In terms of quality, these two concerns comprise the critical few. The implementation of measures to improve these two main problem areas would probably reduce the rate of problems among participants. The level of pain was an important determinant of satisfaction with the upper endoscopic procedure used for gastric cancer screening, especially in the unsedated group. This finding is consistent with the results of previous studies, which reported that higher levels of pain or discomfort were correlated with lower patient satisfaction with the procedure^[15,16]. A second reason for dissatisfaction identified by our study was the adequacy of explanations of any pain or discomfort associated with the procedure. A large percentage of complaints in both sedated and unsedated groups was related to communication problems^[14]. The total problem rates identified by the three questions regarding the adequacy of explanations were greater than 50% in both sedated and unsedated groups, indicating that dissatisfaction with explanations and communication is the most important contributor to the problem rate. This suggests that screenings are often performed without sufficient explanation, even though participants acquire information before this procedure^[17,18]. Before screening, both the preparation for and the actual process of the endoscopy should be explained. It would also be helpful to explain the possible

discomfort associated with this procedure. Additionally, efforts to ensure privacy and improve the interactional style of staff members may improve population screening programmes.

The total gastric cancer-screening rates have been increasing steadily in South Korea, and the rate of upper endoscopic examination has also been increasing^[12]. However, the rate of participation in gastric cancer screening programs is still not optimal^[19]. Previous results of a population-based survey have identified the upper endoscopy as the preferred gastric cancer screening method. Interestingly, respondents with higher income levels were more likely to have had an endoscopic examination compared with those in lower income levels. Under the South Korean NCSP, endoscopic examination, like UGI tests, are free of charge. Despite these programmes, the use of endoscopy varies with household income, suggesting the possible impact of barriers other than the cost of endoscopy *per se*^[6]. Indeed, under this NCSP, participants have to pay for all procedure-related costs associated with sedation, which may represent one of the barriers associated with income disparities.

Patient satisfaction is a crucial parameter in the management of the quality of endoscopies because it directly reflects patient acceptance of procedures and possibly reflects patient compliance with screening and monitoring^[20], thus, dissatisfaction with the screening experience may lead to non-compliance^[13,21-24]. Satisfaction is particularly important when targeting asymptomatic individuals because they have no obvious reason to seek the services of a screening program. Moreover, levels of satisfaction are also important indicators of the quality of care, and feedback from participants can be used to modify program operations^[21]. To increase compliance with the NCSP, we addressed issues related to improving satisfaction with screening services.

Upper endoscopy is a safe and quick procedure, and can be performed without sedation^[25]. However, it can also evoke anxiety, feelings of vulnerability, embarrass-

ment, and discomfort, and the fears and concerns associated with endoscopic procedures decrease patient compliance. Conscious sedation is the method most widely used, and good tolerance or conscious sedation has been related to the acceptance of and higher satisfaction with endoscopic procedures^[1,15,16,26,27]. Although usually safe, gastric cancer screening tests have tradeoffs in terms of efficacy, complications, discomfort, time, and cost^[6,12,28]. The performance of upper endoscopies using sedation is more costly but remains an efficacious strategy because it increases the rates of successful endoscopies, patient satisfaction, and willingness to undergo repeat procedures^[29].

For these reasons, the NCSP should support the cost of sedation for upper endoscopies and let patients choose whether to undergo this procedure with or without sedation. Such decisions should be based on patient preferences and the clinical judgment of endoscopists, which, in turn, are based on patient age, sex, and tolerance for the procedure^[6,16]. Providers' assessment of individuals' screening preferences, in combination with intervention strategies to promote the preferred screening method, may increase compliance with gastric cancer screening recommendations^[28,30]. It will be imperative to consider these results when making decisions about population-based screening strategies^[31].

This study has several limitations, including the possibility of a degree of participant bias. Respondents who completed the follow-up questionnaire were often those who reported discomfort on the post-procedure questionnaire; thus, this group may have been more likely to respond. The study was conducted among healthy individuals (i.e., participants in the National Gastric Cancer Screening Program), and the results may not be applicable to other patient populations. Indeed, participants might have different values, expectations about the procedure, and pain tolerance, which would potentially influence their satisfaction with the endoscopic procedure. Additionally, our study was conducted at a hospital, which may influence the extent to which our findings are generalizable to non-hospital settings such as clinics.

Despite these limitations, the present study used a reliable and valid survey methodology to evaluate satisfaction with the NCSP. The assessment of satisfaction with the NCSP is useful, as the degree of satisfaction with screening programmes is correlated with adherence patterns. The present study serves as a basis for future interventions to improve satisfaction with upper endoscopic procedures, including using sedation or establishing a program for training staff in communication skills and interpersonal interactions. These findings may be used to develop strategies to promote participation in and adherence to the South Korean Gastric Cancer Screening Program.

an important outcome measure of gastrointestinal (GI) endoscopies. Patient satisfaction not only establishes performance standards, but also increases the accountability of physicians and staff, and most importantly, can lead to improvement in the quality of care.

Research frontiers

National gastric cancer-screening rates have been increasing steadily in South Korea. However, the rate of participation in gastric cancer screening programs is still not optimistic. The authors suggest measuring the perceived satisfaction with gastric cancer screening as part of the National Cancer Screening Program so as to identify and ameliorate the issues that contribute most to participant dissatisfaction.

Innovations and breakthroughs

This study shows that the level of pain experienced during the endoscopic procedure and the adequacy of the explanation of any pain or discomfort associated with the procedure constituted the factors that contributed most to the problem rate among participants. The implementation of measures to improve these two main problem areas would probably reduce the rate of problems among participants.

Applications

This study serves as a basis for future interventions to improve the satisfaction with upper endoscopic procedures, including using sedation or establishing a program for training staff in communication skills and interpersonal interactions.

Peer review

The study is well done both number and selection of cases, and the results quite clear.

Abstract

AIM: To determine the seroprevalence of anti-hepatitis A virus (HAV) antibodies in patients with chronic liver disease (CLD) and to justify the need for hepatitis A vaccination.

METHODS: Patients ($n = 119$) were enrolled between July and September 2009. The diagnosis of CLD was based on the presence of viral markers for more than 6 mo. The diagnosis of liver cirrhosis was based on clinical, biochemical and radiological profiles. Patient serum was tested for anti-HAV IgG.

RESULTS: The overall anti-HAV seroprevalence was 88.2%. The aetiology of CLD was hepatitis B in 96 patients (80.7%) and hepatitis C in 23 patients (19.3%). Mean age was 44.4 ± 14 years. Patients were grouped according to age as follows: 24 (20.2%) patients in the 21-30 years age group, 22 (18.5%) in the 31-40 years age group, 31 (26.1%) in the 41-50 years age group, 23

(19.3%) in the 51-60 years age group and 19 (16.0%) patients aged greater than 60 years, with reported seroprevalences of 66.7%, 95.5%, 93.5%, 91.3% and 94.7%, respectively. There was a marked increase of seroprevalence in subjects older than 30 years ($P = 0.001$).

CONCLUSION: Our study demonstrated that patients aged greater than 30 years of age were likely to have natural immunity to hepatitis A. Therefore, hepatitis A vaccination may not be routinely required in this age group.

Anti-hepatitis A seroprevalence among chronic viral hepatitis patients in Kelantan, Malaysia. *World J Gastroenterol* 2011; 17(36): 4130-4134 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i36/4130.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i36.4130>

INTRODUCTION

Hepatitis A remains a significant problem in Malaysia. Malaysia is among those countries reported to be of intermediate endemicity, along with Thailand and Sri Lanka^[1-3]. The hepatitis A virus (HAV) has been reported to be the main cause of symptomatic clinical hepatitis (up to 66.4% in 1996) in the Eastern region of Peninsular Malaysia when compared to other causes of viral hepatitis^[4]. Kelantan is one of the states situated in the Eastern region of Peninsular Malaysia. However, over the last 20 years, pat-

terns of endemicity in South-East Asia have changed due to improvements in living standards, with some countries shifting from high to intermediate or intermediate to low endemicities^[1,3,5-7]. The prevalence of HAV in Malaysia is expected to fall with time; this means, however, that reintroduction of the virus to a non-immune population could produce a community-level outbreak, which may lead to an increase in morbidity and mortality^[2,8].

HAV super-infections in patients with underlying chronic liver disease (CLD) may lead to decompensation of the liver. Acute HAV super-infection is associated with higher morbidity and mortality than are isolated cases of acute HAV infection, leading to an increase in the likelihood of developing a fulminant liver failure^[9-14]. Based on epidemiological studies of large hepatitis A outbreaks in Shanghai in the late 1980s, acute hepatitis A in patients with chronic hepatitis B has an even more severe clinical course and higher risk of death^[15]. The fatality rates for acute hepatitis A were 5.6 times higher among hepatitis B surface antigen (HBsAg) carriers when compared to HBsAg-negative patients^[16]. A similar scenario may also be true for super-infection of hepatitis A in chronic hepatitis C patients. An observational study conducted over a 7-year period among 432 Italian patients with chronic hepatitis C reported that amongst the 17 patients (3.9%) with acute hepatitis A super-infection, 41% progressed into fulminant hepatic failure^[17]. This emphasises the need for vaccination in CLD patients without natural immunity.

In the West, hepatitis A vaccination has been recommended in all patients with CLD to prevent super-infection with HAV, which may cause high morbidity and mortality in this group of patients^[18-20]. However, in countries where hepatitis A is still endemic, such as Malaysia, the utility of this vaccine must be examined, as it is possible that most patients have already acquired natural immunity^[21-23].

Therefore, we aimed to determine the seroprevalence of anti-HAV antibodies in patients with CLD in our region.

