM. To date, the standard approach with regard to adjuvant chemotherapy for CRC patients is a combination of oxaliplatin, fluorouracil and leucovorin[5,6]; termed FOLFOX. Perioperative FOLFOX chemotherapy has been shown to reduce the risk of cancer relapse by a quarter[7]. Thus, the combination of FOLFOX chemotherapy and surgery is a promising tool to improve the prognosis of CRC patients.

It has been shown that both the chemokine CCL20 and its unique receptor CCR6 are expressed in CRC cells[8-11], providing a basis for efficient autocrine and paracrine loops[12]. CCL20 stimulation of CCR6-bearing CRC cells led to increased proliferation and migration *in vitro*[8,9]. Moreover, our recent data suggest that interactions between CCL20 and the corresponding receptor CCR6 are critical components in the regulation of CRC progression and organ selective CRC metastasis to the liver[10,11].

The purpose of this study was to retrospectively analyze the impact of FOLFOX chemotherapy administered to stage Ⅳ CRC patients on CCL20/CCR6 expression in liver metastases. Eighty-two patients underwent radical surgery of the primary CRC and of synchronous and metachronous liver metastases. Twenty-nine patients underwent liver surgery without preoperative FOLFOX and 53 patients received FOLFOX prior to liver surgery. We compared CCL20/CCR6 expression in liver resection specimens from both groups and correlated their expression with proliferation of CRLM cells.

MATERIALS AND METHODS

Materials

Surgical specimens and corresponding normal tissue from the same samples were collected from patients who underwent surgical resection at our department between 2002 and 2008.

Informed written consent for tissue procurement was obtained from all patients and the study was approved by the local ethics commission of the Ärztekammer des Saarlandes.

Eighty-two patients were included in the study, comprising CRC patients who had FOLFOX chemotherapy before liver surgery (n = 53) and CRC patients who did not have FOLFOX before liver surgery (n = 29). Of the 53 patients who received FOLFOX, time to liver surgery was ⩽ 1 mo in 14 patients, ⩽ 1 year in 22 patients and > 1 year in 17 patients, respectively. In every patient sample the corresponding non-affected normal liver tissue was also analyzed, thus a total of 164 samples were analyzed. In the 53 patients who received FOLFOX chemotherapy before liver surgery, two cancers were classified as pT1, six as pT2, forty as pT3 and five as pT4, with positive nodal involvement in 40 cases, according to the UICC TNM classification[13]. In the twenty-nine patients who received no FOLFOX chemotherapy before liver surgery, six cancers were classified as pT1, two as pT2, nineteen as pT3 and two as pT4, with positive nodal involvement in 10 cases. The clinical data and patient characteristics were obtained from a prospective database and are summarized in Table 1. In the group who did not receive FOLFOX, 8 patients underwent CRLM resection less than 6 mo and 21 patients underwent CRLM resection 6 mo and longer after resection of primary tumor. In the patient group who received FOLFOX chemotherapy, 7 underwent CRLM resection less than 6 mo after resection of primary tumor and 45 patients underwent CRLM resection 6 mo and longer after resection of primary tumor. One patient underwent resection of primary tumor and CRLM resection at the same time (Table 2).

Tissue preparation

Tissue specimens were collected immediately after surgical resection, snap frozen in liquid nitrogen and then stored at -80℃ until they were processed under nucleic acid sterile conditions for protein and RNA extraction. For corresponding normal tissue we used adjacent non-affected tissue to the same resected specimen. All tissues obtained were reviewed by an experienced pathologist and examined for the presence of tumor cells. As minimum criteria for usefulness for our study, we only used tumor tissues in which tumor cells constituted at least > 75% of the tumor biopsy.

Single-strand cDNA synthesis

Total RNA was isolated using RNeasy columns from Qiagen (Hilden, Germany) according to the manufacturer's instructions. RNA integrity was confirmed spectrophotometrically and by electrophoresis on 1% agarose gels. For cDNA synthesis, 5 μg of each patient total RNA sample were reverse-transcribed in a final reaction volume of 50 μL containing 1 × TaqMan RT buffer, 2.5 μmol/L random hexamers, 500 μmol/L each dNTP, 5.5 mmol/L $MgCl_2$, 0.4 U/μL RNase inhibitor, and 1.25 U/μL Multiscribe RT. All RT-PCR reagents were purchased from Applied

Biosystems (Foster City, CA). The reaction conditions were 10 min at 25℃, 30 min at 48℃, and 5 min at 95℃.

Real-time PCR

All Q-RT PCR assays containing the primer and probe mix were purchased from Applied Biosystems, (Applied Biosystems, Foster City, CA) and utilized according to the manufacturer's instructions. PCR reactions were carried out using 10 μL 2 × Taqman PCR Universal Master Mix No AmpErase® UNG and 1 μL gene assay (Applied Biosystems, Foster City, CA), 8 μL Rnase-free water and 1 μL cDNA template (50 mg/L). The theoretical basis of the qRT assays is described in detail elsewhere[14]. All reactions were run in triplicate along with no template controls and an additional reaction in which reverse transcriptase was omitted to assure absence of genomic DNA contamination in each RNA sample. For the signal detection, ABI Prism 7900 sequence detector was programmed to an initial step of 10 min at 95℃, followed by 40 thermal cycles of 15 s at 95℃ and 10 min at 60℃ and the log-linear phase of amplification was monitored to obtain C_T values for each RNA sample.

Gene expression of all target genes was analyzed in relation to the levels of the slope matched housekeeping genes phosphomannomutase (PMM1) and β2-microglobulin (β2M)[15]. Data analysis was performed according to the relative standard curve method. Data are presented in relation to the respective housekeeping genes.

[1]Colorectal cancer patients with FOLFOX chemotherapy before colorectal cancer liver metastasis (CRLM) surgery; [2]Colorectal cancer patients without FOLFOX chemotherapy before CRLM surgery.

Isolation of total protein

Protein lysates from frozen tissue were extracted with radioimmunoprecipitation (RIPA) buffer containing Complete, a protease inhibitor cocktail (Roche, Penzberg, Germany). Total protein quantification was performed using the Pierce BCA protein assay reagent kit (Pierce, Rockford, IL., USA).

Sandwich-type enzyme-linked immunosorbent assay

The chemokine protein levels in the different tissue lysates were determined by sandwich-type enzyme-linked immunosorbent assays (ELISA) according to the manufacturer's instructions. Samples were assayed in duplicate with all values calculated as the mean of the two measurements. CCL20 levels were assayed using a validated commercial ELISA (Duo Set R&D Systems, DY360, Minneapolis, MN, USA). The absorbance was read at 450 nm in a 96-well microtiter plate reader. The chemokine concentration from each tissue lysate was normalized to the total protein content of each sample.

Western blotting analysis

Total protein (25 μg/lane) was separated by SDS-PAGE using a 10% gel and blotted onto nitrocellulose membranes (Hybond ECL, Amersham Biosciences, Piscataway, NJ, USA). Membranes were blocked by incubation in Tris-buffered saline (TBS) containing 5% nonfat dry milk and 0.1% Tween 20 for 2 h at room temperature and then incubated overnight at 4℃ with goat anti-human CCR6 antibody (diluted 1:500, C2099-70B, Biomol, Hamburg, Germany). Blots were then washed and incubated at room temperature for 1 h with donkey anti-goat HRP antibody (diluted 1:5000, sc-2056, Santa Cruz Biotechnology, Santa Cruz, CA, USA). Bands were visualized by ECL Western blotting analysis systems (Amersham Biosciences, Piscataway, NJ, USA). The human cell lysate HL-60 (sc-2209, Santa Cruz Biotechnology, Santa Cruz, CA, USA) served as positive control.

Immunohistochemistry

Resected specimens were routinely fixed with formalin in the immediate postoperative period and paraffin-

embedded within the first three hours after procurement. Before staining, 4 μm thick sections were mounted on Superfrost Plus slides, deparaffinized with xylene, and rehydrated in graded ethanol to deionized water. The sections were treated with an antigen retrieval solution (Target Retrieval, Dakocytomation, Carpinteria, CA) and microwaved. CCL20 and CCR6 staining was performed according to the avidin-biotin-peroxidase reaction (Vectastain ABC ELITE Kit, Vector Laboratories Inc., Burlingame, CA) and Ki-67 staining was performed according to the APAAP method (Dako REAL Detection System, Dako, Glostrup, Denmark, K5000). For CCL20 and CCR6 staining, but not for Ki-67 staining, slides were immersed in 3% hydrogen peroxide for 10 min and then treated with avidin and biotin (Avidin/Biotin blocking kit, Vector Laboratories Inc., Burlingame, CA). Sections for CCL20, CCR6 and Ki-67 staining were incubated with serum followed by an overnight incubation with goat anti-human CCR6 polyclonal antibody (1:125, Biomol, Hamburg, Germany, C2099-70B), goat anti-human CCL20 polyclonal antibody (1:150, R&D, Abingdon, UK AF360) or Ki-67 MIB-1 monoclonal antibody (1:75, Dako, Glostrup, Denmark, M7240). Consequently, immunostaining with the avidin-biotin-peroxidase reaction (Vectastain ABC ELITE Kit, Vector Laboratories Inc., Burlingame, CA) was performed on CCL20 and CCR6 slides and a chromogene aminoethyl-carbazide solution (Tissugnost, Darmstadt, Merck) was used. For detection of Ki-67, the alkaline phosphatase-antialkaline phosphatase complex (APAAP) was used with Fast Red Substrate as chromogen (Dako, Glostrup, Denmark, K0597). Consequently, for all sections counterstaining was performed in hematoxylin solution. Negative controls were performed in all cases omitting primary antibody.

Statistical analysis

All data are presented as mean and SE (standard of the mean). Statistical calculations were done with the MedCalc (MedCalc software, Mariakerke, Belgium) software package[16]. The parametric Student's *t*-test was applied, if normal distribution was given; otherwise, the Wilcoxon's rank sum test was used. Statistical significance was considered on a two-sided significance level (α) of 0.05.

RESULTS

Characteristics of patients

Prior to CRLM resection, 82 patients were enrolled in our study over a 6 year period. The median age of patients at surgery was 61.4 years (35-79) in the FOLFOX group and 66.7 years (43-77) in the patient group without FOLFOX. There were 29 males and 24 females in the FOLFOX group and 17 male and 12 female patients in the non-FOLFOX patient group. The demographic and clinical characteristics of patients are shown in Tables 1 and 2. FOLFOX and non-FOLFOX patients showed no statistically relevant differences with respect to T-stage, grading and timing between primary tumor resection and CRLM resection. However, with respect to N-stage our data revealed a significant difference between FOLFOX and non-FOLFOX patients ($P < 0.05$), as shown in Table 1. Thus, the non-FOLFOX group included a higher percentage of patients without lymph node metastasis (65.5%) compared to the FOLFOX group under investigation (24.5%).

Impact of preoperative FOLFOX chemotherapy on CCL20 expression

Significantly greater levels of CCL20 mRNA and CCL20 protein expression were observed in CRLM tissues compared to corresponding normal tissue in all patients ($P < 0.05$ and $P < 0.001$, respectively) (Figures 1 and 2). However, patients who were preoperatively treated with FOLFOX chemotherapy showed significantly higher levels of CCL20 mRNA and CCL20 protein expression as compared to patients without FOLFOX treatment ($P < 0.05$) (Figures 1A and 2A). When the interval between FOLFOX treatment and surgery was considered, only patients who received FOLFOX chemotherapy $\leqslant$ 12 mo before liver surgery expressed significantly higher amounts of CCL20 mRNA and CCL20 protein, as compared to patients without FOLFOX treatment, respectively ($P < 0.05$) (Figures 1B and 2B).

Immunostaining of the CRLM tissue revealed positive staining for CCL20 in 56% (16/29) of patients without and in 87% (46/53) of patients with preoperative FOLFOX chemotherapy (Figure 3A and B), respectively. CCL20 was immunolocalized with lesser intensity in the tumor tissue sections of CRLM patients without FOLFOX, as shown for a representative patient in Figure 3A, compared to patients who underwent preoperative FOLFOX chemotherapy, as shown in Figure 3B for a representative patient.

Impact of preoperative FOLFOX chemotherapy on CCR6 expression

Both CCR6 mRNA and CCR6 protein expression levels were significantly increased in CRLM tissues of all patients compared to the corresponding normal liver tissue ($P < 0.05$) (Figure 4). Further, CCR6 mRNA and CCR6 protein expression levels were significantly higher in CRLM tissues of patients who underwent preoperative FOLFOX chemotherapy compared to patients without FOLFOX ($P < 0.05$) (Figure 4A). CCR6 up-regulation was limited to those patients who received preoperative FOLFOX chemotherapy $\leqslant$ 12 mo before liver surgery ($P < 0.05$) (Figures 4B and 5).

Immunostaining revealed positive staining for CCR6 in 59% (17/29) of patients without and in 87% (46/53) of patients with preoperative FOLFOX chemotherapy (Figure 3C and D), respectively. CCR6 staining intensities were stronger in the FOLFOX group. However, intense laminar CCR6 immunostaining was found mainly in the benign-appearing tissue sections of CRLM patients. Thus, CCR6 staining localized to a streak of hepatocytes along the tumor invasion front. These hepatocytes appeared clearly distinct from normal hepatocytes (Figure 3C and D).

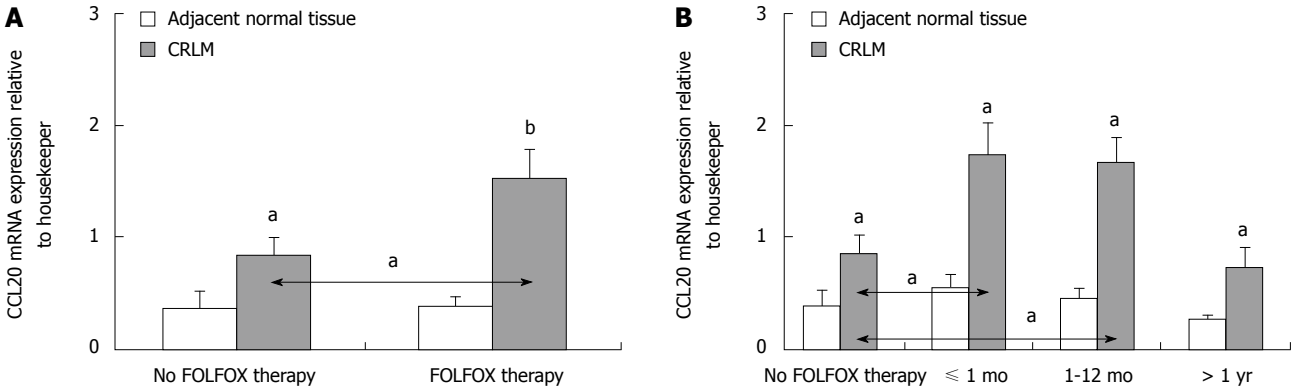

Figure 1 CCL20 mRNA expression relative to PMM1 and β2M in colorectal liver metastasis patients with (*n* = 53) and without (*n* = 29) FOLFOX chemotherapy before colorectal liver metastasis surgery (A) and itemized according to different time periods of FOLFOX treatment before colorectal liver metastasis surgery (no FOLFOX therapy, *n* = 29; FOLFOX treatment ≤ 1 mo, *n* = 14; FOLFOX treatment ≤ 1 year, *n* = 22; FOLFOX treatment > 1 year, *n* = 17) (B). Q-RT-PCR data are expressed as mean ± SE, $^{a}P < 0.05$ and $^{b}P < 0.001$, respectively. CRLM: Colorectal liver metastasis.

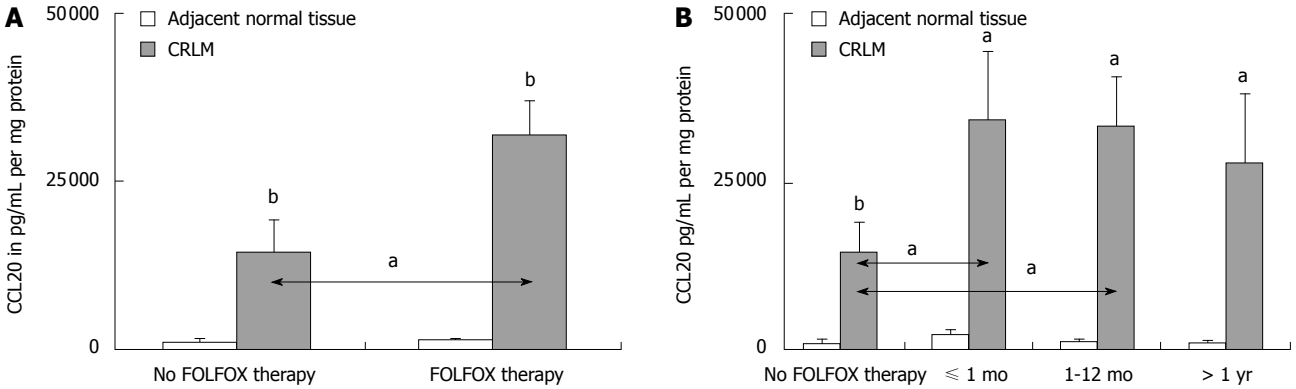

Figure 2 CCL20 protein concentrations (pg/mL pro mg total protein) in colorectal liver metastasis patients with (*n* = 53) and without (*n* = 29) FOLFOX chemotherapy before colorectal liver metastasis surgery (A) and itemized according to different time points of FOLFOX treatment before colorectal liver metastasis surgery (no FOLFOX therapy, *n* = 29; FOLFOX treatment ≤ 1 mo, *n* = 14; FOLFOX treatment ≤ 1 year, *n* = 22; FOLFOX treatment > 1 year, *n* = 17) (B). Protein data are expressed as mean ± SE, $^{a}P < 0.05$ and $^{b}P < 0.001$, respectively. CRLM: Colorectal liver metastasis.

Impact of FOLFOX on proliferation of CRLM cells

Proliferation of CRLM cells as demonstrated by Ki-67 staining revealed a more frequent immunostaining pattern in CRLM tissues of patients who underwent preoperative FOLFOX (Figure 3F) compared to patients without FOLFOX (Figure 3E). In CRLM patients without FOLFOX treatment (*n* = 29) (Figure 3E) we observed weak or no Ki-67 immunostaining in 11 patients (38%), moderate immunostaining intensities in 13 patients (45%) and strong immunostaining intensities in 5 patients (17%). In CRLM patients with preoperative FOLFOX treatment (*n* = 53) (Figure 3F) we observed weak or no Ki-67 immunostaining in 16 patients (30%), moderate immunostaining intensities in 11 patients (21%) and strong immunostaining intensities in 26 patients (49%).

DISCUSSION

At present, standard treatment of CRC patients without distant metastasis consists of surgical resection of the primary tumor followed by adjuvant FOLFOX chemotherapy in patients with lymph node metastasis[17]. For patients with synchronous liver metastasis there are three treatment options: colectomy with synchronous or heterochronous CRLM surgery; perioperative chemotherapy with FOLFOX, FOLFIRI or CapeOX followed by colectomy and CRLM resection; and colectomy followed by chemotherapy and staged CRLM resection[5,6]. As liver resection offers the chance of long-term survival only for patients with resectable CRLM, chemotherapy is often applied to render formerly unresectable CRLM patients resectable. Moreover, superior survival for patients who have undergone resection has been demonstrated by several studies[18,19]. This improved survival may be due to the lower tumor burden.

The impact of chemotherapy on metastatic lymph node lesions was addressed in another study, where patients with 4 or more lymph node metastases around the primary cancer were considered to benefit from perioperative chemotherapy[20]. Chemotherapy options for metastatic CRC have significantly changed in recent years. While the optimal adjuvant systemic chemotherapy has yet to be determined, FOLFOX treatment seems to be one of the most effective CRLM treatment options[21] and perioperative FOLFOX chemotherapy is most commonly used to reduce the risk of cancer relapse in CRC patients[7].

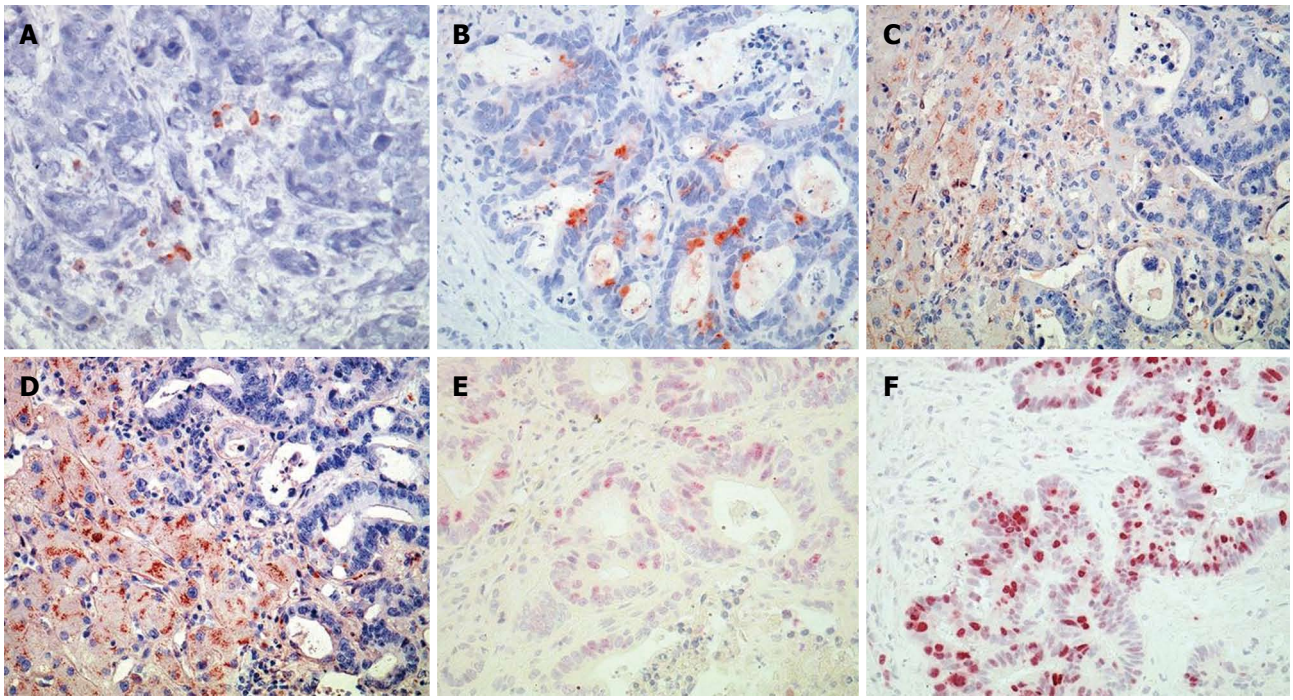

Figure 3 Immunohistochemical staining (original magnification × 200). Representative examples of CCL20 (A, B), CCR6 (C, D) and Ki-67 (E, F) protein expression in colorectal liver metastasis specimens from a colorectal liver metastasis patient without (A, C, E) and with preoperative FOLFOX treatment less than 1 mo before surgery (B, D, F), respectively.

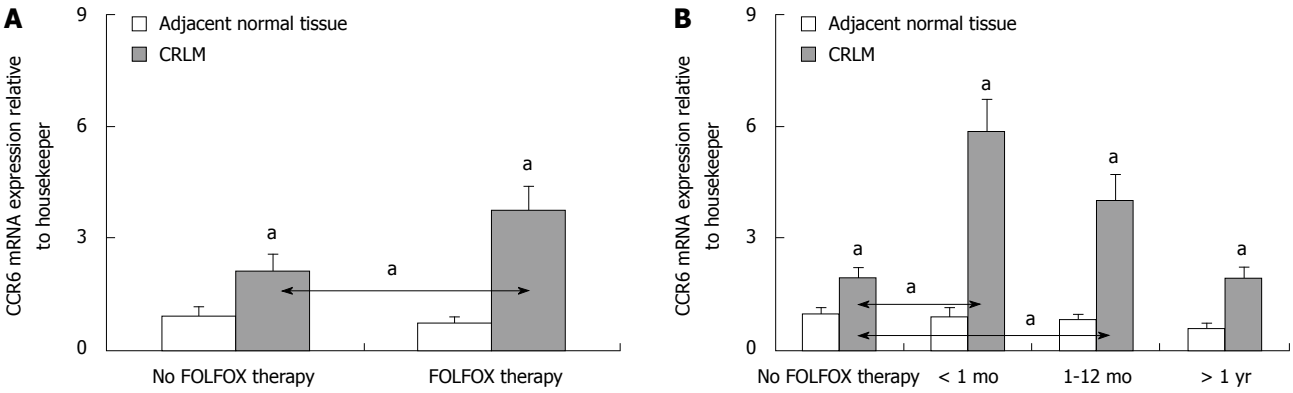

Figure 4 CCR6 mRNA expression relative to PMM1 and β2M in CRLM patients with (*n* = 53) and without (*n* = 29) FOLFOX chemotherapy before CRLM surgery (A) and itemized according to different time points of FOLFOX treatment before CRLM surgery (no FOLFOX therapy, *n* = 29; FOLFOX treatment ≤ 1 mo, *n* = 14; FOLFOX treatment ≤ 1 year, *n* = 22; FOLFOX treatment > 1 year, *n* = 17) (B). Q-RT-PCR data are expressed as mean ± SE, $^{a}P < 0.05$.

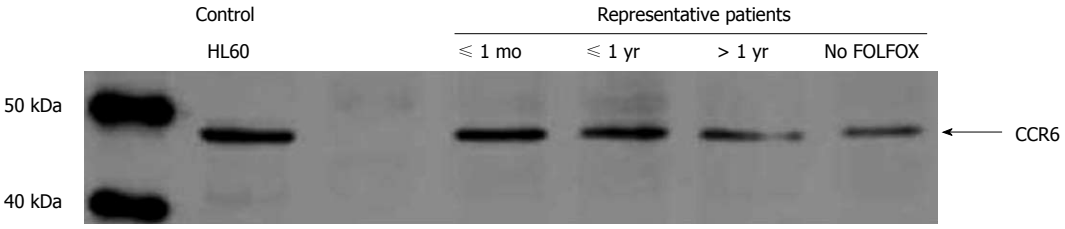

Figure 5 Expression of chemokine receptor CCR6 in colorectal liver metastasis patients itemized according to different time points of FOLFOX treatment before colorectal liver metastasis surgery as determined by Western blotting analysis. Total cell lysates of tumor (P) were immunoblotted with antibodies specifically recognizing chemokine receptor CCR6. Acute leukemia cell line HL60 served as a positive control for the detection of CCR6.

Although pathological effects of chemotherapy for CRLM have been discussed[21-24], the pathological response to chemokine expression in CRLM after chemotherapy has not been reported. Since CCL20 and CCR6 have both been

shown to be expressed on CRC cells[10,11] and CCL20 stimulation of CCR6-bearing CRC cells led to increased proliferation and migration *in vitro*[8,9], we investigated the impact of FOLFOX chemotherapy in stage Ⅳ CRC patients on CCL20/CCR6 expression in liver metastatic tissue.

Our results have shown that both CCL20 and CCR6 expression were significantly increased in patients who had received preoperative FOLFOX chemotherapy ≤ 12 mo before liver surgery as compared to patients who had not received FOLFOX chemotherapy prior to liver surgery. While CCL20 expression was significantly elevated in CRLM tissues, we detected CCR6 signals only sporadically in the tumor cells. Yet, CCR6 expression appeared rather cumulative in deformed hepatic cells along the tumor invasion front, which may represent a stimulative signal for the tumor to further expand into the neighboring hepatic tissue. Further, we demonstrated that CRLM cells of patients who had preoperative FOLFOX chemotherapy are characterized by an increased proliferation rate. This was measured by the expression of the human Ki-67 protein which is strictly associated with cell proliferation. During interphase, the antigen can be exclusively detected within the nucleus, whereas in mitosis most of the protein is relocated to the surface of the chromosomes[25].

Investigating the proliferation of CRLM cells in CRLM resection specimens, we measured proliferation after the event of FOLFOX exposure. FOLFOX treatment promotes apoptosis of CRC cells, thus inhibiting their proliferation. However, after FOLFOX chemotherapy, not only cell proliferation as measured by KI-67 staining, but also CCL20 and CCR6 expression levels, were increased as compared to patients without FOLFOX chemotherapy. *In vitro* data have shown an increased proliferation and migration of CCR6-bearing tumor cells after CCL20 stimulation[8,9]. Thus, the observed up-regulation of CCL20 expression by surviving metastatic CRC cells after FOLFOX treatment might represent a CCL20/CCR6 dependent autocrine mechanism, potentially leading to increased proliferation and migration. Since FOLFOX chemotherapy induces non-specific cell death, this mechanism might be used by surviving metastatic cells within the liver to escape FOLFOX-induced cell death. Interestingly, if the interval between preoperative FOLFOX chemotherapy and liver surgery was > 1 year, the up-regulation of neither CCL20 nor CCR6 remained statistically significant. Generally, this suggests that the up-regulation of CCL20 and CCR6 by FOLFOX is a temporary event.

The disruption of chemokine/chemokine receptor interactions is a promising strategy in the treatment of cancer. A CCR5 inhibitor is already in the clinic for the treatment of human immunodeficiency virus (HIV)-infected patients. Other different chemokine antagonists are currently under investigation in phase Ⅰ-Ⅲ trials for infectious diseases, autoimmune diseases and cancer. Since CCR6 and CCL20 may play a role in CRC, leading to proliferation and migration *via* autocrine or paracrine mechanisms, progression of CRC might be advantaged by CCR6/CCL20 interactions. Thus, the effect of chemotherapy on the expression of cancer-related chemokines and their receptors might explain in part the frequent recurrence of metastasis in patients after this treatment. Therefore, CCL20 and CCR6 interactions may constitute a potential new target for specific treatment interventions in the treatment of CRC. Such a novel approach might be effective in combination with FOLFOX as preoperative treatment prior to resection of CRLM.

COMMENTS

Background

Although long-term survival of patients with colorectal liver metastases (CRLM) can only be achieved by surgical resection, cancer recrudescence can only be avoided if CRLM are thoroughly resected and if no other non-resectable distant metastases are present. As liver resection offers the chance of long-term survival only for patients with resectable CRLM, chemotherapy is often applied to render formerly unresectable CRLM patients resectable. Thus, a combination of perioperative chemotherapy and surgery is frequently applied to improve prognosis in colorectal cancer (CRC) patients.

Research frontiers

As a standard approach of adjuvant chemotherapy, a combination of oxaliplatin, fluorouracil and leucovorin (termed FOLFOX) is most commonly used to reduce the risk of cancer relapse in CRC patients. Although pathological effects of chemotherapy for CRLM have been discussed, the pathological response regarding chemokine expression in CRLM after chemotherapy has not been reported. Thus, application of FOLFOX may enhance the expression of chemokines which are known to be up-regulated with CRC.

Innovations and breakthroughs

Recently, interactions of the chemokine/chemokine receptor pair CCL20/CCR6 became known as critical components in the regulation of CRC progression and organ selective CRC metastasis to the liver. Thus, the authors retrospectively analyzed the impact of FOLFOX chemotherapy in stage Ⅳ CRC patients on CCL20/CCR6 expression in liver metastases. The results have shown that both CCL20 and CCR6 expression levels were significantly increased in patients who had received preoperative FOLFOX chemotherapy ≤ 12 mo before liver surgery as compared to patients who had not received FOLFOX chemotherapy prior to liver surgery.

Applications

As the disruption of chemokine/chemokine receptor interactions is a promising strategy in the treatment of cancer, various chemokine antagonists are currently under investigation in phase I-III trials for infectious diseases, autoimmune diseases and cancer. Since CCL20/CCR6 interactions may play a role in the progression of CRC, the effect of chemotherapy on the expression of cancer-related chemokines and their receptors might explain in part the frequent recurrence of metastasis in patients after this treatment. Thus, CCL20/CCR6 interactions may constitute a potential target for specific CRC treatment interventions, especially in combination with FOLFOX as preoperative treatment prior to CRLM resection.

Peer review

The authors have investigated the expression of CCL20/CCR6 in resected liver metastases of colorectal cancer with regard to preoperative FOLFOX chemotherapy. In their retrospective data analysis, they found a correlation of chemotherapy with an upregulation of CCL20/CCR6 after FOLFOX treatment within 12 mo before surgery. This result is a descriptive observation without further elucidation of the underlying mechanisms. However, it may be a basis for further research in this field to clarify tumor cell resistance against specific chemotherapeutic agents.

Abstract

AIM: To investigate if and how the proinflammatory cytokine interferon γ (IFNγ) affects ghrelin expression in mice.

METHODS: The plasma concentration of ghrelin, and gastric ghrelin and somatostatin expression, were examined in wild-type mice and mice infected with *Helicobacter pylori* (*H. pylori*). Furthermore, ghrelin expression was examined in two achlorhydric mouse models with varying degrees of gastritis due to bacterial overgrowth. To study the effect of IFNγ alone, mice were given a subcutaneous infusion of IFNγ for 7 d. Finally, the influence of IFNγ and somatostatin on the ghrelin promoter was characterized.

RESULTS: *H. pylori* infection was associated with a 50% reduction in ghrelin expression and plasma concentration. Suppression of ghrelin expression was inversely correlated with gastric inflammation in achlorhydric mouse models. Subcutaneous infusion of IFNγ suppressed fundic ghrelin mRNA expression and plasma ghrelin concentrations. Finally, we showed that the ghrelin promoter operates under the control of somatostatin but not under that of IFNγ.

CONCLUSION: Gastric infection and inflammation is associated with increased IFNγ expression and reduced ghrelin expression. IFNγ does not directly control ghrelin expression but inhibits it indirectly *via* somatostatin.

Key words: Ghrelin; Interferon-γ; Somatostatin; Inflammatory diseases; *Helicobacter pylori*

INTRODUCTION

The gastric peptide hormone ghrelin is, in adults, predominantly produced in P/D$_1$ endocrine cells in humans or in A-like endocrine cells in rats and mice, which are located in the oxyntic glands of the gastric corpus[1-5]. Within the oxyntic glands, ghrelin-containing cells are found from the neck to base in both rats and humans[2,6-8]. Ghrelin-producing cells are also found in the antrum of the stomach and proximal small intestine as well as in other organs[2,9-14], but these sites are of lesser importance as the plasma ghrelin concentrations are reduced by 65% after gastrectomy[13]. Plasma ghrelin consists of two forms; the active acylated ghrelin, which is the ligand for the GH secretagogue (GHS) receptor, and the non-acylated ghrelin, which constitutes greater amounts in the blood than the acylated form[11]. Ghrelin is involved in energy homeostasis and ghrelin plasma concentrations are decreased in obesity and increased in states of negative energy balance such as fasting, anorexia or cachexia[11] as well as being inversely correlated to body mass index (BMI) and insulin secretion[11,13]. Ghrelin plasma concentrations increase before meals and decrease after eating[15,16]. However, to what degree ghrelin is important as a meal initiator or cause of increased caloric ingestion in obesity has not yet been determined[17].

Recently, several studies have found that infection with the gram-negative bacteria *Helicobacter pylori* (*H. pylori*) reduces ghrelin concentrations in both humans[7,18,19] and rodents[20]. With regard to various upper gastrointestinal diseases, plasma concentrations of ghrelin were lowest in chronic gastritis and gastric ulcer and highest in acute gastritis[21]. Furthermore, children infected with *H. pylori* have faltering growth[22,23], which suggests that *H. pylori* could alter signals from the stomach related to the control of growth and body weight[24].

The inflammation that occurs in the *H. pylori*-infected host is a Th1-dominated immune reaction which is regulated by, among others, the lymphocyte-derived cytokine interferon-γ (IFNγ)[25]. In the gastrin knockout (KO) mouse, which is another model for chronic gastritis due to bacterial overgrowth, we and others have also found increased gastric production of IFNγ and expression of IFNγ regulated transcripts[26,27]. Furthermore, IFNγ is one of the major cytokines behind the inflammatory response to *H. pylori* as no inflammation occurs during *H. pylori* infection without the presence of IFNγ[25]. Finally, infusion of IFNγ triggers inflammation *in vivo* without *H. pylori*[26]. Since approximately 50% of the world population is infected with this bacteria[28], knowledge of the factors modulating body weight during *H. pylori* infection could have great impact on health in general. Since little is known about the factors that regulate ghrelin expression during *H. pylori* infection and gastric inflammation[29], we examined the effect of IFNγ on ghrelin expression in mice.

MATERIALS AND METHODS

Mice

Groups of wild-type (wt) C57BL/6J mice (aged 12-16 wk), KO mice which are gastrin deficient (aged 12-16 wk or 48-56 wk)[30], histidine decarboxylase (HDC) KO mice (aged 48-56 wk)[31] and matching control mice were used. All mice were male mice that had been backcrossed to the C57BL/6J mouse strain. The mice were kept under specific pathogen-free conditions and monitored according to the Federation of European Laboratory Animal Science Associations recommendations[32] with 12 h light, 12 h dark cycles. The study was approved by the Danish Animal Welfare Committee.

H. pylori infection

C57BL6/J mice (n = 10) were inoculated with a non-mouse-adapted clone of *H. pylori* strain 67:21, originally isolated from an antral biopsy obtained from a Swedish female with gastric ulcer. The strain is VacA$^+$ and contains the entire Cag pathogenicity island (PAI) with genetic stability in the Cag PAI[33]. The mice were inoculated every second day (three times) during a 5-d period. After the mice had been sacrificed, DNA was extracted and analyzed for the presence of *Helicobacter* species using a semi-nested polymerase chain reaction-denaturing gradient gel electrophoresis assay, specific for the genus *Helicobacter*, as described previously[34]. A matched group of uninfected C57BL6/J mice were used as controls. All animal experiments were approved by the Danish Animal Welfare Committee (2005/562-40) and the Danish Forest and Nature Agency (20010077355/6).

IFNγ infusion

Wild-type mice were given a continuous subcutaneous IFNγ infusion (8 μg/kg per hour or 24 μg/kg per hour for 7 d) for each group (n = 6) using osmotic minipumps (Alzet no.2001; Alza Corp., Cupertino, CA). Control mice received a saline infusion instead. The lower dose of IFNγ equals the dose of IFNγ used by Kang *et al*[26].

Tissue and plasma collection

The mice were anesthetized with intraperitoneal 2,2,2 tribromoethanol (Sigma-Aldrich Corp., St. Louis, MO), blood was collected in EDTA-tubes and the stomachs removed. The stomachs of all mice were dissected into fundus and antrum and immediately placed in liquid nitrogen. Plasma and tissue was subsequently stored at -80℃ until further analysis.

Measurement of plasma ghrelin

Plasma ghrelin was measured in EDTA plasma without extraction using RIA no. RK-031-31 (Phoenix Peptides, Belmont, CA). This assay measures the sum of Ser3-octanoyl and Ser3-des-octanoyl ghrelin peptides. The assay has a detection limit of 20 pmol/L, an interassay variation of 13%, and an intra-assay variation of 5%[4].

mRNA extraction and analysis

The stomachs were dissected into fundus and antrum and immediately placed in liquid nitrogen. RNA was extracted using the method described by Chomcynski and

Sacchi[35], and quantitative changes in the specific mRNA were determined by real-time PCR using the Lightcycler (Roche, Mannheim, Germany) as described by Chen *et al*[36]. Quantitations were performed using one of the following primer sets for each analysis: Ghrelin forward primer (FP) 5'-TCTGCAGTTTGCTGCTACTCA-3' and ghrelin reverse primer (RP) 5'-CCTCTTTGACCTCTTCCCAGA-3'; IFNγ FP 5'-CCTTTGGACCCTCTGACTTG-3' and IFNγ RP 5'-CATCCTTTTGCCAGTTCCTC-3'; gastrin FP 5'-CACTTCATAGCAGACCTGTCCA-3' and gastrin RP 5'-CTGGCCTCTGGAAGAGTGTT-3'; somatostatin FP 5'-CCCAGACTCCGTCAGTTTCT-3' and somatostatin RP 5'-TCAGAGGTCTGGCTAGGACAA-3'; iNOS FP 5'-ACCCCTGTGTTCCACCAGGAGATGTTGAA-3' and iNOS RP 5'-TGAAGCCATGACCTTTCGCATTAGCATGG-3' and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) FP 5'-GGTGCTGAGTATGTCGTGGA-3' and GAPDH RP 5'-GTGGTTCACACCCATCACAA-3'. Each run consisted of one negative control, one sample in which the Moloney murine leukemia virus reverse transcriptase had been omitted in the reverse transcription (RT) step, a standard curve generated by 3-fold serial dilution of RT reactions, and seven to nine RT reactions from each of the three strains. Expression of a given transcript was normalized to a GAPDH quantification performed on the same RT reaction as previously described[36].

Immunohistochemical analysis

Stomachs were rinsed in ice-cold PBS, fixed in 4% paraformaldehyde in PBS for 4-6 h and embedded in paraffin. Five-micrometer sections were cut and stained with hematoxylin and eosin. Immunohistochemistry was performed using the rabbit ghrelin antibody H-031-31 diluted 1:1 000 (Phoenix Peptides) detected with Envision-DAB+ (Dako, Glostrup, Denmark) as previously described[37]. The specificity of the immunostaining was tested by absorbing the primary antibodies with antigen before applying them to the slides or omitting the primary antibody when purified antigen was not available. The morphometrical analysis was performed by cell counting in transversely cut sections as described[38].

Cell lines

NCI-H727 cells were grown in RPMI 1640 media (Invitrogen, Carlsbad, CA), 10% FBS (Biowest, Nuaillé, France), *penicillin* (100 U/mL) and *strep*tomycin (100 μg/mL) (Invitrogen) and cultured at 37℃ in 5% CO_2.

Plasmids and transient transfections

A 2.5 Kb fragment containing the mouse ghrelin promoter and exon one was amplified from C57BL6/J genomic DNA using the Expand kit (Roche, Mannheim, Germany) using mGhrMluI primer 5'-ATATACGCGTGTAGAACACTCACCCTAAATCTG-3' and mGhrXhoI primer 5'-ATATCTCGACTGCCTGGGGATGTGGTGCCTG-3'. The fragment was ligated into the pGL3 Bacic reporter vector (Promega, Madison, WI). The promoter sequence was confirmed by sequencing. One day before transfection, 500 000 NCI-H727 cells were seeded in 6-well dishes coated with 0.01% poly-L-lysine. The NCI-H727 cells were transfected using 6 μL TurboFect™ *in vitro* Transfection Reagent (Fermentas, Burlington, Canada); 2 μg ghrelin promoter plasmid and 1 μg pRL-0 (Promega, Madison, WI) were mixed with 200 μL GIBCO™ Opti-MEM I (Invitrogen, Carlsbad, CA) and incubated for 20 min before application to the cells. Twenty-four hours later, the cells were FBS starved in RPMI1640 media containing 0.5% FBS (Biowest, Nuaillé, France) for 24 h before treatment with forskolin (10 mg, Sigma-Aldrich, St. Louis, MO), IBMX (≥ 99.9%, Sigma-Aldrich, St. Louis, MO), octreotide (200 μg/mL, Mayne Pharma, Melbourne, Australia), or IFNγ (0.2 mg/mL, Immukine, Boehringer Ingelheim, Ingelheim, Germany), for 24 h alone or in combination. All treatments were performed in triplicate. IBMX and forskolin were dissolved in 99.9% DMSO (Merck, Darmstadt, Germany). Cells were then harvested and assayed for luciferase activity using the Dual-Luciferase Reporter Assay System according to the instructions by the manufacturer (Promega, Madison, WI) and normalized to Renilla luciferase activity.

Statistical analysis

Student's unpaired *t*-test statistics were used and differences with a $P \leqslant 0.05$ were considered significant. Unless otherwise stated, results are given as mean ± SD.

RESULTS

H. pylori infection is associated with an IFNγ inflammatory response and with suppression of ghrelin expression

The mice were sacrificed 2 mo after inoculation, as earlier studies had shown that a *cag*-dependent inflammation of the corpus mucosa develops at this time and results in a severe active and chronic gastritis[39,40]. At 2 mo, seven out of ten mice tested positive for *H. pylori* using semi-nested PCR with primers for *H. pylori* CagA and urease genes. The non-infected mice were subsequently excluded. All control mice tested negative.

The infection of the mouse stomach by *H. pylori* caused a 2- to 3-fold increase in the fundic expression of IFNγ and of inducible nitric oxide synthase (iNOS) (Table 1). Furthermore, during the 2 mo infection, the *H. pylori*-infected mice did not gain weight in contrast to wild-type mice (Figure 1A). Ghrelin mRNA expression was reduced to 55% in the *H. pylori*-infected mice (Figure 1B). This was associated with a 49% decrease in the plasma ghrelin concentration (Figure 1C). The reduced ghrelin mRNA expression presumably reflects a reduced expression in each cell as opposed to cell atrophy, as the density of fundic ghrelin cells was unaffected (Table 1). In the infected mice the expression of antral somatostatin was suppressed, whereas the fundic somatostatin expression was increased (Table 1).

Ghrelin expression was reduced in old gastrin knockout mice, but not in young gastrin and old histidine decarboxylase knockout mice

To test whether the altered ghrelin expression could also be

Table 1 Fundic somatostatin mRNA increases after 2 mo of *Helicobacter pylori* infection in wild-type mice (mean ± SE)

	Fundus			Antrum

The expression of interferon γ (IFNγ), iNOS and somatostatin mRNA in arbitrary units in *H. pylori*-infected mice (n = 7) 2 mo after inoculation or in uninfected control mice (n = 7). Ghrelin cell density was unchanged. *H. pylori*: *Helicobacter pylori*; NS: Non-significant.

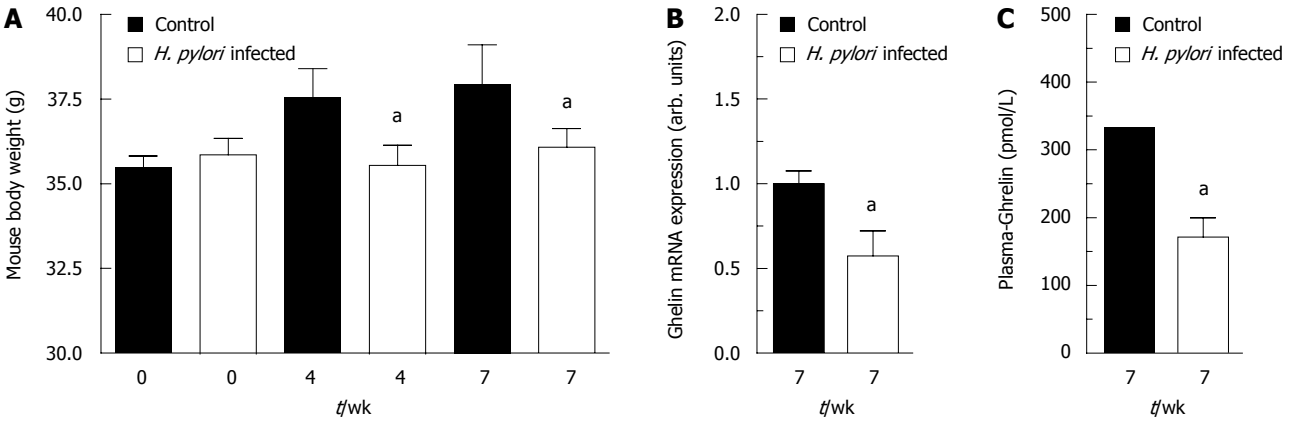

Figure 1 Mice infected with *Helicobacter pylori* have reduced ghrelin expression and do not gain weight. C57BL6/J mice were infected with *Helicobacter pylori* (*H. pylori*) strain 67:21 [this strain is VacA+ and contains a complete genetically stable Cag pathogenicity island (PAI)]. While the control mice gained weight the infected mice did not (A). Mice infected with *H. pylori* had reduced ghrelin expression in the stomach (B) and reduced ghrelin plasma concentrations (C). $^{a}P < 0.05$ *vs* control.

found in other mouse models with gastric inflammation, we examined the expression of IFNγ and ghrelin in two other mouse models; the achlorhydric gastrin KO mice and the hypochlorhydric histidine decarboxylase (HDC) KO mice[41,42].

IFNγ expression was not induced in the old HDC KO mice (Figure 2A), and the ghrelin expression was unchanged in these mice (Figure 2B). Young gastrin KO mice only had moderate inflammation, while the old mice had more inflammation when evaluated by higher IFNγ expression (Figure 2C). Ghrelin expression was unaffected in young gastrin KO mice but reduced in old gastrin KO mice (Figure 2D).

IFNγ suppresses fundic ghrelin mRNA expression and plasma ghrelin concentrations

Since both the *H. pylori* infection and the bacterial overgrowth in the gastrin KO mice were associated with increased expression of IFNγ and reduced ghrelin expression, we examined the effect of IFNγ on ghrelin expression. The fundic ghrelin expression was approximately 30 times higher than the antral (Figure 3A and B). The fundic expression of ghrelin mRNA was halved at both infusion rates of IFNγ (8 μg/kg per hour and 24 μg/kg per hour) examined compared to expression levels in wt mice (Figure 3A and B). In contrast, antral ghrelin expression did not alter significantly under IFNγ infusion at either dose. The reduction in ghrelin expression presumably reflects a reduced expression in each cell as opposed to cell atrophy, as infusion of IFNγ did not change the density of fundic ghrelin cells (Figure 3D). The reduced ghrelin expression was correlated with a 40% reduction in plasma ghrelin concentrations at 7 d of IFNγ infusion (Figure 3C). Furthermore, IFNγ infusion induced the expression of fundic somatostatin, whereas the antral somatostatin expression did not change under the influence of IFNγ (Table 2).

The ghrelin promoter operates under the control of somatostatin but not under that of IFNγ

We next examined the effect of IFNγ and somatostatin on the transcriptional regulation of ghrelin using a 2 kb ghrelin promoter construct. The experiments were carried out in NCI-H727 cells since these are carcinoid cells expressing both somatostatin receptor 2 (SSTR2) and SSTR5. This indicates that they could be a good model for A-like cells in the stomach (Døssing, unpublished data). Treatment with IFNγ did not affect the activity of the ghrelin promoter construct. In contrast, forskolin and IBMX both independently and together activated the 2 kb promoter (Figure 4). Moreover, treatment with octreotide (somatostatin analog) reduced the basal ghrelin promoter activity (Figure 4) as well as forskolin/IBMX-induced ghrelin promoter activation in a dose-dependent manner.

DISCUSSION

Our results show that the gastric expression of ghrelin

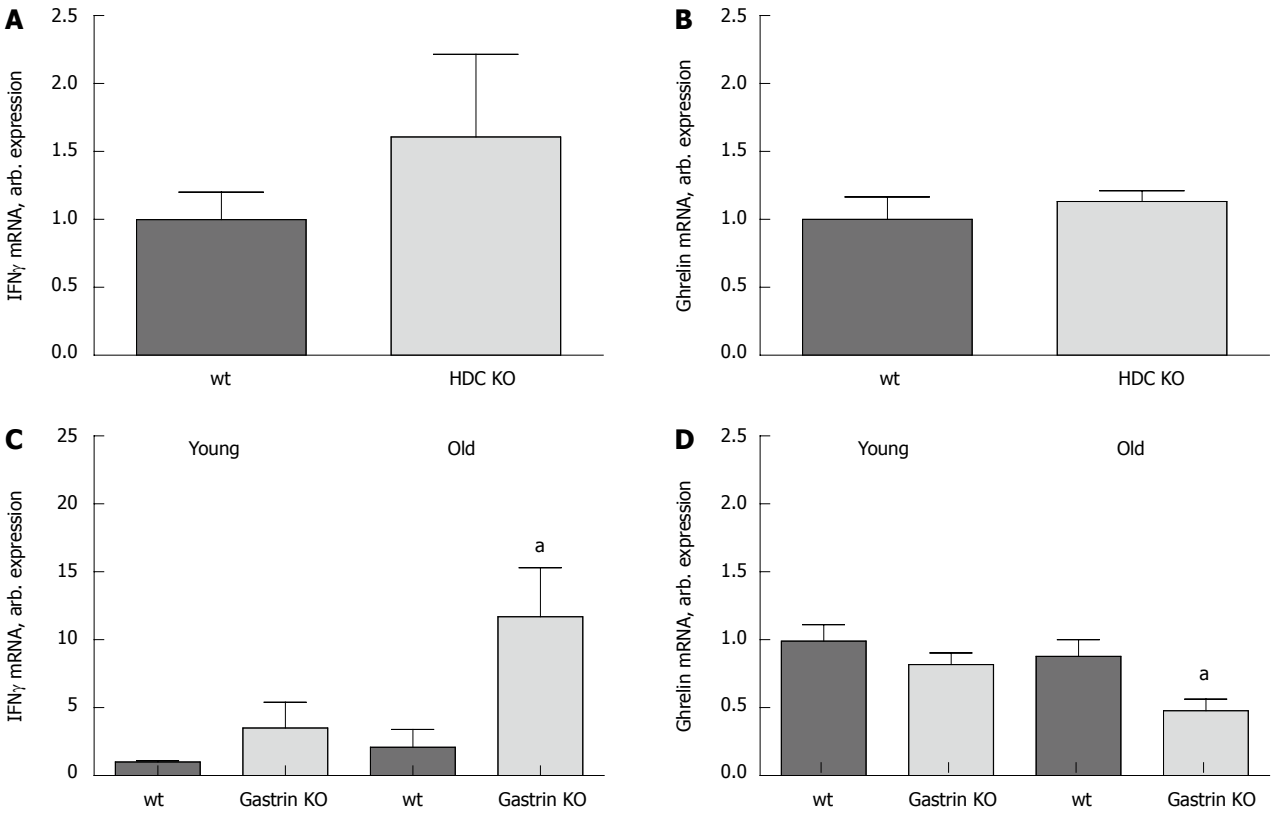

Figure 2 Interferon γ expression is increased and ghrelin expression is reduced in old but not young gastrin knockout mice and histidine decarboxylase knockout mice. The expression of interferon γ (IFNγ) and ghrelin mRNA in young (12-16 wk) and old (48-56 wk) achlorhydric gastrin KO mice and old (48-56 wk) hypochlorhydric histidine decarboxylase (HDC) KO mice (n = 6 in each group) is shown. There is no change in either IFNγ (A) or ghrelin (B) expression in HDC KO mice as compared to wt mice. While the gastric inflammation evaluated by expression of IFNγ increases when the gastrin KO mice get older (C), the expression of ghrelin decreases (D). $^{a}P < 0.05$.

Table 2 Fundic expression of somatostatin mRNA increases during subcutaneous interferon γ infusion (mean ± SE)

	Fundus			Antrum		
	Saline	+ IFNγ	*P*	Saline	+ IFNγ	*P*
Low Dose IFNγ						
Somatostatin mRNA	1.0 ± 0.2	1.9 ± 0.2	< 0.05	1.0 ± 0.2	0.9 ± 0.1	NS
IFNγ mRNA	1.0 ± 0.1	1.1 ± 0.2	NS	1.0 ± 0.1	1.2 ± 0.2	NS
High Dose IFNγ						
Somatostatin mRNA	1.0 ± 0.1	1.6 ± 0.1	< 0.05	1.0 ± 0.1	1.1 ± 0.1	NS
IFNγ mRNA	1.0 ± 0.2	1.3 ± 0.1	NS	1.0 ± 0.1	1.2 ± 0.1	NS

The fundic and antral expression of somatostatin mRNA and endogenous interferon γ (IFNγ) mRNA in arbitrary units in mice infused with either IFNγ or saline (n = 6 in each group). Low dose IFNγ = 8 μg/kg per hour for 7 d and high dose IFNγ = 24 μg/kg per hour for 7 d. NS: Non-significant.

mRNA and the plasma concentration of ghrelin are reduced during gastric infection, either due to bacterial overgrowth in general or to *H. pylori* infection specifically. Both types of infection are associated with an IFNγ inflammatory response. Furthermore, infusion of IFNγ alone could mimic the changes in ghrelin expression and plasma concentration seen during *H. pylori* infection and bacterial overgrowth.

The observation of reduced ghrelin expression in *H. pylori*-infected mice is in agreement with several studies that found reduced ghrelin concentrations in both humans[7,18,19] and rodents[20] infected with *H. pylori*. However, others have reported ghrelin plasma concentration to be unaffected[43,44] or even to increase during *H. pylori* infection[45]. These discrepancies could be due to differences in the severity of the infection. We found gastric ghrelin expression unaffected in young gastrin KO mice and HDC KO mice, both with only mild inflammation as evaluated by the IFNγ response. However, as the gastrin KO mice got older and developed a more severe gastric inflammation, the ghrelin expression decreased. Similar observations have also been observed in humans, where a correlation between increasing degree of chronic inflam-

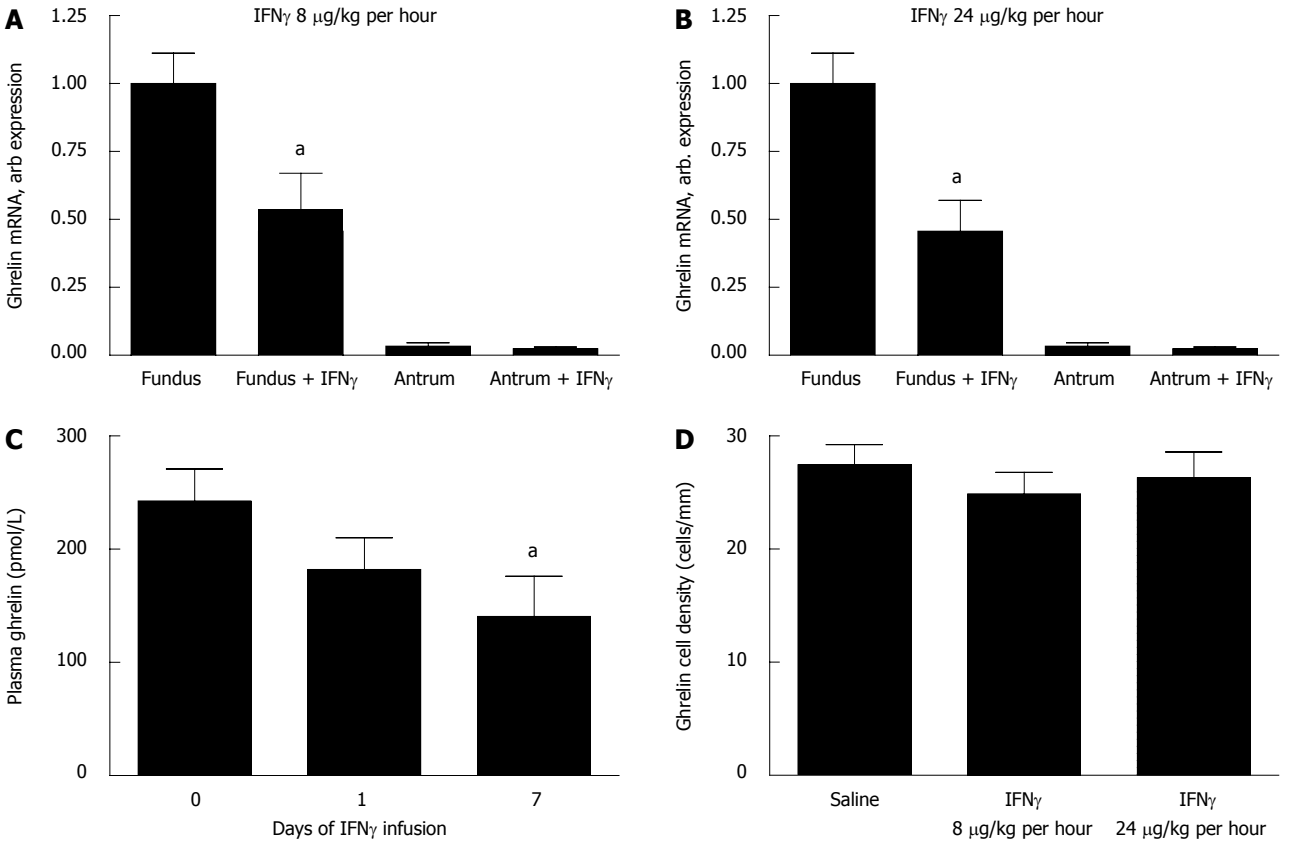

Figure 3 Interferon γ suppresses ghrelin expression in the gastric fundus and ghrelin concentrations in plasma independently of loss of ghrelin-producing cells. Mice infused with interferon γ (IFNγ) as compared to saline infused mice (n = 6 in each group). IFNγ was infused at low dose (LD) = 8 μg/kg per hour for 7 d or high dose (HD) = 24 μg/kg per hour for 7 d. Low (A) and high (B) dose IFNγ infusion decreases the expression of ghrelin mRNA to a similar degree. HD IFNγ represses ghrelin concentrations in plasma gradually over time (C). The density of fundic ghrelin cells is not altered by IFNγ infusion (D). $^aP < 0.05$.

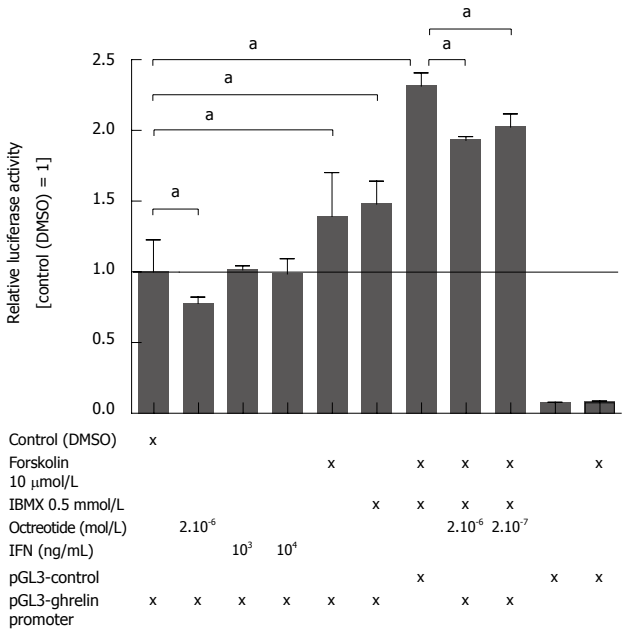

Figure 4 The somatostatin receptor agonist octreotide inhibits activation of the ghrelin promoter. Pulmonary carcinoid NCI-H727 cells were transfected with a 2 kb mouse ghrelin promoter construct and treated for 24 h with forskolin, IBMX, octreotide, and interferon γ (IFNγ) alone or in combination, after which the ghrelin promoter response was measured by the dual-luciferase reporter assay system. Octreotide inhibited both basal and IBMX and/or forskolin-induced ghrelin expression. Forskolin and IBMX were dissolved in dimethyl sulfoxide (DMSO). $^aP < 0.05$.

mation, severity of glandular atrophy and metaplasia and decreasing ghrelin expression was found[8,19].

Reduced gastric ghrelin expression could either be due to a reduced number of ghrelin cells or reduced expression within each cell. Ghrelin-producing cells are primarily found in the oxyntic glands in the stomach[2,3]. The expression of ghrelin mRNA was more than 30 times higher in the fundus than antrum in control mice. Reduced numbers of ghrelin cells in fundic mucosa has indeed been seen in *H. pylori*-infected humans[7] and this correlates with a reduction in plasma ghrelin concentrations.

In our study, the density of ghrelin cells did not change indicating that our observations are due to reduced expression within the cells. The mechanism leading to reduced ghrelin expression during *H. pylori* infection is poorly understood. We found that IFNγ had no direct effect on the ghrelin promoter, suggesting that the IFNγ inhibition of ghrelin expression is mediated *via* other transmitters. In our study, fundic somatostatin was increased both during gastric inflammation and during infusion of IFNγ. Somatostatin is the universal inhibitor of secretion from endocrine cells[46] and also inhibits ghrelin secretion[47]. We show that octreotide (a somatostatin analog) inhibits the activity of the ghrelin promoter. Increased corpus somatostatin has also been found during *H. pylori* infection[48]. However, reduced fundic somatostatin expression has been found in other studies[49,50]. One explanation for

these differences is the degree of fundic atrophy, which affects both ghrelin and somatostatin expression[7].

Immunoregulation of somatostatin has also been demonstrated in *in vitro* studies[51]. These showed that TNFα and IL-1β stimulated somatostatin secretion. IL-4 also stimulated somatostatin secretion and together these changes could explain the hypochlorhydria seen in mice infected with *H. felis*[52]. However, in that study, infusion of IFNγ resulted in a reduction of fundic somatostatin. We have no explanation for the difference in response to IFNγ. The proinflammatory cytokine IL-1β also influences ghrelin levels and seems to suppress excess ghrelin secretion in *H. pylori*-infected mice[53]. Thus, not only IFNγ but other cytokines as well are associated with reduced ghrelin expression.

We have shown that gastric infections either due to *H. pylori* or bacterial overgrowth are associated with reduced fundic ghrelin expression and increased IFNγ production. Infusion of IFNγ in mice alone mimics the changes seen in the mice with gastric infections. Stimulation with IFNγ does not directly inhibit the ghrelin promoter; instead the inhibition is mediated through somatostatin.

COMMENTS

Background

Ghrelin is involved in energy homeostasis and ghrelin plasma concentrations are decreased in obesity and increased during fasting, anorexia or cachexia. Recently, several studies have found that infection with *Helicobacter pylori* (*H. pylori*) reduces ghrelin concentrations in both humans and rodents. Furthermore, children infected with *H. pylori* have faltering growth, suggesting that *H. pylori* may alter signals from the stomach related to the control of growth and body weight. The mechanism(s) through which inflammation modulates ghrelin expression are, however, poorly understood.

Research frontiers

Chronic gastritis induced by *H. pylori* is a Th1-dominated immune reaction which is regulated by, among others, the lymphocyte-derived cytokine interferon-γ (IFNγ). In the gastrin knockout (KO) mouse which is a model for chronic gastritis due to bacterial overgrowth, increased gastric production of IFNγ has been found. Since little is known about the factors that regulate ghrelin expression during *H. pylori* infections and gastric inflammation, the authors examined if, and through which mechanisms, IFNγ modulates ghrelin expression in mice.

Innovations and breakthroughs

H. pylori-infected mice and old gastrin KO mice with inflammation due to bacterial overgrowth of the stomach display an increased expression of IFNγ and a decreased expression of ghrelin. The changes in ghrelin and somatostatin expression can be duplicated by infusion of IFNγ alone. IFNγ does not directly suppress ghrelin expression but inhibits it indirectly by increasing somatostatin secretion.

Applications

A better understanding of the mechanisms that control ghrelin expression during inflammation by either *H. pylori* alone or by gastric bacterial infections in general aids in the understanding of factors modulating growth and body weight during infection. This could have great impact on general health in the population.

Terminology

IFNγ is a cytokine that is important for innate and adaptive immunity against bacterial infections and for tumor control. The most important functions of IFNγ come from its immunostimulatory and immunomodulatory effects. Ghrelin is a hormone produced in the oxyntic glands of the gastric corpus. It is a growth hormone promoting intestinal cell proliferation, and is involved in energy homeostasis. Ghrelin expression was, in this study, found to be inhibited by octreotide, which is an analog of somatostatin. Somatostatin acts as a general inhibitor of secretion from, and growth of, endocrine cells. Somatostatin is widely distributed throughout the body including several locations in the digestive system such as the stomach, intestine and delta cells of the pancreas.

Peer review

This is the first experimental study on the effect of IFNγ on ghrelin expression. It is a very well designed study, using a careful combination of several animal models and different techniques, and the discussion is well structured. The study is valuable in the context of providing evidence on the indirect regulation of ghrelin expression and secretion by IFNγ mediated through somatostatin.

Abstract

AIM: To analyze the long-term prognosis in a cohort of western cirrhotic patients with single hepatocellular carcinoma treated with ethanol injection.

METHODS: One-hundred forty-eight patients with solitary hepatocellular carcinoma were enrolled. The tumor diameter was lower than 2 cm in 47 patients but larger in the remaining 101 patients. The impact of some pre-treatment clinical and laboratory parameters and of tumor recurrence on patients' survival was assessed.

RESULTS: Among the pre-treatment parameters, only a tumor diameter of less than 2 cm was an independent prognostic factor of survival. The occurrence of new nodules in other liver segments and the neoplastic portal invasion were linked to a poorer prognosis at univariate analysis. Patients with a single hepatocellular carcinoma smaller than 2 cm showed a better 5-year cumulative survival (73.0% *vs* 47.9%) (P = 0.009), 3-year local recurrence rate (29.1% *vs* 51.5%) (P = 0.011), and 5-year distant intrahepatic recurrence rate (52.9% *vs* 62.8%) (P = 0.054) compared to patients with a larger tumor.

CONCLUSION: The 5-year survival rate of patients with single hepatocellular carcinoma < 2 cm undergoing ethanol injection is excellent and comparable to that achieved using radiofrequency ablation.

Key words: Hepatocellular carcinoma; Cirrhosis; Percutaneous ethanol injection; Prognosis

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth more common cancer worldwide, and is the leading cause of death among patients with cirrhosis in Europe and the USA[1-3]. Since the rate of tumors diagnosed early in a subclinical stage is still low, screening and surveillance strategies in cirrhotic patients based on an ultrasound (US) study of the liver and serum assay of α-fetoprotein (AFP) have been developed and applied in both the Eastern and

Western world. Accordingly, a trend towards a progressive decrease of the mean diameter of HCC diagnosed by screening during the last few years has been demonstrated, and this seems to improve patients' prognosis by increasing their access to curative treatments[4].

Surgical resection and liver transplantation provide the best effective cure in HCC. However, resection is usually offered to cirrhotics with a single lesion and preserved liver function without severe portal hypertension, while liver transplantation is an effective option for patients with tumors within the Milan criteria (one nodule < 5 cm or no more than 3 nodules < 3 cm), but can only be considered in a limited number of patients due to the problem of organ shortage[5]. US-guided percutaneous ablation is currently regarded as the first line approach in the treatment of early-stage HCC deemed unsuitable for surgery or liver transplantation. Percutaneous ethanol injection (PEI) was the first percutaneous treatment introduced in clinical practice; it has been widely used during the last 20 years with excellent results[6], and was recommended as the standard ablation therapy of HCC according to the European guidelines for the management of HCC published in 2001[7]. At the end of the nineties, radiofrequency ablation (RFA) became available and progressively replaced PEI[8,9]. Accordingly, a question about the usefulness of PEI in the treatment of HCC has been recently raised. In agreement with Forner *et al*[10], we think that PEI is still useful for the treatment of lesions located at risky sites for RFA, for residual areas of viable tumors after RFA, and as a bridge treatment in HCC patients listed for liver transplantation. Furthermore, according to the present guidelines for the management of HCC[11], the efficacy of PEI is probably similar to that of RFA in patients with compensated cirrhosis and single tumors smaller than 2 cm in which 5-year survival has been shown to be higher than 70% in eastern series[9,12,13].

The aim of this study was to assess the factors affecting long term prognosis in a single-centre cohort of western cirrhotic patients with single HCC treated with PEI, focusing on the subgroup of patients with small tumors smaller than 2 cm.

MATERIALS AND METHODS

Two hundred-eighteen cirrhotic patients with single HCC treated with PEI in our centre during the period 1991-2008 were evaluated. In all patients cirrhosis was confirmed by histological and/or clinical findings (blood chemistry, US, and/or endoscopic signs of liver cirrhosis and/or portal hypertension). Most patients were diagnosed during a 6 mo-interval screening program for early diagnosis of HCC based upon ultrasound study of the liver and serum assay of AFP. After detection of the suspicious HCC nodule, all patients underwent characterization of the lesion using computed tomography (CT), magnetic resonance imaging (MRI), contrast enhanced ultrasound (CEUS), and/or fine-needle biopsy, in accordance to the current diagnostic guidelines; for this reason, most of the lesions diagnosed before 2001 were further evaluated using cyto-histological assessment, while lesions larger than 2 cm detected after 2001 were mainly diagnosed using two imaging studies showing coincident typical dynamic findings after contrast enhancement; a cytological and/or histological evaluation using fine-needle biopsy was reserved for lesions showing non-typical features on dynamic imaging study[7]. After 2005 this policy was extended to lesions less than 2 cm in size[11].

Patients were usually staged before treatment using CT scan. MRI was reserved for patients with contraindications to the administration of iodinated contrast media.

Among the 218 patients included in the study group, 48 were excluded because PEI was associated with other locoregional therapies as initial treatment, 19 because complete necrosis was not achieved after treatment completion, and 3 because of insufficient follow-up data. Hence, the study refers to 148 patients with a minimum post-treatment follow-up period of 6 mo. One hundred-three patients were treated during the period 1991-2000 while the remaining 45 patients underwent PEI during the period 2001-2008. All patients gave informed consent to all diagnostic investigations and therapeutic procedures and the study protocol conforms to the ethical guidelines of the of the 1975 Declaration of Helsinki as reflected in a priori approval by the institution's human research committee. For the whole population, the last follow-up data were recorded on February 2010.

The patients were 109 men and 39 women (mean age 67 ± 8 years, range 34-87 years). The cirrhosis etiology was post-hepatic C in 107 cases, post-hepatic B in 18 cases, post-hepatic C and B in 7 cases, alcoholic in 10 cases, and cryptogenic in 6 cases. According to the Child-Pugh scoring system[14], 130 patients were scored Class A, and 18 Class B. Fifteen patients had mild ascites, while 6 patients showed partial non-neoplastic thrombosis of the portal system according to dynamic imaging studies[15]. The mean HCC diameter was 2.8 cm (range 1.1-5.8 cm). Forty-seven patients (31.8%) had a single tumor < 2 cm, 57 (38.5%) between 2 and 3 cm, and 44 (27.0%) > 3 cm. In only 3 cases the tumor diameter exceeded 5 cm. Overall, a cytological and/or histological diagnosis of HCC was available in 63/148 HCCs (well differentiated in 52 cases, moderately differentiated in 10 cases, and poorly differentiated in 1 case).

All patients were excluded from resective surgery due to one or more of the following reasons: severe portal hypertension, impaired liver function, refusal of surgery, presence of severe comorbidities increasing the surgical risk, and severely impaired clotting parameters. Four patients were waiting for liver transplantation and PEI was used as a bridging treatment; all these patients were transplanted and the follow-up period ended at the moment of transplantation. For patients diagnosed after 2000, when RFA became available in our centre, the main reasons for choosing PEI for treatment were the following: impaired clotting parameters preventing the use of large bore needles, location of the tumor in a dangerous position for RFA (e.g. near the gall bladder, the glissonian capsule, or an intestinal loop adjacent to the liver edge), location of

the tumor near a large vessel lowering the level of heating needed to induce tumor necrosis, and patient choice.

Patients were usually treated by multisession US-guided PEI on an out-patient basis. After local antisepsis and intradermal local anaesthesia at the site of the needle insertion, sterile 95% ethanol (Salf, Bergamo, Italy) was injected into the lesion using either a 20-cm-long Chiba needle with an inner calibre of 20 Gauge (Ekoject, Hospital Service, Italy) or a PEI dedicated 20-cm long multi-hole 21-Gauge needle (Peit Needle, Hospital Service, Italy) at a dosage of 1-8 mL per session. The Chiba needles were preferentially employed to treat small tumors while the multi-hole needles were usually reserved for lesions larger than 2-3 cm. Treatment was performed once or twice per week and the total amount of ethanol injected was calculated according to the numerical expression $V=(4/3)\pi(r+0.5)^3$, where V (in mL) is the volume of ethanol and r (in cm) is the radius of the lesion increased by 0.5 cm based on the concept that the volume of ethanol injected must overcome the theoretical volume of the lesion[16]. The number of PEI procedures needed to achieve tumor ablation was 6 on average (range 1-11) in the whole population and 2 (range 1-4) in the subgroup of patients with HCC of up to 2 cm. The amount of ethanol injected per session ranged between 2 and 9 mL, with no more than 15 min needed for each PEI session. The effectiveness of PEI was assessed by CT scan with contrast enhancement performed within one month after treatment completion. Complete necrosis was considered achieved when the lesion appeared as a non perfused area during the arterial phase of the study. In the case of intolerance to iodinated contrast media, MRI with gadolinium contrast enhancement was used. During the last 7 years, we added CEUS in the post-PEI assessment of the treated lesion; our policy was to perform CEUS about one month after PEI; in case of presence of residual arterial enhancement, suggesting the presence of a viable tumor, the lesion was immediately re-treated without further imaging evaluation while in the case of absence of contrast enhancement in the arterial phase, suggesting complete necrosis, we used CT or MRI as a confirmatory test[17].

After completion of treatment, the patients were followed by serum assay of AFP and US liver study performed every 3 mo. Local recurrence of the treated lesion was suspected on the basis of size increase and/or US pattern change; in this case, CEUS, CT scan or MRI were performed to assess the presence of arterial enhancement areas suggesting recurrent disease. Furthermore, each new lesion visualized by US in a liver segment different from that of the first neoplasm was characterized using CEUS, CT scan, MRI, and/or US-guided liver biopsy, following the current guidelines for HCC diagnosis[7,11].

The following clinical and biochemical parameters assessed before PEI were analyzed to examine their value as predictive factors for survival (Table 1): age, gender, hepatitis B surface antigen (HBsAg), hepatitis C virus (HCV) antibody, Child-Pugh class, aspartate aminotransferase (AST) level, alanine aminotransferase (ALT) level, prothrombin time ratio, serum bilirubin, serum albumin, platelet count, presence of ascites, presence of portal thrombosis, serum AFP and HCC size ≤ 2 cm. Finally, the impact on survival of local recurrence (HCC recurrence in the same liver segment), distant recurrence (HCC recurrence in a liver segment different from that of the

first neoplasm), portal invasion (imaging detection or cytological diagnosis of neoplastic thrombosis of the portal tree), and disease free survival (DFS, defined as the interval in months between last PEI session until local HCC recurrence and/or appearance of new HCC lesions within or outside the liver) were also evaluated.

Statistical evaluation

Overall survival was defined as the interval in months between the first PEI session until death or the last recorded follow-up. Cumulative survival and recurrence curves were obtained using the Kaplan-Meier curves. For each variable taken into account, the differences between curves were assessed using the *post hoc* log-rank test. For age, ALT level, AST level, prothrombin time ratio, bilirubin level, albumin level, platelet count, and AFP, the patients were separated into groups: those $\leqslant$ the median and those > the median. For the purpose of the study, patients were split into two subgroups according to a HCC size smaller or larger than 2 cm. The parameters significant at univariate analysis were tested using the Cox's proportional hazard model. The post treatment parameters of neoplastic portal invasion, local recurrence, distant recurrence, and DFS were only tested by univariate analysis. Correlation was analyzed with the Spearman rank test. A *P* value of $\leqslant$ 0.05 was considered significant. All statistical analyses were performed using the SPSS™ 13.0 software package.

RESULTS

The mean follow-up period was 42 mo (range 8-166 mo), and was longer than 60 mo in 34 patients. In no case was the PEI procedure associated with mortality or complications requiring emergency treatment. Seeding of HCC to the abdominal wall was not recorded.

The 1-, 3-, and 5-year survival rate of the entire cohort was 95.8%, 73.4%, and 55.9%, respectively, and the estimated median survival rate was 78 mo [CI 95% 54.38-101.62] (Table 2). During the follow-up, 4 patients underwent OLT and 51 (34.5%) died. The causes of death were: liver failure due to progression of the neoplasm involving more than 50% of the liver parenchyma with or without invasion of the main intrahepatic vessels in 35 cases (68.6%), liver failure unrelated to tumor progression in 7 cases (13.7%), bleeding from esophageal or gastric varices in 2 cases (2.9%), and other extrahepatic diseases in 3 cases (sepsis, myocardial infarction, pulmonary embolism, 5.9%). The cause of death was unknown in 4 cases (7.8%).

Fifty-six patients showed local HCC recurrences, 61 distant recurrences, and 31 both local and distant recurrences. The median time elapsed between the PEI completion and the first detection of local or distant recurrence were 12 mo (CI 95% 7.0-16.5), and 21 mo (CI 95% 14.0-32.0), respectively. No cases of local recurrence were recorded after 36 mo from PEI completion. The overall DFS rate was 71.0%, 33.5%, and 24.1% at 1, 3, and 5 years, respectively (Table 2). Local recurrences were treated with PEI, RFA or transarterial chemoembolization (TACE) in 41 cases (73.2%). The recurrent lesions in segments different from that of the first neoplasm were treated with PEI, RFA, TACE or systemic therapy including tamoxifen, octreotide, or sorafenib in 34 cases (55.7%). In 15 cases of local recurrence and in 27 cases of distant recurrence, no treatment was applied due to one or more of the following reasons: end stage liver failure, multifocal or infiltrative pattern of recurrence with or without vascular invasion, and concomitant diagnosis of extrahepatic spreading.

Of the whole population, HCC size < 2 cm was the only pre-PEI parameter significantly linked to survival ($P = 0.009$). This parameter resulted to be an independent predictor of survival after multivariate analysis using the Cox regression model [HR 0.421 (0.216-0.821); $P = 0.011$]. Among the post-treatment parameters, only distant recurrence and portal invasion were significantly linked to survival ($P = 0.003$ for both parameters) (Table 1).

For further analysis, the 47 patients with a single HCC smaller than 2 cm were compared to the 108 patients with tumors larger than 2 cm. The clinical (age, sex, Child-Pugh class, ascites, portal thrombosis) and laboratory (HBsAg positive, anti-HCV positive, ALT, AST, prothrombin time ratio, bilirubin, albumin, platelet count, AFP) features were not significantly different between groups. As expected, the 1-, 3-, and 5- year survival rate of the patients with HCC < 2 cm (97.8%, 86.3%, and 73.0%) was significantly better than that of patients with larger tumors (94.8%, 67.5%, and 47.9%) ($P = 0.009$) (Figure 1). The estimated median survival of patients with HCC < 2 cm was longer than that of patients with HCC > 2 cm [93 mo (CI 95% 43.9-142.1) *vs* 60 mo (CI 95% 41.9-79.4)]. Furthermore, the cumulative 1-, 2- and 3-year local recurrence (13.2%, 21.6%, and 29.1% *vs* 28.2%, 43.7%, and 51.5%) of the patients with HCC < 2 cm was significantly lower than that of patients with larger tumors (log rank χ^2 0.825, $P = 0.011$). Likewise, the cumulative distant recurrence at 1-, 3-, and 5-years in patients with HCC < 2 cm was lower (2.3%, 27.2%, and 52.9% *vs* 11.0%, 49.6%, 62.2%); this difference demonstrated a clear trend towards statistical significance (log rank χ^2 5.338, $P = 0.054$). In order to analyze the possible influence of local on distant recurrence, we investigated the correlation between these 2 events. Interestingly, 62/92 (67.4%) of patients without local did not experience distant recurrence, while 31/56 (55.4%) of subjects with local developed distant recurrence of HCC.

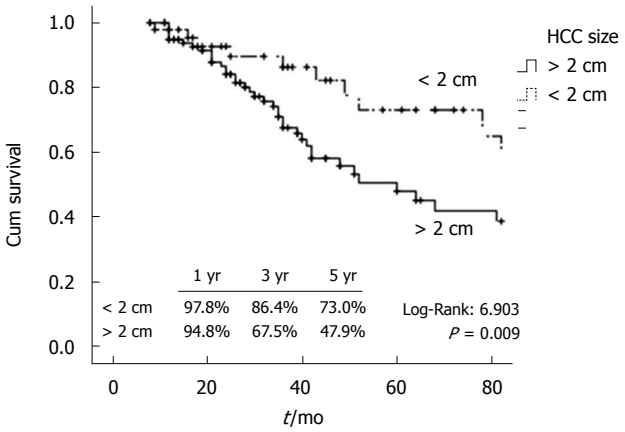

Figure 1 Comparison between cumulative survival rates in 47 patients with solitary hepatocellular carcinoma < 2 cm (dotted line) and 101 patients with solitary hepatocellular carcinoma > 2 cm (continuous line). HCC: Hepatocellular carcinoma.

On this ground, we found a positive correlation at Spearman-rho test (Coefficient: 0.224; $P = 0.006$) and calculated that subjects with local recurrence had an increased risk to develop distant recurrence with an OR of 1.698 (95% CI 1.165-2.473).

DISCUSSION

PEI has been the first ablation technique extensively used for the treatment of HCC and is usually indicated for lesions smaller than 3 cm in diameter since complete tumor necrosis may be achieved in 90%-100% of tumors smaller than 2 cm, 70%-80% of lesions between 2 and 3 cm, and about 50% of lesions between 3 and 5 cm[18]. Furthermore, PEI has been recently shown to achieve complete necrosis of the treated tumors at explant analysis in 38/59 patients (64.3%) undergoing liver transplantation[19]. However, PEI has been largely replaced by RFA during the last years, and this is due to the best predictability of the necrotic effect in all tumor sizes and to the best effectiveness in tumors larger than 2 cm[11]. According to some recent randomized trials involving tumors with a maximal size of 3 or 4 cm, RFA is more efficacious than PEI in terms of initial complete tumor necrosis rate (93%-100% *vs* 66%-100%), 3-year survival rate (63%-81% *vs* 48%-67%) and local tumor recurrence (8%-14% *vs* 22%-34%)[20-25]. Furthermore, a few recent meta-analytic studies support the superiority of RFA versus PEI in terms of patient survival and local disease recurrence[26-28]. However, when the analysis is restricted to lesions smaller than 2 cm, the superiority of RFA is questionable: a recent meta-analysis about the clinical outcomes of RFA, PEI and percutaneous acetic acid injection for HCC shows that for lesions smaller than 2 cm there is no significant difference between RFA and PEI for the proportion of patient mortality and for local recurrence[28].

Our long term cohort study confirms that PEI is still an effective treatment for compensated cirrhotics with a single HCC < 2 cm since the 5-year survival rate was as high as 73.0% and a tumor diameter up to this size was the only pre-treatment parameter independently linked to survival. This datum is comparable to that shown in eastern single center series. In a group of 270 cirrhotics with HCC treated by PEI, Ebara *et al*[13] described a subgroup of 96 Child-Pugh Class A patients with solitary HCC smaller than 2 cm with a 5-year survival of 78.3%. Omata *et al*[9] reported a survival rate of 70% in a series of 144 patients with a single HCC < 2 cm undergoing PEI. Less favourable results were shown by Arii *et al*[29] in a retrospective multicenter Japanese survey, showing a 54% survival rate in 767 patients with Stage I HCC < 2 cm submitted to PEI.

Available data from the literature do not provide unequivocally a survival benefit of RFA over PEI in these patients. A 5-year survival of 83.8% was reported by Tateishi *et al*[30] in a cohort of 87 patients with HCC lower than 2 cm treated by RFA. A similar rate of 5-year survival (83.8%) has been recently reported for Child-Pugh Class A patients with a single lesion of up to 2 cm treated with RFA and registered by the Liver Cancer Study Group of Japan[31]. However, in the recent western series by Livraghi *et al*[32] involving 218 patients with a single HCC < 2 cm undergoing ablation with RFA, the 5-year survival rate was 55% for the whole population and 68% for the subgroup of potentially operable patients.

In our cohort of patients, intrahepatic HCC progression was the cause of death in more than two thirds of the cases, and the 5-year survival of patients with a single nodule < 2 cm was significantly better than that of patients with HCC > 2 cm (73.0% *vs* 47.9%). This is not surprising, considering that in tumors > 2 cm the success of ethanol in achieving necrosis of the entire mass is limited by intratumoral septa, and that in most of these tumors PEI does not induce a peritumoral necrosis, preventing the persistence of peripheral minute neoplastic foci or extra-tumoral satellites[10]. Accordingly, in our group of patients, the cumulative local recurrence rate of tumors smaller than 2 cm was significantly lower than that of patients with larger HCC. The reappearance of a viable tumor in a lesion assessed as completely necrotic shortly after ablation implies, in most cases, the need for additional locoregional therapy and is negatively linked to survival. In a large study by Sala *et al*[33], among Child-Pugh Class A patients, the 5-year survival rate of patients achieving a sustained complete response at the end of follow-up was significantly higher than that of patients without a sustained complete response due to initial treatment failure, late local recurrence, or appearance of new HCC nodules outside the segment of the first neoplasm. Similarly, in our study, distant intrahepatic recurrence was linked to survival and occurred significantly more frequently in patients with tumors larger than 2 cm. This may be in part related to the insufficient local disease control obtained by PEI in tumors more than 2 cm large. Indeed, the reappearance of viable tumor tissue may promote the HCC spreading within the liver through microvessel invasion and satellitosis. The observation of a significantly increased risk of new HCC lesions within the liver in patients with local recurrence in this series reinforces this hypothesis.