MATERIALS AND METHODS

Sample population

Patients with CLD ($n = 119$) attending the Gastroenterology Clinic of Universiti Sains Malaysia, Kelantan between July and September 2009 were enrolled after having signed written informed consents. Diagnosis of CLD was based on the presence of HBsAg or anti-hepatitis C virus antibody (anti-HCV) in serum for a period of at least 6 mo. The underlying liver diseases were classified into either liver cirrhosis (LC) or non-cirrhotic CLD. LC was evidenced by previous ultrasonography (i.e., coarse liver architecture, nodular liver surface and blunt liver edges) as well as confirmation of hypersplenism (i.e., splenomegaly on ultrasonography with a platelet count $< 100\ 000/\text{mm}^3$)^[3]. Patients with underlying CLD of non-viral origin were excluded.

The patients were classified into the following five groups according to age: (1) **Group A: 21 to 30 years**; (2) **Group B: 31 to 40 years**; (3) **Group C: 41 to 50 years**; (4) **Group D: 51 to 60 years**; and (5) **Group E: greater than 60 years of age**. The study was approved by the local university's Research and Ethics Committee and complied with the Declaration of Helsinki.

Detection of HAV IgG, HBV and HCV infections

Immunity towards hepatitis A was established by detection of anti-HAV IgG using commercially available immunoassay kits for anti-HAV IgG (Abbot Laboratories, Chicago, Illinois, United States) that rely on microparticle enzyme immunoassay methods. Presence of hepatitis B virus (HBV) and hepatitis C virus infection was determined by detection of HBsAg and anti-HCV antibodies, respectively.

Statistical analysis

All data analyses were carried out using SPSS statistical software (Version 12.0.1). Continuous variables were expressed as mean and standard deviation for normally distributed data while categorical variables were expressed as frequency and percentage. A chi-square (χ^2) test was used to determine whether significant differences exist between two categorical variables. Results were reported as significant when $P < 0.05$. For multivariate analyses, a stepwise multivariate logistic regression model was employed to assess the relative importance of variables showing a significant association ($P < 0.05$) or any other clinically important variables in univariate analysis ($P < 0.10$). Results of all multivariable analyses were reported as adjusted odds ratio, 95% CI and exact P value.

RESULTS

The mean age at presentation was 44.4 ± 14 years (range 21-76 years). Males comprised the majority of the study population (62.2%). The Malay constituted the highest proportion of the study subjects (80.7%). This distribution reflects the current ethnic diversity in our population.

The aetiology of the underlying liver disease was chronic HBV infection in 96 (80.7%) patients, while chronic HCV infection was present in the remainder of the population (19.3%). The distribution of disease status was LC (14.3%), while others were in the non-cirrhotic group (Table 1).

The overall prevalence of anti-HAV was 88.2% (105/119), while seroprevalence differed greatly based on age group: 66.7% in Group A, 95.5% in Group B, 93.5% in Group C, 91.3% in Group D and 94.7% in Group E (Figure 1). The anti-HAV prevalence was significantly lower in patients younger than 30 years of age when compared to those who were in the older age groups (Table 2). Multivariate analysis of age category variables also showed a significant difference between patients younger than 30 years when compared to those who were in the older age groups, with the exception of

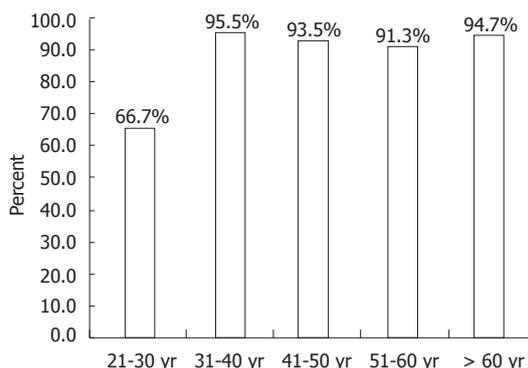

Figure 1 Seropositivity of anti-hepatitis A virus IgG according to age groups.

als from Kuala Lumpur in 1983 and reported a seroprevalence of hepatitis A of 78.2%. In 1985, a study reported that 100% of a Malaysian population were anti-HAV positive by 30 years of age^[25]. However, in 1992, only 45% of the same age group were antibody-positive, indicating a shifting epidemiology, most probably due to improvements in living standards^[25]. In the present study, we found that the overall anti-HAV seropositivity was high, at 88.2%. The higher seroprevalence of hepatitis A in our chronic viral hepatitis patients compared to previously reported seroprevalence for normal individuals was most likely related to the characteristics of the studied population in this region. This study was conducted in Kelantan, which is located in the north-eastern corner of the peninsula facing the South China Sea, with a chiefly agrarian economy. The population has diverse socioeconomic status and large income inequalities. The previous study was conducted in Malaysia's capital, Kuala Lumpur^[24], which has higher living standards, while the other included paediatric age groups with lower expected natural immunity^[26]. Therefore, it is possible that the seroprevalence of HAV in other parts of Malaysia might not be similar to our findings, and we recommend further study in each locality to determine this. It is also possible that CLD patients have a higher prevalence of HAV positivity than the normal population. Contradicting this, Joshi and colleagues have revealed similar hepatitis A seroprevalence differences between CLD and normal populations in India^[21].

We also show that the main factor that influences the rate of positivity is the age group. The seroprevalence

rates in patients in Groups B, C, D and E were greater than 90%, compared to only 66.7% in patients belonging to Group A. These data imply that most patients with chronic viral liver disease who are greater than 30 years of age may have been exposed to HAV infection and have therefore already acquired natural immunity towards the disease. Therefore, routine HAV vaccination cannot be recommended in this age group. However, there remains the need to vaccinate patients aged less than 30 years with chronic liver disease.

Malaysia is a multiracial country consisting of three major ethnic groups: Malay, Chinese and Indian. Because the Indian population is generally very small in Kelantan, we did not manage to enrol any Indian patients, and only the Malay and Chinese races could be compared. There was no significant difference in the seroprevalence rate between these two ethnicities. However, this should be interpreted with caution, as various sociocultural behaviours may also play a role in influencing viral transmission rates.

The anti-HAV seropositive rate was 86.5% in hepatitis B and 95.7% in hepatitis C. Even though chronic hepatitis C is a different disease entity from chronic hepatitis B, there was no significant difference in anti-HAV positivity according to aetiology of underlying chronic liver disease ($P > 0.05$). This could be due to the small sample size of patients with hepatitis C infection ($n = 23$) in our study. Notably, the seroprevalence of hepatitis A was higher in hepatitis C patients than in hepatitis B patients, which is consistent with Korean data, where 100% of chronic hepatitis C patients were anti-HAV IgG positive compared to only 86.1% of hepatitis B patients^[27]. Similarly, the Korean and Indian studies also failed to demonstrate any significance in hepatitis A seropositivity in relation to chronic liver disease aetiology^[21,27].

All cirrhotic patients were anti-HAV positive, compared to only 86.3% in non-cirrhotic liver disease cases. The higher prevalence in cirrhotics was due to these patients falling into an older age group (mean age 52.4 ± 13.4) than non-cirrhotics (mean age 43.06 ± 13.7), as shown by multiple logistic regression analyses. Various studies, particularly those in highly endemic regions such as India, have demonstrated that the majority of cirrhotic patients of any aetiology are positive for anti-HAV IgG. A study from New Delhi revealed that 97.6% of cirrhotics (248/288) were found to be positive for anti-HAV^[28]. Another study from South India demonstrated that 51 out of 52 patients with cirrhosis had antibodies towards HAV^[29]. All these studies proposed that the higher seroprevalence of anti-HAV IgG in cirrhotic patients was actually related to increased age. Our findings are in agreement with the results of these studies.

Our study demonstrated that the overall hepatitis A seroprevalence was higher in CLD patients in Kelantan compared to the previously determined prevalence in normal individuals in other parts of Malaysia. Age was the most important factor in determining anti-HAV positivity, and most patients greater than 30 years of age

were likely to have natural immunity.

ACKNOWLEDGMENTS

We would like to thank Dr. Habsah Hasan for her skilful help in conducting the anti-HAV IgG tests.

COMMENTS

Background

Populations in developed countries may not have had prior exposure to hepatitis A virus (HAV) and, therefore, no natural immunity; thus, there is a need for hepatitis A vaccination in selected high-risk groups. **In view of this, Western guidelines advocate hepatitis A vaccination for those with chronic liver disease (CLD), as infection may lead to further deterioration of liver function, which can then cause significant morbidity and mortality amongst these patients.**

Research frontiers

Over the last 20 years, patterns of endemicity in South East Asia have changed due to improvements in living standards, with some countries shifting from high to intermediate or intermediate to low endemicity. **The question remains as to the importance of hepatitis A vaccination amongst hepatitis B and C CLD patients in Malaysia, a country of intermediate endemicity for hepatitis A. To answer this, a research team from Universiti Sains Malaysia determined the prevalence and associated factors of natural immunity towards hepatitis A amongst these patients in the eastern region of Peninsular Malaysia.**

Innovations and breakthroughs

The study demonstrated that the overall prevalence of natural immunity towards hepatitis A was high (88%). **There was a statistically significant difference when the data were broken down according to age. Results revealed that hepatitis B and C CLD patients less than 30 years of age were significantly less likely to have a natural immunity towards hepatitis A. This implies that although hepatitis A vaccination is not needed for the majority of CLD patients, a subset of patients (particularly patients who are younger than 30 years old) will still benefit from being vaccinated.**

Applications

Study results show that for north-eastern Peninsular Malaysia, there is currently no need for routine hepatitis A vaccination amongst hepatitis B and C CLD patients. **However, CLD patients who are younger than 30 years of age will still benefit from being vaccinated.** Patterns of endemicity in South East Asian countries are expected to change; in Malaysia, the prevalence of hepatitis A viral exposure is expected to fall with time. **Thus, there is a need to repeat this study in the future, as it is expected that the prevalence of natural immunity towards hepatitis A will fall as the country becomes more developed.**

Peer review

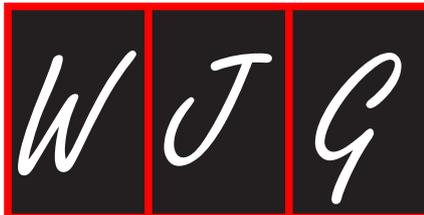

The authors investigated the seroprevalence of anti-HAV antibodies in patients with CLD and the need for vaccination in the region of Kelantan, Malaysia.