In conclusion, our study shows that a tumor diameter of up to 2 cm is an independent predictor of survival in cirrhotics with single HCC treated by PEI. In this subgroup of patients, we observed a 5-year survival rate as high as 73.0%, significantly better than that observed in patients with solitary larger tumors. This datum supports the hypothesis that in compensated cirrhotic patients with small HCC up to 2 cm submitted to ablation the long term prognosis is excellent independently from the application of PEI or RFA as therapeutic procedure[10]. Although PEI could be less effective than RFA in providing complete necrosis of the tumor even in this subset of patients, this is counterbalanced by the universal feasibility of PEI in tumors located at risky sites for RFA, or in which a thermal ablation may be less efficient due to the proximity of large vessels. For these reasons, a large prospective randomized study, designed to assess the overall survival as primary end point according to the principles of the intention-to-treat analysis, taking into account the site of the tumor in the liver, and including a rigorous cost-effectiveness evaluation , is still needed.

COMMENTS

Background

Small hepatocellular carcinomas of up to 2 cm are increasingly being recognized due to the diffusion of the screening program for early diagnosis of this tumor in liver cirrhosis. The ideal treatment of such small lesions is a controversial issue.

Research frontiers

Prospective randomized studies comparing the available treatments for small hepatocellular carcinoma are lacking and should be planned.

Innovations and breakthroughs

This study shows that the survival rate of compensated cirrhotic patients with solitary hepatocellular carcinoma of up to 2 cm treated with percutaneous ethanol injection is higher than 70%. Furthermore, in the series of 148 patients with a single tumor up to 5.8 cm in size treated with this technique, a tumor diameter equal or lower than 2 cm was the only factor significantly linked to survival.

Applications

In authors' opinion, percutaneous ethanol injection is still a valuable treatment of small hepatocellular carcinoma of up to 2 cm in size emerging in liver cirrhosis. In this subset of patients, the demonstration of a better therapeutic performance of radiofrequency ablation in terms of overall survival and cost-effectiveness is still lacking.

Terminology

Percutaneous ethanol injection is a well standardized technique of chemical ablation of hepatocellular carcinoma. When introduced within the neoplasm through a fine-needle, ethanol shows a direct cytotoxic effect and produces coagulative necrosis, followed by fibrosis. In addition, due to the lesive effect of ethanol on the endothelial cells, tumor ischemic necrosis is elicited by thrombosis of the small tumor feeding vessels. The effectiveness of this technique has been questioned after the introduction in clinical practice of the thermal ablation techniques of liver tumors.

Peer review

This is an interesting series showing a continued role for PEI for single small HCC. However, my guess is that RFA has replaced PEI in most centers related to the number of procedures to achieve benefit. There are not many reports from western countries, making this report of interest and worthy of consideration for publication.

Abstract

AIM: To identity the factors influencing colorectal cancer (CRC) screening behavior and willingness among Chinese outpatients.

METHODS: An outpatient-based face-to-face survey was conducted from August 18 to September 7, 2010 in Changhai Hospital. A total of 1200 consecutive patients aged ⩾ 18 years were recruited for interview. The patient's knowledge about CRC and screening was pre-measured as a predictor variable, and other predictors included age, gender, educational level, monthly household income and health insurance status. The relationship between these predictors and screening behavior, screening willingness and screening approach were examined using Pearson's χ^2 test and logistic regression analyses.

RESULTS: Of these outpatients, 22.5% had undergone CRC screening prior to this study. Patients who had participated in the screening were more likely to have good knowledge about CRC and screening (OR: 5.299, 95% CI: 3.415-8.223), have health insurance (OR: 1.996, 95% CI: 1.426-2.794) and older in age. Higher income, however, was found to be a barrier to the screening (OR: 0.633, 95% CI: 0.467-0.858). An analysis of screening willingness showed that 37.5% of the patients would voluntarily participated in a screen at the recommended age, but 41.3% would do so under doctor's advice. Screening willingness was positively correlated with the patient's knowledge status. Patients with higher knowledge levels would like to participate in the screening (OR: 4.352, 95% CI: 3.008-6.298), and they would select colonoscopy as a screening approach (OR: 3.513, 95% CI: 2.290-5.389). However, higher income level was, again, a barrier to colonoscopic screening (OR: 0.667, 95% CI: 0.505-0.908).

CONCLUSION: Patient's level of knowledge and income should be taken into consideration when conducting a feasible CRC screening.

Key words: Colorectal cancer; Screening; Behavior; Willingness; Survey

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies worldwide. The Asian Pacific Working Group on CRC has suggested that some Asian ethnic groups (e.g. Japanese, Korean and Chinese) are more susceptible to CRC than others, with an incidence similar to that of the West[1]. The incidence of CRC in China has increased rapidly since the 1980s[2,3]. CRC now ranks as the fifth leading cause of cancer-related deaths[4]. Screening is an effective tool for early diagnosis[5], but the compliance rates have been low in many countries[6-10]. A study of community-based CRC screening in Hangzhou, China, which involved a population of 34 726 individuals, revealed that the compliance rates for fecal occult blood test (FOBT) and colonoscopy were only 17.5% and 2.8%, respectively[11]. These figures are extremely low compared with those of the United States (overall screening rates were nearly 55% in 2008[12]).

Reasons for low compliance rates may vary among countries. A community-based screening among residents of Beijing revealed that busy work schedules and the complexity of screening procedures were the main barriers to CRC screening[13]. Lack of financial support, fear of pain and the necessity of bowel preparation were barriers to colonoscopic screening in a Hangzhou-based study[14]. Other researchers have doubted the feasibility of population screening in China, due to the requirements for a high awareness of the disease, sufficient medical resources and strong financial support[15]. Opportunistic screening (also called individual screening), which is performed on request from a physician or healthcare provider when a patient presents for consultation for other health reasons[16], has been widely used in most cancer screening protocols throughout the world[17] and may be also suitable for Chinese outpatients. Individuals with more personal experience with illness are more likely compliant with the CRC screening[18]. China has a large population but with an uneven distribution of health resources. Additionally, the general population has a low awareness of CRC and inadequate knowledge regarding CRC and screening[19,20].

Although CRC screening of outpatients might be effective, there have been few studies exploring its availability in China. The 2010 National Institutes of Health (NIH) State-of-the-Science Conference, which aimed to enhance the use and quality of CRC screening, recommended that studies should be carried out about patient screening preferences and other factors influencing informed, shared decision making regarding the choice of CRC screening modalities[12]. Therefore, our study was intended to explore outpatients' screening behavior and willingness as well as to identify influencing factors in Shanghai, China.

MATERIALS AND METHODS

Study population

From August 18 to September 7, 2010, 1200 consecutive outpatients were recruited for our survey from the Outpatient Department of Changhai Hospital, a tertiary care hospital in Shanghai, China. Both sporadic and hereditary cases of CRC were the target of early detection. All these outpatients were over 18 years of age, able to communicate properly and free of mental disorders. Patients with a medical emergency or incurable tumor were excluded. Health care workers including doctors, nurses, medical educators and medical students were not included as subjects of this study.

Study design

A self-designed questionnaire was developed after a literature review, and revised by epidemiologists and clinicians. The following contents were included: (1) Patient general information; (2) evaluation of CRC and screening knowledge; (3) previous screening behavior; (4) screening willingness; and (5) preferred approach. Available screening approaches in our hospital could be classified as fecal test (e.g. FOBT, stool DNA test), blood test (biomarkers in clinical research) and colonoscopy.

A pilot test was conducted in 50 outpatients by trained interviewers on August 18 to verify the feasibility of the survey. The questionnaire was distributed to the patients upon their arrival at the clinic, who were asked to answer the questions under the guidance of interviewers while waiting to see a doctor. To ensure the quality of the survey, additional information about screening was offered to guide the patient's choice of screening approach. This study was approved by the Ethics Committee of Changhai Hospital, and all patients gave written informed consent.

Comparing with other scoring system that evaluated the knowledge about CRC and screening[20,21], several simple factors were taken into account in the evaluation: (1) is the patient familiar with CRC; (2) does the patient understand at least one of the clinical manifestations of CRC; (3) has the patient ever heard of cancer screening; and (4) is the patient familiar with colonoscopy as an early detection method for CRC? Patients were classified as having a high level of knowledge (answered all the questions above), a low level (answered no more than 2 questions) and a moderate level (between high and low).

Statistical analysis

Data were managed using Microsoft Excel software, and duplicate questionnaires were excluded. The results were tabulated and analyzed with the PASW Statistics for Windows release 18.0 (SPSS, Inc., Chicago, Illinois). The primary outcomes were the patient's previous screening behavior, screening willingness and preferred screening approach. Pearson's χ^2 test was used to quantify the association between the outcomes and the predictor variables, which included gender, age, possession of health insurance and monthly household income. A bivariate logistic regression model was used to examine the association between the outcomes and levels of education and knowledge about CRC. Statistical significance was considered at $P < 0.05$, and odds ratios (OR) were given with 95% confidence intervals (CI).

[1]Renminbi is the official currency of the People's Republic of China; [2]Including the status of health insurance application; [3]Including colonoscopy, fecal occult blood test (FOBT) and double contrast barium enema (DCBE). CRC: Colorectal cancer.

RESULTS

A total of 1200 consecutive patients were recruited for the survey. Of these, 1029 (85.75%) were successfully surveyed, and 171 (14.25%) did not respond to this survey. Among the 1029 respondents, 28 (2.72%) were found to have unfilled sections, but no duplicate data were detected. Ultimately, 1001 patients were included in our analysis. A total of 604 patients were not less than 40 years of age, which is the recommended minimal screening age in China for sporadic CRC[22]. The mean age of the patients was 45.25 years (range, 18-86 years). Patients were classified as having a high (n = 466, 46.6%), moderate (n = 247, 24.7%) or low (n = 288, 28.8%) levels of knowledge according to our definitions. Other predictor variables, such as educational level and monthly household income, are listed in Table 1.

Previous CRC screening behavior

Among the 1001 included patients, 22.5% (n = 226) had previously undergone CRC screening. The most common examination method used was colonoscopy (91.6%); other methods (FOBT or double contrast barium enema, DCBE) accounted for a small proportion (8.4%). Factors influencing the participation in the screening were age, possession of health insurance, monthly household income and status of CRC knowledge (Table 2). Patients who had been screened tended to have a good knowledge of CRC and screening (OR: 5.299, P < 0.001), have health insurance (OR: 1.996, P < 0.001) and are older in age (OR: 3.834, P < 0.001). High income, however, was found to be a barrier to the screening (OR: 0.633, P < 0.003).

Screening willingness

The analysis of screening willingness revealed that 37.5% of patients (n = 375) would voluntarily agree to be screened at the recommended age; 41.3% (n = 413) would need a physician's recommendation before attending the screening; and 21.3% (n = 213) refused to be screened (Table 1). We categorized the screening willingness into "attendance" (n = 788) and "rejection" (n = 213) and found that knowledge regarding CRC was the only factor influencing the screening willingness (Table 3). Patients with a high level of knowledge about CRC were more willing to attend the screening than those with a poor knowledge of CRC (OR: 4.352, P < 0.001).

Screening approach

The analysis of patients' preference in screening approach revealed that colonoscopy was the most commonly preferred approach (32.2%, n = 322), while blood testing ranked second (24.9%, n = 249), and a fecal test was the least popular option (18.6%, n = 186). However, 24.4% of patients (n = 244) expressed an equivalent preference for all screening approaches (Table 1).

Colonoscopy is the most precise screening approach for CRC. Thus, the screening approaches were characterized into "precise modes (colonoscopy)" and "normal modes (blood and fecal tests)", and factors influencing the patient's selection of screening approach were investigated. Both CRC-associated level of knowledge and monthly household income influenced the choice of screening approach (Table 4). With an increase in knowledge, the proportion of patients selecting a precise screening approach was increased from 25.4% to 54.4% (P < 0.001). Patients with higher incomes, however, prefer not to adopt precise screening approaches on average (P = 0.010).

DISCUSSION

In this outpatient-based study, we found that a high level of knowledge regarding CRC and screening techniques, possession of health insurance or advanced age were stimulus factors for prior CRC screening. Most of the patients were willing to participate in the screening, but 41.3% were willing to do so under doctor's recommendations before attendance. Level of knowledge was the only factor that influenced screening willingness. Outpatients with a higher level of knowledge were willing to participate in the screening and select colonoscopy as the screening approach. Higher income level, however, was a barrier to both the previous screening and the preference of colonoscopy as a screening methodology. These

results indicated that patients' knowledge and income status should be considered when launching a screening program among outpatients in Shanghai.

To our knowledge, this is the first study to investigate outpatients' CRC screening behavior and to identity their screening preferences in China. The advantages of this study are the use of a prospective face-to-face survey of consecutive outpatients and a relatively large sample size. We attempted to establish a simple method to rapidly evaluate patients' levels of knowledge regarding CRC and screening techniques. This method differs from other scoring systems. Our method allows the physician to evaluate the patient's level of knowledge through asking several simple questions, and an appropriate screening approach can be offered immediately following the evaluation.

Our results have several similarities to those of previous population-based studies that explored factors influencing CRC screening[20,23-26] and analyzed CRC screening willingness in Malaysia[21] and Taiwan[27]; however, there

have also been some inconsistent results.

As shown in the previous studies, a better knowledge of CRC and screening is related to a higher participation rate in population-based screening[20,23-26]. Among our patients, better knowledge was associated with the previous screening. This association is consistent with qualitative evidence in which lack of knowledge about CRC and screening has been cited as a barrier to screening participation in the United States, Canada and China[28].

Lack of health insurance is an important barrier to the screening participation among ethnic groups with all levels of education[29,30]. The US-based 2005 National Health Interview Survey (NHIS) showed that 19% of respondents with no insurance reported having CRC screening (FOBT or endoscopy), compared with over 39% of those who had insurance[29]. In our study, health insurance status was positively associated with the screening behavior. This is an important finding for outpatient screening because more than half of the patients (64.2%) were covered by health insurance. Their compliance with CRC screening may be relatively easy to promote if appropriate screening advice is offered.

Factors that could enhance the screening willingness in previous studies included the followings: being a close relative of a CRC patient[31], perceived susceptibility, perceived less barriers to screening, doctor's recommendation and personal contact with friends or relatives having CRC[21]. In Taiwan, factors related to intentions to have FOBT were influenced by the inconvenience and the unpleasantness of the screening procedure. Participants' gastrointestinal symptoms or family histories and physicians' recommendation or patients' health conditions were relevant to the intentions for a flexible sigmoidoscopic or colonoscopic screening[27]. Additionally, a knowledge of CRC symptoms was associated with willingness to be screened in Malaysia on univariate analysis but not on multivariate analysis[21]. Among the patients in our survey, the knowledge regarding CRC and screening was an important factor that influenced screening willingness, meanwhile 41.3% patients expressed that they would need doctor's recommendation before attending the screening. So interventional studies which intend to increase the patients' knowledge regarding CRC and screening would help enhance the screening willingness.

Income level is another important factor affecting an individual's decision to be screened. Patients with more affluent socioeconomic status have been shown to have a higher average rate of screening than the less affluent[8,32,33]. However, in our study, the high-income patients were found to have a lower rate of screening and the reluctance of colonoscopic screening. This opposite phenomenon might be related to some cultural reasons. High-income patients live in better conditions and tend to get good treatment, so they are less concerned about using the preventive screening because they are more "healthy". Similar trend was detected in a Hong Kong population who perceived their health status to be good and had a less concern about contracting CRC than those who perceived a fair or poor health status[19]. The reluctance of high-income patients to take colonoscopic screening may also be influenced by the complexity of bowel preparation and the uncomfortable feeling caused by colonoscopy.

There are several limitations in this study. First, it was based in a single center. Our preliminary results on outpatient behavior and willingness cannot represent all the outpatients in Shanghai. Second, some patients (14.25%) did not respond to our survey, although great efforts were made to publicize the significance of the survey.

This may cause some patient selection bias, and a multicenter survey may be needed to confirm our results. However, our hospital, which is the largest endoscopy center in Shanghai, attracts many patients for this procedure. Therefore, our results are fairly representative of urban outpatient clinics.

In conclusion, most of the outpatients are willing to participate in CRC screening. A better knowledge about CRC and screening techniques is positively correlated with previous screenings, higher willingness to participate in the screening and a preference for colonoscopy as a screening methodology. However, a higher income level is a barrier to the screening behavior and the selection of colonoscopy. These results may have some implications for outpatient CRC screening and may help guide the further interventional studies.

ACKNOWLEDGMENTS

We thank all the assisting nurses for their hard work during the survey.

COMMENTS

Background

The incidence of colorectal cancer (CRC) in China has increased since the 1980s. Screening is an effective method for early detection of CRC.

Research frontiers

Opportunistic screening which screened CRC among outpatients might be more effective in China, but has not been well illustrated. Studies exploring patient's screening preferences and factors influencing the choice of colorectal cancer screening modalities are needed before the screening is started. In this study, the authors demonstrated the factors influencing outpatients' screening behavior and willingness in Shanghai, China.

Innovations and breakthroughs

This is the first study to report outpatients' screening behavior and willingness as well as to identify influencing factors in Shanghai, China. The results indicate that patients' levels of knowledge and income should be considered when launching a screening program among outpatients.

Applications

By understanding what factors will influence colorectal cancer screening behavior and willingness among Chinese outpatients, this study has provided some implications for screening practice and may help guide further interventional studies.

Peer review

It is a very interesting research for the readers, the conclusions are very valuable and it should be accepted for publication in the journal.

Abstract

AIM: To investigate how to reduce the incidence of biliary complications in rat orthotopic liver transplantation.

METHODS: A total of 165 male Wistar rats were randomly divided into three groups: Group A, orthotropic liver transplantation with modified "two-cuff" technique; Group B, bile duct was cut and reconstructed without transplantation; and Group C, only laparotomy was performed. Based on the approaches used for biliary reconstruction, Group A was divided into two sub-groups: A1 (n = 30), duct-duct reconstruction, and A2 (n = 30), duct-duodenum reconstruction. To study the influence of artery reconstruction on bile duct complication, Group B was divided into four sub-groups: B1 (n = 10), duct-duct reconstruction with hepatic artery ligation, B2 (n = 10), duct-duct reconstruction without hepatic artery ligation, B3 (n = 10), duct-duodenum reconstruction with hepatic artery ligation, and B4 (n = 10), duct-duodenum reconstruction without hepatic artery ligation. The samples were harvested 14 d after operation or at the time when significant biliary complication was found.

RESULTS: In Group A, the anhepatic phase was 13.7 ± 1.06 min, and cold ischemia time was 50.5 ± 8.6 min. There was no significant difference between A1 and A2 in the operation duration. The time for biliary reconstruction was almost the same among all groups. The success rate for transplantation was 98.3% (59/60). Significant differences were found in the incidence of biliary complications in Groups A (41.7%), B (27.5%) and C (0%). A2 was more likely to have biliary complications than A1 (50% *vs* 33.3%). B3 had the highest incidence of biliary complications in Group B.

CONCLUSION: Biliary complications are almost inevitable using the classical "two cuff" techniques, and duct-duodenum reconstruction is not an ideal option in rat orthotopic liver transplantation.

Key words: Rat; Liver transplantation; Biliary complication; Animal model

INTRODUCTION

The occurrence of biliary complications (BC) remains one of the most critical challenges in clinical liver transplantation. According to the literature, the incidence of biliary complication for living-donor liver transplantations (LDLT) is as high as 64%[1-9]. Biliary complications have made biliary reconstruction the "Achilles heel" of liver transplantation. In rat liver transplantation, the occurrence of biliary complications has become a confounding factor in the judgment of experimental results and an obstacle to the practice of transplantion. Unfortunately, few researches could be found to report the incidence of biliary complications in rat liver transplantation. In this study, we investigated the biliary complications after rat orthotopic liver transplantation (ROLT), trying to find a better approach to biliary reconstruction and reduce the incidence of biliary complications after transplantation.

MATERIALS AND METHODS

Animals

Male Wistar rats weighing 200-250 g, were purchased from the Experimental Animal Center of Sun-Yat Sen University and fed in the specific pathogen free (SPF) animal lab. The weight of the recipient was similar to that of the donor. All animals had free access to food and water except the recipients, which had been fasted for 12 h before operation.

Technique

ROLTs were performed using the "two-cuff" technique established by Kamada[10,11]. All surgical procedures were performed by a single operator under naked eye. Napental was used for the anesthesia (40 mg/kg). All experiments were performed in compliance with the standards for animal use and care set by institutional animal care and use Committee.

Donor operation

After laparotomy, the left subphrenic vein was ligated and all the perihepatic ligaments were divided. The bile duct was incised and a stent (0.9-mm inner diameter, 4-mm length) was introduced and tied firmly. The right renal vein was dissociated and the right adrenal venous plexus was ligated. After 150 units of heparin was injected to form systemic heparinization, the liver was irrigated with physiological saline containing heparin (20 U/mL) through the aorta distal to the celiac artery. At the same time, infrahepatic inferior vena cava (IHIVC) and suprahepatic inferior vena cava (SHIVC) were dissected to allow outflow of the perfusate. When the liver turned khaki color, SHIVC was divided along the diaphragm (without the phrenic ring) , and the right renal vein, the portal vein (PV) and IHIVC were skeletonized and divided. The liver was then harvested and the graft was preserved at 4℃ in physiological saline with 20 U/mL heparin.

The PV was induced through the cuff (2-mm inner diameter, 3.5-mm length) and the distal end of the vein was completely reversed and fixed onto the cuff with a 5-0 silk ligation. The same method was used to prepare the cuff (3-mm inner diameter, 4-mm length) for IHIVC. The SHIVC was treated with two 8-0 silk sutures pierced via the two corners of the vein.

Recipient operation

After laparotomy, the self-made retractor was used to expose the operative area, and the left subphrenic vein. The transport vessels between the left liver and esophagus, hepatic artery and the right adrenal venous plexus were ligated orderly. One necessary step was to put a rubber under the SHIVC for the purpose of traction when removing the liver. Then IHIVC and PV were clamped to the anhepatic phase. SHIVC was blocked after exsanguination and the liver removed quickly. SHIVC was sutured by an end to end anastomosis (8-0, nylon suture), PV was reconstructed by means of cuff technique and the anhepatic phase was ended. The same method was used to reconstruct IHIVC. Based on the experimental design, the bile duct was reconstructed differently.

The recipient rats were fasted for at least 12 h after operation but water was permitted.

Biliary reconstruction and hepatic artery ligation

There were two ways to rebuild the biliary tract in this experiment: (1) end-to-end anastomosis with the stent; and (2) end-to-side anastomosis between bile duct and duodenum (1-2 cm away from the pylorus) with the stent.

Experimental design

One hundred and sixty-five male Wistar rats were randomly divided into three groups: Group A, orthotropic liver transplantation by modified two-cuff method; Group B, bile duct was cut and reconstructed without orthotopic liver transplantation; and Group C, sham-operation group. Based on the approaches of biliary reconstruction, Group A was divided into two sub-groups: A1 (n = 30), duct-duct reconstruction, and A2 (n = 30), duct-duodenum reconstruction. To study the influence of hepatic artery on bile duct complication, Group B was divided into four subgroups: B1 (n = 10), duct-duct reconstruction with hepatic artery ligation; B2 (n = 10), duct-duct reconstruction without hepatic artery ligation; B3 (n = 10), duct-duodenum reconstruction with hepatic artery ligation, and B4 (n = 10), duct-duodenum reconstruction without hepatic artery ligation. In Group C (n = 5), only laparotomy was performed.

Samples were harvested 14 d after operation or at the time when any significant biliary complication was found. Serologic samples were collected to test the levels of aspartate transaminase (AST), alanine transaminase (ALT), total bilirubin (TBIL), direct bilirubin (DBIL), gummaglutamyl transpeptidase (GGT) and alkaline phosphatase (ALP). Biliary complications were determined by pathologic examination and serologic analysis.

Statistical analysis

Data were expressed as mean ± SD. Statistical differences

Table 1 Incidence rates of biliary complications in different groups

Groups	*n*	Abscess	Sludge	EBD	IBD	Total	
Group A							41.7%[e] (25/60)
A1	30	26.70% (8/30)	13.30% (4/30)	26.70% (8/30)	13.30% (4/30)	33.30% (10/30)	
A2	30	43.30% (13/30)	20% (6/30)	26.70% (8/30)	10% (3/30)	50%[a] (15/30)	
Group B							32.50% (13/40)
B1	10	10% (1/10)	0	30% (3/10)	0	30% (3/10)	
B2	10	10% (1/10)	0	20% (2/10)	10% (1/10)	20% (2/10)	
B3	10	30% (3/10)	20% (2/10)	40% (4/10)	10% (1/10)	50%[c] (5/10)	
B4	10	20% (2/10)	10% (1/10)	30% (3/10)	10%*t* (1/10)	30% (3/10)	
Group C	5	0	0	0	0	0	0
Total	105	26.70% (28/105)	12.40% (13/105)	26.70% (28/105)	9.52% (10/105)	36.20% (38/105)	

Some rats had two (or more) kinds of biliary complications at the same time. [a]$P < 0.05$ *vs* A1; [c]$P < 0.05$ *vs* B1, B2 and B4; [e]$P < 0.05$ *vs* groups B and C EBD: Extrahepatic biliary dilatation; IBD: Intrahepatic biliary dilatation.

between the control and the experimental groups were analyzed using analysis of variance. $P < 0.05$ was considered statistically significant.

RESULTS

Operation time and success rate

In transplantation groups, the anhepatic phase was 13.7 ± 1.06 min, and cold ischemia time was 50.5 ± 8.6 min. There was no significant difference between A1 and A2 in operating time ($P > 0.05$). And the time for biliary reconstruction was almost the same among all groups ($P > 0.05$).

Recipients surviving at least 24 h were considered as success. The success rate of ROLT was 98.3% (59/60). Only one case in A1 died from bleeding at SHIVC 8 h after operation.

Biliary complications

The incidence rate of biliary complications was 41.7% in Group A, which was much higher than that in Group B (32.5%) and Group C (0%), with significant differences among the three groups ($P < 0.05$). After transplantation, A2 had a higher incidence of biliary complications than A1 (50% *vs* 33.3%, $P < 0.05$). B3 had the highest incidence of biliary complications among the groups without orthotopic liver transplantation ($P < 0.05$). No biliary complication was found in the sham-operation group.

General observation

The color of urine turned yellow in the rats with biliary complications. Other complications were dried hair, reaction retardation, reduced appetite and activities, and eye bleeding in some rats.

Gross anatomy

Biliary complications consisted of abscess, intrahepatic and extrahepatic biliary dilatation and biliary sludge. Abscess (35%) was most frequently seen in Group A, compared with dilatation of extrahepatic bile duct (25%) in Group B. B3 had the highest incidence of biliary complications in non-transplantation groups (50% *vs* 30%, 20% and 30%) and extrahepatic biliary dilatation and abscess were two of the most important complications in this group (Table 1).

Histopathology

In the samples with biliary complications, infiltration of a large number of mononuclear cells in the portal area was the most common change, followed by dilatation of bile ducts. Cellular infiltration of biliary wall and degeneration of epithelial cells, dilatation of the central vein could also be seen. Some samples even showed vacuolar degeneration, necrosis and fibrous tissue hyperplasia. In samples with severe biliary dilatation, the normal bile duct structure had completely disappeared, with a large number of infiltrated inflammatory cells.

Serology

The serum levels of AST, ALT, TBIL, DBIL, GGT and ALP in Group A and Group B were significantly higher than in Group C, particularly AST and TBIL, with significant difference among the three groups ($P < 0.05$). Significant difference could be easily observed between duct-duodenum reconstruction groups and duct-duct reconstruction groups (A2 *vs* A1, B3 *vs* B1, and B4 *vs* B2, $P < 0.05$). Among non-transplantation groups, the serological changes, especially the bilirubin level, were more remarkable in groups with hepatic artery ligation than in those without (B1 *vs* B2 and B3 *vs* B4, $P < 0.05$) (Table 2).

DISCUSSION

Biliary complication is the second most common cause of graft dysfunction in liver transplantation with an incidence rate of as high as 64%[1-9]. Biliary complications may be related to various factors, including hepatic artery thrombosis or stenosis, technical reasons, as well as ischemia-reperfusion injury and immunological injury. High incidence of biliary complication has made biliary reconstruction the "Achilles heel" of liver transplantation.

It has been proved that hepatic artery plays an important role in blood supply of bile duct, the artery must be reconstructed when injured or cut during operation. In the early 90s, Engermann *et al*[12] showed that reconstruction of the hepatic artery can significantly reduce the incidence of biliary complications such as biliary fistula and biliary obstruction after ROLT. But with the cuff method introduced in 1973, ROLT without hepatic artery (HA) recon-

Table 2 Serological values in different groups

	n	AST (U/L)	ALT (U/L)	TBIL (μ mol/L)	DBIL (μ mol/L)	GGT (U/L)	ALP (U/L)
A1	30	452.2 ± 296.9	223.7 ± 194.7	17.1 ± 26.0	14.8 ± 24.1	10.5 ± 6.2	366.5 ± 173.0
A2	30	534.2 ± 373.3	272.8 ± 274.7	11.6 ± 21.8	10.2 ± 20.2	8.0 ± 7.3	282.8 ± 154.9
B1	10	146.6 ± 43.6	75 ± 17.7	0.79 ± 1.59	0.54 ± 1.26	4.6 ± 3.8	208.6 ± 76.4

Group C	5	81.7 ± 13.2	60.7 ± 4.5	0.13 ± 0.15	0 ± 0	2.7 ± 0.58	281.7 ± 139.3

ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; AST: Aspartate aminotransferase; TBIL: Total bilirubin; DBIL: Direct bilirubin; GGT: Gumma-glutamyl transpeptidase.

struction became globally accepted [13-18]. It is reasonable to speculate that biliary complications after liver transplantation might be more common in rats than that in human beings. Unfortunately, few studies can be found to investigate and report the incidence of biliary complications in ROLT. In our study, we simulated the biliary processes of ROLT in Group B, and found that the incidence of complications were significantly higher in groups with hepatic artery ligation than those without, which meant that hepatic artery might play an important role in the occurrence and development of biliary complications, but further investigations are needed to verify the definite mechanism.

Bile duct reconstruction by stent has been well accepted since Kamada introduced the "two-cuff" technique in ROLT[12-18]. But in view of our experience in over 600 cases of rat orthotopic liver transplantation, it seems that biliary complications after orthotopic liver transplantation are almost inevitable in the classical model. Several reasons might be contributed to this: Firstly, the wall of bile duct will become thicker as the rat grows up, constant inner diameter of the stent will definitely make the bile duct relatively narrow. Secondly, the stent would become a foreign body in bile, which will make the eddy come into being at the proximal stent and induce the sludge. So it is a great challenge to seek a new approach to modify the ROLT model. This new approach should reduce the incidence of biliary complications, and be easier to achieve.

Choledochojejunostomy has been proved to be an effective surgery to reconstruct the bile duct in clinical liver transplantation, which does not increase the incidence of biliary complications compared with the end-to-end anastomosis[19-22]. In our study, we simulated the method and designed the duct-duodenum reconstruction model. Unfortunately, this method did not show ideal results, the incidence of biliary complications was significantly higher in A2 (duct-duodenum reconstruction) than that in A2 (duct-duct reconstruction) due to the following reasons: in ROLT, the stent is directly driven into the upper part of the duodenum, which makes the stent easily obstructed by chime and then more likely to have biliary complications. Based on our study, although choledochojejunostomy has been widely used in liver transplantation, duct-duodenum reconstruction is obviously not an ideal choice in ROLT.

In conclusion, biliary complications are almost inevitable using the classical "two-cuff" technique. More attention should be paid to the occurrence of biliary complications in ROLT model. The established mode of hepatic artery and biliary reconstruction should be modified.

COMMENTS

Background

Biliary complication is the second most common cause of graft dysfunction in liver transplantation with an incidence rate of as high as 64%. Unfortunately, few researches could be found to report the incidence of biliary complications in rat liver transplantation. In this study, the authors investigated the biliary complications after rat orthotopic liver transplantation, trying to find a better way to perform biliary reconstruction and reduce the incidence of biliary complications after transplantation

Research frontiers

Classical rat liver transplantation model using the "two-cuff" technique introduced by Kamada has been well accepted since 1983, but the incidence of biliary complications remains extremely high, there is an urgent need to improve the technology for biliary reconstruction.

Innovations and breakthroughs

Most previous studies used the "two-cuff" technique to establish rat liver transplant models, but few focused on the high incidence of biliary complications. In view of the experience in over 600 cases of rat orthotopic liver transplantation in this study, biliary complications are almost inevitable by using the classical "two-cuff" technique.

Applications

More attention should be paid to the occurrence of biliary complications in ROLT model. The established mode of hepatic artery and biliary reconstruction should be modified.

Terminology

Biliary complications: often include hilar abscess, intrahepatic and extrahepatic biliary dilatation, biliary sludge. "Two-cuff" technique: A classical method used in rat liver transplantation, which was first introduced by Kamada *et al*. The key steps are: Portal vein and infrahepatic inferior vena cava are induced through the cuffs and the distal end of the vein is completely reversed and fixed onto the cuff with a 5-0 silk ligation.

Peer review

The paper is well designed and the experience is valuable to be published.

Abstract

AIM: To assess the effects of combined transcatheter arterial chemoembolization (TACE) and percutaneous ethanol ablation (PEA) in patients with large hepatocellular carcinoma (HCC).

METHODS: A total of 63 patients with unresectable large HCC were treated with TACE followed by PEA. The largest dimension of the tumors ranged from 5.3 cm to 17.8 cm. The survival rates, acute effects, toxicity and prognostic factors were analyzed.

RESULTS: The cumulative survival rates at 1, 3 and 5 years were 59.4%, 28.4% and 15.8%, respectively (a median survival of 27.7 mo). Tumor area was reduced by more than 50% in 30 (47.6%) cases. In 56 cases with increased α-fetoprotein (AFP) values, AFP level was declined by more than 75%. The combined therapy was generally well tolerated. Only two patients died from variceal bleeding associated with the therapy. The Cox proportional hazards model showed that the number of tumors, the tumor margin and the ethanol dose were independent prognostic factors.

CONCLUSION: The combined TACE and PEA therapy is a promising approach for unresectable large HCC.

Key words: Hepatocellular carcinoma; Chemoembolization; Ethanol ablation; Combination therapy

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies in the world, responsible for an estimated one million deaths annually. It has a poor prognosis due to its rapid infiltrating growth and complicating liver cirrhosis. Surgery is the only potential cure, but the resection rate for HCC is only 10%-30%. The remaining patients are subjected to various modes of non-surgical therapy. Transcatheter arterial chemoembolization (TACE) has become one of the most popular approaches of non-surgical treatment, being effective in reducing tumor size in HCC and improving survival[1-4]. However, tumor cells remain viable in and

around the capsule, which is supplied by both arterial and portal blood, and these cells are often responsible for later recurrence and spread[5-10]. Further treatment is needed to eradicate residual tumor cells. We used TACE combined with percutaneous ethanol ablation (PEA) to treat 63 patients with large HCC and retrospectively evaluated the effects of this combined therapy and the prognostic factors.

MATERIALS AND METHODS

Ethics

This study was approved ethically by the Sun Yat-Sen University Cancer Center. All patients provided informed written consent. This work was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association.

Patients

From November 2001 to January 2009, 63 consecutive patients with large unresectable HCC were enrolled to this study. In all the patients, the diagnosis of HCC was made based on the histologic or angiographic findings combined with serum α-fetoprotein (AFP) levels. In 41 (65.1%) patients, the diagnosis of HCC was confirmed by histologic examination. The remaining 22 patients were diagnosed according to the findings on ultrasound, CT and angiography, and serum AFP levels. The enrolling criteria were as follows: (1) lesions detectable on ultrasound and CT; (2) tumor/liver volume ratio not above 0.7:1; (3) serum transaminase level under 80 IU/L; and (4) no evidence of extrahepatic metastasis or ascites. Patients who had ascites, extrahepatic metastasis, severe cirrhosis (class C according to Child's classification), or Karnofsky performance score < 70 were excluded. The baseline characteristics of patients are shown in Table 1.

Table 1 Baseline data of the patients

Variables	Values
Mean age (yr)	57.2
Cases of HBV-related liver disease	61.0
Cases of HCV-related liver disease	0.0
Mean AST (U/L)	43.4
Mean ALT (U/L)	49.5
Mean total bilirubin (μmol/L)	26.2
Mean AFP (ng/mL)	963.9
Mean tumor size (cm)	8.3

HBV: Hepatitis B virus; HCV: Hepatitis C virus; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; AFP: α-fetoprotein.

Methods

TACE was performed in the following processes: a 5.0 French catheter (Terumo, Tokyo, Japan) was inserted into the femoral artery by the Seldinger's method. Celiac angiography and selective hepatic arterial angiography were routinely performed to observe the tumorous blood supply, distribution of hepatic arteries and collateral circulation routes. The tip of the catheter was placed at the feeding artery of the tumor, and embolization was performed using emulsionized mixture of lipiodol ultra-fluid (Guerbet, France), Perarubicin (50 mg/m^2) and DDP (80 mg/m^2). The maximum dose for the embolization depended on the size of the tumor, blood supply and hepatic function of the patient. When the tumor was filled well with emulsifier, the embolization ended.

After 1-2 times of TACE, PEA was performed using an ethanol solution (99% concentration, mixed with lipiodol, 9:1 volume ratio) slowly injected into the tumor through a 15-cm 21 gauge Chiba needle (Cook, Bloomington, IN) guided by CT scan. The size of needle, the amount of ethanol injected per procedure and the number of procedures for the entire treatment, were planned depending on the volume of the tumor and the extent of the transient high-density zones induced by ethanol diffusion on CT scans. The procedure was completed when the entire targeted tumor appeared with a high density. PEA was performed 2-5 times for each tumor. The amount of ethanol injected per procedure and per tumor was 3-20 mL (mean ± SD, 8.2 ± 3.4 mL) and per patient 5-40 mL (mean ± SD, 30.5 ± 6.6 mL).

The follow-up protocol after the initial combined therapy was planned according to the volume of the tumor, tumor blood supply and the extent of the high-density zones on CT scans. The standard TACE for a 8.0-10.0 cm HCC needs two steps (3 wk for each step) when a good tumor blood supply was displayed on enhanced CT scan, and the standard PEA protocol for a 5.0-6.0 cm HCC needs three steps (1.5 wk for each step) when tumor blood supply was obviously decreased on enhanced CT scan. The ethanol treatment was ended when the entire targeted tumor appeared with a high density.

The therapeutic efficacy was evaluated by CT scan two mo after the combined treatment.

Prognostic factors

Factors thought to influence survival were selected and classified to obtain survival rates using the Kaplan-Meier method. The significance of the differences was evaluated by the log-rank test with univariate analysis. The following prognostic factors were investigated: sex, age, number of lesions, tumor size, tumor extension, tumor margin (the tumor margin is the edge of the tumor, and the boundary between the tumor tissues and normal tissues was determined based on hepatobiliary phase images), AFP, portal thrombosis, ascites, Child grade, Okuda stage, times of TACE and PEA and the total ethanol dose. Variables with possible prognostic significance were selected, and each variable was divided into 2-4 classes (Table 2). Factors related to the survival rate were used as variables, and stepwise multivariate analysis was performed. Multiple regression analysis was performed using the Cox proportional-hazard model to calculate the relative-risk ratio between each factor and the survival rate.

RESULTS

Recent results, survival and prognostic factors

Tumor area was reduced by more than 50% in 30 (47.6%) cases. In 56 cases with increased AFP, AFP level was declined by more than 75%.

At the end of this study, 11 patients remained alive,

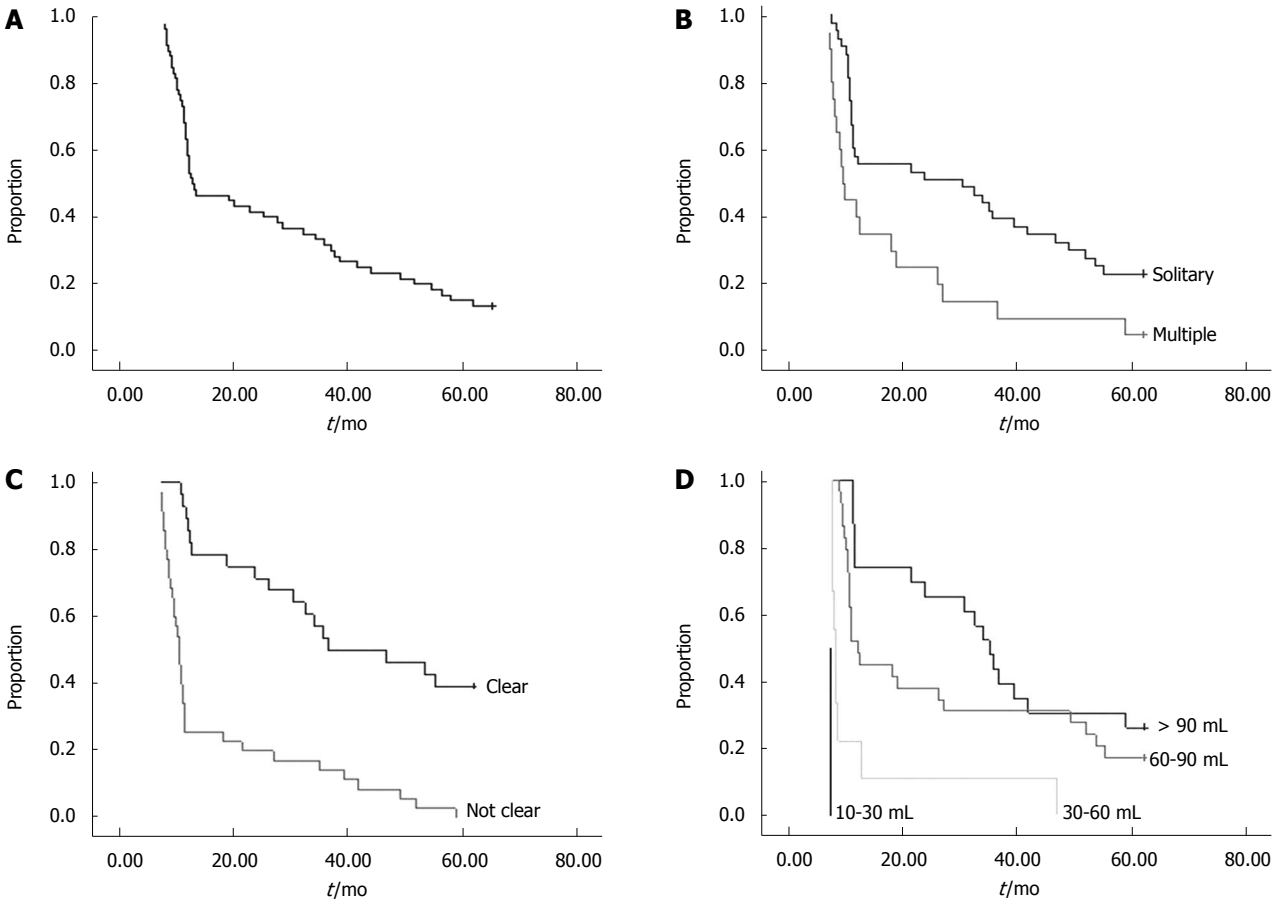

Figure 1 Overall cumulative survival curve and cumulative survival curves in patients based on the number of lesions, tumor margin and percutaneous ethanol ablation dose. A: Overall cumulative survival curve in 63 hepatocellular carcinoma (HCC) patients receiving combined therapy of transcatheter arterial chemoembolization (TACE) and percutaneous ethanol ablation (PEA); B: Cumulative survival curves in patients based on the number of lesions; C: Cumulative survival curves in patients based on the tumor margin; D: Cumulative survival curves in patients based on PEA dose.

Table 2 Variables and classes by univariate and multivariate analyses

Variables	Classes			
	A	B	C	D
Sex	M (52)	F (11)		
Age (yr)	< 55 (36)	> 55 (27)		
No. of lesions	Solitary (43)	Multiple (20)		
Tumor size (cm)	5-10 (41)	> 10 (22)		
Tumor extension	1 lobe (46)	2 lobe (17)		
Tumor margin	Clear (28)	Not clear (35)		
AFP	< 400 (22)	> 400 (41)		
Portal thrombosis	Absent (51)	Present (12)		
Ascites	Absent (56)	Present (7)		
Child grade	A (38)	B (25)		
Okuda stage	Ⅰ (29)	Ⅱ (34)		
TACE (number of times)	1 (11)	2 (26)	3 (20)	4 (6)
PEA (number of times)	1 (3)	2 (6)	3 (31)	> 4 (23)
Total ethanol dose	10-30 (2)	- 60 (9)	- 90 (29)	> 90 (23)

In the parenthesis are numbers of patients. AFP: α-fetoprotein; TACE: Transcatheter arterial chemoembolization; PEA: Percutaneous ethanol ablation.

and 52 patients had succumbed. The survival curve is shown in Figure 1A. Overall survival rates at one, three, and five years were 54.0%, 31.7% and 17.5%, respectively (median survival 27.7 mo).

Univariate analysis indicated that 11 factors significantly influence the survival. Sex, age and TACE times were not significant ($P > 0.05$), (Table 3).

The Cox proportional hazards model showed that only the number of tumors, tumor margin and the total ethanol dose were independent factors predicting survival (Table 4).

The overall survival rates at one, three and five years in the 43 patients with a solitary lesion were 58.1%, 39.5% and 23.3%, respectively, and were 45.0%, 15.0% and 5.0%, respectively in the 20 patients with multiple lesions. The mean survival of patients with a solitary lesion was significantly longer ($P = 0.0145$) than that of patients with multiple lesions (Figure 1B). In the patients with clear tumor margin ($n = 28$), the 1, 3, and 5-year survival rates were 89.3%, 53.6% and 39.3%, respectively, and these figures were significantly higher ($P = 0.0052$) than in the patients without clear tumor margin ($n = 35$), who had survival rates of 25.7% at one year, 14.3% at three years, and 0 at five years (Figure 1C). The mean 1-, 3- and 5-year survival rates were estimated to be 0%, 0% and 0%, respectively, in the 2 patients who received 10-30 mL total ethanol dose; 33.3%, 16.7% and 0% in the 9 patients who received 30-60 mL total ethanol dose; 51.7%, 31.0% and 16.1% in the 29 patients who received 60-90 mL total ethanol dose; and 73.9%, 43.5%, and 26.1% in the 23 patients who received

Table 4 Significant factors predicting survival found using Cox proportional hazards model

Variables	Hazard ratio	*P* value
No. of lesions		
Multiple *vs* single solitary lesions	2.626	0.001
Tumor margin		
Not clear *vs* clear	2.439	0.000
Total ethanol dose		
30-60 mL *vs* 10-30 mL	0.386	0.000
60-90 mL *vs* 10-30 mL	0.202	0.000
> 90 mL *vs* 10-30 mL	0.116	0.000

over 90 mL total ethanol dose. Statistically significant difference was found between the high-dose group and low-dose group ($P < 0.0001$), (Figure 1D).

Side effects

Fever, abdominal pain, nausea and vomiting occurred in most of the patients after TACE and PEA. These symptoms were self-limiting in almost all the patients, lasting less than one week. A slight increase in serum bilirubin (37 cases), elevated serum transaminase level (59 cases), ascites (6 cases), leucopenia (15 cases) and thrombocytopenia (11 cases) were associated with the combined therapy. These side effects were transitory or easily controlled with medication in most of the patients. Two patients died of variceal bleeding because of the increased portal vein pressure caused by deterioration of liver cirrhosis after repeated TACE-PEA, which had an impact on liver function.

DISCUSSION

The rationale for combined therapy of TACE and PEA relies on the fact that after TACE, tumor blood supply is markedly decreased and intratumoral septa are usually destroyed as a result of the necrosis induced by the procedure. These histopathologic changes make subsequent PEA treatment easier as they can provide enhanced ethanol diffusion within the tumor. Consequently, treatment with PEA is facilitated by the TACE-derived fibrous wall around the lesion, which favors a better retention of the injected ethanol within the tumor[11-15]. Tanaka *et al*[14] first reported the effectiveness of TACE combined with PEA for large (> 3.0 cm in diameter) primary HCC compared with that of TACE alone. His study found that a partial

response of the tumor was seen in only 10% of the patients, and the 1-, 2-, and 3-year survival rates were 68%, 37% and 0%, respectively with TACE alone, and histologic examinations showed that TACE alone caused complete necrosis in only 20% of the tumors. In contrast, PEA combined with TACE significantly increased the partial response rate (45%), prolonged the 1-, 2-, and 3-year survival rates (100%, 85% and 85%), and achieved complete histologic necrosis in 83% of the tumors. Dohmen *et al*[15] proved that the combined TACE and PEA treatment had a lower incidence of local recurrence than TACE alone which resulted in an increased survival of the patients with unresectable large HCC.

Ethanol in PEA diffused within the cells, causing immediate dehydration of cytoplasmic proteins with consequent coagulation necrosis followed by fibrosis, and entered the circulation, inducing necrosis of endothelial cells and platelet aggregation with consequent thrombosis of small vessels followed by ischemia of the neoplastic tissues. Advantages of PEA were[16-18]: no remarkable damage to the remaining parenchyma, being safe, easy to be repeated when new lesions appear, low in cost, easy to operate, and possessing good long-term results. PEA can be carried out either in patients with HCC who have a poor liver function or in elderly patients (age $\geqslant$ 70 years)[19,20]. Our results proved that higher doses of ethanol can be injected, which can achieve complete and homogeneous perfusion even in large lesions.

It is necessary to analyze prognostic factors in a large number of patients in sufficient detail and to evaluate the result of each method of treatment between groups with similar prognostic factors. Our study showed that only the number of tumors, tumor margin and the total ethanol dose were independent factors predicting survival. Although various prognostic factors have been reported[21-23], no conclusion has been drawn as to which factor is significant. In this study, the significant factors for better prognosis included the number of tumors, tumor margin and the total ethanol dose. The prognostic factors identified in this study suggested that, therapeutic results in patients with solitary tumors and clear tumor margin treated at a higher total ethanol dose should be better than those in patients with multiple tumors, without clear tumor margin treated at a lower total ethanol dose. It is worth noting the tumor margin is one of the important prognostic factors. It is determined based on hepatobiliary phase images and represents the growth pattern of tumor to some extent. The tumor margin imaging can predict microscopic portal vein invasion, intrahepatic metastasis and early recurrence after hepatectomy in HCC patients[24].

Ebara *et al*[25] and Vilana *et al*[26] proposed tumors < 30 mm in size and < 3 in number as indications for PEA, mainly because of technical limitation such as the inability to inject an effective volume of ethanol into the whole area of the tumor. Our results suggested that some tumors > 50 mm in size could be treated by PEA because the therapeutic results of PEA were also good for large HCC patients with solitary tumors and clear tumor margin at a higher total ethanol dose after TACE.

Long-term survival rates of PEA-treated patients are similar to those obtained in matched patients undergoing partial hepatectomy[27,28]. However, the long-term prognosis remains disappointing because of the high recurrence rate among patients with HCC after PEA, especially in those with multiple lesions, cirrhosis and a high level of AFP and those without a clear tumor margin and peritumoral capsule[29,30]. In fact, histological examination of HCC after PEA reveals that residual tumor tissues remain in portions isolated by septa or with extracapsular or intracapsular invasion. It has been demonstrated that the high vascularity of HCC promotes an early wash-out of injected ethanol, so that PEA for patients with hypervascular tumors may be less effective than for patients with hypovascular tumors[31,32].

COMMENTS

Background

The incidence of large hepatocellular carcinoma (HCC) is increasing in China and HCC has a poor prognosis due to its rapid infiltration and complicating liver cirrhosis. The results in this study indicated that combined transcatheter arterial chemoembolization (TACE) with percutaneous ethanol ablation (PEA) is a promising therapeutic approach for large unresectable HCC.

Research frontiers

The authors analyzed the prognostic factors in a large number of patients in detail and evaluated the result of each method of treatment between groups with similar prognostic factors. This study showed that the number of tumors, tumor margin and the total ethanol dose were independent factors predicting survival.

Innovations and breakthroughs

This is the first study to report that the number of tumors, tumor margin and the total ethanol dose were independent factors predicting survival of large HCC. The combined TACE and PEA therapy is a promising approach for large unresectable HCC.

Applications

By understanding the independent prognostic factors, this study may represent a future strategy in the treatment of patients with large unresectable HCC.

Terminology

TACE has become one of the most popular approaches of non-surgical treatment, with good results in reducing the tumor size of HCC and improving the survival of the patients. PEA is facilitated by the TACE-derived fibrous wall around the lesion, which favors a better retention of the injected ethanol within the tumor.

Peer review

This is a constructive study to report that the number of tumors, tumor margin and the total ethanol dose were independent factors predicting survival of large HCC, which is expected to improve the therapeutic effects for large unresectable HCC.

Abstract

AIM: To analyze the microbiota shift in the distal esophagus of Sprague-Dawley rats fed a high-fat diet.

METHODS: Twenty Sprague-Dawley rats were divided into high-fat diet and normal control groups of 10 rats each. The composition of microbiota in the mucosa from the distal esophagus was analyzed based on selective culture. A variety of *Lactobacillus* species were identified by molecular biological techniques. Bacterial DNA from *Lactobacillus* colonies was extracted, and 16S rDNA was amplified by PCR using bacterial universal primers. The amplified 16S rDNA products were separated by denaturing gradient gel electrophoresis (DGGE). Every single band was purified from the gel and sent to be sequenced.

RESULTS: Based on mucosal bacterial culturing in the distal esophagus, *Staphylococcus aureus* was absent, and total anaerobes and *Lactobacillus* species were decreased significantly in the high-fat diet group compared with the normal control group ($P < 0.01$). Detailed DGGE analysis on the composition of *Lactobacillus* species in the distal esophagus revealed that *Lactobacillus crispatus*, *Lactobacillus gasseri* (*L. gasseri*) and *Lactobacillus reuteri* (*L. reuteri*) comprised the *Lactobacillus* species in the high-fat diet group, while the composition of *Lactobacillus* species in the normal control group consisted of *L. gasseri*, *Lactobacillus jensenii* and *L. reuteri*.

CONCLUSION: High-fat diet led to a mucosal microflora shift in the distal esophagus in rats, especially the composition of *Lactobacillus* species.

Key words: Obesity; *Lactobacillus*; Sprague-Dawley rats; Distal esophagus; Denaturing gradient gel electrophoresis

INTRODUCTION

Gastroesophageal reflux disease (GERD) is one of the most common clinical disorders, and its incidence

has been steadily increasing around the world in recent years[1-4]. Numerous studies have demonstrated that obesity is a risk factor for GERD. The incidence of GERD and its complications in subjects who are overweight or obese is higher than in those with normal weight[1-4]. With obesity gradually increasing worldwide, obesity-associated GERD is becoming a more complicated clinical problem. Unfortunately, to date, the pathogenesis of obesity-associated GERD has not been fully understood. Thus, the usual management of GERD is merely to inhibit acid production and improve motility of the upper gastrointestinal tract to ameliorate symptoms, which can seriously affect quality of life[5-8].

It is well accepted that GERD is mainly due to abnormality of the gastroesophageal junction or a decrease in esophageal clearance capacity. Current data have demonstrated that the association of obesity with GERD is mainly related to changes in lower esophageal sphincter motility or a pressure imbalance between the distal esophagus and gastric fundus[1-8]. However, the detailed mechanism needs to be further elucidated.

Recent studies have found that the composition of intestinal flora in obese individuals differs from that in normal individuals. Bacterial diversity, either different composition or quantity of bacteria in the gastrointestinal tract, is associated with gastrointestinal smooth muscle motility[9-13]. In clinical practice, many bacterial agents have been used for treatment of diarrhea, irritable bowel syndrome and other gastrointestinal motility diseases, and have achieved a positive response. Based upon the published findings, it can be estimated that microflora in the distal esophagus, to some extent, might play a role in regulating smooth muscle motility. However, the features of colonization and functionality of the microflora in the distal esophagus remain obscure. Some evidence has shown that the esophageal bacteria are transitory, and other studies have demonstrated a complex, residential microflora in the distal esophagus. Several studies also have confirmed the presence of a residential bacterial population in the distal esophagus in patients with esophageal-reflux-related disorders[14,15]. More detailed research has shown a significant alteration in the number of lactobacilli in the intestine of obese rats[11,16-19]. Thus, it is reasonable that obesity, a passive risk factor for GERD, might alter the composition of microflora in the distal esophagus, and lead to the formation of GERD.

Therefore, we hypothesize that potential variations in microbial composition in the distal esophagus of obese individuals might influence the distal esophageal motility and lead to GERD. Thus, we focused on the variation in microflora, especially *Lactobacillus* species, in the distal esophagus in obese Sprague-Dawley rats induced by high-fat diet, compared with normal rats, to illustrate the role of obesity or high-fat diet in the microfloral composition shift.

MATERIALS AND METHODS

Animals

Twenty-five healthy male Sprague-Dawley rats (purchased from the Experimental Animal Co., Hayes Lake, Hunan, China) aged 3 wk, weighing 50-70 g, were used. The animal experiments were approved by the Animal Experiment Ethics Committee of Central South University, Changsha, China.

Table 1 Comparison of the components of each diet: high-fat diet and common diet (per 0.1 kg)

Diet	Protein (g)	Fat (g)	Carbohydrate (g)	Energy (KJ)
Common diet	17.53	6.08	59.98	1250
High-fat diet	16.52	25.17	56.66	1810

Establishment of animal model

Sprague-Dawley rats were housed individually in cages at constant room temperature of 18-22℃, 50% humidity, in a 12-h light/dark cycle, and had free access to common diet and water. After 1 wk of adaptive feeding, five rats were killed and the other 20 were randomly divided into two groups of 10. One group was fed a high-fat diet (Dongchuang Nursery, Hunan, China; Table 1) for 6 wk, and the normal control group was fed a common diet. The daily diet was sterilized by Co^{60} irradiation and water by autoclave before feeding to the rats. Rats were killed at the end of 7 wk. Body weight, body length and feed consumption were recorded weekly and daily[20-22].

Histopathological examination of esophageal mucosa

The esophagus of each rat was removed and dissected longitudinally. Esophageal specimens were obtained from 1.5 cm above the gastroesophageal junction. Then 0.5 cm of each longitudinal strip was fixed in 10% formalin-buffered saline, embedded in paraffin, and processed for histopathological analysis. Two sections were cut from each paraffin block and stained with hematoxylin-eosin (HE) for evaluation of inflammation.

Determination of serum lipid levels

After fasting for 10 h, venous blood was obtained at the end of 7 wk. Three hundred microliters of serum for each sample was extracted and stored at -20℃. Serum triglyceride and total cholesterol were detected by GPO-PAP and CHOD-PAP methods, respectively.

Bacterial culture

The esophagus of each rat was removed and dissected longitudinally. Esophageal mucosa samples were obtained from 1 cm above the gastroesophageal junction. After being weighed on an electronic balance, the samples were homogenized immediately, and the homogenates were diluted at 10^{-7} in sterile normal saline. Ten microliters was spread thoroughly over the surfaces of specific medium plates. The media utilized were as follows: Mannitol Salt Agar for *Staphylococcus aureus* (*S. aureus*); Actinomyces Agar for *Actinomyces*; TTC Agar for *Enterococcus*; KF Streptococcus Agar for *Streptococcus*; EMB Agar for *Enterobacter*; Anaerobic Agar for total anaerobes; Clostridium Agar for

Clostridium; PY Agar for *Clostridium perfringens*; LBS Agar for *Lactobacillus* and *Lactobacillus crispatus* (*L. crispatus*); and BL Agar for *Bifidobacterium*. All aerobic plates were incubated at 37℃ for 24 h, followed by incubation for 12 h at room temperature. The LBS plates were incubated in a candle-jar atmosphere of 10% CO_2. Anaerobes were grown in an anaerobic jar at 37℃ for 72 h. The number of colonies from each plate was recorded.

Amplification of Lactobacillus 16S rDNA for denaturing gradient gel electrophoresis

DNA from *Lactobacillus* cultures was extracted according to the protocol of BioTeke Corporation (Beijing, China) and stored at -20℃. Universal bacterial primers (Invitrogen Biotechnology, Shanghai, China) HAD1-GC (CGCCCGGGGCGCGCCCCGGGCGGGGCGGGGGCACGGGGGGGACTCCTACGGGAGGCAGCAGT-3') and HAD2(5'-GTATTACCGCGGCTGCTGGCAC-3')[23] were used to amplify V2 to V3 regions of the bacterial 16S rDNA. PCR reactions were run at 95℃ for 5 min, followed by 38 cycles of amplification at 94℃ for 40 s, 52℃ for 40 s, and 72℃ for 50 s, and a 7-min extension at 72℃.

Denaturing gradient gel electrophoresis

Denaturing gradient gel electrophoresis (DGGE) was performed with the DCode™ Universal Detection System (Bio-Rad) that utilized 16 cm × 16 cm × 1 cm gels. Eight percent polyacrylamide gels were prepared and run with 1 × TAE buffer (2 mol/mL Tris base, 1 mol/mL glacial acetic acid, and 50 mmol/mL EDTA) diluted from 50 × TAE buffer (Sigma, Beijing, China). The denaturing gradient was formed with two 8% acrylamide (acrylamide/bis, 37.5:1) stock solutions (Bio-Rad). The gels contained a 30%-70% gradient of urea and formamide that increased in the direction of electrophoresis. A 100% denaturing solution contained 40% (v/v) formamide and 7.0 mol/mL urea. The electrophoresis was conducted with a constant voltage of 110 V at 60℃ for 12 h. Gels were stained with ethidium bromide solution (5 μg/mL) for 30 min, washed with deionized water, and viewed by UV transillumination (Bio-Rad).

Amplification and sequencing of the 16S V2-V3 region

Single predominant bands of the DGGE gel were selected by cutting with a sterile scalpel, and added to 50 μL deionized sterile water (Fermentas Life Sciences, Shenzhen, China). The gel pieces were placed at 4℃ for 24 h, centrifuged at 12000 × *g* for 10 min, and the supernatants were used as templates for PCR amplification. Universal bacterial primers (Invitrogen Biotechnology) HAD1(5'-TCCTACGGGAGGCAGCAGT-3') and HAD2(5'-GTATTACCGCGGCTGCTGGCAC-3')[23] were used for amplification. For each PCR amplification, 5 μL template was added to 45 μL PCR reaction mixture (Fermentas Life Sciences) that contained 5 μL 10 × PCR buffer, 5 μL 25 mmol/L $MgCl_2$, 1.5 μL 10 mmol/L dNTPs, 1.5 μL 100 ng/μL each primer, and 2.5 U Taq DNA polymerase. Reactions were run at 95℃ for 5 min, followed by 36 cycles of amplification at 94℃ for 30 s, 56℃ for 40 s, and 72℃ for 40 s, and a 10-min extension at 72℃. Wizard PCR Preps DNA Purification System (Promega, Beijing, China) were used to purify the PCR products. The purified products were sent to Beijing Genomics Institute of Technology for sequencing. Blast sequences were obtained through GenBank BLAST searches (http://www.ncbi.nlm.nih.gov/blast).

Statistical analysis

Statistical analysis was performed using SPSS for Windows version 15.0. Results were expressed as measurement and enumeration data. Data are presented as means and SDs. For statistical comparisons, the *t* test and χ^2 test were performed and $P < 0.05$ was considered statistically significant.

RESULTS

High-fat diet resulted in elevated body weight and serum lipid with no significant histological change in vivo

There was no significant change in body weight in the high-fat diet and normal control groups at the end of the first week. Since the second week, the body weight and Lee's index increased weekly (Figure 1A and B). Accordingly, serum triglyceride and total cholesterol in the high-fat diet group were significantly increased compared with the normal control group (Figure 1C). HE staining of esophageal mucosa showed no musculature damage or mucosal injury in the distal esophagus in the high-fat diet or normal control group (Figure 1D).

High-fat diet led to microfloral shift in distal esophagus based on bacterial culture

Bacteria in the distal esophagus were cultured on selective media. In the high-fat diet group, *S. aureus* was absent, and the numbers of total anaerobes and lactobacilli were reduced significantly in the distal esophagus compared with the normal control group. There was no obvious difference between the common and adaptive feeding groups for composition of cultivable bacteria in the distal esophagus of Sprague-Dawley rats (Table 2).

Determination of Lactobacillus species shift in distal esophagus of high-fat diet-fed rats based on DGGE and sequencing

16S rDNA of cultivable *Lactobacillus* from the high-fat and common diet groups was amplified by PCR using universal bacteria primers HAD1-GC and HAD2 (Figure 2A). The amplified products of 16S rDNA were separated by DGGE. The two groups shared dramatically different bands, with bands A, C, D and E in the high-fat diet group, and bands B, C, D and E in the common diet group (Figure 2B). The purified bands were sequenced and BLASTed online with the V2-V3 region. The composition of *Lactobacillus* species in the distal esophagus in the common diet group was *Lactobacillus gasseri* (*L. gasseri*), *Lac-*

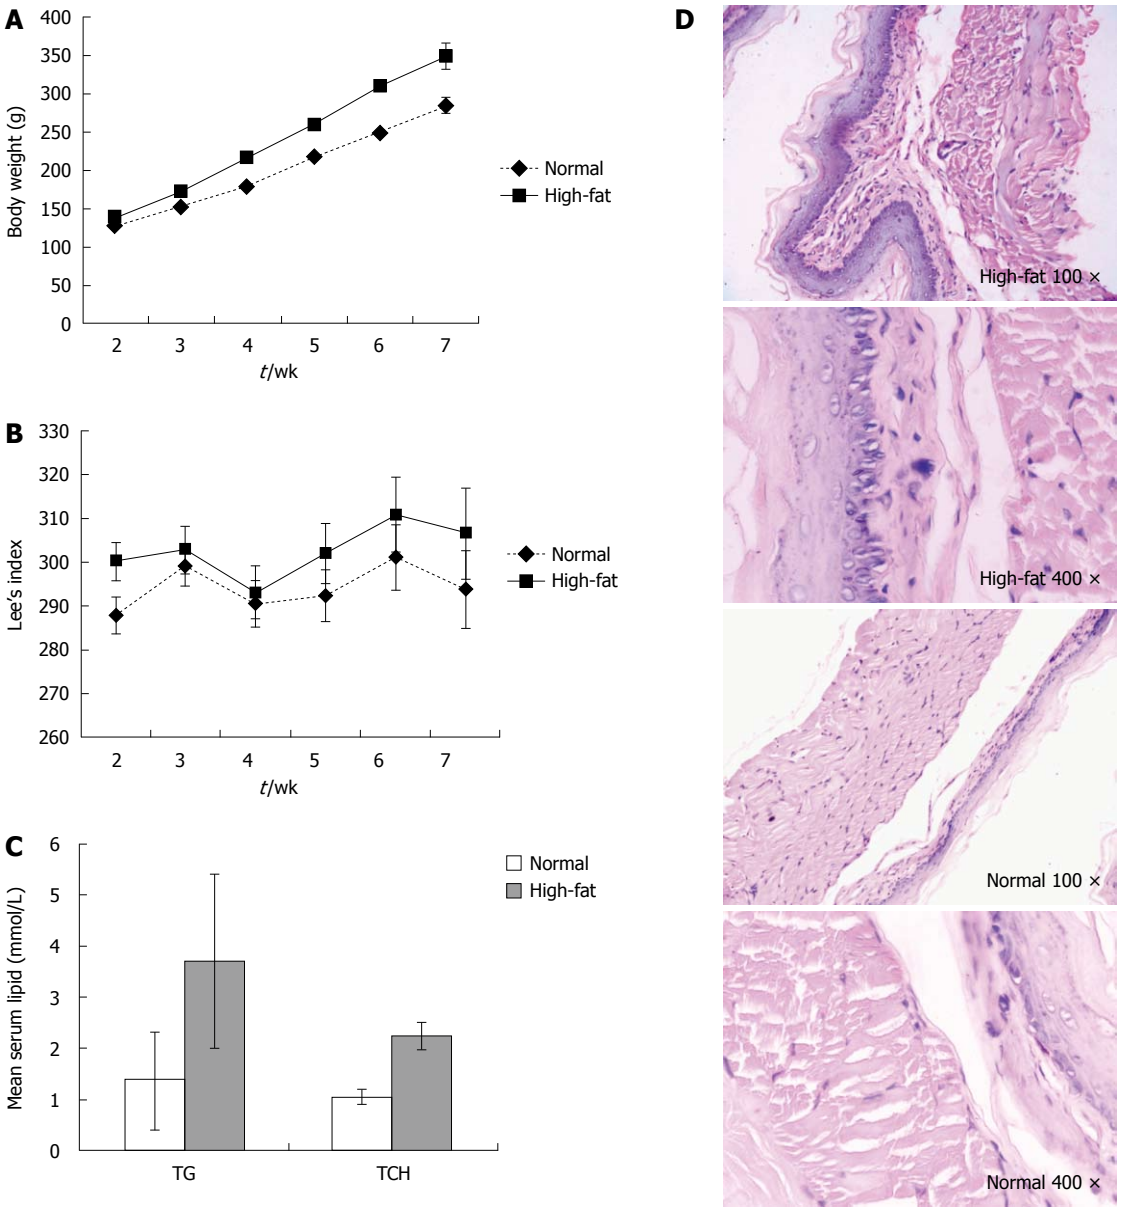

Figure 1 No significant change in distal esophageal mucosa in Sprague-Dawley rats fed a high-fat diet. A: Body weight changes of age- and sex-matched rats in the high-fat diet and normal control groups (n = 10 each); B: Lees index changes for the rats in (A) (n = 10); C: Mean serum lipid for the rats in (A); D: Histological analysis of representative distal esophagus from the rats in (A) (Original magnification, hematoxylin-eosin staining, 100 × or 400 ×).

tobacillus jensenii (*L. jensenii*) and *Lactobacillus reuteri* (*L. reuteri*), whereas the composition shifted to *L. crispatus*, *L. gasseri* and *L. reuteri* in the high-fat diet group (Figure 2C and D).

DISCUSSION

Accumulating evidence has shown that obesity is a risk factor in the development of GERD[1-8,24,25]. However, is not well established how obesity affects the incidence of GERD. According to the published experimental data, no musculature damage has been reported in the distal esophagus of obese rats or mice. However, different components of the microbiota have been identified between obese and lean animals/humans. Based on this evidence, the purpose of this study was to analyze the microbiota composition and focus on how the shift in microflora occurred in the distal esophagus of rats fed a high-fat diet.

To date, the role of microbiota in the distal esophagus under conditions of weight gain remains obscure. Some studies have shown that high-fat/high-sugar chow diet-fed, germ-free mice gain significantly less weight than their control littermates. The absence of microbiota has a protective role against weight gain in mice that consume a Western-style diet. Thus, body weight gain could be associated with a shift in the microbiota in mice fed a western-style diet. On the other hand, current research has demonstrated that there is a complex residential microbiota shift in the distal esophagus of patients with esophageal-reflux-related disorders, such as GERD, reflux esophagitis and Barrett's esophagus[14,15,26]. The possible explanations are that the reflux content might contain gastric bac-

teria or damage the esophageal mucosa and lead to an abnormal inhabitation niche for the distal esophageal microbiota. Thus, the abnormal interactions among distal esophageal residential microbiota, gastric bacteria, and distal esophageal mucosa could lead to a composition shift in the microbiota in the distal esophagus.

Based on analysis of cultivable microbiota of the distal esophagus, we found a certain microbiota compositional shift in the distal esophagus of obese rats. The major microbiota shift in the distal esophagus involved the loss of *S. aureus* and decrease in anaerobes and *Lactobacillus* species. The focus in this research was diet-associated obesity, with integrated esophageal mucosal changes, and no obvious histological changes. This means that the microbiota shift in the distal esophagus was not due to the reflux of gastric content or alteration of the inhabitable niche of microbiota in the distal esophagus. Thus, a possible explanation for this microbiota shift in mice fed a western-style diet, compared with their control littermates, could be the

components of high-energy materials in the distal esophageal mucosa. These high-energy components might alter the mucosal microenvironment and help the local bacteria to colonize the distal esophageal mucosa.

GERD is an obvious motility disorder of the distal esophagus. Recent research has shown that several *Lactobacillus* or other bacterial species can alter the motility of smooth muscle in the distal esophagus[9-12]. It has been shown that different composition of *Lactobacillus* species can lead to different influences on smooth muscle motility in the distal esophagus[9-12]. However, the details are still unclear. Some evidence has shown increased smooth muscle contraction in certain GERD cases, whereas other studies have shown opposite results. The probable reason is that analysis of the shift in *Lactobacillus* was restricted to the level of the *Lactobacillus* genus. Fortunately, with the development of modern molecular techniques, analysis of *Lactobacillus* at the species level has become possible.

In our study, the combination of bacterial culture and DGGE was used to analyze the composition of *Lactobacillus* in the distal esophagus. It was clearly demonstrated that three cultivable *Lactobacillus* species, *L. gasseri*, *L. jensenii* and *L. reuteri*, colonized the distal esophagus in normal control rats. However, the composition of *Lactobacillus* species was shifted to *L. crispatus*, *L. gasseri* and *L. reuteri* in the distal esophagus in high-fat diet-fed rats. Four *Lactobacillus* species constituted a specific group in the distal esophagus of normal control rats as well as in obese rats. To our surprise, *L. jensenii* disappeared from the mucosa of the distal esophagus, which was replaced by *L. crispatus* in obese rats. It is possible that the disappearance of *L. jensenii* and re-colonization with *L. crispatus* results in alteration of smooth muscle motility in the distal esophagus. Therefore, this could probably be involved in the etiology of GERD, because of the variations in cultivable *Lactobacillus* species in the distal esophagus in obese rats. Another reasonable explanation is that different *Lactobacillus* species could have different metabolic characteristics, and influence the inhabitation niche of the microbiota in the distal esophagus. Yet another possibility is that the composition of cultivable *Lactobacillus* species in the distal esophagus of obese rats could be beneficial in preventing esophageal reflux.

Clearly, many unresolved questions remain to be elucidated. Our research will next focus on the effects of the composition shift in *Lactobacillus* on smooth muscle motility in the distal esophagus. Then, we will distinguish between the promoting or inhibitory properties of ingredients or metabolites of different *Lactobacillus* species. Therefore, the data could result in potential therapeutic targets in GERD.

COMMENTS

Background

Obesity is a risk factor for gastroesophageal reflux disease (GERD), but how obesity affects the incidence of GERD is not well established. Current research has demonstrated that there is a complex residential microbiota shift in distal esophagus of esophageal-reflux-related disorders in humans. The different components of the microbiota are identified between obese animals/humans and lean animals/humans. Thus, it is reasonable that obesity, a passive risk factor of GERD, might alter the composition of microflora in the distal esophagus, and lead to development of GERD.

Research frontiers

Bacterial diversity is associated with gastrointestinal smooth muscle motility, and is also identified between obese animals/humans and lean animals/humans. However, the microbiota shift in the distal esophagus in obesity has not been fully addressed. In this study, we demonstrated the composition of cultivable *Lactobacillus* species shift in the distal esophagus of obese rats.

Innovations and breakthroughs

Published data show that different constitution of *Lactobacillus* species may exert different influences on smooth muscle motility in the distal esophagus. However, the details are still unclear. Analysis on the shift in *Lactobacillus* is restrained at the genus level. This study analyzed the composition of *Lactobacillus* in the distal esophagus, and found that the composition of cultivable *Lactobacillus* species shifted in the distal esophagus in obese rats. Therefore, potential variations in microbial composition in the distal esophagus in obesity may influence the distal esophageal motility and lead to GERD.

Applications

This study proved that the composition of cultivable *Lactobacillus* species shifted in the distal esophagus in obese rats, therefore, it may represent a further study between the microbial composition shift in the distal esophagus and GERD. This could lead to the development of a potential therapeutic target in GERD.

Terminology

GERD is a more serious form of gastroesophageal reflux, which is common. Persistent reflux that occurs more than twice weekly is considered GERD, and it can affect people of all ages. The main symptom of GERD in adults is frequent heartburn, also called acid indigestion - burning-type pain in the lower part of the mid-chest, behind the breast bone, and in the mid-abdomen.

Peer review

This study considers the investigation of microbiota composition in the distal esophagus of high-fat-diet-fed rats. The authors hypothesize that potential variations in microbial composition in the distal esophagus of obese individuals may influence distal esophageal motility and lead to GERD. In this study, the composition of *Lactobacillus* spp. was analyzed using the combination of bacterial culturing, denaturing gradient gel electrophoresis and sequencing in a rat model. The interesting and important finding of this study was the fact that high-fat diet led to a shift in mucosal microflora (especially *Lactobacillus* species) in the distal esophagus in rats, which resulted in alteration of smooth muscle motility. This study makes an additional contribution to studies of the etiology of GERD.

Abstract

AIM: To evaluate the clinical outcomes of patients undergoing hepatectomy with hemihepatic vascular occlusion (HHO) compared with total hepatic inflow occlusion (THO).

METHODS: Randomized controlled trials (RCTs) comparing hemihepatic vascular occlusion and total hepatic inflow occlusion were included by a systematic literature search. Two authors independently assessed the trials for inclusion and extracted the data. A meta-analysis was conducted to estimate blood loss, transfusion requirement, and liver injury based on the levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Either the fixed effects model or random effects model was used.

RESULTS: Four RCTs including 338 patients met the predefined inclusion criteria. A total of 167 patients were treated with THO and 171 with HHO. Meta-analysis of AST levels on postoperative day 1 indicated higher levels in the THO group with weighted mean difference (WMD) 342.27; 95% confidence intervals (CI) 217.28-467.26; P = 0.00001; I^2 = 16%. Meta-analysis showed no significant difference between THO group and HHO group on blood loss, transfusion requirement, mortality, morbidity, operating time, ischemic duration, hospital stay, ALT levels on postoperative day 1, 3 and 7 and AST levels on postoperative day 3 and 7.

CONCLUSION: Hemihepatic vascular occlusion does not offer satisfying benefit to the patients undergoing hepatic resection. However, they have less liver injury after liver resections.

Key words: Inflow occlusion; Hemihepatic; Vascular occlusion; Hepatectomy; Pringle maneuver

INTRODUCTION

Liver resection is performed mainly for benign and malignant liver tumors, especially for hepatocellular carcinoma. It is a potential curative treatment option in patients with early stage carcinoma[1]. Intraoperative bleeding is a main concern during liver resections, and mortality and morbidity are clearly correlated with the amount of blood loss

and the subsequent blood transfusions[2]. Many methods of hepatic vascular control have been introduced to control intraoperative blood loss. In 1908, Pringle applied inflow vascular occlusion technique (the Pringle maneuver) at the hepatic hilar for the first time. It is a technique of total compression of the hepatoduodenal ligament and the most commonly used and relatively easy method for controlling afferent blood flow[3]. However, the Pringle maneuver also carries the risk of global ischemic damage to the liver and intestinal congestion, especially in patients with chronic liver diseases, the degree of which is likely to be accentuated by a prolonged period of vascular inflow occlusion[4,5]. In 1987, Bismuth and Makuuchi proposed a hemihepatic vascular occlusion (HHO) technique to reduce the severity of visceral congestion and total liver ischemia, especially for the remaining liver[6,7]. By this method, visceral congestion is considered to be limited, because considerable portal blood flow is preserved and only portions of the liver are rendered anoxic[8]. The technique with occlusion of vessels supplying the hemiliver containing the tumor, has been suggested to reduce intraoperative bleeding and postoperative liver functional disturbances because of the interruption of blood flow to the liver[9]. But, portal vein and artery dissection to perform selective clamping is time consuming and may result in another blood loss[10]. Many prospective randomized controlled trials (RCTs) and retrospective clinical trials have evaluated the feasibility, safety and efficacy of HHO and total hepatic inflow occlusion (THO), however, the clinical significance between the two vascular control methods remain inconsistent. So, the optimal method of vascular control during hepatic resection continues to be debated.

Up to now, a meta-analysis including all available RCTs is still insufficient. We conducted a systematic review and meta-analysis to evaluate the feasibility, safety and efficacy of HHO and THO in patients undergoing hepatectomy.

MATERIALS AND METHODS

Systematic literature search

A systematic literature search was independently conducted by two authors. They systematically searched the Medline, Embase, Science Citation Index, PubMed and CNKI (China National Knowledge Infrastructure Whole Article Database). The following keywords were used: hemihepatic vascular occlusion, hemihepatic occlusion, selective inflow occlusion, selective clamping or selective portal clamping. The literature search was performed with restriction in languages of English or Chinese and types of randomized controlled trial or controlled clinical trial. The last search was done on November 2, 2010.

Inclusion and exclusion criteria

Type of studies: Only RCTs were considered for this review. Quasi-randomized studies, cohort studies, and case-control studies were excluded.

Type of participants: Patients who were about to undergo selective liver resection for benign or malignant liver tumor were included, irrespective of age, gender, cirrhosis, tumor size and nodule numbers. Trials in which patients required contralateral hepatic resection or had distant metastasis or synchronous malignancy in other organs were excluded in the study.

Types of interventions: We included trials comparing total hepatic inflow occlusion with hemihepatic vascular occlusion in hepatectomy, irrespective of ischemic preconditioning before vascular occlusion. Trials only comparing other types of vascular occlusion were excluded.

Type of outcome measures: Primary outcomes: Operative blood loss, biochemical markers of liver injury, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and transfusion requirement. Secondary outcomes: Peri-operative mortality, peri-operative morbidity, operating time , ischemic duration and hospital stay.

Selection of studies

Two authors identified and evaluated independently the trials for inclusion in form of abstracts or full text if necessary. Any disagreement in study selection and data extraction was resolved by discussion.

Data extraction

Two authors extracted the data on a standard form that included population characteristics (sex, age, percentage of major liver resections, methods of ischemic preconditioning and the presence of chronic liver disease) the co-interventions and information on the outcome measures in each trial.

Quality assessment

We assessed the methodological quality of the trials independently. The assessment was made based on sample size calculation; sequence generation; allocation concealment; whether blinding method was adopted for the participants of patients and those who performed the trial and evaluate the outcome; efficacy of randomization; deviations, withdrawals and dropouts; and definition of outcome parameters[11,12].

Statistical analysis

We pooled the synchronized extraction results as estimates of overall therapeutic effects in a meta-analysis using Review Manager Version 5.0 for Windows. The estimated effect measures were odds ratio (OR) for dichotomous data and weighted mean difference (WMD) for continuous data, both reported with 95% confidence intervals (CI). We checked all results for clinical and statistical heterogeneity. Clinical heterogeneity was evaluated based on the study populations and interventions, definition of outcome measures, concomitant treatment, and perioperative management. Heterogeneity was determined by Chi-squared test. P value of 0.10 was considered significant difference and I^2 values were used for the evaluation of statistical heterogeneity (I^2 of 50% or more indicating presence of heterogeneity)[13]. We used a fixed-effects model to synthesize

data when heterogeneity was absent, otherwise a random-effects model would be used. Data were presented as forest plot and funnel plot was used to assess publication bias.

RESULTS

We searched a total of 677 references published between 2002 and 2010. Four RCTs[14-17] including 338 patients met the predefined inclusion criteria (Figure 1). All the trials (Table 1) compared HHO (*n* = 171) with THO (*n* = 167). Three trials enrolled cirrhotic and non-cirrhotic patients[14,16,17] and one trial enrolled only cirrhotic patients[15]. In all trials, both major (> 2 segments) and minor (≤ 1 segments) hepatic resections were performed, but one trial exclusively included patients undergoing complex central liver resections. Tables 2-4 summarize the baseline characteristics and outcomes of the trials. The potential bias of included trials are shown in Table 5. Only one of the trials reported the blinding methods used and the generation of allocation sequence[16].

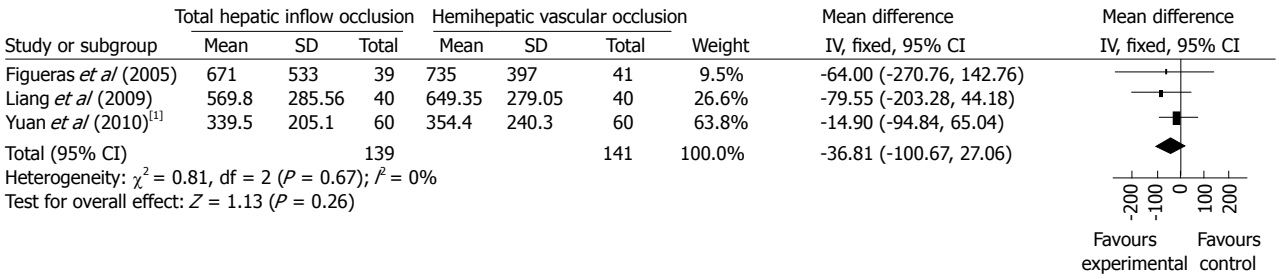

Figure 2 Meta-analysis of blood loss in randomized controlled trials comparing total hepatic inflow occlusion with hemihepatic vascular occlusion. [1]Blood loss.

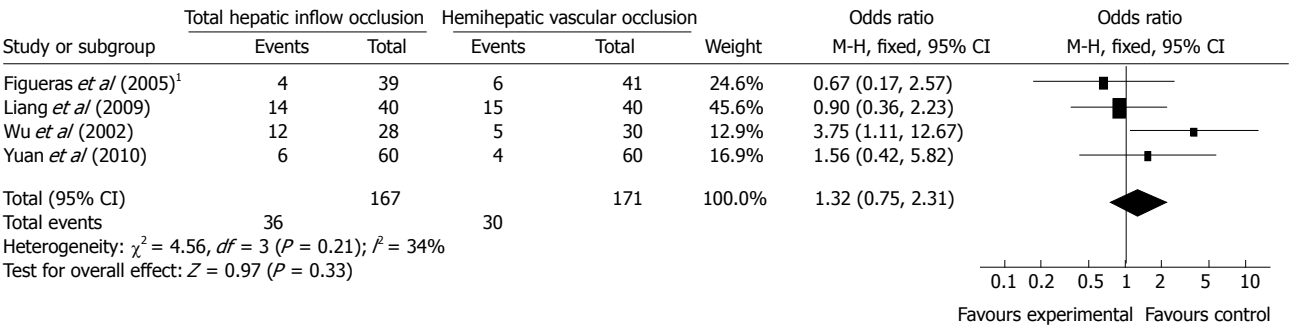

Figure 3 Meta-analysis of aspartate aminotransferase levels on postoperative 1st d. [1]Transfusion requirements (*n*).

available in all analyzed trials. The trial by Wu *et al*[15] reported significantly more blood loss in patients of both groups. Statistical heterogeneity was presented and $P = 0.000\,001$. Funnel plot to evaluate publication bias for outcome of blood loss demonstrated a strong asymmetry, suggesting the existence of severe publication bias. Clinical heterogeneity analysis found that complex central liver resections were performed on cirrhotic patients, and the cut surface area was wider and would increase intraoperative blood loss. Meta-analysis of the other three trials showed no significant difference between THO group and HHO group (WMD -36.81; 95% CI -100.67 to 27.06, $P = 0.26$, $I^2 = 0\%$) (Figure 2).

Transfusion requirement. All trials reported the number of patients who needed transfusion in both groups. Funnel plot did not demonstrate a strong asymmetry. Meta-analysis (Figure 3) indicated no difference in postoperative transfusion requirement between the groups (OR 1.32 95% CI 0.75-2.31, $P = 0.33$, $I^2 = 34\%$). Since there was no uniform definition of the average transfusion volume in the trials, we did not compare the transfusion volume in the study.

Biochemical markers of liver injury. All the four tri-

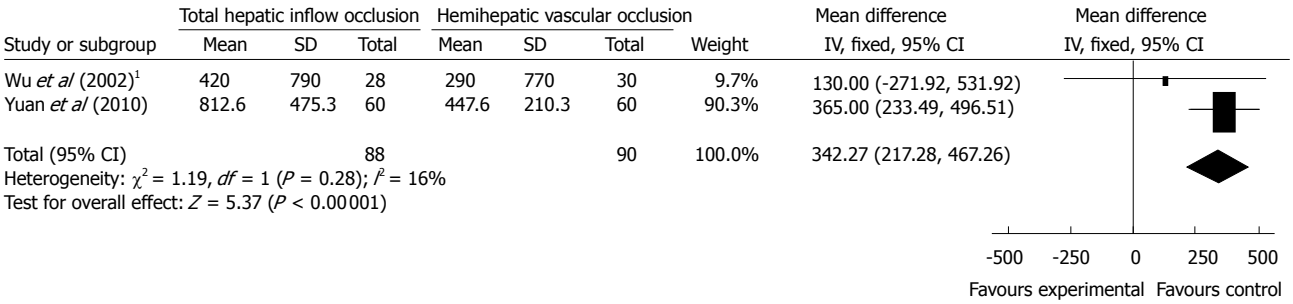

Figure 4 Meta-analysis of aspartate aminotransferase levels on postoperative Day 1. [1]Aspartate aminotransferase (D1).

als provided AST and ALT levels on postoperative days. However, data on AST and ALT were available in only two studies. We did not draw funnel plots to examine the potential publication bias in this review, because the number of the included trials was small. Wu *et al*[15] provided the data of ALT and AST levels on postoperative days 1, 3, 5 and 7, and Yuan *et al*[16] gave the information on postoperative days 1, 3 and 7. The ALT levels on postoperative day 1 in Figueras's study[14] were also available. Meta-analysis of ALT levels on postoperative days 1, 3 and 7 showed no significant difference between the two groups (WMD on day 1/191.03, 95% CI -239.04 to 621.10, $P = 0.38$, $I^2 = 94\%$; WMD on day 3/192.86, 95% CI -163.66 to 549.37, $P = 0.29$, $I^2 = 94\%$, and WMD on day 7/54.43, 95% CI -16.81 to 125.67, $P = 0.13$, $I^2 = 94\%$). Meta-analysis of AST levels on postoperative days 3 and 7 in the two studies showed no significant difference between THO group and HHO group (WMD on day 3/127.52, 95% CI -88.92 to 343.96, $P = 0.25$, $I^2 = 73\%$; WMD on day 7/49.10, 95% CI -9.1 to 107.3, $P = 0.10$, $I^2 = 94\%$). Meta-analysis of AST levels on postoperative day 1 indicated higher postoperative AST levels in the THO group (WMD 342.27; 95% CI 217.28 to 467.26; $P = 0.00001$, $I^2 = 16\%$) (Figure 4).

Peri-operative mortality and morbidity. Four studies provided data on peri-operative mortality and morbidity. In total, two patients died in the four trials. Both died from liver failure, one in THO group and the other in HHO group. Meta-analysis of these studies revealed neither of the two groups showed superiority in overall morbidity (OR 1.28, 95% CI 0.79-2.07, $P = 0.31$, $I^2 = 0\%$) and mortality (OR 1.03, 95% CI 0.14-7.44, $P = 0.98$, $I^2 = 0\%$). Meta-analysis of bile leak (OR 0.92, 95% CI 0.35 -2.44, $P = 0.87$, $I^2 = 0\%$) and hepatic insufficiency (OR 1.02, 95% CI 0.29 - 3.60, $P = 0.97$, $I^2 = 35\%$) showed no statistically significant difference.

Operating time, ischemic duration and hospital stay. There was no statistically significant difference in operating time (WMD -12.44, 95% CI -32.88 to 8.00, $P = 0.23$, $I^2 = 86\%$) between the two groups, also in hospital stay (WMD 0.63, 95% CI -1.60 to 2.85, $P = 0.58$, $I^2 = 91\%$) and in ischemic duration (WMD 0.61, 95% CI -1.40 to 2.61, $P = 0.55$, $I^2 = 43\%$)

DISCUSSION

The key points in hepatectomy are to control intraoperative bleeding and prevent postoperative complications such as liver failure and bile leakage[18]. Intraoperative blood loss has been shown to significantly influence the short-term prognosis of patients undergoing liver resection[19,20]. Hemihepatic vascular clamping selectively interrupts the arterial and venous inflow to the right or left hemiliver and therefore avoids both splanchnic blood stasis and ischemia or ischemia-reperfusion injury to the whole liver[9,21]. A retrospective study[22] indicated that the average bleeding volume and transfusion requirements were less in hemihepatic vascular occlusion group compared with Pringle maneuver group. But, other retrospective studies[8,23] showed no difference between the two groups. Our meta-analysis showed no significant difference in blood loss and transfusion requirements between the two groups. Three[14,16,17] of the four trials in the review showed no difference in the amount of hemorrhage and blood transfusion requirements, but one study[15] reported that the amount of operative blood loss and the incidence of blood transfusion were significantly higher in group THO patients (1685 mL *vs* 1159 mL, $P = 0.049$) and the volume of blood loss was much higher than in other studies. It could be explained by the fact that the patients in the study had cirrhosis and underwent complex central liver resections, while other trials included both cirrhotic and non-cirrhotic patients. The procedures presented herein were more difficult and time-consuming than conventional major hepatectomy and transected plane was also wider[15,24-26]. Both factors induced massive bleeding and difficulties in hemostasia.

Liver injury due to ischemia and subsequent reperfusion are major concerns in inflow vascular occlusion[27-29] and are usually monitored after surgery by measuring aminotransferase levels[30]. We found no significant difference on ALT levels on postoperative days 1, 3 and 7 in the two groups, also on AST levels on postoperative days 3 and 7. Three RCTs[14,15,17] and one retrospective study[18] drew the same conclusion. Theoretically, the blood flow in one lobe of the liver in group HHO is preserved and the liver function damage may be less than that in group THO[31].Yuan *et al*[16] indicated that the Pringle maneuver group was associated with a significantly higher peak in ALT and AST levels ($P = 0.01$). Meta-analysis showed that AST levels on postoperative day 1 were also higher in the THO group (WMD 342.27, 95% CI 217.28-467.26, $P = 0.00001$, $I^2 = 16\%$). Chau *et al*[23] concluded that patients subjected to HHO responded better than those subjected to the Prin-

gle maneuver in terms of earlier recovery of postoperative liver function. Therefore, HHO resulted in less liver injury and was advantageous in the recovery of postoperative liver function.

Unfortunately, only two trials in our analysis included data on ALT and AST levels. There were no significant differences in patients' general characteristics, resection margin, and ratio of cirrhotic to non-cirrhotic patients ($P = 0.05$). However, intermittent clamping was used in the trial by Wu *et al*[15], whereas Yuan *et al*[16] did continuous clamping if transaction time was ≤ 30min, otherwise intermittent clamping would be used. A RCT[32] comparing intermittent portal triad clamping with continuous clamping showed no statistically significant differences, although the peak AST level was lower in the intermittent portal triad clamping. Belghiti *et al*[33] suggested that in chronic patients, the transaminase levels were significantly higher in the continuous portal triad clamping than in the intermittent portal triad clamping. Cirrhotic liver and pre-existing liver were less able to tolerate ischemia than normal liver in clinical observations or animal experiments[28,34,35]. The proportion of chronic patients in the two RCTs were 100% and 61.7% respectively, which may influence the ALT and AST levels in HHO and THO groups and account for the lack of difference between the two groups on postoperative days 3 and 7. Due to the limited number and non-available data in the trials, no subgroup analysis was performed in patients with cirrhosis, which is known to increase the sensitivity of the livers to ischemia[30].

There was one death in Figueras' trials[14] in HHO group as a result of hepatic insufficiency in a patient with hepatitis C virus (HCV) cirrhosis . His blood loss during the operation was 2120 mL and 5 units of red blood cell transfusion were required. Yuan *et al*[16] reported one patient in the Pringle maneuver group who died of liver failure on the 26th d after a right hepatectomy. The total mortality was 0.51% and total peri-operative morbidity was 27.51%. But no statistically significant difference was found in the peri-operative mortality, peri-operative morbidity, operating time, ischemic duration and hospital stay. Complications included ascites, bile leak, hepatic insufficiency, portal thrombosis, pleural effusion, wound infection, hemorrhage and so on. Meta-analysis of bile leak and hepatic insufficiency showed no significant difference between THO group and HHO group.

This review has some limitations. First, our literature search might have not detected all relevant evidences and the number of RCTs included in this review is small. Second, incomplete reporting of important methodological issues, such as sample size calculation, randomization process and blinding assessment of trial quality, might raise doubts on the adequate power of these studies[36]. Third, the heterogeneity of the patients in the included trials may influence the conclusions as some trials included major and complex central liver resections and some included normal and cirrhotic livers.

In conclusion, the current evidence shows no advantage of hemihepatic vascular occlusion over the total hepatic inflow occlusion in terms of blood loss, transfusion requirement, mortality and morbidity, operating time and hospital stay. However, HHO results in less liver injury after liver resections. Further trials are required to assess optimal technique of hepatic vascular control for the patients hepatectomy especially for the patients with chronic cirrhosis.

COMMENTS

Background

Possibility of life-threatening hemorrhage always exists in patients with liver resection, so liver vascular control to reduce blood loss is important. Since the Pringle maneuver technique was successfully applied by Pringle in 1908, many methods of hepatic vascular control have been introduced to accelerate the development of hepatic surgery. Bismuth and Makuuchi proposed the hemihepatic vascular occlusion technique, which attracted much attention among surgeons.

Research frontiers

Both Pringle maneuver and hemihepatic vascular occlusion techniques can reduce blood loss during transaction of the hepatic parenchyma but Pringle maneuver produces ischemic injury to the remaining liver and intestinal congestion. Hemihepatic vascular occlusion technique has become very popular in recent years, because it is thought to limit visceral congestion and can protect the remaining liver. Many studies including randomized controlled trials (RCTs) have been designed to evaluate the safety, feasibility and efficiency of the two methods.

Innovations and breakthroughs

The authors searched and assessed all the RCTs comparing the two techniques and drew a conclusion by a systematic review and meta-analysis. They found that hemihepatic vascular occlusion did not offer benefit to the patients except for reducing ischemic liver injury after liver resections.

Applications

Hemihepatic vascular occlusion technique should be recommended for hepatectomy to reduce peri-operative blood loss and protect the remaining liver after the surgery.

Terminology

Hemihepatic vascular occlusion is a method which selectively interrupts the arterial and portal inflow to the part of the liver (right or left hemiliver) ipsilateral to the lesion that requires resection. It can be achieved after placing a curved renal pedicle clamp across the right or left portal structures. And Pringle maneuver involves compression of the hepatoduodenal ligament to interrupt all arterial and portal inflow to the whole liver.

Peer review

The manuscript is methodologically well designed and is concise in its data and conclusion. However, it should be subjected to linguistic revision to improve several mistakes in grammar and style.

Abstract

Alopecia areata is a disease of the hair follicles, with strong evidence supporting autoimmune etiology. Alopecia areata is frequently associated with immune-mediated diseases with skin manifestations such as psoriasis and lichen planus, or without skin manifestations such as autoimmune thyroiditis and idiopathic thrombocytopenic purpura. *Helicobacter pylori* (*H. pylori*) infection is present in around 50% of the world's population and has been associated with a variety of immune-mediated extra-digestive disorders including autoimmune thyroiditis, idiopathic thrombocytopenic purpura, and psoriasis. A case of a 43-year old man with an 8-mo history of alopecia areata of the scalp and beard is presented. The patient was being treated by a dermatologist and had psychiatric support, without any improvement. He had a history of dyspepsia and the urea breath test confirmed *H. pylori* infection. The patient went into remission from alopecia areata after *H. pylori* eradication. If such an association is confirmed by epidemiological studies designed for this purpose, new therapeutic options could be available for these patients, especially in areas where infection with *H. pylori* is highly prevalent.

INTRODUCTION

Alopecia areata is a disease of the hair follicles, with strong evidence supporting an autoimmune origin[1], although the exact pathogenesis of the disease is not clear. Alopecia areata has a frequency ranging from 0.7% to 3.8% in patients attending dermatology clinics, affects both sexes[2], and a familial occurrence is often reported[3,4]. The pattern of hair loss can vary and can affect any part of the body. Alopecia areata frequently occurs in association with other autoimmune diseases, including autoimmune thyroiditis[5], psoriasis[6-8] and Sjögren syndrome[9], among others.

Helicobacter pylori (*H. pylori*) is a microaerophilic Gram-negative bacterium that colonizes the gastric mucosa[10] and is present in around 50% of the world's population[11], with varying prevalence rates between 7% in the Czech Republic and 87% in a South African population[12]. In the case of Medellín, Colombia, prevalence of *H. pylori* infection in children under 12 years is 60.9%[13] and in adults, it is 77.2%[14]. *H. pylori* infection has been associated with the pathogenesis of gastric disorders such as gastritis, duodenal and gastric ulcers, gastric cancer, mucosa-associated lymphoid tissue lymphoma[10], and a variety of

extra-digestive disorders, many of them clearly identified as immune-mediated[15], such as idiopathic thrombocytopenic purpura[16,17], autoimmune thyroiditis[18,19], Sjögren's syndrome[20,21], rosacea[22] and psoriasis[23,24].

A case of a 43-year-old man with patchy alopecia areata and *H. pylori* infection is presented. The patient had hair regrowth after bacterial eradication.

CASE REPORT

A 43-year-old man presented with an 8-mo history of patchy hair loss in the scalp and beard (Figure 1A-C). He had consulted a dermatologist who prescribed 0.25% desoximetasone and 5% minoxidil, according to the guidelines for the management of alopecia[25], and had psychiatric support with escitalopram 5 mg/d, without any response other than progression of the condition.

The patient had a history of dyspepsia, therefore, he underwent analysis to determine *H. pylori* status. Urea breath test (^{13}C-UBT) (6.95 $\delta^{13}CO_2$; negative, < 1)[26], and *H. pylori* IgG antibodies (IgG index: 52.4; negative, < 9) were positive. Subsequent laboratory evaluation included normal values of ultrasensitive thyroid stimulating hormone, free thyroxine and free tri-iodothyronine; and negative antinuclear, antithyroid peroxidase and intrinsic factor antibodies. The patient was prescribed first line *H. pylori* eradication with proton pump inhibitor (omeprazole) 20 mg twice daily, amoxicillin 1000 mg twice daily, and clarithromycin 500 mg twice daily for 14 d, according to recommendations from the Maastricht Ⅲ Consensus Report[27], and was followed photographically every 2 wk. He was instructed not to take or apply any medications for alopecia areata. *H. pylori* eradication was confirmed 6 wk after treatment with a negative result of the ^{13}C-UBT (0.81 $\delta^{13}CO_2$).

Figure 1 shows the photographic sequence of the lesions before and after *H. pylori* eradication. From week 4, there was evidence of hair regrowth in the scalp and beard (Figure 1D-F). To date, the patient continues in complete remission from alopecia areata, as shown in Figure 1M-O.

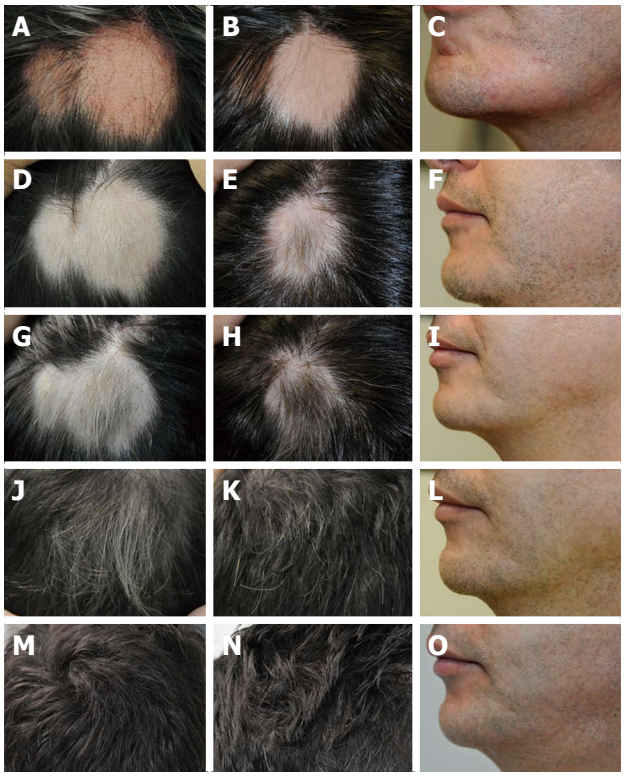

Figure 1 Photographic sequence of lesions before and after *Helicobacter pylori* eradication. A-C: Alopecia areata of the scalp (A and B) and beard (C) at baseline visit (week 0) before *Helicobacter pylori* (*H. pylori*) eradication. Positive ^{13}C-UBT (6.95 $\delta^{13}CO_2$); D-F: Evidence of hair regrowth at week 4; G-I: Hair regrowth at week 8. Negative ^{13}C-UBT (0.81 $\delta^{13}CO_2$); J-L: Hair regrowth at week 16; M-O: Hair regrowth at week 44. Negative ^{13}C-UBT (0.67 $\delta^{13}CO_2$).

DISCUSSION

H. pylori infection has been associated with numerous immune and non-immune disorders including dermatological conditions, such as chronic urticaria[28-30], rosacea[22,28,31-39], psoriasis[23,24], Schönlein-Henoch purpura[40-46], Behçet's disease[47,48], prurigo nodularis[49], chronic cutaneous pruritus[50], progressive systemic sclerosis[51-54], Sjögren's syndrome[20,21,55-57], and Sweet's syndrome[58]; many of them improving or going into remission after eradication of *H. pylori* infection[24,30,49,59-61]. Several mechanisms have been suggested to mediate the systemic effects of *H. pylori* infection, including the development of antigen-antibody complexes and cross-reactive antibodies (by molecular mimicry)[61-63], where antibodies developed against *H. pylori* cross-react with autoantigens to cause tissue damage, as has been reported in atrophic gastritis[62,64], chronic gastritis[65-67], chronic idiopathic thrombocytopenic purpura[16,17,68-70], Hashimoto's thyroiditis[19], atherosclerosis[71], arterial hypertension[72], unstable angina pectoris[73], ischemic heart disease[74,75], Alzheimer's disease[76], systemic sclerosis[77,78], central serous chorioretinopathy[79], iron deficiency[80,81], autoimmune pancreatitis[82-86], and chronic urticaria[87].

Alopecia areata has been described to be of autoimmune origin[88], with the presence of inflammatory cells around and within the human hair follicles. Alopecia areata has been associated with other autoimmune disorders including thyroid disease[89-93], psoriasis[6,7], and celiac disease[94-97]; conditions that have also been associated with *H. pylori* infection.

In the literature, there is ample evidence to suggest an association between *H. pylori* and alopecia areata that could explain the cure in this patient after eradication of infection. There is concurrent alopecia areata with immune diseases that are also concurrent with *H. pylori* infection. There are three different scenarios: immune-mediated skin diseases associated with *H. pylori* infection and alopecia areata, including psoriasis[6,7,23,24,98-103] and lichen planus[101,104-109]; immune-mediated non-skin conditions associated with *H. pylori* infection and alopecia areata, including autoimmune thyroiditis[18,19,110-115], celiac disease[94-97,116-118], idiopathic thrombocytopenic purpura[119,120], and autoimmune pancreatitis[82,84,85,121-124]; and laboratory findings that show the immunological nature of the conditions that are found in *H. pylori*-infected patients as well as in alopecia areata patients, including parietal cell antibodies[117,125-127] and thyroid antibodies[90,128].

After reviewing the medical literature, an association between *H. pylori* infection and alopecia areata has not been clearly demonstrated; only three reports have explored such association and had different results[129-131]. Abdel Hafez *et al*[131] have compared 31 patients with alopecia areata with 24 healthy controls and have found no significant difference in the *H. pylori* status, as determined by an antigen stool test. Rigopoulos *et al*[130] have compared *H. pylori* seroprevalence in 30 patients with alopecia areata and 30 healthy controls, and found no significant difference between the groups, whereas Tosti *et al*[129] have found, in a group of 68 patients with alopecia areata, that the seroprevalence of *H. pylori* infection was higher than in matched controls. It is of note that the presence of IgG antibodies against *H. pylori* does not confirm current infection and is only an indicator of previous exposure to the bacterium[132]. However, none of the studies tried to eradicate the infection and evaluate posterior hair regrowth.

Here, I have described the case of one patient who had patchy hair loss of the scalp and beard. The patient's condition started to improve within 4 wk of completing *H. pylori* eradication (Figure 1D-F). By week 16 (Figure 1J-L), the patient had completely reversed the hair loss, and by week 44 (Figure 1M-O), he remained *H. pylori*-negative and completely cured of alopecia areata. Although prior studies have only reported the prevalence of *H. pylori* infection in alopecia areata patients, to the best of my knowledge, this is the first documented case of reversed hair loss after *H. pylori* eradication.

There have been a few early studies in which antibiotic treatment was used in an attempt to cure alopecia areata, but in no case was there information on whether the patients were infected with *H. pylori*. Dapsone was used unsuccessfully[133,134]. There was one case of a 13-year-old girl with multiple autoimmune diseases who was successfully treated for alopecia areata with co-trimoxazole, a drug with antibiotic properties and immunomodulatory effects that could have been responsible for hair regrowth. Finally, there was one case in the literature describing the occurrence of alopecia areata after antibiotic treatment with rifampicin[135]. However, further case-control studies could be useful to rule out this possibility completely.

Hence, a common denominator in various autoimmune diseases is *H. pylori* infection; therefore, *H. pylori* status could be determined in several autoimmune conditions, and if positive, eradication treatment could follow as an initial step. More studies are needed to clarify the reality of the proposed association.

ACKNOWLEDGMENTS

The author gratefully acknowledges Ana Isabel Toro for the photographic assistance, her insightful discussions and help with the English translation, as well as the patient's willingness and collaboration.

Abstract

The development of hepatocellular carcinoma (HCC) is attributed to several factors, including chronic viral infection, alcohol consumption, exposure to aflatoxin B1 and metabolic disorders. Several recent reports have shown that HCC can occur in patients with long-standing Crohn's disease (CD) in the absence of other underlying high-risk liver diseases. There may be an association between CD and hepatocarcinogenesis, however, the precise mechanism for this requires further investigations.

Key words: Inflammatory bowel disease; Crohn's disease; Hepatocellular carcinoma; Intestinal flora; Azathioprine; Enterohepatic circulation

Peer reviewer: Heitor Rosa, Professor, Department of Gastroenterology and Hepatology, Federal University School of Medicine, Rua 126 n.21, Goiania - GO 74093-080, Brazil

TO THE EDITOR

We have read with great interest the article by Ishida *et al*[1], which was recently published in *World J Gastroenterology*, issue No. 25, 2010. The authors reported a case of hepatocellular carcinoma (HCC) that occurred in a patient with Crohn's disease (CD) in the absence of chronic hepatitis or liver cirrhosis. This suggested that Azathioprine treatment could be related to hepatocarcinogenesis in CD patients. Upon reading this interesting case report, we wondered whether the risk factor for the development of HCC in the setting of CD was CD itself or its treatment.

Azathioprine is currently the most common immunosuppressive drug for the treatment of inflammatory bowel disease (IBD), particularly for maintaining the remission of the patients with a complex clinical course. There is little doubt that, once this drug is indicated, its treatment should be continued for an extended period of time. Whether or not immunosuppressive therapy increases the risk of malignancy in IBD patients is controversial. Although the prolonged use of Azathioprine is considered theoretically to increase the occurrence of cancer, studies aimed at elucidating the risk of neoplasia in IBD patients treated with Azathioprine have concluded that Azathioprine does not substantially increase the risk of cancer development[2-4]. A global consensus about the association between immunosuppressants and malignancies has suggested a favorable risk/benefit ratio in the long-term use of Azathioprine[5].

Although the causes of IBD remain incompletely understood, the prevailing consensus is that the intestinal flora drives an unmitigated intestinal immune response and inflammation in the genetically susceptible host. CD is considered to be a systemic disorder that often involves multiple organs including the gastrointestinal tract. A meta-analysis[6] that assessed the relative risk of all types of cancers occurring outside the gastrointestinal tract found an increased risk in CD patients; and a potential correlation between long-standing CD and the development of HCC may therefore exist. A recent study[7]

revealed an intimate cross-talk between gut microbes, the lower bowel and liver in the evolution of HCC, and demonstrated that gut microbes could promote HCC. Several mechanisms could be involved. Firstly, bacteria may alter the colonic mucosal integrity and/or receptor activation, permitting the passive or facilitated the entry of harmful bacteria or their products into the circulation. Secondly, the microbial colonization of the bowel may invoke the release of numerous cytokines from the intestine and/or mesenteric lymph nodes that act upon the liver. Finally, intestinal bacteria may disrupt enterohepatic feedback loops, such as those associated with bile acid recirculation.

Recently, enterohepatic *Helicobacter* species, such as *H. hepaticus*, *H. bilis*, *Helicobacter sp. flexispira* and *H. cinaedi*, which belong to a rare phyla of luminal flora, have been identified in the lower intestinal and biliary tract of animals, and their overgrowth may cause chronic inflammatory bowel and liver diseases in rodents, poultry and primates. These bacteria have also been implicated in gastroenteritis, cholecystitis and certain liver diseases, including HCC in humans[8-11]. Several clinical observations have indicated that the modulation of the gut-liver axis using probiotics may play a therapeutic role, especially in the pathophysiological conditions where intestinal microflora may be involved as a cofactor of chronic liver damage.

In summary, it is possible that several factors related to CD may directly or indirectly affect the development of HCC in patients with CD. We consider that altered gut microbes would more likely disrupt enterohepatic homeostasis and promote the development of liver cancer than medication. A study of cumulative cases and further researches may unmask the intestinal bacteria that are associated with the increased risk of HCC in humans. Such microbes may represent attractive therapeutic targets.

ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

Guidelines: http://www.wjgnet.com/1007-9327/g_info_20100312232134.htm

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

It is widely believed that infection of pancreatic necrosis is a late event in the natural course of acute pancreatitis. This paper discusses the available data on the timing of pancreatic infection. It appears that infected pancreatic necrosis occurs early in almost a quarter of patients. This has practical implications for the type, timing and duration of preventive strategies used in these patients. There are also implications for the classification of severity in patients with acute pancreatitis. Given that the main determinants of severity are both local and systemic complications and that they can occur both early and late in the course of acute pancreatitis, the classification of severity should be based on their presence or absence rather than on when they occur. To do otherwise, and in particular overlook early infected pancreatic necrosis, may lead to a misclassification error and fallacies of clinical studies in patients with acute pancreatitis.

Key words: Acute pancreatitis; Classification; Enteral nutrition; Infected pancreatic necrosis; Pancreatic infection

INTRODUCTION

Mortality in patients with acute pancreatitis is determined by both local and systemic factors[1,2]. The local factor is infection of pancreatic and peripancreatic necrosis/collections. The systemic factor is organ dysfunction, especially when it persists and/or when multiple organ systems are involved. The timing of these local and systemic factors is thought to be important, and thus acute pancreatitis is generally regarded as having an early and late phase[3,4]. Infected pancreatic necrosis (IPN) is considered the cardinal feature of the late phase[5-7]. This view is, however, challenged by a body of evidence that demonstrates that IPN also occurs early in some patients with acute pancreatitis. The present editorial will examine the time course of IPN and consider the clinical implications of the timing of pancreatic infection.

EARLIER SURGICAL STUDIES

The incidence and significance of early IPN can be reliably examined as there are published series that include operations performed during the first and second week. In 1986, Beger and colleagues published a seminal prospective clinical study from Germany that evaluated the bacteriological status of pancreatic necrosis in relation to the timing of surgery for acute pancreatitis[8]. Overall, 39% (45/114) of the consecutive series of patients had a

IPN: Infected pancreatic necrosis.

positive bacteriological culture of the debrided necrosis. Although pancreatic infection was most often detected after the second week, it is pertinent to note that 11% and 29% of the patients developed IPN within the first 7 and 14 d after onset of acute pancreatitis, respectively (Table 1). Another study, from the Warshaw group, looked back at 44 patients with proven IPN and demonstrated a similar incidence of early IPN with 5% and 28% within the first 7 and 14 d, respectively[9].

FNA STUDIES

Further evidence regarding the timing of development of IPN comes from studies that evaluated the utility of fine-needle aspiration (FNA) for the diagnosis of pancreatic infection. The first rigorous study was reported in 1987 by Gerzof and colleagues who performed computed tomography (CT)-guided percutaneous FNA and Gram staining in 60 patients with suspected pancreatic infection[10]. Overall, 60% (36/60) had pancreatic infection confirmed, with 22% (8/36) within 7 d of the onset of acute pancreatitis and 56% (20/36) within 14 d (Table 1). Similarly, in a study from Germany (1988-1996) on the utility of ultrasound-guided FNA in 98 patients with CT-proven pancreatic necrosis, it was shown that the overall incidence of IPN was 34%. During the first week, 21% (7/33) of patients had a positive FNA, and this was confirmed by bacteriological culture of the debrided necrosis[11].

BIOMARKER STUDIES

Another potential source of evidence regarding the timing of IPN in acute pancreatitis comes from studies that evaluated different serological markers of infection, for instance procalcitonin[12,13]. These studies used FNA as the gold standard to diagnose IPN but they did not formally report on the timing of the onset of IPN. However, it is interesting to note that in some cases FNA yielded a positive result as early as day 2[14] and day 3[15].

MOST RECENT STUDIES

The timing of diagnosing of IPN has been specifically examined in two recent studies, both published in 2009. In a study from China (2000-2008) there were 336 patients with predicted severe acute pancreatitis and all received intravenous antibiotic prophylaxis for 14 d from admission[16]. Infected pancreatic necrosis was confirmed by FNA in 19% (66/336) of patients overall and 25% (16/66) of these patients had proven IPN within the first 14 d (Table 1). In a study from the Netherlands (2004-2007) there were 154 patients with pancreatic necrosis and all received enteral nutrition (EN)[17]. Infected pancreatic necrosis was confirmed in 64% (98/154) of patients overall. In 5% (5/98) of these patients, IPN was proven within the first 7 d and in 18% (18/98) within the first 14 d (Table 1). These modern studies are in accordance with earlier studies, which showed that IPN occurs early in a notable proportion of patients. Furthermore, the two most recent studies may have underestimated the incidence of early IPN for three reasons. The first is that they were carried out in an era when there was a waning enthusiasm for the liberal use of FNA[18-20] and it is probable that some patients with early IPN were overlooked. The second is that there is a reported false negative rate for FNA of up to 10%[9,11]. The third reason is that the use of antibiotics and EN in the two studies may have prevented or postponed the clinical manifestation of IPN beyond the first two weeks after onset[21-23].

TRENDS IN THE INCIDENCE OF PANCREATIC INFECTION

Comparison of earlier studies with more recent studies reveals an apparent reduction in the incidence of early IPN from 29% in the 1980s[8] to 18% in the 2000s[17], but not in the overall incidence of IPN during the same time period. The explanation for this reduction is a matter of speculation, but it is worth noting that both studies[8,17] included patients with pancreatic necrosis and all patients had intra-operative confirmation of IPN. What was different between the two studies is the employed management strategies: "nil-by-mouth" and early surgery in the 1980s[8] in contrast to EN and late surgery in the 2000s[17]. The observation that there is a reduction in the early incidence, but not overall incidence, of IPN raises the questions as to whether standard EN is only able to prevent early IPN, whether it is delivered for long enough to prevent late IPN, and which criteria ought

Table 2 The new classification of severity of acute pancreatitis (Modified from[2])

Severity category	Local determinants		Systemic determinants
Mild	No (peri)pancreatic necrosis	and	No organ failure
Moderate[1]	Sterile (peri)pancreatic necrosis	or	Transient organ failure
Severe[1]	Infected (peri)pancreatic necrosis	or	Persistent organ failure
Critical	Infected (peri)pancreatic necrosis	and	Persistent organ failure

[1]Severity is graded on the basis of more severe local or systemic determinants (e.g. sterile pancreatic necrosis without organ failure has to be graded as moderate; sterile pancreatic necrosis with persistent organ failure has to be graded as severe).

to be used to stop EN. If standard EN cannot prevent late IPN then it is important to evaluate more advanced enteral formulations, including those supplemented with glutamine, antioxidants, and/or other targeted treatments[24-27].

CONCLUSION

With the main focus on the diagnosis and treatment of late IPN it appears that early IPN may have been overlooked. There are two important practical clinical implications that derive from giving due recognition to the importance of early IPN. The first is that more effective prophylactic strategies are required, as it would appear that the overall incidence of IPN has not decreased, and may even be increasing. The cornerstone of this prophylactic strategy must be EN[22,23,26], but there remain questions about when to start, what to give and when to stop. The second implication relates to the importance of IPN in determining the severity of acute pancreatitis and how this might be reflected in any classification of severity. More specifically, the severity of acute pancreatitis relates to the presence or absence of IPN rather than whether it occurs early or late in the disease course. The timing of IPN varies widely between patients and, as discussed above, occurs during the first two weeks after onset of acute pancreatitis in almost a quarter of patients. The recently proposed classification of the severity of acute pancreatitis (Table 2) takes this into account as it is based on the presence or absence of local and systemic complications[2]. It also recognizes the dynamic nature of these complications allowing for the transition from sterile to infected pancreatic and peripancreatic necrosis, and transient to persistent organ dysfunction. Furthermore, the new classification of severity takes into account the interaction between the local and systemic determinants as it has been shown that mortality rate is significantly worse in patients with both IPN and organ failure, than either alone[1]. This new severity classification system is based on actual determinants of severity and will prove useful to practicing clinicians managing individual patients through the early and late phases of acute pancreatitis and will provide a more reliable way of selecting and matching groups of patients for clinical trials, including those seeking to prevent or treat IPN in patients with acute pancreatitis.

FROM THE EDITOR

Inflammatory bowel diseases (IBD) are chronic disorders of the intestine with increasing incidence in Europe, Northern America and Asiatic countries such as china. Thus, we have putted together these topic highlight articles to give insights into the current understanding of IBD pathogenesis, diagnostics and treatment. The articles[1-6] aim at informing both expert gastroenterologists and physicians who are not very familiar with IBD. We are focusing mainly on topics that have undergone basic changes within the last decade. In view of diagnostic, modern high resolution ultrasound has become an important instrument for clinical monitoring of disease activity in some countries. Detection of intraepithelial neoplasia (IEN) and the therapeutic algorithm of IEN management in ulcerative colitis have undergone changes. Furthermore, the change of paradigm in Crohn`s disease surgery towards a very cautious extent of bowel resection combined with minimal invasive (endoscopic) surgery has ameliorated the outcome. In this context, some new data about the postoperative recurrence of Crohn's disease and its management are pointed out. Even in this field, prognostic parameters and data about the adequate therapeutic option in the case of recurrence are lacking. Thus, we give overview concerning the main issues in surgery and disease recurrence as well as current treatment options. To get insights into IBD pathogenesis, we inform about the mucosal interface and the immune system also highlighting the link between inflammation and carcinogenesis.

Abstract

Inflammatory bowel diseases are the consequence of a dysregulated mucosal immune system. The mucosal immune system consists of two arms, innate and adaptive immunity, that have been studied separately for a long time. Functional studies from *in vivo* models of intestinal inflammation as well as results from genome-wide association studies strongly suggest a cross-regulation of both arms. The present review will illustrate this interaction by selecting examples from innate immunity and adaptive immunity, and their direct impact on each other. Broadening our view by focusing on the cross-regulated areas of the mucosal immune system will not only facilitate our understanding of disease, but furthermore will allow identification of future therapeutic targets.

Key words: Inflammatory bowel diseases; Immune system

INTRODUCTION

The pathogenesis of inflammatory bowel diseases (IBD) has not been completely resolved. However, the general hypothesis that in genetically predisposed people the exposure to distinct environmental factors results in a dysregulation of the mucosal immune system is still valid. Before genetics started to dominate the field, immunology identified various factors as critical in initiating intestinal inflammation. These studies included the functional characterization of T cell subpopulations and the relevance of the specific cytokines released. While the effector T cell response reflects one arm of the immune system, genetic work as well as studies on barrier function shed light on the second arm of the immune system. These two forms of immunity can be described as: (1) a more simplistic innate form, recognizing evolutionary conserved bacterial and viral patterns, resulting in a rapid but limited response; and (2) the adaptive form develops a highly specific immune response, that requires more time to evolve but provides immunological memory.

Each component plays a key role in the pathogenesis of IBD. Thus research in the field could be divided into groups focusing on the adaptive immune system, while other groups revealed innate factors at the site of epithelial cells or within the lamina propria which play a critical role. Cross-regulation of the innate and adaptive immune system was widely ignored.

Genome-wide association studies (GWAS) shed new light into the understanding of the pathogenesis[1,2].

The results obtained from GWAS not only confirmed the relevance of earlier characterized pathways, but also opened novel avenues and, in particular, provided strong evidence for a close link between the innate and the adaptive immune system in regulating the sensitive balance of the mucosal immune system.

Probably even more remarkable is the fact that GWAS have identified a large number of major loci, with many associations shared between various autoimmune diseases. These associations highlight key roles for lymphocyte activation, and prioritize specific cytokine pathways and mechanisms of host-microbe recognition[3]. Thus the close link and cross-regulation between the innate and adaptive immune system plays a critical role not only in IBD, but also in other autoimmune diseases. Interestingly, similarities of association patterns between various autoimmune diseases are particularly intriguing. Thus the question occurs as to which cells belong to the innate and which to the adaptive immune system.

In the intestine, innate immunity includes the epithelial barrier and phagocytic cells within the lamina propria (e.g. macrophages, dendritic cells, and neutrophils). Notably, patients exhibiting genetic defects in innate immunity (e.g. chronic granulomatous disease, Hermansky Pudlak syndrome) have an increase incidence of IBD[4,5]. This correlation has led to the development of agents used to boost innate immunity (e.g. granulocyte macrophage colony-stimulating factor) as therapeutic agents in IBD[6].

T lymphocytes represent the key cell population of the adaptive immunity arm. T cells become activated, secrete cytokines and affect all other cell types within a local environment (macrophages, dendritic cells, neutrophils, epithelium, endothelial cells, stromal elements). Both human and murine studies have led to the recognition that different T cell subpopulations are aberrantly activated in Crohn's disease (CD) *versus* ulcerative colitis (UC)[7,8]. T helper cell type 1 (Th1)-mediated immune responses are typically evoked in response to an intracellular pathogen presented by an antigen-presenting cell in the presence of interleukin (IL)-12. The coordinated immune response is elicited to localize the infectious agent and to secrete factors that either promote apoptosis [e.g. interferon (IFN)-γ, tumor necrosis factor-α] or induce the differentiation of cytotoxic T lymphocytes. The hallmark of a Th1 response is granuloma[9]. Recently, an additional Th subset has been described, the so-called Th17 cells[10]. These cells produce IL-17 and IL-22, both of which are pro-inflammatory cytokines capable of promoting local tissue destruction. Th17 cells are activated by the combination of IL-6 and transforming growth factor (TGF)-β and are induced to further differentiate to mature IL-17-secreting cells by IL-23[11]. IL-23 belongs to the IL-12 family and shares the p40 subunit with IL-12. IL-17 as well as IL-22 are found at increased levels in inflamed CD mucosa suggesting that these cytokines play a role in disease pathogenesis[12,13]. Functional data from mice and men are in support of this hypothesis as described in more detail below. An additional Th subset consists of Th2 cells. These secrete IL-4, IL-5, and IL-13[14]. Th2 cells promote atopy with induction of IgE responses, and eosinophil and mast cell activation. UC was thought to represent a Th2-driven disease, but the absence of IL-4 in colonic tissue from UC patients and the observation that both IL-13 and IFN-γ are found at elevated levels in UC mucosa changed this dogma[15]. Recent data suggest that IL-13 originates from a natural killer T cell, and targets the epithelial cell to become dysfunctional[7,16]. Consequently, UC may be more of a superficial epithelial injury disorder.

Last, there are regulatory T cell subpopulations. This is of particular importance since the immunological defense of the intestine, in contrast to the systemic immune system, is one of suppression. Healthy individuals generally do not develop systemic immune responses against commensal flora or dietary antigens. Regulatory cells are responsible for the immunologically suppressed milieu in the intestinal mucosa. One group of regulatory cells contributing to this milieu are regulatory T cells[17,18]. Various subsets have been described as being involved in suppressing mucosal responses, but the detailed description is beyond the scope of this review. Tr1 secrete IL-10[19], a potent anti-inflammatory cytokine. The impact in intestinal inflammation is underlined by the fact that IL-10-deficient mice develop spontaneous intestinal inflammation[20]. Th3 cells produce TGF-β, another potent immunosuppressant cytokine that promotes IgA production while suppressing T and B cell activation[21]. In addition, there are $CD4^+$ $CD25^+$ Treg requiring the transcription factor FoxP3[17,18]. Remarkably, the absence of FoxP3 in humans (IPEX syndrome)[22,23] and mouse (Scurfy) is followed by an autoimmune endocrine disease, immunodeficiency, and an enteropathy mainly affecting the small bowel.

Although there are specific T cell subpopulations, exclusive activation of a single T cell subpopulation during the course of an immune response is impossible. There is additional experimental evidence suggesting that the classification of T cell subpopulations on the basis of cytokine secretion profiles are helpful but not absolute. It seems to be more important to underscore that a dysregulated immune response of any type is poorly tolerated by the gastrointestinal tracts and thus results in intestinal inflammation.

Under which conditions does dysregulation of innate and adaptive immunity occur? Luminal antigens cross the epithelial barrier, and this process is significantly increased during intestinal inflammation. The role of epithelial and Paneth cells within the first line of defense is discussed within this issue by others. The antigens reaching the lamina propria will first activate the innate immune system via pattern recognition receptors and second, be presented by professional antigen-presenting cells resulting in an effector T cell response as described above.

The present review will serve to illustrate the cross-regulation of the innate and adaptive immune system within this process and the impact on the pathogenesis of IBD. The cross-regulation will be described by selecting two examples. First, NOD2 a pattern recognition receptor, thus belonging primarily to the innate immune system. However, we will demonstrate that NOD2 ex-

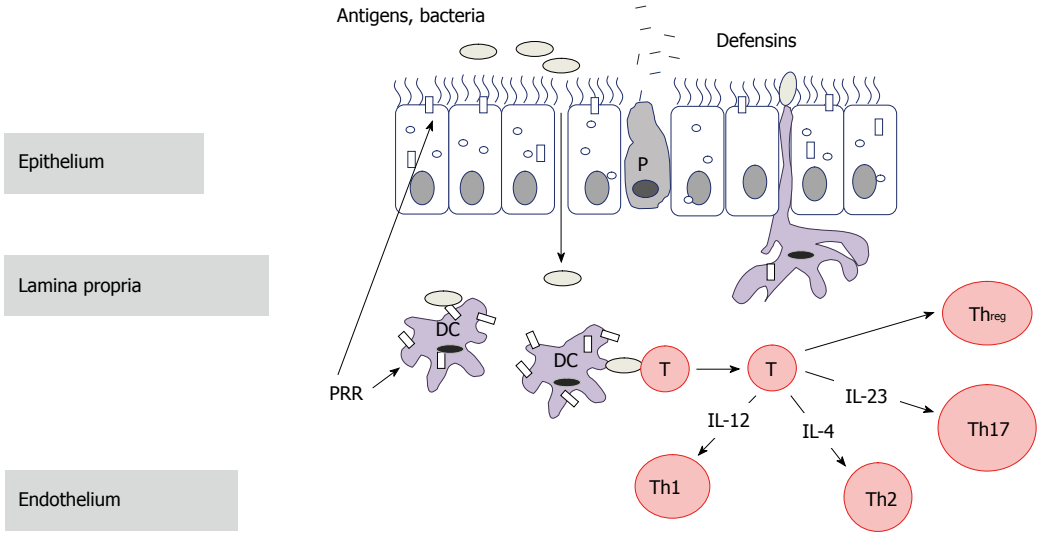

Figure 1 Cell populations primarily belonging to the innate immune system are marked blue, and cells primarily categorized as cells of the adaptive immune system are marked red. Purple marked cells identify the cross-link between both systems. IL: Interleukin.

erts a direct impact on the regulation of the adaptive immune system. This cross-regulation leads to the second example that is directly linked to NOD2, namely the IL-12 family (for illustration see Figure 1).

NOD2

NOD2 (also designated *CARD15*) was identified by fine mapping of the IBD1 locus by positional cloning and candidate gene analysis as the first gene to be firmly associated with CD susceptibility in North American and European populations[24-26]. Three main variants, *R702W*, *G908R*, and *1007fs*, exhibit the strongest CD association[27]. All three variants alter the C-terminal third of the gene product, and are within or close to a region of leucin-rich repeats thought to be involved in ligand recognition. Individuals with one of the three major disease-associated alleles have a 2-4-fold increased risk of developing CD, whereas homozygous or compound heterozygous carriers have a 15-40-fold increase in risk[28]. NOD2 is a cytoplasmic protein that serves as a microbial sensor for muramyl dipeptide (MDP), a peptidoglycan motif present in the cell wall of Gram-positive and Gram-negative bacteria[29,30]. There are currently three mechanistic explanations for the apparent inflammation-promoting functions of the variant NOD2 proteins in the literature. These hypotheses are not mutually exclusive and may remain valid in combination.

Transfection of wild-type, but not mutant *NOD2* into intestinal epithelial cells inhibited uptake or growth of invasive bacteria[31]. Accordingly, mice lacking *NOD2* showed a defect in intestinal innate defence against oral infection with *L. monocytogenes*, which was accompanied by diminished expression of at least two Paneth cell-derived antimicrobial peptides, Defcr4 and Decfcr-rs10[32]. CD patients with mutant *NOD2* were shown to have decreased expression of the human Paneth cell α-defensins HD-5 and HD-6 in the small intestine[33], suggesting that CD-associated *NOD2* mutations may be functionally equivalent to the loss of the protein in knockout mice. This model would initially restrict the function of NOD2 to the innate system, however when considering that a decrease in antimicrobial peptides results in an increase of bacterial translocation and thus activation of the adaptive immune system, the link becomes apparent.

Incubation of normal murine splenic macrophages with MDP resulted in suppression of IL-12p40 and IL-12p70 secretion induced by stimulation with Toll-like receptor (TLR) 2 ligands, such as peptidoglycan[34]. This suppression did not occur in cells lacking *NOD2*, or in cells expressing a mutant form of *NOD2* after transfection. A similar mechanism appeared to act *in vivo*, as systemic administration of peptidoglycan to *NOD2*$^{-/-}$ mice induced more serum IL-12p40 and IL-12p70 compared to wild-type mice. The IL-12-enhancing effects occurred only *via* TLR2, but not other TLRs[34]. Thus TLR2 would be expected to be uniquely capable of promoting colonic inflammation under conditions of NOD2 deficiency. In this model NOD2 is activated as an innate receptor, however the effector response directly activates the adaptive immune system. This is further underlined by the findings described below for the IL-12 family.

Macrophages of mice homozygous for a mutant *NOD2* allele (*NOD*^{2939iC}) equivalent to the most common CD-associated allele (*3020insC*) were shown to secrete higher levels of the mature form of IL-1β and have elevated IL-1β mRNA levels, as well as increased IkB kinase and nuclear factor-κB activities, upon stimulation with MDP relative to wild-type macrophages but retain normal responses to TLR ligands[35]. Simultaneously, these mice exhibited greater colonic inflammation upon experimental challenge with dextran sulfate sodium, a phenotype that was attenuated by treatment with an IL-1 receptor antagonist[35]. These data suggest that the variant NOD2 protein expressed in these mice promotes processing of proIL-1β to mature, biologically active, IL-1β. Consistent with a

role of IL-1β in regulating colitis, mice deficient in IL-1β converting enzyme have reduced inflammation in an experimental colitis model[36].

IL-12 FAMILY

A key role for the IL-12 family in the pathogenesis of IBD was initially suggested over a decade ago. In this study neutralizing antibodies targeting "IL-12" resulted in an amelioration of TNBS-induced colitis in mice[37]. In 2004, anti-IL-12 treatment showed efficacy in patients with CD, although the primary endpoint of this study was safety and not clinical efficacy[38]. In a more recent study investigating an anti-IL-12 antibody in patients with CD, the primary endpoint, namely the clinical response at week 8 was not achieved[39]. At this time, since IL-12 is the key Th1 cytokine, CD was classified as a Th1-mediated disease. These findings additionally supported the concept that CD is driven by the acquired immune system. In 2006, another member of the IL-12 family, namely IL-23, came into the focus in IBD. GWAS revealed a highly significant association between CD and the *IL-23R* gene on chromosome 1p31, which encodes a subunit of the IL-23 receptor. An uncommon coding variant confers strong protection against CD[40,41].

IL-12 and IL-23 share the subunit p40 that builds a heterodimer with p35, in the case of IL-12, and with the subunit p19, in the case of IL-23. IL-23 caused some confusion in the field, since the antibody administered in the clinical study published in 2004 targeted the IL-12 subunit p40, thus it suddenly became unclear whether the beneficial effect observed had been mediated by neutralizing IL-12 or IL-23. Several animal studies added valuable information to this controversy. In a model of CD40-induced colitis, neutralizing either the subunit p40 or the subunit p19 was followed by a significant reduction of the macroscopic and histologic inflammation score, indicating that in this model, IL-23 represents a critical pro-inflammatory mediator[42]. However, from this data one could not draw a conclusion on the relevance of IL-12. This question been answered in the following by applying the transfer model of colitis. In this model the disease-inducing population of naïve T cells isolated from wild-type mice is transferred to immunodeficient *Rag*$^{-/-}$ mice. Transfer of naïve T cells in either *p40*$^{-/-}$ or *p19*$^{-/-}$ *Rag*$^{-/-}$ mice failed to induce colitis, while no difference between the transfer of naïve T cells into *Rag*$^{-/-}$ versus *Rag*$^{-/-}$ *p35*$^{-/-}$ mice was observed. Consequently, at least in this model, IL-23 but not IL-12 represents the key pro-inflammatory cytokine[43]. However, selective neutralization of IL-23 may not always be beneficial. *p19*$^{-/-}$ mice are highly susceptible to T cell-mediated colitis induced by hapten. In the absence of IL-23, gut dendritic cells produced excessive amounts of IL-12 as a result of the missing regulatory effect of IL-23[44]. Thus, in the absence of IL-23, mice developed enhanced IL-12-driven mucosal immunopathology; whether such cross-regulation is relevant in patients with IBD remains to be determined.

The IL-12 family is closely linked to the innate immune system. IL-12 and IL-23 within the lamina propria are predominantly produced by macrophages and dendritic cells. Both cell populations can be activated via innate receptors on one hand and via the development of an adaptive immune response on the other hand. NOD2 is probably the best example for this central function. As described above, a mutation in *NOD2* is followed by an increase in IL-12p70[34], thus directly linking a receptor of the innate immune system with the effector cascade of the adaptive immune system.

PERSPECTIVE

The aim of this review was to illustrate the tight cross-regulation between the innate and the adaptive immune system. The study of either system alone will be complemented by focusing on pathways directly linking both systems. This is not only of interest for the understanding of disease pathogenesis but also may have an impact on future therapeutic directions.

Abstract

The risk of developing neoplasia leading to colorectal cancer is significantly increased in ulcerative colitis (UC) and most likely in Crohn's disease. Several endoscopic surveillance strategies have been implemented to identify these lesions. The main issue is that colitis-associated neoplasms often occurs in flat mucosa, often being detected on taking random biopsies rather than by identification of these lesions *via* endoscopic imaging. The standard diagnostic procedure in long lasting UC is to take four biopsies every 10 cm. Image enhancement methods, such as chromoendoscopy and virtual histology using endomicroscopy, have greatly improved neoplasia detection rates and may contribute to reduced random biopsies by taking targeted "smart" biopsies. Chromoendoscopy may effectively be performed by experienced endoscopists for routine screening of UC patients. By contrast, endomicroscopy is often only available in selected specialized endoscopic centers. Importantly, advanced endoscopic imaging has the potential to increase the detection rate of neoplasia whereas the interplay between endoscopic experience and interpretation of histological biopsy evaluation allows the physician to make a proper diagnosis and to find the appropriate therapeutic approach. Colitis-associated intraepithelial neoplasms may occur in flat mucosa of endoscopically normal appearance or may arise as dysplasia-associated lesion or mass (DALM), which may be indistinguishable from sporadic adenomas in healthy or non-colitis mucosa [adenoma-like mass (ALM)]. The aim of this review was to summarize endoscopic and histological characteristics of DALM and ALM in the context of therapeutic procedures.

INTRODUCTION

Inflammatory bowel disease (IBD) encompasses two major forms of chronic intestinal disorders, Crohn's disease and ulcerative colitis (UC). Evidence suggests that IBD results from an inappropriate inflammatory response to intestinal microbes in a genetically susceptible host environment[1]. Increased production of proinflammatory cytokines and increased resistance to apoptosis finally lead to an uncontrolled chronic activation of the mucosal immune system[2]. Previously, it was shown that proinflammatory cytokines, such as Interleukin-6 produced by lamina propria mononuclear cells, directly contribute to tumor growth and to cancer development in UC[3,4]. Although the association between IBD and colorectal cancer (CRC) is well-established, there are still concerns regarding adequate diagnosis and treatment of early preneoplastic and neoplastic lesions.

The overall prevalence of CRC in UC patients was recently analyzed in a large meta-analysis and estimated to be 3.7%[5]. In this context, the duration and anatomical extent are well-established risk factors for cancer development. Patients with a course of disease longer than 10 years and with pancolitis are at the highest risk. Additionally, patients with left-sided UC or those with more proximal disease are considered to be at high risk for cancer development[6]. Therefore, surveillance colonoscopy is considered to be the gold standard in diagnosing intraepithelial neoplasia (formerly termed dysplasia) and cancer in IBD patients. Nevertheless, to date, no randomized controlled studies have shown a reduced risk of CRC development by surveillance colonoscopy in IBD patients.

The main aim of surveillance programs in IBD is to detect early dysplastic alterations. Dysplastic alterations of the intestinal mucosa in IBD patients may occur in flat or raised mucosal lesions, and are differentiated by the terms dysplasia-associated lesion or mass (DALM, Figure 1) and adenoma-like mass (ALM, Figure 2)[6-8].

The differential diagnosis between colitis associated intraepithelial neoplasms and sporadic adenoma in patients with UC may be difficult, especially if only biopsy specimens are obtained[9,10]. Even carcinomas are difficult to diagnose because of their commonly well-differentiated morphology, and accurate diagnosis may only be possible in a resection specimen showing unequivocal invasion into the submucosal layer. Thus, in approximately 40% of cases with high-grade intraepithelial neoplasia on biopsy, diagnosis of the corresponding resection specimen shows invasive adenocarcinoma[11-13]. In low-grade intraepithelial neoplasia, the prevalence of carcinoma in the resection specimen has historically been believed to be up to 19%[14]. More recent data, however, indicate a significantly lower prevalence, indicating that a diagnosis of low-grade intraepithelial neoplasia does not justify prophylactic colectomy and local endoscopic treatment should not be ruled out[15].

ENDOSCOPIC DIAGNOSIS

Often the macroscopic endoscopic appearance of a lesion does not render the crucial clue to differential diagnosis, because colitis associated neoplasms may show subtle macroscopic features mimicking a broad range of lesions, ranging from inflammatory appearance to suspicion of carcinoma. Data from the literature indicate that in 50%-80% of cases with colitis-associated neoplasms, the lesions are not visible upon endoscopy[11].

Adenomas are mainly sharply delineated, with or without a stalk, and often show a smooth surface with Kudo surface pit pattern ⅢS (small roundish or tubular pits), ⅢL (large roundish or tubular pits), or Ⅳ (branch-like or gyrus-like pits)[16,17]. The gross appearance of colitis-associated neoplasms varies from case to case. These lesions can be endoscopically invisible or may be encountered as irregularly delineated, plaque-like, or irregularly elevated, lesions or verrucous structures. Some cases even show a combination of different types (Figures 1 and 2).

Previously, it was reported that to exclude dysplasia in colonic mucosal biopsies, at least 56 or 33 non-targeted jumbo-forceps biopsies have to be taken (95% and 90% confidence, respectively)[6]. In 2005, an international consensus conference agreed that a minimum of 32 biopsies should be performed at each surveillance colonoscopy by obtaining four-quadrant biopsies every 10 cm. In addition, separate jars should be used for each quartet and suspicious lesions[18].

To avoid sampling error in IBD-cancer surveillance, new endoscopic imaging techniques were introduced, including chromoendoscopy, magnification endoscopy, and confocal laser endomicroscopy (Table 1, Figures 3-6)[19].

In 2003, Kiesslich and colleagues conducted the first study of chromoendoscopy in IBD patients[20]. One hundred and sixty-five patients with long standing UC were randomized in a 1:1 ratio to undergo conventional colonoscopy or colonoscopy with chromoendoscopy using 0.1% methylene blue. In the chromoendoscopy group, significantly more intraepithelial neoplasms were detected compared to the conventional colonoscopy group (32 *vs* 10, $P = 0.003$). Another "back-to-back" colonoscopy study included 100 patients with longstanding UC[21]. Patients received both random and directed biopsies, followed by spraying of the entire mucosa with 0.1% indigo carmine, and subsequent biopsy of any additional visible abnormality. There was a strong trend towards statistically increased dysplasia detection following dye spraying (7/100 patients *vs* 2/100 patients, $P = 0.06$). The targeted biopsy protocol detected dysplasia in significantly more patients than the non-targeted protocol (7/100 patients *vs* 0/100 patients, $P = 0.02$). Additionally, the targeted biopsy protocol with pancolonic chromoendoscopy required fewer biopsies than taking multiple non-targeted biopsies (157 biopsies *vs* 2904 biopsies).

However, dye-based chromoendoscopy has some potential limitations, as it harbors additional costs for the equipment needed for dye spraying and is a time consuming procedure. Additionally, the dye often does not coat the entire surface and it does not allow for a detailed analysis of subepithelial capillary network, which is an

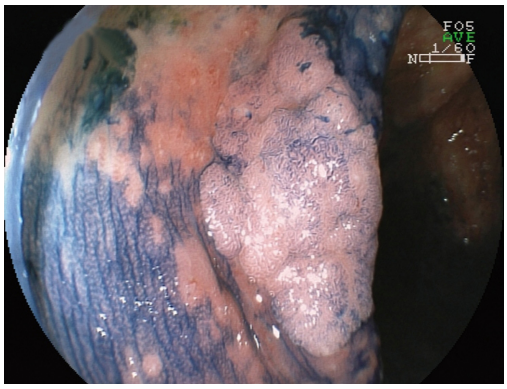

Figure 1 Visualization of a dysplasia-associated lesion or mass after topical application of indigo carmine. Surface analysis revealed a Kudo pit pattern 3L.

important feature in the early diagnosis of gastrointestinal neoplasia (Figure 4).

Therefore, dye-less chromoendoscopy (also called virtual chromoendoscopy) has been developed, including narrow band imaging (NBI; Olympus, Tokyo, Japan), Fujinon intelligent color enhancement (FICE; Fujinon, Tokyo, Japan), and i-Scan (Pentax, Tokyo, Japan). NBI

Figure 4 Chromoendoscopy with indigo carmine allows distinct surface analysis and demarcation of subtle lesions in long standing ulcerative colitis.

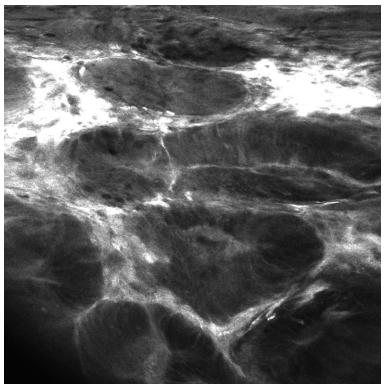

Figure 5 Fluorescein-guided confocal laser endomicroscopy (iCLE, Pentax, Tokyo, Japan) of dysplasia-associated lesion or mass. Endomicroscopy visualizes tubular architecture and enlarged cells with depletion of goblet cells. The shape and size of the crypts is irregular, and leakage, demonstrated by the extravasation of fluorescein, is visible.

is based on optical filters within the light source of the endoscope, which narrow the bandwidth of spectral transmittance such that the blood vessels are enhanced and are thus seen more easily. FICE and i-Scan use an endoscopic image from the video processor and reconstruct virtual images in real time, resulting in an improved contrast of the capillary patterns and enhancement of the mucosal surface[19,22].

The first pilot study on NBI in patients with UC included 46 patients. Suspicious lesions were observed by magnifying NBI-colonoscopy and were subsequently classified based on their surface appearance into honeycomb-like, villous, or tortuous patterns. The tortuous pattern determined by NBI-colonoscopy may be a clue for the identification of dysplasia during surveillance for UC[23].

One recently published study assessed the value of endoscopic tri-modal imaging, incorporating white light endoscopy (WLE), autofluorescence imaging (AFI), and NBI for the detection and classification of neoplasia in 50 patients with longstanding UC[24]. Neoplasia miss-rates for AFI and WLE were 0% and 50%, respectively (P = 0.036). The Kudo classification by NBI had a sensitivity and specificity of 75% and 81%, respectively. Thus, in

this study, AFI improved the detection of neoplasia in patients with UC and decreased the yield of random biopsies, while pit pattern analysis by NBI had a moderate accuracy for the prediction of histology.

While both vital and virtual chromoendoscopy offer the identification of subtle lesions and their borderlines, subsequent magnification endoscopy has the capability to enable detailed surface analysis and pit pattern classification of those lesions.

Indeed, Hurlstone and colleagues prospectively analyzed 162 patients with longstanding UC using magnifying chromoendoscopy with 0.5% indigo carmine[25]. Selective chromoendoscopy was used, following detection of subtle mucosal changes. Magnification chromoendoscopy with targeted biopsies significantly increased diagnostic yield for intraepithelial neoplasia (42 lesions *vs* 11 lesions, $P < 0.001$) and the number of flat lesions with intraepithelial neoplasia as compared to conventional colonoscopy (31 lesions *vs* 6 lesions, $P < 0.001$). The overall sensitivity and specificity of magnification chromoendoscopy in predicting neoplasia was 97% and 93%, respectively. These data were also confirmed in a larger cohort of patients[26]. A total of 350 patients with longstanding UC underwent surveillance colonoscopy using high-magnification chromoendoscopy. Quadrantic biopsies at 10-cm intervals were taken on extubation, in addition to targeted biopsies of abnormal mucosal areas, and data were compared to 350 disease duration- and disease extent-matched control patients who had undergone conventional colonoscopic surveillance. Magnification chromoendoscopy detected significantly more intraepithelial neoplastic lesions compared with controls (69 lesions *vs* 24 lesions, $P < 0.0001$). In addition, chromoendoscopy detected more flat lesions with intraepithelial neoplasia compared with controls (53 lesions *vs* 14 lesions, $P < 0.001$).

Taken together, this study indicates that magnification chromoendoscopy has the capability to predict neoplastic and non-neoplastic mucosal changes with a high overall accuracy.

Although high-magnification endoscopy enables detailed surface analysis and pit pattern classification, it cannot visualize cellular and subcellular details. Certainly, diagnosis of intraepithelial neoplasia is mostly based on alterations of cellular and subcellular structures. Additionally, magnifying chromoendoscopy cannot differentiate between colitis-associated intraepithelial neoplasms and adenoma, because the staining pattern of both entities is similar[27].

Recently, confocal laser endomicroscopy was intro-

duced, allowing real-time *in vivo* imaging of the gastrointestinal mucosa at 1000-fold magnification, thereby providing an optical biopsy (Figures 5 and 6)[28].

One randomized controlled trial assessed the value of combined chromoendoscopy (0.1% methylene blue) and endomicroscopy for the *in vivo* diagnosis of intraepithelial neoplasia in patients with UC[29]. One hundred and fifty-three patients with long-term UC in clinical remission were randomized in a 1:1 ratio to undergo conventional colonoscopy or chromoendoscopy with endomicroscopy. In the combined group, 4.75-fold more neoplasms were detected compared to conventional colonoscopy (P = 0.005) and 50% less biopsy specimens were required (P = 0.008). Moreover, if only circumscribed lesions would have been biopsied, the total number of biopsy specimens could have been reduced by more than 90%. Overall, endomicroscopy predicted the presence of neoplastic changes with high sensitivity, specificity, and accuracy (94.7%, 98.3%, and 97.8%, respectively).

Recently, a study by Hurlstone and colleagues evaluated the clinical applicability and predictive power of endomicroscopy for the *in vivo* differentiation of DALM and ALM. Thirty-six patients with 36 lesions were prospectively included. The accuracy of endomicroscopy was 97%, and there was an excellent agreement between endomicroscopy and histopathological diagnosis (κ = 0.91)[30].

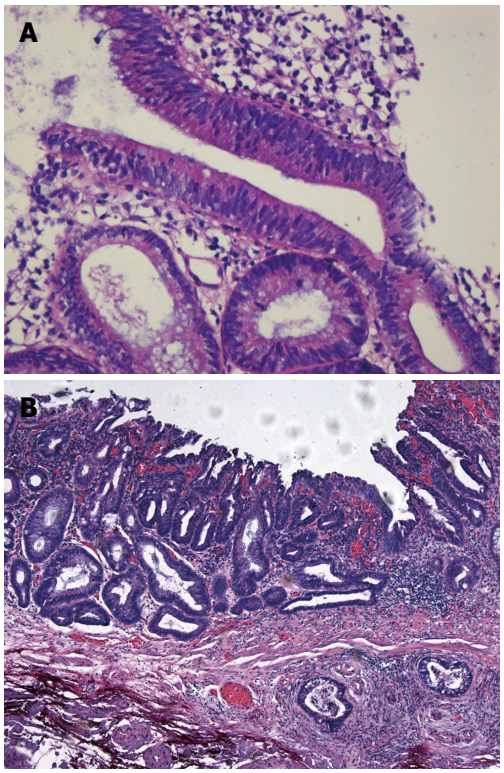

Figure 7 Histopathological image of dysplasia-associated lesion or mass with low-grade intraepithelial neoplasia in a patient with quiescent ulcerative colitis (A). Panel B illustrates colitis-associated cancer with submucosal invasion.

HISTOPATHOLOGICAL DIAGNOSIS

The histopathological differential diagnosis between colitis-associated neoplasms and sporadic adenoma is difficult (Figure 7)[31]. Both entities are defined as unequivocal intraepithelial neoplasms that can show either low-grade or high-grade intraepithelial neoplasia. The lesions are mainly differentiated by combined analysis of histological growth pattern and gross appearance[32]. Clinically, accurate pathological diagnosis is very important with respect to different therapeutic consequences: endoscopic polypectomy *vs* potential surgical proctocolectomy.

Clinically-based criteria for the differentiation of patients with sporadic adenoma from those with colitis-associated neoplasia have been known from the early 1990s. Thus, patients with adenomas differ from those with colitis-associated neoplasms with respect to age, onset age of colitis, number of lesions and extent of colitis[33].

Glands

In sporadic adenomas, the glands are round or oval shaped with regular structure, equal configuration, and similar diameter. Furthermore, sporadic adenomas show a "top-down" morphology, whereas colitis associated neoplasms show a "down-top" morphology, with glands that are irregular in size, shape, configuration, and diameter.

Proliferation zone

The proliferation zone in sporadic adenomas starts from the apical/luminal part of the mucosa ("top-down"). In contrast, the proliferation zone of colitis-associated neoplasms starts from the base of the mucosa ("down-top"); the neoplastic epithelium ultimately covers the whole length of the crypts, finally reaching the mucosal surface. Horizontal tubular proliferations above the muscularis mucosae are typically found in colitis-associated neoplasms.

Mucin vacuoles

In adenomas, mucin vacuoles are evenly distributed within the neoplastic epithelium and are mostly found in the apical part of the cytoplasm. Colitis-associated neoplasms show irregularly distributed mucin vacuoles. Often so-called "dystrophic" goblet cells are found, which are characterized by mucin vacuoles located in the basal parts of the cytoplasm, i.e. between nucleus and basal membrane.

Nuclei

Sporadic adenomas show palisading of elongated hyperchromatic nuclei, which are regular in shape and diameter. In colitis-associated neoplasms, nuclei are oval to round, less densely packed, and vary in diameter and configuration. These nuclei are often more irregularly arranged within the glands compared with sporadic adenomas, and may show greater variation in chromatin content.

Stroma

In between the glands of a sporadic adenoma, the stromal tissue is loosely and evenly arranged, whereas in colitis-associated intraepithelial neoplasms, the stromal tissue is often irregularly packed between the glands, with bands of connective tissue largely varying in shape and

thickness. Depending on the activity of the underlying disease, mixed inflammatory infiltrates, with cryptitis and crypt abscess formation, may be observed.

Delineation of the lesion towards the adjacent mucosa

Sporadic adenomas commonly show sharp and abrupt delineation between neoplastic glands and adjacent non-neoplastic epithelium. In colitis-associated neoplasms, this delineation is more irregular and less well defined.

The question of whether a lesion is a sporadic adenoma or a colitis-associated neoplasm depends on all of the above named criteria. Making a definite diagnosis based upon a single criterion is largely unreliable in this respect. In addition, other factors should be taken into account, such as the endoscopic appearance of a particular lesion, the age of the patient, duration and extent of the underlying disease, and the localization within or above the segment of colon affected by colitis. The use of immunohistochemistry is not very helpful in differentiating the two entities and consequently cannot be recommended[31].

DNA-cytometry

This tool may help to differentiate sporadic adenomas from colitis-associated neoplasms in selected cases. A small study assessing 19 patients showed that all sporadic adenomas evaluated were euploid, in contrast to only four out of 19 colitis-associated neoplasms. Fourteen of the remaining 15 lesions were unequivocally aneuploid[34].

Molecular analysis

While APC-mutations (adenomatous polyposis coli protein) and shift from cytoplasmic to nuclear β-catenin expression are common findings in sporadic adenomas, they are infrequent in colitis-associated neoplasms[35-37]. In contrast, p53 mutations are less common in sporadic adenomas compared with colitis-associated neoplasms (4% *vs* 40%), where they have been identified as the most common initiating mutation within micro-dissected individual neoplastic crypts[31,38]. Similarly, abnormalities of the p16 gene locus are far more common in colitis-associated neoplasms compared with sporadic adenomas[39]. Cyclin-D1 upregulation and p21 (WAF/CIP1) downregulation occur early in colitis-associated carcinogenesis. However, cyclin-D1 upregulation in colitis-associated cancers is less common than in sporadic colon cancers[40]. Finally, LOH analyses (loss of heterozygosity) have shown more frequent deletions on chromosome 3p within the von-Hippel-Lindau gene locus in colitis-associated neoplasms compared with sporadic adenomas in colitis patients[41].

These molecular features may only give a first insight into ongoing research work. However, nuclear β catenin expression appears to be a promising marker, especially if used in combination with ki67 immunohistochemistry, which may facilitate detection of "down-top" or "top-down" morphology as mentioned above[42]. Of note, however, no molecular marker, including those mentioned above, has yet entered daily practice to aid the differential diagnosis between sporadic adenomas and colitis-associated intraepithelial neoplasms. The skills of an experienced histopathologist remain the golden standard. In critical cases, obtaining a second opinion may be helpful to ensure the diagnosis and subsequent therapeutic approaches.

MANAGEMENT OF DALM AND ALM

Macroscopically flat or raised lesions without proper delineation to the surrounding mucosa that occur in long standing IBD are mostly diagnosed as DALM and harbor a high risk of progression to CRC (Figure 1). Furthermore, the occurrence of DALM is frequently associated with synchronic or metachronic neoplasia. Therefore, patients with DALM are recommended to undergo prophylactic proctocolectomy with ileoanal pouch. In contrast, the term ALM describes sporadic adenomas that are similar to those observed in non-IBD patients and which are treated by standard polypectomy (Figure 2).

From the clinical perspective, the endoscopic resectability of a lesion is more important than whether it is thought to be a sporadic adenoma (ALM) or a DALM. One essential point is that the lesion, whether DALM or ALM, should be removed in its entirety.

Early data support the hypothesis that ALMs can be successfully removed using standard polypectomy techniques, with little risk of subsequent malignancy on follow-up[43-45].

In a retrospective study, including 525 patients with UC, a total of 110 neoplastic areas were detected in 56 patients. Eighty-five (77.3%) of the lesions were macroscopically visible at colonoscopy. Fifty patients (89.3%) had macroscopically detectable neoplasia, and six (10.7%) had macroscopically invisible lesions. Importantly, the frequency of cancer in patients who had endoscopic resection of neoplasia did not differ from that of the surveillance population as a whole, irrespective of whether the lesion was thought to be an adenoma or a DALM. Conversely, a high proportion of unresectable lesions harbored cancer[46].

Additionally, in a large retrospective study Vieth and coworkers showed that endoscopic resection of ALMs represents an adequate treatment for those lesions[47]. Furthermore, it was shown that an adenoma based on biopsy material from a patient with UC must be subjected to endoscopic resection, both to confirm the biopsy-based adenoma diagnosis and to exclude colitis-associated intraepithelial neoplasms. In this large retrospective cohort, 2.3% of patients developed a colitis-associated carcinoma (follow up 6 years). Importantly, these carcinomas were located in a segment of the colon other than that bearing the primarily endoscopically resected adenoma.

CONCLUSION

Considerable progress has been made recently in both the diagnosis and treatment of adenomatous and non-ad-

enomatous lesions in UC. New and emerging endoscopic imaging techniques, like chromoendoscopy, magnification endoscopy, and confocal laser endomicroscopy, offer the potential for real time *in vivo* diagnosis of surface, vascular, and cellular patterns, and to perform tactical and targeted biopsies thereby increasing the diagnostic yield for intraepithelial neoplasia.

The following seven basic rules for the detection of neoplasia should be taken into account and applied in accordance with international guidelines, respectively. (1) Experienced gastroenterologist; (2) Endoscopic and bioptic control in remission phase; (3) Examination outside routine schedule without time limitation; (4) Ileocolonoscopy with special focus on the detection of DALMs and step (quadrant) biopsies from the rectum to the cecum in 10 cm intervals (sigmoid and rectum: quadrant biopsies at 5 cm intervals); (5) ALMs with low-grade intraepithelial neoplasia and clear cut margins can be resected endoscopically; (6) Experienced histopathologist who has all clinical and endoscopy data readily available; and (7) Second opinion recommended in cases of histological diagnosis of neoplasia.

In any event, patient follow-up will disclose whether the histopathological diagnosis of sporadic adenoma or colitis-associated neoplasms was justified. Nevertheless, the biopsy-based diagnosis of adenoma is uncertain. Therefore, endoscopic resection of suspicious lesions should be preferred. Several studies are available indicating that polypectomy of sporadic adenomas is an adequate and curative treatment. Of note, all patients with UC should undergo regular surveillance colonoscopies 8 years after the first appearance of symptoms (in the case of pancolitis); repeat colonoscopy with random biopsies in 10 cm intervals should be recommended every 1 to 2 years. Alternatively, chromoendoscopy with targeted biopsies may be applied in specialized centers. Patients that have been diagnosed with left-sided colitis should undergo colonoscopy in year eight after the first appearance of symptoms. If the colitis is still restricted to the distal colon (left-sided) surveillance may start at year 15. If colitis has progressed to pancolitis surveillance colonoscopies should be performed every 1 to 2 years. In general, if intraepithelial neoplasia is present in random biopsy specimens, colectomy should be recommended. If an adenomatous lesion with intraepithelial neoplasia was resected endoscopically control colonoscopy should be performed within 6 mo.

Abstract

Diagnosis of chronic inflammatory bowel diseases (IBD) is based on a combination of clinical symptoms, laboratory tests and imaging data. Imaging of the morphological characteristics of IBD includes the assessment of mucosal alterations, transmural involvement and extraintestinal manifestations. No single imaging technique serves as a diagnostic gold standard to encompass all disease manifestations. Ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) allow cross-sectional imaging of the transmural alterations and extraintestinal manifestations. While in the USA the technique of choice is CT, in Europe the focus is more on MRI and ultrasound (US). Most patients with chronic IBD are diagnosed at a young age. After baseline diagnosis many of these young patients have to undergo repetitive imaging procedures during the variable clinical course of the disease, characterized by alternate periods of remission and active disease, and in monitoring the response to treatment. US has the advantage of being noninvasive, less costly, and easily repeatable, and thus can be very useful in following up patients with IBD. In addition, rising concern about radiation exposure in young adults indicates the demand for radiation-sparing techniques like US and MRI. This article focuses on the current clinical practice of US in IBD, describing the current technologies used in transabdominal intestinal US and the characteristic sonographic findings in Crohn´s disease and ulcerative colitis.

Key words: High-frequency waves; Ultrasound; Clinical practice; Inflammatory bowel disease; Color Doppler; Contrast agents

ULTRASOUND TECHNOLOGY

Ultrasound (US) for inflammatory bowel diseases (IBD) requires high-frequency (5-17 MHz) linear array probes. High-frequency linear-array probes provide increased spatial resolution of the intestinal wall, which is essential for the assessment of wall diameter and wall layer discrimination. In modern high-frequency probes the creation of special modulated US pulses in transmission results in greater penetration of high frequency US. Compounding technology allows image reconstruction using signal responses from different frequencies or from viewing indifferent directions that results in an increase in contrast resolution and border definition of bowel wall architecture. Color or power Doppler imaging and contrast-enhanced US (CEUS) provide detailed information on mural and extraintestinal vascularity, which reflect inflammatory disease activity.

US EXAMINATION

Conventional transabdominal US with a conventional 3.5-5 MHz convex probe is recommended prior to high-frequency US of the intestinal tract so as not to overlook

underlying extraintestinal causes of abdominal discomfort. Special attention should be paid to the lower abdomen (urogenital tract) and the individual patient's pain location. High-frequency US of the intestinal tract requires extra time and patience of the examiner. With the exception of emergency situations the standard US examination should be performed preprandial in the morning or at least after 4 h fasting to diminish peristaltic movements and the amount of intraluminal air. Gradual compression of the bowel with the US probe helps to reduce intraluminal air. The application of intraluminal fluid as used in bowel preparation for colonoscopy or the use of enteral contrast medium[1-4] has been shown to improve the delineation of the wall architecture and the detection of jejunal and colonic lesions in patients with IBD, but these more sophisticated techniques have not been transferred into routine clinical practice. For US diagnosis of IBD, an understanding of the anatomical location of Crohn's disease (CD) and ulcerative colitis (UC), and of the more difficult or non accessible parts of the small and large bowel is essential for a systemic US approach to the patient. Transabdominal high-frequency US does not provide a continuous and complete examination of the small and large bowel. The ileocecal region and the sigmoid colon can be identified in all patients. The left and right colon can be adequately evaluated in most of patients. The colonic flexures (especially the left flexure) are more difficult to visualize due to their cranial position and ligamentous fixation to the diaphragm. The colon transversum can be identified in most patients, but complete examination is not easy to achieve because of its variable anatomy. The rectum and anal region cannot be visualized accurately by the transabdominal route due to their pelvic location. Transperineal US is useful in the evaluation of the perianal region and the distal rectum[5]. A proposal for a systematic approach in IBD patients could be to start in the left lower abdomen with transverse scans using the left iliac artery and vein as landmarks to visualize the sigmoid colon. The sigmoid colon can be easily identified by its prominent hypoechoic muscle layer (muscularis propria). Examination of the left colon can then be adequately performed by continuous scanning from the rectosigmoid transition along the colon descendens upwards to the left costal arch. Gradual compression is recommended to follow the left-sided colon along. The next step of a systematic examination could be visualization of the ileocecal region with transverse scans in the right lower abdomen using the right iliac artery and vein as landmarks and gradual compression. A variable location of ileocecal region in the right middle abdomen (also a frequent location of the neoterminal ileum after surgical resection) can be identified after manual palpation of the right spina iliaca anterior superior as a landmark. Moving the US probe in transverse sections from the right spina iliaca anterior superior upwards to the right costal arch with graded compression helps to find the lumen of the colon ascendens with its characteristic broad lumen (hyperechoic air filled lumen or hypoechoic fluid filled lumen). The cecum can easily be found by turning the probe towards a longitudinal position to follow the colon ascendens downwards until the broad luminal echo disappears. The distal part of the ileum can also be identified by transverse scanning from the cecum towards the middle and lower parts of the abdomen, again using the right iliac artery and vein and the urinary bladder as landmarks. Whereas the distal part of the small intestine (terminal ileum) can be evaluated in all patients, a complete and continuous evaluation of the proximal parts of the ileum and jejunum is not possible due to multiple overlying bowel loops. However, for a systematic approach to the proximal small intestine, four scanning positions in the upper and lower, right and left abdominal quadrants are recommended as final steps of a systematic approach to search for thickened intestinal wall segments.

Table 1 Sonoanatomy of the normal intestinal wall

Layer echogenicity	Anatomic structure
Hypoechoic (fluid) or hyperechoic (air) lumen	
Hyperechoic entrance	Transition lumen/mucosa
Hypoechoic	Mucosa
Hyperechoic	Submucosa
Hypoechoic	Muscularis propria
Hyperechoic	Transition muscularis propria/serosa, surrounding structures (fat, peritoneal wall)

SONOMORPHOLOGY OF THE INTESTINAL WALL

With the use of high US frequencies in the range from 7.5 MHz to 17 MHz, the wall of the intestine usually exhibits five different layers (Table 1). The small and large bowel can usually be distinguished in various stages of filling during movement by scanning the haustra of the colon and/or the circular folds of Kerckring in the small intestine. Measurement of the wall thickness is crucial for the diagnosis of IBD. Discrepancies in the measurements are mainly due to the presence or absence of graded compression during the examination by the operator in addition to various technical causes (US frequency, equipment). With modern high-frequency linear array probes the normal intestinal wall thickness is generally $\leqslant$ 3 mm (using mild compression) ranging from small diameters in the jejunum, ileum and proximal colon to larger diameters in the sigmoid colon (due to the hypertensive function of the sigmoid zone). Physiological contraction of the intestine leading to a thickened wall segment may cause misinterpretation, therefore bowel motions have to be taken into account before measurements are performed. In addition to wall thickening, echomorphology (integrity of wall architecture) and surrounding structures have also to be considered in the interpretation of the intestinal wall diameter.

CROHN'S DISEASE

CD can be localized in any part of the gastrointestinal tract, although the main location is the terminal ileum.

Small intestinal localization of the disease is found in 30%-40% of patients with CD (with involvement of the terminal ileum in 90%), and 40%-55% of the patients show an ileum and colonic localization. Only in a minority of patients (15%-25%) is colonic localization only observed. A systematic examination in patients with IBD should include complete scanning of the ileocecal region and sigmoid colon as well as the remaining parts of the colon, and evaluation of the small intestine (in sections) and surrounding mesenteric structures.

Assessment of bowel wall involvement

The most widely used diagnostic criterion for the diagnosis of IBD is bowel wall thickening with increased vascularization (with maintenance or loss of wall stratification).

In most studies, the bowel is considered to be thickened when the wall diameter exceeds 3 mm (Figure 1). The diagnostic accuracy of different cut-off values in CD were compared in a metaanalysis by Fraquelli *et al*[6]. Sensitivity and specificity of 88% and 93%, respectively, were achieved when a bowel wall thickness threshold greater than 3 mm was used, and sensitivity and specificity of 75% and 97%, respectively, were achieved when a threshold greater than 4 mm was used. Several studies report a relation between bowel wall thickness and clinical disease activity using the Crohn´s Disease Activity Index (CDAI) or Harvey Bradshaw Index (HBI) at initial diagnosis and during the clinical course of CD and in relation to endoscopic findings[7-9].

Bowel ultrasonographic signs used in CD can be standardized as most show a fair to good reproducibility. In particular, bowel wall thickness, the most relevant parameter for CD detection, showed an excellent reproducibility[10]. Color or power Doppler imaging of the vascularity of thickened wall segments using semiquantitative scores has proved useful in the distinction between remission or the active phase in CD and correlated with the clinical and endoscopic activity scores in adults[9,11] and children[12]. A reduction in wall thickness and mural vascularity (color Doppler imaging) could be shown in patients with a positive clinical-biological response to anti-tumor necrosis factor-α induction therapy in a small study in 24 patients. Maintenance of wall thickness and increased mural vascularity were seen in all non-responders ($n = 7$). Sonographic normality (defined as wall thickness ⩽ 3 mm and Doppler flow grade = 0) was only seen in 5 of 17 patients with a positive clinical-biological therapeutic response (29%)[13]. Most studies on Doppler US include a subjective semiquantitative assessment of mural vascularity, e.g. grade 0 = no vascular signal, grade 1 = barely visibly signals, grade 2 = moderate vascularity, grade 3 = marked vascularity. Currently there is no objective scale to determine the degree of disease activity on Doppler US.

CEUS is the most sensitive technique to visualize microperfusion and has been shown to be superior to conventional color or power Doppler imaging in determining tumor vascularity[14]. Currently, the clinical value of CEUS in IBD is not well defined. Most studies on CEUS have been feasibility or pilot studies.

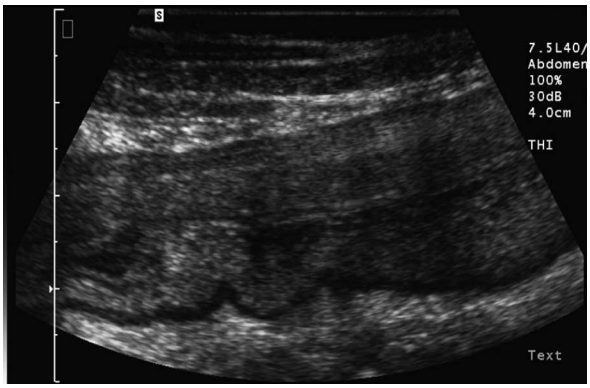

Figure 1 Sonographic appearance of an inflamed colon segment in Crohn's disease. Characteristic appearance: thickened wall diameter (almost 1 cm), partial loss of wall stratification, prominent submucosal layer, narrowed lumen and mesenteric fat hypertrophy.

In a small study (21 patients) with histologically confirmed CD and bowel wall diameters > 5 mm, contrast enhancement was observed after a mean of 13.4 s (± 4.2 s; range, 7-19 s) with a maximum vascularity after 30 s[15]. In addition, the length of contrast-enhanced bowel segments in US correlated significantly with the length of thickened bowel segments in magnetic resonance imaging (MRI)[16]. In a retrospective analysis, the assessment of the bowel wall vascularization in CD was performed using quantification software, indicating that CEUS data can not only be analyzed in a semi-quantitative way, but also in a reproducible, quantitative manner[17]. Using time-intensity curves, patients with CD showed a maximum enhancement 36 s after injection with 9 dB (range, 5.9-13.2 dB), while healthy volunteers reached the maximum level of 2.8 dB (range, 2-3.8 dB) after 23 s ($P < 0.05$)[18].

Correlation of CEUS with disease activity (endoscopy, histology, CDAI) indicate that active disease can be identified by CEUS)[19,20]. Characterization of the enhancement pattern in relation to wall thickness was shown to distinguish CD patients with active and inactive disease[21]. Lower levels of bowel contrast enhancement were observed in some patients who responded to anti-inflammatory treatment[22,23], as was shown in power Doppler imaging a few years ago. CEUS may be a useful method to assess the therapeutic effectiveness of specific medical anti-inflammatory treatment in patients with CD, or to differentiate inflammatory from fibrotic bowel wall changes. In addition, CEUS was suggested to be helpful in surgical management, in deciding upon conservative *vs* surgical treatment[24,25]. However, the role of CEUS in addition to conventional Doppler imaging is not yet well defined in clinical studies. Pilot studies on CEUS are promising, but studies on larger patient numbers, including the objective contrast enhancement score are needed before CEUS can be considered a clinical useful tool.

Mesenteric blood flow parameters

Patients with CD had significantly higher portal vein and mesenteric flow and a lower resistance index than con-

trols[26]. Blood flow in the superior mesenteric artery (SMA) has shown an increase in the postprandial pulsatility index (PI) in remission[27] in Doppler US. A decrease in PI predicted a non responder to azathioprine therapy and clinical relapse in a 12-mo follow-up[28]. Contrast enhancement in the SMA and vein, and calculation of splanchnic transit time showed a reduction in transit time (4.0 s *vs* 6.9 s) in patients with active CD[29]. However, in our own experience splanchnic transit time measurement in CEUS was not correlated with clinical disease activity (HBI) in mild stages of CD.