Abstract

AIM: To characterise the viral kinetics of enterovirus 71 (EV71).

METHODS: In this study, human rhabdomyosarcoma (RD) cells were infected with EV71 at different multiplicity of infection (MOI). After infection, the cytopathic effect (CPE) was monitored and recorded using a phase contrast microscope associated with a CCD camera at different time points post viral infection (0, 6, 12, 24 h post infection). Cell growth and viability were measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay in both EV71 infected and mock infected cells at each time point. EV71 replication kinet-

ics in RD cells was determined by measuring the total intracellular viral RNA with real-time reverse-transcription polymerase chain reaction (qRT-PCR). Also, the intracellular and extracellular virion RNA was isolated and quantified at different time points to analyze the viral package and secretion. The expression of viral protein was determined by analyze the levels of viral structure protein VP1 with Western blotting.

RESULTS: EV71 infection induced a significant CPE as early as 6 h post infection (p.i.) in both RD cells infected with high ratio of virus (MOI 10) and low ratio of virus (MOI 1). In EV71 infected cells, the cell growth was inhibited and the number of viable cells was rapidly decreased in the later phase of infection. EV71 virions were uncoated immediately after entry. The intracellular viral RNA began to increase at as early as 3 h p.i. and the exponential increase was found between 3 h to 6 h p.i. in both infected groups. For viral structure protein synthesis, results from western-blot showed that intracellular viral protein VP1 could not be detected until 6 h p.i. in the cells infected at either MOI 1 or MOI 10; and reached the peak at 9 h p.i. in the cells infected with EV71 at both MOI 1 and MOI 10. Simultaneously, the viral package and secretion were also actively processed as the virus underwent rapid replication. The viral package kinetics was comparable for both MOI 1 and MOI 10 infected groups. It was observed that at 3 h p.i., the intracellular virions obviously decreased, thereafter, the intracellular virions began to increase and enter into the exponential phase until 12 h p.i. The total amounts of intracellular virions were decreased from 12 to 24 h p.i. Consistent with this result, the increase of virus secretion occurred during 6 to 12 h p.i.

CONCLUSION: The viral kinetics of EV71 were established by analyzing viral replication, package and secretion in RD cells.

INTRODUCTION

Enterovirus 71 (EV71) is a member of human enterovirus species which belongs to the *Picornaviridae* family. It is one of the major causative agents for herpangina and hand, foot and mouth disease (HFMD)^[1,2]. Among young children, acute EV71 infection may also cause severe neurological diseases such as encephalitis and meningitis that lead to significant mortality^[3,4]. Recently, outbreaks of EV71 infection have been frequently reported throughout the world^[5-10]. In China, a recent outbreak of EV71 infected more than 1.4 million children and caused 760 deaths from January to July, 2010. It is also noted that an adult died due to EV71 infection in Hong Kong in May, 2010 (http://www.hkcd.com.hk/content/2010-05/28/content_2531606.htm).

EV71 is a small RNA virus containing a non-enveloped capsid and a single-stranded positive genomic RNA (about 7400 bp)^[11]. The life cycle of EV71 was speculated according to studies on other enteroviruses. EV71 would attach to the host cell *via* its specific receptors^[12] and then the viral genomic RNA is released into the cytoplasm, where it directly translates into a polyprotein. This precursor protein can subsequently be cleaved into four structural (VP1, VP2, VP3 and VP4) and seven non-structural (2A, 2B, 2C, 3A, 3B, 3C and 3D) proteins^[4]. For virus RNA replication, a complementary minus-strand RNA is synthesised in the cytoplasm and then this minus-strand RNA can serve as a template for new plus-strand RNA molecules. Newly synthesized virus RNA may go into another round of translation and replication, or is packaged into capsid proteins to produce infectious viral particles (see review in Ref.[13]). Studies on other viruses demonstrate that the knowledge of virus kinetics is important for clarifying viral pathogenesis and exploring effective treatments. The knowledge of the viral kinetics on human immunodeficiency virus, hepatitis B virus and hepatitis C virus has greatly improved the understanding of the cell response to these viruses and mechanisms of related antiviral therapy^[14-16]. In the *Picornavirus* family, the kinetics of swine vesicular disease virus (SVDV) and foot-and-mouth disease virus (FMDV) have been described in several studies^[17,18]. However, little information is known about EV71 infec-

tion. In this study, we used rhabdomyosarcoma (RD) cells as an *in vitro* model and intensively investigated the viral kinetics of EV71, including the kinetics of viral replication, viral protein synthesis, packaging and secretion.

MATERIALS AND METHODS

Cell culture and virus propagation

RD cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% (v/v) fetal bovine serum (FBS), 100 U/mL penicillin and 100 µg/mL streptomycin. EV71 strain SHZH98 (GenBank accession number AF302996.1) was obtained from Shen-zhen Center for Disease Control and Prevention, Shenzhen, China. To prepare virus stocks, viruses were propagated on a 90% confluent cell monolayer in DMEM with 2% FBS. The viral titres were measured by the cytopathic effect (CPE) microtitration assays and expressed as 50% tissue culture infective dose (TCID₅₀) per millilitre (mL) according to the Kärber formula^[19].

Viral infection and cytopathic effects assay

RD cells were cultured in 12-well plates and infected with nil or EV71 at multiplicity of infection (MOI) 1 and 10, respectively. Briefly, plated cells were washed twice with phosphate buffered saline (PBS) and infected with EV71. Time was set as zero after adsorption for 1 h. The culture media were removed and cells were washed twice with PBS to remove unattached virus before adding 1 mL of DMEM medium containing 10% FBS to each well. The cells were cultured at 37 °C in 5% CO₂. The cell morphology was monitored and recorded using a phase-contrast microscope associated with a CCD camera and computer at different time points. The infected cells and culture supernatants were harvested to isolate RNA and proteins.

MTT assay

MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] assays were performed to determine the cell viability upon EV71 infection. Briefly, RD cells were set in 96-well plates at 1×10^4 cells per well 24 h before infection with EV71 at MOI 1 or MOI 10. The medium was then replaced with 0.5 mg/mL MTT medium at different time points and incubated for another 4 h. The MTT solution was removed from the wells and the formazan crystals were dissolved in DMSO. Absorbances of the formazan products were measured at 550 nm with the reference wavelength at 690 nm.

RNA isolation

For intracellular viral RNA quantification, the total cellular RNA was isolated from EV71 infected cells using TRIzol reagent (Invitrogen, United States) according to the manufacturer's instructions. To quantitate the extracellular virions, we first isolated the virions from the culture media of infected cells. The media were harvested and briefly centrifuged to remove cell debris. Viral core

particles were then precipitated with 10% polyethylene glycol 8000 containing 0.5 mol/L NaCl at 4 °C overnight. After centrifuging for 30 min at 16000 *g*, viral particles were pelleted and treated with 100 µg/mL of RNase A (Sigma, United States). To isolate the intracellular virions, EV71 infected cells were lysed with lysis buffer (1% Triton 100 and 1 × Roche protease inhibitor cocktail in PBS). Then the cell lysates were used to isolate viral particles as described above. The virion-associated RNA was then isolated by using TRIzol reagent. To set up the standard curve of infectious viruses, the viral titres were first determined by CPE assay. Then the viral RNA was extracted from those infectious EV71 viruses. RNA was diluted at ten-fold serial and used to reflect the calculated PFU from 10 to 1 × 10⁷ live virions.

Quantitative reverse transcription-polymerase chain reaction

The one-step quantitative real-time polymerase chain reaction (qRT-PCR) was carried out using the ABI 7500 Real-Time PCR system (Applied Biosystems) with QuantiTect SYBR Green RT-PCR Kit (Qiagen) and specific forward EV71-VP1F (5'-GCAGCCCCAAA-GAAGTTTCAC-3') and reverse EV71-VP1R (5'-ATTTCAGCAGCTTGGAGTGC-3') primers targeting a conserved region of the VP1 gene^[20]. PCR assay was carried out in a 20 µL volume consisting of 10 µL of 2 × QuantiTect SYBR green RT-PCR Master Mix, containing HotStarTaq DNA polymerase, 1 µL of 10 µmol/L of each oligonucleotide primer, 0.2 µL of 100 × QuantiTect RT Mix (containing Omniscript and Sensiscript reverse transcriptases) and 2 µL of RNA extracted from samples or from ten-folds serial diluted virus RNA standard (from 10⁷ to 10 copies). The target fragment amplification was carried out as follows: reverse transcription at 50 °C for 30 min; initial activation of HotStar Taq DNA Polymerase at 95 °C for 15 min; 45 cycles in four steps: 94 °C for 10 s, 56 °C for 30 s, and 72 °C for 30 s. At the end of the amplification cycles, melting temperature analysis was carried out by a slow increase in temperature (0.1 °C/s) up to 95 °C.

Western blotting

To prepare total cellular protein extracts, the cells were lysed with RIPA buffer (50 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl, 1 mmol/L EDTA, 1% Triton X-100, 0.1% SDS, 1 × Roche protease inhibitor cocktail) with occasional vortexing. Lysates were collected by centrifugation at 14000 *g* for 10 min at 4 °C and protein concentrations were measured by the Bradford method (Bio-Rad, United States). Equal amounts (20 µg) of proteins from each sample were separated through 12% SDS-PAGE and transferred onto polyvinylidene difluoride (PVDF) membranes (Amersham Biosciences). Membranes were blocked by 5% skim milk in Tris-Buffered Saline Tween-20 (TBST) (20 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, 0.1% Tween 20) followed by incubation with specific antibodies against VP1 (PAB7631-

D01P, Abnova) or GAPDH (Santa Cruz Biotechnology). Target proteins were visualized with horseradish peroxidase-conjugated secondary antibodies (Santa Cruz Biotechnology) and a chemiluminescence detection system (Amersham Biosciences). Each immunoblotting was carried out at least three times.