Extraintestinal findings

In addition to the assessment of bowel thickness and increased mural vascularity, the surrounding structures (fat, lymph nodes, free fluid accumulation) may indicate a peritestinal inflammatory reaction. Mesenteric fat hypertrophy correlated with biochemical and clinical activity of CD and with internal fistulas and increased bowel wall thickness. In quiescent CD, mesenteric hypertrophy does not appear to be a risk factor for relapse[30]. US is very sensitive for the detection of free fluid in CD[31]. The presence of regional lymph nodes shows only a weak correlation with clinical and biochemical CD activity[32]. Furthermore, the finding of mesenteric lymph nodes is non-specific and may reflect disease activity, but infectious intestinal diseases have to be excluded by stool and serologic tests.

Since US can find both intraluminal and peri-intestinal pathological features, it is a particularly valuable tool for the detection of complications of CD, such as stenosis, fistulas, and abscesses. Sensitivity and specificity for detecting fistulae in transabdominal US have been reported as 50%-89% and 90%-95%, respectively[33]. Sensitivity and specificity for detecting abscesses in transabdominal US is even higher with sensitivities of 71%-100% and specificities of 77%-94%[33-36]. In a series of 58 patients with CD, including 28 patients with bowel stenosis, 23 patients with fistulas and 10 patients with abscesses, high-resolution US showed a high diagnostic accuracy in comparison to clinical, endoscopic, radiological and operative findings[37]. The sensitivity, specificity, positive predictive and negative predictive values for US were 86%, 90%, 83% and 92%, respectively, for stenosis and 78%, 95%, 86% and 91%, respectively, for fistulas. The highest diagnostic accuracy was found for abscesses with sensitivity, specificity, positive predictive and negative predictive values 90%, 99%, 90% and 99%, respectively.

ULCERATIVE COLITIS

UC exclusively affects the colon with a predictable way of spreading from distal to proximal colon in a continuous manner. UC is classified by disease extent into proctitis, left-sided colitis and extensive colitis beyond the splenic flexure. A solitary rectal location of UC cannot be visualized accurately due to the pelvic location of the rectum. Mural stratification is preserved in most UC patients due to the superficial pattern of inflammation. The spatial resolution of US is not high enough to allow detection of mucosal pathology but bowel wall thickening is also a characteristic feature of UC[38].

The clinical role of US in UC is less well established as compared with CD. In contrast to CD, bowel thickening in UC could not be correlated with clinical disease activity in some studies[39,40]. However, compared with endoscopic findings, with an overall accuracy of 89% for US (bowel wall thickness > 3 mm and increased Doppler signal) and 73% for MRI (contrast enhancement in bowel wall) in identifying active IBD, the diagnostic accuracy was better in patients with UC than in patients with CD for both US and MRI[41].

Mucosal healing (MH) after short-term medical treatment is being considered as an important step in the therapeutic work-up of IBD patients due to the potential prognostic role of MH in predicting disease outcome. However, IBD patients are reluctant to be re-endoscopes during follow-up; therefore, there is a need for a non-invasive alternative index of MH which can replace endoscopy in clinical practice. In a prospective trial in 83 patients with UC with a follow-up of 15 mo, a high and consistent concordance between endoscopic and US scores was shown. In patients with UC, moderate-to-severe endoscopic and US scores at 3 mo were associated with a high risk of endoscopic activity at 15 mo, indicating that bowel US may be used as a surrogate of colonoscopy in assessing the short-term response of severe forms of UC to therapy. In addition, the US score and endoscopic score after 3 mo of steroid therapy predicted the outcome of disease at 15 mo[42,43].

Splanchnic flow measurements in the inferior mesenteric artery have been shown to be closely related to clinical and endoscopic disease activity in patients with UC[44,45]. In a small trial, CEUS showed entire bowel wall vascularity in correlation to clinical nonresponders to cytapheresis for steroid-refractory or -dependent UC[46]. So far CEUS is not routinely used in UC.

CONCLUSION

Transabdominal US is currently accepted as a clinically important first-line imaging technique in IBD in initial diagnosis and during the clinical course of the disease.

Abstract

The pathogenesis of both entities of inflammatory bowel disease (IBD), namely Crohn's disease (CD) and ulcerative colitis (UC), is still complex and under investigation. The importance of the microbial flora in developing IBD is beyond debate. In the last few years, the focus has changed from adaptive towards innate immunity. Crohn's ileitis is associated with a deficiency of the antimicrobial shield, as shown by a reduced expression and secretion of the Paneth cell defensin HD5 and HD6, which is related to a Paneth cell differentiation defect mediated by a diminished expression of the Wnt transcription factor TCF4. In UC, the protective mucus layer, acting as a physical and chemical barrier between the gut epithelium and the luminal microbes, is thinner and in part denuded as compared to controls. This could be caused by a missing induction of the goblet cell differentiation factors Hath1 and KLF4 leading to immature goblet cells. This defective Paneth and goblet cell differentiation in Crohn's ileitis and UC may enable the luminal microbes to invade the mucosa and trigger the inflammation. The exact molecular mechanisms behind ileal CD and also UC must be further clarified, but these observations could give rise to new therapeutic strategies based on a stimulation of the protective innate immune system.

Key words: Inflammatory bowel disease; Paneth cells; Goblet cells; Cell differentiation; TCF4; Hath1; KLF4

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are the 2 main entities of inflammatory bowel disease (IBD). Whereas CD mostly involves the distal ileum and/or the colon, the inflammation in UC is restricted to the colon. Since both disease locations are characterized by a high concentration of intestinal bacteria (10^7-10^8 organisms/g luminal content in the distal ileum and 10^{11}-10^{12} in the colon), it is not surprisingly that these luminal microbes are playing an important role in the development of IBD (see our review in the *World Journal of Gastroenterology*[1]). In healthy mucosa, these microbes are sufficiently con-

trolled by an adequate secretion of antimicrobial peptides and by the mucus layer, acting as a physical and chemical barrier (Figure 1A). Even if the pathogenesis of both forms of IBD is still under investigation, the last few years have revealed evidence that the differentiation from the intestinal stem cell towards the Paneth cell in ileal CD and towards the goblet cell in UC may be disturbed. This may result in a defective antimicrobial and mucus barrier, which enables the intestinal bacteria to invade the mucosa and trigger the inflammation. In this review, we focus on the intestinal stem cells, their differentiation towards Paneth and goblet cells, and the defective antimicrobial shield in ileal CD and mucus layer in UC as a consequence of a stem cell differentiation defect.

INTESTINAL STEM CELLS AND THEIR MARKERS

The whole intestinal tract is a rapidly self-renewing tissue maintained by a population of intestinal stem cells. For many decades, scientists tried to identify these relatively undifferentiated enigmatic cells - unfortunately with limited success due to a lack of good cellular markers. Nevertheless, about 30 years ago, 2 models were established concerning intestinal stem cell location in the human gut, which are still debated. The first hypothesis is called the "+4 position model". It assumes the intestinal stem cells to be located above the Paneth cells at position +4 relative to the crypt base[2]. The second hypothesis, also called the "stem cell zone model", proposed that the crypt base columnar cells, a cell population at the bottom of the crypt, represent the intestinal stem cells[2]. Both models suggest that about 6 intestinal stem cells are found in each crypt[2], surrounded by epithelial and mesenchymal cells regulating stem cell behavior[3].

The intestinal stem cells differentiate into 4 epithelial cell types[3]. The most abundant cells in the epithelium are the columnar cells. Their main function is the absorption of nutrients by apical microvilli. Goblet cells produce and secrete mucins in order to form a protective luminal mucus layer. Neuroendocrine cells release hormones in an endocrine and paracrine fashion. Finally, the Paneth cells, located in the crypt base of the small intestine and ascending colon secrete defensins and other antimicrobial peptides to keep the crypts sterile[4].

In 2007, Hans Clevers and his group found the Wnt target gene leucine-rich-repeat-containing G-protein-coupled receptor 5 (Lgr5) to be expressed in cells at the crypt base[5]. Furthermore, irreversible labeling of these cells revealed, that all 4 epithelial cell types (columnar cells, goblet cells, Paneth cells and neuroendocrine cells) arise from these cells. Since LGR5-positive cells are located at the crypt base, are pluripotent and also self-renewing, they concluded that LGR5 is a good marker for the intestinal stem cells[5]. In 2009, the same group found olfactomedin 4 (also known as OLFM4, hGC1 or GW112), a protein with unknown function, to be a robust and specific marker for these LGR5 stem cells in the human intestine[6].

Intestinal stem cells are regulated by several cell signaling pathways, including the Wnt and Notch pathway[7,8]. Defects in these pathways are known to be related to the development of intestinal cancer[3,8,9]. The role of stem cell differentiation towards Paneth cells in ileal CD and towards goblet cells in UC is a new and promising field of science which could contribute to a better understanding of these 2 diseases[10,11].

DEFECTIVE PANETH CELL DIFFERENTIATION IN ILEAL CD IS RELATED TO α-DEFENSIN DEFIENCY

Paneth cells were first described more than 100 years ago as granular cells at the base of the intestinal crypts of Lieberkühn[12]. About 5-12 Paneth cells can be found in each small intestinal crypt and, in contrast to columnar cells, goblet cells and neuroendocrine cells, they do not migrate upwards in the crypt but remain beneath or between the stem cells in the crypt base[13]. Their numerous apical cytoplasmic granula are filled with antimicrobial peptides, especially the α-defensins HD5 and HD6, but also other antimicrobials such as lysozyme and phospholipase A2[14]. These Paneth cell defensins, which are active against a large number of microbes, including Gram-positive and Gram-negative bacteria, fungi and viruses[15], can be released into the crypt lumen in order to regulate the microbial density and therefore protect the intestinal epithelium against bacterial invasion and inflammation.

Paneth cells derive from intestinal stem cells under the control of the Wnt signaling pathway. In particular, the Wnt transcription factor TCF4 is essential in Paneth cell differentiation, as shown in the embryonic mouse intestine[16]. After the activation of Wnt signaling, an intracellular β-catenin-TCF4-complex is formed and translocates into the nucleus, where the compound acts as a transcription factor controlling the expression of several downstream target genes, such as Paneth cell defensins. This was shown in TCF4 null mice, where TCF4 regulates the expression of the cryptids (the mouse homologs to the human α-defensins)[16].

This Paneth cell differentiation factor TCF4 was found to be reduced in ileal CD as compared to colonic CD and colonic UC[10]. Interestingly, this observation was independent of the degree of inflammation and independent of the NOD2 genotype[10]. In human samples HD5 and HD6 expression correlated well with TCF4, thus it seems that not only in animal models, but also in humans, Paneth cell defensins are regulated by TCF4[10]. The functional relevance of this TCF4 decrease was shown in TCF4 knockout mice: the reduced TCF4 expression apparently resulted in a decreased HD5 and HD6 expression[10]. Moreover, we found a high affinity binding site in the HD5 and HD6 promotor for TCF4, and notably, we detected genetic variants in the putative promoter region

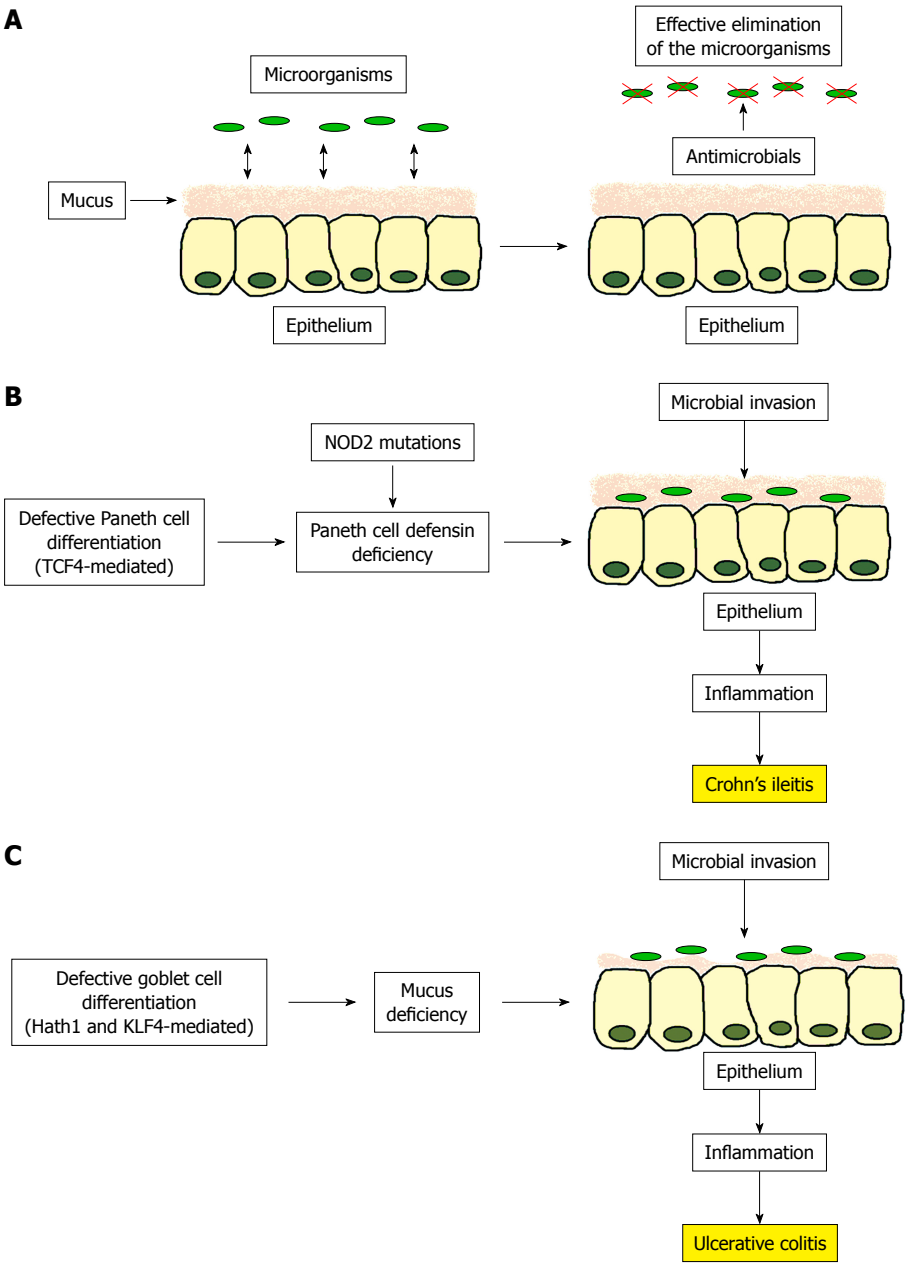

Figure 1 Proposed model for the pathogenesis of ileal Crohn's disease and ulcerative colitis. A: In the healthy ileal and colonic mucosa, luminal microbes are sufficiently controlled by an adequate secretion of antimicrobials peptides and a sufficient mucus layer; B: In ileal Crohn's disease, defective Paneth cell differentiation mediated by a reduction of the Wnt transcription factor TCF4 leads to a decreased Paneth cell defensin secretion, especially in case of NOD2 mutations. This allows the luminal microbes to attach and invade in the mucosa causing inflammation; C: In ulcerative colitis, a defective goblet cell differentiation based on a missing induction of the transcription factors Hath1 and KLF4 results in mucus deficiency enabling the luminal microbes to invade the mucosa and trigger inflammation.

of the Wnt transcription factor TCF4 (TCF7L2) to be associated with ileal CD[17]. This genetic finding emphasizes the primary role of the TCF4 defect in CD.

This also explains in part why in ileal CD, but not in colonic CD or UC, and also not in pouchitis samples, we had found a decreased expression of the α-defensins HD5 and HD6[14,18]. The other Paneth cell products were unchanged or even increased as compared with control samples[14]. This observation was independent of the degree of inflammation[14,18], and even more pronounced in patients with NOD2 mutations[14,18], which are clearly associated with ileal CD[19,20]. This is interesting, since Kobayashi *et al*[21] found NOD2-deficient mice to be susceptible to bacterial infection and, in addition, NOD2 seems to be essential for the expression of cryptdins. Elphick *et al*[22] confirmed this low defensin formation in ileal CD especially in those with a NOD2 mutation. Another study showed the same low defensin synthesis in CD but linked it to inflammation and loss of Paneth cells[23]. In contrast to this observation, Kelly *et al*[24] and also our group found an unaltered number of Paneth cells in ileal CD[14]. We were also able to demonstrate a reduced antibacterial activity in mucosal extracts from patients with ileal CD suggesting that the missing expression of Paneth

cell defensins in humans leads to a defective antimicrobial shield[14]. Since transgenic mice with human HD5 expression had an abnormal composition of the luminal microbial flora, it seems plausible that Paneth cell defensins can influence the makeup of the bacterial flora[14].

Taken together, the defective differentiation from the intestinal stem cell towards the Paneth cell is mediated by a diminished expression of the Wnt signaling transcription factor TCF4 resulting in a specific deficiency of the Paneth cell defensins in humans, especially in case of NOD2 mutations. This leads to a dysfunction of the mucosal barrier, which enables the luminal microbes to invade the mucosa and cause inflammation (Figure 1B). Besides the genetic link of TCF4 to ileal CD, other molecules, such as NOD2, ATG16L1, XBP1, KCNN4 and HD5 are genetically defective in ileal CD. As all these molecules are necessary for Paneth cell function, it seems to be plausible that the decrease in Paneth cell α-defensins is a primary (genetic) factor in disease pathogenesis[17,25].

IMPAIRED GOBLET CELL DIFFERENTIATION IN UC IS LINKED TO A DEFECTIVE MUCUS LAYER

Goblet cells are glandular epithelial cells scattered among the absorptive cells in the epithelium. The cytoplasm of these cells is filled with granula containing mucins, which are secreted into the intestinal lumen. These mucins form the mucus layer, acting as a barrier between the luminal contents and the epithelial surface[26].

Goblet cells derive from intestinal stem and progenitor cells located in the lower part of the crypt. Their differentiation is controlled by several transcription factors, especially by the basic helix-loop-helix transcription factor Hath1, the zinc-finger transcription factor KLF4 and the Notch target gene Hes1. For example, Math1 null mice (Math1 is the mouse homologe of human Hath1) are not able to develop goblet cells, whereas the columnar cells are intact[27]. In accordance to Hath1, goblet cell differentiation was also defective in KLF4 null mice as shown by a decrease of about 90% of colonic goblet cells in these mice[28]. Hath1 seems to be involved in an early stage of goblet cell differentiation, KLF4 appears to play a crucial role especially in the terminal stage of goblet cell differentiation[28]. In contrast, the genetic knockout of Hes1 gives rise to an increased number of goblet cells accompanied by a reduced number of nonsecretory cells[27,29,30], suggesting that Hes1 is a antagonist of Hath1[31]. In particular, the balance between Hath1 and Hes1 seems to be essential in controlling goblet cell differentiation in the epithelium, at least in the small intestine[31].

In 2009, we investigated these 3 crucial goblet cell differentiation factors in IBD. We found a significant induction of the goblet cell differentiation factors Hath1 and KLF4 in noninflamed *vs* inflamed CD, but not in UC[11]. Particularly in inflamed CD, the expression of Hath1 and KLF4 was about twice as high as that in inflamed UC samples[11]. For Hath1, these mRNA data were confirmed on the protein level by immunohistochemistry and Western blotting. Interestingly, this attenuated induction of Hath1 and KLF4 in UC was independent of the degree of inflammation and seems not to result from a down-regulation by increased Notch activity[11]. Hes1 expression was also augmented in inflamed CD as compared to inflamed UC, but without reaching significance[11].

In contrast to CD, the expression of the colonic antimicrobials is increased in inflamed UC suggesting that the antimicrobial shield is intact in these patients[32-34]. Nevertheless, the colonic mucus layer, which cover the whole gastrointestinal tract and act as a physical and chemical barrier against the luminal microbes, is altered and even deficient in UC[35-37]. The thickness of the mucus layer in the healthy colon was measured between 100 and 300 μm, increasing from the ascending colon to the rectum[36,38,39], whereas in UC, this mucus layer is thinner, more variable and in part denuded[35,36].

Since the "raison d'être" of goblet cells is to secrete mucus, it is not surprising that a decrease of the mature goblet cells, located in the upper part of the crypts, was found in UC compared with controls[11]. Moreover, in our samples the expression of the main colonic mucins (Muc1, 2 and 4) tended to increase in inflamed IBD, whereas this induction was clearly less pronounced in inflamed UC compared with inflamed CD[11]. Since Hath1 and KLF4 were also highly correlated with these mucins, it is possible that the defective mucus layer in UC is related to these 2 differentiation factors[11].

Overall, the defective differentiation from intestinal stem cells towards goblet cells, which is mediated by the 2 crucial transcription factors Hath1 and KLF4, may lead to goblet cell depletion and deficient mucin induction in active UC. This could explain the defective mucus barrier in UC, resulting in a collapse of the physical barrier, which enables the luminal microbes to invade the mucosa and trigger inflammation (Figure 1C). The role of mucins in host defense was shown by MUC2-deficient mice which spontaneously develop colitis[40]. As Swidsinski *et al*[41] found high concentrations of mucosal bacteria in patients with IBD, and as kationic defensins bind to the negatively charged mucins[42], we hypothesize that in UC the mucosa is not capable of holding back the fecal bacteria based on a defective mucus layer which is unable to bind the adequate amounts of secreted defensins.

CONCLUSION

The pathogenesis of IBD is certainly complex and still under investigation. Nevertheless, ileal CD and colonic UC are associated with defects in stem cell differentiation either to protective Paneth cells or goblet cells. Diminished Paneth cell defensins result in a defective antimicrobial barrier in ileal CD, whereas in UC, an insufficient induction of goblet cell mucins can lead to a disturbed

mucosal barrier. In both cases, luminal microbes are allowed to invade the mucosa and cause inflammation. New therapeutic strategies should focus on a stimulation of the antimicrobial shield in ileal CD and stabilization of the mucus layer in UC.

Abstract

Ulcerative colitis (UC) is a chronic disease featuring recurrent inflammation of the colonic mucosa. The goal of medical treatment is to rapidly induce a steroid-free remission while at the same time preventing complications of the disease itself and its treatment. The choice of treatment depends on severity, localization and the course of the disease. For proctitis, topical therapy with 5-aminosalicylic acid (5-ASA) compounds is used. More extensive or severe disease should be treated with oral and local 5-ASA compounds and corticosteroids to induce remission. Patients who do not respond to this treatment require hospitalization. Intravenous steroids or, when refractory, calcineurin inhibitors (cyclosporine, tacrolimus), tumor necrosis factor-α antibodies (infliximab) or immunomodulators (azathioprine, 6-mercaptopurine) are then called for. Indications for emergency surgery include refractory toxic megacolon, perforation, and continuous severe colorectal bleeding. Close collaboration between gastroenterologist and surgeon is mandatory in order not to delay surgical therapy when needed. This article is intended to give a general, practice-orientated overview of the key issues in ulcerative colitis treatment. Recommendations are based on published consensus guidelines derived from national and international guidelines on the treatment of ulcerative colitis.

INTRODUCTION

Ulcerative colitis (UC) is a chronic disease with recurrent uncontrolled inflammation of the colon. The rectum is always affected with inflammation spreading from the distal to the proximal colonic segments. The terminal ileum is typically not involved but some patients with extensive disease may show endoscopic signs of "backwash ileitis". As the course of disease and extent vary considerably among patients, an individualized diagnostic and therapeutic approach is necessary.

The purpose of clinical practice guidelines is to indicate the best approaches to medical problems based on scientific findings. However, in the case of UC, if we consider just 3 different distribution patterns (proctitis, left-sided, pancolitis), 4 disease activities (remission, mild, moderate, severe), and 4 possible disease courses (asymptomatic after initial flare, increase in severity over time, chronic continuous symptoms, chronic relapsing symptoms), 48 different situations have to be evaluated before giving scientific advice. With the addition of further important factors such as the patient's extra-intestinal manifestations, age, concomitant diseases, previous operations, medical intolerances, lifestyles and personal wishes this number exceeds a thousand possible regimes.

So guidelines can only aim to indicate the preferable but not necessarily the only acceptable therapeutic approach and are meant to be used flexibly in a manner best suited to the individual patient. Therefore, the therapeutic approaches described in this article are meant to provide a general, practice-orientated overview of the important issues on UC treatment. Recommendations are based on published consensus guidelines of the national German [Deutsche Gesellschaft für Verdauungs- und Stoffwechselkrankheiten (DGVS)][1,2] and international societies [American College of Gastroenterology (ACG)[3], European Crohn's and Colitis Organisation (ECCO)][4-6] as well as on the authors' experience. Evidence levels (EL) and recommendation grades (RG) are given according to the Oxford Centre for Evidence-Based Medicine, EL 1 being the highest evidence level and RG A the strongest recommendation. ACG and DGVS guideline recommendations are graded from A (highest) to D (lowest).

The goal of medical treatment in UC is the rapid induction of a steroid-free remission and the prevention of complications of the disease itself and its treatment. In Crohn's disease experts are currently debating the usefulness of a "top-down" strategy, giving highly potent drugs in the early stages of the disease in order to prevent complications. In contrast, guidelines on UC, a putatively curable disease (by means of colectomy), still favor a pyramidal step-up approach where 5-aminosalicylic acid (5-ASA) is considered the baseline medication, steroids and immunomodulators function to intensify the treatment, while infliximab (IFX), calcineurin inhibitors [cyclosporine A (CsA), tacrolimus] or surgery are considered as rescue therapy.

MANAGEMENT OF ACTIVE UC

Symptoms of new onset UC or recurrent flare-ups usually consist of abdominal pain, bloody and/or mucous diarrhea. Severe cases present with weight loss, tachycardia, fever, anemia and bowel distension. Before starting medical treatment other etiologies of colitis/enteritis such as infections [*Clostridium difficile*, cytomegalovirus (CMV)], toxic reactions (e.g. antibiotics, NSAID colitis), mesenteric ischemia or intestinal malignancies should be ruled out. Opportunistic infections (e.g. CMV infection) need to be excluded prior to medical therapy escalation, especially in patients under immunosuppressive therapy with a corticosteroid-refractory course.

Although there is no gold standard, minimal diagnostic workup for UC includes medical history, clinical evaluation (focusing on extraintestinal manifestations), full blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), stool microbiology, ultrasound and endoscopy with mucosal biopsies[6]. If there is any doubt about the diagnosis in the acute setting, endoscopic and histological confirmation should be repeated after a period of time has passed (ECCO EL 5, RG D; DGVS C).

The choice of treatment depends on the degree of activity, distribution (proctitis, left-sided or extensive colitis), course of disease, frequency of relapses, extraintestinal manifestations, previous medications, side-effect profile and the patient´s individual wishes.

The degree of activity can be classified according to the Montreal classification as: Remission (S0): 3 or less stools per day without any presence of blood or increased urgency of defecation; Mild (S1): up to 4 stools per day, possibly bloody. Pulse, temperature, hemoglobin concentration and ESR are normal; Moderate (S2): 4 to 6 bloody stools daily, no signs of systemic involvement; Severe (S3): more than 6 bloody stools daily, signs of systemic involvement (temperature above 37.5°C, heart rate above 90/min, hemoglobin concentration below 10.5 g/dL, or ESR above 30 mm/h).

Distribution patterns depend on the part of the colon involved and are designated according to the Montreal classification as proctitis (E1), left-sided colitis (E2, limited to the sigmoid and descending colon) or extensive colitis (E3, also referred to as pancolitis). A graphical treatment algorithm is shown in Figure 1.

Proctitis/distal colitis

Colitis limited to the rectum with mild or moderate activity should be initially treated topically[7]. A 5-ASA suppository (e.g. mesalazine 1 g/d) is the drug of first choice (ECCO EL 1b, RG B; DGVS EL A) and induces remission in 31-80% of patients compared to 7-11% in the placebo-treated group[8]. There is no dose response to topical therapy above 1 g mesalazine daily. 5-ASA foam enemas are an alternative, but suppositories deliver the drug more effectively to the rectum and are often better tolerated by patients due to their smaller volume[9].

Topical corticoids (budesonide 2-8 mg/d, hydrocortisone 100 mg/d) are less effective than topical mesalazine[10]. If no therapeutic effect is observed, treatment escalation using a combination of oral mesalazine (2-6 g/d for induction), together with topical mesalazine and/or a topical steroid is recommended as second-line therapy (ECCO EL 1b, RG B; DGVS A). If symptoms do not resolve within 2-4 wk, the patient's adherence to medical treatment should be evaluated. Repeated exclusion of infectious colitis and endoscopic reconfirmation of persisting inflammatory proctitis might be helpful to guide the subsequent therapeutic approach, as an unrecognized co-existing irritable bowel syndrome or infectious colitis may be the reason for the refractory course. CMV infection is best diagnosed using immunohistochemical staining of viral proteins in mucosal biopsies, while conventional staining often gives false negative results. Quantitative CMV PCR presents the dilemma that positive results cannot distinguish between the presence of CMV as an innocent bystander in inflamed mucosa and its causative role in inflammation[11].

Confirmed persistent proctitis, in spite of combined local and topical therapy, is best treated as if it were more extensive or severe colitis.

Left-sided UC

Left-sided active UC of mild-to-moderate severity should be initially treated with topical aminosalicylates (ECCO

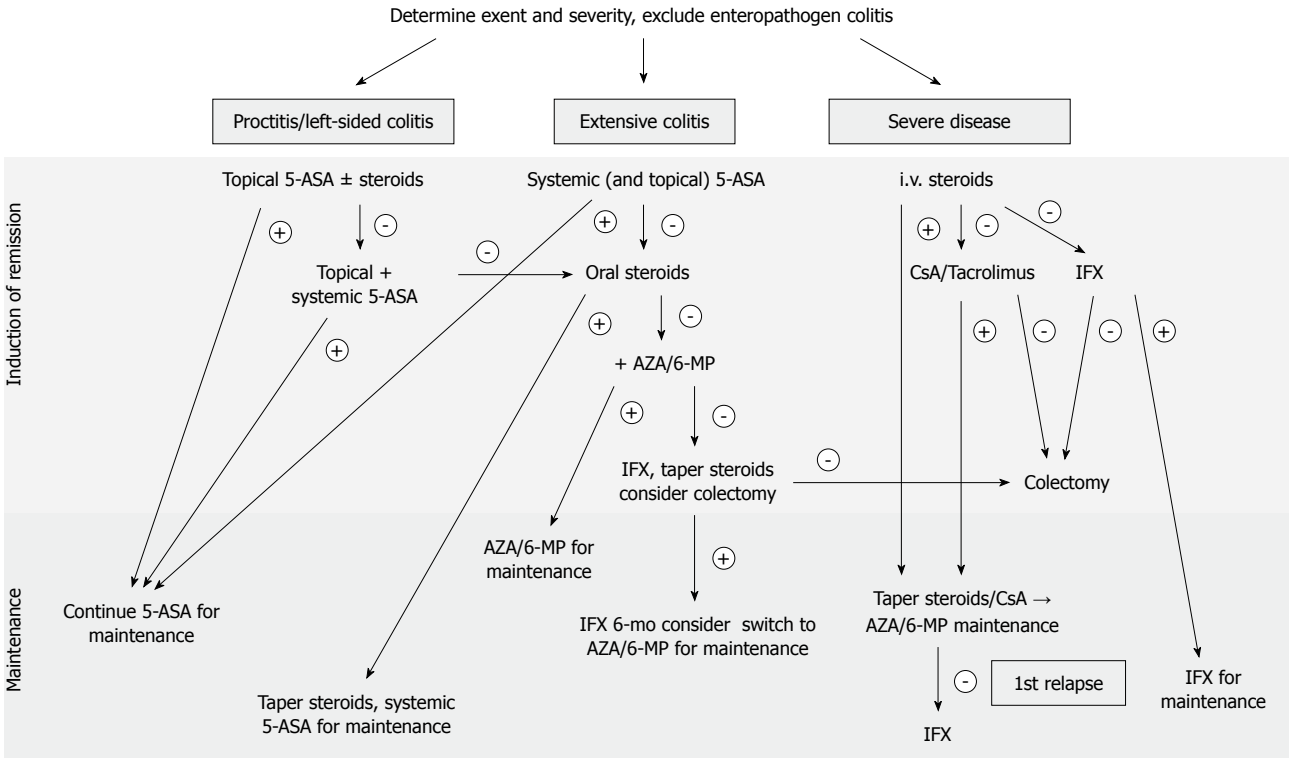

Figure 1 Treatment algorithm for ulcerative colitis. 5-ASA: 5-Aminosalicylic acid; AZA: Azathioprine; CsA: Cyclosporine A; IFX: Infliximab; 6-MP: 6-Mercaptopurine.

EL1b, RG B; ACG EL A) combined with > 2 g/d oral mesalazine. Comparative trials revealed a dose-response of oral mesalazine (< 2.4 g *vs* 4.8 g/d) with more rapid clinical improvement and cessation of rectal bleeding in patients taking a higher dose (16 d *vs* 9 d, $P < 0.05$), but failed to show significant differences in remission rates 20.2% *vs* 17.7% (not significant)[12,13]. Again, treatment escalation by a combination of topical mesalazine with oral 5-ASA and/or topical steroids is possible (ECCO EL 1b, RG B). If rectal bleeding persists after 10-14 d despite combined treatment, systemic steroids should be introduced (ECCO EL 1b, RG C; DGVS EL B; ACG EL C). The steroid starting dose is 40-60 mg orally once daily. Marked differences between 40 and 60 mg starting doses have not been found (DGVS EL A)[14], and steroid regimes differ depending on country and hospital. Without proven superiority, common regimes start with 40 mg prednisolone daily for 1 wk, followed by 30 mg/d for another week and 20 mg/d for 1 mo, before decreasing the dose by 5 mg/d per week. Concerns about possible steroid side effects have led to a more restrictive introduction of steroids in the US compared with European countries and the development of promising new oral steroid formulas with mainly colonic release and low systemic bioavailability (e.g. beclomethasone dipropionate, budesonide)[15,16].

Severe left-sided colitis is usually an indication for hospital admission and systemic therapy (ECCO EL 1b, RG B).

Extensive UC

Extensive UC of mild-to-moderate severity should initially be treated with oral sulfasalazine at a dose titrated up to 4-6 g/d (ACG EL A) or a combination of oral and topical mesalazine (ECCO EL 1a, RG A; DGVS EL A). However, oral 5-ASA formulas induce remission in only approximately 20% of patients[17]. Patients who do not respond to this treatment within 10-14 d or who are already taking appropriate maintenance therapy should be treated additionally with a course of oral steroids (ECCO EL 1b, RG C; ACG EL B). In the case of steroid-dependency (ECCO EL 1a, RG A) or steroid refractory course (ECCO EL 1a, RG B, ACG A), azathioprine (2.5 mg/kg per day) or 6-mercaptopurine (1.5 mg/kg per day) should be introduced for induction of remission and remission maintenance.

Severe UC

Severe UC is defined as more than 6 bloody stools per day and signs of systemic involvement (fever, tachycardia, anemia). These patients should be hospitalized for intensive treatment and surveillance (ECCO EL 5, RG D) as the development of a toxic megacolon and perforation is a potentially life-threatening condition. Intravenous steroids (e.g. methylprednisolone 60 mg/d or hydrocortisone 400 mg/d) remain the mainstay of conventional therapy to induce remission (ECCO EL 1b, RG D; DGVS C). Patients refractory to maximal oral treatment with prednisolone and 5-ASA can be given the tumor necrosis factor (TNF)-α blocker IFX at 5 mg/kg (ACG EL A).

Nevertheless, colectomy rates are as high as 29% in patients with severe UC and who need intravenous corticosteroids[18]. They should therefore be presented to the colorectal surgeon on the day of admission. It is crucial

that gastroenterologists and surgeons provide joint daily care in order to avoid delaying the necessary surgical therapy. In the case of a worsening condition or a lack of amelioration after 3 d of steroid therapy, colectomy should be discussed, since extending steroid therapy beyond 7 d without clinical effect carries no benefit[18], but causes otherwise preventable postoperative wound-healing disorders[19]. The response to intravenous steroids is best assessed by stool frequency, CRP and abdominal radiography on day 3 (ECCO EL 2b, RG B). If drug therapy fails, either proctocolectomy (DGVS EL C, ACG EL B) or rescue therapy with CsA (ACG EL A) is recommended.

In order to prevent immediate surgical therapy in corticoid resistant cases calcineurin inhibitors (CsA, tacrolimus) and IFX are available as second-line therapies, as detailed below.

Continuous intravenous CsA monotherapy with 4 mg/kg per day is effective and can be an alternative for patients with contraindications for corticosteroid therapy (e.g. a history of steroid psychosis, DGVS EL A). After successful induction of remission, an immunosuppressant such as azathioprine (2.5 mg/kg per day) should soon be added, CsA switched to oral therapy with tacrolimus and tapered over a period of 3-6 mo (DGVS C). Note that it may take up to 3 mo for the therapeutic effects of azathioprine and 6-mercaptopurine to develop. Neither CsA nor tacrolimus are indicated for maintenance therapy. Intravenous CsA achieves marked short-term responses in 50%-80% of patients receiving CsA as rescue therapy[20,21]. However, studies on long-term outcomes indicated that 58%-88% of these patients underwent colectomy within the following 7 years[21,22]. One major advantage of CsA over IFX in rescue therapy is its short half-life. If it proves ineffective it is cleared within a few hours, whereas IFX will circulate for weeks.

Tacrolimus is another calcineurin inhibitor given in an oral dose of 0.1-0.2 mg/kg per day or 0.01-0.02 mg/kg per day intravenously to achieve trough concentrations of 10-15 ng/mL[23]. A retrospective uncontrolled study indicated that lower trough levels of 4-8 ng/mL are also effective and are associated with fewer side effects[24].

Due to the elevated risk of opportunistic infection with *Pneumocystis jiroveci*, chemoprophylaxis is recommended in patients under triple immunosuppressive therapy (DGVS EL B). Possible regimes are trimethoprim-sulfamethoxazole 160/800 mg twice a week or, in case of intolerance, inhalation of 300 mg pentamidine once per month.

According to the ECCO and the newer ACG guidelines, IFX *may* be effective in the prevention of colectomy. In clinical practice it is widely considered a second choice due to its long half-life compared to CsA. Infliximab is given intravenously at a single dose of 5 mg/kg followed by scheduled infusions on weeks 2 and 6, and every 8 wk thereafter. One controlled trial on 45 patients with severe corticoid-refractory colitis compared IFX *versus* continued intravenous betamethasone. A significantly lower number of patients, 7/24 *vs* 14/21 ($P = 0.017$; odds ratio 4.9; 95% confidence interval (CI), 1.4-17), proceeded to colectomy within 3 mo with IFX[25]. In a recent trial of infliximab IFX as rescue therapy in tacrolimus-refractory patients with active UC, about a quarter of patients (6 of 24) responded to IFX[26]. Nevertheless, effectiveness is not yet proven, as the present number of case series of infliximab IFX rescue therapy in steroid-refractory severe extended colitis is small, with wide differences concerning colectomy rates (20% to 75%)[27,28]. Patients who required IFX to induce remission should receive regular maintenance therapy with IFX for at least 6 mo. Adalimumab, a fully humanized TNF-α blocker, is not yet available for the treatment of UC.

Selective physical apheresis of activated immune cells involved in the inflammatory process of UC (leukocytapheresis) is an alternative strategy proposed for the treatment of active UC, but its role remains controversial. Although trials in Japan showed leukocytapheresis to be equal to corticoid treatment for inducing remission while displaying fewer side effects[29,30], the most recent study of an international cohort did not show significant differences in clinical outcome between the apheresis- and sham-treatment groups[31].

Only a small amount of data is available on methotrexate (MTX) for induction of remission. The only randomized placebo-controlled study did not show any effect in UC. Neither did a comparative study of 6-mercaptopurine, oral MTX or 5-ASA additional to prednisolone in 34 steroid-dependent UC patients, with remission rates of 58.3% in the MTX group compared with 35% in the 5-ASA group ($P > 0.5$). This disappointing effect may result from the very low doses of MTX (15 mg/kg per week) administered orally in both studies. Although existing guidelines do not generally recommended MTX, in individual cases therapy with an initial dose of 25 mg/wk followed by dose reduction to 15 mg/wk after achieving remission can be tried. Significant side effects (hepatotoxicity, bone marrow depression, MTX-induced lung injury) should be monitored and strict contraception performed (risk of teratogenicity). In order to reduce side effects 5 mg oral folic acid given on the morning after MTX administration is effective and safe[32].

Adjuvant therapeutic considerations in severe UC

Antibiotic therapy is only recommended if infection is considered (DGVS EL A). Application of metronidazole or tobramycin has not shown consistent benefit in severe UC[33-35]. Patients should be given enteral nutrition if tolerated and subileus/ileus are absent (DGVS EL B/C) since bowel rest in acute colitis did not alter the outcome and enteral nutrition was shown to be associated with significantly fewer complications (9% *vs* 35%)[36].

Prediction of outcome and surgical therapy

In a recent population-based European study, the global risk of colectomy in UC was 8.7% over 10 years. Efforts have been made to identify patients who are at high risk of not responding adequately to pharmacological therapy. In Crohn's disease, factors such as young age at first di-

agnosis, early steroid use, ileal disease, mucosal healing, and smoking were identified as important for developing disabling disease or for major abdominal surgery[37]. Much less is known in UC. According to data from different population-based studies, including the recent 10-year data from the Norwegian IBSEN cohort, initial extensive colitis, elevated ESR (> or = 30 mm/h) and sclerosing cholangitis were associated with an increased risk of colectomy[38-40]. In contrast, older age at disease onset (> or = 50 years)[40] and smoking[41,42] reduced the risk of subsequent colectomy. In a prospective study evaluating 49 hospitalized patients with severe UC, patients treated with steroids and/or CsA, a stool frequency of > 8/d or 3-8 stools/d, and increased CRP (> 0.45 mg/L) on day 3 predicted the need for colectomy with 85% certainty[43]. Further work to identify predictive parameters of refractory courses should help to prevent a delay in inevitable surgical therapy.

Emergency indications for surgery includes refractory toxic megacolon, perforation and continuous severe colorectal bleeding (ACG EL C)[44,45]. In this situation the recommended operation is colectomy and ileostomy, leaving the rectum *in situ*, since reconstruction is not an option in the acute setting (ECCO EL 4, RG C).

Elective surgery is indicated in chronic continuous colitis refractory to immunosuppressive treatment, detection of dysplasia or malignancy, and stricturing disease causing partial or total intestinal obstruction. In elective surgery common surgical therapy is total proctocolectomy with ileal J-pouch anal anastomosis (IPAA). Although with IPAA a curative therapy for UC is available, high rates (up to 20%) of postoperative complications with abscesses, sepsis, fistulas[46], and postoperative impaired fertility and sexual function are unsolved problems[47,48]. Ileorectal anastomosis is a temporary alternative in selected cases (e.g. young women who have not had children), but harbors the risk of disease recurrence and/or cancer development in the remaining rectal segment[45].

MAINTENANCE OF REMISSION

Remission is clinically defined by 3 or less stools per day without any presence of blood or increased urgency of defecation. The major goal of maintenance therapy is a steroid-free remission to avoid severe and partially disabling long-term side effects of corticoid treatment. Continuing medical therapy that does not achieve this goal is therefore not recommended and should be changed (ECCO EL 5, RG D). More than half of patients with UC have a relapse in the year following a flare. In a recent population-based outcome survey conducted in Copenhagen with a cohort of 1575 patients with newly diagnosed UC, 13% had no relapse within the following 5 years, 74% had less than 5 relapses and 13% suffered an aggressive course with more than one relapse per year[49]. Maintenance treatment is therefore recommended for all patients (ECCO EL 1a, RG A), but intermittent therapy is also acceptable for a few patients with an indolent course of the disease.

First line therapy for maintenance of remission is 5-ASA administered orally or (in the case of left-sided colitis) rectally[13,50]. All the available different 5-ASA preparations are effective and no convincing data are available favoring any specific preparation. Sulfasalazine, an azo-bound combination of mesalazine and sulfapyridine, is equally or even slightly more effective. While the ACG guidelines recommend it for induction as well as remission therapy, the European guidelines reserve its use for induction and maintenance therapy in patients with additional joint manifestations due to its higher toxicity (ECCO EL 1a, RG A). First-line medical therapy for proctitis and left-sided colitis consists of topical 5-ASA with a minimum dose of 1 g 3 times a week (ECCO EL 1b, RG B; ACG EL A). Oral mesalazine can be added as second-line therapy and has been shown to be superior compared with monotherapy (ECCO EL 1b, RG B), or it can be given alone if long-term rectal treatment is not accepted by the patient. For extensive disease, oral mesalazine is the therapy of first choice. It is effective and well tolerated at doses > 800 mg/d for maintenance of remission[13], although a clear dose-response effect has yet to be established.

Compliance is a key factor in disease control and maintenance of remission. In an internet-based survey of 1595 UC patients receiving 5-ASA therapy, major reasons for poor compliance were identified as 'too many pills' and 'dosing required too many times each day'[51]. In a prospective survey in Michigan only 71% of the originally prescribed medical therapy was finally taken by the patients included in the study[52]. A new generation of aminosalicylates with prolonged release formulations has been engineered over the last few decades (e.g. Eudragit-S-coated, pH-dependent mesalamine, ethylcellulose-coated mesalamine, and multimatrix-release mesalamine). All three currently available trials comparing a once *versus* a twice daily dose of prolonged release mesalamine for maintenance of remission in mild-to-moderate UC did show non-inferiority or even superiority of a once daily medication, in part due to increased compliance[53-55]. Once daily dosing of a prolonged release formulation could therefore be a promising approach to further reduce recurrent flares in maintenance therapy.

In case of side effects of the 5-ASA treatment with the probiotic strain *Escherichia coli Nissle* is an alternative for maintenance of remission with comparable efficacy (ECCO EL 1b, RG A)[56,57].

Azathioprine and 6-mercaptopurine are indicated as steroid-sparing agents for steroid-dependent patients or for patients not adequately sustained and with frequent relapses under aminosalicylate treatment (ECCO EL 5, RG D; ECCO EL A). The optimal dose (1.5-2.5 mg/kg per day) can be taken once daily. Therapy should be monitored by a leucocyte count of lower than 4.5×10^9/L but higher than 2.5×10^9/L. If remission is successfully induced it is recommended to continue maintenance therapy for at least 3-5 years[58,59], although there is no hard evidence on the optimal duration of treatment. Side effects such as bone marrow suppression, progressive elevation of lever enzymes, toxic pancreatitis may

occur (usually within the first weeks) and require immediate termination of azathioprine treatment. A 3-fold increased risk of opportunistic infection is estimated under azathioprine therapy, especially when used in conjunction with IFX and steroids[60].

IFX is effective in maintaining improvement and remission and is therefore recommended for those patients who initially respond to the IFX induction regime (ECCO EL 1b, RG A)[61]. The standard IFX dose is 5 mg/kg. Higher initial treatment doses have not been shown to be of any benefit. As shown for Crohn's disease, 25%-40% of patients with initial response to IFX develop loss of response and benefit from dose escalation to 10 mg/kg or shortening dosing intervals during further therapy[62,63].

For maintenance therapy, scheduled intravenous administration every 8 wk has been proven to be more effective and safer than periodic application, probably due to a reduced formation of antibodies (ABs) against anti-TNF agents[64,65]. Most infusion reactions are mild-to-moderate and consist of flushing, headaches, dizziness, chest pain, dyspnea, fever or pruritus. Halting or lowering the infusion rate often provides relief. In order to prevent adverse reactions and AB formation, premedication with steroids prior to IFX administration is recommended (ECCO EL 2, RG C)[66]. Serious infection occurred in approximately 3% of patients treated with IFX in the ACT 1 and ACT 2 trials[61]. Although the information available from meta-analyses, from IFX safety registries in Crohn's disease, and from IFX therapy in rheumatoid arthritis differ widely, a 3-fold higher rate of opportunistic infectious under IFX therapy is estimated[67-70]. In order to prevent reactivation of latent infection, exclusion of latent tuberculosis and hepatitis B should be performed by chest radiography, serologic testing, skin test and/or lymphocyte stimulation test (QuantiFERON-TB Gold®).

There is no existing recommendation on the duration of IFX treatment in stable remission. In stable long-term remission, interruption of IFX treatment while continuing 5-ASA or switching maintenance therapy to azathioprine/6-mercaptopurine are possible de-escalation approaches.

MTX for maintenance therapy can be considered in individual cases, especially when other immunosuppressants are not tolerated. Furthermore, patients with refractory arthropathy may benefit. Because the available data are restricted to one randomized prospective study[71] and several retrospective series with a total of only 91 patients[72-74], no consensus recommendation for MTX in UC is given[6].

ALTERNATIVE AND FUTURE TREATMENTS

Several alternative therapies have emerged for the treatment of UC. Ova of the non-pathogenic helminth *trichiuris suis* taken orally has shown initial success in a double-blind placebo-controlled trial, inducing remission in 43% of patients taking ova compared with 16.7% in the placebo group[75]. Transdermal administration of nicotine was proposed as being effective in active UC. A systematic review and analysis of 5 relevant studies demonstrated its effectiveness in achieving remission compared with placebo. However, direct comparative trials with 5-ASA are still missing. Omega-3 fatty acids, which are largely present in fish oil, have shown anti-inflammatory properties by reducing the production of leukotriene B_4[76]. However, in a meta-analysis of the 3 available studies on 138 UC patients in remission, no evidence was found to support the use of omega-3 fatty acids for maintenance of remission as similar relapse rates were found in the study group and the placebo group (relative risk, 1.02; 95% CI, 0.51-2.03; $P = 0.96$)[77]. Taken together, due to a lack of data on efficacy, safety and adverse events, no recommendation is given for the therapies mentioned above.

Advances in the field of biological therapy focus on novel target molecules and alternative means of administration, some of which have already been approved for the treatment of Crohn's disease. Further TNF-α AB preparations include certolizumab, etanercept and adalimumab - approval of the latter for the treatment of UC could be expected this year. Other biologicals such as natalizumab (anti-α4-integrin AB), visilizumab (anti-CD3 receptor AB), fontolizumab (anti-interferon gamma AB), alicaforsen (anti-sense oligonucleotide to human ICAM1), basiliximab (IL-2 receptor AB), anti-IL12 ABs and anti-IL-6 ABs have in part been tested in acute steroid-refractory UC but data on maintenance of remission are not available as yet.

RECOMMENDATIONS FOR CANCER SURVEILLANCE

Patient with UC have an elevated risk of developing colon cancer. After 8-10 years of colitis, annual or biannual surveillance colonoscopy with multiple biopsies at regular intervals should be performed (ACG EL B; ECCO EL5, RGD). Detection of high grade dysplasia in flat mucosa has to be confirmed by a second pathologist and is an indication for colectomy (ACG EL B; ECCO EL2, RG B).

The sensitivity of random biopsies is a matter of debate and uncertainty as dysplasia in flat mucosa can be easily overlooked. Implementation of advanced endoscopic imaging techniques such as high-resolution white-light endoscopy, autofluorescence and narrow-band imaging may help to better identify pathological lesions and optimize cancer surveillance in inflammatory bowel disease in the future[78-80].

Abstract

Crohn's disease (CD) is a chronic inflammatory disease of the digestive tract with systemic manifestations. Etiology is unknown, even if immunological, genetic and environmental factors are involved. The majority of CD patients require surgery during their lifetime due to progressive bowel damage, but, even when all macroscopic lesions have been removed by surgery, the disease recurs in most cases. Postoperative management represents therefore a crucial mean for preventing recurrence. Several drugs and approaches have been proposed to achieve this aim. Endoscopic inspection of the ileocolic anastomosis within 1 year from surgery is widely encouraged, given that endoscopic recurrence is one of the greatest predictors for clinical recurrence. A strategy should be planned only after stratifying patients according to their individual risk of recurrence, avoiding unnecessary therapies when possible benefits are reduced, and selecting high-risk patients for more aggressive intervention.

Key words: Crohn's disease; Recurrence; Postoperative treatment; Surgery; Surveillance

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disease of the digestive tract with associated several systemic manifestations. Etiology of CD seems to be multifactorial, which results from an interaction of genetic susceptibility, immunological dysregulation of the mucosal immune system, gut microflora and environmental factors, but the final cause remains still unknown. Pathologically, CD is characterized by non-caseating granulomas and transmural inflammation, which can affect all the digestive tract from the mouth to the anus[1]. The most commonly affected sites are the ileum and ascending colon and the disease recurs in most cases after surgical resection of macroscopically affected segments[1]. For this reason, almost all studies on postoperative recurrence are primarily focused on ileocolic disease. CD patients have a high likelihood of undergoing repeated surgery for disease recurrence during their lifetime, with risk for short bowel syndrome: surgery in these patients is as conservative as possible in order to reduce this risk. Two distinct approaches are possible in clinical practice for postoperative CD management: starting prophylactic medical therapy after surgery, which aims to avoid or postpone recurrence;

or waiting for endoscopic recurrence, and eventually starting or adapting medical therapy before the patient becomes symptomatic. Both these strategies are rational and can be indicated in specific situations. Recurrence risk assessment after surgery is critical for correct decision making about medical prophylaxis and surveillance, and has to consider many different variables. Regueiro *et al*[2] have considered three grades of recurrence risk: (1) very low, defined as long-standing, first surgery, short stricture; (2) low-moderate, i.e. < 10-year-long history of CD, presence of a long stricture or any case of inflammatory CD; and (3) high risk, defined as presence of penetrating disease or patients with repeated intestinal resection (more than twice). Those patients may require a more aggressive approach[2]. This review provides an overview on this relevant and debated clinical topic.

NATURAL HISTORY

Schofield introduced the definition of "natural history" for ulcerative colitis first and later for regional enteritis[3]. The natural history of CD is characterized by the progression of bowel injury, which leads to surgery in up to 80% of patients during their lifetime[4]. Surgery in CD is not curative, even when all of the macroscopic disease has been removed. Disease recurrence typically presents at an anastomotic site, mostly in the preterminal ileum in patients with previous ileal involvement[4]. Endoscopic surveillance programs for operated CD patients has led to identification of endoscopic lesions (endoscopic recurrence) that, in most cases, precede clinical symptoms (clinical recurrence). Clinical recurrence rates and reoperation rates increase over the years: about 80% of patients will experience clinical recurrence within 20 years from surgery, and about 50% will undergo repeated surgery during the same time in most series[4,5].

Regarding location, CD tends to be stable, since only about 6.5% of the patients will experience a change of site in disease involvement over time[4]. Henriksen has investigated the changes in disease location in the Inflammatory Bowel South-Eastern Norway (IBSEN) population-based study. Of 200 CD patients, only 14% changed affected site after 5 years[6].

It has to be underlined that biological therapies are relatively new in the management of CD, and most of the studies on CD natural history refer to an era when the efficacy of medication was lower compared to the present. Anti-tumor necrosis factor (TNF)-α antibodies like infliximab and adalimumab show strong efficacy in inducing mucosal healing: they could possibly modify the natural history of the disease, but data on reduction of the need for repeated surgery in the long-term are still not available. Data from clinical trials in inflammatory bowel diseases (IBD) patients treated by anti TNF-α show that scheduled therapy significantly reduces the risk of hospitalization and surgery related to CD up to 55 mo on average[7,8]. There is then a reasonable perspective that scheduled therapy by infliximab or adalimumab might prevent or delay postoperative recurrence in high-risk patients, with a significant change in the natural history of the disease, although further large prospective studies focused on this topic are needed.

Today, surgery remains part of the clinical history of CD patients[9,10]. In recent years, laparoscopic surgery is gaining a place in the surgical treatment of CD, especially for ileocecal disease[4].

The assessment of activity, severity and complications of CD that may require surgical procedures remains a big challenge for physicians. Different kinds of objective measures of those parameters are available, but none of them is comprehensive for all aspects of the disease. The Crohn's disease activity index (CDAI)[11] and the Harvey-Bradshaw index[12] are commonly used to assess the activity and severity of the disease, but they can be affected by other non-CD gastrointestinal or extraintestinal disorders that may affect the correct evaluation of the disease. These scores do not include the endoscopic features of the disease that can be measured using two other different scores: the Crohn's Disease Endoscopic Index of Severity[13] and the Simplified Endoscopic Score-Crohn's Disease[14]. Other methods to assess disease activity include the level of fecal markers, such as fecal calprotectin, fecal lactoferrin and polymorphonuclear neutrophil elastase, which are produced in the course of bowel inflammation, and that can be detected in fecal samples. They have been shown to be more sensitive, specific and accurate than C-reactive protein in differentiating active from inactive disease, and to distinguish between CD-related symptoms and irritable bowel syndrome[15]. These non-invasive biomarkers can also be used in the postoperative follow-up in order to distinguish bowel symptoms related to mechanical causes (such as shortening of the small bowel, colonic resection, bile salt diarrhea) from a clinical recurrence of CD. None of these tools is comprehensive for all aspects of CD; therefore, a new global score that considers clinical, endoscopic, radiological parameters and surgical history to assess the disease activity, severity and organ damage is urgently needed.

CD RECURRENCE

Definition

Recurrence is defined as reappearance of lesions after complete surgical resection[16]. Recurrence can be assessed by endoscopy, radiology or surgery. Clinical recurrence is defined as the appearance, after complete resection of macroscopic disease, of CD symptoms, which confirms recurrence of the lesions[16]. This confirmation is important because postoperative recurrence-like symptoms may be due to causes other than CD, such as motility disturbances or bile malabsorption.

Endoscopic assessment

The severity of recurrence assessed by endoscopy is the best predictor of clinical outcome in postoperative CD[17-21]. In order to correlate the endoscopic findings with the risk of clinical recurrence, Rutgeerts has validated an endoscopic scoring system to be assessed at the first ileocolonoscopy, 6-12 mo after surgery: it divides patients into

Table 1 Endoscopic recurrence score as reported by Rutgeerts *et al*[17]

Endoscopic score	Definition
i0	No lesions
i1	≤ 5 aphthous lesions
i2	> 5 aphthous lesions with normal mucosa between the lesions, or skip areas of larger lesions, or lesions confined to the ileocolic anastomosis
i3	Diffuse aphthous ileitis with diffusely inflamed mucosa
i4	Diffuse inflammation with already large ulcers, nodules, and/or narrowing

Remission: Endoscopic score i0 or i1; Recurrence: Endoscopic score of i2-i4.

five groups (i0-i4, see Table 1)[17], according to the severity of endoscopic lesions; in the i0-i1 group, there is < 5% recurrence at 3 years; in i2, about 15%; in i3, 40%; and i4, > 90%[17]. The most common endoscopic lesions are aphthous ulcerations that are located in the neoterminal ileum near to the anastomotic area[17]. In the absence of treatment, such lesions can evolve into large ulcerations or tight strictures: Rutgeerts has reported that only 20% of these patients become clinically symptomatic within 1 year after surgery[17]. Symptoms develop only after a lesion has been established, and it is not uncommon to find endoscopic severe lesions in an asymptomatic patient. Clinical scoring systems such as the CDAI may therefore be of little help in identifying patients with postoperative recurrence[22].

Risk factors

Most patients experience disease recurrence over time, but long-term medical strategies for prevention of recurrence can carry various risks: risk-benefit analysis should be individualized to each patient. Identification of risk factors for CD recurrence is therefore extremely important in order to identify high-risk patients, who are more likely to benefit from an aggressive therapeutic strategy.

Several factors have been studied as possible contributors to CD recurrence, including age, sex, cigarette smoking, age at onset of disease, duration of disease, anatomical site, extent and severity of disease, previous surgery, and disease phenotype, disease-free margins, anastomotic technique, blood transfusion, and occurrence of complications.

Among these many factors, the following have been shown to predict early recurrence in the majority of studies: smoking[23], prior intestinal surgery (including appendectomy)[24], penetrating disease behavior[25], perianal involvement, and extended small bowel resection (> 100 cm)[26]. Absence of prophylactic therapy is associated with early relapse (defined as a flare of symptoms)[27].

Reese *et al*[28] in a recent meta-analysis have reported that clinical relapse occurred in 58.3% of smoking patients, compared with 39% of non-smokers ($P < 0.005$). The 5-year reoperation rate was higher among smokers, but not significantly (34.2% *vs* 31.1%); however, this difference becomes significant when considering the 10-year reoperation rates: 55.5% in smokers and 17.5% in non-smokers ($P < 0.04$)[28]. No differences were noted between ex-smokers and non-smokers[28].

Data about sex, age at onset of the disease, duration of the disease, resection margins, type of surgery are discordant and inconclusive[27].

POSTOPERATIVE MANAGEMENT STRATEGIES

General management

Postoperative management of CD represents a hard challenge. Stratifying patients according to their risk is essential: not all the patients benefit from maintenance therapy, and a patient at high risk of recurrence requires a different, stronger therapy than others. Cigarette smoking is consistently correlated with CD recurrence and, among the known related risk factors, it is the only potentially modifiable factor[29]. Therefore, as a first step for preventing recurrence, it should be stressed to every patient the importance to stop smoking after surgery for CD[29]. Smoking cessation decreases risk to the level of that of non-smokers[28].

Drug prophylaxis of recurrence

Prophylactic drugs have considerable costs and risks, with limited efficacy[4]. It has to be underlined that there is currently no evidence that, in terms of reduction of hospitalization or need for surgery, prophylactic therapy gives any advantage over a strategy of surveillance with prompt treatment of recurrence[4]. An overview of the most important drugs used to prevent recurrence follows.

5-Aminosalicylic acid: 5-Aminosalicylic acid (5-ASA) has been extensively studied in postoperative management of CD. Lochs *et al*[30] and Florent *et al*[31] have treated patients with 5-ASA (mesalazine 4 g/d) or placebo for > 18 mo postoperatively, and have shown that clinical recurrence rates are lower in the 5-ASA group (24.5% *vs* 31.4%), although the difference was not statistically significant. In a study by Florent *et al*, mesalazine (2.4 g/d) did not significantly reduce endoscopic recurrence rates at 12 wk (50% *vs* 63%)[27]. Ewe *et al*[32] have demonstrated that sulfasalazine (3 g/d) significantly reduces clinical recurrence rates at 1 year (16% *vs* 28%, $P < 0.01$), with effects maintained at 2 years. Endoscopic recurrence has been shown to occur more rarely after 12 mo mesalazine treatment (3 g/d); however the clinical recurrence rates were similar in the two groups[33]. In a recent double-blind trial, two groups were randomized to receive 4 g or 2.4 g/d of mesalazine at 2 wk after surgery. At 12 mo, endoscopic recurrence was higher in the second group, although clinical recurrence rates were similar in both groups[12]. The current evidence seems to indicate that 5-ASA is generally safe in postoperative CD prophylaxis, even if it seems to provide, at best, only a small reduction in clinical and endoscopic recurrence[1].

Antibiotics: Two randomized clinical trials[34,35] have

evaluated antibiotic therapy in the prevention of CD recurrence after surgery. In the first study, patients treated with metronidazole (20 mg/kg per day, for 3 mo after surgery) had a reduced incidence of severe endoscopic recurrence after a follow-up of 1 year (4% *vs* 25%), but experienced a three times higher incidence of side effects than the placebo group (23.3% *vs* 6.7%)[36]. Similar results were obtained by another study by the same group on another nitroimidazole antibiotic, ornidazole (1 g/d), administered for 1 year: recurrence rates were reduced at 1 year, but not maintained at 2 and 3 years. The therapy in these studies was not well tolerated. Nitroimidazole antibiotics have shown efficacy in reducing severe endoscopic recurrence in the short- and medium-term and can be eventually associated with other treatments in the first postoperative period[1]. The possible use of other more tolerable antibiotics such as rifaximin or ciprofloxacin has still to be evaluated.

Budesonide: Two large randomized clinical trials have found that oral budesonide is ineffective in reducing postoperative recurrence rates after surgery for CD[37]. Ewe *et al*[32] have found that endoscopic and clinical recurrences after 1 year were not significantly different when comparing budesonide to placebo treatment; Hellers *et al*[38] have not found differences between the two groups at 3 and 12 mo regarding endoscopic recurrence rates.

Immunomodulators: The thiopurines azathioprine (AZA)/6-mercaptopurine (6-MP) have proven efficacy and are widely recommended for postoperative prophylaxis of recurrence after surgery for CD. Ardizzone *et al* have demonstrated that patients after surgical resection benefit more from AZA than mesalazine for prevention of clinical recurrence, despite the side effects experienced by patients in the AZA group (22% *vs* 8% compared to the mesalazine group)[1]. Hanauer *et al*[36] have found that clinical recurrence at 2 years was 50% in the 6-MP group, 58% in the mesalazine, and 77% in the placebo group. In this study, only 69% of patients assigned to 6-MP was able to complete the treatment, because of the significant side effects. A recent meta-analysis of four controlled studies of AZA for recurrence prohylaxis has demonstrated its efficacy for reducing the incidence of overall recurrence at 12 mo. On the other hand, the rate of adverse events leading to therapy withdrawal was higher in the AZA group than in the control groups[39]. Thiopurines have been shown to be more effective than mesalazine for prevention of postoperative recurrence, despite the higher rate of side effects reported[1].

Anti-TNF agents: There is only one randomized, double-blind, placebo-controlled trial that has assessed the efficacy of infliximab for reducing postoperative recurrence rates after ileocolic resection[2]: 24 patients were randomized to receive 5 mg/kg infliximab with a standard three-dose induction and a maintenance dose once every 8 wk, for 1 year, versus placebo. In the infliximab group, 9.1% developed endoscopic recurrence compared with 84.6% in the placebo group (P = 0.0006). Infliximab patients experienced a significantly lower risk of endoscopic, histological and clinical recurrence at 1 year[2]. No data are available about other anti-TNF agents for preventing CD recurrence after surgery.

Other therapies

Different types of probiotics have been evaluated, but none of them has showed a significant effect over placebo in preventing recurrence. There is no evidence for the use of other agents such as synbiotics or interleukin-10 for preventing CD recurrence after surgery[40-44].

Endoscopic surveillance strategy

Surgery for CD treats complications such as strictures, abscesses or fistulae, but it cannot interrupt the course of the disease. Postoperative recurrence rate in absence of treatment reaches 65%-90% within 12 mo and 80%-100% within 3 years from surgery[27], with an increase of 22%-25% per year[19,45]. Moreover, about 50% of the patients will need reoperation within 10 years after the first bowel resection[9,16,24-26,46,47]. It is therefore important to plan a surveillance of the patient after having assessed their risk of recurrence and chosen the most indicated treatment.

The CDAI can be used to assume the possible activity of the disease, but in postoperative settings it does not reach a sufficient sensitivity to predict disease recurrence accurately: patients with a high CDAI may be completely asymptomatic[22]. Fecal markers can play a role, but their use for this particular indication needs further investigation.

Rutgeerts *et al*[47] have developed a validated endoscopic score to measure the postoperative recurrence and stratify patients, according to their endoscopic findings, in five categories, already described (see Table 1 for details). The severity of endoscopic lesions correlates with the risk of disease progression. Endoscopic signs of recurrence do appear before symptomatic disease, which allows early treatment that may be effective in modifying the natural course of the disease, preventing clinical recurrence and possibly, the need for new surgery.

Patients presenting with no or minimal endoscopic lesions (endoscopic score i0-2) may not benefit from therapy; on the contrary, severe endoscopic recurrence (endoscopic score i3-4) should promote aggressive therapy. Based on correlation data between endoscopic lesions and clinical recurrence, and on data about risk factors for postoperative CD recurrence, patients can be considered at low risk if their disease is long-standing, mainly fibrostenotic, and involves a limited bowel segment; on the other hand, all other patients, especially active smokers, with prior intestinal surgery, perianal disease, perforating and inflammatory disease, who have undergone extensive bowel resection should be considered at high risk for recurrence. It can be a rational strategy to wait to treat low-risk patients until performing the first ileocolonoscopy, 6 mo to 1 year postoperatively, and reserving the immediate start of postoperative prophylactic therapy (with thiopurines or anti-TNF) for high-risk patients. For low-risk patients, if there is endoscopic recurrence at ileocolonoscopy, im-

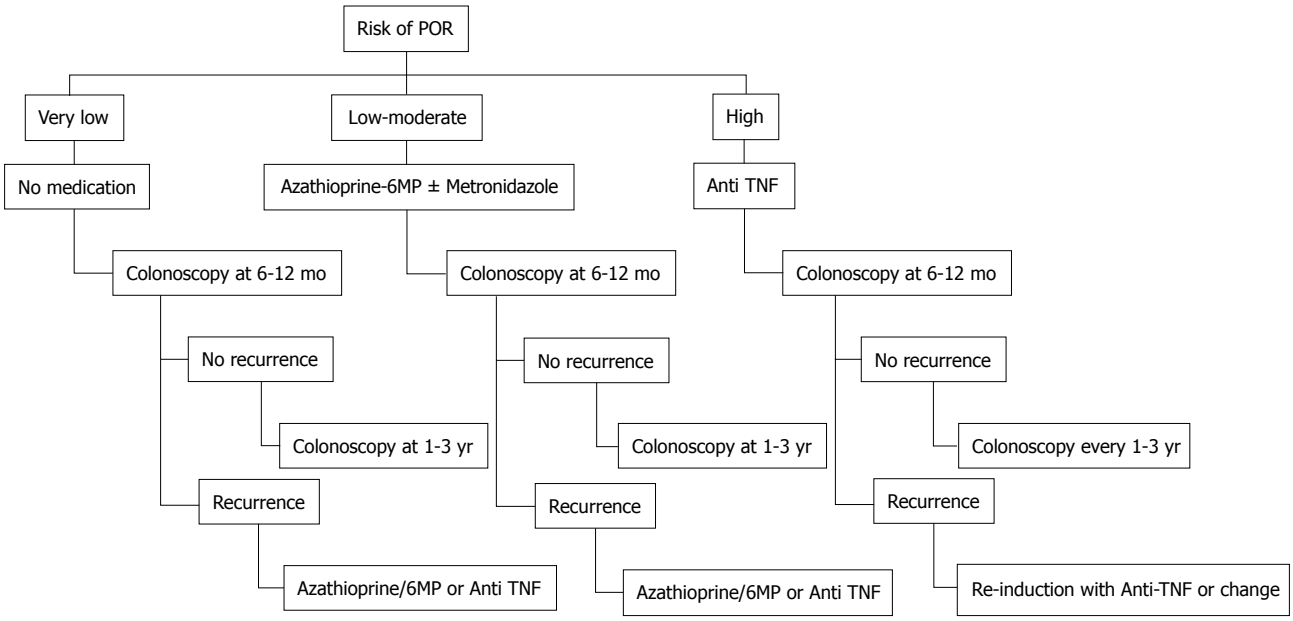

Figure 1 Flow-chart for treatment of postoperative recurrence of CD (adapted from Regueiro[29]). 6-MP: 6-mercaptopurine; TNF: Tumor necrosis factor; POR: postoperative recurrence.

munomodulatory or anti-TNF therapy could be started; if negative, only a new endoscopic surveillance can be performed 1-3 years later. Further optimization or modification of therapy could be performed according to the severity of endoscopic lesions, repeating ileocolonoscopy after another 6-12 mo. For patients at high risk of recurrence, thiopurines or anti-TNF treatment is recommended, starting a few weeks after surgery; if endoscopic controls during surveillance reveal recurrence of disease, it is possible to intensify the dose or switch to another agent[29].

Surgical strictureplasty represents a valid treatment for most patients with small bowel strictures, while its role in duodenal and colonic disease remains debated[48]. A recent meta-analysis by Yamamoto *et al*[48] has shown that younger age, short duration of the disease, and short interval from previous resection can increase the risk of recurrence. Differently form what previously reported[49], the most recent evidence has shown that the number of strictures and strictureplasties do not affect the risk of recurrence[48]. Except for the duodenum and the last ileal loop, small bowel is difficult to be explored endoscopically; therefore, data regarding the CD recurrence are focused on ileocecal resection, and there is no evidence that medical management or timeline for surveillance after strictureplasty is different than in patients undergoing ileocecal resection.

CONCLUSION

CD recurrence after surgery is very frequent. Identification of risk factors for recurrence is extremely important in order to stratify patients according to their risk, identifying those who can benefit from an aggressive medication regimen, possibly modifying the natural course of the disease. If postoperative prophylaxis of recurrence is indicated, then thiopurines (eventually with metronidazole) and anti-TNF agents are the most effective choices. Ileocolonoscopy within 1 year of surgery, regardless of the eventual postoperative treatment, is widely recognized as the best tool for early detection of CD recurrence, allowing tailoring the appropriate therapy to the individual patient. A summary of the suggested management of postoperative recurrence is shown in Figure 1. Cooperation between gastroenterologists, endoscopists and surgeons is desirable in order to assess the risk of recurrence, to plan postoperative surveillance (not limited to symptomatic flares), and to offer the most appropriate treatment strategy to the patient. Which approach would be better for treating and preventing postoperative recurrence of CD remains debatable.

Abstract

AIM: To investigate the expression levels of lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1), vascular endothelial growth factor receptor-3 (VEGFR-3) and CD44 genes and the relationship between their levels and clinicopathological parameters in gastric cancer.

METHODS: Tissue samples were obtained from 33 patients (8 females) with gastric cancer. mRNA levels of LYVE-1, VEGFR-3 and CD44 in normal and tumor tissues were quantitatively measured using real time polymerase chain reaction. The results were correlated with lymph node metastasis, histological type and differentiation of the tumor, T-stage, and presence of vascular, perineural and lymphatic invasions. The distribution of molecules in the tissue was evaluated using immunohistochemistry.

RESULTS: LYVE-1, CD44 and VEGFR-3 gene expression levels were significantly higher in gastric cancer than in normal tissue. While there was no correlation between gene expressions and clinicopathologic features such as histologic type, differentiation and stage, gene expression levels were found to be increased in conjunction with positive lymph node/total lymph node ratio and the presence of perineural invasion. A significant correlation was also found between LYVE-1 and CD44 over-expressions and perineural invasion and lymph node positivity in gastric cancers. When the distribution of LYVE-1 antibody-stained lymphatic vessels in tissue was evaluated, lymphatic vessels were located intra-tumorally in 13% and peri-tumorally in 27% of the patients. Moreover, lymph node metastases were also positive in all patients with LYVE-1-staining.

CONCLUSION: LYVE-1, VEGFR-3 and CD44 all play an important role in lymphangiogenesis, invasion and metastasis. LYVE-1 is a perfectly reliable lymphatic vessel marker and useful for immunohistochemistry.

Key words: CD44; Gastric cancer; Lymphatic metastasis; Lymphatic vessel endothelial hyaluronan receptor-1; Metastasis; Vascular endothelial growth factor receptor-3

INTRODUCTION

Gastric cancer is the second most common cause of cancer deaths worldwide[1]. As the stage of disease has definitive influence on survival, earlier diagnosis is highly critical. Lymphatic spread of gastric cancer cells to regional lymph nodes is one of the earliest events associated with distant metastasis and poor prognosis[2]. Depth of invasion, lymph node metastases and presence of distant metastases have all been found to be essential prognostic factors[3]. Vascular endothelial growth factor receptor-3 (VEGFR-3) is a tyrosine kinase receptor and is expressed in lymphatic endothelial cells. Increased VEGFR-3 expression correlates with regional lymph node metastasis in colorectal cancers[4-6]. In particular, VEGF-D and VEGFR-3 were recently reported to be independent prognostic markers in gastric cancer, and VEGF-D was found to be correlated with lymphatic metastasis[7]. Many factors have recently been proposed as markers for lymphatic endothelium. Lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) is the lymphatic vessel endothelial hyaluronic acid (HA) receptor, located in lymph nodes and in the luminal and abluminal surfaces of lymphatic vessels. LYVE-1 is very effective in the passage of lymphocytes and tumor cells into the lymphatics[8,9]. CD44 is another cell surface receptor for HA, expressed by lymphocytes, macrophages and tumor cells. CD44 is also responsible for the passage of lymphocytes and tumor cells into the lymphatics, similar to LYVE-1[10]. LYVE-1 has 43% similarity with CD44 but its specificity to HA is higher than that of CD44[11]. Quantification of the lymphatic vessel density (LVD) in the tumor might also be important for the evaluation of lymphangiogenesis and lymphatic metastasis[11].

The present study aimed to investigate the expression levels of LYVE-1, VEGFR-3 and CD44 genes in human tissues with or without tumor using real-time polymerase chain reaction (RT-PCR), and to evaluate the relationship between these expression levels and clinicopathological parameters such as tumor type, stage, differentiation, and the presence of lymph node metastasis, vascular invasion and neural/perineural invasion in gastric cancer. The LYVE-1, CD44 and VEGFR-3 protein expressions in tissues were also demonstrated using immunohistochemical and Western blotting (WB) analysis.

MATERIALS AND METHODS

All tissue samples used in this study were obtained from patients who underwent radical surgery for gastric cancer in the 7th Surgical Clinic of the Ankara Numune Teaching and Research Hospital. All molecular studies were carried out in the research laboratories of Hacettepe University Institute of Oncology and Department of Pathology, Ankara Numune Hospital.

The study protocol was approved by the local ethics committee of Hacettepe University (04/12-19), in accordance with the Declaration of Helsinki, and all participants provided written informed consent.

Patients

Thirty-three patients [8 females; median age (range) 58 years (42-78)] with gastric cancer who underwent radical gastrectomy and D2α lymph node dissection were included in the study. All patients provided written informed consent for the procedure and to participate in the study. During and after surgery, paired tissue samples (tumoral and normal tissues) from all patients were obtained according to the protocol. During surgical removal of each tumor, an adjacent section of normal tissue was also removed following pathological confirmation that it was free from tumor deposits. Samples were then transferred to the laboratory and kept at either -20℃ (tissues in RNA-Later) or -80℃ (tissues in liquid nitrogen), for further testing.

Surgical sampling technique

During the operations, lymph nodes were sampled according to the Japanese Research Society of Gastric Cancer classification[12]. Macroscopically involved lymph nodes or lymph nodes of more than 1 cm in size were sampled. The same procedure was applied for the normal-appearing lymph nodes. After laparotomy, in parallel with the dissection protocol, paraaortic lymph nodes were sampled first, followed by perivascular (celiac trunk) and perigastric lymph nodes sampling. After completion of surgery and total or subtotal removal of the stomach, samples were obtained from the tumor and normal tissues. Routine pathological examination of surgical specimens was carried out to determine the lymph node status and for accurate staging.

RNA isolation

Total RNA was extracted from normal/tumoral tissues (200 mg) and normal/tumoral lymph node specimens (100 mg) using an RNeasy Midi Kit (Qiagen, CA, USA) according to the manufacturer's instructions. Tissue lysis was performed with Mini Bead Beater-8 (Biospec, OK, USA). Concentration and purity of RNAs were determined on the NanoDrop 1000 spectrophotometer (Thermo, DE, USA). All samples were run on denaturing agarose gel. cDNA was subsequently synthesized using the RevertAid First Strand cDNA Synthesis Kit (Fermentas, MD, USA) with 800 ng of total RNA isolated for each sample.

PCR: Polymerase chain reaction; LYVE-1: Lymphatic vessel endothelial hyaluronan receptor-1; VEGFR-3: Vascular endothelial growth factor receptor-3.

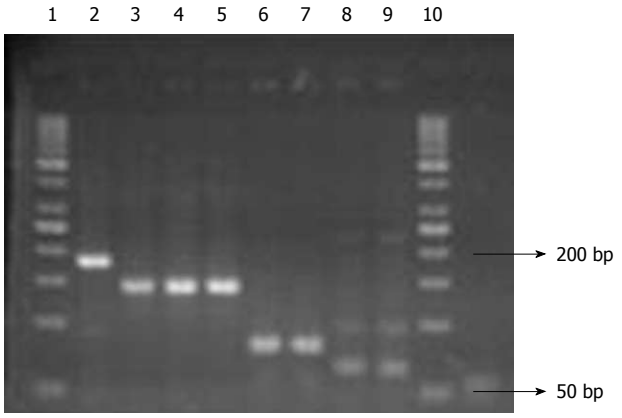

Figure 1 Polymerase chain reaction products of genes. 1: Ladder (50 bp); 2: Lymphatic vessel endothelial hyaluronan receptor-1 (184 bp), gastric tissue; 3-5: GAPDH (143 bp), in colon, stomach and pancreas, respectively; 6, 7: CD44 (80 bp) in stomach and colon; 8, 9: Vascular endothelial growth factor receptor-3 (63 bp) in stomach and colon; 10: ladder (50 bp).

PCR

Before RT-PCR, traditional PCR was performed in order to test the primers of LYVE-1, VEGFR-3, CD44 and GAPDH genes and the annealing degrees of the primers, as well as to optimize the levels of $MgCl_2$. The primers for the genes are given in Table 1. To ensure that the correct products were obtained, amplified products were separated by 3% agarose gel electrophoresis (Figure 1).

RT-PCR

The quantitative RT-PCR (qRT-PCR) assays were performed with the Corbet 6000 (Rotor-Gene, CA, USA) instrument using Lightcycler-DNA master SYBR Green I (Roche Diagnostics, Mannheim, Germany), and the expression levels of lymphangiogenic genes were quantified. The RT-PCR reactions were set up in a volume of 20 μL, containing 5 μL of sample cDNA, 1 × SYBR Green I dye, 1.5 mmol/L $MgCl_2$, and 5 pmol of LYVE-1, VEGFR-3, CD44 and GAPDH specific primers. The cycling conditions were as follows: 95℃ for 30 s, 60℃ for 30 s, 81℃ for 5 s and 72℃ for 30 s for 40 cycles, with initial melting at 95℃ for 5 min.

Relative expression levels were calculated using the PCR threshold cycle number (C_T) for each tissue and control sample using the formula $2^{-(\Delta CT\text{sample} - \Delta CT\text{control})}$[13,14]. ΔC_T represents the difference in C_T values between the target and *GAPDH* transcripts. RT-PCR was performed in duplicate for each sample and average C_T values were calculated.

Immunohistochemistry

Consecutive 4-μm-thick sections were cut from each paraffin sample. Sections were immunolabeled for LYVE-1, VEGFR-3 and CD44.

The stains were carried out using the Bond Max (Leica Microsystems - Biosystems Division, Wetzlar, Germany) with the Polymer Refine Detection Kit (Vision Biosystem, MA, USA). Immunohistochemical stains were performed with rabbit polyclonal antibodies LYVE-1 (Abcam, MA, USA) (1:100), VEGFR-3 (Gene-Tex, CA, USA) and CD44 (Gene-Tex, CA, USA).

LVD was determined from the counts of LYVE-1-positive vessels. Vessel density was assessed by light microscopy of the intratumoral region containing the greatest number of capillaries and small venules. Highly vascular areas were identified by scanning tumor sections at low power (× 40 and × 100). After the six areas of greatest neovascularization were identified, a vessel count was performed at X200, and the mean count of six fields was calculated. In slides immunolabeled for LVYE-1 and VEGFR-3, only vessels with typical morphology (including a lumen) were counted as lymphatic vessels[15]. CD44-positive cells were determined in tumor and normal tissue sections and compared.

Statistical analysis

Data from patients and laboratory studies were stored and evaluated using SPSS 15.00 for Windows (SPSS, Chicago, IL, USA). All descriptive data were expressed as median (range). The relationships between these and expression levels of LYVE-1, VEGFR-3 and CD44 were evaluated using the Fisher Exact Probability test. As the distribution of genes was not normal, the nonparametric tests were used for evaluation. The comparison between clinicopathological characteristics and gene expression levels was performed using Mann-Whitney *U* and Kruskal-Wallis tests. The correlation between clinicopathological features and gene expression levels was evaluated

using logistic regression analysis and Spearman's correlation coefficients. *P*-values less than 0.05 were considered significant.

RESULTS

Clinicopathological features and relative gene expression levels

All information on patients with gastric cancer, including age, sex, Lauren histological tumor type, degree of differentiation, T-stage, final stage, number of total lymph nodes (TLN) removed, number of positive lymph nodes (PLN), the PLN/TLN ratio, presence of vascular, neural and perineural invasion, and relative expression levels of LYVE-1, VEGFR-3 and CD44 calculated using qRT-PCR and the $2^{-\Delta\Delta CT}$ method[13,14], was stored and evaluated using SPSS 15.00 for Windows.

LYVE-1, VEGFR-3 and CD44 gene expression levels in relation to clinicopathological features are shown in Table 2.

Expression levels of LYVE-1, VEGFR-3 and CD44 genes were significantly higher in tumoral tissues than in the normal tissues in gastric cancer patients, which was found to be independent of the age and gender of the patients ($P < 0.001$) (Figure 2). There was a linear correlation between the expression levels of LYVE-1 and CD44 molecules, and the same correlation was also found between their over-expression levels (Spearman's rank correlation, $P = 0.025$ and $P = 0.033$).

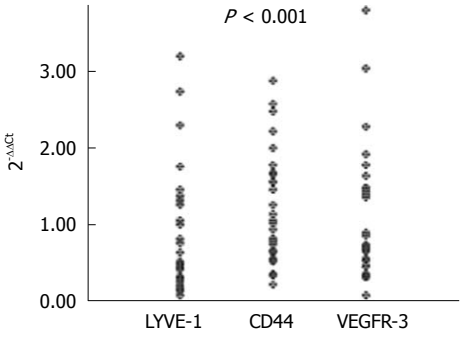

Figure 2 Lymphatic vessel endothelial hyaluronan receptor-1, CD44 and vascular endothelial growth factor receptor-3 expression levels are increased in tumor tissues as compared to normal tissues in patients with gastric cancer (*P* < 0.001). LYVE-1: Lymphatic vessel endothelial hyaluronan receptor-1; VEGFR-3: Vascular endothelial growth factor receptor-3.

The expression levels of the genes were higher in patients with lymph node metastases than patients without metastases, however, the difference did not reach the level of significance. When the PLN/TLN ratio was investigated, the expression levels of LYVE-1, VEGFR-3 and CD44 genes were significantly less in patients with a ratio of ≤ 0.20 than in patients with a PLN/TLN ratio of ≥ 0.4 ($P = 0.001$). Both expression levels and over-expression of the genes were increased with increased PLN/TLN ratio (Spearman's rank correlations; $P = 0.01$ for LYVE-1, $P = 0.036$ for CD44 and $P = 0.016$ for VEGFR-3). The value of significance was most appar-

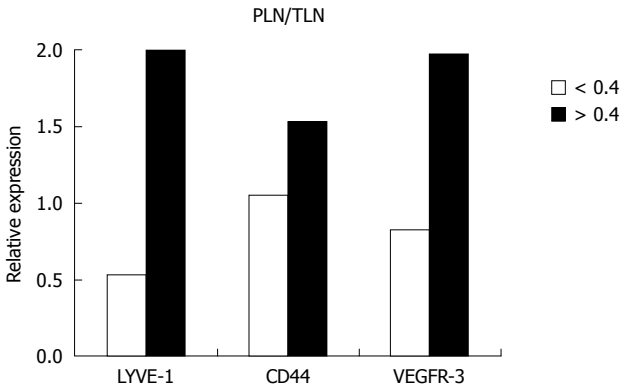

Figure 3 The positive lymph nodes/total lymph nodes ratios and the relative expression levels. The expression levels of lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) are increased in conjunction with increased positive lymph nodes (PLN)/total lymph nodes (TLN) ratio (P = 0.003). VEGFR-3: Vascular endothelial growth factor receptor-3.

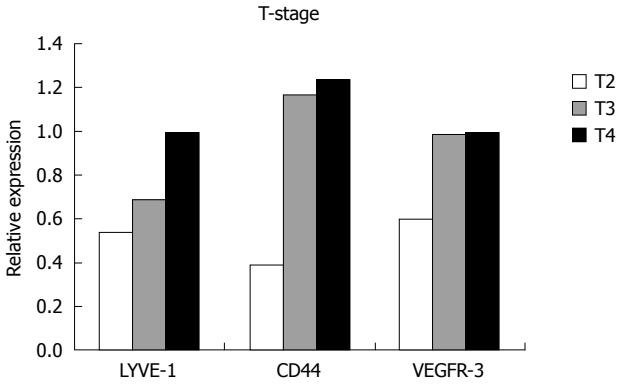

Figure 4 The relative expression levels and T-stage. No correlation was found between expression levels and T-stage. LYVE-1: Lymphatic vessel endothelial hyaluronan receptor-1; VEGFR-3: Vascular endothelial growth factor receptor-3.

ent when the PLN/TLN ratio was taken as ⩾ 0.4 or < 0.4 (Figure 3). There was also a significant correlation between the PLN/TLN ratio, tumor volume and number of PLN (P < 0.001). When the expression levels of the genes in the lymph nodes of the stations were evaluated, it was found that their levels increased in parallel with expression levels in the tumor, but the difference was not found to be statistically significant.

When the relationship between the T-stage of the tumor and relative expression levels of the genes was evaluated, we found that expression levels increased with increased T-stage, however, this increase was not statistically significant. Although the number of patients in earlier stages was too small, expression levels were much higher in T4-stage than T2, but the difference did not reach statistical significance, and no correlation was found between the T-stage and over-expressions (Figure 4).

On the other hand, there was a significant correlation between the final stage and T-stage, presence of lymph node metastasis, number of PLNs, and the PLN/TLN ratio.

There was also no correlation between over-expressions and neural invasion, whereas relative expression levels of LYVE-1, VEGFR-3 and CD44 were significantly increased with the presence of perineural invasion and reached statistical significance for LYVE-1 and CD44 (P < 0.001). All three genes were found to be over-expressed with perineural invasion and a statistically significant correlation was found between them (Figure 5).

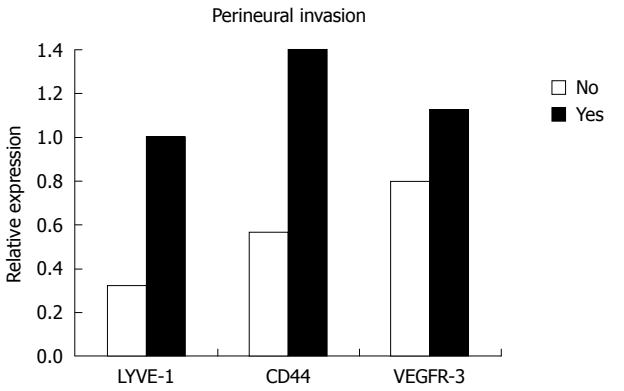

Figure 5 The relative expression levels and perineural invasion. The expression levels of lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) and CD44 were significantly increased with the presence of perineural invasion. VEGFR-3: Vascular endothelial growth factor receptor-3.

Although the relative expression levels of all three genes were increased with the presence of vascular invasion, the difference was not statistically significant.

Immunohistochemistry

The expressions of LYVE-1, VGFR-3 and CD44 were all shown in tumor tissues using immunohistochemistry (Figure 6A-C). When the LVD at the central zone and periphery of the tumor was measured, 13% of patients had intratumoral staining and 27% had peritumoral staining for LYVE-1. Although the peritumoral distribution of LYVE-1$^+$ LVD was higher, the difference was not statistically significant (χ^2 test, 2.773, Df = 1, P = 0.09). Lymph node metastasis was positive in all patients with LYVE-1-stained lymphatic vessels, whether the LVD was peritumoral or intratumoral. However, we failed to find any correlation between LVD and lymph node metastasis (Spearman's rank correlation coefficient, 0.26, P = 0.92).

DISCUSSION

The present study was designed to investigate whether LYVE-1, which is a specific molecule for lymphatics, as well as CD44 and VEGFR-3 might be used as markers for lymph node metastases of gastric tumors. We chose gastric cancer since it is well known to exhibit early metastasis to lymph nodes.

We evaluated the expressions of LYVE-1, VEGFR-3 and CD44 in normal gastric tissues, tumoral gastric tissues and lymph nodes with or without metastases using RT-PCR. The levels were compared to those in normal tissues.

Using qRT-PCR, we were able to show significantly

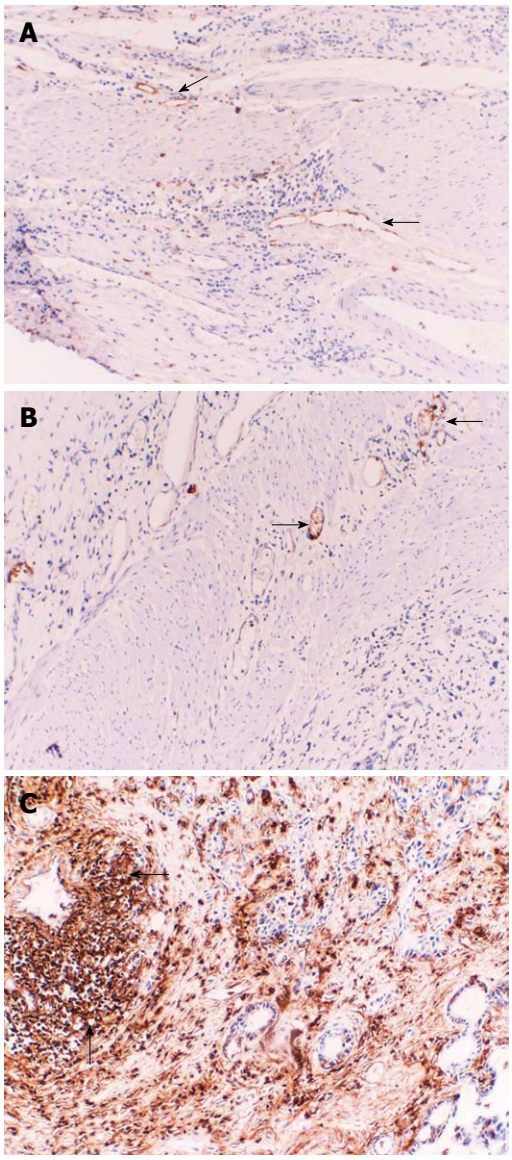

Figure 6 Expressions of lymphatic vessel endothelial hyaluronan receptor-1, vascular endothelial growth factor receptor-3 and CD44 by immunohistochemistry. A: Arrows indicate the lymphatic vessel endothelial hyaluronan receptor-1-positive lymphatic vessels in gastric tumor (× 100); B: Arrows indicate vascular endothelial growth factor receptor-3-3-positive lymphatic vessels in gastric tumor (× 100); C: Arrows indicate CD44-positive lymphoid cells in gastric tumor (× 100).

higher relative expression levels of all three genes in tumoral tissue than in the normal tissue counterparts. The expression levels of LYVE-1, VEGFR-3 and CD44 were higher in patients with lymph node metastasis than in those without metastasis, however, the difference was not statistically significant. On the other hand, when we measured the correlation between the PLN/TLN ratio and relative expression levels of LYVE-1 in tumors, levels were significantly higher in patients with a PLN/TLN ratio $\geq$ 0.4. There was no significant correlation for VEGFR-3 or CD44. Over-expressions of LYVE-1, VEGFR-3 and CD44 were all significantly increased with the increased number of involved lymph nodes.

The lymphatic metastatic process of tumor cells follows a series of complex biologic reactions. In the initial phase, tumor cells first invade the stroma and penetrate into lymphatic vessels and reach the lymph nodes *via* lymphatic flow. Lymphangiogenesis plays a very important role in this stage. The secretion of growth factors such as VEGF-C, platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF) from tumor cells increases the expression of VEGFR-3, which triggers lymphangiogenesis followed by the development of new lymphatic capillaries and increases the number of LYVE-1-secreting cells[16]. The increase in VEGFR-3 and LYVE-1 expressions is highly critical because it reflects lymphangiogenesis, indicating how tumor cells might easily reach the lymphatic system[17]. Molecules such as LYVE-1 and VEGFR-3 provide information on the behavior of the tumor, as the increase in these molecules reflects the increase in the number of lymphatic endothelial cells.

LYVE-1, VEGFR-3 and CD44 expression and over-expression levels were increased with the presence of neural and perineural invasion; on the other hand, VEGFR-3 and LYVE-1 were both increased with vascular invasion. However, the increase in LYVE-1 and CD44 was only significant in the presence of perineural invasion, which might be explained partly by the size of the study, heterogeneity of the patients and variation in tumor behavior.

The present study also investigated the correlation between increased expression levels of the genes and poor prognostic factors. It was found that expression levels did not change with Lauren type or with the degree of differentiation. LYVE-1, VEGFR-3 and CD44 expression levels were increased in conjunction with T stage.

We evaluated the gene expression levels in metastatic lymph nodes and found that the expression levels of LYVE-1, VEGFR-3 and CD44 all increased in parallel with the expression levels in tumor tissue, which was most apparent in LYVE-1 levels. When the relationships between the gene expression levels were analyzed, it was found that CD44 levels increased in parallel with LYVE-1 expression in tumors.

Hyaluronic acid (HA) is an extracellular matrix glycosaminoglycan found in tissues and body fluids, and plays a role in inflammation, leukocyte extravasation, wound healing, and metastasis of tumor cells[18]. The CD44 molecule is one of the most well-defined HA cell surface receptors with a very important role in HA homeostasis and is expressed on the surface of endothelial, mesenchymal and lymphoid cells. However, CD44 is functionally silent in resting leukocytes and is activated only to bind HA[19].

Lymphatic vessel endothelial HA receptor (LYVE-1) is a receptor for hyaluronan and is expressed by the endothelial cells of the lymphatic vessels. LYVE-1 is located both intra- and extra-luminally in these vessels; therefore, it is thought that LYVE-1 plays an important role in the transportation of both lymphocytes and other similar cells into the lymphatic system. Lymphocytes are routed into the lymphatic flow and caught by lymph nodes with the help of CD44 cells integrated with HA and with LYVE-1. As it is specific to the lymphatic endothelium,

LYVE-1 might be a useful marker in identifying tissue lymphatics.

Vascular endothelial growth factor receptor-3 (VEGFR-3) is another lymphatic endothelial cell receptor that has an important role in lymphangiogenesis. Increased expression of VEGF-C during growth of the tumor increases the development of new lymphatic vessels so that VEGF-C may be considered as a marker of lymph node metastasis. VEGFR-3 might also be a marker for lymphangiogenesis; however, it appears to be inadequate for suggesting lymph node metastasis. Despite the definitions of LYVE-1, VEGFR-3 and CD44 and rapidly growing information on tumor biology, the molecular mechanisms regarding lymphatic invasion and the metastatic process to lymph nodes remain unclear.

Lymphatic vessels act not only in metastasis but also in the invasion of cancer cells. The molecules that are released from lymphatic endothelial cells such as matrix metalloproteinases and urokinase plasminogen activators increase invasion by helping tumor cell movement in adjacent tissues[20]. VEGF-C stimulates the secretion of CCL1 chemokine from endothelial cells, which interacts with CCR8 expressed by tumor cells and moves tumor cells towards lymphatic vessels[21]. This interaction is one of the most important steps in metastasis. All these molecules are secreted by both the endothelium of new lymphatic capillaries and that of other lymphatics already present around the tumor[22,23]. In addition to lymphatic markers such as LYVE-1 and VEGFR-3, we also used lymphatic involvement and perineural, neural and vascular invasion in order to better explain the process of tumor invasion and metastasis. Information gathered from this study supports this relationship.

CD44, which is secreted by tumor cells, binds HA, and during the transport of HA, it also intervenes in the transportation of tumor cells into the lymphatic flow[24]. Furthermore, over-secretion of CD44 by tumor cells might cause tumor cells to be perceived as lymphocytes by the immune system, which might trigger the occurrence of immune escape[25]. As we have shown, increased secretion of CD44 mRNA in gastric cancer might be an important indicator of the biologic process explained above.

We are not aware of any previous study investigating LYVE-1 mRNA levels in gastric cancer. In two previous studies, VEGFR-3 expressions were shown to be increased in tumor tissues and with the presence of lymph node involvement using RT-PCR[26,27]. It was recently shown that there was a correlation between increased VEGFR-3 levels and metastasis[11,28]. It has also been reported that increased expression levels of VEGFR-3 might be a prognostic indicator, especially in patients with advanced gastric cancer[7,29].

To our knowledge, there has only been one published study investigating the quantitatively measured relative expression levels of the CD44 gene in human gastric cancer[30]. Most of the previous studies on CD44 were based on immunohistochemical analysis and analyzed the correlation between poor prognosis and presence of CD44[31-33].

We found that 40% of cases (13/33) had lymphatic vessels in tumor tissue; 27% were located peritumorally and 13% were located intratumorally. However, we failed to find any correlation between LVD and lymph node metastasis, possibly due to the small study size.

There is still controversy regarding whether the intratumoral or the peritumoral lymphatics are functional, and which should be used for evaluation[34,35]. Although our study population was too small to comment, peritumoral lymphatics with wide lumens seem to be more functional and effective for the occurrence of metastasis as compared to the intratumoral lymphatics with either narrow or obstructed lumen. This hypothesis appears to be in accordance with previous findings obtained from animal studies[17,36,37]. It is also known that the lymphatic vessels are located at the submucosa and extend through the muscularis propria. When tumor cells reach this anatomic location, they can easily move to the lymphatic vessels, thereby increasing metastatic potential[17].

The question of whether the tumor uses new lymphatic capillaries occurring at its center due to lymphangiogenesis or lymphatic vessels already located peritumorally remains unanswered[36]. We believe that peritumoral lymphatics have a very important role in the metastatic process.

The present study also shows that immunohistochemical staining using LYVE-1 antibodies is more sensitive than staining using VEGFR-3 antibodies, which is in parallel with previous findings by other researchers[38]. VEGFR-3 antibodies stain venous capillaries as well as lymphatic vessels, which makes differentiation difficult. The presence of VEGFR-3 proteins in both normal and tumor tissues was shown by Western blotting, which correlated with the findings of Yonemura *et al*[26].

A previous study in patients with colorectal cancers revealed that the expression levels of VEGFR-3 are increased, whereas LYVE-1 levels were decreased in tumor tissue[39]. LYVE-1 levels were found to be increased in another study using immunohistochemistry, but the authors failed to show any increase in quantitatively measured relative expression levels[40]. Yuanming *et al*[28] investigated the expression levels of LYVE-1 and VEGFR-3 in gastroenteric tumors and evaluated their relationships with lymphatic metastasis and tumor progression. They concluded that VEGFR-3 expression was increased when lymph node metastasis was present, but they failed to show any correlation with LYVE-1. By using LYVE-1 antibody and immunohistochemistry, they found that there was a correlation between LVD and lymph node metastasis[28]. Although we were unable to show this correlation using immunohistochemistry, we were able to determine that relative expression levels of LYVE-1 increased with lymph node involvement in parallel with PLN/TLN ratios. Therefore, the findings of Chen *et al*[41] using immunohistochemistry support our study based on quantitative measurements. In the literature, there are

only a few immunohistochemical studies on the quantitative evaluation of CD44 in gastric cancer and they did not reach a definitive conclusion[41,42].

In conclusion, we found that the expression levels of LYVE-1, CD44 and VEGFR-3 genes in gastric tumors were significantly increased when compared to levels in normal tissue. We failed to show any correlation between these expression levels and clinicopathological features such as histological type, differentiation and stage, however, a significant correlation was found between relative expression levels of LYVE-1 and CD44 genes and perineural invasion and lymphatic involvement, which supports the hypothesis that those genes play an important role during the process of lymphangiogenesis, invasion and lymph node metastasis in gastric cancer.

Although it is not possible to make definitive comments based on our findings regarding the relationships between clinicopathological features and peritumoral/intratumoral LVD and their effects on prognosis, LYVE-1 appears to be an excellent lymphatic vessel marker and LVD can be evaluated using immunohistochemical techniques. We believe that increased expression levels of these genes in biopsy specimens can be used as a predictor of metastasis, which might further facilitate disease staging, treatment planning and prognosis estimation.

COMMENTS

Background

Lymph node metastasis is one of the most important prognostic factors in gastric cancer. Quantification of the lymphatic vessel density in the tumor may be important for the evaluation of lymphangiogenesis and lymphatic metastasis. Lymphatic metastasis involves a series of complex reactions. Tumor cells first invade the stroma, penetrate the lymphatic vessels and reach the lymph nodes *via* lymphatic flow. Lymphangiogenesis is involved in this stage. The secretion of growth factors from the tumor cells increases the expression of vascular endothelial growth factor receptor-3 (VEGFR-3) which triggers lymphangiogenesis followed by the development of new lymphatic capillaries and an increase in the number of lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) secreting cells. The increase in VEGFR-3 and LYVE-1 expressions is very important as it reflects lymphangiogenesis which allows tumor cells to reach the lymphatic system easily. Molecules such as LYVE-1 and VEGFR-3 provide information on the behaviour of the tumor, as an increase in these molecules reflects the increased number of lymphatic endothelial cells. Furthermore, over-secretion of CD44 by tumor cells might cause tumor cells to be perceived as lymphocytes by the immune system which might trigger the occurrence of immune escape. The present study aimed to investigate the expression levels of LYVE-1, VEGFR-3, CD44 genes and the relationship between these levels and clinicopathological parameters in gastric cancer.

Research frontiers

To briefly introduce important areas in the research field related to this article.

Innovations and breakthroughs

Using quantitative real-time polymerase chain reaction, the authors were able to show significantly higher relative expression levels of all three genes in tumoral tissue than in the normal tissue counterparts. They failed to show any correlation between expression levels and clinicopathological features such as histological type, differentiation and stage, however, a significant correlation was found between relative expression levels of LYVE-1 and CD44 genes and perineural invasion and lymphatic involvement, which supports the hypothesis that these genes play an important role during the process of lymphangiogenesis, invasion and lymph node metastasis in gastric cancer.

Applications

Increased expression levels of these genes in biopsy specimens can be used as a predictor of metastasis, which might further facilitate disease staging, treatment planning and prognosis estimation.

Peer review

This paper investigates the importance of LYVE1, VEGFR-3 and CD44 expression levels in gastric cancer and its relation to the metastasis.

Abstract

AIM: To evaluate the oncologic outcomes of primary and post-irradiated early stage rectal cancer and the effectiveness of adjuvant chemotherapy for rectal cancer patients.

METHODS: Eighty-four patients with stage I rectal cancer after radical surgery were studied retrospectively and divided into ypstage I group (n = 45) and pstage I group (n = 39), according to their preoperative radiation, and compared by univariate and multivariate analysis.

RESULTS: The median follow-up time of patients was 70 mo. No significant difference was observed in disease progression between the two groups. The 5-year disease-free survival rate was 84.4% and 92.3%, respectively (P = 0.327) and the 5-year overall survival rate was 88.9% and 92.3%, respectively, for the two groups (P = 0.692). The disease progression was not significantly associated with the pretreatment clinical stage in ypstage I group. The 5-year disease progression rate was 10.5% and 19.2%, respectively, for the patients who received adjuvant chemotherapy and for those who rejected chemotherapy in the ypstage I group (P = 0.681).

CONCLUSION: The oncologic outcomes of primary and post-irradiated early stage rectal cancer are similar. Patients with ypstage I rectal cancer may slightly benefit from adjuvant chemotherapy.

Key words: Rectal cancer; Neoadjuvant radiotherapy; Total mesorectal excision

Oncologic outcomes of primary and post-irradiated early stage rectal cancer: A retrospective cohort study. *World J Gastroenterol* 2011; 17(27): 3229-3234 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i27/3229.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i27.3229

INTRODUCTION

Rectal cancer is a worldwide health concern[1,2]. It is the fifth leading cause of cancer-related death and its incidence is increasing at a rate of 4.2% per year in China[2].

Currently, the management of rectal cancer has become multidisciplinary[3-5]. Neoadjuvant therapy, including long- or short-course chemo- and radiotherapy, can control locally advanced rectal cancer and increase the sphincter preservation rate[6-8].

Neoadjuvant therapy can decrease the tumor size and histopathological stage in a considerable number of rectal cancer patients, depending on the dose of radiation, chemotherapy regimen, and many other factors[9-12]. The pathologic stage of tumor after neoadjuvant therapy (ypstage) is one of the most important factors for oncologic outcome, and the clinical and pathologic meanings of ypstage are different from those of primary pathologic TNM stage (pstage)[13,14]. For example, patients with early stage rectal cancer (pT1-2N0M0) have a low risk of progression and no indication for adjuvant chemotherapy. Nevertheless, patients with ypstage I rectal cancer should undergo postoperative chemotherapy according to the National comprehensive cancer network guidelines[15], since some studies suggested that adjuvant chemotherapy may further decrease the risk of rectal cancer progression in patients who have received preoperative radiation[13-16]. However, to date, no worldwide consensus has been reached on whether adjuvant chemotherapy is proper for patients with ypstage I rectal cancer. Few studies have neither specifically compared the prognostic difference in ypstage I and pstage I rectal cancer, nor investigated the effectiveness of adjuvant chemotherapy for post-irradiated early stage rectal cancer. Thus, this study was to compare the long-term outcomes of ypstage I and pstage I rectal cancer patients after radical resection, and the outcomes of ypstage I patients who received post-operative chemotherapy with those who did not receive chemotherapy.

MATERIALS AND METHODS

Data were collected from all patients with pathologic stage I rectal cancer admitted to Peking University Cancer Hospital from February 1998 to February 2005. The inclusion criteria were those with histologically identified primary adenocarcinoma of the rectum before treatment, resectable rectal cancer 12 cm or less from the anal verge, evaluated by endorectal ultrasound (ERUS) or magnetic resonance imaging (MRI) before treatment, no clinical evidence of synchronous distant metastases, transabdominal radical resection based on the principle of total mesorectal excision (TME), and R0 resection.

The exclusion criteria were those with transanal excision, pathologic complete response to neoadjuvant radiotherapy, multiple primary malignancy or history of other malignant tumors within 5 years, familial adenomatous polyposis and hereditary non-polyposis colorectal carcinoma, and those who died of complications or due to other non-cancer related reasons.

Finally, 84 eligible patients were included in this study and divided into ypstage I group (n = 45) and pstage I group (n = 39). Demographic and clinical data of the patients are presented in Table 1.

Neoadjuvant radiotherapy

Neoadjuvant radiotherapy was indicated for patients with clinical T stage more than T2 (T3 or T4), or with nodes involved. We adopted the regimen recommended by the Chinese Anti-Cancer Association[17]. The patients were irradiated with a 10 MV dual photon linear accelerator using a 3-field box technique (posteroanterior and bilateral fields). The total radiation dosage was 3000 cGy in 10 fractions delivered within 2 wk, with a biological equivalent dose of 36 Gy. The radiation field was set at the upper margin 1.5 cm above the sacral promontory (L5 level), bilateral margin 1 cm outside the pelvic brim, and inferior margin 3 cm below the lower margin of the tumor, or at the anal verge in some lower rectal cancer cases. Surgery was performed 2-3 wk after radiotherapy.

Surgery

All included patients underwent radical resection according to the TME principles[18], irrespective as to whether they received abdominoperineal resection or low anterior resection. All surgeries were performed by sharp pelvic dissection under direct vision along the Holly plane. The

mesorectum was excised 4-5 cm from the distal inferior edge of upper rectal cancer, and TME was performed in mid-level and lower rectal cancer. The bowel wall was excised at least 2 cm from the distal inferior edge of the tumor. All surgeries were performed by the same surgeon. R0 resection was defined when no microscopic residual tumor cells were found at the distal and circumferential resection margins.

Pathologic evaluation

Pathologic evaluation was performed again by one senior pathologist who was blinded to the clinical and oncologic outcome of the patients. All resected specimens were stained with hematoxylin and eosin, and evaluated for tumor differentiation and invasion, lymph node metastases, and lymphovascular invasion (LVI). The pathologic stage of rectal cancer was evaluated according to the 6th UICC TNM Staging System after histopathological examination.

Adjuvant chemotherapy

Of the 45 patients in the ypstage I group who were recommended to receive postoperative chemotherapy, 19 accepted chemotherapy and 26 refused adjuvant chemotherapy because of lack of authoritative evidence and consensus in China. The patients underwent adjuvant chemotherapy with 5-FU or capecitabine in combination with FOLFOX and CapeOX or capecitabine alone, according to their condition for 8-12 cycles. Patients in the pstage I group had no indications for chemotherapy, and were thus observed after surgery with a regular follow-up.

Follow-up

All patients were followed up every 3 mo during the first 2 years after surgery, and then every 6 mo for 5 years. Clinical examination was performed and serum Carcinoembryonic antigen (CEA) was detected at each follow-up. Abdominal ultrasound, pelvic MRI, and chest radiograph were performed every 6 mo, and colonoscopy was performed annually. The follow-up time was 3-131 mo (mean 70 mo). The terminal time for evaluation of outcomes was 5 years. The follow-up rate was 89.3% with 9 inconclusive results (follow-up was lost in 2 patients after disease progression).

Statistical analysis

Statistical analysis was performed using SPSS 16.0 statistical software (SPSS Inc., Chicago, IL, USA). Categorical variables were analyzed by Pearson chi-squared or Fisher's exact test when appropriate. Kaplan-Meier survival curve was used to estimate the number of patients surviving or remaining disease-free at each time. Disease-free survival (DFS) and overall survival (OS) curves were compared between the two groups using the Wilcoxon test for time-to-event parameters. Multivariate Cox proportional hazards regression (forward stepwise selection) was used to analyze the major factors affecting DFS rate. All statistical tests were 2-sided, and $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of patients

Eighty-four patients (49 males and 35 females) were included in this study with a median age of 64 years (range, 28-80 years). Complete follow-up information about the patients was available except for 9 patients (5 in ypstage I group and 4 in pstage I group) after surgery. No statistically significant difference was observed in gender and age of the patients, surgery, number of examined lymph nodes and LVI between the two groups (Table 1). However, a significant difference was found in distal anal verge (DAV), preoperative serum CEA level, histological differentiation, and pathologic T stage between the two groups, indicating that the condition of patients is better in pstage I group than in ypstage I group (Table 1).

Disease progression

Local recurrence was noted in 3 patients (3.6%). The 5-year local recurrence rate was 4.4% in ypstage I group and 2.6% in pstage I group (Table 2). Distant metastasis was observed in 9 patients (10.7%), which initially occurred in the liver of 5 patients (55.6%), in the lung of 3 patients (33.3%), and in the ovary of 1 patient (11.1%). The 5-year distant metastasis rate was 13.3% in ypstage I group and 7.7% in pstage I group (Table 2).

Disease progression was observed in 7 patients of the ypstage I group. Of the 7 patients, 4 had lymph node involvement based on ERUS/MRI before treatment and 3 were staged as T3-4N0. Pretreatment clinical stage was not significantly associated with disease progression in ypstage I group [odds ratio (OR) = 0.31-8.43, $P = 0.670$, Table 3].

Five-year DFS and 5-year OS rate

The overall 5-year DFS and 5-year OS rate was 88.1%, and 90.5%, respectively for the two groups. The 5-year DFS rate was 84.4% and 92.3%, respectively ($P = 0.327$,

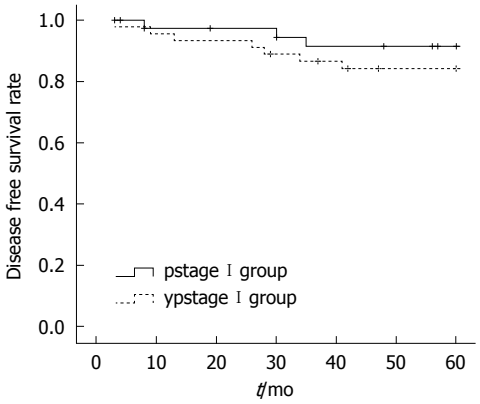

Figure 1 Five-year disease-free survival rate for patients in two groups.

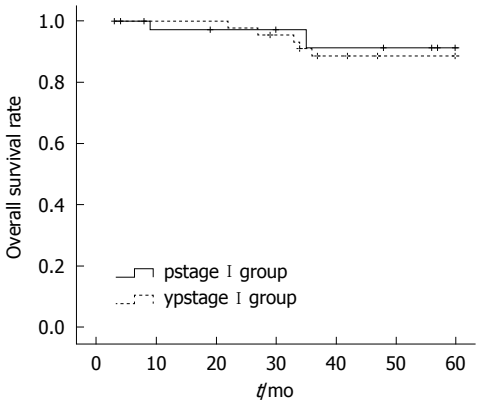

Figure 2 Five-year overall survival rate for patients in two groups.

Figure 1, Table 2) while the 5-year OS rate was 88.9% and 92.3%, respectively ($P = 0.692$, Figure 2, Table 2) for the two groups.

Effectiveness of chemotherapy for ypstage I patients

Of the 45 patients in ypstage I group, 19 received adjuvant chemotherapy and 26 rejected chemotherapy. The 5-year disease progression rate was 10.5% and 19.2%, respectively, for the patients who accepted chemotherapy and those who rejected chemotherapy (OR = 0.09-2.87, $P = 0.681$, Table 4).

Prognostic factors affecting DFS rate

Multivariate analysis demonstrated that the pretreatment serum CEA level was the major factor affecting the 5-year DFS rate for early stage rectal cancer patients (Table 5). Gender, age, neoadjuvant radiotherapy, DAV, histological differentiation, pathologic T stage, lymph nodes, LVI, and adjuvant chemotherapy were not the independent factors for the long-term DFS rate.

DISCUSSION

Currently, multidisciplinary management of advanced rectal cancer has gained wide acceptance[3-5]. Neoadjuvant radiotherapy is an effective treatment modality for locally advanced rectal cancer with respect to resectability, local control, and survival benefit[19-21]. The tumor stage decreases in approximately 40%-60% of rectal cancer patients obtain after neoadjuvant radiotherapy, which is related to a long-term favorable oncologic outcome[11,13,22]. One fifth of patients with ypstage I rectal cancer can directly benefit from neoadjuvant therapy[23,24]. Although it is widely acknowledged that ypTNM stage and primary TNM stage are different in terms of clinical meaning[9,25,26], few studies have specially compared the difference in early stage rectal cancer between post-irradiated patients and those undergoing direct surgery. In this study, patients with early stage rectal cancer were selected to undergo radical surgery instead of transanal local resection as a control in order to enhance the comparability of the two arms.

In the present study, the pstage I rectal cancer patients undergoing radical surgery had a favorable outcome, with a 5-year disease progression rate of < 10% and an OS rate of > 90%, which is consistent with the reported data[27,28]. Compared the patients in pstage I group, those in ypstage I group had several potential risk factors for poor oncologic outcomes, such as higher CEA level, more advanced T stage, and poorer histological differentiation, which is consistent with the reported data[29,30]. However, the patients in ypstage I group did not exhibit a higher disease progression rate or cancer-related death than those in pstage I group. Multivariate analysis also revealed that only serum CEA level was the major factor affecting DFS rate for early stage rectal cancer patients. Reerink *et al*[25] also showed that the prognosis of of patients with initially unresectable rectal tumor down-staged to pT2 and those

with primary resectable cancer with the same T classification is similar. Our study further demonstrated that post-irradiated early stage rectal cancer has no significant heterogeneity in prognosis compared to primary early stage rectal cancer.

Up to date, no general agreement has been reached on the indications of adjuvant chemotherapy for post-irradiated patients. Short-course radiation is predominantly used in European countries, although no consensus has been reached. Most doctors believe that postoperative pathologic stage of rectal cancer is still the decisive factor for adjuvant chemotherapy, since its down-staging rate is less than 1%[31]. The role of adjuvant chemotherapy in down-staged patients after preoperative long-course radiation is controversial. It has been demonstrated that chemotherapy, whether preoperative or postoperative, reduces the overall risk of disease progression in patients undergoing neoadjuvant radiotherapy[16]. However, which patients would benefit from adjuvant chemotherapy needs to further investigated[32]. Fietkau *et al*[33] reported that postoperative chemotherapy is not necessary for patients with ypN0 after neoadjuvant chemo- and radiotherapy because no obvious improvement has been achieved in 3-year DFS rate. Collette *et al*[13] suggested that patients with down-staged ypT0-2, irrespective of ypN status, can benefit from adjuvant chemotherapy. No consensus has been reached on the indications of chemotherapy for post-irradiated patients in China. The results of this study suggest that adjuvant chemotherapy may be beneficial for the patients with ypT1-2N0 after neoadjuvant radiotherapy alone, since its outcome is better in patients after chemotherapy. Although the difference in disease progression rate did not show statistical significance, this two-fold difference is of clinical significance. Moreover, the results were largely influenced by the small sample size of patients in this study, thus further randomized study with a large sample size is needed.

In conclusion, the oncologic outcome of primary and post irradiated early stage rectal cancer after neoadjuvant radiotherapy is similar. Furthermore, patients with ypstage I rectal cancer may slightly benefit from adjuvant chemotherapy.

ACKNOWLEDGMENTS

The authors appreciate Dr. Abraham KC Ho in Peking University Health Center for his great effort on this study.

COMMENTS

Background

Currently, neoadjuvant radiotherapy has been regarded as an effective treatment modality for locally advanced rectal cancer in terms of improving its local control and increasing the sphincter preservation rate. The pathologic stage of rectal cancer after neoadjuvant therapy (ypstage) is one of the most important factors affecting its oncologic outcome, and the clinical and pathologic meanings of ypstage are different from those of primary pathologic TNM stage (pstage). However, few studies have specially investigated the prognosis of post-irradiated early stage rectal cancer patients. Thus, this study was conducted to compare the long-term outcomes of ypstage I and pstage I rectal cancer patients after radical resection, and the outcomes of ypstage I patients who received postoperative chemotherapy with those who did not receive chemotherapy.

Research frontiers

This study specially addressed the long-term oncologic outcome of post-irradiated early stage rectal cancer by well-designed cohort study.

Innovations and breakthroughs

This study demonstrated that the oncologic outcome of primary and post-irradiated early stage rectal cancer was similar. Furthermore, patients with ypstage I rectal cancer may slightly benefit from adjuvant chemotherapy.

Applications

The post-irradiated early stage rectal cancer has a good oncologic outcome, and the clinical value of postoperative adjuvant chemotherapy should be further studied with a large sample size.

Peer review

This retrospective study comparing the ypstage I and pstage I rectal cancer patients after radical resection demonstrated that down-staging of rectal cancer was related to a long-term favorable oncologic outcome (5-year local recurrence rate, disease-free and overall survival rate). Pretreatment serum Carcinoembryonic antigen level was the major factor affecting the 5-year disease-free survival rate. On the other hand, it showed that patients with ypstage I rectal cancer could benefit from adjuvant chemotherapy.

Abstract

AIM: To investigate the influence of irritable bowel syndrome (IBS)-like symptoms on treatment outcomes with pantoprazole in gastroesophageal reflux disease (GERD) in a real life setting.

METHODS: For this prospective, open-label, multinational, multicentre study, 1888 patients assessed by the investigators as suffering from GERD were recruited. The patients were additionally classified as with or without IBS-like symptoms at baseline. They were treated with pantoprazole 40 mg once daily and completed the Reflux Questionnaire™ (ReQuest™) short version daily. Response rates and symptom scores were compared after 4 and 8 wk of treatment for subgroups defined by the subclasses of GERD [erosive (ERD) and non-erosive reflux disease (NERD)] and the presence of IBS-like symptoms.

RESULTS: IBS-like symptoms were more prevalent in NERD than in ERD (18.3% *vs* 12.7%, $P = 0.0015$). Response rates after 4 and/or 8 wk of treatment were lower in patients with IBS-like symptoms than in patients without IBS-like symptoms in both ERD (Week 4: $P < 0.0001$, Week 8: $P < 0.0339$) and NERD (Week 8: $P = 0.0088$). At baseline, ReQuest™ "lower abdominal complaints" symptom scores were highest in NERD patients with IBS-like symptoms. Additionally, these patients had the strongest symptom improvement after treatment compared with all other subgroups.

CONCLUSION: IBS-like symptoms influence treatment outcome and symptom burden in GERD and should be considered in management. Proton pump inhibitors can improve IBS-like symptoms, particularly in NERD.

INTRODUCTION

Complaints in the lower abdomen associated with altered stool habits were commonly considered the leading char-

acteristic of irritable bowel syndrome (IBS). However, despite the overlap between gastroesophageal reflux disease (GERD) and IBS being recognised for more than 20 years[1-3], there is still much debate about the pathophysiology and clinical management of lower abdominal complaints in patients with GERD[4-7]. Two theoretical frameworks have been proposed to account for the high prevalence (up to 71%[4,8,9]) of IBS symptoms in GERD patients[8,10].

The first defines GERD and IBS as distinct disorders that share common underlying mechanisms [e.g. gastrointestinal (GI) dysmotility[9] or visceral hypersensitivity[7]] in symptom genesis. In contrast, the second theory integrates IBS-like symptoms into the spectrum of GERD complaints, and is supported by evidence that shows that IBS-like symptoms improve after the administration of proton pump inhibitors (PPIs) for the treatment of GERD[11-14].

Interestingly, the prevalence of IBS-like symptoms[15-17], symptom burden[15], and treatment response following PPI administration[18,19] differ among patients with erosive GERD (ERD) and non-erosive GERD (NERD). Furthermore, current data suggest that the presence of IBS-like symptoms unfavourably affects treatment outcome with PPIs in some patients with GERD[8,20].

Given that symptom resolution is the primary goal of treatment for both physicians and patients, identifying and understanding the spectrum of symptoms influencing the treatment outcome in patients with GERD seen in routine clinical practice is essential for providing optimal primary patient care. We therefore designed a study to closely resemble the conditions of ordinary clinical practice to investigate these issues of practical clinical concern in the management of GERD. The aim of the current paper is to evaluate the influence of the presence of IBS-like symptoms on treatment response to the PPI pantoprazole in patients with GERD (including both ERD and NERD) in a real-life setting.

MATERIALS AND METHODS

Study design and patients

This prospective, open-label, phase Ⅲ study (BY1023/M3-341, ClinicalTrials.gov Identifier: NCT00312806) used a pragmatic trial design to assess the effectiveness of treatment with pantoprazole in managing GI symptoms in patients considered by physicians to have both GERD and IBS-like symptoms. A pragmatic trial design (as opposed to an explanatory trial) was chosen for this study to reflect variations among patients and doctors in real clinical settings, thus more accurately reflecting patients within the community in whom the treatment will be applied and optimising the applicability of the trial findings to those clinical settings[21,22]. The current study was conducted worldwide in 167 centres in 21 countries (Argentina, Australia, Austria, Belgium, Brazil, Canada, France, Germany, Hong Kong, India, Italy, Malaysia, Mexico, Poland, Singapore, South Africa, South Korea, Spain, Switzerland, Taiwan, and the United Kingdom) according to ICH-GCP guidelines. Ethics approval was obtained locally by all participating centres.

Patients aged ≥ 18 years (≥ 21 years in Argentina) were included if they were considered by the investigator to have symptoms of GERD and to likely comply with requirements for the completion of the ReQuest™. All patients provided written informed consent prior to participation.

Patients were excluded if they: had a history of Zollinger-Ellison syndrome or other gastric hypersecretory condition; were suffering from acute peptic ulcer and/or ulcer complications, inflammatory bowel disease, or other severe concomitant diseases; or had acid lowering surgery or any other surgery of the esophagus and/or upper gastrointestinal tract (excluding polypectomy and cholecystectomy). Those who had used acid suppressing medication in the last 7-10 d prior to enrolment, or any medication for *Helicobacter pylori* eradication during the last 28 d prior to the study were also excluded, as were those who had received systemic glucocorticoids or non-steroidal anti-inflammatory drugs including COX 2 inhibitors more than 5 d on demand but not more than 3 consecutive days during the last 28 d (with the exception of regular intake of acetylsalicylic acid in dosages up to 163 mg/d). Medications for the relief of acid-related symptoms, and systemic glucocorticoids or non-steroidal anti-inflammatory drugs, were not permitted during the study.

At baseline, all patients underwent upper GI endoscopy to determine whether they had ERD or NERD; the grade of GERD was determined according to the LA classification for all patients[23]. During this visit, the investigator also enquired about the presence of symptoms that would be consistent with IBS and answered "yes", "no", or "I do not know" to the question: "Is it possible that this patient does not only suffer from GERD-related symptoms, but also from symptoms caused by irritable bowel syndrome (IBS)?".

Enrolled patients were treated with the PPI pantoprazole-Na, 40 mg, provided as an oral enteric-coated tablet, to be taken one hour before breakfast once daily for eight weeks. During the eight-week period, three study visits were performed: visit 0 (V0, baseline), visit 1 (V1) after four weeks of treatment (Week 4), and visit 2 (V2) after eight weeks of treatment (Week 8).

Assessments

Patients completed the ReQuest™ at baseline and then daily starting on Day 1 (the day after V0), and continuing until V2 on Day 56. The ReQuest™ is a fully validated and easy-to-handle self-administered symptom assessment tool reliable for the evaluation of treatment effects in ERD and NERD[11,24-27]. It comprises 67 items assigned to six dimensions of GERD: acid complaints (e.g. heartburn, acid regurgitation, and esophageal or upper abdominal burning); upper abdominal/stomach complaints (e.g. upper abdominal pressure, pain or burning, feeling or fullness or incomplete bowel evacuation, and upper or lower back pain); lower abdominal/digestive complaints (e.g. pressure, cramps or pain in the lower abdomen, flatulence, diarrhoea and constipation); nausea; sleep disturbances; and other complaints[28]. For each dimension, symptom intensity is assessed on a 100 mm visual analogue scale (VAS; ranging from "not at all" to "extremely severe") and symptom frequency is measured using a 7-point Lik-

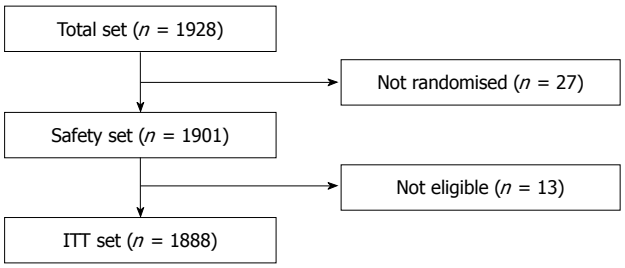

Figure 1 Flowchart of patient disposition. *n*: Number of patients; ITT: Intention-to-treat.

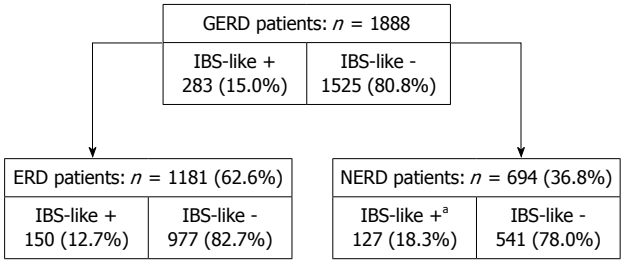

Figure 2 Subgroups of gastroesophageal reflux disease patients according to esophagitis and irritable bowel syndrome-like symptoms. Percentages do not equal 100% due to missing values. [a]*P* = 0.0015, irritable bowel syndrome (IBS)-like +: patients with non-erosive reflux disease (NERD) *vs* patients with erosive (ERD). *n*: Number of patients; GERD: Gastroesophageal reflux disease.

ert scale (ranging from "0" to "more than 10 times per day" or "continuously"). The ReQuest™ also includes a question about general well-being, evaluated using a VAS ranging from "wonderful" to "extremely poor".

The dimensions of the ReQuest™ can be grouped into two subscales: ReQuest™-GI, which includes acid complaints, upper abdominal/stomach complaints, lower abdominal/digestive complaints, and nausea; and ReQuest™-WSO, comprising general well-being, sleep disturbances, and other complaints[28]. Each dimension is weighted, resulting in the following score ranges: (1) ReQuest™ total score: 0 to 46.28; (2) ReQuest™-GI: 0 to 30.77; and (3) ReQuest™-WSO: 0 to 15.51.

The score range of the two weighted individual dimensions of special interest, i.e. "acid complaints" and "lower abdominal complaints", is 0 to 7.692. Patients were considered to have responded to treatment (responders) if their ReQuest™-GI score was below 1.6[28] over three consecutive days prior to the two scheduled visits at Week 4 and Week 8.

Statistical analysis

The sample size was calculated based on response rates seen in previous studies after 8 wk of treatment and envisaged a total of 2000 patients, approximately half with and half without esophagitis. A two-sided 95% confidence interval for a single proportion using the large sample normal approximation was expected to extend 0.019 from the observed proportion for an expected proportion of 0.100 in patients with esophagitis (sample size 1000) and 0.025 from the observed proportion for an expected proportion of 0.200 in patients without esophagitis (sample size 1000). Subsequently, a total of 1928 outpatients were screened, resulting in an intention-to-treat (ITT) population of 1888 patients.

Table 1 Demographic data and baseline characteristics [intention-to-treat population, number of patients (*n*) = 1888]

Age (yr), mean (SD)	47 (14.3)
Height (cm), mean (SD)	167.5 (9.6)
Weight (kg), mean (SD)	74.2 (15.8)
BMI (kg/m^2), mean (SD)	26.4 (4.8)
Gender, *n* (%)	
Female	978 (51.8)
Male	910 (48.2)
Esophagitis, *n* (%)	
Non-erosive	694 (36.8)
Grade A	680 (36.0)
Grade B	381 (20.2)
Grade C	97 (5.1)
Grade D	23 (1.2)
Ethnic origin, *n* (%)	
White	1326 (70.2)
Asian	352 (18.6)
Other	167 (8.8)
Black	43 (2.3)
Smoker, *n* (%)	
Never	1179 (62.4)
Former	360 (19.1)
Current	349 (18.5)

BMI: Body mass index.

Response rates were calculated at Week 4 and Week 8, and baseline scores and the pre-post differences (baseline to Week 4 and Week 8) were determined for the individual dimensions "acid complaints" and "lower abdominal complaints" of the ReQuest™-GI. Subgroup analyses were performed based on the presence or absence of esophagitis (i.e. ERD or NERD), IBS-like symptoms, and the combination thereof. The comparison of the response rates between these subgroups was performed using Fisher's exact test. The baseline scores were compared with the Wilcoxon rank sum test, the pre-post differences with the Wilcoxon signed rank test.

RESULTS

Demographics and baseline characteristics

In total, 1928 outpatients were recruited in 167 centres in 21 countries worldwide; 27 patients were not randomised and 13 were not eligible for inclusion, resulting in an ITT population of 1888 patients with GERD (Figure 1). Table 1 presents patient demographic and baseline characteristics; percentages do not equal 100% due to missing values. In total, 694 patients (36.8%) were diagnosed with NERD and 1181 (62.6%) with ERD. Of the ERD patients, 680 (57.6%) had esophagitis grade A, 381 (32.3%) grade B, and 97 (8.2%) grade C. Esophagitis grade D was diagnosed in 23 ERD patients (1.9%). Of the 1888 GERD patients, 283 presented with IBS-like symptoms (15.0%) and 1525 presented without those symptoms (80.8%). IBS-like symptoms were significantly more frequent in NERD (18.3%) than in ERD patients (12.7%, *P* = 0.0015; Figure 2).

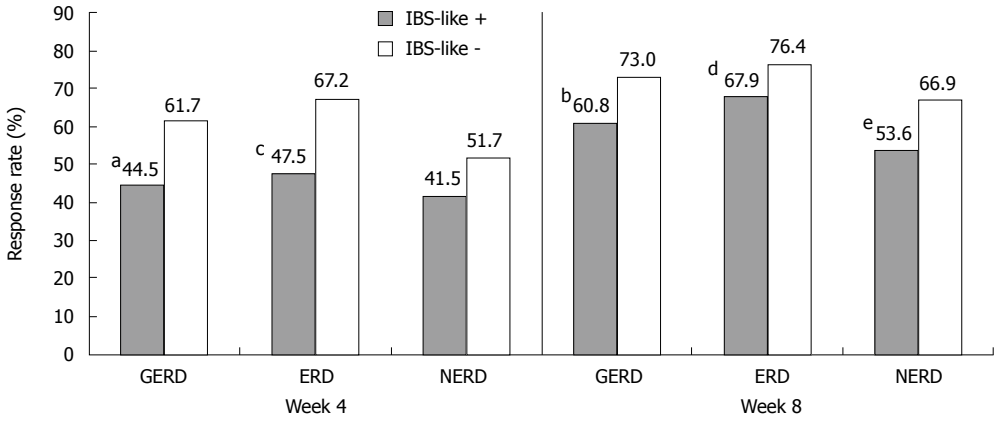

Figure 3 Response rates for gastroesophageal reflux disease/erosive/non-erosive reflux disease patients with or without irritable bowel syndrome-like symptoms after 4 and 8 wk of treatment with pantoprazole. [a]*P* < 0.0001 irritable bowel syndrome (IBS)-like + *vs* IBS-like - in patients with gastroesophageal reflux disease (GERD) after 4 wk; [b]*P* < 0.0001 IBS-like + *vs* IBS-like - in patients with GERD after 8 wk, [c]*P* < 0.0001 IBS-like + *vs* IBS-like - in patients with erosive reflux disease (ERD) after 4 wk, [d]*P* = 0.0339 IBS-like + *vs* IBS-like - in patients with ERD after 8 wk, [e]*P* = 0.0088 IBS-like + *vs* IBS-like - in patients with non-erosive reflux disease (NERD) after 8 wk.

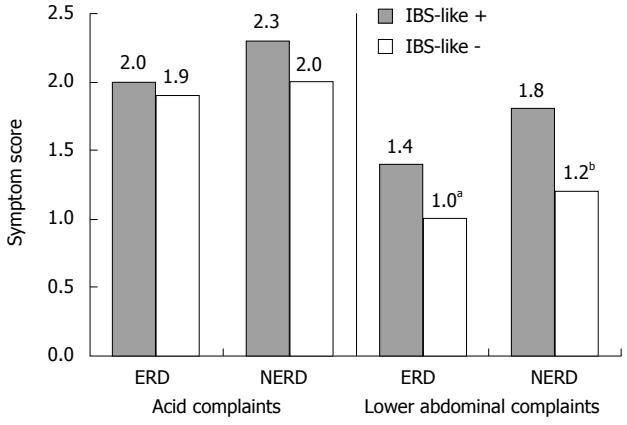

Figure 4 Symptom scores for "acid complaints" and "lower abdominal complaints" in erosive and non-erosive reflux disease patients with and without IBS-like symptoms at baseline. [a]*P* < 0.0001 irritable bowel syndrome (IBS)-like + *vs* IBS-like - in patients with erosive reflux disease (ERD) at baseline, [b]*P* < 0.0001 IBS-like + *vs* IBS-like - in patients with non-erosive reflux disease (NERD) at baseline.

Treatment response rates for ReQuest™-GI

In total, 58.9% of patients with GERD responded to pantoprazole treatment at Week 4; this increased to 71.2% of patients at Week 8. Response rates were significantly higher for ERD patients than for NERD patients at both Week 4 (64.6% *vs* 49.2%, $P < 0.0001$) and Week 8 (75.5% *vs* 64.5%, $P < 0.0001$). Both patients with and without IBS-like symptoms responded to treatment at Weeks 4 and 8 (Figure 3); however, response rates in GERD patients without IBS symptoms were significantly higher than in those with IBS-like symptoms at both time points (both $P < 0.0001$; Figure 3). Similarly, for patients with either ERD (Week 4: $P < 0.0001$; Week 8: $P < 0.0339$) or NERD (Week 8: $P = 0.0088$) response rates were higher if IBS-like symptoms were absent than if they were present (Figure 3).

Acid complaints and lower abdominal complaints

At baseline, the symptom scores for the ReQuest™ dimension "acid complaints" were 2.0 for both ERD and NERD ($P = 0.6269$). Scores remained similar irrespective of the presence of esophagitis or IBS-like symptoms (Figure 4). In contrast, baseline symptom scores for "lower abdominal complaints" were statistically significantly different in patients with ERD compared with those with NERD (1.1 *vs* 1.3, $P = 0.0012$). Furthermore, in both the ERD and NERD subgroups, patients with IBS-like symptoms had a significantly higher baseline score than those without IBS-like symptoms (both $P < 0.0001$, Figure 4).

There were no statistically significant differences in changes from baseline for the dimension "acid complaints" at Week 4 or Week 8 in ERD or NERD patients with IBS-like symptoms compared with those without IBS-like symptoms (Table 2). Similarly, for patients with ERD, pre-post differences in the dimension "lower abdominal complaints" did not statistically differ in those with IBS-like symptoms compared with those without IBS-like symptoms at either timepoint. In contrast, NERD patients with IBS-like symptoms showed significantly higher pre-post differences in the dimension "lower abdominal complaints" at Week 4 ($P = 0.049$)

Table 2 Pre-post differences of "acid complaints" and "lower abdominal complaints" in erosive and non-erosive reflux disease patients with and without irritable bowel syndrome-like symptoms after 4 and 8 wk

	ERD		NERD	
	IBS-like +	IBS-like -	IBS-like +	IBS-like -
Acid complaints				
4 wk	1.6	1.6	1.6	1.4
8 wk	1.6	1.7	1.7	1.6
Lower abdominal complaints				
4 wk	0.7	0.7	1.0[a]	0.7
8 wk	1.0	0.8	1.2[b]	0.8

[a]*P* = 0.049 irritable bowel syndrome (IBS)-like + *vs* IBS-like -; [b]*P* = 0.0092 IBS-like + *vs* IBS-like -. ERD/NERD: Erosive/non-erosive reflux disease.

and Week 8 (P = 0.0092) than did NERD patients without IBS-like symptoms (Table 2). Furthermore, for both ERD and NERD patients a higher increase of the pre-post differences could be shown between Week 4 and Week 8 for patients with IBS-like symptoms.

DISCUSSION

Using a pragmatic trial design, we investigated the influence of IBS-like symptoms on treatment response to pantoprazole and symptom burden in patients with GERD in a real-life setting. To represent the situation in real life clinical practice, patients were identified as suffering from GERD solely by their symptomatology, i.e. without knowledge of presence/absence of esophageal lesions. All patients then underwent upper GI endoscopy at baseline to determine whether they had ERD or NERD and to grade GERD (LA classification). Consistent with a pragmatic design, the presence of IBS-like symptoms was determined by the investigator by answering "yes", "no", or "I do not know" to the question: "Is it possible that this patient does not only suffer from GERD-related symptoms, but also from symptoms caused by Irritable Bowel Syndrome (IBS)?". This is reflective of real life clinical practice in many countries where general practitioners may not be familiar with the Rome Ⅲ criteria and IBS is largely diagnosed based on patient history[29,30]. Similarly, so as to reflect ordinary practice, pragmatic trials do not usually monitor patient compliance with trial medication in the way that is necessary in most explanatory trials[31]. Consequently, we did not do so. Results demonstrated a significantly higher occurrence of IBS-like symptoms in patients with NERD than in those with ERD. The presence of IBS-like symptoms reduced response to PPI treatment in patients with GERD, irrespective of endoscopic diagnosis of ERD or NERD. However, IBS-like symptoms may also show substantial improvement with placebo, making the lack of a placebo arm a limitation of this study. Nonetheless, results are reflective of what may be expected in clinical practice.

The significantly higher occurrence of IBS-like symptoms in patients with NERD (18.3%) than in those with ERD (12.7%) observed in the current study has also been shown in the literature (ERD range: 12.0%-48.0%; NERD range: 21.2%-63.6%)[15,17], although inconsistently[32,33]. However, the prevalence of IBS-like symptoms reported in the literature was generally higher than that in our study, possibly because of differences in symptom reporting and patient groups. For example, prevalence in the current study was based on the investigator's assessment of symptoms as opposed to prevalence derived from patient-reported symptoms in the literature. Furthermore, the current investigation was restricted to patients with GERD seeking help in a real life setting in contrast with population based studies presented in the literature[34].

We demonstrated a statistically significantly lower treatment response to pantoprazole therapy in GERD patients with IBS-like symptoms than in GERD patients without these symptoms. This difference occurred in both ERD and NERD, although in the latter group statistical significance was only found after 8 wk of treatment. The response rates observed in the real life setting of this study were similar to those reported in the literature and were consistent with lowered treatment responses in patients with NERD than in those with ERD[19]. They were also consistent with data from the literature showing that the presence of IBS-like symptoms unfavourably affects the treatment response to PPIs, although data remain limited, especially in subpopulations of patients with ERD and NERD[8,15]. In the current study, the calculated response rates were based on the symptom burden assessed using the ReQuest™, whereas previous studies defined response solely based on a reduction of symptom burden[20,32,35], thus lacking a valid definition of a response threshold. Nonetheless, findings based on these two approaches are likely to be comparable.

In accordance with a previous analysis of baseline symptom burden in GERD patients[33], baseline "acid complaints" symptom scores were similar in ERD and NERD patients and in patients with and without IBS-like symptoms in the current study. Furthermore, the observed similar pre-post differences in "acid complaints" in the two GERD subgroups were expected based on previous studies using the ReQuest™, which have demonstrated similar improvements of acid-related symptoms during PPI therapy in both ERD and NERD patients[11,24,25]. This effect was independent of IBS status, which is in line with existing data[32].

In this real life setting, "lower abdominal complaints" scores at baseline were significantly higher in NERD than in ERD patients, supporting previous results from Neumann *et al* (2008), which showed that NERD patients suffered more frequently from IBS symptoms than did patients with ERD or Barrett's esophagus in a small patient population[15]. Both studies contrast with earlier evaluations of the ReQuest™ database, which revealed no baseline score differences between ERD and NERD[33]. The ReQuest™ database contains data from 23 clinical studies with symptom assessment based on the ReQuest™, thus representing a selected patient population, which may account for the differences in results compared with the current study conducted under real life conditions, in which patients were included based only on their GERD symptomatology.

We also found that patients with IBS-like symptoms had significantly higher baseline scores for "lower abdominal complaints" than patients without IBS-like symptoms in both GERD subclasses, a finding concordant with previous studies[20,32]. Baseline symptom score differences between IBS+ and IBS- patients were even more pronounced than those between ERD and NERD. These results show that the investigator assessment of the presence of IBS-like symptoms was congruent with patient symptom assessment *via* the ReQuest™.

Lower abdominal symptoms improved with pantoprazole treatment in both ERD and NERD patients. This finding corresponds with earlier findings in therapeutic

studies using PPIs as GERD treatment[28]. Interestingly, of the four subgroups, patients with NERD and IBS-like symptoms had the highest "lower abdominal complaints" symptom score at baseline and the largest clinical improvement following PPI therapy after 4 and 8 wk.

Although typical GERD symptoms, i.e. acid complaints, improved with pantoprazole therapy at 4 wk in this study, treatment response rates continued to increase from Week 4 to Week 8, suggesting that continued elevation of response rates may result from a reduction of other symptoms. These results support the concept that GERD is more than heartburn and IBS-like symptoms can be a part of the GERD symptom spectrum.

The proportion of patients with ERD in the current study was higher than what might be expected based on the literature. However, because our patients were a mix of primary and secondary care cases and came from many different countries, there is no good basis for estimating what the ERD:NERD ratio should be in this study. We can therefore only speculate on the possible explanations for the observed ratio. Symptom-based diagnosis of GERD is most reliable when heartburn and/or regurgitation are the patient's dominant or only symptoms. When abdominal symptoms such as dyspepsia or IBS, which are more prevalent in NERD than in ERD, are also present, physicians may be less confident about making a diagnosis of GERD. Enrolment into the trial was based on "patients considered to have symptoms of GERD"; thus, recruitment may have been inadvertently biased against enrolling patients with NERD, thereby affecting the ERD:NERD ratio. Nonetheless, this possibility should not affect the validity of the conclusions as the results relate to patients in whom physicians are prepared to make the GERD diagnosis on the basis of symptoms.

In conclusion, IBS-like symptoms have a distinct influence on the response of GERD patients to treatment with the PPI pantoprazole. The presence of IBS-like symptoms reduces response rates and appears to be higher in patients with NERD than in those with ERD. The exact underlying mechanisms for this remain to be elucidated. These findings are of particular interest for the medical community as the symptom based identification of GERD is reflective of the real life situation in daily practice. The results suggest the need to enhance the awareness of physicians for the possible co-morbid occurrence of IBS symptoms in GERD to improve diagnosis and treatment of individuals bothered by this intricate complex of symptoms.

COMMENTS

Background

The overlap of symptomatology between gastroesophageal reflux disease (GERD) and irritable bowel syndrome (IBS) has been increasingly recognised, and one theory integrates IBS-like symptoms into the spectrum of GERD complaints. The presence of IBS-like symptoms may unfavourably affect treatment outcome in some patients with GERD, thus highlighting the importance of identifying and understanding the spectrum of symptoms influencing the treatment outcome in GERD patients in ordinary clinical practice.

Research frontiers

Research suggests that IBS is common in patients with GERD (both ERD and NERD), although these data are from a small study of outpatients (n = 71) from only one clinic. In the current study, the authors further evaluate the interrelationship between IBS-like symptoms and GERD in a large (n = 1888), prospective, multicentre study of outpatients in a real-life setting, to help understand the spectrum of symptoms influencing the treatment outcomes for improved patient management in practice.

Innovations and breakthroughs

In a recent publication by Neumann *et al* (2008), IBS symptoms were common in GERD and found to be slightly more prevalent in NERD than in ERD; however, differences were not statistically significant, which may have resulted from the small sample size. The study is the largest to date to evaluate the presence of IBS-like symptoms in both ERD and NERD patients, and to establish the impact these symptoms may have on treatment response in GERD patients.

Applications

By understanding the impact of IBS-like symptoms on response to proton pump inhibitor (PPI) treatment in patients with GERD, physicians can better predict treatment response in their patients.

Terminology

ReQuest™: a fully validated, reliable, self-administered symptom assessment tool for the evaluation of treatment effects in ERD and NERD. It comprises six dimensions of GERD: acid complaints, upper abdominal/stomach complaints, lower abdominal/digestive complaints, nausea, sleep disturbances, and other complaints which are assessed for symptom intensity and symptom frequency. The ReQuest™ also includes a question about general well-being.

Peer review

The authors investigated the influence of IBS-like symptoms on treatment outcomes with pantoprazole in GERD in a real life setting. The authors concluded that the presence of IBS-like symptoms influences treatment outcome and symptom burden in GERD. They also supported the theory incorporating IBS-like symptoms into the spectrum of GERD by demonstrating good PPI response. Overall, this topic would raise quite an interest with readers. In view of the rarity of studies of IBS in GERD with a pragmatic attitude, this manuscript could possibly get frequent citations by other researchers.

Abstract

AIM: To investigate whether there were symptom-based tendencies in the *Helicobacter pylori* (*H. pylori*) eradication in functional dyspepsia (FD) patients.

METHODS: A randomized, single-blind, placebo-controlled study of *H. pylori* eradication for FD was conducted. A total of 195 FD patients with *H. pylori* infection were divided into two groups: 98 patients in the treatment group were treated with rabeprazole 10 mg twice daily for 2 wk, amoxicillin 1.0 g and clarithromycin 0.5 g twice daily for 1 wk; 97 patients in the placebo group were given placebos as control. Symptoms of FD, such as postprandial fullness, early satiety, nausea, belching, epigastric pain and epigastric burning, were assessed 3 mo after *H. pylori* eradication.

RESULTS: By per-protocol analysis in patients with successful *H. pylori* eradication, higher effective rates of 77.2% and 82% were achieved in the patients with epigastric pain and epigastric burning than those in the placebo group ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 46%, 36%, 52.5% and 33.3%, respectively, and there was no significant difference from the placebo group (39.3%, 27.1%, 39.1% and 31.4%) ($P > 0.05$). In 84 patients who received *H. pylori* eradication therapy, the effective rates for epigastric pain (73.8%) and epigastric burning (80.7%) were higher than those in the placebo group ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 41.4%, 33.3%, 50% and 31.4%, respectively, and did not differ from those in the placebo group ($P > 0.05$). By intention-to-treat analysis, patients with epigastric pain and epigastric burning in the treatment group achieved higher effective rates of 60.8% and 65.7% than the placebo group (33.3% and 31.8%) ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 34.8%, 27.9%, 41.1% and 26.7% respectively in the treatment group, with no significant difference from those in the placebo group (34.8%, 23.9%, 35.3% and 27.1%) ($P > 0.05$).

CONCLUSION: The efficacy of *H. pylori* eradication has symptom-based tendencies in FD patients. It may be effective in the subgroup of FD patients with epigastric pain syndrome.

INTRODUCTION

Functional dyspepsia (FD) is considered to possess a wide spectrum of nonspecific upper gastrointestinal symptoms without any organic alteration[1], accounting for 60% of patient referrals to gastroenterology clinics[2]. Despite being barely life-threatening, this disease can lead to a poor quality of life and a high economic burden in the patients[3].

However, without a clear understanding of its pathogenesis, the optional clinical strategy for FD remains a controversial issue. *Helicobacter pylori* (*H. pylori*) is considered to play a role in the pathogenesis of FD, and therefore, *H. pylori* detection and eradication are performed for FD treatment. But it is still dubious that patients with FD can benefit from *H. pylori* eradication. In our opinion, one of the factors that could contribute to the various outcomes of trials regarding the efficacy of *H. pylori* eradication for FD may be the diversity and inconsistency in FD symptoms, suggesting that this strategy might be effective only for certain dyspeptic symptoms in FD patients.

We conducted a prospective randomized, single-blind and placebo-controlled study and analyzed the efficacy of *H. pylori* eradication therapy for FD patients with *H. pylori* infection to find symptom-based predictors that can guide the clinical application of *H. pylori* detection and eradication.

MATERIALS AND METHODS

Patients

Patients with FD were admitted to the digestive outpatient clinics of three medical centers.

Patients who met the following criteria were enrolled into this study: (1) aged 18-75 years; (2) a definitive diagnosis of FD defined by Rome Ⅲ criteria (2006)[1]; (3) absence of organic diseases, such as ulcer, bleeding, erosion, atrophy, tumor, and esophagitis in gastroscopic examination; (4) laboratory tests, ultrasonography, and X-ray showing no structural diseases in other organs, such as liver, gall bladder, pancreas, kidney, intestine, and colon; (5) both rapid urease test (RUT) and ^{13}C-urea breath test (^{13}C-UBT) confirmed *H. pylori* infection; and (6) not receiving antacids, antibiotics, prokinetic drugs, or nonsteroidal anti-inflammatory drugs within the previous 4 wk.

We excluded the patients who (1) had a drug hypersensitivity history; (2) were previously treated with *H. pylori* eradication therapy; (3) were complicated with irritable bowel syndrome (defined by Rome Ⅲ criteria); (4) were pregnant or nursing; (5) could not describe subjective complaint accurately; (6) were complicated with diabetes, connective tissue disease, neuromuscular disease, or any other severe systematic diseases; (7) had a history of abdominal surgeries; and (8) drank alcohol more than 40 g a day.

This study was approved by the Institutional Review Board and the Ethics Committee of each medical center and was conducted in accordance with the Helsinki Declaration. Written informed consent was obtained from each subject before enrollment into this study.

Intervention

Gastroscopy and ^{13}C-UBT were performed, and samples of the gastric mucosa were collected during gastroscopy and used for further RUT testing. Patients who were positive in both the RUT and ^{13}C-UBT tests were considered suitable candidates for the proposed *H. pylori* eradication therapy. Patients were blinded to this study and randomly assigned by an independent investigator using a computer-generated random number table into one of the two groups, the treatment group and placebo group. The allocation ratio was 1:1. Patients in the treatment group were administered with rabeprazole 10 mg *bd* for 2 wk, and amoxycillin 1 g *bd* and clarithromycin 500 mg *bd* for 1 wk; patients in the placebo group were given placebos as control. No other medication was used during the proposed treatment.

Data collection and follow-up

The symptoms of suitable candidates were recorded on admission, and the proposed 2-wk eradication therapy was administered. Patients were returned for a ^{13}C-UBT test 4 wk after completing the therapy, wherein negative results were considered as definitive evidence of successful eradication. All patients were followed up for 3 mo.

Assessment of clinical efficacy

Six common symptoms of FD, including postprandial fullness, early satiety, nausea, belching, epigastric pain and epigastric burning, were assessed before and 3 mo after the eradication therapy. Symptom scores were graded according to severity as follows: (0) absent; (1) being aware of symptoms but no interference with daily activities; (2) having persistent discomfort with some interference with daily activities; (3) having severe discomfort and being unable to conduct daily work; and (4) suffering from worsening symptoms and having an extreme influence on daily life.

Clinical efficacy was calculated using the reduction rate of the total score of the six symptoms with the following formula: Reduction rate = (total score before treatment - total score after treatment)/ total score before treatment × 100%.

If the reduction rate was ⩾ 75%, the patient was considered to experience clinical recovery; a reduction rate ⩾ 50% referred to a significant improvement, a reduction

rate ⩾ 25% meant an improvement, and a rate < 25% meant invalidation. The total effective rate was calculated based on the clinical recovery rate and the significant improvement rate.

Safety assessment

Before treatment and during the follow-up, the basic vital signs and laboratory results, including routine blood, urine and stool tests, were monitored and documented. Any suspected adverse events observed during treatment were also recorded for further analysis.

Statistical analysis

Sample size was calculated based on the assumption of a 40% response in the drug arm *vs* 20% in placebo arm using the χ statistic to compare dichotomous variables with $\alpha = 0.05$ (two-tailed) and $\beta = 0.20$. The estimated sample size was 81 patients per arm. All data were processed using SPSS 11.0. The effective rates of symptoms were analyzed according to per-protocol (PP) and intent-to-treat (ITT) methods. The χ^2 test with 2 × 2 tables was used to analyze the efficacy. $P < 0.05$ was considered significant difference.

RESULTS

Patient population

From September 2008 to May 2010, 195 FD patients with *H. pylori* infection were enrolled into this study. Number, mean age, gender distribution and total scores of symptoms before treatment were similar in the two groups (Table 1).

H. pylori eradication rate and safety analysis

Totally, 195 FD patients with *H. pylori* infection were included. Twenty-two were excluded for discontinuation of medication due to severe diarrhea (3 in the treatment group) or for being lost to follow-up (11 in the treatment group and 8 in the placebo group). The others (84 in the treatment group and 89 in the placebo group) received complete treatment and follow-up examinations on schedule. In the treatment group, the successful *H. pylori* eradication rate was 85.7% (72/84).

Adverse reactions documented during treatment included: mild diarrhea in 7 cases, severe diarrhea in 3 cases, stomach discomfort in 4 cases, and simultaneous diarrhea and stomach discomfort in 1 case. Except for one patient who withdrew due to severe, unbearable diarrhea, the adverse events in the patients disappeared spontaneously after the eradication treatment. The basic vital signs and routine blood, urine and stool tests were normal in all the participants.

Total clinical efficacy

By PP analysis, in 72 patients with successful *H. pylori* eradication, the total effective rate was 44.4% 3 mo after treatment. In 84 patients who received *H. pylori* eradication therapy, the total effective rate was 42.9%, which was higher than that in the 89 patients of the placebo group (21.4%) ($P < 0.05$) (Table 2).

By ITT analysis, the total effective rate was 36.7% in the treatment group, and 19.6% in the placebo group. There was significant difference between the two groups ($P < 0.05$) (Table 2).

Table 1 Baseline demographic and clinical characteristics of patient population

	Treatment group	Placebo group
No. of patients	98	97
Age (yr, mean ± SD)	49.2 ± 14.1	45.5 ± 14.9
Gender (male/female)	47/51	42/55
Total scores of symptoms before treatment (mean ± SD)	9.0 ± 2.8	8.4 ± 2.6

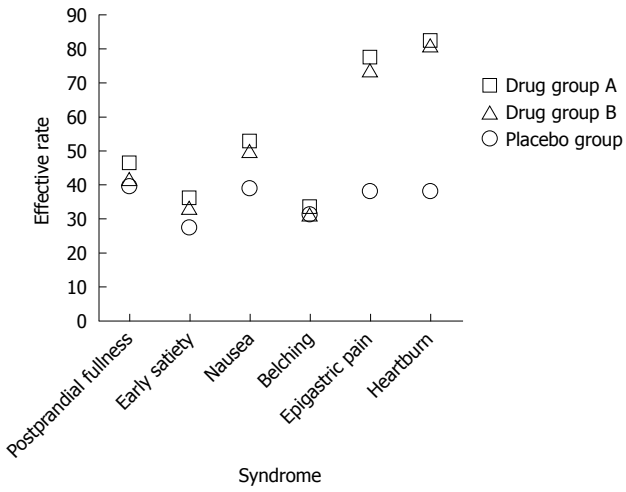

Figure 1 Respective effective rates of six common symptoms in functional dyspepsia patients by per-protocol analysis.

Efficacy for symptom improvement

By PP analysis 3 mo after treatment, among the 72 patients with successful *H. pylori* eradication, those with epigastric pain and epigastric burning achieved higher effective rates of 77.2% and 82% than the patients in the placebo group (38.2% and 38.2%) ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 46%, 36%, 52.5% and 33.3%, and 39.3%, 27.1%, 39.1% and 31.4%, respectively in the placebo group ($P > 0.05$) (Table 3 and Figure 1).

Correspondingly, in 84 patients who received *H. pylori* eradication therapy, the effective rates for epigastric pain (73.8%) and epigastric burning (80.7%) were higher than in the placebo group ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 41.4%, 33.3%, 50% and 31.4%, respectively, and did not differ from those in the placebo group ($P > 0.05$) (Table 3 and Figure 1).

Similar results were obtained by ITT analysis. In the treatment group, patients with epigastric pain and epigastric burning also achieved higher effective rates of 60.8%

and 65.7% than those in the the placebo group (33.3% and 31.8%) ($P < 0.05$). The effective rates for postprandial fullness, early satiety, nausea and belching were 34.8%, 27.9%, 41.1% and 26.7% in the treatment group, and 34.8%, 23.9%, 35.3% and 27.1% in the placebo group ($P > 0.05$) (Table 3 and Figure 2).

DISCUSSION

FD is a common disease, accounting for a majority of upper gastrointestinal symptoms. The pathogenesis of FD is unknown. Various pathophysiological mechanisms, such as gastroduodenal dyskinesia[4], visceral paraesthesia[5], vagal dysfunction[6], *H. pylori* infection[7], and psychosocial factors[8], have been proposed to promote the development of FD. Without a clear understanding of its pathogenesis, it is not surprising that standard and effective strategies for treatment of this disease are still unavailable. Consequently, patients with FD now receive symptomatic treatment with prokinetics, antacids, and digestive enzymes empirically, which are prone to unfavorable responses and an extremely high risk of relapse.

H. pylori infection is the sole cause of FD that can be successfully eliminated by well-established medical interventions. Furthermore, 40%-60% of FD patients suffer from a detectable *H. pylori* infection[9,10], which can induce chronic inflammation and in turn the development of symptoms[11]. Evidence suggests that *H. pylori*-associated dyspepsia is caused by effects of the bacteria, such as increased secretion of gastric acid, elevated fasting and postprandial levels of serum gastrin, and declines in somatostatin in gastric mucosa. All these abnormalities can be corrected after *H. pylori* eradication[12]. If symptomatic benefits can be achieved after *H. pylori* eradication, the potential implications for this treatment will be enormous.

Unfortunately, whether *H. pylori* eradication is beneficial in FD remains controversial. Several studies have demonstrated that *H. pylori* eradication is efficacious[13-17]. A double-blind study of Asian populations suggested that patients with FD benefit from the *H. pylori* treat-

ment, who gained as much as a 13-fold greater chance for symptom improvement[18]. Another systematic review of FD patients with *H. pylori* infection showed that improvement of symptoms could be achieved by up to 3.5 folds with *H. pylori* eradication therapy[19].

Other clinical trials, however, have noted that *H. pylori* eradication therapy has a moderate but statistically significant effect on FD patients with *H. pylori* infection[13,20]. A long-term study attributed the relief of symptoms to natural fluctuations in dyspeptic symptoms[21]. Evenly, low relief rates[22] and the persistence of symptoms[23] were observed in some reports, indicating no benefit of *H. pylori* eradication. Some researchers also found that dyspeptic symptoms had a negative correlation with the severity of *H. pylori*-associated inflammation and oxidative damage in FD patients[11].

Nevertheless, in most trials, the follow-up period was less than 1 year, creating a dearth of information about the long-term effects of *H. pylori* eradication. Recently, several long-term prospective researches have shown promising benefits[24,25]. Maconi *et al*[24] reported that at a 7-year follow-up, 33.9% of patients with successful *H. pylori* eradication were more likely to be asymptomatic. This percentage was slightly higher than in symptom-free patients with persisted bacteria infection. Yet, there were some confounding factors in the study. Some patients continued to use antisecretory agents, and 40% of patients still used or had been using anti-dyspeptic medications, which might bias the results and render them disputable[24]. Therefore, the evidence that FD patients with *H. pylori* infection benefit from *H. pylori* eradication therapy is inconclusive[26].

The consensus on *H. pylori* treatment in China, reached in 2003[27], and its new version published in 2007[28], recommended but did not stipulate *H. pylori* eradication therapy in "some patients with FD" or those who had "dyspeptic symptoms that were accompanied by chronic gastritis." As such, questions on whether routine *H. pylori* detection should be applied in patients with FD, whether *H. pylori* eradication treatment must be conducted in these patients, and whether the relief of symptoms can be expected following successful eradication have become critical issues. These issues can result in negative consequences, including over-examination and over-treatment, vague evaluations of prognoses, panic psychology in patients with *H. pylori* infection, and decreased treatment compliance among irresponsive patients.

To our knowledge, no study has yet focused on the symptom-based tendencies of *H. pylori* eradication. Based on our prospective study, patients with epigastric pain and epigastric burning could experience greater improvement 3 mo after treatment than those with postprandial fullness, early satiety, nausea, and belching. The Rome Ⅲ consensus classifies FD into two subgroups: postprandial distress syndrome, which presents with postprandial fullness, early satiety, postprandial nausea and over-belching; and epigastric pain syndrome, which features epigastric pain or epigastric burning[1]. This indicated that *H. pylori* eradication might be more effective in the subgroup of FD patients with epigastric pain syndrome.

But the mechanism of this symptom selectivity and tendency of *H. pylori* eradication therapy, however, is unknown. Gastric emptying in patients with FD is usually delayed or accelerated. The former can lead to abdominal distention, early satiety and nausea, and the latter can result in epigastric pain[15]. *H. pylori* infection is associated with faster gastric emptying and aggravates abdominal pain[15]. This result supports our findings that *H. pylori* eradication significantly improves the symptoms of epigastric pain. With regard to the relief of epigastric burning in our patients, the intake of antacids might be a half-convincing explanation.

In the further study, we will classify FD patients into two subgroups by the Rome Ⅲ consensus to observe the symptom response to *H. pylori* eradication therapy, in order to investigate whether the efficacy of *H. pylori* eradication can be predicted by assessing the initial dyspeptic symptoms.

There are, however, regional differences in the prevalence of various dyspeptic symptoms in patients with FD. For instance, compared with Asian populations, the symptoms of epigastric pain and epigastric burning are more common in Western FD patients[29]; there is a higher prevalence of *H. pylori* infection in Asian populations than in Western populations[30]. Hence, global multicenter studies regarding the symptom-based tendencies of *H. pylori* eradication treatment are needed for further evaluation of this regimen.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) eradication is performed commonly as a treatment in functional dyspepsia (FD) patients with *H. pylori* infection. But whether *H. pylori* eradication is beneficial for the improvement of symptoms in FD is still controversial.

Research frontiers

Characteristics of FD patients with *H. pylori* infection who benefit from *H. pylori* eradication are being investigated.

Innovations and breakthroughs

Up to now, no study has yet focused on the symptom-based tendencies of *H. pylori* eradication in FD patients. The authors conducted a prospective randomized, single-blind and placebo-controlled study and analyzed the efficacy of *H. pylori* eradication therapy for FD patients with *H. pylori* infection to find symptom-based predictors that can guide the clinical application of *H. pylori* detection and eradication.

Applications

This article indicated that *H. pylori* eradication might be more effective in the subgroup of FD patients with epigastric pain syndrome.

Peer review

The authors hypothesized that *H. pylori*-infected FD patients should have significant improvement of symptoms after *H. pylori* eradication, and the study was designed to test it. This study (hypothesis and methodology) is simple and clearly presented. The manuscript is well organized. However, a little bit more details are expected in the methodology section.

Abstract

AIM: To investigate the association between *GSTM1* and *GSTT1* polymorphisms and the risk of hepatocellular carcinoma (HCC) in Chinese population.

METHODS: Literature databases including PubMed, ISI web of science and other databases were searched. Pooled odds ratio (OR) and 95% CI were calculated using random- or fixed- effects model. Subgroup analysis and sensitivity analysis were also performed.

RESULTS: Nineteen studies of *GSTM1* (2660 cases and 4017 controls) and 16 studies of *GSTT1* (2410 cases and 3669 controls) were included. The *GSTM1*/*GSTT1* null genotypes were associated with increased risk of HCC in Chinese population (for *GSTM1*, OR = 1.487, 95% CI: 1.159 to 1.908, *P* = 0.002; for *GSTT1*, OR = 1.510, 95% CI: 1.236 to 1.845, *P* = 0.000). No publication bias was detected. In subgroup analysis, glutathione S-transferases polymorphisms were significantly associated with HCC risk among the subjects living in high-incidence areas, but not among the subjects living in low-incidence areas.

CONCLUSION: The present meta-analysis suggests that *GSTM1*/*GSTT1* null genotypes are associated with increased risk of HCC in Chinese population.

Key words: *GSTM1*; *GSTT1*; Polymorphism; Hepatocellular carcinoma; Liver cancer

INTRODUCTION

Liver cancer is one of the most common types of cancer and one of the most common causes of cancer-related

death[1]. The death rates have increased for both men and women with liver cancer over the past two decades[2]. The incidence and mortality rates of liver cancer vary considerably among racial and ethnic groups[3]. Asians, particularly Chinese, have a high risk of developing liver cancer[4]. About 80%-90% of all cases of primary liver cancer are hepatocellular carcinoma (HCC).

The pathogenesis of HCC may have a genetic and environmental basis[5,6]. Epidemiological studies have shown that HCC is associated with many environmental factors, including alcoholism, chronic infection with hepatitis B virus (HBV), hepatitis C virus (HCV), and dietary exposure to aflatoxin B1 (AFB1)[7]. These hepatocarcinogens result in increased generation of reactive oxygen species and free radicals that cause liver damage and repair. Thus the accumulated multistage genetic mutations may lead to liver carcinogenesis[8-11].

During liver carcinogenesis, cellular defense mechanisms can alleviate the effects of oxidative stress and exogenous toxins. One of the essential antioxidant is the reducing compound glutathione. Reduced glutathione can be conjugated to various xenobiotics and endobiotics by glutathione S-transferases (GST), a superfamily of cytosolic soluble detoxification enzymes. In humans, cytosolic soluble GSTs are encoded by seven distinct genes: Alpha, Mu, Omega, Pi, Sigma, Theta and Zeta[12-14]. GSTs play an important role in cellular protection against oxidative stress and exogenous toxins. Homozygous deletion of GST genes (null genotype) results in decreased enzyme activity, which will impede detoxification and may ultimately increase the risk of many diseases, including HCC[13-16]. *GSTM1* and *GSTT1* have been the most extensively studied GST genes. While many studies have investigated the relationship between *GSTM1* and *GSTT1* polymorphisms and HCC risk, so far the results have been inconsistent.

Recently, a meta-analysis result did not suggest a statistically significant increased risk of HCC with the *GST* null genotypes[17]. However, a large number of studies were not reported in that meta-analysis (which included only 9 studies of *GSTM1* and 8 studies of *GSTT1* in Chinese population)[17]. Since the ethnic background and the environmental exposures may vary greatly across populations in different geographic regions, the conclusion could not be drawn[17]. During the preparation of this paper, another meta-analysis was published showing that the null genotypes of *GSTM1* and *GSTT1* are both associated with an increased HCC risk[18]. However, these investigators omitted some important data and introduced some incorrect information[18]. For example, Indians are mainly of Indo-European and Dravidian ancestries, which should be distinguished from East Asian population[18]. Many studies, including our previous studies[16,19-22], have reported on the effects of ethnic differences on genetic predisposition to human diseases. In addition, it is important to note that the allele frequencies and the genotype distributions for GST genes differed significantly across ethnic groups[23]. For example, the frequency of *GSTM1* null genotype is about 0.53 in Caucasians/Asians and about 0.28 in Africans; and the frequency of *GSTT1* null genotype is about 0.20 in Caucasians and about 0.52 in Asians[23]. Therefore, heterogeneity was introduced in that meta-analysis, which may not accurately assess the effects of *GSTM1* and *GSTT1* null genotypes on the risk of HCC[18]. In this study, we reinvestigated the relationship between *GSTM1*/*GSTT1* polymorphisms and the risk of HCC. We focused on the association between GST polymorphisms and the risk of HCC in Chinese population, because Chinese are at a much greater risk of developing HCC compared to other ethnic groups. A total of 19 studies of *GSTM1* (2660 cases and 4017 controls) and 16 studies of *GSTT1* (2410 cases and 3669 controls) were included. This meta-analysis has a much greater number of subjects and thus a much greater statistical power; therefore, it may define the effects of GST gene polymorphisms on the risk of HCC more precisely.

MATERIALS AND METHODS

Literature and search strategy

We searched the literature databases including PubMed (1950 to 2010), ISI web of science (1975 to 2010), Embase (1966 to 2010), Chinese Biomedical Database (1978 to 2010), China National Knowledge Infrastructure (1979 to 2010, in Chinese) and Wanfang Data (1982 to 2010, in Chinese).

The search strategy to identify all possible studies involved use of combinations of the following key words: ("glutathione S-transferase" or "GST" or "GSTM1" or "GSTT1") and ("hepatocellular carcinoma" or "liver cancer" or "HCC") and ("China" or "Chinese"). The reference lists of reviews and retrieved articles were also searched. Supplementary data were searched for missing data points. If more than one article were published using the same case series, only the study with largest sample size was selected. The literature search was updated on Oct. 20th, 2010.

Inclusion criteria and data extraction

The studies included in the meta-analysis must meet all the following inclusion criteria: (1) evaluating the association between *GSTM1* or *GSTT1* null genotypes and HCC risk; (2) case-control design; (3) in Chinese population; and (4) sufficient data for calculation of odds ratio (OR) with CI. The following information was extracted from each study: (1) name of the first author; (2) year of publication; (3) language of publication; (4) residence area of the subjects; (5) source of control subjects; (6) numbers of cases and controls; (7) numbers of null genotypes for *GSTM1* and *GSTT1* in cases and controls; and (8) OR and 95% CI. The authors independently assessed the articles for compliance with the inclusion/exclusion criteria, resolved disagreements and reached a consistent decision.

Statistical analysis

The association between *GSTM1*/*GSTT1* polymorphisms and the risk of HCC was estimated by calculating pooled

NA: Not available; OR: Odds ratio.

OR and 95% CI. The significance of the pooled OR was determined by Z test with $P < 0.05$ considered statistically significant. Q test was performed to evaluate whether the variation was due to heterogeneity or by chance. A random- (DerSimonian-Laird method[24]) or fixed- (Mantel-Haenszel method[25]) effects model was used to calculate pooled effect estimates in the presence ($P \leqslant 0.10$) or absence ($P > 0.10$) of heterogeneity, respectively. Begg's funnel plot, a scatter plot of effect against a measure of study size, was generated as a visual aid to detecting bias or systematic heterogeneity[26]. An asymmetric funnel plot indicates a relationship between effect and study size, which suggests the possibility of either publication bias or a systematic difference between smaller and larger studies ("small study effects"). Publication bias was assessed by Begg's test and Egger's test[27] with $P < 0.05$ considered statistically significant. Subgroup analyses were performed to examine the effect of heterogeneity on meta-analysis results. The following subgroup comparisons were analyzed: residence area of the subjects (high-incidence area *vs* low-incidence area), number of cases (< 100 *vs* ⩾ 100), and source of controls (population-based *vs* hospital-based). To evaluate the stability of results, sensitivity analysis was performed by removing one study at a time and calculating the overall homogeneity and effect size. Data analysis was performed using STATA version 10 (StataCorp LP, College Station, Texas, USA).

RESULTS

Characteristics of the studies

The literature search identified a total of 137 potential relevant papers. The full text articles were retrieved and carefully reviewed to assess the eligibility according to the inclusion criteria. Forty-three papers met the inclusion criteria[28-70]. However, 23 papers were excluded because they were earlier or smaller reports from the same groups[29,30,32-37,43-46,48-50,53,55-58,61,62,64]. Nineteen studies of *GSTM1* (2660 cases and 4017 controls) and 16 studies of *GSTT1* (2410 cases and 3669 controls) were included in the meta-analysis, respectively. Most of the cases and controls included in this meta-analysis were HBV carriers. The characteristics of the included studies are listed in Tables 1 and 2.