Statistical analysis

Data are depicted as mean ± SD. All statistical analyses were carried out with SPSS 14.0 software (SPSS Inc.). Two-tailed Student's *t* test was applied for two-group comparison. *P* < 0.05 was considered statistically significant.

RESULTS

Cytopathic effects and the kinetic of cell viability

Morphological changes were observed as early as 6 h p.i. when RD cells were infected with EV71 at either MOI 1 or 10 (Figure 1A, panels f and j). Initially, the cells rounded up and became more refractile. As the culture progressed, some infected cells detached from the culture plate and floated into the medium (Figure 1A, panels g, h, k and l). Compared with the cells infected at MOI 1, more cells were unhealthy at 6 h p.i. when infected at MOI 10 (Figure 1A, panel j *vs* f). Later on, the cells infected with EV71 both at MOI 1 and 10 underwent significant cell death and detached from the surface of culture dishes (Figure 1A, panels g and k). At 24 h p.i., most of the cells were detached from the surface of the plate in both infected groups (Figure 1A, panels h and l). The MTT assay showed that the viability of the cells infected with EV71 at MOI 1 did not significantly decrease at 12 h p.i., but slightly reduced in cells infected at MOI 10 (Figure 1B). At 18 and 24 h p.i., the viability of the cells infected with EV71 either at MOI 1 or 10 significantly decreased.

The kinetics of viral replication

To examine the kinetics of viral replication, the levels of intracellular viral RNA were measured by qRT-PCR at each time point. As shown in Figure 2, the intracellular viral RNA began to increase as early as 3 h p.i. and the exponential phase was from 3 to 6 h p.i. in both infected groups. In the case of infection at MOI 1, the intracellular viral RNA continually increased from 6 to 12 h p.i., and then gradually decreased until 24 h p.i. In the case of MOI 10, the intracellular viral RNA reached a peak between 6 and 9 h p.i., and then began to decrease.

The kinetics of viral protein synthesis

The intracellular viral protein VP1 was not detected until 6 h p.i. in the cells infected at MOI 1 and 10 (Figure 3). The VP1 protein level reached a peak at 9 h p.i. in the cells infected with EV71 at both MOI 1 and MOI 10. Obviously, the VP1 levels were much higher in the cells infected at MOI 10 than at MOI 1. In the case of infection at MOI 1, the VP1 level was maintained until 12 h p.i.; whereas the

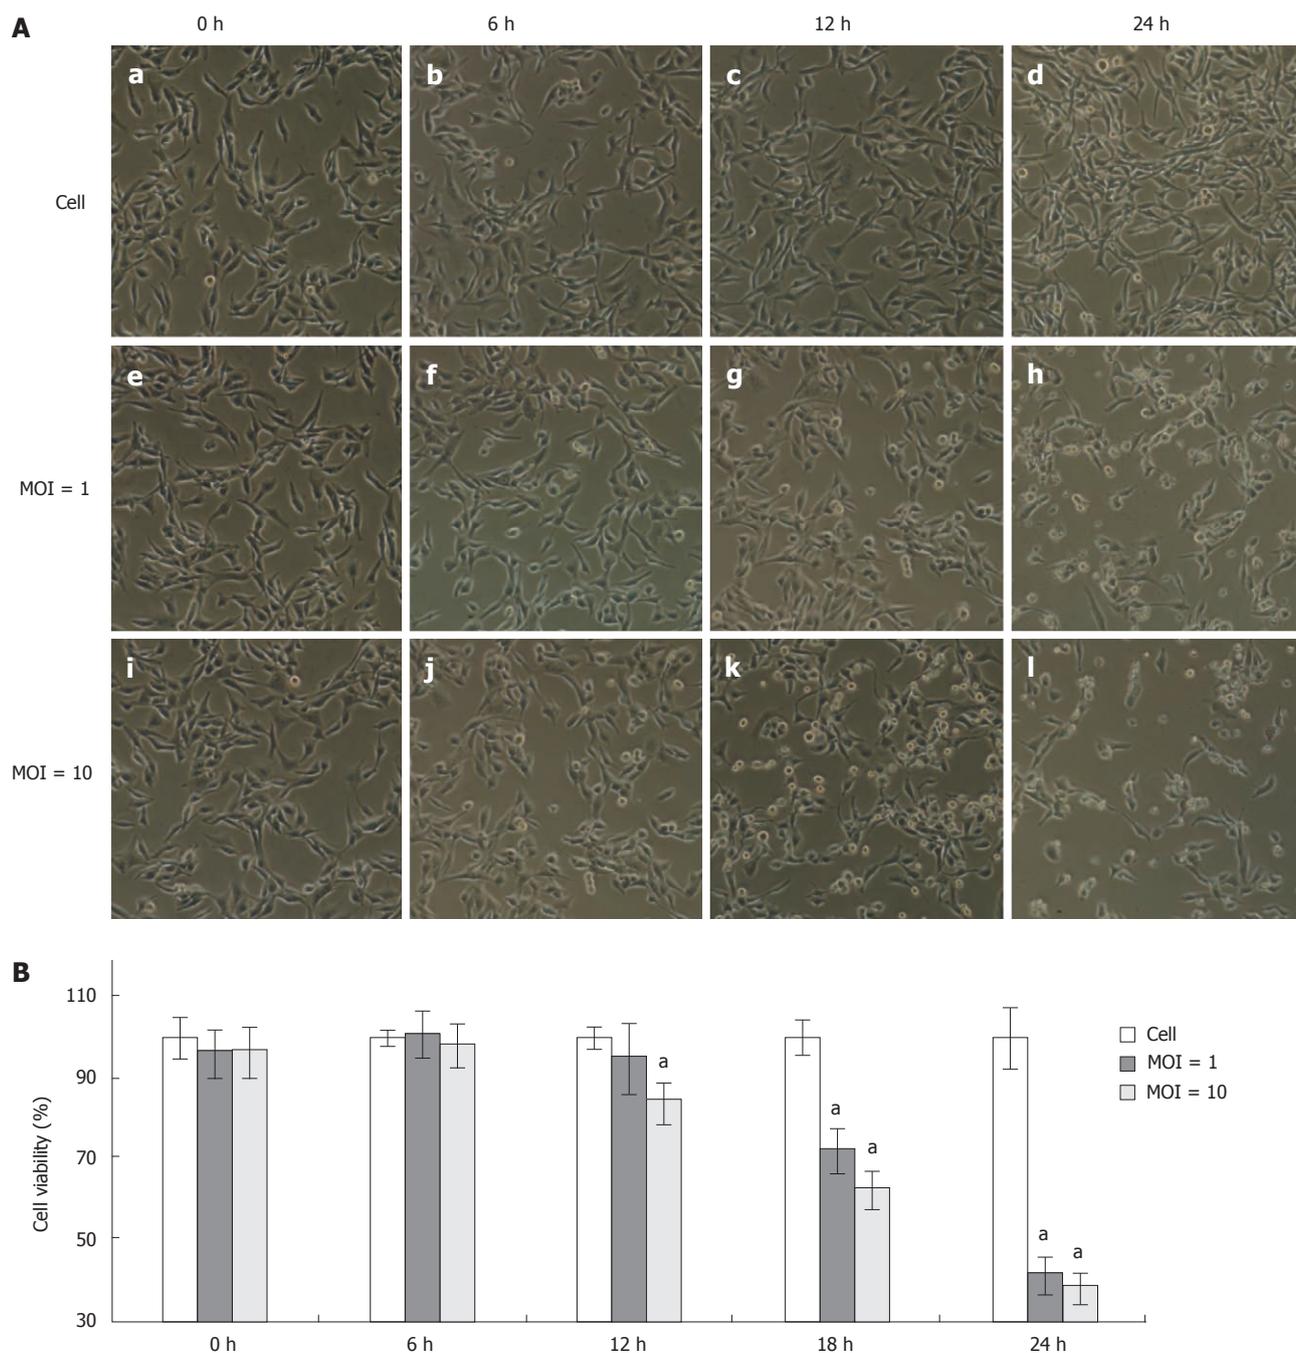

Figure 1 Cytopathic effects and kinetics of cell viability upon enterovirus 71 infection. Rhabdomyosarcoma cells were infected with enterovirus 71 (EV71) at multiplicity of infection (MOI) 1 or MOI 10. A: The cytopathic effects were shown by cell morphological changes (original magnification, $\times 100$); B: Cell viability was measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assays at different time points after EV71 infection. Data are the mean \pm SD of three independent experiments, each carried out in triplicate. $^{\#}P < 0.05$.

VP1 protein level rapidly decreased after 9 h p.i. when the cells were infected with EV71 at MOI 10.

The kinetics of viral package

To determine the kinetics of virus package, the intracellular EV71 virions were quantified at different time points p.i. At 3 h p.i., the intracellular virions significantly decreased. Thereafter, the intracellular virions began to increase and enter into the exponential phase until 12 h p.i. when the amount of intracellular virions reached a peak.

The viral package kinetics were comparable for both the MOI 1 and MOI 10 infected groups (Figure 4). The total amounts of intracellular virions then decreased from 12 to 24 h p.i.