Meta-analysis results of the association between GSTM1 polymorphisms and HCC

Nineteen studies of *GSTM1*, including 2660 cases and 4017 controls, were included in the meta-analysis. The relative frequency of *GSTM1* null genotype among control groups ranged from 0.384 to 0.683 in Chinese population. Using a random-effects model, the overall meta-analysis result showed that there was a statistically significant association between *GSTM1* null genotype and HCC risk in Chinese population (OR = 1.487, 95% CI: 1.159 to 1.908, $P = 0.002$). The forest plot is shown in Figure 1.

Meta-analysis results of the association between GSTT1 polymorphisms and HCC

Sixteen studies of *GSTT1*, including 2410 cases and 3669 controls, were included in the meta-analysis. The relative frequency of *GSTT1* null genotype among control groups ranged from 0.183 to 0.602 in Chinese population. Using a random-effects model, the overall meta-analysis result showed that there was a statistically significant association between *GSTT1* null genotype and HCC risk in Chinese

population (OR = 1.510, 95% CI: 1.236 to 1.845, P = 0.000). The forest plot is shown in Figure 2.

Subgroup analysis

To examine the effect of heterogeneity between studies on meta-analysis results, we conducted subgroup analyses stratified by the following: residence area of the subjects (high-incidence area vs low-incidence area), number of cases (< 100 *vs* ≥ 100), and source of controls (population-based vs hospital-based). GST polymorphisms were significantly associated with HCC risk among the subjects living in high-incidence areas (Jiangsu, Zhejiang, Guangxi and Guangdong provinces), but not among the studies living in low-incidence areas. The result of subgroup analysis is shown in Tables 3 and 4.

Sensitivity analysis

Sensitivity analysis was performed by excluding each study at a time. The analysis confirmed the stability of the association between *GSTM1* and *GSTT1* polymorphisms and HCC risk (data not shown).

Potential publication bias

Begg's funnel plots were generated to assess potential publication bias (Figure 3 for *GSTM1* and Figure 4 for *GSTT1*). No publication bias was detected (Egger's test,

DISCUSSION

GST polymorphisms are implicated in the development of HCC. In the present study, we investigated the relationship between *GSTM1* and *GSTT1* polymorphisms and the risk of HCC in Chinese population. To minimize language bias, all available studies published in both English and Chinese languages were assessed, including a total of 19 studies of *GSTM1* (2660 cases and 4017

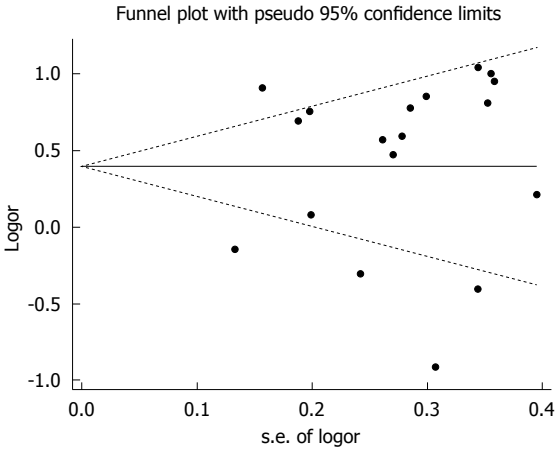

Figure 3 Funnel plot of the meta-analysis of the association between *GSTM1* polymorphism and hepatocellular carcinoma risk.

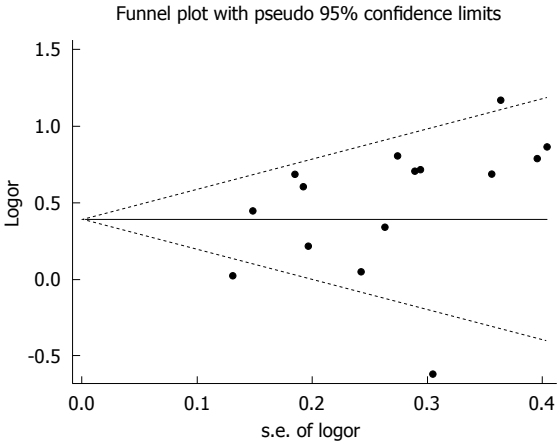

Figure 4 Funnel plot of the meta-analysis of the association between *GSTT1* polymorphism and hepatocellular carcinoma risk.

controls) and 16 studies of *GSTT1* (2410 cases and 3669 controls). The present meta-analysis has a much greater number of subjects and thus a much greater statistical power; therefore, it can define the effect of GST genes polymorphisms on HCC risk more precisely. The pooled analysis of two genes produced similar risk estimates (for *GSTM1*, OR = 1.487, 95% CI: 1.159 to 1.908, P = 0.002; for *GSTT1*, OR = 1.510, 95% CI: 1.236 to 1.845, P = 0.000), suggesting that both *GSTM1* and *GSTT1* null genotypes are associated with an increased risk of HCC in Chinese population.

The difference between our meta-analysis and the previous metaanalysis may be due to language bias introduced in the previous metaanalysis, which was based primarily on reports in English[17]. Therefore, all available studies published in both English and Chinese languages were assessed in the current meta-analysis. Another recent meta-analysis suggested that null genotypes of *GSTM1* and *GSTT1* were both associated with increased risk of HCC[18]. However, these investigators omitted some data and included some studies with incorrect information[52,53,59,65,69]. Therefore, the effects of *GSTM1* and *GSTT1* null genotypes on HCC was not assessed accurately[18]. Considering that Chinese people are at a much greater risk of developing HCC, we focused on the relationship between GST polymorphisms and HCC risk in Chinese population, thereby minimizing ethnic/racial differences. In the subgroup analysis, GST polymorphisms were significantly associated with HCC risk among the subjects living in high-incidence areas, but not among the subjects living in low-incidence areas. This result suggests that the effect of GST polymorphisms on HCC risk may be enhanced by environmental risk factors, such as dietary exposure to AFB1. Since sample size could influence the results, we also performed subgroup analysis stratified by sample size of cases. The results showed that the studies with either large (number of cases $\geqslant$ 100) or small sample size (number of cases $<$ 100) had similar risk estimates, indicating that small study effects may not exist in this meta-analysis. In addition, we generated Begg's funnel plots and found no publication bias among the studies included in this meta-analysis (Begg's test and Egger's test, $P > 0.1$).

The current meta-analysis has vital advantages compared to other studies; however, it does have some limitations. First, the present meta-analysis was based on unadjusted effect estimates and confidence intervals due to insufficient data available for most of the studies. Although the cases and controls were matched on age, sex and residence in all studies, these confounding factors might slightly modify the effect estimates. Second, the effect of gene-environment interactions was not studied in this meta-analysis. Alcoholism, HBV/HCV infections, and dietary exposure to AFB1 may be environmental risk factors that modify the effect estimates. Third, although most primary liver cancer cases are HCC, some of the included studies did not state whether the primary liver cancer patients were histologically confirmed to be HCC. Fourth, the heterogeneity between studies was not well addressed by subgroup analysis, suggesting there were other potential confounding factors in the included studies. Fifth, the results of subgroup analysis should be interpreted with caution because of limited statistical power. We anticipate these issues will be addressed in future studies.

In summary, our research suggests that *GSTM1*/*GSTT1* null genotypes are associated with increased risk of HCC in Chinese population. Considering the increasing prevalence of HCC in China and other countries worldwide, our finding may have important clinical and public health implications. More epidemiological and mechanistic studies are needed to further elucidate the role of GST polymorphisms in HCC and other liver cancers.

COMMENTS

Background

Asians, particularly Chinese, have a high risk of developing liver cancer. About 80%-90% of all cases of primary liver cancer diagnosed are hepatocellular carcinoma (HCC). Previous studies suggest that glutathione S-transferase (GST)

polymorphisms (*GSTM1* and *GSTT1*) may be risk factors for HCC. However, recent findings have been inconsistent.

Research frontiers

Meta-analysis was performed to assess the association between *GSTM1* and *GSTT1* polymorphisms and HCC risk in Chinese population.

Innovations and breakthroughs

The meta-analysis provided new evidence for the association between *GSTM1* and *GSTT1* polymorphisms and HCC risk in Chinese population. The results of this meta-analysis show that the *GSTM1* and *GSTT1* null genotypes are both associated with increased risk of HCC in Chinese population, suggesting that *GSTM1*/*GSTT1* null genotype carriers have 1.5 fold higher risk of developing HCC.

Applications

Since *GSTM1*/*GSTT1* polymorphisms are implicated in the pathogenesis of HCC, population-based genetic screening in future may help to identify the individuals at high risk of developing liver cancers.

Terminology

Meta-analysis, which combines the results of several studies that address a set of related research hypotheses, is an important component of a systematic review procedure.

Peer review

This meta-analysis provided new insights into liver cancer research.

Abstract

AIM: To describe survival trends in patients in Northeast China diagnosed as gastric cancer.

METHODS: A review of all inpatient and outpatient records of gastric cancer patients was conducted in the First Affiliated Hospital of China Medical University. All the gastric cancer patients who satisfied the inclusion criteria from January 1, 1980 through December 31, 2003 were included in the study. The main outcomes were based on median survival and 3-year and 5-year survival rates, by decade of diagnosis.

RESULTS: From 1980 through 2003, the median survival for patients with gastric cancer (n = 1604) increased from 33 mo to 49 mo. The decade of diagnosis was not significantly associated with patient survival for gastric cancer (P = 0.084 for overall survival, and P = 0.150 for 5-year survival); however, the survival rate of the 2000s was remarkably higher than that of the 1980s (P = 0.019 for overall survival, and P = 0.027 for 5-year survival).

CONCLUSION: There was no significant difference of survival among each period; however, the survival rate of the 2000s was remarkably higher than that of the 1980s.

Key words: Survival trends; Gastric cancer; Northeast China

INTRODUCTION

Although the prognosis of gastric cancer have improved due to early diagnosis, radical operation, and the development of adjuvant therapy, patients with gastric cancer still have a poor prognosis[1,2]. Since the 1980s, there have been substantial changes in the incidence of gastric cancer[3,4] and the causes for this change remain highly debated. Possible causes include the obesity epidemic, decreasing *Helicobacter pylori* (*H. pylori*) prevalence, and dietary changes[5,6].

Currently, various surgical approaches are being practiced, including conventional surgery, function preserving surgery, minimally invasive surgery and less extensive lymph node dissection. Previously, surgical interventions had been associated with significant perioperative risk; recently, however, this risk appears to be decreasing[7,8]. The role of chemotherapy, both preoperatively and postoperatively, has been extensively studied[9-11]. Despite these changes in treatment, it is unclear whether the survival of patients with gastric cancer has significantly improved since the 1980s.

The purpose of the current study was to use a sample population over a 24-year period to describe changes in the survival of gastric cancer patients. We compared patient survival in the 1980s with the 1990s and the 2000s, since patient survival might have improved as a result of advances in the quality of surgical techniques and other medical management.

MATERIALS AND METHODS

Patients

We enrolled 1604 histologically confirmed gastric cancer patients who underwent an operation at the First Affiliated Hospital of the China Medical University between 1980 and 2003. Of these patients, 496 were allocated to 1980s, 673 to 1990s and 435 to 2000s. The inclusion criteria were as follows: (1) gastric cancer was histologically confirmed; (2) an operation was performed; and (3) a complete medical record was available.

Follow-up for all patients was conducted by mailing letters or telephone interviews. The follow-up was completed in December 2008, with a total follow-up rate of 89%. Clinical findings, surgical findings, pathological findings and every follow-up were collected and recorded in the database. The study protocol was approved by the Ethics Committee of China Medical University.

Statistical analysis

Kaplan-Meier survival curves were used to estimate patient survival. Cox proportional hazards regression models were used to assess associations of risk factors with survival. For univariate analyses, we put the prognostic factor of interest and the diagnosis period as covariates in the Cox regression model. In multivariate analyses, the prognostic factor detected in univariate analysis and the diagnosis period were the covariates included in the Cox regression model.

Two-sided *P* values were calculated for all tests and are reported here. *P* values less than 0.05 were considered statistically significant. Analyses were performed using SPSS software, version 16.0.

RESULTS

In total, 1604 patients diagnosed with gastric cancer were enrolled in the 24-year study period. The median survival for gastric cancer patients increased during the 2 decades studied from 33 mo in the 1980s, and 39 mo in the 1990s to 49 mo in the 2000s. The 3-year survival for patients in the 1980s, 1990s, and 2000s was 47.6% (95% CI: 43.3%-51.9%), 51.4% (95% CI: 47.7%-55.1%), and 55% (95% CI: 49.5%-60.5%), respectively. Five-year survival estimates were 39.1% (95% CI: 34.8%-43.4%), 39.8% (95% CI: 36.1%-43.5%), and 45% (95% CI: 37.9%-52.1%) in the 1980s, 1990s, and 2000s, respectively. There was no significant difference in survival among the three periods (P = 0.084 for overall survival, and P = 0.150 for 5-year survival); however, the survival rate in the 2000s was remarkably higher than that of the 1980s

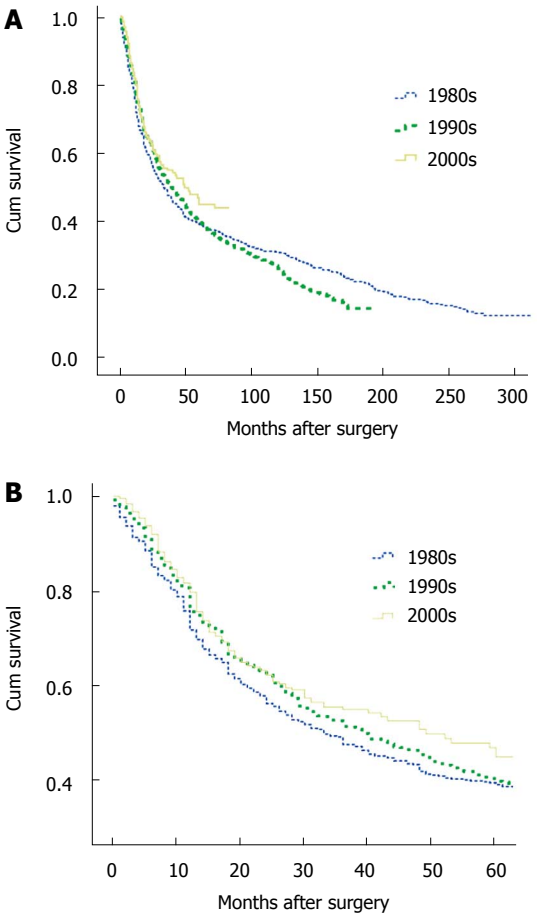

Figure 1 Kaplan-Meier survival curves for patients with gastric cancer by decade. A: Overall survival for gastric cancer patients; B: Five-year survival for gastric cancer patients.

(P = 0.019 for overall survival, and P = 0.027 for 5-year survival). Kaplan-Meier survival curves for patients with gastric cancer, by decade, are shown in Figure 1.

For those patients who had undergone resection with curative intent, the median survival of patients was 85 mo in the 1980s, 58 mo in the 1990s, and 72 mo in the 2000s, respectively The 3-year survival for patients in the 1980s, 1990s, and 2000s were 65.3% (95% CI: 60.0%-70.6%), 60.8% (95% CI: 56.5%-65.1%), and 61.0% (95% CI: 55.3%-66.7%), respectively. Five-year survival estimates were 55.6% (95% CI: 50.1%-61.1%), 48.9% (95% CI: 44.6%-53.2%), and 50.4% (95% CI: 42.8%-58.0%) in the 1980s, 1990s, and 2000s, respectively. There was no significant difference in survival among the three time periods (P = 0.169 for 5-year survival).

The distributions of patient characteristics by decade are shown in Table 1. Significant changes were detected in all areas except in the distribution of number of involved lymph nodes, hepatic metastasis and type of gastrectomy during the 24 years studied (P = 0.072, 0.244 and 0.073, respectively). The median age was 56 in the 1st period, 60 in the 2nd period, and 58 in the 3rd period. There was also a change in male to female ratio from 4:1 to 7:3. Among tumor factors, whole stomach tumors decreased from 12% to 5%, while T1 stage tumor and node negative

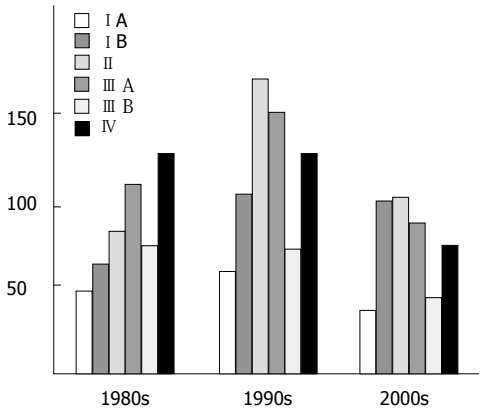

Figure 2 The shift in the distribution of TNM stage of disease at diagnosis.

cancers were found more frequently in the later periods, though this may not be significant, as early gastric cancers increased only from 20% to 24%. Curative resection rates were markedly increased during the 24-year period. Most recently, the curative resection rate was 92% (Table 1). Most cases were diagnosed at advanced stages (T2-T4, N1-N3) throughout the 2-decade period. Figure 2 shows the shift in the distribution of TNM stage of disease at diagnosis.

The operative mortality rate in the 1st period was 2% and 1.3% in the 2nd period, whereas it was less than 1% in the 3rd period. The multivariate Cox proportional hazards models for gastric cancer are shown in Table 2. In the Cox model for gastric cancer, adjusting for sixteen variables, there was no significant association between the decade of diagnosis and patient survival ($P = 0.385$). For the decade of the 1990s relative to the 1980s, the hazard ratio for gastric cancer cases was 1.025 (95% CI: 0.807-1.301), and for the decade of the 2000s relative to the 1980s, the hazard ratio was 0.914 (95% CI: 0.674-1.241). Patient survival was significantly associated with surgical extent ($P = 0.000$). Cases involving curative surgery were associated with prolonged survival. Figure 3 illustrate the Kaplan-Meier survival curves of patients with gastric cancer, by surgical intervention (absolutely curative, relatively curative, and palliative). Stage-by-stage comparison was performed among the 3 periods; for the Ⅱ stage patients the survival rate of 1990s was significantly worse than that of the 1980s.

DISCUSSION

In this study of gastric cancer diagnosed in Northeast China, we found that the median survival of patients with gastric cancer actually appeared to increase between 1980 and 2000. There was a significant change in patient survival in the 2000s compared to that in the 1980s, and decade of diagnosis was not significantly associated with

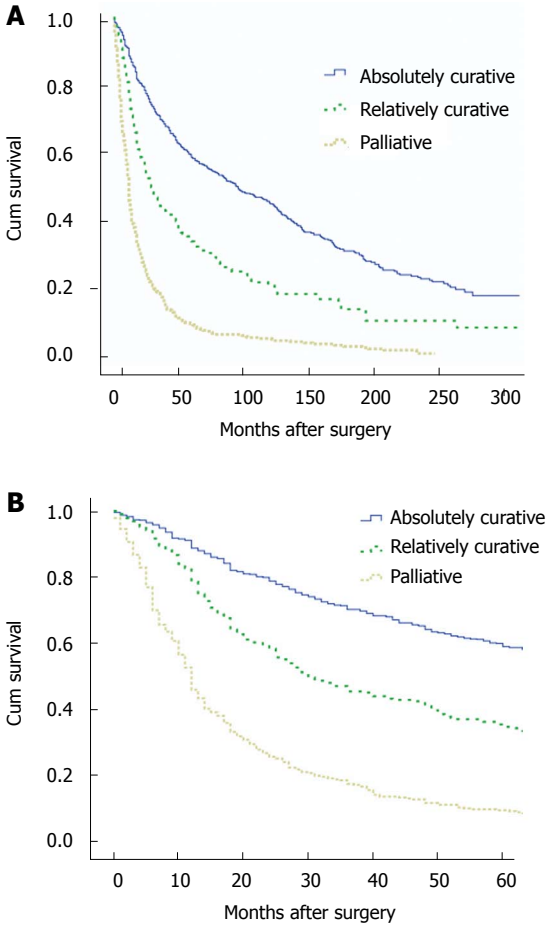

Figure 3 Kaplan-Meier survival curves of patients with gastric cancer, by surgical intervention (absolutely curative, relatively curative, palliative). A: Overall survival for gastric cancer patients; B: Five-year survival for gastric cancer patients.

patient survival for gastric cancer during the 24 years. The improving prognosis of gastric cancer in recent years has been reported[12-18]. For example, the 5-year relative survival rate for gastric cancer increased from 13% to 18% in Sweden from 1960-1964 to 1985-1986[13]. However, for those patients who had a curative intent resection, there was no significant difference in survival between 1980 and 2000. As the patients operated on for palliative purpose decreased with percentages over time, it is possible that the inclusion of these patients could explain

some of the trend of increasing survival between 1980 and 2000.

In this study, we found that the proportion of patients with early gastric cancer increased to 24% in the 3rd period. With the increasing incidence of early gastric cancer, node negative cancers were also increased; however, as the increasing proportions were too little and may not be significant, there were still too many patients diagnosed at an advanced stage. We also found that the incidence among women increased in the later period from 20% to 30%. We speculate that this may be due to the changes in lifestyle of Chinese women, such as more smoking and greater alcohol intake, suggesting that we should strengthen the primary prevention of gastric cancer. Currently, a surgical cure remains the only intervention that may significantly improve a patient's chance of survival; moreover, surgery is the only treatment modality offering hope for a cure. Nevertheless, most patients die from locoregional recurrence or distant metastasis even after curative surgery for advanced stage cancers[19]. As metastasis to lymph nodes is linked to the outcome, extensive lymph node dissection is a statistically favorable prognostic factor[20]. Without surgical intervention, 2-year survival for patients with gastric cancer remained essentially zero[21]. Baba *et al*[22] reported that the rate of recurrence was higher in patients treated with dissection of group 1 lymph nodes than for those with dissection of group 2 or 3 nodes. In our study, 84% of the patients were treated with D2 or D3 lymph node dissection in the later period, which was much more than in the previous two periods. Besides the increase of early gastric cancer patients, advances in treatment factors mostly contributed to the improved survival.

Early diagnosis has markedly improved the survival of patients with gastric cancer, and mass screening has a definite role in diagnosing gastric cancer in its early stages[23]. In Japan, where the incidence of gastric cancer is high, survival of patients with gastric cancer does seem to be improving. This improvement appears to be the result, at least in part, of the frequent diagnosis of early-stage gastric cancer in a mass population screening program in Japan[24]. The high curative resectability rate in the screened group is related to a smaller tumor size and to a lower incidence of lymph node metastasis, liver metastasis and peritoneal dissemination than in the non-screened group. Depth of tumor invasion, lymph node involvement and distant metastasis are important prognostic factors according to the UICC/AJCC staging system of gastric cancer[25]; therefore, every attempt should be made to increase early diagnosis. Currently, gastric cancer is one of the most prevalent cancers in China, making endoscopic or radiologic examinations more common. Awareness among Chinese has also increased, similar to colorectal or prostate cancer in Western countries[26,27]. However, because of the huge rural population whose diseases are often diagnosed at a more advanced stage, current efforts at cancer prevention and early screening of high-risk populations for premalignant lesions have not resulted in a significant change in the stage of presentation of disease. Following the mass population screening being carried out widely in China, especially these past ten years, the proportion of early gastric cancer has increased very slowly.

Another important change observed in this study was the decreased prevalence of operative mortality. Although the surgical extent of recent years was more extensive than before, postoperative mortality in the 3rd period was decreased to less than 1%. The large decrease in operative mortality is due to improved surgical techniques and also to improvements in anesthesia, metabolic care and intravenous nutrition[28]. Besides these factors, the accumulation of treatment experience with gastric cancer and becoming a large volume hospital also have an impact on the improved treatment outcome of gastric cancer patients[29-34]. The specialization in gastric cancer treatment might also influence the lower mortality rate, especially in addition to technical advances.

Therefore, currently in China, we need increased efforts at refining prevention and early diagnosis of gastric cancer as only resection offers the best hope for a cure[21]. We should put emphasis on rural gastric cancer screening, improve the rural level of diagnosis and treatment, and progress the health education of gastric cancer-related knowledge.

COMMENTS

Background

Although the results of gastric cancer have improved due to early diagnosis, radical operation, and the development of adjuvant therapy, patients with gastric cancer still have poor prognosis. To describe survival trends in patients in Northeast China diagnosed as gastric cancer, the authors conducted a review of records of gastric cancer patients from 1980 to 2003 in the First Affiliated Hospital of China Medical University.

Research frontiers

Currently, gastric cancer in China is one of the most prevalent cancers, making endoscopic or radiologic examinations more common. However, because of the huge rural population whose diseases are often diagnosed at a later stage, current efforts at cancer prevention and early screening of high-risk populations for premalignant lesions have not resulted in a significant change in the stage of presentation of disease, and following the mass population screening being carried out widely in China, especially these ten years, the proportion of early gastric cancer has increased very slowly.

Innovations and breakthroughs

In this article, the authors found that there was no significant difference of survival among the three periods. Besides that, they also found that the proportion of patients with early gastric cancer increased in the later period, as well as the proportion of node negative cancers, and the incidence among women increased from 20% to 30%.

Applications

All the findings indicate that, nowadays in China, the authors need increased efforts at refining primary prevention and early diagnosis of gastric cancer as only resection offers the best hope for cure, and they should put emphasis on rural gastric cancer screening, improve the rural level of diagnosis and treatment, and improve health education with regard to gastric cancer-related knowledge.

Peer review

Dr. Zhang *et al*. described survival trends of gastric cancer among Chinese between 1980 and 2003. Although there is no significant change in survival between these periods, the authors observed a significantly increased survival rate in 2000s as compared to that of 1980s. Results of this study were supported by many previous studies. Strengths of this study are (1) a large sample size; and (2) long follow-up data.

Abstract

We report a rare case of Pseudo-Meigs' Syndrome caused by ovarian metastasis from sigmoid colon cancer, which was accompanied by peritoneal dissemination. A 58-year-old female patient presented with massive right pleural effusion, ascites and a huge pelvic mass. Under the diagnosis of an advanced ovarian tumor, bilateral oophorectomy was performed and sigmoidectomy was also carried out after intraoperative diagnosis of peritoneal dissemination involving the sigmoid colon. However, immunohistochemical staining revealed that the ovarian lesions were metastasis from the primary advanced colon cancer. Postoperatively, ascites and pleural effusion subsided, and the diagnosis of Pseudo-Meigs' Syndrome due to a metastatic ovarian tumor from colon cancer was determined. The patient is now undergoing a regimen of chemotherapy for colon cancer without recurrence of ascites or hydrothorax 10 mo after the surgery. Pseudo-Meigs' Syndrome due to a metastatic ovarian tumor from colon cancer is rare but clinically important because long-term alleviation of symptoms can be achieved by surgical resection. This case report suggests that selected patients, even with peritoneal dissemination, may obtain palliation from surgical resection of metastatic ovarian tumors.

INTRODUCTION

Meigs' Syndrome is characterized by pleural effusion and ascites associated with ovarian fibroma or fibroma-like tumors, which are relieved by resection of the responsible lesions. When associated with other types of ovarian tumor, the condition is termed Pseudo-Meigs' Syndrome[1,2]. Malignancy from the gastrointestinal tract, including colon cancer, is a rare etiology for this syndrome and only a few cases have been reported[3-7]. This case report documents our clinical experience, reviews previously reported cases and discusses

the diagnosis and treatment of Pseudo-Meigs' Syndrome caused by ovarian metastasis from colorectal cancer.

CASE REPORT

A 58-year-old female presented to the hospital with a 1-mo history of general fatigue, dyspnea, abdominal distention, loss of appetite and decreased urine volume, which had worsened progressively over the previous few days. Her past medical history was unremarkable. Physical examination found a large mass in her lower abdomen. The peripheral blood test showed elevated levels of carcinoembryonic antigen (CEA): 63.8 ng/mL (normal, < 5 ng/mL), and carbohydrate antigen (CA) 125: 921 U/mL (normal, < 45 U/mL) and a normal level of CA19-9: 2 U/mL (normal, < 37 U/mL). Enhanced computed tomography (CT) demonstrated fluid retention and a round mass with a maximum diameter of 15 cm in the pelvic cavity (Figure 1A). Peritoneal dissemination was highly suspected (Figure 1B), and further examination of the ascites was not performed. The massive right pleural effusion occupied the pleural cavity causing atelectasis and compression of the mediastinum to the left side (Figure 1C). Intermittent drainage of pleural effusion was performed to alleviate severe dyspnea, yielding 4000 mL of serous fluid without malignant cells on cytological examination over 3 d. The patient's poor general condition and refusal prevented us from further examination including routine gastrointestinal endoscopy, and advanced ovarian cancer was tentatively diagnosed. Subsequent palliative surgery disclosed an enlarged right ovarian tumor and sparsely distributed peritoneal dissemination with mid-sigmoid colon involvement. In addition to bilateral oophorectomy, sigmoidectomy and primary anastomosis were carried out in case of colonic obstruction.

Histopathological examination of resected specimens showed that both the ovarian and colonic lesions were composed of well-differentiated adenocarcinoma (Figure 2A and B). The dissected paracolic nodes showed positive malignant cells. However, immunohistochemical staining of cytokeratin 7, mucin-5AC and CA125 was negative and that of cytokeratin 20, CEA and CDX-2 was positive (Figure 2C and D), confirming the ovarian tumors were metastases from primary colon cancer[8]. The postoperative course was uneventful and ascites and pleural effusion subsided. 5-fluorouracil (5-FU), leucovorin and oxaliplatin (FOLFOX) were administered every 2 wk for 5 mo and then changed to 5-FU, leucovorin and irinotecan (FOLFILI) due to neuropathy. Ten months after the surgery, tumor markers were within the normal range and abdominal CT showed no sign of tumor growth or recurrent fluid retention either in the pleural or abdominal cavity. She did not experience a marked change in bowel habit after the surgery and during chemotherapy. The diagnosis of Pseudo-Meigs' Syndrome due to metastatic ovarian tumor from colon cancer was determined.

DISCUSSION

Pseudo-Meigs' Syndrome caused by ovarian metastasis from colon cancer is a rare condition. In 2000, Nagakura *et al*[3] reviewed 5 cases including 3 Japanese cases. Thereafter only 4 subsequent reports of Pseudo-Meigs' Syndrome with the same etiology were reported (Table 1). The age of the patients was relatively low considering that the mean age of occurrence of colorectal cancer is approximately 64-71 years[9,10]. Pleural effusion is more prevalent in the right side, and the ovarian tumor is usually large (mean diameter 16 cm) and predominantly bilateral.

The diagnosis of Pseudo-Meigs' Syndrome is difficult because of its rarity and the similarity of the symptoms and signs to those of terminal malignant disease. Negative cytological results of ascites and pleural effusion might be informative for differentiating between Pseudo-Meigs' Syndrome and advanced cancer. Ascites due to peritoneal dissemination or peritonitis carcinomatosa is generally refractory to surgical or medical treatment, rendering sur-

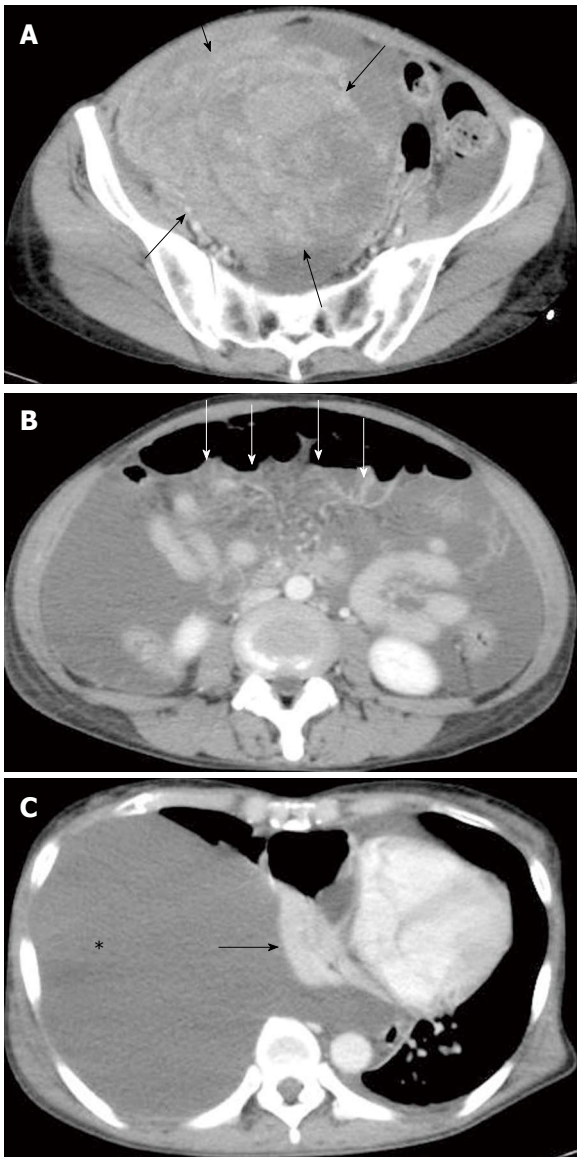

Figure 1 Computed tomography. A: A huge round mass in the pelvis suggesting a bilateral ovarian tumor (black arrows); B: Massive ascites and thickness of omentum (white allows) suggesting peritoneal dissemination; C: Right pleural effusion with atelectasis (black allow) and left-side compression of the mediastinum.

Figure 2 Microscopic features. Okuchi *et al*[7]	42	Synchronous	Right	Liver, lung	11.5	Left	12 mo, died
Present case	58	Synchronous	Right	Peritoneum	15	Bilateral	10 mo, alive

gical intervention for patients with this condition mostly harmful. Nevertheless, a negative result of cytology or peritoneal dissemination is not necessarily a requirement for the diagnosis of Pseudo-Meigs' Syndrome. Three out of 10 reported cases of Pseudo-Meigs' Syndrome due to metastatic colorectal cancer had peritoneal dissemination (Table 1).

Recently, an elevated level of vascular endothelial growth factor (VEGF) in blood and ascites were reported in a patient with Pseudo-Meigs' Syndrome due to colon cancer[7]. In that case, the hypersecretion of VEGF from oviducts was considered to play a key role in the pathogenesis of ascites and pleural effusion[7]. VEGF levels in blood and ascites might be useful for determining which patients would recover from massive fluid retention by surgical resection of metastatic ovarian tumors, even with a positive cytological result of ascites.

In the cases reviewed, the postoperative course was uneventful, symptoms were rapidly relieved, and palliation of the symptoms was long lasting[3-7]. A study from a single institute in Japan reported that the 3-year survival-rate of 5 cases of pseudo-Meigs' Syndrome was 37.5%[11]. However, surgeons should be prudent in the use of surgery. In general, colon cancer with ovarian metastasis is hard to cure[12]. Colon cancer with ascites is associated with frequent postoperative complications[13]. In addition, publication bias must be considered when interpreting rare conditions. Without obvious evidence, a regional lymphadenectomy should be reserved for selected patients, and oophorectomy with colorectal resection with minimal invasion should be the first choice surgical strategy.

In conclusion, ovarian metastasis from sigmoid colon cancer is a potential cause of Pseudo-Meigs' Syndrome. Surgical resection can be the treatment of choice for a selected patient even with the apparent peritoneal dissemination, because it can provide long-term palliation.

Abstract

We report a rare case of duodenal pseudolymphoma without any symptoms. The lesion located in front of the head of the pancreas was found accidentally during a medical examination. The findings of computed tomography and positron emission tomography-computed tomography suggested a stromal tumor or malignant lymphoma. Surgical resection was performed. The lesions were pathologically diagnosed as duodenal pseudolymphoma.

Key words: Pseudolymphoma; Duodenum

INTRODUCTION

Pseudolymphoma is rare, and is thought to be a benign nodule lesion characterized by marked proliferation of polyclonal and non-neoplastic lymphoid cells forming follicles and active germinal centers. It is difficult to differentiate pseudolymphoma from a malignant tumor, and the accurate diagnosis of pseudolymphoma depends on histopathological examinations. Pseudolymphoma may be found in various organs, including the skin, orbit, thyroid,breast, lung, stomach, liver, small intestine, spleen, pancreas, kidney, uterus and testis[1,2]. However, to our knowledge, duodenal pseudolymphoma has never been reported before. We report a case of duodenal pseudolymphoma and review the literature below.

CASE REPORT

A 23-year-old woman underwent a routine medical examination, during which a space-occupying lesion was found in front of the head of the pancreas by ultrasonography (USG) on April 28, 2010. Computed tomography (CT) performed on May 4th revealed several isodense masses in front of the pancreatic head. The largest one was 30 mm in diameter and well-defined, and the surrounding pancreas, pylorus and duodenal bulb appeared compressed. There was no significant invasion, and it was strongly enhanced after injection of contrast medium. Pancreas was of uniform density without a significant space-occupying lesion. A para-aortic lymph node was seen, approximately 5 mm × 8 mm in size, well-defined, moderately enhanced in arterial phase. The CT scan diagnosis was metastatic stromal tumor (Figure 1A and B); white blood cell count 7.5×10^9/L and hemoglobin 92 g/L, and platelets 419×10^9/L; carcinoembryonic an-

tigen 0.58 ng/mL (normal, 0.00-5.00) and carbohydrate antigen 8.64 U/mL (normal, 0.00-5.30). The patient was asymptomatic and physical examination revealed no abnormalities. She was admitted to our hospital for further treatment on May 17th, and laboratory data on admission including liver function, renal function and electrolyte tests were all unremarkable. PET-CT performed on May 25th demonstrated multiple low-density nodules behind the gastric antrum and in front of the pancreas head. PET regions showed a non-uniform abnormal focus of uptake. Standard uptake value (SUV) was about 2.9-5.8. The pancreas, skeleton, muscle and tissue showed no obvious abnormalities. There was no retroperitoneal and pelvic lymph node enlargement. PET-CT diagnosis was stromal tumor or malignant lymphoma (Figure 1C).

Laparotomy was performed on May 26th. The tumor was found located in the duodenal bulb with extended

growth from the back to the bottom of the intestinal wall, and firmly attached to the head of the pancreas and the root of the mesocolon. There were several hard enlarged lymph nodes located near the root of middle colic vessel and behind the head of pancreas about 10-30 mm in diameter. Lymph nodes near the transverse colon were resected for frozen biopsy, which showed that lymph nodes had chronic inflammation and lymphoid hyperplasia. Due to the limitation of the frozen biopsy and the general form of the lymph nodes and the tumor growth pattern, we could not completely rule out the possibility of malignancy. Thus the complete resection of the tumor and enlarged lymph nodes was performed. The postoperative pathological examination report suggested lymph nodes with chronic inflammation and lymphoid hyperplasia. Duodenal pseudolymphoma was confirmed (Figure 2A and B). Immunohistochemical staining for CD79a, L-26, CD3 and UCHL-1 was positive, and for TDT it was negative (Figure 3A-E). The patient was discharged 10 d after surgery and showed no sign of recurrence in the follow-up of five months.

DISCUSSION

Pseudolymphoma, also named reactive lymphoid hyperplasia, was first described in 1963 by Saltzsein[3], and since then cases of pseudolymphoma of different organs have been successively reported although it is a rare disease.

At present, the exact pathogenesis of pseudolymphoma remains unknown. It has been reported that drugs (Phenyt-

oin, Carbamazepine, Felodipine), foreign antigens (trauma, tattoo dyes and immunization), infection and sunlight allergy can cause cutaneous pseudolymphoma[4]. Autoimmune diseases (Sjogren's syndrome and thyroiditis) are thought to be associated with pulmonary and hepatic pseudolymphoma[5]. *Helicobacter pylori* infection plays an important role in the etiology of gastric pseudolymphoma[6].Our patient had no obvious predisposing factors. She was asymptomatic and physical examination result was not remarkable. It was accidentally discovered during a routine USG. Therefore, more data are needed for further studies on the risk factors and onset mechanism of pseudolymphoma.

The preoperative diagnosis of pseudolymphoma is difficult. It should be differentiated from malignant lymphoma and other malignant tumors. Gastric pseudolymphoma is easily misdiagnosed as gastric cancer on barium meal and gastroscopy examinations. Radiologically, hepatic pseudolymphoma has been often misdiagnosed as hepatocellular carcinoma. The diagnosis of our case on imaging studies could not be discriminated from stromal tumor and malignant lymphoma and a final diagnosis relied on the pathological examinations. Microscopically, pseudolymphoma is characterized by the presence of hyperplastic lymphoid follicles with germinal centers, consisting of polymorphic and polyclonal cell populations and aggregations of mature lymphocytes, mature plasma cells, macrophages and other types of inflammatory cells. Immunohistochemical tests showed negative results for bcl-2. Immunoglobulin heavy chains (IgH) and T cell receptor (TCR) gene rearrangement analysis revealed polyclonal proliferation or no gene rearrangement[7]. In malignant lymphoma, lymphoid follicles and germinal centers were not found, cellular atypia was significant, caryocinesia was easily observed and the infiltrating lymphocytes were monoclonal. Muria *et al*[8] considered that it is not possible to rule out the diagnosis of pseudolymphoma with the absence of germinal centers and that the pseudolymphoma has mainly mature lymphocytes while lymphoma has non-mature lymphocytes, so they were able to be distinguished according to the differentiation degree of the infiltrating lymphocytes. Takeshita *et al*[9]reported that the Southern blot analysis showed immunoglobulin heavy chain JH and light chain J-κ clone rearrangement, which helped distinguish pseudolymphoma from malignant lymphoma. Therefore, in addition to pathological examination, immune phenotype and gene rearrangements can also be used to further confirm the diagnosis of pseudolymphoma. On the histopathological examination, various sized and shaped lymphoid follicles with reactive germinal center formation were seen in our patient. Infiltrating polymorphic lymphocytes and polyclonal cell populations were composed of lymphoblastoid cells, plasma cells and macrophages without atypical and obvious caryocinesia.

Immunohistochemical studies revealed polyclonality, lymphoid cells positive for L-26 and CD 79a (B cell marker), mainly aggregated in the germinal centers, while those positive for CD3 and UCHL-1 (T cell marker) were present around the germinal centers. These findings were compatible with reactive lymphoid hyperplasia. Positive TDT has been often seen in lymphoblastic lymphoma. In our case, immunohistochemical staining for TDT was negative, which further confirmed the diagnosis of pseudolymphoma.

Although pseudolymphoma is generally considered to be a benign tumor, there is a risk of malignant transformation into lymphoma. It has been reported that some cases such as cutaneous, pulmonary, gastric and hepatic pseudo lymphomas initially diagnosed as pseudolymphoma had

transformed into lymphoma several years later[10,11]. So surgical resection remains the best option for treatment of pseudolymphoma at present**.** Intraoperative frozen biopsy can be used to diagnose pseudolymphoma and if cell variation within frozen section makes the feature of the lesion unclear, it can be treated according to the therapeutic principle of malignant tumors. Whether it is necessary to perform postoperative adjuvant chemotherapy remains inconclusive, as pseudolymphoma is mainly composed of mature lymphocytes, and less sensitive to chemotherapy. The lesions are not easily dissipated, and it has been reported that pseudolymphoma after chemotherapy still transformed into malignant lymphoma. Therefore, more cases should be accumulated to determine whether chemotherapy is necessary. Duodenal pseudolymphoma has never been reported before and its prognosis is not so clear. Although our patient had an early diagnosis, complete tumor resection, enlarged lymph nodes dissection and uneventful postoperative course, she must be followed up carefully because of the possible later development of malignant lymphoma.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Peri-anal fistulae are a worldwide health problem that can affect any person anywhere. Surgical management of these fistulae is not free from risks. Recurrence and fecal incontinence are the most common complications after surgery. The cumulative personal surgical experience in managing cases with anal fistulae is significantly considered as necessary for obtaining better results with minimal adverse effects after surgery. The purpose for conducting this survey is to facilitate better outcome after surgical interventions in idiopathic anal fistulae' cases.

Key words: Peri-anal fistulae; Surgery; Fecal incontinence; Recurrence; Complications

El-Tawil AM. Management of fistula-in-ano: An introduction. *World J Gastroenterol* 2011; 17(28): 3271 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i28/3271.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i28.3271

A fistula-in-ano is a granulating track between the anorectum and the perineum. A fistula may consist of primary and secondary tracks. Many fistulas are low lying, consisting of a single straight track from the skin to the anal canal, just passing through the lower fibers of the internal sphincter The majority of such fistulas can, therefore, be managed by simply lying opening the track (fistulotomy), which produces a good prospect of cure and with no impairment of continence. However, the same can not be said for fistulae which pass through the external sphincter. Some of these fistulas are complex, with secondary pararectal or supralevator tracks. Opening such fistulas may be risky and there is growing evidence that even division of a part of the external sphincter leaving the puborectalis undisturbed is associated with considerable impairment of anorectal function[1]. Unless all the secondary tracks are also treated, there is a risk of recurrent sepsis and fistulation.

This highlights the quandary for the surgeons. Possibly in no other field of anorectal surgery is appropriate treatment so critical. The potential for incurring life-long morbidity may be greater than in any other area of large bowel surgery, for example, even partial sphincter division is complicated by perirectal fibrosis and the resulting gutter deformity can rarely be resolved by later reconstructive surgery[1]. Thus fistulas-in-ano have an unenviable reputation for recurrence ad compromised continence. There are few procedures in surgery where the outcome is so greatly influenced by the experience and judgment of the surgeon. For improving our awareness and for better outcome after surgical management of cases with non-specific fistulae-in-ano, I was invited, on behalf of the *World Journal of Gastroenterology* (*WJG*) to ask experienced senior colorectal surgeons to report their considerate and views.

The benefits of face to face meetings as a source for exchange of information can not be overlooked but they are limited. Yet, *WJG* offers 24/7 service on its website and this channel could be used efficiently for exchanging this valuable data. I hope that the readers of the journal will enjoy reading the following manuscripts and that this trial will be repeated.

Abstract

Anal fistula surgery is a commonly performed procedure. The diverse anatomy of anal fistulae and their proximity to anal sphincters make accurate preoperative diagnosis essential to avoid recurrence and fecal incontinence. Despite the fact that proper preoperative diagnosis can be reached in the majority of patients by simple clinical examination, endoanal ultrasound or magnetic resonance imaging, on many occasions, unexpected findings can be encountered during surgery that can make the operation difficult and correct decision-making crucial. In this article we discuss the difficulties and unexpected findings that can be encountered during anal fistula surgery and how to overcome them.

INTRODUCTION

Anal fistula is a common disease that has long challenged surgeons' skills. It is no wonder that Frederick Salmon, more than 170 years ago, was frustrated by the high recurrence rate after surgery for perianal fistula that he launched "The Infirmary for the Relief of the Poor afflicted with Fistula and other Diseases of the Rectum". This later became St Marks Hospital, the famous British hospital for treating colorectal and small intestinal disorders.

Perianal fistula, if not treated properly will result in one of two terrible complications, recurrence or incontinence. Despite many preoperative investigations that can help to identify the correct anatomy of the fistula, one might face difficult or unexpected intraoperative findings that require wise decisions. Appropriate decisions in such circumstances have a significant impact on the outcome of surgery and the patient' quality of life.

Difficulties in anal fistula surgery can be related to the anatomy of the fistula or the integrity of the anal canal. In this review, we will attempt to draw a roadmap to be followed if a difficult situation is encountered during anal fistula surgery.

INTERNAL OPENING COULD NOT BE IDENTIFIED

Proper identification of the internal opening is an integral part of fistula surgery if an unacceptable high recurrence rate is to be avoided[1,2]. In our opinion, recurrence is inevitable if the correct internal opening is not identified and dealt with. This is simply because in such cases,

the original source of sepsis will not be eliminated.

Every effort should be made to localize the correct internal opening preoperatively. Besides clinical examination, many investigations can help in preoperative localization of the internal opening[3-7]. Unfortunately, none of these investigations are particularly accurate. Thus, it is not uncommon to operate on patients with unidentified or inaccurately identified internal openings. In such cases, accurate intraoperative localization is essential. This can be a simple task if external probing is easy and successful. Otherwise, we are dealing with a difficult internal opening which requires careful maneuvers for correct localization.

First, one should know where the internal opening is. The famous Goodsall's rule relates the radial location of the internal opening of the fistula to the position of the external opening. However, fallacies in Goodsall's rule have been reported and its overall accuracy is limited[8,9]. Thus, it is unsafe to confidently rely on Goodsall's rule for identification of the internal opening. In our practice, we still use Goodsall's rule as a preliminary guide for localization of the internal opening. With regard to the cranio-caudal disposition of the internal opening along the anal canal, the vast majority of internal openings are located at the dentate line[10].

Palpation and internal probing should then be attempted starting at the expected site of the internal opening. Probing should be carried out gently in order to avoid the creation of a false internal opening. Sometimes, the internal opening can be palpated as a dimple, an elevation, a fibrous pit or soft granulation tissue pimple. In addition, a palpable trans-sphincteric track can guide to the site of the internal opening. Posterior horseshoe fistulae almost exclusively have their internal openings at the level of the dentate line at the 6 o'clock position.

Another method which has been used for localization of the internal opening is the injection of hydrogen peroxide[11] or methylene blue[12] into the external opening and observing the flow of air bubbles in the former or colored material in the latter from the internal opening. We personally prefer injection of air and have found this method useful on many occasions. This is because we believe that the injection of colored material will cause undesirable staining of tissues which will obscure vision of the opened track and its granulation tissue, both of which are important for confident laying open of the track to its very end into the anal mucosa, an essential step to avoid recurrence. We also believe that the effervescence of hydrogen peroxide is too much and unnecessary for localization of the internal opening.

Finally, if all methods fail to identify the internal opening, we then perform a preliminary fistulectomy. This is not a complete fistulectomy, but it is a limited fistulectomy aimed at proper localization of the internal opening as a prerequisite for a successful lay open procedure. In a preliminary fistulectomy, the track is dissected short of the external sphincter, at which point, the track is gently pulled while the anal mucosa is carefully inspected. The track will pull on the offending pit, and the anal mucosa at this site will be indrawn. At this stage, the probe can be inserted confidently into the correct track, and the internal opening and fistula can be confidently laid open.

If after using all means, the internal opening is not identified, we prefer to abandon the procedure and to give the patient another chance of accurate assessment and investigations. Although we are confident that, at this stage, we are not curing the patient, we believe that this is better than harming the sphincters without major benefit.

THE FISTULOUS TRACK COULD NOT BE PROBED

Probing of the fistulous track is essential to perform the lay open operation. A fistulous track can be difficult to probe if it is narrow, obstructed, kinked or branched. Forcible probing in such cases will result in the creation of a false track or a false internal opening or both. This will very likely result in recurrence.

If external probing fails, it is advisable to try gentle internal probing starting at the site of a palpable or expected internal opening. If internal probing fails, one can lay open the track piecemeal until the whole track is eventually opened. We do not prefer this technique because inadequate hemostasis can obscure the track making further progression with the lay open procedure difficult. This is especially true when the track is deep, narrow or recurrent. Our preferred technique is preliminary fistulectomy, as mentioned in the previous section. In this situation, preliminary fistulectomy has many advantages. First, if failure of probing was due to the presence of kinks in the track, all such kinks are straightened and this, by itself, can make probing possible. Second, probing of the track is done under vision so that all stenotic segments in the track, if any, are probed with confidence and without fear of creating a false passage. Third, the site of the internal opening can be identified confidently by pulling on the mobilized track and observing dimpling in the anal mucosa as previously mentioned. Finally, during fistulectomy if dissection is performed in the wrong plane and the track is opened, granulation tissue will immediately be seen raising a red flag to warn the surgeon to return to the proper plane.

UNEXPECTED ANATOMY

We believe that the correct anatomy in the majority of perianal fistulae can be disclosed preoperatively[13-15]. However, occasionally, undiagnosed difficult anatomy is encountered during surgery. Special types of difficult fistulae which can be missed clinically only to be discovered during surgery are as follows: classic posterior horseshoe fistula with or without a blind supralevator track, intersphincteric fistula with high component, high arching trans-sphincteric fistula and anterior track with special proximity to the male urethra. These fistulae do not re-

quire specific treatment, however, they need expert experienced management. Anterior fistulae near the base of the scrotum can be very close to the bulbous urethra risking its injury during the procedure. We advise inserting a urethral catheter in such cases for better identification of the urethra. For high arching fistulae, one of the sphincter-saving procedures[16-20] can be performed or otherwise a seton can be placed[21,22] and the situation is reassessed with the patient awake. Placement of a seton will also allow the different treatment options to be discussed with the patient. Inters-phincteric fistulae can reach high into the rectum entailing the use of a self-retaining anal retractor, special instruments that suit endoanal surgery, good suction and light.

FISTULAE WITHOUT AN EXTERNAL OPENING

The vast majority of anal fistulae are cryptogenic in origin[23]. This means that the fistula starts as an infection in one of the perianal glands that extends to drain itself in the perianal skin. A fistula without an external opening simply presents before external drainage occurs. This problem is uncommon and is not specifically discussed in the literature. In our experience, the majority of fistulae without an external opening are inter-sphincteric fistulae, however, as the pathogenesis implies, any type of cryptogenic fistula can present without an external opening.

Absence of an external opening is unlikely to be first discovered intraoperatively, However, because the location of the external opening is significantly related to the complexity of the fistula[13], such fistulae are frequently underestimated and the presence of a fistula of significant magnitude might be discovered at operation. Thus, the main track may not be completely palpable, probing can be difficult or impossible and side tracks might be missed. Our own plan of management is as follows: First, we try to disclose the anatomy and complexity of the fistula by palpating the fistulous tracks to assess their number, extent and depth. Then we try to identify the internal opening and carry out internal probing. If this is successful, we proceed to lay open the track keeping the risk of incontinence and recurrence in mind, in view of the anatomy of the fistula and the status of the anal canal. If internal probing fails, we then perform a limited fistulectomy in which we mobilize a limited segment of the track that will allow proper handling and manipulation. We start the procedure by making a curvilinear incision incorporating the blind end of the fistulous track (the presumed site of external opening). This point is located by meticulous palpation. In inter-sphincteric fistulae, this point might be high in the rectum entailing the use of special instruments as previously mentioned. When a good segment of the track is dissected, it is opened transversely, probed and laid open as in the classic lay open operation. If probing fails, we proceed with complete fistulectomy until the whole track is excised (in inter-sphincteric fistula) or until we reach the external sphincter (in trans-sphincteric fistula) and then we proceed as mentioned previously in preliminary fistulectomy.

Absence of an external opening is particularly difficult in cases of classic posterior horseshoe fistulae. Internal probing and lay open of this track is not enough because it will only drain the trans-sphincteric component of the fistula and not the horseshoe component. Thus, in this type of fistula, we start by mobilizing the anal canal from the sacrum and coccyx, then we lay open the horseshoe track, possibly guided by a probe placed from the internal opening for correct identification of the horseshoe track and then eventually we lay open the trans-sphincteric track.

SYNCHRONOUS FISTULA

A synchronous fistula is a fistula which has a separate track and a separate internal opening and which exists synchronously with the original fistula. This is to be differentiated from a branching fistula in which all branches eventually open into a single internal opening. A synchronous fistula can have an external opening or it can be without an external opening.

Synchronous fistulae are generally uncommon. With personal experience of over 1300 fistulae, we encountered synchronous fistulae in nine patients (unpublished data). In two patients there were three synchronous fistulae.

Synchronous fistulae should be detected preoperatively. However, this is not always the case, especially if they are minute or when they lack external openings. They can even be missed at operation or may be considered to be a branch of the original fistula. In this latter case, the synchronous fistula track might be laid open or excised together with the original fistula, missing its internal opening which will result in recurrence. This dictates careful anal and perianal examination at the beginning of surgery.

Dealing with synchronous fistulae is not difficult and they do not require a special surgical technique. The problem is deciding whether to lay them open or not. If the anal canal is adequate and the fistulae are superficial, one can lay open all the synchronous fistulae without major risk of incontinence. However, if there is any doubt about the integrity of the anal canal or the anatomy of the fistulae, it is advised that only the primary or offending fistula be laid open keeping the other tracks either for staged procedures or other sphincter-saving operations.

COMPROMISED ANAL CANAL

Anal fistula surgery carries an inherent risk of fecal incontinence because part of the anal sphincter is essentially divided in the procedure. The incidence of fecal incontinence after surgery can reach up to 64%[24-26]. Postoperative incontinence is a function of the anatomy and complexity of the fistula on the one hand, and the adequacy of anal canal function on the other hand. Thus, laying open a high fistula with adequate anal canal function can result in a reduced degree of incontinence than

laying open a low fistula with a compromised anal canal. This implies that assessment of the anal canal integrity is very important in anal fistula surgery.

Assessment of the anal canal integrity is basically performed preoperatively, clinically in the majority of situations and by anorectal physiology testing in certain selected patients[26]. However, due to the difficulty of anal examination while the patient is awake, it is not uncommon to encounter unexpected intraoperative findings of compromised anal canal. Patients at risk are female patients, patients with previous anal surgery, patients who had previous proctectomy or extensive colectomy, patients with chronic diarrheal states, anterior fistulae, high arching trans-sphincteric fistulae, supra-sphincteric fistulae and fistulae with high internal openings.

Generally speaking, one should never divide the sphincter if there is any doubt about the integrity of the anal canal or the anatomy of the fistula. In this situation, it is better to abandon the procedure and refer the patient to an expert center where a sphincter-saving procedure can be performed or placement of a seton. We usually place a draining seton rather than a cutting seton as the latter has been shown to result in incontinence and recurrence[27]. The seton allows for better assessment of the anal canal while the patient is awake. The patient then has one of three options depending on the relative risk of incontinence: If there is a high risk of incontinence, the patient can live with the seton in place permanently to drain the fistula track, or he can have one of the sphincter-saving procedures risking higher recurrence. If the risk of incontinence is low, then the patient can have the classic lay open operation that has a high chance of curing the fistula. If the operation results in a degree of incontinence, the patient still has the option of a sphincter repair at a later date.

Many sphincter-saving procedures are available for fistula patients, however, the results in terms of fistula recurrence are always inferior to the classic lay open operation. Moreover, the risk of incontinence is not completely eliminated. Injection of a mixture of fibrinogen and thrombin into the fistulous track was first described by Hjortrup in the early 1990s aimed at the formation of a fibrin plug that would obliterate the track and cure the fistula[28]. The author reported healing in half of the patients. More recent studies have reported poorer results[29-31]. We believe that the high recurrence rate after fibrin glue injection is because the glue will never fill a complex track, a kinked track, a narrow track or a long track. It can also be extruded from the track after successful injection. The Surgisis fistula plug has been introduced to avoid these drawbacks. A healing rate as low as 13.9% has been reported[32] with the majority of studies reporting a healing rate around 40%[33,34]. We believe Surgisis is only suitable for short wide fistula tracks. A mucosal advancement flap depends on obliterating the internal opening by advancing a mucosal flap from the anorectum. Recurrence has been reported in up to two thirds of patients, with slightly better results when a musculo-mucosal flap is used rather than a pure mucosal flap[18,35,36]. Our personal experience with mucosal advancement is disappointing. Recurrence is probably caused by infection in one or more of the stitches holding the flap. This is very likely in view of the septic medium in which the flap resides.

FISTULA IN INFLAMMATORY BOWEL DISEASE

The last point we are going to discuss is fistula in inflammatory bowel disease (IBD). Basically, this should be a preoperative diagnosis. However, fistula in a patient with IBD may only be discovered intraoperatively when perianal disease is the first presentation in the patient. This is especially true in places where IBD is uncommon. Fistulae commonly occur in patients with Crohn's disease but can also be seen in ulcerative colitis. Classic and aggressive surgery in these patients will not cure the fistula but will very likely result in significant incontinence. The procedure in this situation is to take a frozen section biopsy if this is available or a biopsy for paraffin section examination. If IBD is confirmed, minimum action should be taken such as drainage of an abscess or placement of a seton to drain the fistulous track. Attention should then be directed to treatment of the original disease.

Abstract

Fistula-in-ano is the most common form of perineal sepsis. Typically, a fistula includes an internal opening, a track, and an external opening. The external opening might acutely appear following infection and/or an abscess, or more insiduously in a chronic manner. Management includes control of infection, assessment of the fistulous track in relation to the anal sphincter muscle, and finally, definitive treatment of the fistula. Fistulotomy was the most commonly used mode of management, but concerns about post-fistulotomy incontinence prompted the use of sphincter preserving techniques such as advancement flaps, fibrin glue, collagen fistula plug, ligation of the intersphincteric fistula track, and stem cells. Many descriptive and comparative studies have evaluated these different techniques with variable outcomes. The lack of consistent results, level I evidence, or long-term follow-up, as well as the heterogeneity of fistula pathology has prevented a definitive treatment algorithm. This article will review the most commonly available modalities and techniques for managing idiopathic fistula-in-ano.

Key words: Anal fistula; Seton; Fistulotomy; Advancement flap; Fibrin glue; Fistula plug

INTRODUCTION

Fistula-in-ano is a devastating problem which has been described since the "Corpus Hippocratum". Although the disease has been well described, no definitive mode of management has been established. The most widespread traditionally accepted treatment has been fistulotomy. Problems with management are due to the heterogeneity of fistulas, and to the potential adverse effects on continence arising from division of the involved anal sphincter. Because of a desire to maintain continence, a variety of therapeutic alternatives to fistulotomy have been described[1]. The etiology includes idiopathic and iatrogenic fistulas, and fistulas secondary to other causes. This article will focus on idiopathic fistula-in-ano.

Idiopathic fistula-in-ano most commonly occurs in healthy subjects, with cryptoglandular infection being the most widely accepted etiologic factor. The anal crypt gland penetrates the anal sphincter to varying degrees. Once obstructed, infection will ensue and suppuration will follow the least resistant path, which accordingly determines the location of the abscess (perianal, ischiorectal, inter-sphincteric) and the type of fistula. Therefore, understanding the anatomy is essential to manage this disease.

Based on the relationship with the anal sphincter muscles, fistulas are classified into 5 main types: (1) submucosal: the fistula track passes superficially beneath the submucosa and does not involve any sphincter muscle; (2) intersphincteric fistula: the track passes through the internal sphincter and continues in the inter-sphincteric plane to the perianal skin, not including the external anal sphincter;

(3) trans-sphincteric fistula: the track cross through the internal and external anal sphincter on its exit towards the perianal area. The amount of involved external anal sphincter further subdivides the type of fistula into low when up to one-third of the distal external anal sphincter or less is involved, and high if a larger area of the external sphincter is included; (4) suprasphincteric fistula: the fistulous tract passes through the internal sphincter but traverses the external sphincter below the puborectalis muscle; and (5) extrasphincteric fistula: the fistulous track may pass outside the sphincter complex through the ischiorectal fossa to the perianal skin. In this case, the origin of the fistula is not from the dentate line but could be from a rectal, pelvic or supralevator origin, usually secondary to an inflammatory or neoplastic process.

A fistula-in-ano can be "simple" or "complex"[2,3]. Fistulas with multiple external openings, those involving more than 30%-50% of the anal sphincter (high transsphincteric fistulas), those lying above the sphincter (suprasphincteric), extrasphincteric, or have high blind extensions, or horseshoe tracts, or are anterior in a female patient are considered complex, with higher risk of continence disturbance posed by surgically managing these fistulas. Alternatively, an anal fistula in patients with a preexisting history of fecal incontinence, Crohn's disease, or local irradiation are also considered complex. Submucosal and low intersphincteric (traversing less than 30% of anal sphincter muscle) as well as low transsphincteric fistulas are considered simple[4].

The management of fistulas-in-ano includes 3 main goals: to cure the fistula, to prevent or minimize recurrence, and to retain continence. Regardless of the type of fistula, there are certain principles that lead to successful management: the infection/inflammatory process should be resolved, the source of pathology should be addressed, and when treating the fistula, the internal opening should be closed with least risk to continence. This goal can be achieved with care taken not to jeopardize the integrity of the anal sphincter complex. In a retrospective study of 404 male patients with fecal incontinence, the most common confounding factor in patients younger than 70 years was a surgical history of fistulectomy or hemorrhoidectomy[5].

PREOPERATIVE ASSESSMENT AND PLANNING

Preoperative evaluation is very important. Medical history and physical examination are most important in the assessment phase. The patient's continence is another important facet that needs to be included, as well as any history of anorectal surgery. Anal ultrasound with hydrogen peroxide is another important adjunct for preoperative evaluation. This procedure is simple, fast, may be done in the same office visit, and provides information about the fistula track, the type and complexity and whether the anal sphincter muscle is normal, scarred, or disrupted, as well as the presence of an abscess cavity[6,7]. Anal ultrasound is operator-dependent; scars and defects may confuse sonographic interpretation and might render delineation of the fistulous track difficult[8].

Magnetic resonance imaging (MRI) has become an integral part of the assessment of fistula as it can distinguish between sepsis and granulation tissue from sphincter muscles[9]. A prospective study compared the preoperative MRI assessment of the anal fistula and intraoperative findings. High concordance rates were reported in terms of recognizing the course of primary tracks (86%), demonstrating secondary tracks (91%), and horseshoe extension (97%), as well as identifying internal opening (80%)[10]. Furthermore, MRI accurately detected previously missed secondary tracks when compared with the clinical examination, and correctly identified the level of the fistula with respect to the anal sphincters[11]. An endocoil greatly increases tissue resolution and provides superior anatomical details[12,13]. However, it has a limited field of view (about 2-3 cm from the coil) in which any fistulous extension in this zone might be missed, and is not widely available and is very uncomfortable for the patient[14,15].

Although anal manometry may provide information about sphincter pressures, obtaining a fecal incontinence score will also yield clinically relevant information[16]. Collectively, this information will help select the best choice for treatment, and allows the surgeon to counsel the patient about expectations and probabilities of success. Pescatori *et al*[17] prospectively studied the impact of preoperative anal manometry for guiding the surgical approach, on functional outcomes of fistula surgery. In this study 96 patients underwent pre- and post-operative anal manometry and were compared with a control group of 36 patients who did not have anal manometry. Internal sphincterotomy was performed for effective drainage of the intersphincteric plane in less than 50% of both groups (45 and 15, respectively). While 24% (11/45 patients) from the anal manometry group had postoperative soiling, 53% (8/15 patients) of the control group did. As for recurrence, 3% and 13%, respectively, experienced recurrence. Another study of 45 patients assessed the clinical and manometric effects of fistulotomy for intersphincteric fistulas on anal sphincter function. Although there was a significant decrease in resting pressures throughout the distal 2 cm of the anal canal after surgery, the maximum squeeze pressures did not change. Continence problems arose in patients who had lower preoperative resting pressures[18].

In the majority of patients with idiopathic fistulas-in-ano, a thorough history and physical examination may suffice for surgical planning. When in doubt or if a complex fistula is suspected, an ultrasound is justified for further evaluation. Complexity and or sepsis might require further magnetic resonance imaging assessment. Anal manometry is especially useful in patients in whom postoperative continence is a concern.

MANAGEMENT OF FISTULA-IN-ANO

Management may be achieved by one of the following methods: (1) keep the track from closing around a remnant septic focus preventing further abscess formation using a non-cutting seton; (2) expose the track and let it

heal secondarily heal following a fistulotomy; (3) excise the whole fistulous tract: fistulectomy; (4) excise the internal opening and cover the defect with healthy mucosa as an advancement flap; (5) obliterate the fistulous track with glue, or a collagen and fistula plug; (6) ligate and disconnect the fistula tract in the inter-sphincteric plane as a LIFT (ligation of the intersphincteric fistula tract) procedure; (7) ablate the tract and induce scarring with radiofrequency waves; and (8) induce regeneration in the tract with biologic agents or stem cells.

OPERATIVE APPROACH AND SURGICAL MANAGEMENT

Seton

One of the simplest modes of treating anal fistulas involves passing a thread through the anal fistula tract. The material used may be a non-absorbable suture, drain, rubber band, or even a vessel loop. Setons are a viable option for high trans-sphincteric fistulas, for those fistula involving more than half of the sphincter, and anterior fistulas in female patients[19,20]. There are basically two types of setons used in treating anal fistulas. A cutting seton is used to slowly cut through the tissue allowing for healing from inside to outside thus minimizing the risk of incontinence. In this case, after identifying the external and internal openings of the fistula tract, the skin and anal mucosa overlying the sphincter are incised, and subsequently the seton is passed through and tightened. In a study conducted among 160 patients with a fistula-in-ano, 10% received seton placement for either high transsphincteric or suprasphincteric fistulas. The authors reported that all of the patients in whom a seton was placed had encountered temporary alterations in continence to gas only, for an unreported length of time[20]. Parks and Stitz treated 80 patients with a seton for high transsphincteric fistulae (n = 23) and suprasphincteric fistula (n = 57), of whom a total of 30 (8 and 22, respectively) patients underwent division of residual external sphincter muscle at the time of seton removal. Sixty eight patients were available for functional assessment. The authors found that 17% of those patient who had a seton alone without muscle division complained of partial loss of continence as opposed to 39% of those who had muscle division, emphasizing the importance of conserving muscle as much as possible even if it necessitates a longer healing time[21]. Thirty-four patients (aged between 20 and 57 years), of whom 31 patients had normal preoperative continence, were offered a 2-stage seton procedure for high anal fistulas (16 extrasphincteric and 18 trans-sphincteric). All trans-sphincteric fistulas healed and there were only 2 recurrences. Among 29 patients with preoperative normal fecal control who were available for follow-up, postoperative continence was normal in 12 patients; while 5 patients had no control over flatus, 11 were incontinent for liquid stool or flatus, and one had continued fecal leakage. The authors did not recommend the 2-stage seton technique for fistulas with high anal or rectal openings[22].

In a review of the literature, including 37 different studies on cutting setons, the average incontinence rate was 12%. The more proximal the location of the internal opening the higher was the incontinence rate. Among the studies which described alterations to continence, incontinence to liquid was most common followed by incontinence to flatus. The authors concluded that, when feasible, other sphincter-preserving techniques should be employed especially with high anal fistulas[23]. The cutting seton requires further follow-up visits for subsequent tightening of the seton to achieve the desired effect. The time for a fistula to heal with this method ranged from 1 mo to more than a year[24,25].

The second type of seton, the non-cutting seton, is used primarily for draining, especially in the acute setting, or where other modalities cannot be implemented or have failed previously, and in certain disease entities such as Crohn's disease, and HIV[26,27]. In the acute setting it provides rapid and safe relief of the infection, with no compromise to the sphincter complex, providing time for the inflammation to resolve, and better assessment and decision-making. Furthermore, keeping the seton in place helps prevent abscess recurrence and can act as a guide to the internal and external opening for following treatment(s). A recent consensus conference on fistulas concluded that setons should be used as an initial method until there is no evidence of acute inflammation[28].

Fistulotomy

Fistulotomy is considered to be the procedure of choice for low, single tract, anal fistulas, especially when submucosal, since the risk for incontinence or recurrence is very low[29]. However, others use this procedure for low intersphincteric as well as for trans-sphincteric fistulas[19,30]. According to the practice parameters for the treatment of perianal abscess and fistula-in-ano presented by Whiteford and colleagues (2005), fistulotomy may be used in the treatment of perianal simple anal fistulas in cryptoglandular disease[30]. In this report, a simple fistula was defined as a single, non recurrent tract that crossed less than 30%-50% of the external anal sphincter, not the anterior sphincter in women, and was present in subjects with perfect continence and no history of Crohn's disease or pelvic radiation. Furthermore, the authors suggested the use of tract debridement and/or fibrin glue as these methods do not impose a risk on continence, and, despite the associated higher recurrence rate, still offer the opportunity for alternative treatment.

While some surgeons use fistulotomy only for submucosal fistulas[29], others apply this technique to more complex fistulas, including recurrent, high trans-sphincteric, or extra-sphincteric fistulas[31], in conjunction with sphincter reconstruction. To perform fistulotomy, the internal and external sphincters are divided, accessory tracts are excised, and eventually overlapping sphincter reconstruction is performed. Thirty five patients underwent fistulotomy with sphincter reconstruction for complex anal fistulas (high

transsphincteric = 30, suprasphincteric = 4, extrasphincteric = 1). Eleven patients reported preoperative fecal incontinence, and fistulas were recurrent in 16 patients (8 with preoperative incontinence). Mean follow-up was 32 mo (range, 24-42). Two patients suffered from recurrence at 3 and 6 mo, respectively. One presented with a recurrent fistula. While 3 (12.5%) of the preoperatively fully continent patients (n = 19) experienced minor alterations in incontinence in terms of control of flatus and soiling, all of the preoperatively incontinent patients demonstrated significant improvement in fecal control after surgery. The authors suggested that fistulotomy with sphincter reconstruction provides an effective resource in the management of complex fistula-in-ano[31]. The same technique was applied to 16 recurrent complex fistulas (4 patients experienced at least 2 recurrences) with a mean follow-up of 40 mo. Seven of the 8 patients who had previous fecal incontinence significantly improved. One patient experienced recurrence after 6 mo and was offered the same procedure after 38 mo without recurrence[32]. The same authors, in a randomized controlled study, compared the advancement flap (n = 27) to fistulotomy with sphincter reconstruction (n = 28) for managing primary complex fistula-in-ano, in terms of recurrence and anal function. Fistulas were classified as high transsphincteric fistula (n = 44) and suprasphincteric fistula (n = 11) which were comparable between groups. After a mean follow-up of 36 mo (range, 24-52), there were 2 recurrences in each group (7.4% and 7.1%, respectively). There was no significant difference between the 2 groups regarding continence either before or after surgery, as 77.8% of the flap group and 82.1% of the fistulotomy and reconstruction group were fully continent prior to surgery whereas 70.4% and 67.9%, respectively, maintained postoperative continence[33].

The incontinence rate associated with fistulotomy varies from 0% to 40%[34,35]. In a prospective randomized study among 148 patients with inter-sphincteric fistulas, age, gender, duration of disease, location of the internal orifice, and previous surgery were not found to be significant factors influencing postoperative incontinence[36]. However, in the same study, low voluntary squeeze pressure and multiple prior drainage procedures were deemed as predisposing factors for postoperative incontinence. The authors recommended anal manometry prior to fistulotomy, and not to use this technique in patients with a past history of multiple drainage[36]. Other authors found similar results[34]. However, Garcia-Aguilar *et al*[37] reported that previous surgery, female gender, high internal orifice, type of surgery performed in high fistulas were all risk factors for developing postoperative incontinence following fistulotomy[37].

Others have concluded that trans-sphincteric fistulas and the extent of external sphincter involvement are significant risk factors for post-fistulotomy incontinence[35]. In this retrospective study, 64% of the population (n = 110) experienced at least occasional incontinence episode(s). Lifestyle restriction was found to be mild in 14% and moderate in 10%; mild and moderate depression were encountered in 9% and 4%, respectively, with 5% of patients having moderate embarrassment[35].

Endorectal advancement flaps

Advancement flaps were implemented as a sphincter-saving method since there is no division of the sphincter muscles, and are mainly used for complex or high fistula. Basically, an incision is made distal to the internal opening of the fistula, a flap of healthy tissue is elevated, the diseased part is excised, and the internal opening is closed followed by advancement of the flap to cover the closed internal opening, and is finally sutured in place. There are a few crucial points to help ensure an optimal outcome. Dissection is started in the submucosal level. As the dissection proceeds proximally, the thickness of the flap increases without injuring the sphincter. In addition, the wide base of the flap should ensure a tension-free flap with a good blood supply. Alternatively a curvilinear (semicircular) flap could be raised to avoid ischemia at the edges[38]. Regardless of the incision used, it should not be very close to the anoderm to avoid ectropion. The healing rates, shown in Table 1, range from about 57% to more than 90% with an acceptable period of follow-up.

In a retrospective review of 91 patients who underwent flap repair for complex fistulas, the recurrence rate was 19% after a median follow-up of 42 mo (range, 24-65)[48]. The authors noted in their cohort that the median time to relapse was 5 mo with no recurrences after 1 year.

Abbas and colleagues[50] conducted a study to determine the long-term outcome of an endorectal advancement flap for complex anorectal fistulas in 36 patients. The primary success rate was 83%. Transient fecal incontinence was reported by 3 male patients, but this problem spontaneously resolved in all 3 patients in 2 mo. Transient and minor continence-related problems have been encountered in other studies[8,29,43,44,51]. Long-term functional outcome was assessed among 179 patients after surgical treatment of cryptoglandular fistulas, 70 of whom received

advancement flaps. The 3-year recurrence rate was 21% soiling was reported in 40% of the patients[34]. Fifty six patients underwent prospective clinical and manometric evaluation after receiving advancement flaps. Four (7.1%) patents had recurrence and were offered the same procedure with a successful outcome. After surgery, 78.6% of patients maintained their continence, 7 patients (12.5%) reported minor incontinence problems and 5 patients (9%) suffered from major continence disturbances. Three months after surgery there was an overall reduction in maximum resting and squeeze pressures. Age, gender, and previous fistula surgery did not affect outcome in multivariate analysis[44].

Dubsky *et al*[47] retrospectively compared full thickness flaps (n = 20) to partial thickness (mucosal) flaps (n = 34). Although incontinence was found in 5 (11.1%) patients, full transection of the rectal wall for flap creation did not pose a threat to continence as only one of the 5 patients belonged to the full thickness flap group. The overall recurrence rate was 24%, occuring mainly in patients who had undergone multiple prior fistula-related procedures. Similarly, one patient (5%) experienced recurrence from the full thickness flap group as opposed to 12 patients (35.3%) from the partial (mucosal) thickness group.

The endorectal advancement flap provides sphincter preservation, and is a relatively safe alternative for managing fistulas-in-ano, with acceptable outcomes. The associated fecal disturbance is temporary in the majority of cases, yet necessitates awareness during preoperative assessment, patient counseling and the operative procedure.

Fibrin glue

During World War I, fibrin glue was initially implemented in surgery for hemostasis. Later, the material was utilized in different fields of surgery mainly as a sealant[52] till 1992 when Hjortrup and colleagues[53] used it to seal anal fistulas. The fibrinogen, thrombin, and calcium mixture in the fibrin glue seal the fistulous track by virtue of inducing clot formation. The initial soluble clot results from cleavage of fibrinogen to fibrin, which transforms to a stable clot once thrombin and calcium activates factor XIII. This reaction takes about 30-60 s. Subsequently, the glue promotes the migration of fibroblasts and pluripotent cells to start healing the fistula by laying down collagen. Over the following 7-14 d, the initially formed fibrin clot starts to dissolve by the lysis action of the plasmin present in the surrounding tissues while the tract is filled with synthesized collagen fibers[54].

For the procedure to be successful, both internal and external openings of the fistula tract need to be identified. Injecting hydrogen peroxide or methylene blue can help to identify the openings. A loaded double-barrel syringe is introduced into the tract till the tip is seen through the internal opening. The syringe is emptied allowing the components of the glue to mix then exit the syringe to fill the fistula tract while steadily withdrawing the syringe outwards with a simultaneous compression to fill the fistula tract from inside out avoiding any filling deficiencies. The injection is followed by a ten minute wait to allow the reaction to stabilize the clot. While some authors advocate suturing the internal and external openings[55], others found no benefits[56,57]. The success rate varies, ranging from 31% to 85% as shown in Table 2.

n: Number of patients

Various reasons have been suggested to explain success or failure, which includes technical-related and postoperative care issues. Dislodgement of the fibrin plug has been one of the most common proposed reasons[56]. Based upon this theory many surgeons instruct their patients to follow a sedentary lifestyle in the immediate postoperative period, and to avoid heavy lifting or any strenuous activity. Others prescribe stool softeners, or suggest that fistula tract preparation by mechanical curettage is a key to success, such that inadequate removal of granulation tissue could lead to failure of the glue[54].

Postoperative infection and abscess formation are other causes of failure. These postoperative septic sequelae may be due to a technical, improper cleansing of the tract prior to instillation of the glue, or a non-resolved infection[60,61]. The length of the fistula tract has also been related to success or failure. While some surgeons have demonstrated higher success rates when using fibrin glue in long tracts (> 3.5 cm)[58,60], assuming that fibrin glue has greater liability to leak from shorter tracts, others have shown greater success rates in shorter tracts[59,61,65].

As previously mentioned, the length of follow-up is an important facet in evaluating such new techniques. Sentovich *et al*[59], in their initial study showed a success rate of 85% over a follow-up period of 10 mo. This rate became 69% after 22 mo of follow-up[61]. Queralto *et al*[66], offered 34 patients with high cryptoglandular fistula synthetic glue. At 1 mo, the healing rate was 67.6%. This rate remained almost the same during a median follow-up period of 34 mo (range, 21-43), with no continence problems.

Despite the inconsistent success rates, the majority of studies showed that in properly selected patients, fibrin glue can achieve 30%-60% success rates. The technique is simple, less invasive to the anal sphincter complex, and in case of failure, it does not preclude the patient from receiving other methods of treatment.

Fistula plug

Another less invasive, sphincter preserving technique is the fistula plug. This biologic plug (Surgisis® Anal Fistula Plug, Cook Surgical, Belington, IN, USA) is manufactured from porcine small intestinal mucosa. The plug characteristically is resistant to infection, and ideally, does not induce a foreign body reaction. Furthermore, it invites host cells to populate it, promoting multiplication and ultimately filling the fistulous tract[67].

Prior to usage, the plug should be rehydrated in 0.9% normal saline for 3-5 min. During this time the surgeon should have identified both the internal and external openings of the fistula tract in the usual manner. The plug should be inserted in the fistula tract through its internal opening. Once light resistance is encountered, the plug is trimmed if needed, and secured at the internal opening, since dislodgement is a primary cause of plug failure[68]. Similarly, the excess at the external opening is trimmed at the skin level, but the external opening is left opened for drainage in an attempt to reduce the possibility of infection and failure of treatment. Similar to fibrin glue, the results of the anal fistula plug vary greatly as shown in Table 3.

Preoperative bowel preparation, perioperative antibiotics, and prone operative position of patient, are not mandatory but preferred by most surgeons[80]. The prior use of a seton not only ensures the elimination of any inflammation or infection, but has been postulated to prepare the tract, making the wall more fibrotic, with an ultimate increase in success rates[75,77]. Conversely, seton use has not been found to correlate with increased healing rates in other studies but seems to facilitate the procedure by identifying the fistula anatomy[68,70].

Several authors have tried to assess predictors of success and to identify causes of failure. Following the previously mentioned technique, with mechanical bowel preparation, hydrogen peroxide irrigation of the fistula tract before plug insertion, strict postoperative limitation of activity, and topical metronidazole, Johnson *et al*[69] reported an 87% success rate at 14 wk, and 83% at 12 mo[68]. O'Connor *et al*[70] achieved an 80% success rate with the addition of seton placement prior to plug insertion, while Garg[71] reported a 71% success rate without using hydrogen peroxide, which is thought to clear the tract of all debris that might interfere with cell migration induced by the plug and hence prevent healing[72].

An anal fistula plug has also been used for complex anal fistulas. Ellis *et al*[81] retrospectively studied the long-term outcomes of an anal fistula plug in complex fistulas in patients who had at least 1 year of follow-up since their last treatment. Sixty three patients were identified, 51 of whom (81%) had had clinical healing of the fistula. When applying multivariate analysis, the authors noted that tobacco smoking, a history of prior plug failure, and a posterior fistula were all predictive factors for failure. This study concluded that the anal fistula plug is an effective method for long-term closure of complex anal fistulas[81]. Similarly, Lenisa *et al*[82] studied 60 consecutive patients with complex fistulas through a prospectively maintained database. Eleven patients had multiple fistula tracts, 17 were located anteriorly in female patients, and the remaining were trans-sphincteric, while 38 tracts were recurrent in nature. At a mean follow-up of 13 mo, the success rate was 60% in all patients and 70% for the fistula tracts. The mean time for recurrence was 5.7 mo. Replugging successfully managed 2 recurrent patients, and 5 patients received successful post-plug fistulotomy. This resulted in a global healing rate of 72% with no continence impairment. The authors concluded that an anal fistula plug remains a safe option in treating complex anal fistulas and the reasons and risk factors for recurrence remain to be discovered.

Table 3 Results of anal fistula plug

Author	*n*	Follow-up months (mean)	Success rate (%)
Johnson *et al*[69]	25	3	87
Champagne *et al*[68]	46	12	83
O'Connor *et al*[70]	20	10	80
Ellis *et al*[4]	18	10	78

Lawes *et al*[78]	20	7.4	24
Safar *et al*[79]	35	4	14

n: Number of patients.

The higher than expected recurrence rate with the glue and plug, and the associated risk of incontinence with other conventional methods prompted the search for other techniques to find an optimal treatment for fistula-in-ano.

Ligation of the intersphincteric fistula tract

Initially described by Rojanasakul[83], Ligation of the intersphincteric fistula tract (LIFT) involves a small incision in the intersphincteric groove where the fistula tract crosses from the internal sphincter to the external sphincter. Dissection is carried out till the fistula tract is clearly identified, ligated, then divided. The initial report showed healing in 17 out of 18 patients by a mean time of 4 wk.

Bleier *et al*[84], applied the technique in 39 patients, 74% of whom had undergone a median of 2 previous attempted repairs. Follow-up data on 35 patients at a median follow-up of 20 wk revealed a success rate of 57% (20/35) and a duration of failure of 10 wk (range, 2-38), with no subjective decrease in continence. Shanwani *et al*[85], applied the same technique on 45 patients (transsphincteric = 33, complex = 12), with 5 patients presenting with recurrent fistula after prior surgical intervention. After a median follow-up of 9 mo (range, 2-16), the primary healing rate was 82% (37/35), with a median healing time of 7 wk

(range, 4-10). Recurrence was encountered in 8 patients over a period of 3 to 8 mo, with no significant morbidity.

Radiofrequency

Radiofrequency ablation of the fistula was used in an effort to reduce continence-related problems by limiting damage to the surrounding muscle. Gupta[86,87] conducted a study among 100 patients with low anal fistulas comparing radiofrequency to conventional fistulotomy. The radiofrequency group was found to have less gas incontinence; 4% *vs* 12%.

Stem cells

Patients' adipose-derived stem cells have been used to treat complex fistulas, either cryptoglandular or Crohn's-related[88]. In a separate procedure, and under complete aseptic techniques, adipose tissue was obtained from the patients, processed and centrifuged to provide adipose-derived stem cells. These cells were cultured, then in a second procedure, were injected into the fistula tract.

In a comparative study in 49 patients with cryptoglandular or Crohn's-related fistulas, the healing rate was 71% in the stem cell group in addition to fibrin glue *vs* 16% in the fibrin glue group, with no difference in adverse reactions among the groups. At 1 year follow-up, recurrence rate was 17.6 % in the stem cell group, with the earliest recurrence occurring at 7 mo, while no recurrences were observed in the control group. The authors concluded that this method was safe and had the potential of healing fistulas in complex disease[88].

CONCLUSION

An anal fistula is a common disease which is devastating to the patients and imposes challenges to the surgeon. Proper management requires knowledge of the etiology and an understanding of the anatomy. So far, the available treatment methods have not achieved the main goals of preventing recurrence and preservation of continence. The lack of level I evidence, absence of long follow-up periods, inconsistent results, and varying methodology among published studies has resulted in the current lack of consensus. However, the higher than accepted recurrence rates, and fear of incontinence, has prompted a search for newer methods. Nevertheless, the variability in success and incontinence and/or recurrence rates could be related to surgeon expertise and/or technique and/or patient selection.

Abstract

Fistula-in-ano is a difficult problem that physicians have struggled with for centuries. Appropriate treatment is based on 3 central tenets: (1) control of sepsis; (2) closure of the fistula; and (3) maintenance of continence. Treatment options continue to evolve - as a result, it is important to review old and new options on a regular basis to ensure that our patients are provided with up to date information and options. This paper will briefly cover some of the traditional approaches that have been used as well as some newer promising procedures.