The kinetics of viral secretion

To determine the kinetics of virus secretion, the extracellular EV71 virions were quantitated. The EV71 virions began to be released from the cells infected either at MOI 1 or 10 3 h p.i. (Figure 5). The amounts of extra-

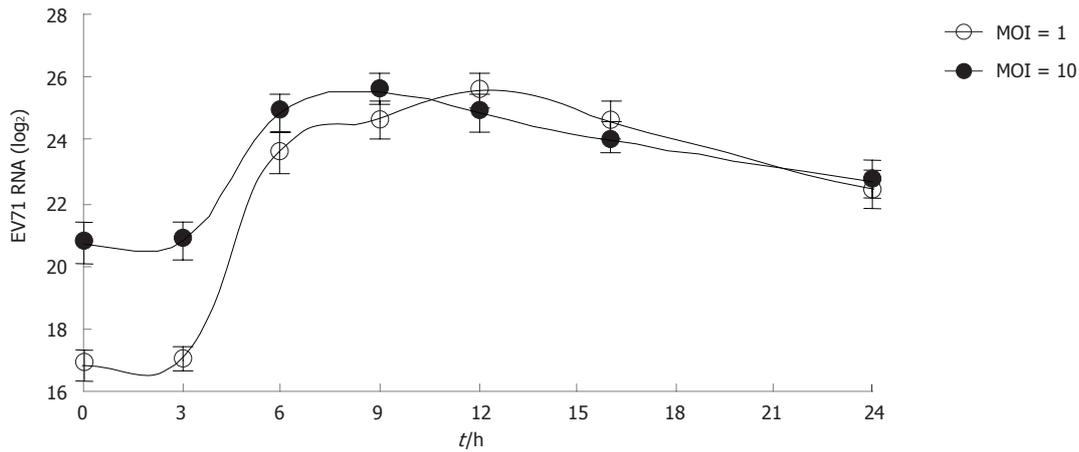

Figure 2 The kinetics of enterovirus 71 Replication. Rhabdomyosarcoma cells were infected with enterovirus 71 (EV71) virus at multiplicity of infection (MOI) = 1 or MOI = 10. At the indicated time points, the levels of total intracellular viral RNA were measured by quantitative real-time polymerase chain reaction. Data are the mean ± SD of three independent experiments; each carried out in triplicate.

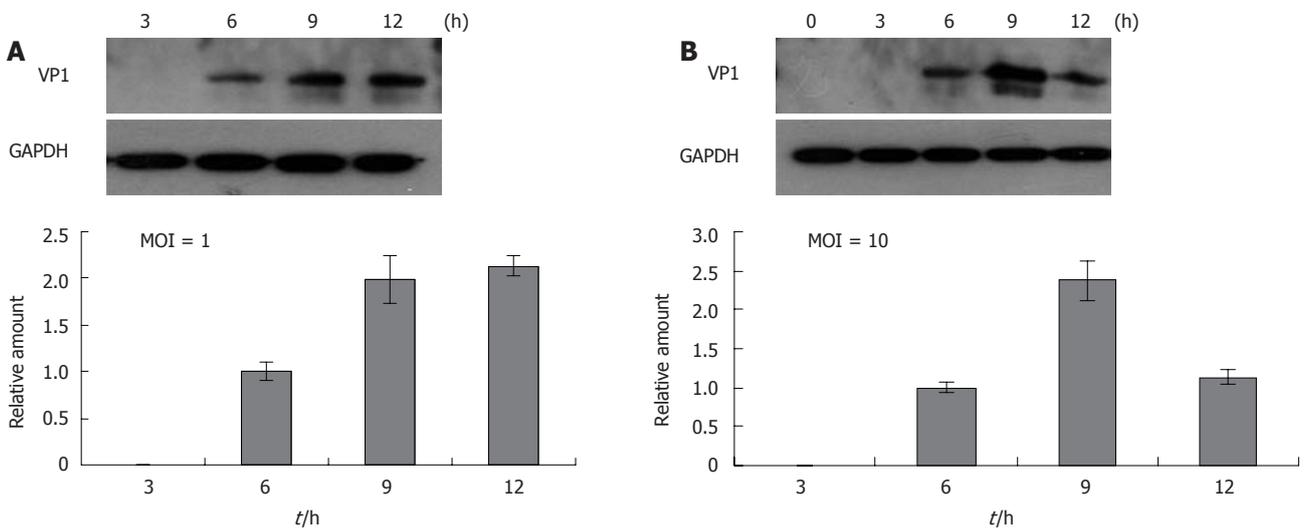

Figure 3 The kinetics of virus VP1 protein synthesis. Rhabdomyosarcoma cells were infected with enterovirus 71 (EV71) virus at multiplicity of infection (MOI) = 1 (A) and MOI = 10 (B). The intracellular viral protein VP1 was measured by Western blotting. The relative VP1 levels (the density of VP1/GAPDH) were calculated and are shown as solid bars.

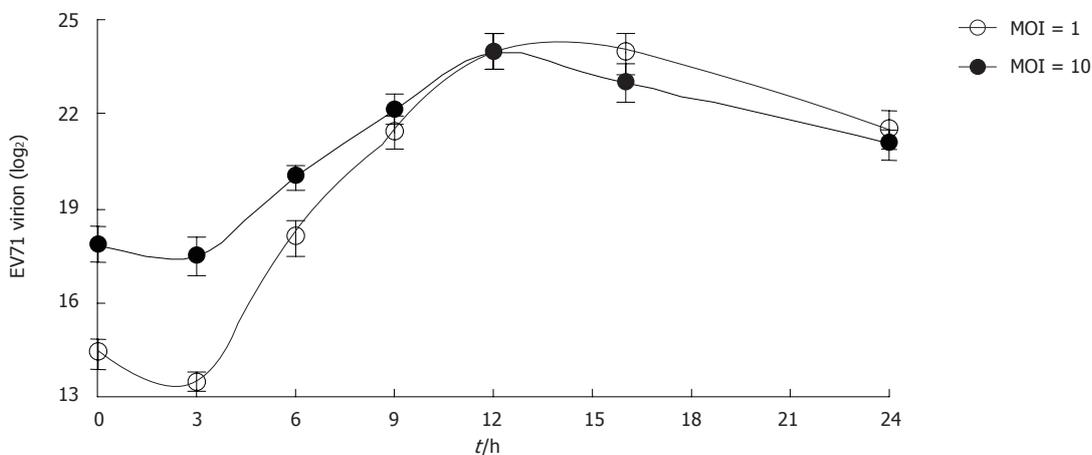

Figure 4 The kinetics of enterovirus 71 virus package. Rhabdomyosarcoma cells were infected with enterovirus 71 (EV71) virus at multiplicity of infection (MOI) = 1 or MOI = 10. The intracellular virus particles were isolated to measure the virion RNA by quantitative real-time polymerase chain reaction. Data are the mean ± SD of three independent experiments; each carried out in triplicate.

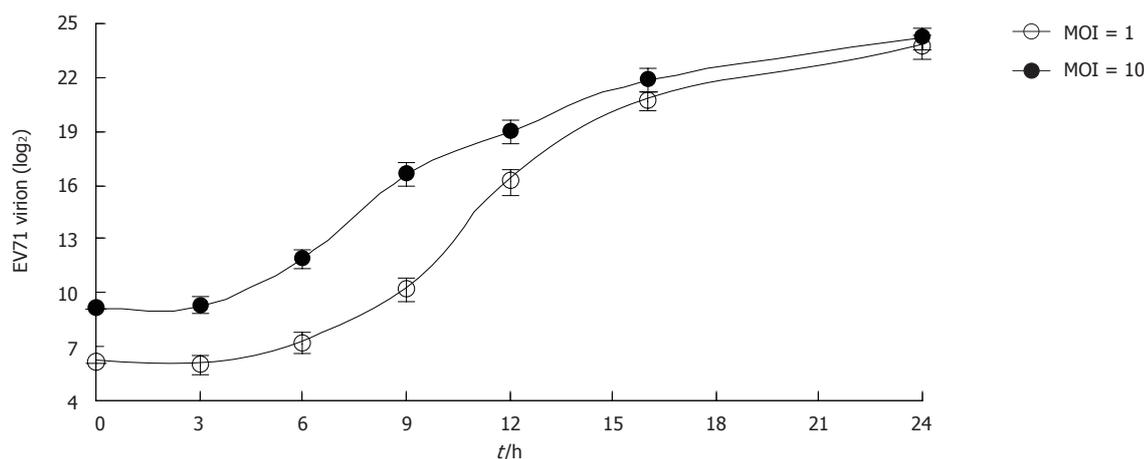

Figure 5 The kinetics of enterovirus 71 virus secretion. Rhabdomyosarcoma cells were infected with enterovirus 71 (EV71) virus at multiplicity of infection (MOI) = 1 or MOI = 10. Extracellular EV71 virions in the culture media were measured by quantitative real-time polymerase chain reaction at different time points post infection. Data are the mean \pm SD of three independent experiments; each carried out in triplicate.

cellular EV71 virions in the cultures of the two groups were constitutively increased. From 3 to 6 h p.i., the virions were slowly secreted into the culture media, and the virus secretion entered into the exponential phase from 6 to 12 h p.i. At 12 h p.i., the rate of increase declined and the total amount of extracellular virions reached a maximum at 24 h p.i. For cells infected at MOI 1 or 10, the virions in the culture media were similar at 24 h p.i.

DISCUSSION

Viral kinetics is an important parameter for demonstrating viral activities in the host cells and provides basic information on viral-host interactions and pathogenesis. The kinetics of some picornaviruses such as SVDV and FMDV have been described in several studies^[17,18]. However, little information on EV71 is available. Some studies provided brief descriptions on EV71 RNA replication and the growth kinetics of EV71 infected cells, however, the infection ratios used in these studies were too low (MOI \leq 0.01) to guarantee the synchronicity of infection^[21,22]. In this situation, some cells were undergoing cell death, whereas others just had a chance to be infected by new EV71 viruses secreted from the first round infected cells. Therefore, the viral life cycle could not be accurately examined. In addition, with the exception of RNA synthesis, no information was provided on viral protein expression, virus package and secretion. Our study, for the first time, comprehensively described the detailed viral kinetics in human RD cells. As RD cells infected by EV71 would develop cellular pathogenesis (CPE), these cells have been extensively used to investigate the viral activities of EV71 and host responses to EV71 infection^[23-26]. To obtain a synchronized infection, RD cells were pulse infected at high MOIs (MOI 1 and 10) to ensure that the majority of the cells were primarily infected in our study. Following infection, the unattached viruses were removed by washing the cells twice with PBS. This would minimize the interference of non-infectious virions. In this study, the kinetics of

viral replication, gene expression, package and secretion as well as the effects of viral activities on host cells were carefully examined at different time points.

We showed here that the intracellular virions significantly decreased by over 90% at 3 h p.i. (Figure 4), while the total intracellular RNA copies remained almost at the same levels (Figure 2). These results suggested that the virions were immediately uncoated after entry and virus replication was inactive within the first 3 h after infection. During this phase, the viral RNA could be translated to generate viral proteins essential for viral replication. From 3 to 6 h p.i., the virus underwent fast replication and the total intracellular viral RNA was rapidly accumulated (Figure 2). Similar results were also reported in other poliovirus infection^[27]. The total intracellular viral RNA increased by more than 64-fold within this period. In the meantime, viral gene expression was also initiated along with viral replication, as viral VP1 proteins in the host cells were clearly detected at 6 h (Figure 3). The viral package was also started (Figure 4) but very few virions were secreted (Figure 5). At 6 h p.i., about 1% (MOI 1) to 3% (MOI 10) of viral RNA was packaged into virions (Figures 2 and 4). Although the virus was rapidly replicating, the host cells were generally healthy during this period. From 6 to 9 h p.i., some cells became unhealthy (Figure 1), the viral replication entered a static stage as the total intracellular viral RNA only increased by about 2-fold in the MOI 1 and MOI 10 group. In the case of MOI 1, the total intracellular viral RNA increased a further 2-fold from 9 to 12 h p.i., but began to decrease 9 h p.i. in the cells infected at MOI 10. This suggested that viral RNA in cells infected with higher MOI reached maximal levels earlier. The viral gene expression and package were also actively processed in this period. The viral protein VP1 levels reached a peak at 9 h p.i. and rapidly decreased at 12 h p.i. in the MOI 10 group. In the case of MOI 1, the VP1 levels also reached a maximum at 9 h p.i. and maintained the same levels at 12 h p.i. Following viral protein synthesis, the intracellular virions also rapidly increased over 16-fold (MOI 10) or

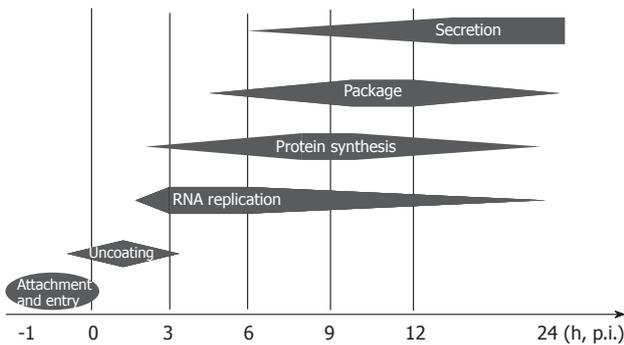

Figure 6 Schematic view of enterovirus 71 activities in rhabdomyosarcoma cells. Within one hour of inoculation, enterovirus 71 would first attach and enter into the host cell *via* its specific receptors. The virus was then uncoated in the first 3 h and started to synthesize the essential viral proteins for replication. From 3 to 6 h p.i., the virus rapidly replicated its genomic RNA and initiated structure protein synthesis. Fast viral package was observed from 6 to 12 h p.i. and virion secretion increased from 6 h p.i. to the end of the observation period.

64-fold (MOI 1). In both cases, the intracellular virions reached a peak and about 30% of viral RNA was packaged into the virions at 12 h p.i. (Figure 4 *vs* Figure 2). In the case of MOI 1, the extracellularly accumulated virions increased 8- and 64-fold from 6 to 9 h, and 9 to 12 h, respectively; while the extracellularly accumulated virions increased 30- and 5-fold during the same periods in the MOI 10 group. From 12 to 24 h p.i., as more and more infected cells became unhealthy and died, the intracellular viral RNA levels significantly decreased and viral replication became less active. These findings suggested that the cells could no longer sustain further viral replication and died^[28-30]. This was further supported by the data on intracellular and extracellular virion levels. We showed here that the intracellular virions maintained high levels at 16 h p.i. although more and more virions were secreted into the culture media. After that, the ratio of packaged viral RNA to total viral RNA was constant at about 50% in both the MOI 1 and MOI 10 group.

In summary, we have established a viral kinetics model of EV71 in human RD cells (Figure 6). We showed that upon infection, the virus uncoated within the first 3 h and started to synthesize the essential viral proteins for replication. From 3 to 6 h p.i., the virus rapidly replicated its genomic RNA and initiated viral package. The fast viral package displayed from 3 to 12 h p.i. and virion secretion from 6 h p.i. continued until death of the host cells. Host cells started to become unhealthy as early as 6 h p.i. but still supported viral replication, package and secretion until death. Thus, our study provides important information for further investigations into virus-host interactions and host pathogenesis.

COMMENTS

Background

Enterovirus 71 (EV71) infection causes hand-foot-and-mouth disease (HFMD) and neurological disease. Recently, EV71 infection has become a major health threat in China. However, the mechanisms of these diseases caused by EV71

infection are still largely unknown.

Innovations and breakthroughs

Studies on other human viruses such as human immunodeficiency virus, hepatitis C virus and hepatitis B virus have highlighted the importance of understanding viral kinetics. In this study, for the first time, the authors fully described the viral kinetics of EV71 in rhabdomyosarcoma (RD) cells and characterized the activities during each step of viral replication in detail.

Applications

Accurate information on viral kinetics will provide a valuable reference for investigating EV71-host interactions and the pathogenic mechanisms of diseases caused by EV71 infection.

Terminology

EV71 is a small positive RNA virus. During viral replication, the complementary minus-strand RNA is synthesised first and serves as a template for the next round of translation and replication. Thus, the viral RNA levels in cells, viral particles and culture supernatants represent the relative levels of viral replication, package and secretion.

Peer review

The authors provided detailed information on EV71 replication, package, secretion and viral protein expression in RD cells. The rapid increase of intracellular EV71 viral RNA and viral particles revealed that EV71 RNA was synthesized soon after infection and the viral particles could immediately package and released. These results will provide important information for further understanding the viral pathogenesis and EV71-host interactions.

Abstract

AIM: To evaluate the comparative therapeutic efficacy of radiofrequency ablation (RFA) and hepatic resection (HR) for solitary colorectal liver metastases (CLM).

METHODS: A literature search was performed to identify comparative studies reporting outcomes for both RFA and HR for solitary CLM. Pooled odds ratios (OR) with 95% confidence intervals (95% CI) were calculated using either the fixed effects model or random effects model.

RESULTS: Seven nonrandomized controlled trials studies were included in this analysis. These studies included a total of 847 patients: 273 treated with RFA and 574 treated with HR. The 5 years overall survival rates in the HR group were significantly better than those in the RFA group (OR: 0.41, 95% CI: 0.22-0.90, $P = 0.008$). RFA had a higher rate of local intrahe-

patic recurrence compared to HR (OR: 4.89, 95% CI: 1.73-13.87, $P = 0.003$). No differences were found between the two groups with respect to postoperative morbidity and mortality.

CONCLUSION: HR was superior to RFA in the treatment of patients with solitary CLM. However, the findings have to be carefully interpreted due to the lower level of evidence.

INTRODUCTION

Colorectal cancer continues to be one of the most common human malignancies, afflicting nearly one million individuals worldwide every year^[1]. Approximately 50% of patients with colorectal cancer develop hepatic metastases during the course of their disease. Survival without treatment is very limited, with a median of 7.4 to 11 mo^[2]. Hepatic resection (HR) is the only chance of cure for patients with colorectal liver metastases (CLM) and 5 years survival rates after radical resection are about 27%-58%^[3]. However, the great majority of

patients with CLM present with unresectable disease, mainly due to the extent or distribution of their disease, or concurrent medical disability, so only up to 20% of patients are candidates for HR^[4,5]. So, many nonsurgical ablative methods have been developed. The most widely utilized modality is radiofrequency ablation (RFA), which includes generation of high-frequency alternating current which causes ionic agitation and conversion to heat, with subsequent evaporation of intracellular water which leads to irreversible cellular changes, including intracellular protein denaturation, melting of membrane lipid bilayers, and coagulative necrosis of individual tumor cells.

Although RFA has established its role in the treatment algorithm of patients with inoperable CLM as a safe, well tolerated, easily repeated and less invasive procedure^[2,6,7], the therapeutic efficacy of RFA for those with resectable CLM remains controversial, especially for solitary lesions. For example, Oshowo *et al*^[8] reported equivalent median (41 mo *vs* 37 mo) and 3 years overall survival rates (55.4% *vs* 52.6%) between HR and RFA groups, whereas White *et al*^[3] reported better 5 years (71% *vs* 27%) and overall median survival (56 mo *vs* 36 mo) for resection *vs* RFA.

Meta-analysis can be used to evaluate the existing literature in both a qualitative and quantitative way by comparing and integrating the results of different studies and taking into account variations in characteristics that can influence the overall estimate of the outcome of interest^[9]. Therefore, we evaluated the available evidence comparing the clinical efficacy and safety of RFA and HR for treatment of solitary CLM using meta-analysis.

MATERIALS AND METHODS

Study selection

A MEDLINE, EMBASE, OVID, and Cochrane database search was performed on all studies between 1996 and 2010 to compare RFA and HR for solitary CLM. The following MeSH search headings were used: “colorectal liver metastases”, “hepatic resection”, “radiofrequency ablation” and “comparative study”. Only studies on humans and in English language were considered for inclusion. Reference lists of all retrieved articles were manually searched for additional studies.