INTRODUCTION

Fistula-in-ano is a difficult problem that physicians have struggled with since the time of Hippocrates. The ideal treatment is based on 3 central tenets: (1) Control of sepsis; (2) closure of the fistula; and (3) maintenance of continence. Treatment options have continued to evolve - as a result, it is important to review old and new options on a regular basis to ensure that our patients are provided with up to date information and options. The incidence of fistula-in-ano is 9 per 100 000 (compared to 6 per 100 000 for Crohn's disease and 8 per 100 000 for ulcerative colitis)[1], and is therefore a problem commonly encountered. This paper will briefly cover some of the approaches that have traditionally been used as well as some newer promising procedures.

The reader should be aware that despite the long standing history of fistula-in-ano and the multiple approaches that are utilized, there is a paucity of high quality data to guide decision making. A recent Cochrane review concluded among other things that there was a "crying need for well powered, well conducted randomized controlled trials" and that recurrence and rates of incontinence were the most important factors when considering repair[2]. We agree with this assessment, and base our management on the best available data. However, this illustrates the need for continual review of appropriate management techniques.

One of the most clinically useful classification systems for perianal fistulas (by the American Gastroenterological Association) divides them into simple and complex - this classification facilitates operative decision making[3].

Simple fistulas are low - i.e. they involve a small (or sometimes none) portion of the sphincter complex. These fistulas include superficial, low intersphincteric or low transsphincteric fistulae. In addition, communication between the anal canal and skin is only *via* one tract and is not associated with inflammatory bowel disease, radiation or involving any other organs.

Conversely, complex fistulas are anatomically higher: they involve significant portions of the sphincter musculature, may have multiple tracts, involve other organs (i.e. vagina) and may be associated with radiation or inflammatory bowel disease. Recurrent fistulas are usually included in this category as well.

Superficial fistulae

The management of superficial fistulae is fairly straightforward. Superficial or simple fistulas that, by definition, do not traverse any (or an insignificant portion) of the sphincter musculature should be treated with simple fistulotomy. This is a time-honored, effective approach with a success rate that approaches 100%, with little or no effect on continence[4]. Lay-open fistulotomy is easy, and management of these wounds is straightforward. These procedures involve unroofing of the fistula tract and curettage of the epithelialized lining. Conservative wound care with sitz baths and analgesics postoperatively is usually all that is needed. There is some evidence to suggest that healing is quicker with marsupialization of the tract[5].

Intersphincteric fistulae arise from cryptoglandular infections that remain contained between the internal and external sphincters. Partial division of the internal sphincter alone is standard treatment for other benign anorectal disease such as anal fissure, and is similarly safe. This technique involves cutting a portion (usually to a maximum of 30%) of the internal sphincter only, and yet maintains excellent preservation of continence. From this we extrapolate that division of the internal sphincter along the length of an intersphincteric fistula is similarly safe, and with limited changes in continence, is also an acceptable form of treatment of intersphincteric fistula. If an intersphincteric fistula involves a significant portion of the internal sphincter (over 30%) then thought should be given to a sphincter sparing-type procedure - incontinence can result if too much internal sphincter muscle is divided.

Complex fistulae

Fistulae that traverse a significant portion of both sphincter muscles are termed trans-sphincteric and are part of the group of complex fistulae. Lay-open fistulotomy along these tracts are effective at fistula closure for the same pathophysiologic reasons as simple fistulae but, based on the amount of musculature involved, may result in significant changes in continence, violating one of the basic principles of appropriate management. Thus, this is no longer considered an acceptable approach.

Seton placement

Initial management of complex or trans-sphincteric fistulae begins with control of the septic focus. Initially this may involve drainage of anorectal abscess, and if the fistula tract can be identified, a draining seton should be placed. This is a foreign piece of material inserted through the fistula tract which functions to maintain the fistula tract in an open state, preventing a closed space infection, and allowing for drainage and sepsis resolution. This is a safe, and usually simple, method for control of the basic pathophysiologic insult that creates the fistula. Appropriate complex fistula management almost always indicates initial seton placement. By allowing for resolution of sepsis, and establishment of a well-formed tract, the clinician is offered the luxury of time and the ability to characterize the anatomy of the fistula, which underpins effective subsequent management.

The draining seton is usually a silastic or similarly biologically inert, low profile material that does not incite an inflammatory reaction. We typically use a vessel loop. The fistula tract is identified, and traversed with a fistula probe if possible. A suture is then attached and pulled through. The other end is then tied to the vessel loop and then pulled through. The vessel loop is tied to itself with a permanent suture in a loose fashion. In addition, the external fistula opening is usually widened and debrided of chronic granulation tissue. In this manner, almost any fistula, with its associated local sepsis is temporized, and infection and inflammation can clear. Appropriate anorectal hygiene in the form of sitz baths or showering is used until the infection clears. This creates a stable situation in which a fistula can be maintained indefinitely. Once sepsis and inflammation have cleared, the presence of the seton in an uninfected tract allows for accurate delineation of the fistula anatomy, either *via* careful clinical exam, ultrasound or radiologic study. If there is any question as to the possibility of a significant trans-sphincteric component at the time of initial operation, a seton should be placed, and minimal added morbidity will be incurred.

One option for subsequent management of a transsphincteric fistula is the use of a cutting seton. The principle that underlies this is the hypothesis that slow division of the muscle allows for fibrosis and scarring and that overall integrity of the sphincter complex is maintained. The technique involves sequential tightening of the seton through the fistula tract by way of serial placement of additional suture material on the seton and/or by asking the patient to pull on the seton at a regular frequency (once every few days), or by tightening of the original seton. Many different types of setons can be used for this, including the initially placed silastic seton, or more commonly, the silastic seton is replaced with a silk suture which is narrower, and inflammation-inducing. This allows for faster cutting and induction of scarring. This procedure, however, has several disadvantages, despite a sound theoretical basis: It requires frequent office visits for tightening, sometimes weekly or bi-weekly. It is usually quite uncomfortable or painful for the patient, and usually results in the need for narcotic or non-steroidal analgesia. Most importantly, there is substantial literature which demonstrates that despite the scarring through a

maintained sphincter complex, continence can be negatively affected. This procedure must be approached with caution, especially in view of the sphincter sparing procedures, which are available. While reported success rates have been reported as similar to fistulotomy, changes in continence have been reported in greater than 60% of patients[6].

Advancement flaps

The advancement flap is a technique which is designed to address the pathophysiology of the fistula in a sphincter-sparing approach by closing the internal opening, thus depriving the fistula of it's source of sepsis, and allowing the defunctionalized tract to heal by secondary intention.

The endoanal advancement approach involves advancing a healthy sleeve of rectal wall over the debrided internal opening, and suturing the flap over and distal to the internal opening. This is based on a broad pedicled flap dissected from the healthy proximal rectum. This procedure is technically more difficult and is often plagued by difficult exposure, especially on posteriorly located fistulae within the rectal hollow. Fistulas with higher internal openings are often quite difficult to reach as well. Additionally, this procedure involves the creation of a large defect in previously undamaged rectum, and runs the risk of devascularization and loss of a much larger portion of rectal wall. Failure or ischemia of these flaps may result in the creation of a much larger defect than existed previously. In addition, dissection in a scarred or chronically inflamed plane can place the sphincter at risk. Success rates for this approach vary widely through the literature, and range from 0 to 63%[7,8].

Cutaneously based flaps are advanced from the anodermal skin over the internal opening, and are based on pedicled flap principles as well. These flaps avoid placing otherwise healthy rectum at risk, but also have their own associated morbidities. These similarly require extensive experience with maintaining viability of skin-based flaps, and also run the risk of injuring the sphincter. Additionally, advancement of anodermal skin into the anal canal may result in chronic irritation and seepage, pathophysiologically akin to the ectropion, which may be the result of over-extensive hemorrhoidectomy. Data are sparse regarding the optimal flap approach. Mucosa-only flaps may minimize the risk to unaffected rectum, but a randomized trial comparing partial thickness advancement to mucosa alone demonstrated improved efficacy in fistula closure with thicker flaps. A retrospective study by the Cleveland Clinic, Florida found only a 33% recurrence rate for flaps used in non-inflammatory bowel disease (IBD) patients. Zimmerman[9] reported on his group's success with anodermal advancement flaps and found that when used as initial therapy, this method had a greater than 75% success rate, with maintained continence in over 80%. Importantly Mitalas[10] found that repeat approaches using endoanal flaps still had a significant success rate, with 67% of patients having long-term success.

Fistulectomy

Fistulectomy is a less commonly performed technique for trans-sphincteric fistulae. It is based on the principle that removal of the chronic, epithelialized tract will allow healing by secondary intention of healthier tissue. Typically, the fistula tract is cored out over a probe or seton, leaving healthy peri-rectal fat only. Dissection is typically carried out from the external opening up to the external sphincter. This is a difficult and potentially morbid technique which may leave large tissue defects and may involve injury to the sphincter complex. Success rates are similar to fistulotomy, and subsequent incontinence rates have been shown to be as high as 15%[11]. Malik's meta-analysis found only 2 studies comparing fistulectomy to fistulotomy, and found no significant difference between the two[5].

Fibrin glue

Fibrin glue injection was the first exciting modern development in sphincter-sparing approaches to complex fistulae. The technique is based on the injection of a liquid fibrin matrix through any fistula tract which would facilitate healthy tissue ingrowth and fistula closure. The major advantage is the extremely benign nature of the approach. It requires no dissection or risk to the sphincter musculature regardless of the anatomy or complexity of the fistula tract, and has potential applications in IBD as well. However, despite early enthusiasm, long-term results have been quite disappointing with success rates as low as 16%[12-16]. Few randomized trials document fibrin glue efficacy; only one small trial comparing it to conservative management showed improved outcomes with glue therapy. Draining setons were used, resulting in an unsurprisingly low 13% (since no fistulae were deliberately closed) cure rate, while 43% were cured with fibrin glue. A more recent review reported on a recurrence rate ranging from 10%-78%[17]. Newer approaches have modified the use of fibrin glue with the addition of adipose-derived stem cells, and this approach shows promise: in one study 71% of patients with the enhanced approach healed their fistulae, compared to 16% with fibrin glue alone.

Currently, we do not advocate this approach as a primary therapy given its lack of demonstrated success. Currently, it is most often used as an adjunct measure when combined with other methods such as advancement flap, but has demonstrated little success in the literature[13]. Nevertheless, it remains a very safe technique with minimal downside other than expense and time, and may be considered prior to more invasive options when other methods have failed.

Anal fistula plug

The anal fistula plug (AFP) is a simple repair that does not involve an extensive dissection and therefore is a very attractive approach. Essentially, the plug is pulled through the fistula tract and secured in place at the internal opening (the wider portion of the plug is at the internal open-

ing) and trimmed to the skin at the external opening with the external opening left open to drain.

Initial reports documented a very high success rate, with the initial descriptions by Ellis and Johnson documenting close to 80% success[18]. This was further supported by a study from Case Western documenting an 83% success rate[19], however, with more studies the overall success rate has been found to be lower with some studies reporting a 20% success rate[18,20,21]. Jacob and Keighley's recent meta-analysis found success rates ranging from 35%-85%[2].

Thus far, it does not appear to be associated with any major complications and can be regarded as a sphincter-sparing approach. No impact on continence has been found. Wang compared the use of the fistula plug to endoanal flap advancement; both "sphincter-sparing" approaches, and found that the flap approach enjoyed an improved long-term closure rate[22]. These results were echoed by a study from the University of Minnesota[23]. Currently, we are conducting a randomized prospective trial comparing the plug to the ligation of the intersphincteric fistula tract (LIFT) procedure (see below).

LIFT procedure

In 2007, Rojanasakul described the LIFT procedure, in which the fistula tract is identified between the internal and external sphincters (intersphincteric space) and subsequently divided and ligated. His group initially reported a 94% success rate with no impact on continence (Figure 1)[24]. The procedure is appealing as it appears to be a "sphincter-sparing" technique and is a relatively simple operation to perform. The first step is to identify the intersphincteric groove. Once the skin is incised in this area, a combination of blunt and sharp dissection is used to identify the fistula tract - a task made easier if a draining seton has been left in place for at least 6 wk (Figure 1). Once the tract is identified, it is ligated on both sides and divided (Figure 2).

There have been further reports from North America and Malaysia - these have shown lower success rates of 57% and 77%, respectively[25,26]. However, compared to other procedures this still offers a comparable success rate. Other advantages of the procedure are the low cost and the fact that that even if it does not work, other approaches can still be utilized. The long-term success of this technique remains to be determined, as well as waiting to see if these success rates can be duplicated by other centers. Other studies are underway examining the efficacy of the LIFT and there is also a randomized controlled trial comparing the LIFT to the AFP.

BioLIFT

Recently, a modification of the LIFT procedure has been described. After the fistula tract is identified and divided, a biologic mesh is placed in the intersphincteric space to act as a barrier to re-fistulization. A video presented at the 2010 American Society of Colon and Rectal Surgeons meeting demonstrated this technique with promising results in a single surgeon series. This procedure entails a significant dissection of a large portion of the intersphincteric space, all the way up to the levator musculature, and the placement of a large piece of biologic mesh. Given the complexity and magnitude of this method, it may not be appropriate as first-line therapy.

WITH ALL THESE OPTIONS, WHAT IS THE TAKE HOME MESSAGE?

First, is the fistula simple or complex? This will be elucidated by history, physical and appropriate use of imaging.

If it is a simple fistula, a primary fistulotomy with marsupialization of the wound is likely the best option as the addition of marsupialization may lead to faster wound healing.

In a complex fistula, treatment should be individualized. However, the authors advocate sphincter-sparing approaches first (after a draining seton has been placed for 6-12 wk). Based on evidence and simplicity of approach, the authors generally begin with either a fistula plug or LIFT procedure (and since we had clinical equipoise concerning these two repairs we are involved in a randomized controlled trial comparing the two; there is a PLUG trial also underway comparing the plug to advancement flap). We do not use the advancement flap as our first option because it is a more extensive operation and the "downside" of failure is bigger. An important point regarding the use of LIFT is the fact that it appears to "burn no bridges"; if a LIFT procedure fails, it sometimes results in an intersphincteric fistula, which then may more safely be treated with a primary fistulotomy, and there have been no reported issues in continence after this procedure. Alternatively, the failure may still result in a trans-sphincteric fistula (and when the plug fails it always results in the same type of fistula that was originally treated). Prior to attempting definitive management again, a draining seton is usually replaced, remaining in place for 6-12 wk. We usually try a LIFT or plug again but if this fails, we then move on to other options. Further imaging after failures can also be helpful to ensure that additional tracts have not been missed.

Special cases

Crohn's disease: Thirty percent of Crohn's patients will experience perianal disease, including fistula-in-ano. Fistulae in Crohn's patients usually have complex tracts and are often multiple and arborizing, making the treatment challenging. Collaboration between surgeon and gastroenterologist is critical with this condition as medical treatment with immunomodulators (i.e. Remicade and Humira) have demonstrated significant success in perianal fistula closure.

Like other cryptoglandular fistulae, these fistulas can have an acute and chronic phase - in the acute phase they can be associated with local infection and prior to initiating medical treatment, this focus of sepsis usually needs to be dealt with. An examination under anesthesia with drainage of the septic source, as well as placement of a draining seton (or setons) is appropriately employed.

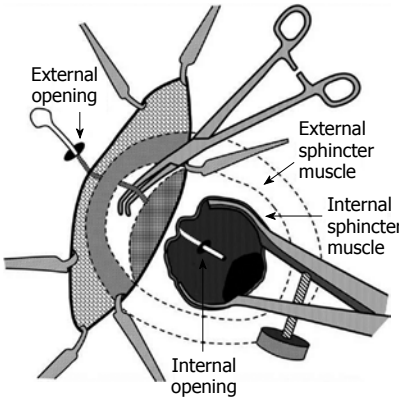

Figure 1 The fistula is identified as it crosses the plane between the internal and external sphincters. Reprinted with permission from the American Society of Colon and Rectal Surgeons.

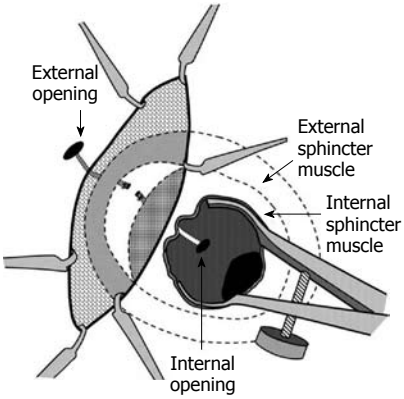

Figure 2 The fistula is dissected free, ligated and divided. Reprinted with permission from the American Society of Colon and Rectal Surgeons.

With the draining seton in place, it is rare to develop a recurrent abscess and medical therapy can be initiated. Chronic inflammation and proctitis usually define the chronic phase of this disease. Communication between surgeon and gastroenterologist should occur to determine optimal initial medical management, and subsequently, to decide if there is a role for removing the seton when the Crohn's disease seems more quiescent. Further options can be considered as discussed below.

If there is a well-established, chronically draining fistula without associated abscess at initial presentation, treatment can be individualized, but in cases where there is still occasional purulent drainage, placement of a draining seton is encouraged to help resolve any residual infection. Primary fistulotomies should be avoided in Crohn's patients as these are usually complex tracts involving significant portions of the sphincter, and impairment of sphincter function, especially in patients who are prone to looser bowel movements, can exacerbate continence issues. In addition, in the presence of multiple fistulas, the cumulative effect of several (even if they are superficial) fistulotomies can cause significant sphincter dysfunction. Treatment of a Crohn's fistula depends on what technique the surgeon is most comfortable with, but conservative, sphincter-sparing approaches are the most appropriate. Options include mucosal advancement flaps, AFPs, the LIFT and possibly, the BioLIFT. Because of the potential for changes in continence that can be seen with a cutting seton, this approach is not one advocated by the authors. It is important to note that most approaches to repair are doomed to failure in the face of active proctitis, and thus all definitive treatment other than sepsis control need to be delayed until effective management of the disease process has been achieved.

Rectovaginal and rectourethral fistula: The vast majority of rectovaginal (RV) fistulas (> 80%) are the result of obstetrical trauma[27]. Other causes include inflammatory bowel disease, infection (from cryptoglandular origin, diverticulitis or Bartholin's gland infection), radiation or neoplasm. RV fistulas are classified as "high" or "low". Anovaginal fistulas are considered low fistulas and involve the sphincter mechanism. High fistulas are those that have their origin above the sphincter complex. The operative approach differs widely based on this anatomic classification. A careful history and physical examination is used to determine the underlying etiology. Further investigations such as colonoscopy, computed tomography scan, ultrasound, and pelvic magnetic resonance imaging can be useful to identify the etiology and anatomy. If obstetrical trauma is the suspected cause, an endoanal ultrasound can be used to assess if there is a sphincter defect along with manometry to document sphincter resting and squeeze pressures. Pudendal nerve latency testing can also be done to give the patient an idea of potential success rate if a sphincteroplasty is performed (if there appears to be nerve damage, a sphincteroplasty will have a lower success rate).

With a RV fistula and concomitant sphincter injury from obstetrical trauma, a sphincteroplasty is the best option. Although the technique may be beyond the scope of this review, this involves a perineal approach and has good short-term success but longer term functional outcome begins to drop off in 3-5 years.

Low RV fistulas that are not associated with a sphincter defect are classified as complex perianal fistulas as discussed in the Introduction. Options that can be used include advancement flaps (both rectal and vaginal), LIFT procedure, BioLIFT, and AFP. In some cases where the fistula is large or after the failure of multiple previous attempts at local closure, the use of pedicled muscle flaps, such as the bulbocavernosus (Martius) or gracilis flap may be required, usually accompanied by temporary gastrointestinal (GI) tract diversion.

High RV fistulas such as those that result from diverticulitis are managed by a transabdominal approach, usually requiring proctectomy or colectomy. Continuity *via* a coloanal anastomosis can be restored depending on the clinical scenario.

Rectourethral (RU) fistula is a rare complication usually seen after intervention in the male genitourinary tract. Appropriate management and maximizing success in treating RU fistulas relies on knowing the etiology and

prior history of the patient. RU fistula most commonly arises as a complication after radical prostatectomy. Iatrogenic injuries to the rectum or local sepsis after anastomotic dehiscence are the most common causes. Rarely, minimally symptomatic patients may be observed, or an initial attempt at local repair with flap techniques may be employed. The use of an indwelling catheter is critical to healing. Although success rates are low, there is little downside to such an attempt in this highly-selected population. In cases where there are significant symptoms, and there is no history of pelvic radiation or IBD, the most appropriate first step in management is GI diversion. Up to one third of RU fistulas may heal with diversion alone[28]. Local flap repairs may then be employed if spontaneous healing does not occur. Success rates of local advancement flaps are improved if the patient is diverted.

If initial attempts at closure fail, the defect is very large, or if the patient has had prior pelvic irradiation, local closure techniques are doomed to failure. Repairs using local pedicle muscle flaps (i.e. gracilis or dartos flaps) are usually required for successful closure. Once closure of the fistula is documented (usually *via* contrast study) the diverting stoma can be closed.

CONCLUSION

Perianal fistulas present a common but challenging problem because of the involvement of the sphincter complex. Complex fistula treatment must always take in to account the need to spare sphincter function. Various treatments exist which indicates that there is no universally successful solution. Sphincter-sparing options continue to evolve and continued review of new techniques is important prior to proceeding with procedures that may impair continence; it is important that clinicians stay abreast of these changes so patients can be given the opportunity to access sphincter-sparing options.

Abstract

Anal fistula is among the most common illnesses affecting man. Medical literature dating back to 400 BC has discussed this problem. Various causative factors have been proposed throughout the centuries, but it appears that the majority of fistulas unrelated to specific causes (e.g. Tuberculosis, Crohn's disease) result from infection (abscess) in anal glands extending from the intersphincteric plane to various anorectal spaces. The tubular structure of an anal fistula easily yields itself to division or unroofing (fistulotomy) or excision (fistulectomy) in most cases. The problem with this single, yet effective, treatment plan is that depending on the thickness of sphincter muscle the fistula transgresses, the patient will have varying degrees of fecal incontinence from minor to total. In an attempt to preserve continence, various procedures have been proposed to deal with the fistulas. These include: (1) simple drainage (Seton); (2) closure of fistula tract using fibrin sealant or anal fistula plug; (3) closure of primary opening using endorectal or dermal flaps, and more recently; and (4) ligation of intersphincteric fistula tract (LIFT). In most complex cases (i.e. Crohn's disease), a proximal fecal diversion offers a measure of symptomatic relief. The fact remains that an "ideal" procedure for anal fistula remains elusive. The failure of each sphincter-preserving procedure (30%-50% recurrence) often results in multiple operations. In essence, the price of preservation of continence at all cost is multiple and often different operations, prolonged disability and disappointment for the patient and the surgeon. Nevertheless, the surgeon treating anal fistulas on an occasional basis should never hesitate in referring the patient to a specialist. Conversely, an expert colorectal surgeon must be familiar with many different operations in order to selectively tailor an operation to the individual patient.

Key words: Fistula; Abscess; Fibrin sealant; Anal fistula plug; Dermal advancement flap; Endorectal flap; Ligation of intersphincteric fistula tract procedure

INTRODUCTION

The treatment of anal fistula has challenged physicians and healers for millennia. References to fistulous disease and use of both fistulotomy and setons can be found in the writings of Hippocrates, dating from 400 BC[1]. This

disease process has also been mentioned in non-scientific writings through the years. The great English author and playwright William Shakespeare used what many believe to be a historical fact, that the French King, Charles V, battled with fistula-in-ano, as a comedic plot for his play "All's well that ends well"[2]. Two thousand years have passed since Hippocrates' writings and the science of medicine has taken enormous leaps, yet we continue to struggle with fistula-in-ano.

The etymology of the word fistula comes directly from its Latin counterpart which means "pipe". In medical terminology, a fistula translates to an abnormal connection between a set of organs or vessels that do not normally connect e.g. the connection between the distal alimentary tract and the integument. For years, it has been accepted that the abnormal communication of the lower gastrointestinal system with the perianal region is due to a cryptoglandular infection. It is believed that the anal crypts become blocked by inspissated debris or stool. As a result, an infection develops at the anal glands, which extends in a path of least resistance, forming an abscess in the intersphincteric space leading to the development of a fistula in about one third of patients[3]. However, this explanation does not take into account fistulas caused by Crohn's disease, tuberculosis, lymphogranuloma venereum, and actinomycosis, first reported by Swinton in 1964[4]. This duality of cryptoglandular *vs* non-cryptoglandular fistula is also distinguished in differing treatment strategies. For instance, in actinomycosis, effective treatment mandates surgical therapy with the addition of organism-specific antibiotic therapy. Also, with the recent strides seen in Crohn's fistula treatment with immunotherapy, one begins to question whether we truly understand the pathophysiology of what we conveniently group into "cryptoglandular" fistulas in the classical sense[4,5].

Current demographic data for fistula-in-ano in the United States are difficult to ascertain, as the Health Care Utilization Project (HCUP), since 1979, has recorded only inpatient procedures through its discharge data from the National Inpatient Sample. Data from a 1979 Ambulatory Care Survey of the National Center of Health Statistics listed 24 000 individuals with the diagnosis of fistula-in-ano[6]. This corresponds to the incidence of 8.6 per hundred thousand per year reported by Sainio in 1984 in the city of Helskini[7]. Another similarity seen in these studies is the 2:1 ratio of men to women in both the US and Finland[6,7]. A more current analysis of data from Europe has been performed by Zanotti in 2007, where queries of databases in the UK, Spain, Germany and Italy showed an incidence ranging from 1.04 per 10 000 in Spain to 2.32 per 10 000 in Italy[8]. These numbers are considerably higher than those reported from Finland in the 1980s.

A common theme in this disease process in all its forms is the presence of stool within the wound, both before and after any treatment strategies. Surgeons abhor the thought of stool in surgical wounds, yet in fistula-in-ano we have to accept the fact that a fresh surgical wound will be bathed in feces on a daily basis. In Crohn's fistulous disease, it has been shown that proximal diversion helps decrease activity of disease and degree of sepsis. Interestingly, this finding is independent of the severity of Crohn's-related rectal inflammation, and thus is believed to be directly related to the diversion of stool[9]. Nevertheless, proximal diversion for what we classify as routine "cryptoglandular" fistulous disease would be considered excessive to both patients and providers. Surgeons promote cleanliness with vigilant wound care and sitz baths; however, the fact remains that from simple fistulotomy to the most sophisticated repair, we accept that patients' wounds will encounter stool, mucus, and purulence on a daily basis.

The goals of the treatment of fistula-in-ano include resolving the acute-on-chronic inflammatory process, maintaining continence, and preventing future recurrence. In reality, treatment-related incontinence, either to gas, stool or both, is the most important consideration of effective eradication of disease. Continence-related morbidity has plagued physicians through history, a fact that is evidenced even in antiquity, by the use of horse hair setons described by Hippocrates in his writings[1].

For years surgeons have performed a straightforward and effective treatment for fistula-in-ano. Simple fistulotomy, i.e. the complete laying open of the tract between the external secondary opening and the internal primary opening has resulted in success rates in the 95% range[10]. Marsupialization of the tract with a locking absorbable suture (as opposed to allowing healing by secondary intention) has been shown to decrease healing time by reducing the size of the open wound[11]. At first glance, fistulotomy should prove to be the ideal treatment method, especially when compared to the much less desirable success rates seen for treatments of other fistulous diseases such as rectovaginal or enterocutaneous fistulas. However, anorectal fistula may present in a variety of forms, and fistulotomy alone can only be used safely for "simple" disease, comprising of intersphincteric fistulas, which represent about 45% of all fistulas[12]. Similarly, if a fistula is transsphincteric but superficial in nature, and not in the anterior hemisphere in women, one may opt to perform fistulotomy with relative safety. It is important to remember, however, that fistulotomy, even for what is classified as "simple" fistula, will result in some form of incontinence in about 12% of patients[13]. The existence of complex fistulas, or those where a fistulotomy would result in incontinence, comprise approximately 50% of this disease process. These complex fistulas include high transsphincteric, suprasphincteric, extrasphincteric, all anterior transsphincteric fistulas in women and those caused by Crohn's disease and secondary to coloanal anastomosis[14].

The aim of surgical therapy of fistula is cure. If one is too aggressive with fistulotomy, cure may be achieved at a cost of incontinence. On the other hand, being too conservative, while striving to maintain continence, will result in recurrence or persistence of the fistula.

SETONS

The utilization of cutting setons, whose origins can be traced to the writings of Hippocrates, attempts to address the issue of incontinence with the performance of a fistulotomy in "complex" fistulas. In theory, it is believed that sequential tightening of a seton, over the course of weeks, will produce fibrosis and avoidance of a major sphincter defect, thus effectively allowing preservation of external sphincter function. Vial *et al*[15] performed a systematic review of 18 studies, with over 440 patients. They ascertained a recurrence rate of 5.0% for patients where the internal sphincter was not divided at the time of initial surgery, and 3.0% in instances where the internal sphincter was divided. They noted an overall fecal incontinence rate of 5.6% and 25.2%, with the latter number representing the group with intraoperative internal sphincter division. However, others have suggested an overall incontinence rate of up to 67% with the use of this technique[16]. Furthermore, the use of cutting seton for complex disease creates the problem of substantial patient morbidity with severe patient discomfort associated with incremental tightening of the seton.

Others have described attempts in converting high or complex fistulas into processes amenable to fistulotomy. The placement of a draining seton, with the hopes of converting the tract into more superficial processes, or by developing fibrosis within the transsphincteric tract, have been cited as continence-preserving options in "complex" fistulas. The use of draining setons has also been attempted as a bridging therapy in two-stage sphincter-preserving procedures, in order to allow sufficient time for the subsiding of the inflammatory or infectious process, while better defining the epithelial tract of the fistula. This then allows the utilization of one of many relatively recently defined options for sphincter-preserving treatments of fistula-in-ano. Two-stage procedures, with return to the operating room for fistulotomy, have led, however, to subsequent overall incontinence in 66% of patients[16].

FIBRIN SEALANTS AND BIOPROSTHETIC PLUGS

The injection of fibrin sealants and the more recent use of collagen plugs were initially approached with fervor. In theory, the benefits of the avoidance of post-procedure incontinence, due to the lack of sphincterotomy with the use of either modality, were enticing. Furthermore, both procedures are well tolerated by patients due to minimal dissection. It is important to note that salvage treatment is possible and that the use of either technique does not preclude subsequent treatment with other modalities, and thus does not "burn a bridge" to effective treatment of complex fistulas.

FIBRIN SEALANTS

The use of fibrin sealant was initially seen as a promising treatment strategy due to its relative ease of application, and minimal post-procedure discomfort. Its application usually follows the placement of a draining, non-cutting seton. Although authors such as Tyler *et al*[17] have reported up to 62% success rates following application, with 57% resolution at re-application for patients who failed initial treatment, other reports such as those by Loungnarath *et al*[14], with reported 69% overall fistula recurrence, have caused the modality to fall out of favor. Furthermore, Ellis *et al*[18] reported nearly double the percentage of recurrence of fistulas associated with the use of fibrin glue in combination with advancement flap repair of complex fistulas, when compared to flap alone, in a randomized controlled trial.

ANAL FISTULA PLUGS

Most of the studies on bioprosthetic plugs focus on plugs made of treated porcine submucosa; however, newer synthetic plugs have recently come onto the market. A consensus conference for use of the Surgisis plug was held in Chicago in 2007 to address the discrepancy of trials regarding the efficacy of the plug. It was concluded at the meeting that trans-sphincteric fistulas would be ideal candidates for this method of treatment. However, the plug could be used if deemed appropriate in settings of intersphincteric and extrasphincteric fistulas. Absolute contraindications to the use of bioprosthetic plugs included active infectious disease or abscess, simple fistulas, allergy to pork products, and pouch-vaginal and recto-vaginal fistulas, due to the presence of short tracts. The operative procedure entails accurate identification of the external and internal openings and drainage of any active inflammatory disease or abscess with use of a seton. Once all inflammatory disease is resolved in 6 to 8 wk, the plug is placed after debridement of the internal opening. The plug is drawn snug at the internal opening and sutured in place, and then cut flush at the external opening without fixation at this location[19]. Initial studies after the consensus statement showed success rates from 62% to 83%[20,21]. Most recently, however, McGee *et al*[22] showed a 43% success rate at a mean follow-up of 25 mo, and noted a three-fold likelihood of resolution of disease with tracts greater than 4 cm.

FLAP PROCEDURES

The relatively more recent use of endoanal rectal advancement flaps, and subsequently perianal dermal-island anoplasty, has shown some promise. The short term success rate of endoanal advancement flaps in complex fistulas has been seen in some studies to be as high as 82%[23]. Similarly a 77% success rate has been shown with the use of a dermal-island anoplasty in complex transsphincteric fistula[24].

Endoanal advancement flaps were first described in 1902 by Noble *et al* for dealing with rectovaginal fistulas following childbirth[25]. Elting *et al*[26] first reported the use of this technique for use in fistula-in-ano in 1912. However, its usage in complicated anal fistulous disease

became better known in 1985, after Aguilar *et al*[27] published their results in 189 patients, with 3 recurrences and approximately 7% incidence of incontinence to flatus and no reports of incontinence to stool. The surgical technique, as described by Aguilar, includes complete subcutaneous excision of the external opening, along with all other secondary openings, to the external sphincter muscle margin. Subsequently, a flap originating from the intersphincteric groove is raised and includes anoderm, mucosa and submucosa. The flap should extend 3 to 4 cm proximal from the internal opening, and be trapezoidal in nature, with the base wider than the apex to allow adequate blood supply. The internal opening is excised, and the internal sphincter is closed using absorbable sutures. The flap is then sutured, without tension, to the intersphincteric groove[28]. A recent meta-analysis of 35 studies by Soltani *et al*[29], including over 1600 patients, showed a success rate of over 80% for fistulas of cryptoglandular origin, with a 13% incidence of some form of incontinence. Further derivatives of this technique have been described, in combination with the use of bioprosthetic plugs or fibrin glue, with mixed results. The endoanal advancement flap, although not always ideal, has become a promising tool. However, its major limitation is that it frequently results in a mucosal ectropion, which produces mucus and gives patients the false sensation of incontinence due to spontaneous discharge and soiling.

Dermal island-flap anoplasty was first described by Del Pino *et al*[30] in 1996, as an alternative to rectal advancement flaps, in order to reduce risk of mucosal ectropion and anal discharge. The operative technique entails the formation of a tear drop-shaped incision encompassing the perianal skin containing the external opening. The incision is extended just proximal to the internal opening of the trans-sphincteric fistula. Subsequently, the internal opening is excised and debrided, and the internal sphincter at this level is closed using absorbable suture. The flap is mobilized without undermining, and the dermal island is sewn to the rectal mucosa with absorbable sutures. The external opening is neither excised nor debrided. Nelson *et al*[6] found a procedure failure rate of 23% with an associated patient failure rate of 20% with this method, in a mean follow-up period of 28.4 mo. As of recent publications, incontinence data is not available; however, it is safe to assume it to be similar to that of endoanal rectal advancement flaps.

LIGATION OF INTERSPHINCTERIC FISTULA TRACT

Most recently, the introduction of the ligation of intersphincteric fistula tract (LIFT) procedure has sparked interest with good short term results. This procedure, first proposed by Rojansakul in 2007, focuses on the ligation of the intersphincteric tract of the fistula, and can be applicable for both complex and recurrent fistula[31]. In recurrent fistula, previous internal sphincterotomy will impede proper dissection of the tract. This method delineates the trans-sphincteric tract, with careful dissection in the intersphincteric groove, with or without the help of a fistulotomy probe. Once the fistula track is isolated it is ligated with absorbable suture on both proximal and distal sides and divided between the ligatures. The success of LIFT procedure is reported to be 75%-80%[32-34].

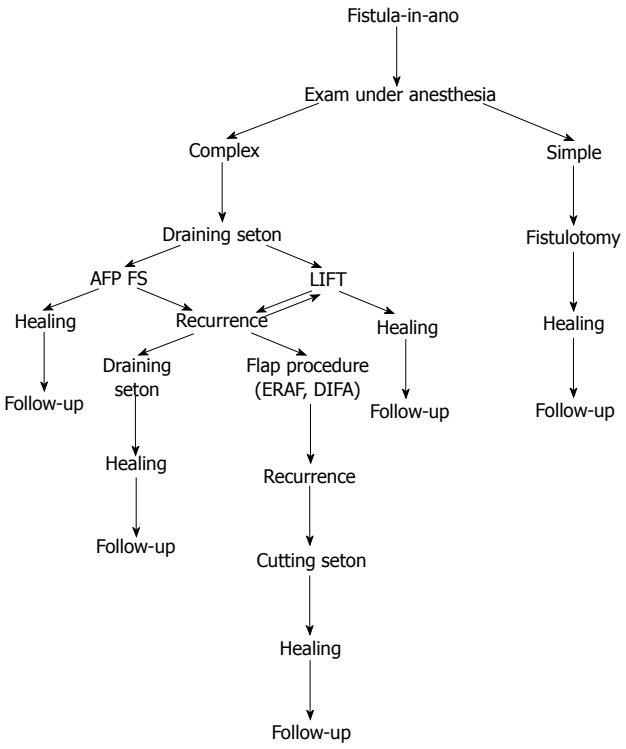

Figure 1 Treatment algorithm. AFP: Anal fistula plug; FS: Fibrin sealant; ERAF: Endoanal advancemnt flap; DIFA: Dermal island flap anoplasty; LIFT: Ligation of intersphincteric fistula tract.

TREATMENT STRATEGY

In our experience, simple fistulotomy is attempted if none or minimal amount of external sphincter is involved in the fistulous tract. In all other cases, a draining seton is placed as a bridging therapy for a minimum of six to eight weeks. After this time, a controlled exam under anesthesia is performed, and if the acute inflammatory process is resolved, then our treatment algorithm follows that of conservative management for continence preservation. If at this point minimal sphincter involvement is identified, then simple fistulotomy with marsupialization is performed. If the tract is deemed "complex" in nature, then a flap, either dermal-island or endoanal advancement, is used, with adequate drainage of the tract through the external opening using a small caliber Malecot drain. If the tract appears to be of sufficient length, then use of bioprosthetic plug is considered. Currently we are studying the utility and efficacy of the LIFT procedure; however, early results seem promising in nature (Figure 1).

Fistula-in-ano continues to prove a formidable chal-

lenge to surgeons. Our understanding of the disease process, although well established, contains gaps in the understanding of complex pathophysiology. While effective treatment has been established for "simple" cases, the concern for iatrogenic sphincter injuries, with resulting incontinence, continues to plague cases of "complex" disease with major sphincter involvement. Recent strides in the development of sophisticated procedures for continence preservation appear to be promising. However, due to location of fistula, contamination of all repairs with feculent soilage challenges the integrity our results. Concern for incontinence has resulted in trading a single-stage curative procedure (fistulotomy) for multiple sphincter-preserving operations, each with varying success rates.

Abstract

"Why do we have to review our experience in managing idiopathic fistula-in-ano regularly?" In order to answer this apparently simple question, we reviewed our clinical and surgical cases and most important relevant literature to find a rational and scientific answer. It would appear that whatever method you adopt in fistula management, there is a price to pay regarding either rate of recurrence (higher with conservative methods) or impairment of continence (higher with traditional surgery). Since, at the moment, reliable data to identify a treatment as a gold standard in the management of anal fistulas are lacking, the correct approach to this condition must consider all the anatomic and clinicopathological aspects of the disease; this knowledge joined to an eclectic attitude of the surgeon, who should be familiar with different types of treatment, is the only guarantee for a satisfactory treatment. As a conclusion, it is worthwhile to remember that adequate initial treatment significantly reduces recurrence, which, when it occurs, is usually due to failure to recognise the tract and primary opening at the initial operation.

"Why do we have to review our experience in managing idiopathic fistula-in-ano regularly?"

The answer to the above question is quite straightforward: surgeons are aware of the poor levels of evidence in anal fistula surgery. Despite the high frequency of suppurative ano-perianal lesions of suspected cryptoglandular origin (idiopathic abscess and fistula-in-ano), the ideal treatment with outcomes of no recurrence, minimal incontinence and good quality of life is still a matter of debate. The traditional surgical treatments which include a division of a continuous part of the sphincteric complex (in particular of the superficial external sphincter in transphincteric fistulas) have been strongly challenged, especially in the last 10-20 years since high rates of impairment of continence have been reported in several experiences[1,2].

In spite of a high successful healing rate varying from 87% to 100%[3], the traditional invasive methods of fistulotomy (with/without draining or slow-cutting seton) and fistulectomy (with closure of internal opening with/without sphincter defect repair) have given way to a number of sphincter-sparing methods: endorectal muscular or mucosal advancement flap[4,5], island flap anoplasty[6], radiof-

requency ablation[7], fistulous tract filling with fibrin or cyanoacrylate glue[8,9], porcine small intestine submucosa-derived anal fistula plug[10], ayurvedic seton[11], ligation of intersphincteric fistula tract (LIFT) procedure[12,13], glue containing adipose-derived stem cells[14], and finally VAAFT (video-assisted anal fistula treatment) carried out with the Storz Meinero fistuloscope®[15].

This continuous research for an ideal conservative method is compelled by concepts recently restated by the Standards of Practice Task Force of the American Society of Colon and Rectal Surgeons[16] and by the Association of Coloproctology of Great Britain and Ireland: division of > 30% of the external sphincter should be undertaken with considerable caution for the relevant risk of impairment of anorectal continence, particularly in females, those with anterior fistulas, advanced aged patients, history of previous anorectal surgery, childbirth, fistula associated with Crohn's disease and obviously in patients with a history of continence impairment not related to the fistula[17].

Indeed, the necessity to identify patients with high risk of incontinence after classic surgical treatment has been stressed over the past few years[18,19]. These patients, representing a limited number of subjects, have been treated with a conservative approach usually represented by the non-cutting draining seton. Thus, considering that the reported rate of impairment of continence after traditional fistula surgery varies from 0% to 82%[20], the doubt arises that the definition of "incontinence" is not the same for all authors and that factors other than the amount of divided sphincter may have a role in continence disturbance. In addition, as already observed by Parks[18], the degree of impairment of anal continence after fistulotomy is not strictly tied to the type of fistula treated and the amount of severed muscle; patients treated for suprasphincteric fistulas (theoretically at higher risk of incontinence) fared better than patients treated for transphincteric fistulas[18]. Nevertheless, it seems obvious that a risk of continence impairment is present when a sphincter is cut or stretched. Also, a trivial lateral internal sphincterotomy for the cure of fissure or a hemorrhoidectomy has a risk of continence impairment[2].

As regards fistula treatment, the question is whether a real advantage is offered by the new proposed methods, especially in the management of the so-called "complex fistulas".

According to several authors[4,18,21], a complex fistula must have one or more of the following features: the tract crosses more than 30% to 50% of the external sphincter; the fistula is anterior in a female; multiple tracts are present; the fistula is recurrent; there is pre-existing incontinence; the perianal area has been irradiated; there is concomitant Crohn's disease.

A recent review of randomized studies in the literature[11] evaluated some proposed conservative methods *vs* traditional surgery (in particular: anal sphincter-preserving seton, conventional seton, ayurvedic seton, conventional fistulotomy with/without seton, radiofrequency, advancement flap with/without fibrin glue, island flap anoplasty, fistulectomy) and concluded that there were no significant differences in recurrence rates or incontinence rates in any of the studied comparisons, except in the case of advancement flaps where the lowest incontinence rates were reported. However, in other experiences of advancement flap procedures, which have been demonstrated as reliable with 77% to 100% healing rates and 21% recurrences, nevertheless 40% of patients had some impairment of continence and 9% presented major disturbance[22,23]. Advancement flap is not a simple procedure and damage of the sphincter is possible. In fact, it has been reported[24] that patients with complex fistulas undergoing fistulectomy with immediate sphincter repair had less recurrences and continence impairment than patients submitted to endoanal advancement flap.

It would appear that whatever method you adopt in fistula management, there is a price to pay regarding either rate of recurrence (higher with conservative methods) or impairment of continence (higher with traditional surgery).

The point is that it is difficult to establish whether, and to what degree, an impairment of continence has a negative effect on the quality of life (QoL) greater than the distress caused by multiple recurrences of a fistulous abscess or fistula.

The assessment of personal impairment in relation to objective medical findings represents a problem in the evaluation of incontinence. The degree of sphincter dysfunction does not always correlate with the patient's subjective awareness of his functional deficit[2]. QoL parameters in fistula surgery are generally based on incontinence scores; however, QoL has a multidimensional aspect that must be taken into account.

The promising results reported by some authors regarding the two least invasive conservative methods, fibrin glue[25] and Surgisis® AFP™ anal fistula plug[10], are interesting (almost none of the patients report impairment of continence); however, their efficacy in healing the fistulas needs to be better evaluated. Healing rates from 31% to 85% have been reported for fibrin glue and from 14% to 87% for the plug[9]. Most of the reported experiences suffer from a small number of patients and short follow-up (often less than 6 mo), with the highest rate of success being for simple uncomplicated fistulas in which traditional treatments have also a high rate of success with low rate of continence impairment[9]. Lack of long-term randomized studies is the other limiting factor for evaluating the efficacy of these procedures. Immediate healing of a fistulous tract does not mean that the infection has disappeared. A fistula can recur after months or years in the same tract or nearby. It must also be considered that when a fistula recurs, patients tend to change surgeon; similarly to what happens in recurring inguinal hernia. Regardless, the adoption of bioprosthetic material as a first-line treatment in complex anal fistulas is recommended by several authors[26,27] ahead of the more prudent suggestions of the consensus conference promoted by the Association of Coloproctology of Great Britain and Ireland[28].

Since, at the moment, reliable data to identify a treatment as a gold standard for the management of anal fistula are lacking, the correct approach to this condition must be to consider all the anatomic and clinicopathological aspects of the disease. This knowledge joined to an eclectic attitude of

the surgeon, who should be familiar with different types of treatment, is the only guarantee for a satisfactory outcome.

As a conclusion, it is worthwhile to remember the following concepts and facts: an adequate initial treatment significantly reduces recurrence, which when it occurs is usually due to failure to recognise the tract and primary opening at the initial operation[19,29-31]; many complex fistulas are iatrogenic in origin[32]; in the acute phase (fistulous abscess) a radical treatment should be attempted only by experienced colorectal surgeons[19]; primary suprasphincteric or extrasphincteric fistulas (according to Parks' classification) of cryptoglandular origin are very rare if not nonexistent[32]; it is essential to have a three dimensional vision of the anorectal region to understand the pathway of diffusion of cryptoglandular infections; a preoperative evaluation of risk factors for incontinence, including frequency of defecation, bowel function and sphincter function, is also mandatory in non-complex fistulas.

Abstract

AIM: To investigate the role of host and bacterial arginases in the colonization of mice by *Helicobacter pylori* (*H. pylori*).

METHODS: *H. pylori* produces a very powerful urease that hydrolyzes urea to carbon dioxide and ammonium, which neutralizes acid. Urease is absolutely essential to *H. pylori* pathogenesis; therefore, the urea substrate must be in ample supply for urease to work efficiently. The urea substrate is most likely provided by arginase activity, which hydrolyzes L-arginine to L-ornithine and urea. Previous work has demonstrated that *H. pylori* arginase is surprisingly not required for colonization of wild-type mice. Hence, another *in vivo* source of the critical urea substrate must exist. We hypothesized that the urea source was provided by host arginase Ⅱ, since this enzyme is expressed in the stomach, and *H. pylori* has previously been shown to induce the expression of murine gastric arginase Ⅱ. To test this hypothesis, wild-type and arginase (*rocF*) mutant *H. pylori* strain SS1 were inoculated into arginase Ⅱ knockout mice.

RESULTS: Surprisingly, both the wild-type and *rocF* mutant bacteria still colonized arginase Ⅱ knockout mice. Moreover, feeding arginase Ⅱ knockout mice the host arginase inhibitor S-(2-boronoethyl)-L-cysteine (BEC), while inhibiting > 50% of the host arginase Ⅰ activity in several tissues, did not block the ability of the *rocF* mutant *H. pylori* to colonize. In contrast, BEC poorly inhibited *H. pylori* arginase activity.

CONCLUSION: The *in vivo* source for the essential urea utilized by *H. pylori* urease is neither bacterial arginase nor host arginase Ⅱ; instead, either residual host arginase Ⅰ or agmatinase is probably responsible.

Key words: Arginase; *Helicobacter pylori*; S-(2-boronoethyl)-L-cysteine; Urease; Mice

INTRODUCTION

Helicobacter pylori (*H. pylori*) causes gastritis[1-3], peptic ulcers[3], and is a significant risk factor for gastric adenocarcinoma[4]. Although the mechanisms behind this spectrum of diseases are not well understood, the very powerful bacterial urease is clearly central to pathogenesis[5-9]. Urease remains a key enzyme for diagnosing *H. pylori* infection[10].

Urease hydrolyzes urea to carbon dioxide (carbonic acid) and ammonium; the latter of which serves to protect the bacterium by neutralizing the acidic microenvironment[11]. Urease is the most abundant protein in *H. pylori*, and accounts for up to 10% of the total cellular protein[5]. It is assumed that urea, the substrate for urease, must be provided abundantly *in vivo* from either the bacterium or the host in order for urease to function efficiently (Figure 1). Indeed, the *in vivo* concentration of urea in the stomach is approximately 5 mmol/L[12,13], which is well above the K_m for urease, and yet the *in vivo* source of the urea for *H. pylori* urease has remained unknown. It originally had been hypothesized that the urea comes from the bacterial arginase, RocF. Arginase catalyzes the hydrolysis of arginine to ornithine and urea (Figure 1). The surprising finding that arginase (*rocF*) mutants of *H. pylori* can still colonize mice suggests that another *in vivo* source of urea must exist[14]. The urea may come from direct release from gastric epithelial cells or other cells in gastric pits lining the stomach. Alternatively, the urea may diffuse into the gastric juice from the bloodstream. In either case, host arginases would be responsible.

We hypothesized that the host arginases are responsible for the urea that is needed by the *H. pylori* urease. There are two known host arginases: arginase Ⅰ and arginase Ⅱ. Arginase Ⅰ is the cytoplasmic enzyme that is expressed heavily in the liver and at lower levels in a few other tissues, whereas arginase Ⅱ is the mitochondrion-associated enzyme that is expressed in many tissues and cells, including the stomach, kidneys and macrophages[15]. Further support for a host-derived stomach source of arginase also comes from the findings that: (1) the arginase Ⅱ gene is expressed in the stomach in mice and humans[16]; and (2) arginase immunohistochemistry staining is markedly elevated in human gastric cancer[17,18]. Both arginase Ⅰ and arginase Ⅱ knockout mice have become available[19,20]. Arginase Ⅰ knockout mice have severe health problems and die between neonatal days 10 and 14[19], which makes it nearly impossible to use this model with *H. pylori*. In contrast, arginase Ⅱ knockout mice have no reported overt health problems[20], although they appear to have reduced fecundity (McGee, unpublished observations).

Arginase Ⅱ is expressed in the human and mouse stomach[16], therefore, we reasoned that the arginase Ⅱ knockout mouse would allow us to determine the relative contributions of host *versus* bacterial arginase to colonization *in vivo*, through the production of urea. The *rocF* arginase mutant of *H. pylori* was included in this study in case the bacterial arginase became an important source of urea in the context of the arginase Ⅱ knockout mice. Also, recent evidence has indicated that *H. pylori* induces murine and human gastric arginase Ⅱ[16], which supports the logical choice of arginase Ⅱ knockout mice as the ideal model for these experiments.

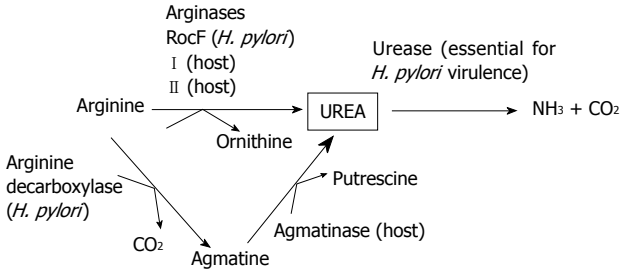

Figure 1 Overview of possible urea sources for *Helicobacter pylori* urease. *Helicobacter pylori* (*H. pylori*) urease is essential for colonization of mice, which indicates that the substrate for the enzyme, urea, is also essential. This study examines the three possible arginase-mediated sources for the urea (underlined): arginase from *H. pylori* (RocF), arginase Ⅰ (host) and arginase Ⅱ (host). Another possible urea source is host agmatinase. *H. pylori* does not have an agmatinase, but does have an enzyme, arginine decarboxylase, that can synthesize agmatine. Arginine is an essential amino acid for *H. pylori* and serves as a substrate for both arginase and arginine decarboxylase.

We infected wild-type or *rocF* mutant *H. pylori* into homozygous arginase Ⅱ knockout mice to decipher whether bacterial or host arginase Ⅱ was important for *H. pylori* colonization. To our surprise, the *rocF* mutant *H. pylori* colonized the arginase Ⅱ knockout mice similar to wild-type mice, which suggests that the *in vivo* source of urea for *H. pylori* urease hydrolysis is from another pathway. Partial inhibition of host arginase Ⅰ by the potent arginase inhibitor S-(2-boronoethyl)-L-cysteine (BEC)[21] still permitted colonization of the *rocF* mutant at or near wild-type levels in the arginase Ⅱ knockout mice.

MATERIALS AND METHODS

Bacterial strains, growth conditions, primers, and plasmids

H. pylori strains SS1[22] and the isogenic *rocF* mutant[14] were routinely grown on *Campylobacter* agar (Becton Dickinson, Sparks, MD, USA) with 10% (v/v) sheep defibrinated blood (CBA; blood from Quad Five, Ryegate, MT, USA) for 2 d, using the CampyPak Plus system (Becton Dickinson), or in a humidified microaerobic atmosphere (5% O_2, 10% CO_2, and 85% N_2). Kanamycin (10-15 μg/mL) was added as needed.

For mouse inoculation, wild-type SS1 and the isogenic *rocF* mutant were passaged an equal number of times from frozen stocks onto CBA. Strains were then grown overnight in a T 25 cm^2 tissue culture flask without aeration in 5 mL Mueller-Hinton broth that contained 1% heat-inactivated fetal bovine serum (FBS). Strains were then diluted 1:40 in 40 mL F-12 plus FBS (2%) in a T 75 cm^2 tissue culture flask and allowed to grow for an additional 16-18 h at 37℃ under microaerobic conditions. All strains grew equally well under these conditions and were inspected by light microscopy for motility and purity. Bacteria were harvested by centrifugation, washed with 1 × PBS (Invitrogen, Carlsbad, CA, USA), resuspended in 1 mL

PBS, and used for inoculation of animals.

Arginase activity by detection of ornithine

Arginase activity to detect ornithine production was determined as described previously[23] using a heat-activation step in the presence of 5 mmol/L cobalt chloride (*H. pylori*) or manganese chloride (mouse/rat) for 30 min at 50-55℃, followed by 1 h incubation at 37℃ in arginase buffer [15 mmol/L MES (pH 6.0) plus 10 mmol/L L-arginine for *H. pylori*; 15 mmol/L Tris (pH 9.0) plus 10 mmol/L L-arginine for mouse or rat]. Absorbance at 515 nm was determined.

Purification of H. pylori arginase

Enzymatically active *H. pylori* RocF was purified as a six-histidine-tagged fusion protein (His_6-RocF) as described previously[23].

Construction of pGEN222-rocF

Plasmid pGEN222, kindly provided by Dr. Jim Galen (University of Maryland, Center for Vaccine Development)[24], was digested with *Sal* I and *Bam*H I and the 1.1 kb *rocF* gene with its own promoter was excised from pBS-*rocF*[14] using the same enzymes. The ligated construct was transformed into *Escherichia coli* (*E. coli*) DH5α and confirmed by digestions and sequencing.

Rat arginase I

A plasmid carrying the rat arginase I gene, pARGr-2[25], kindly provided by Dr. Sid Morris (University of Pittsburgh), was transformed into *E. coli* DH5α, and plasmid extraction and restriction analysis showed that the construct was correct.

Mouse genotyping

Mouse genotyping was similar to that described by Shi *et al*[20], with modifications described below. Chromosomal DNA was isolated from mouse ear (approximately 2 mm diameter) or tail snips using a lysis buffer (10 mmol/L Tris, pH 7.8, 75 mmol/L NaCl, 25 mmol/L EDTA pH 8.0, 1% SDS, 500 μg/mL Proteinase K) followed by phenol-chloroform extraction, ethanol precipitation, and elution in 10 mmol/L Tris/1 mmol/L EDTA, pH 8.0. This template was used in PCR with 200 pmol of each primer, 0.25 mmol/L dNTPs, and *Taq* DNA polymerase under the following conditions: 94℃, 5 min for one cycle; 94℃ for 1 min, 53℃ for 1 min, 72℃ for 1 min for 35 cycles; and 72℃ for 5 min. Primer sequences were as follows: DM52: 5'-TCCTTTCTCCTGTCTAATTC-3'; DM53: 5'-CTAGCATCTAATTGACTGCC-3'; DM54: 5'-CCATGATGGATACTTTCTC-3'. Expected product sizes were: DM 52/53 = 500 bp (wild-type mice); DM 52/54 = 870 bp (arginase knockout mice). Heterozygotes have both products.

Mouse inoculation experiments

This study was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. All animal experiments were approved by the Institutional Animal Care and Use Committee at LSU Health Sciences Center-Shreveport (protocol # 06-020). Euthanasia was done by carbon dioxide asphyxiation. Arginase Ⅱ knockout mice were initially bred from a homozygous knockout female and a heterozygous male generously provided by Dr. W O'Brien (Baylor College of Medicine, Houston, TX, USA). Offspring were genotyped and homozygous knockouts were retained for further breeding. Heterozygotes were euthanized from the colony. Male and female homozygous knockouts were used. The wild-type mice were C57BL/6 (Charles River Laboratories; ⩾ 4 wk old), because homozygous wild-type littermates were euthanized from the breeding colony about 6 mo after the knockout line was established. Following the experiments, the breeding colony and all excess mice were euthanized due to insufficient resources.

Animals were inoculated orally (25-0 μL approximately 10^8-10^9 viable CFU/mL) with bacteria suspended in PBS (pH 7.4). Control animals received PBS. At various time points post-infection, animals were euthanized by cervical dislocation under anesthesia. Stomachs were removed, dissected longitudinally along the greater curvature, and the chyme removed. The rest of the stomach was usually dissected into antrum (distal region), body (middle region) and fundus/cardia (proximal region) portions, weighed, and homogenized (Ultra-Turrax T25, IKA Works, Inc; 10-15 s at a setting of 3) in 1.0 mL sterile PBS. There was insufficient stomach material to measure urea content. Stomach homogenates and dilutions thereof (serial 10-fold in 96-well microtiter dish) in PBS were plated for viable counts in duplicate on CBA plates that contained six antimicrobials to suppress normal flora as described previously[26]. *H. pylori* is resistant to these antimicrobials. Plates were incubated at 37℃ for 5 d in a microaerobic atmosphere. Data are presented as CFU/g stomach or tissue section. Other organs were removed, weighed and homogenized in PBS, and assayed immediately for arginase activity.

BEC experiments

BEC is a potent inhibitor of host arginases and was chemically synthesized according to published procedures[21]. BEC was given to animals (50 mmol/L) in the drinking water *ad libitum*, or directly given orally twice daily to mice (20 μL; approximately 50-100 μmol/L final concentration). BEC was also used *in vitro* for biochemical experiments.

Statistical analysis

Arginase and animal data were analyzed by unpaired, two-tailed *t* test, Welch corrected. $P < 0.05$ was considered significant. InStat software was used (GraphPad Software, San Diego, CA, USA).

RESULTS

Arginase I knockout mice breeding and genotyping

We received a heterozygous male and a homozygous female from the established arginase Ⅱ knockout mouse breeding colony[20], therefore, we internally bred for the ho-

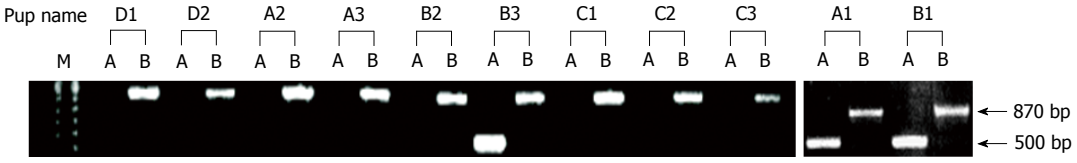

Figure 2 Genotyping of mice to determine whether they are heterozygous or homozygous arginase Ⅱ knockouts. Pups obtained from breeding heterozygous males to arginase Ⅱ knockout females were genotyped by PCR analysis. Wild-type band = 500 bp ("A" lanes); mutant band = 870 bp ("B" lanes). Eight of the 11 pups were homozygous knockouts. Pups A1, B1, and B3 were heterozygous because they contained wild-type and mutant copies of arginase Ⅱ. M: 100 bp marker (Bio-Rad).

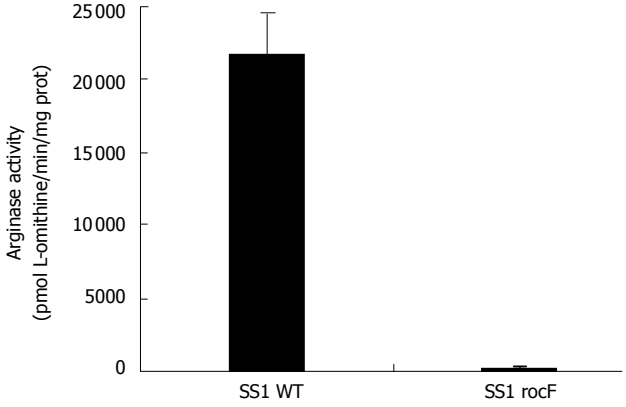

Figure 3 The *rocF* mutant of *Helicobacter pylori* strain SS1 is devoid of arginase activity. Bacteria were harvested in 0.9% NaCl and ice-bath-sonicated (25% intensity, 2 pulses of 30 s each, with 30 s rests on ice between pulses). Following centrifugation (12000 *g*, 2 min, 4℃), supernatants were retained on ice. Equal volumes of extract and 10 mmol/L cobaltous chloride ($CoCl_2$•6 H_2O, final concentration of 5 mmol/L) were preincubated for 30 min at 50-55℃ to activate the enzyme. Arginase buffer (15 mmol/L Tris, pH 7.5, or 15 mmol/L MES, pH 6.0, plus 10 mmol/L L-arginine) was added and incubated at 37℃ for 1 h. The reaction was stopped by addition of 750 μL acetic acid, and the color developed by addition of 250 μL ninhydrin (4 mg/mL) at 95℃ for 1 h and read at 515 nm. The data are presented in units where 1 U is defined as one pmol L-ornithine/min/mg protein + SD. Details of this assay have been reported previously[23].

mozygous arginase Ⅱ knockout mice and genotyped the offspring, similar to that described by Shi *et al*[20]. We successfully obtained homozygous arginase Ⅱ knockout mice (Figure 2). Once the homozygous arginase Ⅱ knockout line was firmly established, we euthanized all heterozygotes from the colony to ensure that no contamination occurred. The homozygous arginase Ⅱ knockout mice were then periodically PCR confirmed for the knockout. Occasionally, we observed reduced fecundity with the arginase Ⅱ knockout colony, although we did not pursue this.

Arginase activity by measurement of ornithine

Arginase activity, determined by ornithine detection in the presence of arginine, was measured from extracts of wild-type SS1 and the isogenic *rocF* mutant grown on CBA plates. No appreciable activity was detected in the mutant, in contrast with the wild-type strain, which had arginase activity (Figure 3). Omission of arginine led to no detectable ornithine, which showed that all of the ornithine that was detected was produced by arginine hydrolysis (data not shown). These results demonstrated that the *rocF* mutant of *H. pylori* had no arginase activity and did not appear to have alternative mechanisms of producing ornithine under these conditions. Using nuclear magnetic resonance, we have previously reported that the *rocF* mutant of SS1 has no arginase activity[14]. There is no evidence for the existence of an alternative urea-generating pathway in *H. pylori*, based on biochemical, genomics and metabolic networking approaches (McGee, unpublished observations)[27], but we cannot completely rule out this possibility.

Arginase Ⅱ knockout mice become infected with arginase mutant H. pylori

We have previously demonstrated that wild-type and *rocF* mutant *H. pylori* strain SS1 colonize wild-type mice[14]. To determine whether arginase Ⅱ knockout mice were colonized by *H. pylori*, these mice were inoculated with wild-type or *rocF* mutant SS1 *H. pylori*. At 2 wk post-infection, there was a trend towards a 1 log_{10} decrease in colonization of the entire stomach by the *rocF* mutant compared with the wild-type strain, but this did not reach statistical significance (Figure 4A). By 10 wk post-infection, there was no difference in colonization between the wild-type and the *rocF* mutant (Figure 4B). We concluded that the *rocF* mutant devoid of arginase activity colonized arginase Ⅱ knockout mice at or near the levels of the wild-type strain of *H. pylori*.

The experiment was repeated, but this time the antrum and body portions were separated, in order to understand whether there might be tropism differences. At 4 wk post-infection, the wild-type and *rocF* mutant both colonized the antrum and body regions of the stomach of arginase Ⅱ knockout mice at similar levels (data not shown).

H. pylori wild-type and *rocF* mutant both induced similar levels of gastritis in the arginase Ⅱ knockout mice (inflammatory score = 2.5 for wild-type; 2.5 for *rocF* mutant, four mice in each group).

BEC decreases in vivo host arginase activity

The *rocF* mutant surprisingly colonized the arginase Ⅱ knockout mice, yet the urea substrate must be available for *H. pylori* urease to function *in vivo*, therefore, we abandoned the hypothesis that arginase Ⅱ generates the essential urea substrate for *H. pylori* urease. Instead, we reasoned that the source of the urea must originate from host arginase Ⅰ. Arginase Ⅰ knockout mice die at neonatal days 10-14, therefore, we could not test the role of arginase Ⅰ directly. Thus, we used the host arginase inhibitor BEC. Preliminary experiments using different concentrations of BEC in mice suggested a concentration of 50 mmol/L would have at least some arginase inhibitory activity in the

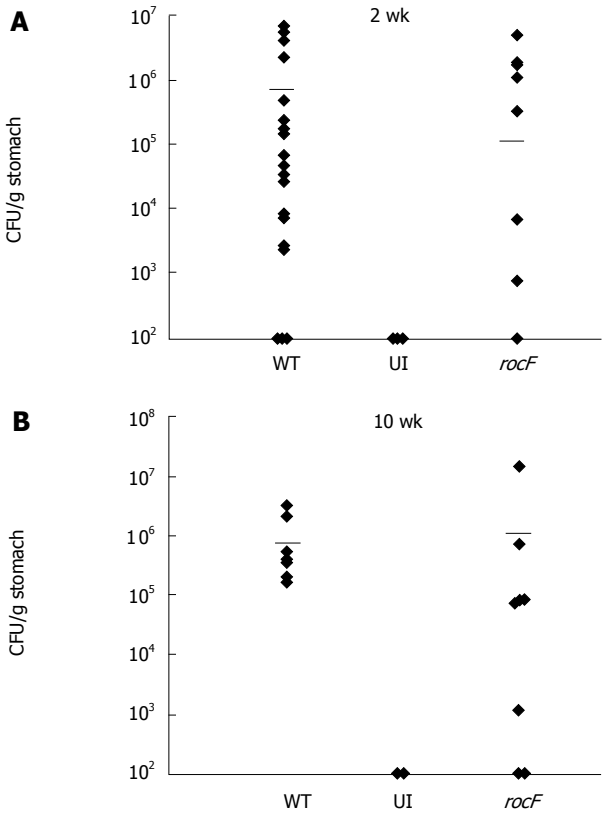

Figure 4 The *rocF* mutant of *Helicobacter pylori* colonizes the stomach of arginase Ⅱ knockout mice. Arginase Ⅱ knockout mice were inoculated with either the wild-type SS1 strain (WT) of *Helicobacter pylori* (*H. pylori*) or the isogenic *rocF* mutant (*rocF*). Number of animals used per group were as follows: 2 wk experiment: 13 for WT, nine for *rocF* mutant; 10 wk experiment: eight for WT, eight for *rocF* mutant. At 2 (A) or 10 (B) wk post-infection, stomachs were removed, completely homogenized, and plated for *H. pylori*. UI, uninfected controls (n = 2 at 2 and 10 wk). Limit of detection: ~100 CFU/g stomach; all animals that lacked *H. pylori* were set to this detection limit. Bar, mean CFU/g stomach. At 2 wk post-infection, P = 0.65 by unpaired two-tailed t test between the mean CFU/g tissue for the wild-type versus the *rocF* mutant. Each symbol represents one mouse. In some cases there are two mice represented by a symbol if the data overlapped.

stomach (data not shown). The expense and concern of toxicity to the animals precluded using higher concentrations. Also, preliminary experiments that compared BEC given *ad libitum* in the drinking water *versus* twice daily by pipetting 20 μL of 50 mmol/L concentration directly into the oral cavity revealed that the latter gave more consistent inhibition of arginase activity (data not shown), and lower quantities of the inhibitor could be used. Thus, oral delivery was used for subsequent experiments.

To demonstrate that BEC inhibited arginase *in vivo*, we fed uninfected arginase Ⅱ knockout mice with BEC by direct oral delivery to inhibit host arginase Ⅰ. The data showed that exceptionally high levels of arginase activity occurred in the liver, as expected for the known location of highest expression of arginase Ⅰ [15]. About 50% of this strong activity was inhibited by BEC (Figure 5A), which indicated that oral BEC delivery had a systemic effect on inhibiting arginase Ⅰ activity. In the kidney, very low levels of arginase Ⅰ activity were detected and this was reduced more than fivefold by BEC (Figure 5B). In the antrum region of the stomach, arginase Ⅰ activity was intermediate to that of the liver or kidney and could be inhibited by more than threefold by BEC (Figure 5C). In contrast, in the body (Figure 5D) and the fundus (data not shown), BEC did not appreciably inhibit the arginase activity, although there was a lot of animal to animal variability. Arginase activity was also much lower in these other gastric regions than in the antrum. We conclude that BEC inhibits at least some of the arginase Ⅰ activity *in vivo*, but residual activity still occurs.

If arginine was omitted from the enzyme buffer, no ornithine was detectable in the stomach (data not shown), which indicated that the tissues did not have appreciable amounts of pre-formed ornithine.

BEC does not inhibit H. pylori arginase activity, but does block arginase Ⅰ activity

BEC is an established, potent eukaryotic arginase inhibitor with a K_i of 400-600 nmol/L[21], therefore, we questioned whether BEC would inhibit *H. pylori* arginase, which shares very limited amino acid homology with human arginases (data not shown). A BEC dose-response curve using extracts from *E. coli* that expressed the *H. pylori rocF* gene (Figure 6A) revealed only partial inhibition of *H. pylori* arginase activity at very high BEC concentrations (≥ 25 μmol/L). Even at 1000 times above the K_i for eukaryotic arginases, 400 μmol/L BEC only inhibited about 50% of the *H. pylori* activity. To show that this lack of inhibition was not due to the complexity of extracts, we purified the *H. pylori* arginase and tested whether BEC would inhibit *H. pylori* arginase activity. BEC used at the K_i for eukaryotic arginases (400 nmol/L) completely failed to inhibit *H. pylori* arginase activity (Figure 6B). To prove that the BEC was working properly under these conditions and also to show directly that BEC can inhibit arginase Ⅰ *in vitro*, we used extracts from *E. coli* that expressed the rat arginase Ⅰ. Rat and mice arginase Ⅰ share 93% amino acid identity and 96% similarity (http://blast.ncbi.nlm.nih.gov/Blast.cgi), therefore, we assume that both enzymes behave in a similar fashion with respect to BEC inhibition. BEC was shown to inhibit 70% of the rat arginase Ⅰ activity at just 80 nmol/L and > 97% at concentrations of ≥ 4 μmol/L (Figure 6C), which was in good agreement with the published K_i values[21]. These results show that BEC strongly inhibits eukaryotic arginase Ⅰ under these enzyme assay conditions, yet BEC is a poor inhibitor of *H. pylori* arginase[21].

rocF mutant of H. pylori colonizes BEC-treated wild-type and arginase Ⅱ knockout mice

Wild-type or arginase Ⅱ knockout mice were pretreated with BEC or water and inoculated with wild-type or *rocF* mutant *H. pylori*. Animals were euthanized at 1 wk post-infection. The *rocF* mutant of *H. pylori* colonized the BEC-treated wild-type mice (Figure 7). Remarkably, the *rocF* mutant also colonized BEC-treated arginase Ⅱ knockout mice (Figure 8) at levels similar to wild-type *H. pylori* (P > 0.05). This similar colonization occurred in all three regions of the stomach (antrum, body and fundus). The experiment was repeated in the arginase Ⅱ knockout mice

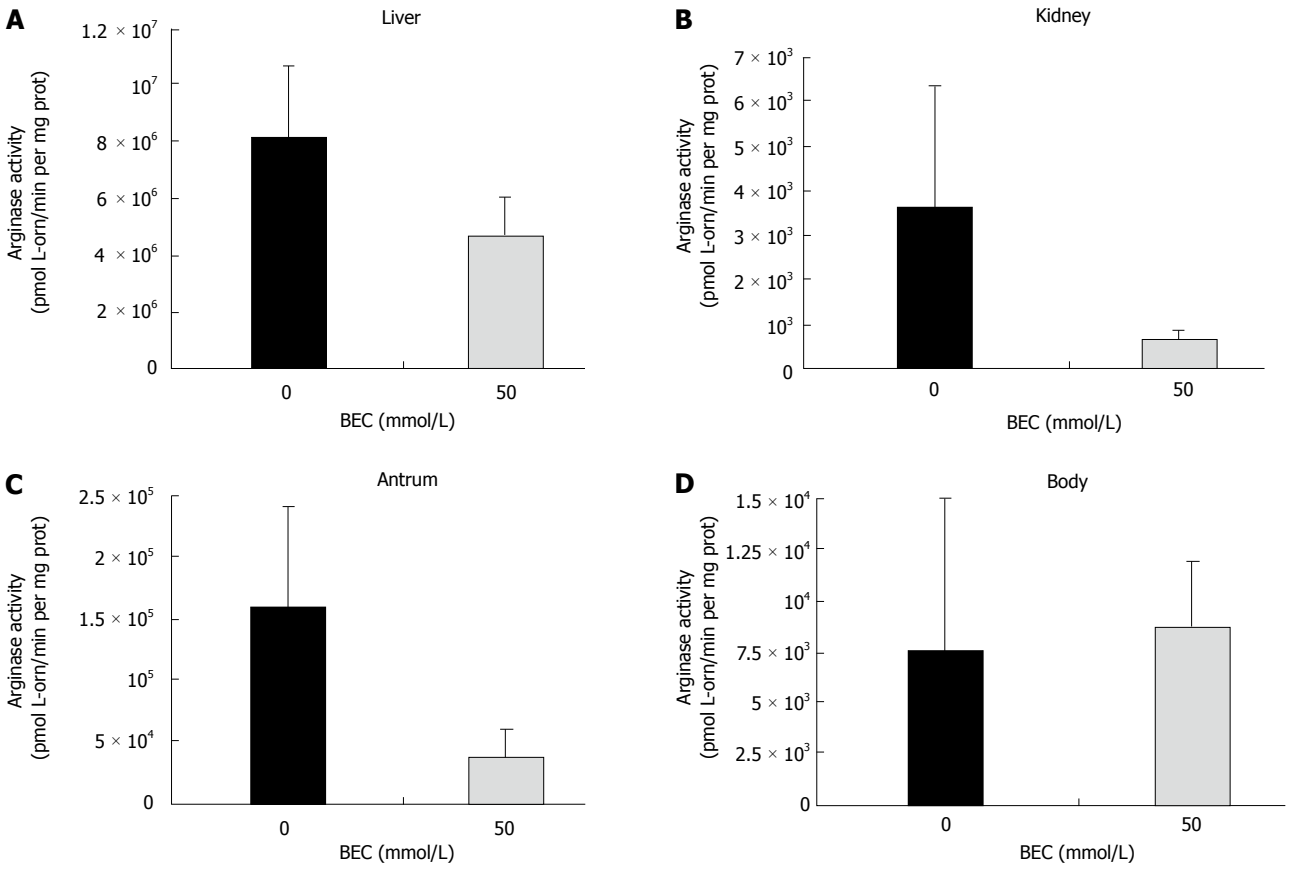

Figure 5 ***Ex vivo*** **arginase activity of organs from arginase Ⅱ knockout mice fed water or the arginase inhibitor S-(2-boronoethyl)-L-cysteine.** Mice were administered 20 μL water or 50 mmol/L S-(2-boronoethyl)-L-cysteine (BEC) once or twice daily for 3 d by direct oral delivery *via* pipetting. Animals were euthanized and organs removed and homogenized. The data represent the average arginase activity of four to five mice ± SD, with each mouse organ measured in duplicate or triplicate using arginine buffer at pH 9.0 in the presence of manganese. A: Liver. Arginase activity was inhibited almost 50% in the liver by BEC. $P = 0.0006$ between the two groups; B: Kidney. Arginase activity was inhibited > 75% in the kidney by BEC. $P = 0.0033$ between the two groups; C: Antrum. Arginase activity was inhibited > 75% in the antrum by BEC. $P = 0.0007$ between the two groups; D: Body. No inhibition was observed in the body ($P > 0.05$).

alone (n = 5 or 6 mice per group), and only the antrum and body were processed. Essentially identical results were obtained (data not shown).

DISCUSSION

We demonstrated that the *H. pylori rocF* mutant, which has no detectable arginase activity, colonized host arginase Ⅱ knockout mice. These data are very surprising, because host arginase Ⅱ is expressed in the stomach, and is even upregulated by *H. pylori* infection[16]. Moreover, inhibiting at least some of the host arginase Ⅰ by BEC treatment failed to block the ability of the *rocF* mutant to colonize arginase Ⅱ knockout mice. The data suggest that *H. pylori* must obtain its urea from either the residual arginase Ⅰ that is not inhibitable by BEC, or an alternative pathway of host urea generation, such as agmatinase. The data also suggest that enzymatically active host arginase Ⅰ occurs in the stomach, as has also been suggested previously[28]. A recent study from Wilson and colleagues also have demonstrated that BEC inhibits murine macrophage arginase activity; this leads to an increase in nitric oxide production *via* increased host nitric oxide synthase protein in an arginine-dependent fashion when stimulated by *H. pylori*[29]. Gastric macrophages from *H. pylori*-infected arginase Ⅱ knockout mice that had been given BEC in the drinking water did not produce more nitric oxide than macrophages from WT mice, which suggests that arginase Ⅱ, but not arginase Ⅰ is important for protection of *H. pylori* from nitric oxide[29]. Although arginase Ⅱ clearly plays a crucial role in protection of *H. pylori* from nitric oxide, it is not essential for *H. pylori* colonization of the gastric mucosa, based on the findings reported here.

One other surprise in this study was a lack of substantial inhibition of *H. pylori* arginase by BEC. Only about 50% of the *H. pylori* arginase could be inhibited by very high concentrations of BEC. This finding may be due to the very distant evolutionary relationship between *H. pylori* and host arginases, as well as the finding that *H. pylori* arginase preferentially uses cobalt for enzyme activity[23] *versus* manganese for the host arginases. BEC is known to bind to eukaryotic arginases where the binuclear manganese center is situated[21], and perhaps the presence of cobalt in the *H. pylori* arginase weakens this inhibitory interaction. The very well conserved DAHAD divalent metal binding motif in eukaryotic arginases is completely conserved in *H. pylori*, which suggests that

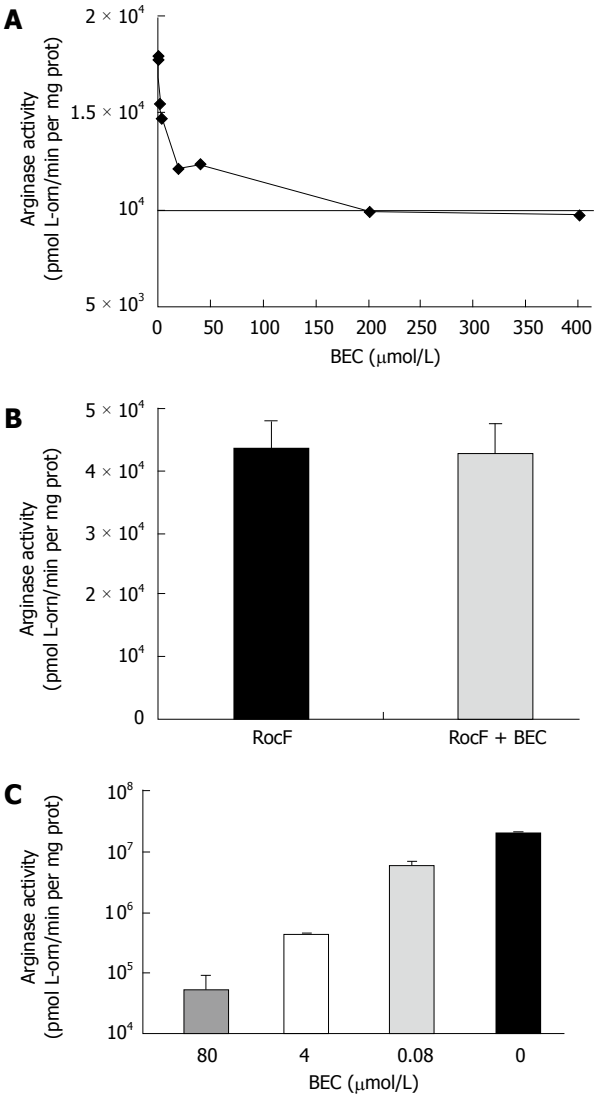

Figure 6 S-(2-boronoethyl)-L-cysteine does not strongly inhibit *Helicobacter pylori* arginase activity *in vitro*. A: Arginase-containing extracts from *Escherichia coli* (*E. coli*) expressing the *Helicobacter pylori rocF* gene on pGEN222. Extracts were incubated in the presence or absence of various concentrations of S-(2-boronoethyl)-L-cysteine (BEC) and measured for arginase activity at pH 6.0 in the presence of cobalt; B: Purified arginase (His6-RocF) was incubated in the presence or absence of BEC (400 nmol/L) and assayed for arginase activity in the presence of cobalt at pH 6.0; C: Extracts from *E. coli* expressing rat arginase Ⅰ were prepared and incubated in the presence of different concentrations of BEC and then assayed for arginase activity in the presence of manganese at pH 9.0. Graph plotted on a logarithmic scale due to magnitude of arginase activity.

other amino acid residues in these proteins are responsible for the differential BEC inhibition observed between eukaryotic and *H. pylori* arginase.

The arginase from *Bacillus anthracis* (*B. anthracis*) has best catalytic activity with nickel[30]. Arginase activity from the purified *B. anthracis* RocF (active site = DAHGD) was not inhibited at all by up to 400 μmol/L BEC (assayed at pH 9.0), and instead, a stimulatory activity was noticed at 40 and 400 μmol/L BEC (Viator and McGee, unpublished observations). Whether the A to G amino acid substitution in the *B. anthracis* DAHGD metal-binding site is responsible for this lack of BEC inhibition is not yet known. Nonetheless, the data suggest that bacterial and eukaryotic arginases have distinct properties with respect to the BEC inhibitor.

The abundant urease must obtain copious amounts of urea for the urease to function efficiently *in vivo*, since urease is absolutely essential for colonization[8,9]. Urea is essential for urease activity, and urease is largely cytosolic in *H. pylori*, therefore, there must be a mechanism to transport urea. Indeed, the *H. pylori* UreI protein, expressed from the urease operon, is an urea transporter[31]. Mutation in *ureI* renders *H. pylori* attenuated in gerbils[32], which illustrates how crucial it is for urea to enter the bacterial cell and allow *H. pylori* to survive at pH < 4.0. Important future experiments are to examine the role of urease in more depth in this arginase Ⅱ knockout mouse background, and to monitor closely intragastric pH and urea concentrations in the different stomach compartments in wild-type and arginase Ⅱ knockout mice.

Although the data showed that BEC could almost completely inhibit arginase Ⅰ *in vitro*, the same was not true *in vivo*. Several possibilities may account for this. First, oral delivery of BEC leads to the dilution of the inhibitor in the gastric juice, which could decrease its effective inhibitory concentration. Second, the acidity of gastric juice could alter inhibitory properties of BEC by protonation of BEC. This may explain why BEC inhibits arginase activity in the antrum, but not the body, where there is much stronger acid production. Third, BEC may not be able to enter the host cell with great efficiency to inhibit arginase Ⅰ, which is found in the host cytosol. In the *in vitro* biochemical experiments, arginase is freed from the cells by a lysis step, which allows BEC direct access to the arginase. Finally, the complexities of the *in vivo* environment may lead to BEC being degraded or sequestered from reaching the arginase Ⅰ. Despite these potential limitations it was demonstrated that oral delivery of BEC could block at least some of the arginase Ⅰ in several tissues examined. However, the residual arginase Ⅰ that remains may have been enough to provide the necessary urea substrate for *H. pylori* urease to utilize. Alternatively, another host urea-generating enzyme, agmatinase[33,34], may be responsible.

Agmatine is prevalent in the stomach[35,36] and 60% of this agmatine goes to the liver[37]. Interestingly, agmatine levels are higher in the gastric juice of *H. pylori*-infected patients versus uninfected patients[36]. Moreover, *H. pylori* has a putative arginine decarboxylase that could theoretically generate the agmatine. There is also the possibility that intestinal normal flora bacteria could provide the urea[38].

Future studies will center on attempting to eliminate host arginase Ⅰ in the stomach. This may pose a challenge, due to the crucial role that arginase Ⅰ plays in mice, which die of hyperammonemia shortly after birth if they are disrupted for arginase Ⅰ[19]. Several possible strategies to inhibit completely host arginase Ⅰ could be inhibitory RNA knockdown experiments, or construction of tissue-specific arginase Ⅰ knockout mice that hopefully would live normally but just fail to produce arginase Ⅰ in the stomach. However, urea could also diffuse to the stomach from arginine hydrolysis in other organs, which might complicate

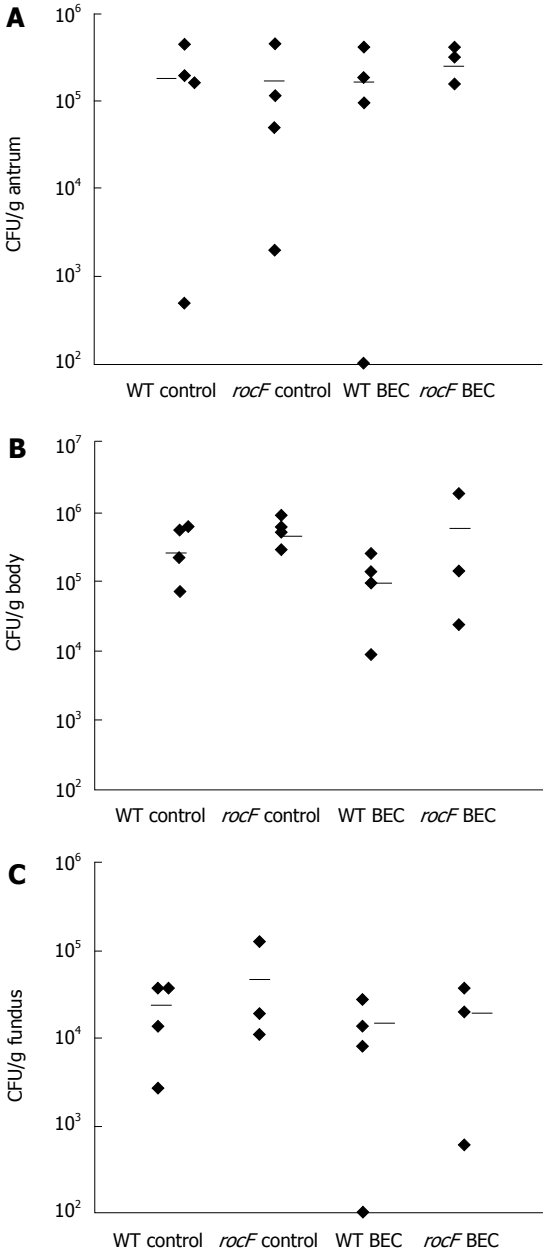

Figure 7 The *rocF* mutant of *Helicobacter pylori* colonizes wild-type mice treated with the arginase inhibitor S-(2-boronoethyl)-L-cysteine. Wild-type (C57 BL/6) mice (n = 3 or 4 per group) were orally fed water or S-(2-boronoethyl)-L-cysteine (BEC) (50 mmol/L) once or twice daily for 3 d before oral inoculation with wild-type or *rocF* mutant *Helicobacter pylori* (*H. pylori*) strain SS1 (~108 CFU). The BEC animal groups continued to receive BEC daily until animals were euthanized. At 1 wk post-infection, animals were euthanized and the stomach dissected into antrum (A), body (B), or fundus (C). Limit of detection was ~100 CFU/g stomach and all animals that lacked *H. pylori* were set to this detection limit. Bar, mean CFU/g tissue. Usually each symbol represents one mouse. In some cases there are two mice represented by a symbol if the data overlapped.

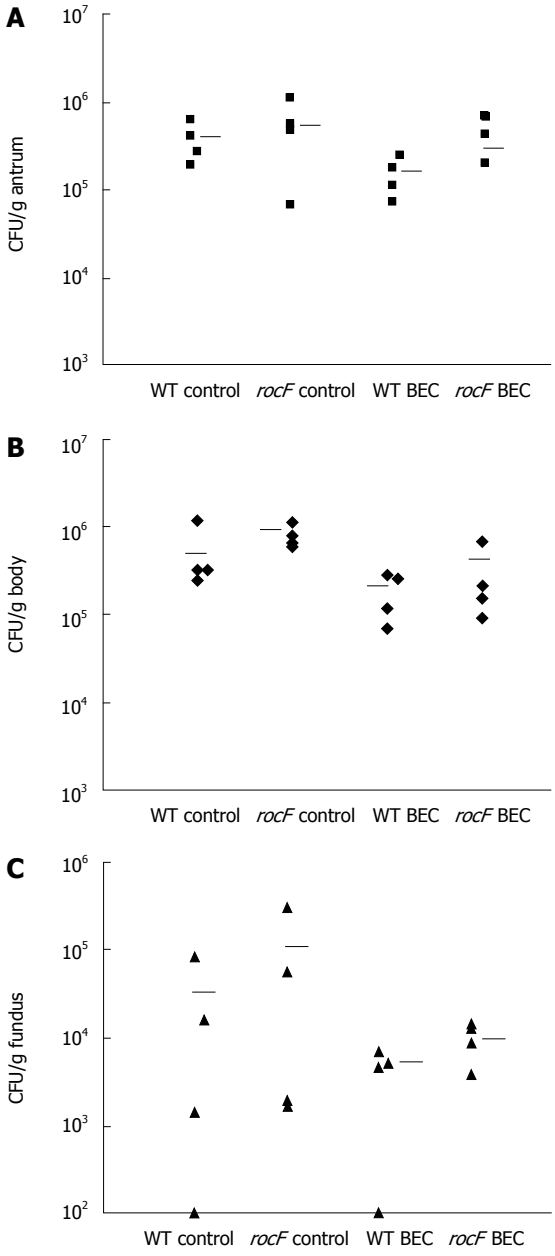

Figure 8 The *rocF* mutant of *Helicobacter pylori* colonizes arginase Ⅱ knockout mice treated with the arginase inhibitor S-(2-boronoethyl)-L-cysteine. Arginase Ⅱ knockout mice (n = 3 or 4 per group) were orally fed water or S-(2-boronoethyl)-L-cysteine (BEC) (50 mmol/L) once or twice daily for 3 d before oral inoculation with wild-type or *rocF* mutant *Helicobacter pylori* strain SS1 (~108 CFU). The BEC animal groups continued to receive BEC daily until animals were euthanized. At 1 wk post-infection, animals were euthanized and the stomach dissected into antrum (A), body (B), or fundus (C). Limit of detection: ~100 CFU/g tissue. Bar, mean CFU/g stomach.

a tissue-specific arginase Ⅰ knockout strategy. The recent study that used an arginase-containing adenovirus delivery system to complement the arginase Ⅰ $^{-/-}$ mouse led to a doubling of survival to 27 d[39]. Further refinements to this exciting model may hold promise for additional exploration of the role of arginase Ⅰ in *H. pylori* pathogenesis.

The *in vivo* source of urea still remains a mystery. However, it is clear that the *in vivo* source of urea for the crucial enzyme urease does not originate from the bacterial arginase or from host arginase Ⅱ. Instead, the data suggest that urea originates from host arginase Ⅰ or an alternative urea-generating pathway.

ACKNOWLEDGMENTS

We thank Sangeetha Bathala, Jeff Bolland, Karla McInnis,

Ryan Viator, and Emily Watson for animal assistance. We are grateful to Dr. W O'Brien for providing breeding pairs that were used to establish the arginase Ⅱ knockout colony, Dr. J Galen for providing pGEN222, and Dr. S Morris for providing pARGr-2.

COMMENTS

Background

The bacterium *Helicobacter pylori* (*H. pylori*) causes stomach problems, such as ulcers and inflammation and can lead to stomach cancer. One of the important proteins it makes that contributes to disease is called urease, an enzyme that converts urea to ammonia and carbon dioxide. Urease is required for bacteria to cause disease, and thus the substrate urea is also required. In this study, the authors designed experiments to determine from where this urea is coming: bacterial or host sources.

Research frontiers

The most likely enzyme that provides the urea source is arginase and both *H. pylori* and humans have arginases (two in humans, one in *H. pylori*). The authors used a mouse model in which one of the arginases, arginase Ⅱ, was knocked out, along with *H. pylori* wild-type or an arginase knockout bacterium (*rocF*). An arginase inhibitor called S-(2-boronoethyl)-L-cysteine (BEC) was also used to knock down the second mouse arginase (arginase Ⅰ). The authors found that neither the bacterial arginase (*rocF*) nor arginase Ⅱ from the mouse was important to provide the urea, which implies the involvement of either arginase Ⅰ or another pathway (agmatinase).

Innovations and breakthroughs

The study provides the first steps towards the foundation needed to understand where the urea originates for the crucial urease enzyme. Much remains to be done, including completely knocking down arginase Ⅰ in mice and determining whether another enzyme, agmatinase could be involved.

Applications

By understanding where the urea originates, the authors hope to develop novel anti-*Helicobacter* drugs. New therapies are sought because *H. pylori* is becoming resistant to antibiotics.

Terminology

H. pylori causes infection in the stomach, which leads to inflammation, ulcers and cancer. Urease is an enzyme made by *H. pylori* the converts urea to ammonia and carbon dioxide. Arginase is an enzyme that converts arginine to ornithine and urea and is made by humans, mice and *H. pylori*. Knockout refers to a gene that is disrupted and no longer functional.

Peer review

The authors found that the *in vivo* source for the essential urea substrate for the *H. pylori* urease is neither bacterial arginase nor host arginase Ⅱ. Based on these results, they hypothesized that either host urea-generating pathway such as agmatinase or the residual host arginase Ⅰ might be responsible.

Abstract

AIM: To examine the effect of doxycycline on the activity of matrix metalloproteinases (MMPs) and oxidative stress in gastric tissues of rats following gastric injury.

METHODS: Gastric ulcers were generated in rats by administration of 70% ethanol, and activity of doxycycline was tested by administration 30 min prior to ethanol. Similarly, the effect of doxycycline was tested in an indomethacin-induced gastric ulcer model. The activities and expression of MMPs were examined by zymography and Western blot analysis.

RESULTS: Gastric injury in rats as judged by elevated ulcer indices following exposure to ulcerogen, either indomethacin or ethanol, was reversed significantly by doxycycline. Indomethacin-induced ulcerated gastric tissues exhibited about 12-fold higher proMMP-9 activity and about 5-fold higher proMMP-3 activity as compared to control tissues. Similarly, ethanol induced about 22-fold and about 6-fold higher proMMP-9 and proMMP-3 activities, respectively, in rat gastric tissues. Both proMMP-9 and MMP-3 activities were markedly decreased by doxycycline in ulcerogen treated rat gastric tissues. In contrast, the reduced MMP-2 activity in ulcerated tissues was increased by doxycycline during ulcer prevention. On the other hand, doxycycline inhibited significantly proMMP-9, -2 and -3 activities *in vitro*. In addition, doxycycline reduced oxidative load in gastric tissues and scavenged H_2O_2 *in vitro*. Our results suggest a novel regulatory role of doxycycline on MMP-2 activity in addition to inhibitory action on MMP-9 and MMP-3 during prevention of gastric ulcers.

CONCLUSION: This is the first demonstration of dual action of doxycycline, that is, regulation of MMP activity and reduction of oxidative stress in arresting gastric injury.

Key words: Doxycycline; Extracellular matrix; Matrix metalloproteinases; Reactive oxygen species; Tissue inhibitor of metalloproteinase

INTRODUCTION

Matrix metalloproteinases (MMPs) are a class of zinc-de-

pendent endopeptidases that degrade matrix macromolecules and numerous other components such as growth factors, proteinases, and plasma proteins[1,2]. MMPs are best known for their action on extracellular matrix (ECM) remodeling, wound healing and angiogenesis, and have been implicated in the pathogenesis of various diseases including gastric ulcers[3-6]. The endogenous inhibitors of MMPs [tissue inhibitors of metalloproteinases (TIMPs) and α-2 macroglobulin] play a major role in balancing protease-antiprotease action[7,8]. MMPs are synthesized and secreted by gastric epithelial cells, macrophages, and neutrophils[9,10]. Numerous exogenous factors including nonsteroidal anti-inflammatory drugs (NSAIDs), stress, alcohol and *Helicobacter pylori* infection have been implicated in the etiology of gastric ulceration[11-14]. We have previously demonstrated that MMP-9 increases significantly in indomethacin-induced as well as ethanol-induced gastric ulcers[3,4,12]. Overexpression of MMP-9 has been attributed to coronary artery disease, retinopathy, renal disease, chronic obstructive pulmonary disease and atherosclerosis[15-17]. Involvement of several MMPs including gelatinases and stromelysins in various pathological conditions has been documented[5]. However, downregulation of MMP-2 activity in retinal and renal vasculature leads to thickening of the basement membrane due to collagen deposition and contributes to diabetic retinopathy and nephropathy, respectively[18]. Research into the pathophysiology of gastric ulcers suggests a central role of reactive oxygen species (ROS) in the development of the disease. MMP can be activated by ROS *in vitro*, and thus, imbalance of MMP activation and inactivation occurs[19]. An imbalance of MMP activity can lead to release of growth factors, and therefore, inhibition of MMPs can be a potential therapy for various diseases[20]. Ulcer healing is a complicated process that requires interactions between ECM proteins including collagens, proteases, cytokines, and growth factors. Repair of gastric wounds encompasses a series of cell-matrix interactions that involve cellular proliferation, migration, and differentiation[3,4,12,21]. Doxycycline, which belongs to the tetracycline family, is a pluripotent drug that affects many cellular functions including cell proliferation, matrix remodeling and apoptosis, in addition to its use as an antibiotic[22,23].

Doxycycline as well as tetracycline are non-specific potent MMP inhibitors[23-27]. Doxycycline has been used at a dose of 100-300 mg/d for the protection of pancreatitis-associated lung injury and abdominal aneurysm[28,29]. Doxycycline treatment greatly potentiates vasoconstriction, which is attributed to inhibition of MMP-2 and MMP-9 and restoration of elastic fiber integrity during prevention of aortic aneurysm in mice[29]. However, the mechanism of its actions on gastric ulcers, especially at the MMP level, remains unknown and needs to be resolved. Considering a value of 56 for human/rat conversion coefficient, assuming rat and human weights of 200 and 70 kg, respectively, 5-10 mg/kg doxycycline is equal to the 2-3 mg/kg recommended human dose[30,31]. It has been widely available in the market as an antibiotic for over three decades and has become established for long-term use too. However, its use against inhibition of overexpression of MMPs has not been investigated to date in therapeutic trials for gastric ulcers.

This study was conducted to evaluate the ability of the broad-spectrum MMP inhibitor doxycycline to prevent gastric ulcers in rats. In this paper, we report that doxycycline inhibited MMP-3 and MMP-9 activity and expression during prevention of indomethacin- and ethanol-induced gastric ulcers. Remarkably, doxycycline upregulated MMP-2 activity and expression *in vivo*, whereas it downregulated the same activity *in vitro*. Finally, we suggest that doxycycline might exert its regulatory role in addition to its inhibitory role on MMPs *in vivo*, which may be associated with ROS scavenging activity. These results provide an insight into the gastroprotective mechanisms of doxycycline that underlie the dual actions, antioxidant and MMP modulatory role. Hence, establishment of use of doxycycline as an effective therapy will be a boon to gastric ulcer patients.

MATERIALS AND METHODS

Materials

Gelatin from porcine skin, casein, Triton X-100 (TX), 1, 10 phenanthroline, catalase and protease inhibitor cocktail were obtained from Sigma Chemicals (St. Louis, MO, USA). MMP-9 and MMP-2 were purchased from Chemicon (UK). Polyclonal anti-MMP-2, anti-MMP-3, anti-MMP-9, anti-TIMP-1, anti-TIMP-2, and anti-β-tubulin antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Doxycycline was purchased from Dr. Reddy's Laboratory (India), and all other chemicals were purchased from Sisco Research Laboratory (Mumbai, India).

Animals used

Sprague-Dawley rats (180-220 g) bred in-house with free access to food and water were used for all experiments, which were carried out following the guidelines of the animal ethics committee of the institute. Experiments were designed to minimize animal suffering and to use the minimum number associated with valid statistical evaluation. Animals were anesthetized by ketamine (12 mg/kg), followed by cervical dislocation for killing. Animals in control and experimental groups were fasted overnight with free access to water before each experiment.

Gastric ulceration and protection studies

Indomethacin (48 mg/kg) was dissolved in distilled water with a minimum amount of NaOH and was orally fed to rats to induce a maximum level of acute gastric ulcer. The control group received the vehicle only. After 4 h, the animals were sacrificed, gastric lesions in the fundic stomach were scored and expressed as ulcer index as follows: 0 =

no pathology; 1 = a small pinhead ulcer spot; and 2-5 = a band-like lesion of 2-5 mm in length. The sum of the total scores divided by the number of animals was expressed as the mean ulcer index[3]. Again, rats were orally fed with 70% ethanol at 4 mL/kg to induce maximum level of acute gastric ulcer or 2 mL/kg to induce moderate ulcer, while the control group received sterile water only. Animals were sacrificed after 3 h, and stomachs were scored for ulcer index as described by Pradeepkumar Singh *et al*[12]. The sum of the total scores divided by the number of animals indicates the mean ulcer index. Doxycycline at a dose of 50 mg/kg was administered orally 30 min prior to indomethacin or ethanol treatment to test the gastroprotective effects.

Measurement of glutathione level

A homogenate of stomach tissue without the connective tissue layer was made in 0.2 mol/L Tris, pH 8.2, which contained 20 mmol/L EDTA, and centrifuged at 12000 r/min for 15 min at 4℃. An aliquot of 1.0 mL homogenate was precipitated with 10% TCA and centrifuged at 14000 r/min for 3 min at 4℃. The supernatant (1 mL) was added to 2 mL of 0.8 mol/L Tris-HCl, pH 9.0, which contained 20 mmol/L EDTA and mixed with 0.1 mL 10 mmol/L 5,5'-dithiobis-2-nitrobenzoic acid (DTNB). The intense yellow color of nitromercaptobenzoate was read at 412 nm. For calibration, a standard curve was prepared treating varied concentrations of reduced glutathione with DTNB under identical conditions[3].

Measurement of lipid peroxidation

The mitochondrial membrane fraction from gastric tissue homogenate was used for measurement of lipid peroxide content as thiobarbituric acid reactive species (TBARS). Briefly, 1 mL of the membrane fraction was allowed to react with 2 mL of TCA/TBA/HCl (15% TCA, 0.375% TBA, 0.25N HCl) reagent, heated in a boiling water bath for 15 min, cooled and centrifuged at 1000 r/min for 10 min at 4℃. The absorbance of the supernatant was measured at 535 nm and nmol TBARS produced was determined from a standard curve using tetraethoxypropane as standard[3,12].

Measurement of protein carbonyl content

Protein oxidation was measured as carbonyl content in the low speed supernatant of the gastric tissue homogenate[3,12]. The stomach from control, indomethacin-treated and doxycycline (50 mg/kg) pretreated indomethacin-treated rats was homogenized in 50 mmol/L sodium phosphate buffer, pH 7.4, in a Potter-Elvehjem glass homogenizer for 2 min, to obtain 20% homogenate. After centrifugation at 600 *g* for 10 min, the proteins from 1.0 mL of the supernatant were precipitated with 10% TCA and allowed to react with 0.5 mL 10 mmol/L 2,4-dinitrophenylhydrazine for 1 h. After precipitation with 20% TCA, the protein was washed three times with a mixture of ethanol-ethyl acetate (1:1), dissolved in 1.0 mL of a solution that contained 6 mol/L guanidine HCl in 20 mmol/L potassium phosphate, adjusted to pH 2.3 with TCA, centrifuged at 1000 r/min for 5 min at 4℃, and the supernatant was read for carbonyl content at 362 nm (e = 22000/M per centimeter).

Tissue extraction

The whole stomach (including fundic, body and pyloric parts) was washed with saline and used for extraction. Gastric tissues were suspended in 10 mmol/L phosphate buffered saline (PBS) containing protease inhibitors, minced, and incubated for 10 min at 4℃. After centrifugation at 12000 *g* for 15 min, the supernatant was collected as PBS extracts. The pellet was then extracted in lysis buffer (10 mmol/L Tris-HCl, pH 8.0, 150 mmol/L NaCl, 1% TX and protease inhibitors) and centrifuged at 12000 *g* for 15 min to obtain TX extracts. PBS and TX extracts were preserved at -70℃[3,12].

Gelatin and casein zymography

For assay of MMP-2 and MMP-9 activity, PBS and/or TX extracts were electrophoresed in 8% SDS-polyacrylamide gel containing 1 mg/mL gelatin under non-reducing conditions. For assay of MMP-3 activity, tissue extracts were electrophoresed in casein gel instead of gelatin. The gels were washed in 2.5% TX and incubated in calcium assay buffer (40 mmol/L Tris-HCl, pH 7.4, 0.2 mol/L NaCl, 10 mmol/L $CaCl_2$) for 18 h at 37℃, and stained with 0.1% Coomassie Blue followed by destaining[3,12,13]. The zones of gelatinolytic or caseinolytic activity came as negative staining.

MMP inhibition assay

Equal amount of PBS extract from ulcerated tissue were incubated with two different concentrations of doxycycline (100 and 200 μmol/L) in calcium assay buffer (40 mmol/L Tris-HCl, pH 7.4, 0.2 mol/L NaCl, 10 mmol/L $CaCl_2$) for 1.5 h at 37℃. Gelatin and casein zymography were performed from the samples as described previously[3,12,13]. Parallel assays were performed with the addition of phenanthroline (100 and 200 μmol/L in 10% DMSO) to show that inhibition could be attributed to MMP-2, MMP-3 and MMP-9 activity. PBS extract incubated with requisite volume of 10% DMSO was used as a control[32].

Effect of H_2O_2 on MMP-2 activity in vitro

To determine the effect of H_2O_2, equal amounts of PBS extract from control stomach (60 μg) were incubated with 500 μmol/L concentration of H_2O_2 at 37℃ for 1 h. To examine the protective effect of doxycycline on H_2O_2 mediated changes in MMP-2 activity, equal amounts of PBS extract were pretreated with doxycycline (200 μmol/L) prior to incubation with 500 μmol/L H_2O_2. Pretreatment with catalase followed by incubation with H_2O_2 was used as a positive control. Gelatin zymography was performed with the samples as described previously[19].

Western blotting

PBS extracts (100 μg/lane) were resolved by 8% reducing SDS-PAGE and processed for Western blotting[13].

Proteins were transferred to membranes, blocked in 3% BSA solution in 20 mmol/L Tris-HCl, pH 7.4, containing 150 mmol/L NaCl and 0.02% Tween 20 (TBST), and incubated at 4℃ in 1:200 dilutions of the respective primary antibodies in TBST containing 0.2% BSA. The membranes were then washed with TBST, incubated with alkaline-phosphatase-conjugated secondary antibody, and bands were visualized using 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium substrate solution.

Statistical analysis

Ulcer index data were fitted using Sigma plot software. Data were presented as the mean ± SE. Statistical analysis was performed using Student-Newman-Keuls test (ANOVA). $P < 0.05$ was considered statistically significant.

RESULTS

Effect of doxycycline on gastric ulceration induced by indomethacin or ethanol in rats

Indomethacin- and ethanol-induced gastric ulcer models in rat were used to test the protective effect of doxycycline against gastric damage. Doxycycline, a tetracycline analogue, has a number of non-antibiotic properties including inhibition of connective tissue breakdown. The action of doxycycline treatment on gastric damage was evaluated in rats by measuring ulcer index. One single dose of doxycycline (50 mg/kg) was selected for our study. Gastric ulceration was not detected in doxycycline-pretreated, indomethacin-treated rat gastric tissues. Figure 1A illustrates the effect of doxycycline on significant reduction in ulcer indices that occurred due to indomethacin-induced ulceration. In addition, doxycycline caused a significant decrease in ulcer index score from 50 to 15 when administered to high-dose ethanol-treated rats. Similarly, ulcer index score was reduced by less than 5 from 20 in low-dose ethanol-treated rats (Figure 1B). Thus, doxycycline arrested gastric damage by > 70% in rats with severe or moderate ulceration.

Effect of doxycycline on secreted and synthesized proMMP-9 and -2 activities

The gastroprotective action of doxycycline and association with MMP-2 and MMP-9 activities were examined in rat gastric tissues. Figure 2A and C shows that doxycycline inhibited proMMP-9 activity in PBS- and TX-extracted gastric tissues during protection against indomethacin-induced ulcer. PBS and TX extracts represented secreted and synthesized proMMP-9, respectively. ProMMP-9 activity is an inflammatory indicator of gastric damage and it increased with increasing gastric indices. Secreted and synthesized proMMP-9 activity was increased by about 12-fold and about 16-fold in indomethacin-ulcerated gastric tissues as compared to the controls, and doxycycline reduced the activity by 80% and 70%, respectively (Figure 2B and D). In contrast, doxycycline upregulated proMMP-2 activity at the level of secretion and synthesis, while protecting against indomethacin-induced gastric ulcer (Figure 2A and C). Indomethacin treatment decreased proMMP-2 activity by about 50% and docycycline pretreatment reversed the activity almost to control levels for both secretion and synthesis (Figure 2B and D). Doxycycline significantly reduced proMMP-9 activity in gastric tissues both at the level of secretion and synthesis in ethanol-induced ulcerated rats that were doxycycline treated, compared to untreated controls (Figure 3A and C). Doxycycline caused a reduction in secreted proMMP-9 activity to about 5-fold and about 1.5-fold, which was increased about 20-fold and about 7-fold during ulceration by high and low doses of ethanol, respectively (Figure 3B). Similarly, there was a decrease in synthesized proMMP-9 activity by about 18-fold and about 7-fold by doxycycline during protection of ethanol-induced ulceration by low and high doses (Figure 3B). In contrast, doxycycline-pretreated, ethanol-treated rats showed an increase in MMP-2 activity in gastric tissues at the level of secretion and synthesis (Figure 3A and C). Upregulation of MMP-2 activity by doxycycline was more prominent with low-dose compared to high-dose ethanol-induced ulceration (Figure 3D). Thus, MMP-9 activity was downregulated while proMMP-2 activity was

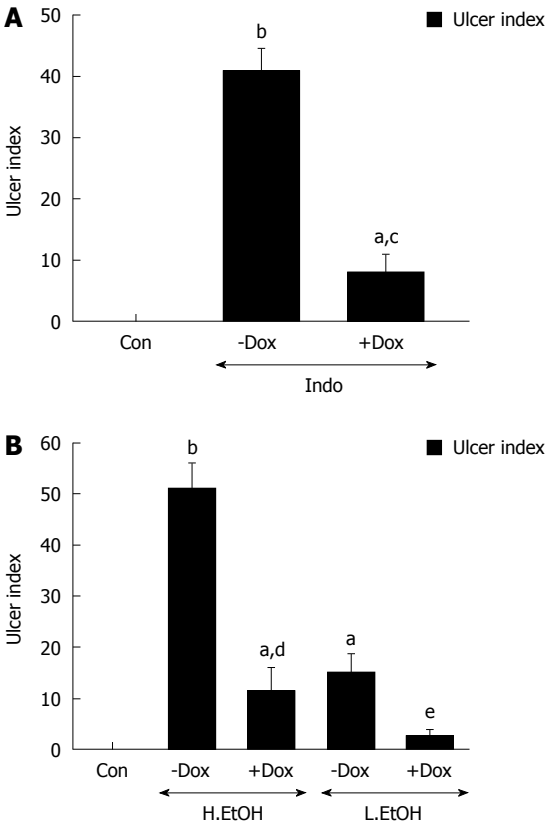

Figure 1 Protective effect of doxycycline on gastric injury. Gastric ulcers were induced in rats by oral administration of 48 mg/kg indomethacin or 70% ethanol (low and high) doses. Doxycycline (50 mg/kg) was administered orally prior to ulcerogen treatment to assess the protective effect. Control rats received sterile water only. After 3 h, rats were sacrificed and ulcer indices were scored. Mean ulcer index for indomethacin-induced (A) and ethanol-induced (B) ulceration in each group of rats was plotted. Dox: Doxycycline; Con: Control; Indo: Indomethacin; L.EtOH: Low dose ethanol; H.EtOH: High dose ethanol. Data expressed as mean ± SE. $^{a}P < 0.05$, $^{b}P < 0.001$ *vs* control; $^{c}P < 0.001$ *vs* indomethacin; $^{d}P < 0.001$ *vs* high dose ethanol; $^{e}P < 0.01$ *vs* low dose ethanol.

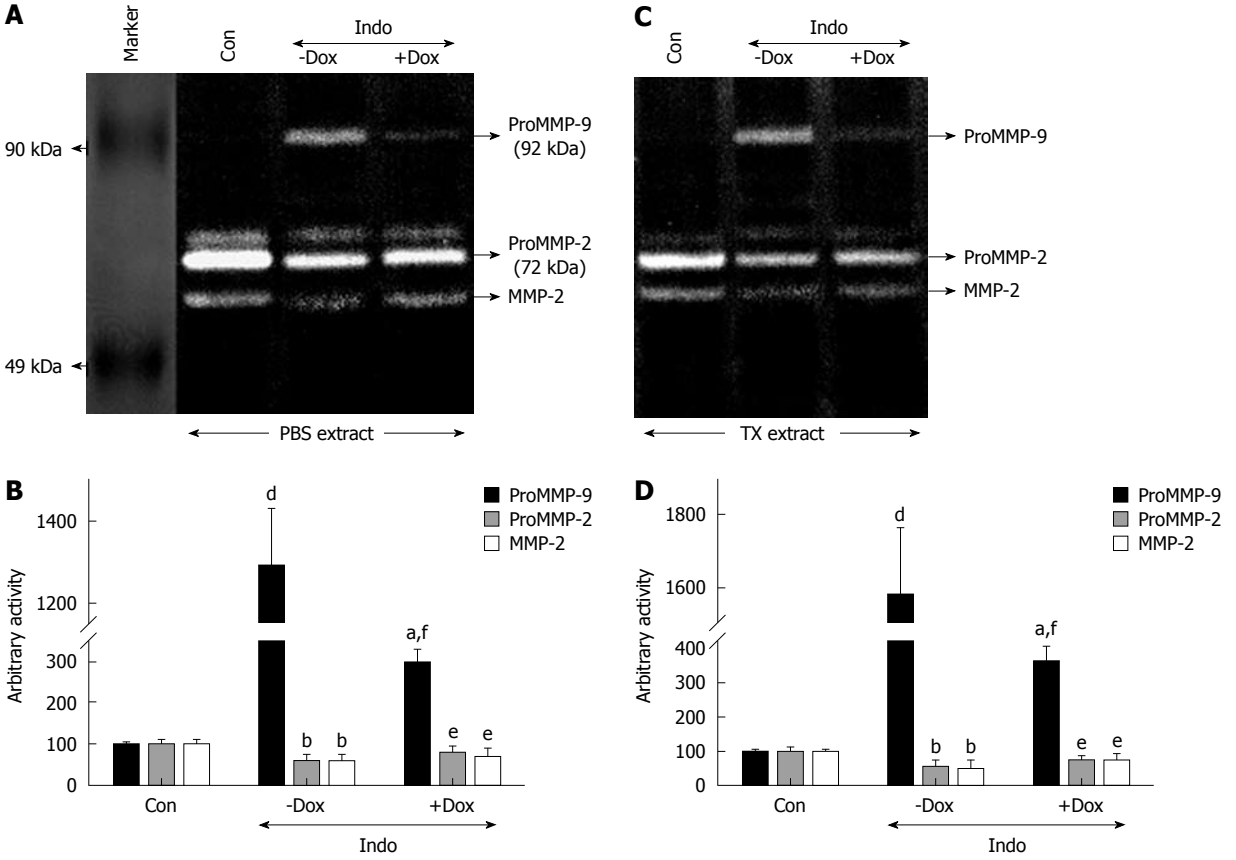

Figure 2 Effect of doxycycline on secreted and synthesized matrix metalloproteinase-2 and -9 activities during protection against indomethacin-induced ulcers. Gastric ulcer was induced by intragastric administration of 48 mg/kg indomethacin in rats, and doxycycline was given 30 min prior to indomethacin for protection studies. Gelatin zymography was performed using phosphate buffered saline (PBS) (A) and Triton X-100 (TX) (C) extracts of gastric tissue from different groups of rats. Histographic representation of arbitrary activity of pro-matrix metalloproteinase (MMP)-9 (B) and proMMP-2 (D) in PBS and TX extracts of gastric tissues, as measured by Lab Image software using the above zymogram and two other representative zymograms from independent experiments. Data expressed as mean ± SE. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{d}P < 0.001$ *vs* control; $^{e}P < 0.05$, $^{f}P < 0.01$ *vs* indomethacin.

upregulated in rat gastric tissues during gastroprotection by doxycycline. Expression of MMP-2 was also examined by Western blot analysis (Figure 3E) in doxycycline-pretreated, ethanol-treated gastric tissues. Figure 3F reveals that upregulation of proMMP-2 reached control levels in doxycycline-pretreated, ethanol-treated (low dose) rat gastric tissues. Similarly, upregulated expression of MMP-2 was also reflected in doxycycline-pretreated, ethanol-treated (high dose) rat gastric tissues. β-tubulin was run in parallel to confirm equal protein loading.

Effect of doxycycline on expression MMPs and TIMPs during gastroprotection

To investigate the ability of doxycycline to regulate MMP-3 during prevention of ulcers, indomethacin- and ethanol-induced ulceration were both examined. Figure 4 suggests that indomethacin increased proMMP-3 activity significantly in ulcerated gastric tissues. Figure 4A and C shows that doxycycline inhibited proMMP-3 activity very significantly in PBS- and TX-extracted gastric tissues during protection against indomethacin-induced ulcer. ProMMP-3 inhibitory activity of doxycycline was at a magnitude of about 75% and about 66% for secreted and synthesized protein, respectively, during protection of indomethacin-induced gastric ulcer (Figure 4B and D). Doxycycline inhibited the activity of secreted proMMP-3 while preventing both severe and moderate gastric ulceration induced by ethanol (Figure 5A). Doxycycline downregulated the activity by about 2-fold while protecting ethanol-treated gastric tissues, and the efficacy was greater for low-dose ethanol-treated tissues (Figure 5B). In other words, doxycycline exhibited an inhibitory effect on proMMP-3 activity by about 50% and about 70% for high-dose and low-dose ethanol-treated gastric tissues, respectively, as depicted in Figure 5B. The effect of doxycycline on MMP-9 and MMP-3 expression in rats was analyzed by Western blotting (Figure 5C). Both high and low doses of ethanol increased the expression of MMP-9 by about 21-fold and about 7-fold, respectively, in rat gastric tissues compared to controls, while treatment with doxycycline inhibited MMP-9 expression by 95% and 85%, respectively. Similarly, MMP-3 expression increased by about 6.5-fold and about 3.5-fold for high- and low-dose ethanol treatment, respectively, and doxycycline reduced their expression by 60% and 80%, respectively (Figure 5C). Moreover, the effect of doxycycline was more pronounced when ulcer was moderate rather than severe. To ascertain the regulatory role of TIMPs in ethanol-induced gastric ulcer,

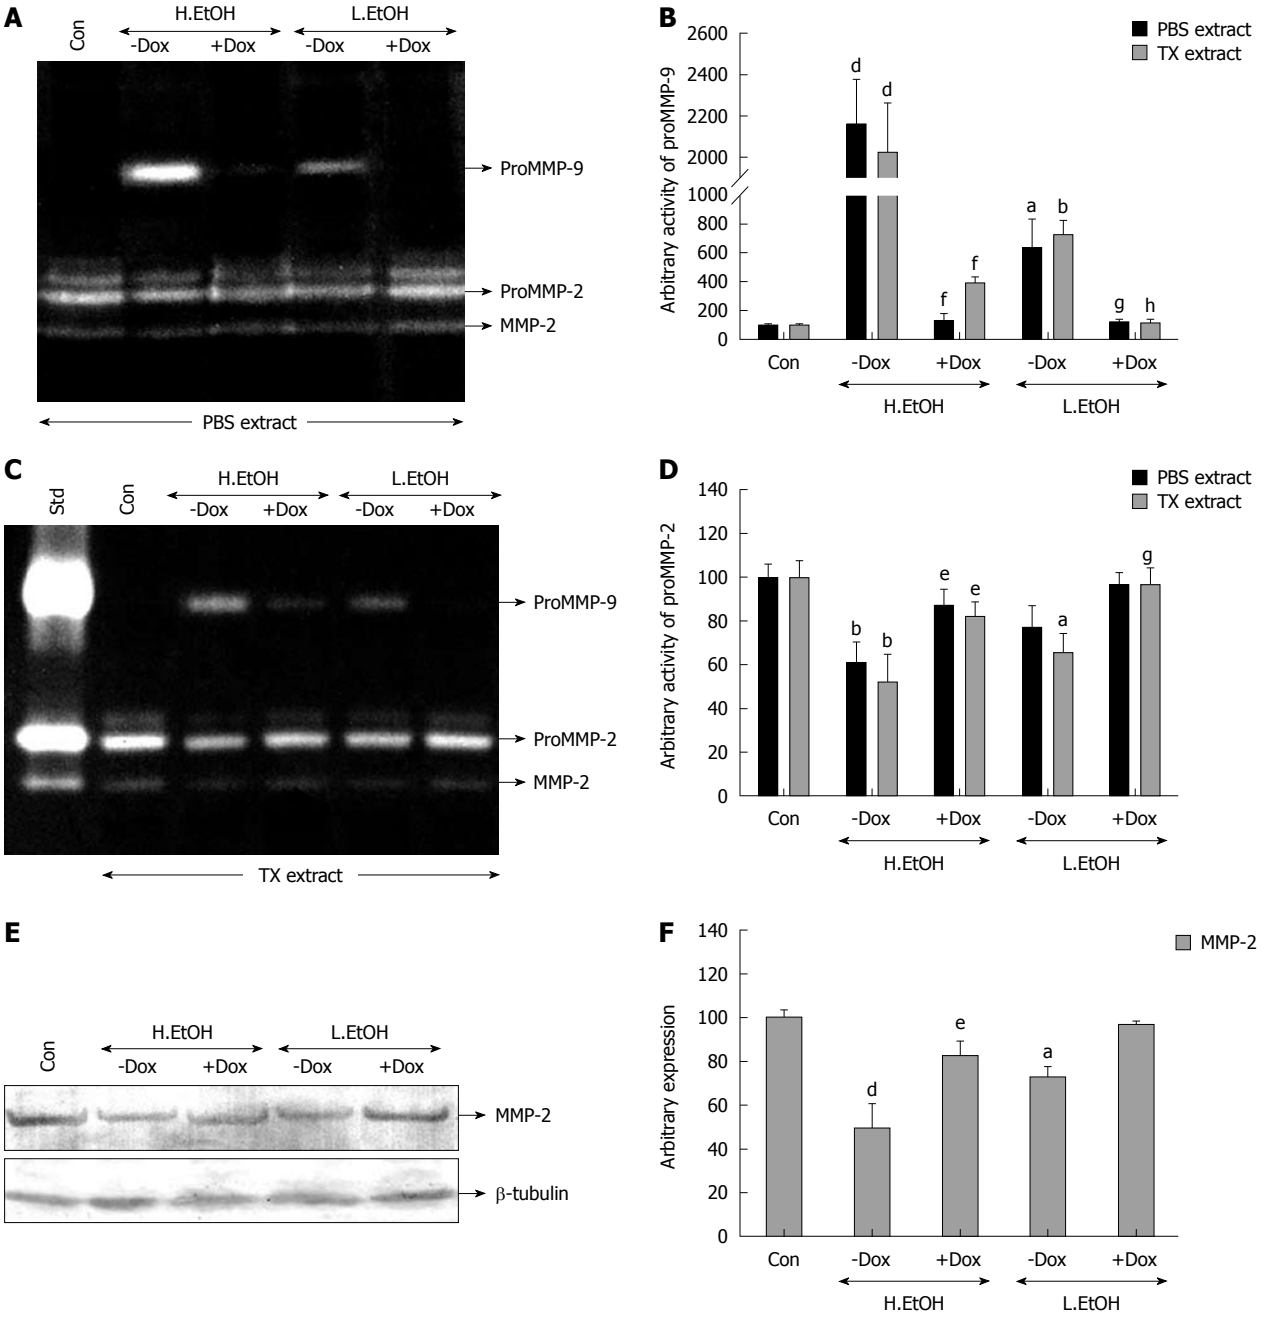

Figure 3 Effect of doxycycline on secreted and synthesized matrix metalloproteinase-2 and -9 activities during protection of ethanol-treated gastric ulcer. Low (0.4 mL/rat) and high (0.8 mL/rat) doses of 70% ethanol were administered intragastrically to induce moderate and maximum gastric ulcers, and doxycycline was administered 30 min prior to ethanol. Gelatin zymography was performed using phosphate buffered saline (PBS) (A) and Triton X-100 (TX) (C) extracts of gastric tissues from different group of rats. Histographic representation of arbitrary activity of pro-matrix metalloproteinase (MMP)-9 (B) and proMMP-2 and MMP-2 (D) in PBS and TX extracts of gastric tissues as measured by Lab Image software using the above zymogram and two other representative zymograms from independent experiments. PBS extracts were subjected to Western blotting (E) and probed with polyclonal anti-MMP-2 and β-tubulin antibody. Fold changes of MMP-2 (F) are represented in a histogram as measured by Lab Image software using the above western blot and two other representative blots from independent experiments. Data expressed as mean ± SE. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{d}P < 0.001$, *vs* control; $^{e}P < 0.05$, $^{f}P < 0.001$ *vs* high-dose ethanol; $^{g}P < 0.05$, $^{h}P < 0.01$ *vs* low-dose ethanol of respective PBS and TX extracts. L.EtOH: Low dose ethanol; H.EtOH: High dose ethanol.

TIMP-1 and TIMP-2 expression was checked by Western blot analysis. TIMP-1 expression was reduced by 40% and 60% for high- and lose-dose ethanol, respectively, and doxycyline reversed TIMP-1 expression almost to control values. On the other hand, TIMP-2 expression followed an opposite trend. It increased in rat gastric tissue after ethanol treatment. TIMP-2 expression induced by 1.6-fold and 1.3-fold, respectively, and doxycyline reduced TIMP-2 expression near to control levels. β-tubulin was run in parallel to confirm equal protein loading.

Inhibitory effect of doxycycline on MMP-9, -2 and -3 activities in vitro

The effect of doxycycline on MMP activity *in vitro* was

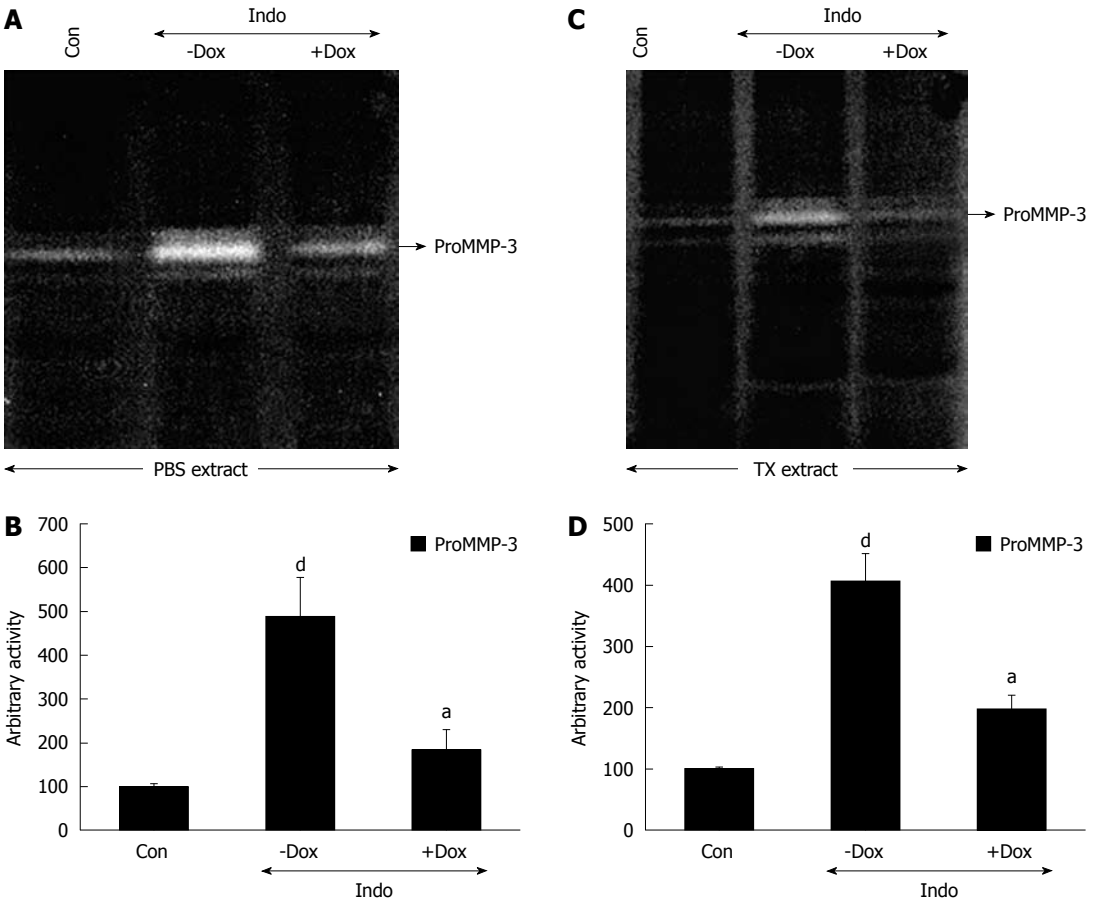

Figure 4 Effect of doxycycline on matrix metalloproteinase-3 activity during protection against indomethacin-induced gastric ulcer. Gastric ulcer was induced by intragastric administration of 48 mg/kg indomethacin in rats, and doxycycline was given 30 min prior to indomethacin for protection studies. Casein zymography was performed using phosphate buffered saline (PBS) (A) and Triton X-100 (TX) (C) extracts of gastric tissue from different groups of rats. Histographic representation of arbitrary activity of pro-matrix metalloproteinase (MMP)-3 in PBS (B) and TX (D) extracts of gastric tissues as measured by Lab Image software designed using the above zymogram and two other representative zymograms from independent experiments. Data expressed as mean ± SE. $^{a}P < 0.05$, *vs* indomethacin; $^{d}P < 0.001$ *vs* control.

evaluated by casein as well as gelatin zymography. Gastric tissue extracts with detectable MMP-2, MMP-3 and MMP-9 activities were used as controls for the inhibition experiment. Doxycycline inhibited MMP-2, MMP-3 and MMP-9 activities dose dependently, as judged by zymography (Figure 6A). Doxycycline at a dose of 100 μmol/L and 200 μmol/L inhibited MMP-9 activity by 30% and 50%, respectively, while MMP-2 and MMP-3 activities were inhibited by 65% in each case. *In vitro* inhibition studies of MMP activity were also performed in parallel using zinc chelator (1, 10 phenanthroline) to confirm the metalloprotease property. Phenanthroline at a dose of 100 μmol/L inhibited MMP-2, MMP-3 and MMP-9 by about 60%, about 62% and about 55%, respectively. In addition, the activity of MMP-2, MMP-3 and MMP-9 were further decreased by 10-15% more at high doses of phenanthroline (200 μmol/L) in each case (Figure 6B).

Reduction of oxidative stress by doxycycline in vivo and in vitro

Oxidative damage of cellular lipid and protein is directly associated with gastric ulceration. To determine the effect of doxycycline on oxidative damage of gastric tissues due to indomethacin, we measured protein oxidation and lipid peroxidation in control, indomethacin-treated, and indomethacin-treated doxycycline-pretreated gastric tissue homogenates. Indomethacin caused excessive oxidative damage that was associated with a about 2.5-fold and about 2-fold increase in lipid peroxidation and protein oxidation, respectively, while doxycycline treatment reduced them by about 80% and about 93%, respectively (Table 1). Moreover, the antioxidant, glutathione was reduced by about 36% compared to controls, and doxycycline recovered the glutathione content up to 92% during gastroprotection. In order to assess the possible antiulcer mechanism of doxycycline, we examined its protective effect on H_2O_2-mediated suppression of proMMP-2 activity *in vitro*. PBS-extracted gastric tissues from control rats were incubated with 200 μmol/L doxycycline followed by H_2O_2 treatment for 1 h at 37℃, and gelatin zymography was performed. The activity of MMP-2 in the zymogram (Figure 7A) was decreased by about 45% compared to the controls by H_2O_2, and doxycycline rescued H_2O_2-mediated suppression of MMP-2 activity by about 80% (Figure 7B). As expected when H_2O_2 treated samples were incubated with catalase, it failed to suppress MMP-2

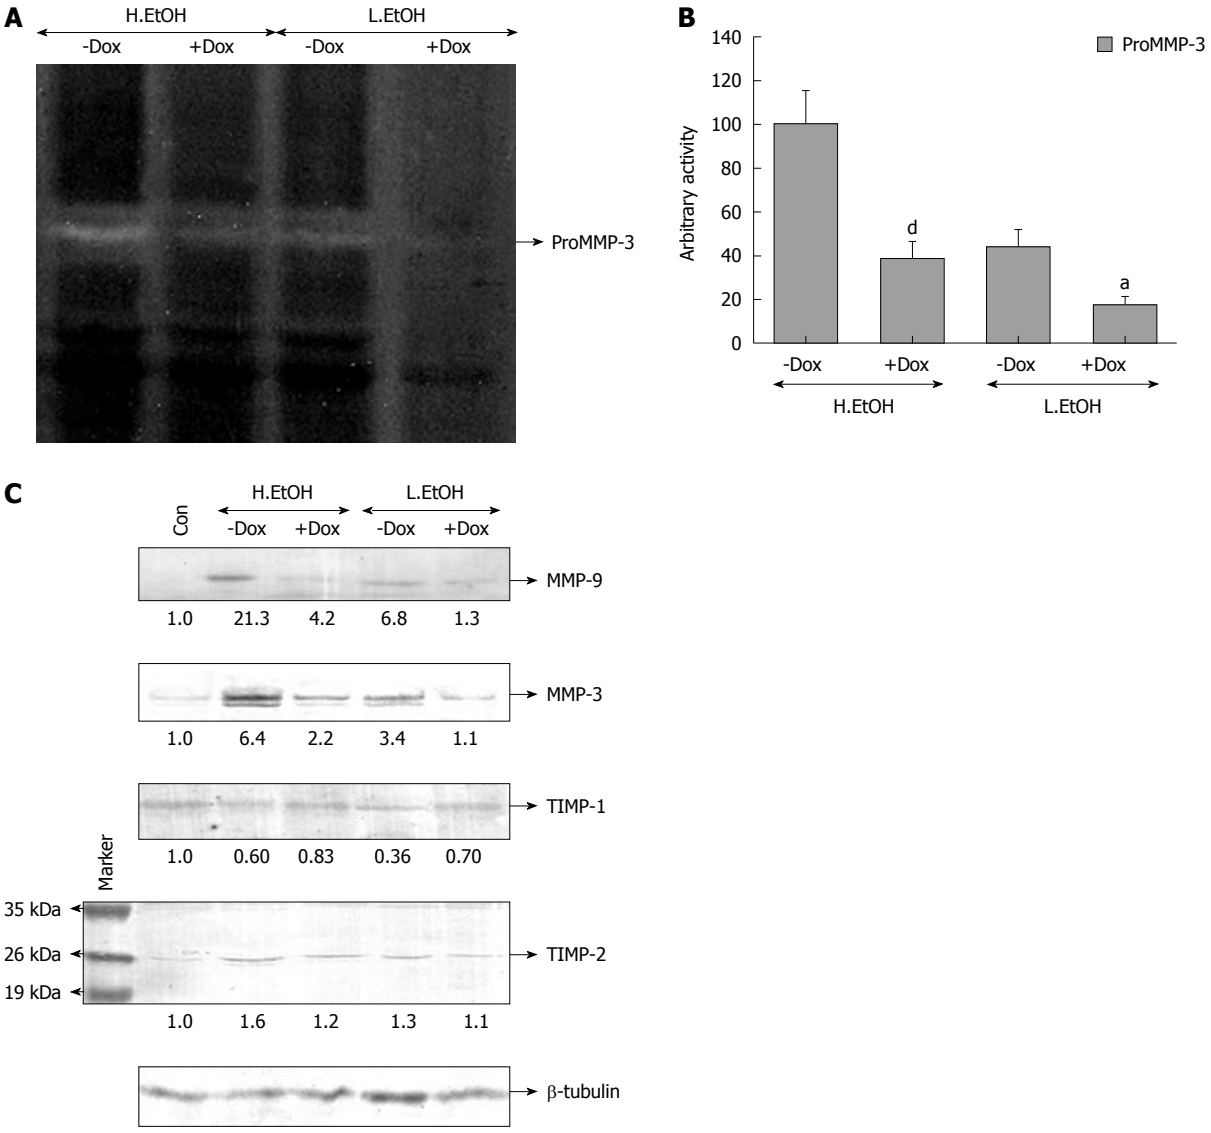

Figure 5 Effect of doxycycline on matrix metalloproteinase and tissue inhibitors of metalloproteinase activity and expression during protection against ethanol-treated gastric ulcer. Ulcers were induced in rat using 70% ethanol at low and high doses, and protection by doxycycline was performed. Casein zymography (A) was performed using phosphate buffered saline (PBS) extract of different gastric tissues. Histographic representation (B) of arbitrary activity of pro-matrix metalloproteinase (MMP)-3 as measured by Lab Image software using the above zymograms and two other representative zymograms from independent experiments. PBS extracts of gastric tissues from different experimental groups were subjected to Western blot blotting (C) and probed with polyclonal anti-MMP-9 and -3, tissue inhibitors of metalloproteinase (TIMP)-1 and -2, and anti-β-tubulin antibodies. Fold changes of proteins as represented below each band were measured by Lab Image software using the above wester blots and two other blots from independent experiments. Data expressed as mean ± SE. $^{a}P < 0.05$ *vs* low-dose ethanol; $^{d}P < 0.01$ *vs* high-dose ethanol. L.EtOH: Low dose ethanol; H.EtOH: High dose ethanol.

activity. Indomethacin-induced ulceration is associated with generation of H_2O_2, which in turn, damages tissues by interacting with protein and lipid. Thus, neutralizing H_2O_2-mediated damage by doxycycline suggests the antioxidant property of doxycycline.

DISCUSSION

NSAIDs, along with other aggressive factors like ethanol, *Helicobacter pylori* infection, stress and steroids, increases the risk of gastric ulcer formation[3,4,11-13,19]. Increased production of ROS and inflammatory cytokines, inhibition of cell proliferation, infiltration of inflammatory cells, reduced production of mucus, growth factors, and prostaglandins are factors involved in the pathogenesis of gastric ulcers[9,11]. Research has been focused recently on the importance of ECM and its turnover in the ulcerated margins of gastric tissue. Increased epithelial cell turnover is associated with the repair process without altering the composition and organization of the gastric ECM. Matrix proteins are secreted by different cell types including fibroblasts and epithelial and endothelial cells and assemble into an ECM network in the spaces surrounding the cells[5,9,10]. Recent studies have described the involvement of MMPs in cleaving and remodeling of ECM. MMPs have been implicated in various processes including tumor growth metastasis, chronic ulceration, fetal tissue development, and bone resorption. MMPs

Table 1 Effect of doxycycline on glutathione, lipid peroxidation and protein oxidation level in indomethacin-induced gastric ulcer

Samples	Glutathione (nmol/g tissue)	Lipid peroxidation (nmolTBARS/mg protein)	Protein oxidation (nmol/mg protein)
Control	182 ± 6.50	1.13 ± 0.16	2.66 ± 0.12
Indomethacin	116.50 ± 7.72^{b}	2.52 ± 0.07^{b}	5.14 ± 0.32^{b}
Doxycycline + indomethacin	167.25 ± 8^{d}	1.27 ± 0.06^{d}	3.36 ± 0.25^{a,d}

Doxycycline was administered 30 min before indomethacin in Sprague-Dawley rats. Control animals received vehicle orally. Glutathione content (n = 18), lipid peroxidation (n = 18), and protein carbonylation (n = 18) were measured in gastric tissue homogenate. Results are represented as mean ± SE. Data expressed as mean ± SE. $^{a}P < 0.05$, $^{b}P < 0.001$ *vs* control; $^{d}P < 0.01$ *vs* indomethacin.

capable of degrading ECM proteins are believed to play a significant role during the pathogenesis and healing of gastric ulcer[3,4,12]. These enzymes are synthesized as latent proenzymes and their activity is tightly regulated at

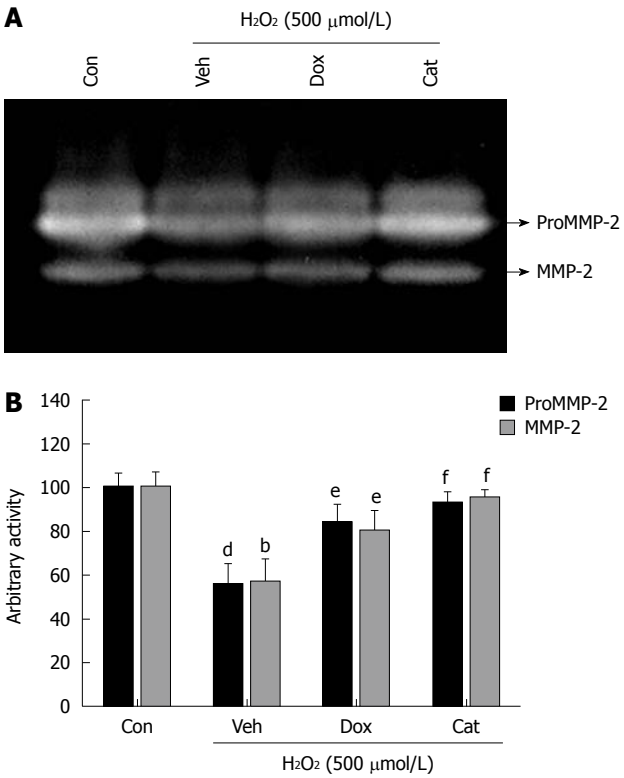

Figure 7 H_2O_2 scavanging activity of doxycycline. A: Gelatin zymography of phosphate buffered saline (PBS) extract from control gastric tissue was incubated with H_2O_2 (500 mmol/L) at 37℃ for 1 h. Equal amounts of PBS extract were pretreated with doxycycline (200 μmol/L) before incubation with H_2O_2. In one lane (Cat, lane 4), the extract was pretreated with catalase before reaction with H_2O_2; B: Histographic representation of pro-matrix metalloproteinase (MMP)-2 and MMP-2 activities as measured by Lab Image software using the above zymograms and two other representative zymograms from independent experiments. Veh: Vehicle; Cat: Catalase. Data expressed as mean ± SE. $^{b}P < 0.01$, $^{d}P < 0.001$ *vs* control; $^{e}P < 0.05$, $^{f}P < 0.01$ *vs* vehicle.

several levels including the post-translational level[33]. The coordinate action of proteases, in particular the MMPs and antiproteases, including the TIMPs, is thought to play an important role in connective tissue degradation[5]. In the present study, the authors intended to assess the relationship between MMP-2, MMP-3 and MMP-9 activity due to induction of gastric injury. Herein, doxycycline has been used to examine its gastroprotective potential.

Doxycycline, a widely prescribed antibiotic, is also a non-specific MMP inhibitor. It also possesses antiangiogenic and anti-inflammatory and neuroprotective properties, and is a convenient drug with low cost, and clinical tolerability without serious side effects[34]. Ryan *et al*[35] have reported divalent chelating activity of doxycycline. The beneficial effects of doxycycline are mainly mediated by its inhibition of MMP-9 and MMP-2. Doxycycline is safe in treating certain diseases because it reduces the level of pathophysiologically excessive MMPs but not to the level below normal physiological conditions. The effective dose of doxycycline is 100-200 mg/d for adult humans[36].

In the present study, we primarily showed that doxycycline potentially inhibited MMP-9 and MMP-3 activity

while arresting gastric damage in rats. It is noteworthy that doxycycline upregulated MMP-2 activity and expression during gastroprotection. Our results suggest that doxycycline acts through mechanisms distinctly different from its inhibitory effect on MMPs. Thus, doxycycline has a different action on MMP-2 activity in gastric damage, and indicates its regulatory role in addition to its inhibitory effect on MMPs. The increased MMP-2 activity may be required for preservation of matrix integrity, because function of the gastric epithelial and mucosal layer could be modulated by ECM components in gastric tissues[3,19]. Herein, an interesting feature of doxycycline is that it reduced MMP-2 activity *in vitro* and increased it *in vivo*. One interpretation is that doxycycline binds to Ca^{2+}/Zn^{2+} at catalytic sites of MMP *in vitro* and inhibits the enzymatic activity of MMPs[22,35]. Another interpretation may be that doxycycline perturbs the signaling pathways related to mitogen-activated protein kinase or Smad[27], and subsequently leads to beneficial systemic changes. *In vivo* upregulation of MMP-2 activity could be explained as an anti-apoptotic role of doxycycline during gastroprotection[34]. An alternative interpretation is that doxycycline inhibits oxidative stress and upregulates expression of MMP-2, or decreases antiprotease expression, thus shifting the protease/antiprotease balance towards high enzymatic activity. The beneficial effect on gastric damage may not be solely attributed to MMP-9 and MMP-3 inhibition. Other proteases and antiproteases may play a critical role, and pleiotropic effects of doxycycline may offer a better approach. This study provided convincing data to suggest a new pharmacological approach for the drug doxycycline for prevention of NSAID- or ethanol-induced gastric ulcers.

While the exact mechanism of gastric ulceration is still not completely understood, various cellular stresses including oxidative stress play a central role in the progression of gastric ulcers. Inflammatory reactions induced by indomethacin are a significant source of ROS, for example, H_2O_2 and the superoxide radical, which play a causative role in gastric injury[19]. ROS generally modulate MMP activity either indirectly through redox-dependent regulation of MMP gene transcription or directly through modification of MMP structure[2]. However, the direct association of ROS with the regulation of MMPs during gastric ulceration is not well studied. Several *in vivo* and *in vitro* cell culture studies have hypothesized activation of gelatinases through ROS or ROS generators when applied time and dose dependently. Herein, incubation of pro-MMP-2 in an *ex vivo* system with H_2O_2 resulted in suppression of enzyme activity, which suggests that ROS play a significant role in modulating MMP-2 activity. We also showed that doxycycline possessed inhibitory activity against H_2O_2-mediated suppression of MMP-2 activity, which indicated the antioxidant action of doxycycline. Doxycycline offered gastroprotection by preventing oxidative damage caused by lipid peroxidation and protein oxidation. Ulcerated samples exhibited reduced thiol content, whereas that was almost completely restored to control levels by doxycycline during gastroprotection. Although doxycycline has been reported as a potent inhibitor of MMPs, the antioxidant activity is worth mentioning in arresting gastric injury.

The major observations of the present study highlight that: (1) gastric injury is associated with upregulation of proMMP-3 and -9 activity, as well as expression in rat gastric tissues; (2) doxycycline is very effective in preventing gastric damage, and the mechanism of gastroprotection is attributable to its inhibitory effect on proMMP-3 and -9, while enhancing MMP-2 *in vivo*; and (3) doxycycline has a modulatory role with TIMP-1 and TIMP-2 during protection against gastric ulcers. The regulatory role of proMMP-2 activity may be dependent on the antioxidant action of doxycyline. We showed that doxycycline provides protection against gastric damage *via* inhibition of protein oxidation, lipid peroxidation and glutathione depletion. Moreover, suppression of MMP-2 activity by oxidative stress is rescued by doxycycline. Overall, this study is believed to be the first to demonstrate effectiveness of doxycycline in prevention of gastric damage *via* regulation of MMPs. Doxycycline therefore, may be considered as a candidate towards a therapeutic strategy for gastric ulcers. Also, proMMP-3 and -9 overexpression in gastric injury may be exploited as therapeutic targets, and doxycycline may be used as target-based therapy.

COMMENTS

Background

A class of zinc-dependent enzyme named matrix metalloproteinases (MMPs) is capable of degrading proteins of cellular and extracellular origin of various tissues. Their function is regulated by endogenous inhibitors such as tissue inhibitor of metalloproteinases and α-2 macroglobulin, which helps to maintain the protease-antiprotease balance. Imbalance in MMPs action is implicated in different diseases including gastric ulcer. Various factors mainly alcohol, non-steroidal anti-inflammatory drugs and infection with *Helicobacter pylori* cause gastric injury. In recent years, there has been a paradigm shift in understanding the mechanism of gastric ulcers, which includes regulation of MMPs and remodeling of the matrix surrounding the cells. Healing of gastric injury is a complicated process that comprises a series of cell-matrix interactions, and cell-cell signaling. Existing drugs against gastric injury have some limitation and side effects. Researchers are looking for novel drugs that have fewer side effects, easy availability, and low cost. A research group in India has examined the effect of doxycycline on gastric injury *via* regulation of MMPs.

Research frontiers

Doxycycline (derivative of tetracycline) is used commonly as an antibiotic. However, the antiulcer mechanism of doxycyline has not yet been explored fully. This study is believed to be the first to investigate the regulation of MMP-2 expression by doxycycline while preventing gastric injury.

Innovations and breakthroughs

The gastroprotective effect of doxycycline was tested against ethanol- or indomethacin-induced gastric mucosal injury in rats. Doxycycline prevented oxidative damage caused by lipid peroxidation and protein oxidation. Ulcerated samples exhibited reduced glutathione content, and it was almost completely restored to control levels by doxycycline during gastroprotection. Injured tissues exhibited significantly higher MMP-3 and MMP-9 activities, while doxycycline treatment markedly decreased both enzymes during gastroprotection. In contrast, the reduced MMP-2 activity in injured tissues was reversed by doxycycline during ulcer prevention. In addition, *in vitro*, doxycycline inhibited significantly all MMPs and proMMP-2, -3 and -9. Swarnakar *et al* have demonstrated a novel role of doxycycline in the upregulation of MMP-2 activity and expression during protection against gastric ulcers.

Applications

Altogether, the work established the use of doxycycline as an antiulcer drug that may lead to effective therapy for gastric ulcer. Combination therapy of doxycycline along with other existing antiulcer drugs such as famotidine, ranitidine or omeprazole may be better for treatment of gastric inflammation.

Peer review

This is believed to be the first demonstration of the dual action of doxycycline, namely, upregulation of MMP-2 activity and reduction of oxidative stress, in arresting gastric injury. Long-term use of doxycycline may provide therapeutic intervention for chronic gastric ulceration that poses a risk of progression to carcinoma.

Abstract

AIM: To investigate the expression of programmed death (PD)-1, PD ligand 1 (PD-L1) and PD-L2 in liver tissues in the context of chronic hepatitis and hepatocellular carcinoma (HCC).

METHODS: Liver biopsies and HCC specimens from patients were collected and histologically examined. The expression of PD-1, PD-L1, and PD-L2 in biopsy specimens of chronic hepatitis and HCC specimens was evaluated by immunohistochemical staining. The association between the expression level of PD-1, PD-L1, and PD-L2 and clinical and pathological variables was analyzed statistically.

RESULTS: Expression of PD-1 was found in liver-infiltrating lymphocytes. In contrast, PD-L1 and PD-L2 were expressed in non-parenchyma liver cells and tumor cells. The expression of PD-L1 was significantly correlated with hepatitis B virus infection (1.42 ± 1.165 *vs* 0.50 ± 0.756, $P = 0.047$) and with the stage of HCC (7.50 ± 2.121 *vs* 1.75 ± 1.500 *vs* 3.00 ± 0.001, $P = 0.018$). PD-1 and PD-Ls were significantly up-regulated in HCC specimens (1.40 ± 1.536 *vs* 5.71 ± 4.051, $P = 0.000$; 1.05 ± 1.099 *vs* 4.29 ± 3.885, $P = 0.004$; 1.80 ± 1.473 *vs* 3.81 ± 3.400, $P = 0.020$).

CONCLUSION: PD-L1 may contribute to negative regulation of the immune response in chronic hepatitis B. PD-1 and PD-Ls may play a role in immune evasion of tumors.

INTRODUCTION

Though active vaccination against hepatitis B virus (HBV) infection is successful, chronic HBV infection remains an important medical issue. There are approximately 400 million individuals chronically infected with HBV worldwide. Chronic HBV infection is one of the major causes of liver cirrhosis and hepatocellular carcinoma (HCC).

It is generally accepted that an appropriate T-cell response to HBV is crucial for viral elimination[1]. It has been suggested that HBV-specific CD8+ T cells have dual functions: the production of antiviral cytokines to down-regulate HBV replication in hepatocytes and the elimination of residual HBV-infected cells by cytotoxic activities[2]. Chronic HBV infection is characterized by weak or absent specific T-cell responses to HBV in peripheral blood. In the liver, low numbers of HBV-specific CD4 and CD8 T cells have been found. However, those T cells show a low expression of interferon (IFN)-γ and low cytotoxic activity[3,4]. Mechanisms leading to decreased cellular immune responses to HBV are not yet defined. Though there are many approaches suitable for priming specific CTL responses, their ability to break immune tolerance mechanisms in chronically infected HBV patients requires further investigation. In this respect, understanding tolerance mechanisms in chronic HBV infection will further help the design of strategies to overcome the unresponsiveness of T cells.

Programmed death (PD)-1 is a member of the CD28 family and is involved in the regulation of T-cell activation[5]. PD-1 is expressed on T cells, B cells, and myeloid cells. Two ligands for PD-1, PD ligand 1 (PD-L1) and PD-L2 (also known as B7-H1 and B7-DC), have been identified and have features as co-stimulatory molecules. A large number of publications have indicated a role for PD-L1 in the negative regulation of T-cell functions and the maintenance of peripheral tolerance[6]. The exact role of PD-L2 requires further definition. In murine liver tissues, PD-L1 was found to be expressed on Kupffer cells (KCs) and liver sinusoidal epithelial cells (LSECs)[7]. Hepatocytes express constitutively low levels of PD-L1 but show enhanced expression of PD-L1 upon stimulation with interferons[8]. It has also been shown in cell culture that PD-L1 expression on hepatoma cells induces apoptosis in T-cells. PD-L1 deficiency leads to hepatic accumulation and impaired apoptosis of T-cells in a murine model[9], and PD-1 deficiency leads to enhanced proliferation of effector cells in the liver during adenoviral infection[10].

Recent data from other chronic viral infections, such as lymphocytic choriomeningitis virus, human immunodeficiency virus, and hepatitis C virus infections, indicate that up-regulation of the PD-1/PD-L1 system may be responsible for the impairment of T-cell function[11-18]. Blocking of PD-L1 led to the rescue of exhausted CD8 T-cells even in the absence of Th functions[15-18]. Kassel *et al*[19] examined the expression of PD-1, PD-L1, and PD-L2 in patient liver samples and found that there was a direct link between the degree of inflammation and the expression of PD-1/PD-L1. Gao *et al*[20] found in patients with HCC that overexpression of PD-L1 significantly associates with tumor aggressiveness and postoperative recurrence.

The expression of PD-Ls was further suggested as a mechanism of immune evasion for tumors[21]. Elevated expression of PD-L1 was found in different tumor entities[22-29]. It could be shown that tumor cells expressing PD-L1 were able to induce apoptosis of T-cells. Thus, it is necessary to investigate the expression of PD-L1/2 and PD-1 in the liver in the context of viral hepatitis and HCC.

MATERIALS AND METHODS

Specimens

Specimens of liver tissues were obtained by biopsy or surgery from 20 hepatitis patients (including 12 with HBV infection and 8 with non-viral hepatitis) and 26 HCC patients (including 21 with HBV infection) at Tongji Hospital of Tongji Medical College, Huazhong University of Science and Technology, China, between 2006 and 2007 (Tables 1-3). Surgically resected or biopsy specimens were fixed in formalin and embedded in paraffin for routine histological diagnosis, and then embedded in OCT compound and snap frozen in liquid nitrogen for immunohistochemical analysis. The histological activity index (HAI) was assessed according to the classification of Ishak *et al*[30], which combines grading and staging scores (Table 2). All patients with hepatitis C virus (HCV) and human immunodeficiency virus (HIV) infection were excluded. No patient underwent antiviral drug treatment prior to biopsy. Tumors were classified as stage I to Ⅲ based on the Chengdu conference[31] and as grade I to Ⅳ based on the Edmondson-Steiner Guidelines (Table 3). The Chengdu conference stage classification was based on tumor dimension and lobar distribution, vascular thrombosis, lymph node metastasis, distant metastasis and Child-Pugh staging. No patient underwent radiation or chemotherapy prior to surgery.

Immunohistochemical staining

Four micron sections of the specimens were air-dried for 10 min and then fixed in acetone for 10 min. Endogenous peroxidase activity was blocked by treatment with 0.3% hydrogen peroxidase in PBS for 30 min at room temperature. Sections were then washed three times in PBS. After blocking nonspecific binding with normal goat serum for 20 min at room temperature, sections

were incubated with primary antibodies in a humidified chamber at 4℃ overnight. Anti-PD-1 (J116), anti-PD-L1 (MIH1), anti-PD-L2 (MIH18), anti-FoxP3 (236A/E7) and anti-CD3(UCHT1) antibodies were purchased from eBioscience (San Diego, CA) and used as primary antibodies at the final concentrations of 5, 10, 5, 10 and 5 μg/mL, respectively. The bound primary antibodies were detected with a Dako Envision™ Kit according to the manufacturer's instructions, and sections were counterstained with hematoxylin. IgG fractions from naïve mice were used instead of the primary antibody as negative controls.

The expression levels of PD-1, PD-L1 and PD-L2 were defined as the quickscore which was calculated according to the Detre S's method[32]. In brief, the proportion of cells staining positively throughout the section was termed category A and was assigned scores from 1 to 6 (1 = 0%-4%; 2 = 5%-19%; 3 = 20%-39%; 4 = 40%-59%; 5 = 60%-79%; 6 = 80%-100%). The whole section was scanned at low power in order to gauge the general level of intensity throughout. The average intensity, corresponding to the presence of negative, weak, intermediate, and strong staining, was given a score from 0 to 3, respectively, and termed category B. The product (A × B) was recorded as the quickscore.

HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus.

Statistical analysis

The association between the expression level of PD-1, PD-L1, and PD-L2 and clinical and pathological variables was analyzed statistically by the Student's t test and Correlation analysis using SPSS 12.0 software. Values of $P < 0.05$ were considered to indicate statistical significance, and all tests were two-tailed.

RESULTS

Immunostaining of PD-1

Typically, lymphocyte infiltration occurred in liver tissues of patients with hepatitis (Figure 1A). In these tissues, lymphocytes were recognized as small mononuclear cells and showed positive staining with anti-PD-1. The pattern of staining was consistent with the fact that PD-1 molecules are associated with cell membranes. The PD-1 positive cells showed a scattered pattern in liver tissues. Liver cells were not stained with anti-PD-1, which is consistent with the tissue specificity of PD-1 expression. The expression of PD-1 in liver tissues from patients with hepatitis had no relation to age, gender, alanine aminotransferase (ALT) and total bilirubin (TB) level, HAI or etiology (Table 4).

In peritumoral regions of HCC and within tumor tissues, PD-1 positive cells accumulated as massive lymphocyte infiltration took place (Figure 1D and G). Therefore, the expression level of PD-1 was determined by lymphocyte infiltration and was not dependent on the parameters

[1]The significance among different stages is mainly the difference between stage Ⅰ and Stage Ⅱ (including Ⅱa and Ⅱb) according to the SNK analysis. PD: Programmed death; PD-L: Programmed death ligand; HBV: Hepatitis B virus.

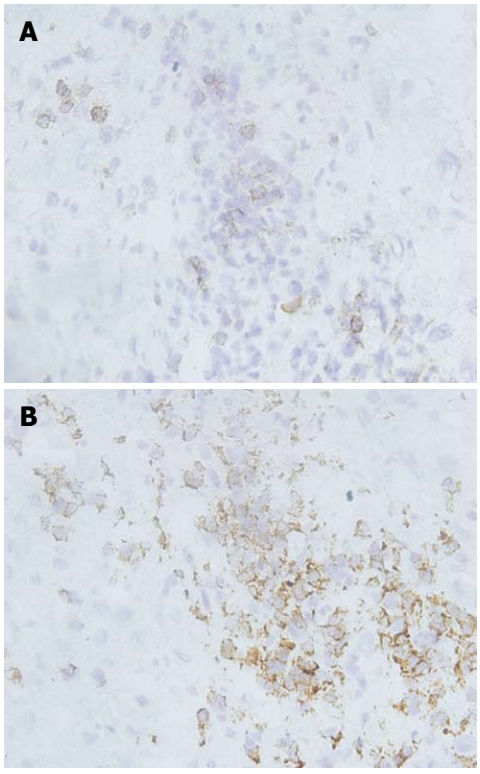

Figure 2 Expression of CD3 and programmed death-1 on regular liver sections from a patient with hepatocellular carcinoma. Serial sections were prepared from the same liver sample of a patient with hepatocellular carcinoma; CD3 and programmed death (PD)-1 were stained on these serial sections. CD3 was expressed on the membrane of liver-infiltrating lymphocytes, and the expression of PD-1 had a similar pattern to that of CD3, indicating PD-1 was also expressed on liver-infiltrating lymphocytes. A: PD-1; B: CD3.

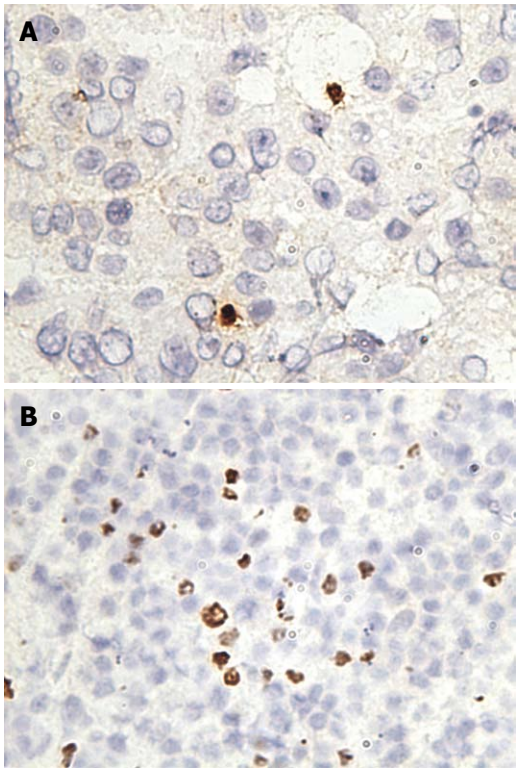

Figure 3 Immunohistochemical staining of liver tissues from patients with hepatocellular carcinoma for FoxP3. FoxP3 was expressed in liver-infiltrating lymphocytes in liver tissues with hepatocellular carcinoma. Liver infiltrating lymphocytes were mainly FoxP3 positive. A: Intratumoral region; B: Peritumoral region.

of age, gender, tumor stage or grade, or HBV infection (Table 5).

PD-1 was expressed on infiltrating lymphocytes (Figure 2A). These lymphocytes were CD3 positive, as both T-cell types were present in liver tissues and HCC tissues (Figure 2B). In addition, a significant portion of infiltrating lymphocytes were FoxP3 positive, indicating that negative regulation by regulatory T cells is operative in HCC (Figure 3).

Immunostaining of PD-L1 and PD-L2 in hepatitis

It has been reported that PD-L1 and PD-L2 are abun-

Table 6 Comparison of programmed death 1/programmed death-L expression in liver tissues of patients with hepatitis or hepatocellular carcinoma (mean ± SD)

Diagnosis	*n*	PD-1	*P*	PD-L1	*P*	PD-L2	*P*
Hepatitis	20	1.40 ± 1.536	0.000	1.05 ± 1.099	0.004	1.80 ± 1.473	0.020
HCC	26	5.71 ± 4.051		4.29 ± 3.885		3.81 ± 3.400	

PD: Programmed death; PD-L: Programmed death ligand; HCC: Hepatocellular carcinoma.

dantly expressed on KCs and LSECs[7]. In liver tissues with hepatitis, the expression of PD-L1 and PD-L2 was weakly detectable (Figure 1B and C), and the percentages of PD-L1 and PD-L2 positive cells were found to be only 0.57% and 1.29% of total cell counts, respectively. Cells with PD-L1 and PD-L2 expression were clearly different from lymphocytes and hepatocytes and represented rather KCs and LSECs.

The PD-L1 expression in liver tissues from patients with hepatitis had no relation to age, gender, or ALT and TB level (Table 4). Enhanced PD-L1 expression seemed to be associated with HBV infection, as compared with non-viral hepatitis (Table 4). In contrast, there was no relationship between PD-L2 expression and age, gender, ALT and TB level, or the etiology of hepatitis (Table 4).

The HAI was assessed to evaluate inflammation in the liver according to the classification of Ishak *et al*[30]. As shown in Table 4, a weak correlation between PD-L1 expression and HAI was found, which is consistent with previous observations that PD-L1 expression can be stimulated by viral infection and further pulse with IFNs[8]. The correlation between HAI and PD-L1 expression might be explained by the production of proinflammatory cytokines by infiltrating lymphocytes in chronic viral hepatitis. In contrast, there was no relationship between PD-L2 expression and HAI (Table 4).

Immunostaining of PD-L1 and PD-L2 in HCC

It has been reported that PD-L1 is abundantly expressed on cancer cells in various types of tumors. Therefore, 26 HCC specimens and peritumoural tissues prepared from surgery were examined for the expression of PD-L1 and PD-L2. The tumors were classified as stage Ⅰ (n = 5), stage Ⅱa (n = 6), or stage Ⅱb (n = 5) based on the Chengdu conference, and as grade Ⅰ (n = 10), grade Ⅱ (n = 2), grade Ⅲ (n = 7), or grade Ⅳ (n = 3) tumors based on the Edmondson-Steiner Guidelines (Table 3).

In peritumoural tissues, the expression of PD-L1 and PD-L2 was significantly elevated. However, the expression of PD-Ls appeared to still be restricted to cell types like KCs and LESCs (Figure 1E and F). Compared with liver tissues from patients with hepatitis, the expression of PD-Ls was recognizably enhanced in intensity for IHC staining with respective antibodies.

PD-L1 and PD-L2 had focal or scattered expression in 24 (92.6%) and 23 (88.9%) of 26 HCC specimens, respectively (Figure 1H and I). Thus, the enhanced expression of PD-Ls was a general phenomenon in HCC. In tumor tissues, tumor cells expressing PD-L1 and PD-L2 were detected. These cells had a different morphological appearance and were characterized by large nuclei surrounded by thick cytoplasm (Figure 1H and I). Tumor cells were heterogeneous in regards to the expression of PD-L1 and PD-L2 molecules, and less than 50% of cells in tumor tissues expressed these molecules. Thus, the expression of PD-L1 and PD-L2 did not appear to be regulated by an exogenous inducer for cancer cells, but rather was an intrinsic characteristic of these cancer cells.

The expression of PD-L1 was more pronounced at an early stage of HCC, while there was a lower level of PD-L1 expression with increasing stage of HCC (Table 5). Thus, the expression of PD-L1 appeared to be an early event during tumor progression. In contrast, there was no significant correlation between tumor grade and PD-L1 expression level. In addition, HBV infection had no significant influence on PD-L1 or PD-L2 expression in HCC (Table 5).

Compared to liver tissues from patients with chronic HBV infection, PD-1, PD-L1, and PD-L2 expression levels in HCC were greatly enhanced (Table 6).

DISCUSSION

It has been demonstrated that the PD-1/PD-L1/PD-L2 system can deliver a negative signal to T cells and lead to T-cell exhaustion or apoptosis[9,10,33,34]. To assess the role of the PD-1/PD-L1/PD-L2 system in chronic HBV infection and HCC, we analyzed the expression of these molecules in liver tissues from patients with these conditions. From the results of this study, we conclude the following: (1) the expression of PD-L1 and PD-L2 is detectable on KCs and LSECs in liver tissues with viral and non-viral hepatitis; (2) PD-L1 expression in liver tissues is enhanced in patients with chronic hepatitis B; and (3) PD-1 and PD-Ls expression are significantly enhanced in peritumoral and tumor tissues. The first two findings are in agreement with previous findings[19,20]. It will be interesting to investigate the role of PD-L1 expression in chronic HBV infection. While KCs and LSECs are the cell types expressing PD-L1 and PD-L2 in peritumoral tissues, a portion of tumor cells in HCC gained the ability to express PD-L1 and PD-L2. PD-L1 and PD-L2 expression in tumor tissues occurred in the early stage and may represent an important contribution to immune evasion during tumor progression. Thus, HCC may evade immune control by different mechanisms including negative regulation of T-cells.

PD-1/PD-L1 expression may play a role in viral hepa-

titis[13,14,17,18]. Upon activation, T-cells express PD-1 and are therefore susceptible to negative signaling by its ligands[33,34]. In our work, it is evident that liver-infiltrating lymphocytes were positive for PD-1. The activated T-cells may enter liver tissues due to attraction by chemokines. Due to the expression of PD-L1 and PD-L2 on KCs and LSECs in liver tissues and on cancer cells in HCC, liver-infiltrating cells would frequently encounter negative signals and become "exhausted" T-cells.

In chronic viral infection, virus-specific T cells are dysfunctional either because of interaction with regulatory T cells[35] or interaction between PD-1 and its ligand PD-L1, which results in the down-regulation of T-cell functions[11-14]. Recently, blockage of PD-L1 emerged as an effective measure to promote the proliferation and functions of T-cells in lymphocytic choriomeningitis virus infection of mice[15]. Barber *et al*[15] demonstrated that virus-specific, exhausted cytotoxic T-lymphocytes regained their ability to proliferate and perform functions such as IFN-γ production and killing of target cells. In HIV- and HCV-positive patients, virus-specific cells also have high expression levels of PD-1, which may explain their dysfunction[12-14,16-18]. Therefore, the blockage of PD-L1 and PD-L2 may restore impaired T-cell functions in individuals with persistent HBV infection and may lead to effective immunological control of viral infection. It is evident that T-cell functions are impaired in patients chronically infected with HBV. In our work, PD-L1 is up-regulated in chronic HBV, suggesting that PD-L1 may play an important role in chronic HBV infection due to the negative control of proliferation and functions of liver-infiltrating T-cells. A recent study demonstrated that a blockage of PD-L1 could restore the functions of peripheral and intrahepatic T-cells from patients with chronic hepatitis B[36].

Our findings have important implications for immunotherapeutic approaches to chronic hepatitis and HCC. Until now, the focus of experimental approaches has been to improve the ability of vaccines to induce a broad, strong T-cell response. However, these efforts could be compromised by the fact that specific T cells may be unable to exert their functions in the liver due to negative regulation, despite effective priming in the peripheral and local lymphoid organs. Thus, future research on immunotherapeutic approaches should consider the blockage of negative T-cell regulation in combination with immunostimulation.

Taken together, PD-L1 and PD-L2 were expressed by KCs and LSECs independent of viral and non-viral hepatitis and were up-regulated by chronic HBV infection and in HCC. The presence of PD-L1 and PD-L2 may lead to the suppression of immune responses and therefore facilitate viral persistence and carcinogenesis. Furthermore, the expression of PD-1, PD-L1, and PD-L2 in HCC was significantly higher than in hepatitis and correlated with the stage of HCC and the number of infiltrating lymphocytes, indicating the importance of the PD-1/PD-Ls system in tumor development.

COMMENTS

Background

Chronic hepatitis B and hepatocellular carcinoma (HCC) remain the big problem in China and around the world. Immune tolerance characterized with weak or absent specific T-cell responses to hepatitis B virus (HBV) or tumor is responsible for the pathogenesis of hepatitis and tumor. In this content, understanding tolerance mechanisms in chronic hepatitis B and HCC will further help the design of strategies to overcome the unresponsiveness of T cells.

Research frontiers

It has been demonstrated that the programmed death (PD)-1/PD ligand 1 (PD-L1)/PD-L2 system can deliver a negative signal to T cells and lead to T-cell exhaustion or apoptosis. Recent data from other chronic viral infections, such as lymphocytic choriomeningitis virus, human immunodeficiency virus, and hepatitis C virus, and other tumors, such as breast cancer, pancreatic cancer, and non-small cell lung cancer, indicated that up-regulation of the PD-1/PD-L1 system may be responsible for the impairment of T-cell function. In this study, the authors investigated the expression of PD-L1/2 and PD-1 in the liver in the context of chronic hepatitis B and HCC.

Innovations and breakthroughs

Recent reports have highlighted the importance of PD-1/PD-Ls system as a negative immune regulator in pathogenesis of chronic viral infection and tumors. In this study, the authors found: (1) the expression of PD-L1 was significantly correlated with HBV infection and with the stage of HCC; (2) PD-1 and PD-Ls were significantly up-regulated in HCC specimens, which indicated for the first time that PD-L1 may contribute to negative regulation of the immune response in chronic hepatitis B; and (3) PD-1 and PD-Ls may play a role in immune evasion of HCC.

Applications

By identifying the fact that expression of PD-1/PD-Ls is highly up-regulated in hepatitis B and HCC, our study indicated the PD-1/PD-Ls system plays a role in immune tolerance of hepatitis B and HCC, and thus may represent a future strategy for therapeutic intervention in the treatment of patients with hepatitis B or HCC.

Terminology

PD-1 is a member of the CD28 family and is involved in the regulation of T-cell activation. PD-1 is expressed on T cells, B cells, and myeloid cells. Two ligands for PD-1, PD-L1 and PD-L2 (also known as B7-H1 and B7-DC), have been identified and have features as co-stimulatory molecules. A large number of publications have indicated a role for PD-L1 in the negative regulation of T-cell functions and the maintenance of peripheral tolerance. The exact role of PD-L2 requires further definition.

Peer review

This manuscript is impressive in that it investigated the expression of PD-1 and PD-Ls in liver tissue from patients with hepatitis and HCC using immunostaining in detail.

Abstract

AIM: To examine the interactions between cytotoxin-associated gene (*CagA*) positive *Helicobacter pylori* infection and smoking in non-cardiac gastric cancer.

METHODS: A case-control study (257 cases and 514 frequency-matched controls) was conducted from September 2008 to July 2010 in Xi'an, China. Cases were newly diagnosed, histologically confirmed non-cardiac cancer. Controls were randomly selected from similar communities to the cases and were further matched by sex and age (± 5 years). A face-to-face interview was performed by the investigators for each participant. Data were obtained using a standardized questionnaire that included questions regarding known or suspected lifestyle and environmental risk factors of gastric cancer. A 5 mL sample of fasting venous blood was taken. *CagA* infection was serologically detected by enzyme-linked immunosorbent assays.