Data extraction

Two reviewers (BL and TW, respectively) independently extracted the following parameters from each study: (1) first author and year of publication; (2) number of patients, patients’ characteristics, study design; and lastly (3) treatment outcome. All relevant text, tables and figures were reviewed for data extraction. Discrepancies between the two reviewers were resolved by discussion and consensus.

Criteria for inclusion and exclusion

For inclusion in the meta-analysis, a study had to fulfill

the following criteria: (1) compare the initial therapy effects of RFA and HR for the treatment of solitary CLM; (2) report on at least one of the outcome measures mentioned below; (3) clearly document indications for RFA and HR; and (4) if dual (or multiple) studies were reported by the same institution and/or authors, the one of higher quality or the most recent publication was included in the analysis.

Abstracts, letters, editorials and expert opinions, reviews without original data, case reports and studies lacking control groups were excluded. The following studies were also excluded: (1) those dealing with multiple CLM; (2) those with no clearly reported outcomes of interest; and (3) those evaluating patients with primary liver cancer.

Study objectives

The primary outcome was efficacy, including 5 years overall survival, local intrahepatic recurrence or 5 years disease-free survival. The secondary outcome was safety, including the morbidity and mortality.

Statistical analysis

The meta-analysis was performed using the Review Manager (RevMan) software, version 4.2.7. We analysed dichotomous variables using estimation of odds ratios (OR) with a 95% confidence interval (95% CI). Pooled effect was calculated using either the fixed effects model or random effects model. Heterogeneity was evaluated by χ^2 and I^2 . We considered heterogeneity to be present if the I^2 statistic was $> 50\%$. $P < 0.05$ was considered significant.

RESULTS

Selection of trials

After initial screening, 13 potentially relevant clinical trials were identified^[3,8,10-20]. Of these, in three trials including patients with multiple metastases, it was impossible to extract or calculate the appropriate data regarding solitary CLM^[10-12], two trials included patients with non-colorectal cancer^[13,14], and one trial lacked information concerning 5 years overall survival^[15]; all 6 studies were excluded. Finally, a total of 7 nonrandomized studies published between 2003 and 2009 matched the inclusion criteria and were therefore included^[3,8,16-20].

The characteristics of these 7 studies are summarized in Table 1. The 7 studies included a total of 847 patients: 273 in the RFA group and 574 in the HR group. Four studies were conducted in United States^[3,16,17,20], two in Korea^[18,19], and one in United Kingdom^[3]. The sample size of each study varied from 45 to 192 patients. The proportion of men ranged from 46.6% to 66.6%. Median duration of follow-up ranged from 17 to 68 mo.

Efficacy

The pooled analysis of the 7 studies furnishing data demonstrated a significant improvement in 5 years overall survival favoring HR over RFA (OR: 0.41, 95% CI:

Review: Meta-analysis of radio frequency ablation *vs* hepatic resection for solitary colorectal liver metastasis

Comparison: 01 Efficacy

Outcome: 01 5 years overall survival

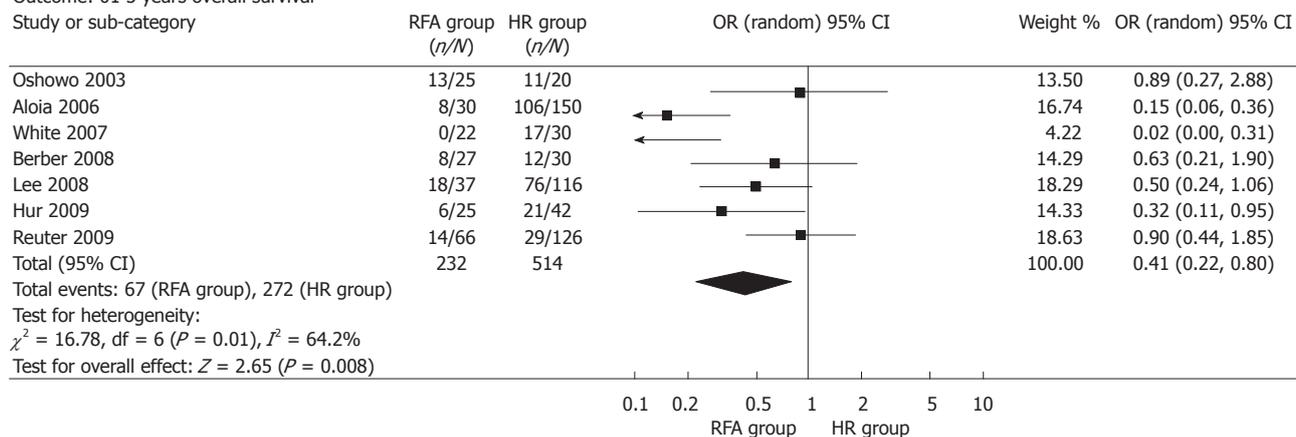

Figure 1 Results of the meta-analysis on 5 years overall survival. RFA: Radiofrequency ablation; HR: Hepatic resection; OR: Odds ratios; CI: Confidence intervals.

0.22-0.90, $P = 0.008$, $I^2 = 64.2\%$) (Figure 1).

Six trials investigated local intrahepatic recurrence^[3,16-20]. Local recurrence was more frequently observed after RFA than after HR (OR: 4.89, 95% CI: 1.73-13.87, $P = 0.003$, $I^2 = 77.3\%$) (Figure 2).

Only two studies reported on 5 years disease-free survival. Aloia *et al*^[16] reported that 5 years disease-free survival rates were higher after HR compared with RFA (50% *vs* 0%), whereas Lee *et al*^[18] reported equivalent results between two groups (25.7% *vs* 30.1%). We did not perform an analysis because of the small number of trials included in the review.

Safety

There was no statistically significant difference in the post-operative morbidity (five trials reported this data^[3,8,17,19,20], OR: 0.32, 95% CI: 0.07-1.52, $P = 0.15$, $I^2 = 75.6\%$) and mortality (all trials reported this data, OR: 0.58, 95% CI: 0.06-5.66, $P = 0.64$, $I^2 = 0\%$) between the two groups (Figures 3 and 4). There were no deaths reported in the

RFA group, and 2 in the HR group.

DISCUSSION

This meta-analysis shows that the HR treatment group had better 5 years survival outcomes than the RFA treatment group for solitary CLM. The major contributing factor for this finding may be the higher local recurrence rate after RFA. In addition to being more likely to have a recurrence, RFA patients also recurred earlier than resection patients^[3,20]. This could be due to incomplete ablation secondary to lesion size, heat sink effect, or the limitations of the modality^[20]. Resection of the entire area of preexisting tumor is more oncologically sound than attempting thermal destruction of a frequently ill defined region in the liver^[21]. This may explain the better outcomes following HR.

In a mouse xenograft model of CLM, von Breitenbuch *et al*^[22] revealed that RFA led to an increased survival of residual neoplastic cells and significantly promoted the

proliferation of neoplastic cells. Recently, Nijkamp *et al*^[23] found that RFA treatment resulted in a highly localized

hypoxia-driven acceleration of tumor growth occurring in the transition zone between necrosis induced by RFA and the normal liver tissue, and that the stimulated outgrowth of perilesional micrometastases is associated with profound and chronic microvascular disturbances, chronic tissue and tumor hypoxia, and stabilization of hypoxia-inducible factor (HIF)-1 α and HIF-2 α . These experimental findings may further explain the better outcome after RFA compared with HR in current study.

For liver metastases ≤ 3 cm, Mulier and colleagues found that local recurrence after RFA is extremely low in a recent review, and the authors proposed a randomized trial comparing resection and RFA for resectable CLM ≤ 3 cm is warranted^[24]. However, in a study of 79 patients with solitary CLM ≤ 3 cm, RFA treatment resulted in a higher local recurrence rate than HR treatment (31% *vs* 3%, respectively). RFA was also associated with a marked decrease in the 5 years survival rate and the 5 years local recurrence-free rate compared with those of HR (18% *vs* 72% and 66% *vs* 97%, respectively)^[16]. Similarly, another study of 60 patients showed that both time to recurrence after treatment of liver metastases and overall survival were significantly shorter, and marginal recurrence significantly more frequent, in the RFA group^[15]. Although Hur *et al.*^[19] reported equivalent 5 years survival rates (56.1% *vs* 55.4%) and local recurrence-free survival rates (95.7% *vs* 85.6%) between HR and RFA groups in patients with tumors ≤ 3 cm, it must be noted that the limited number of patients ($n = 38$) in their study might have insufficient power to detect any differences.

In that review, Mulier *et al.*^[24] stated that the two randomized clinical trials^[25,26] showed equivalent survival after percutaneous RFA and surgical resection for small HCC will encourage the use of RFA for resectable CLM. However, in one of the two studies, 19 of 90 patients (21%) who were randomized for RFA converted to HR^[25]. More importantly, a recently published meta-analysis and a randomized clinical trial both found that HR was superior to RFA in the treatment of patients with small HCC with respect to survival and local control of the disease^[27,28]. Thus, we agree with the idea proposed by Curley that “it is not yet time for a randomized clinical trial comparing resection with RFA for resectable CLM.”

The results of this meta-analysis should be interpreted with caution for several reasons. First, all of data in the present study comes from nonrandomized studies, and the overall level of clinical evidence is low. Second, there is important heterogeneity between two groups, because it was not possible to match patients characteristics in all studies. We applied a random effect model to take between study variation into consideration. This does not necessarily rule out the effect of heterogeneity between studies, but one may expect a very limited influence. Finally, potential publication bias might be present due to the small number of trials included in the current study.

In summary, HR was superior to RFA in the treatment of patients with solitary CLM. RFA should be reserved for patients who are not optimal candidates for

resection, rather than being used as a first-line therapeutic option. However, the findings have to be carefully interpreted due to the lower level of evidence.

COMMENTS

Background

Hepatic metastases are the commonest cause of morbidity and death of patients with colorectal cancer. Survival without treatment is very limited, with a median of 7.4 to 11 mo. Hepatic resection (HR) is the only chance of cure for patients with colorectal liver metastases (CLM) and 5 years survival rates after radical resection are about 27%-58%. Unfortunately, only up to 20% of patients are candidates for HR.

Research frontiers

Radiofrequency ablation (RFA) is an established effective nonsurgical ablative method for treatment of inoperable CLM, but its therapeutic efficacy for resectable CLM remains controversial, especially for solitary lesions.

Innovations and breakthroughs

This meta-analysis shows for the first time that HR was superior to RFA in the treatment of patients with solitary CLM with respect to survival and local control of the disease.

Applications

The results suggest that RFA should be reserved for patients with solitary CLM who are not optimal candidates for resection, rather than being used as a first-line therapeutic option.

Peer review

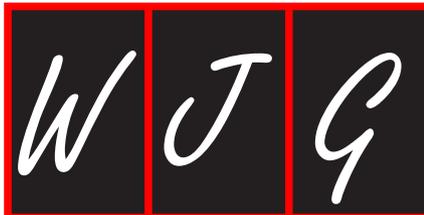

The article is a well written, well analysed one that is worth publishing.

Abstract

Understanding all facets of membrane microdomains in normal and cancerous cells within the digestive tract is highly important, not only from a clinical point of view, but also in terms of our basic knowledge of cellular transformation. By studying the normal and cancer stem cell-associated molecule CD133 (prominin-1), novel aspects of the organization and dynamics of polarized epithelial cells have been revealed during the last decade. Its association with particular membrane microdomains is highly relevant in these contexts and might also offer new avenues in diagnosis and/or targeting of cancer stem cells.

TO THE EDITOR

We read with great interest a recent Editorial entitled “Multifaceted nature of membrane microdomains in colorectal cancer” by Jahn *et al*^[1] published in issue 17 of the *World Journal of Gastroenterology* 2011 which proposes to describe the pioneering and recent studies on membrane microdomains (the so-called lipid rafts) and their potential roles in cancers. An important section dealing with prominin-1 (alias CD133), a cholesterol-binding glycoprotein often described as a stem and cancer stem cell marker, is unfortunately entirely based on a single publication released in 2009^[2], thus leaving out valuable biochemical and morphological information concerning CD133 and membrane microdomains from earlier works. We fear that as such, it might lead to underestimation of the importance and complexity of such a molecular association and contribute to certain confusion, particularly with regard to the debated AC133 epitope of CD133 and its association with cancer. We propose to expose here earlier overlooked data regarding its expression in epithelial cells and summarize the current knowledge on its cell biology and association with distinctive membrane microdomains. We hope that this might enlighten current issues regarding the implication of CD133 in colorectal cancer, whether it is in metastases, or as a prognostic marker or as a cancer stem cell marker.

Actually, the demonstration of the presence of CD133 in Caco-2 cells and its association with membrane microdomains is much less recent than 2009, since it was more than a decade ago that we reported its presence

in this widely used human colon carcinoma-derived cell line^[3]. The detection of CD133 by immunolabeling was originally documented by its particular epitope AC133 that appeared to be restricted to stem/progenitor cell populations but was also thought to be dependent on conformation and/or sensitive to changes in glycosylation^[4]. This antigen was attractive in the context of stem/progenitor and cancer stem cells and has often been used to define them in numerous organ systems including the digestive tract, but at the same time controversy was generated on the implication of CD133 as a specific marker^[5-10].

We have previously demonstrated in a key publication of 2000 using the Caco-2 cells as a model of enterocytic epithelial differentiation^[3] together with a later study^[11], that the AC133 epitope, but neither the CD133 transcript nor the CD133 protein, is down-regulated upon differentiation, with the result that only a minute sub-fraction of CD133 molecules will carry it^[11]. We have therefore stressed several times in the literature that it is important to consider that AC133 antibody detects only a subpopulation of human prominin-1/CD133 glycoproteins carrying the AC133 epitope, and that consequently, AC133 antigen is not fully synonymous with CD133^[11-13]. The importance of CD133 glycosylation states for the definition of cancer stem cells has been analyzed by Bindlingmaier and colleagues^[14]. In the meantime, the *prominin-1* (*PROM1*) gene was shown to be transcriptionally active all along the gastrointestinal tract as CD133 mRNA is detectable by Northern blot^[15], and several studies have demonstrated that in humans, as in mice, its protein is physiologically expressed in several differentiated epithelia^[11,16-20]. Thus, the AC133 epitope might be simply down- or up-regulated during the process of differentiation or transformation, respectively^[11]. The alteration of the general glycosylation pattern of intestinal cells might explain such a phenomenon^[21]. Importantly, the lack of AC133 detection might additionally reflect its instability^[22] or its differential accessibility^[19] (see below). Of note, the proportion of CD133 molecules carrying (or not) the AC133 epitope in a given differentiated cell remains, however, unknown.

As proposed earlier^[19] and pointed out in the Editorial of Jahn and colleagues, the molecular environment surrounding CD133 within the plasma membrane might influence the detection of certain epitopes (e.g., AC133 or those within putative ganglioside-binding sites^[2]). To fully appreciate the importance of CD133, one should bear in mind that, at the subcellular level, CD133 selectively marks plasma membrane protrusions, e.g., microvilli and primary cilia, that are located in the apical domain of polarized epithelial cells including Caco-2 cells, and was therefore originally named prominin (from Latin, *prominere*)^[3,16,23,24]. Within these protrusions, CD133 binds directly to plasma membrane cholesterol^[25,26] and is incorporated into membrane microdomains that differ from those found in non-protruding areas of the plasma membrane, as demonstrated biochemically using mild

detergents^[25], and morphologically by co-localization with the ganglioside GM1^[27]. Such protein-lipid interactions appear essential to maintain the proper localization of CD133 in microvilli^[25], and potentially its physiological function which yet remains elusive^[28,29]. Thus, the direct binding of certain gangliosides to CD133^[2,27] within the densely packed lipid microdomain might mask some CD133 epitope(s), particularly those in the vicinity of the membrane. Technically, they might be revealed, at least in part, using sensitive methods including harsh conditions for antigen retrieval as in the case of native tissues^[8,19,30,31], upon cell-detachment as in the case of cell lines (e.g., Caco-2 cells)^[32], or by chemical interference with membrane microdomain integrity^[2].

Although tightly associated with plasma membrane, CD133 is nonetheless released into numerous physiological body fluids including urine, saliva, seminal fluids and cerebrospinal fluids in association with small membrane vesicles^[33]. It is important to point out that such vesicles are budding from the tip of a microvillus or primary cilium by a molecular mechanism involving cholesterol-dependent membrane microdomains^[26,34]. In other words, their release might be modulated by the cholesterol level (and possibly that of other lipids) within the plasma membrane. Interestingly, such release occurs solely during and after the differentiation of Caco-2 cells or, *in vivo*, of neural progenitor cells^[33]. Based on the latter observation and the expression of CD133 (AC133 epitope in the case of humans) by numerous somatic stem cells, the concept of “stem cell-specific membrane microdomains” was postulated^[33]. Given that membrane microdomains are implicated in several signaling cascades by allowing the formation of active transduction complexes^[35], CD133-containing membrane microdomains might carry and/or functionally organize molecular determinants essential to maintain the stem cell and undifferentiated cell properties and their loss or disposal, e.g., *via* membrane vesicles, and could modify the status or even the fate of the cells^[33,36]. Yet, these microdomains, given their dependence on cholesterol, seem to differ from those defined by Hakomori and co-workers in the glycosynapse concept, and which have been implicated in several biological phenomena related to tumorigenesis^[37,38]. However, the coalescence of small CD133-lipid entities into the largest platform within the microvillar membranes might be dragged by carbohydrate moieties, as proposed earlier^[13,25,28]. Thus, a certain interdependence of lipid rafts and glycosynapses *per se* might exist. Whether CD133 molecules carrying AC133 epitope are preferentially released upon differentiation remains to be determined. Collectively, numerous physiological and technical parameters might interfere with immunodetection of certain CD133 epitopes, and importantly, the lack of their detection needs to be evaluated with some caution, and maybe alternative methods such as *in situ* hybridization should complement the investigation^[18,39].

Clinically, in addition to its potential value as a biomarker in tissue diagnosis, the association of CD133/

lipid complexes with extracellular membrane vesicles might offer an alternative screening method for the detection of cancers associated with the digestive tract as demonstrated for central nervous system diseases^[40]. Moreover, CD133 expression by cancer stem cells might contribute to outlining new prospects for more effective cancer therapy by targeting tumor-initiating cells.

Acknowledgments to reviewers of World Journal of Gastroenterology

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Gloria González Aseguinolaza, BSc, MSc, PhD, Department of Gene Therapy in Hepatology, FIMA, CIMA University of Navarra, Navarra, Spain

Dario Conte, Professor, GI Unit - IRCCS Osp. Maggiore, Chair of Gastroenterology, Via F. Sforza, 35, Milano 20122, Italy

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copy-right” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D, Ocean International Center, No. 62 Dongsihuan Zhonglu,

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Peritoneal carcinomatosis in gastric cancer is associated with a dismal prognosis. Systemic chemotherapy is not effective because of the existence of a blood-peritoneal barrier. Cytoreductive surgery and intraperitoneal chemotherapy can improve survival and quality of life in selected patients. Patient selection for this multimodal approach is one of the most critical issues, and calls for interdisciplinary evaluation by radiologists, medical and surgical oncologists, and anaesthetists. This article sets forth criteria for selection of gastric cancer patients suffering from peritoneal carcinomatosis.

INTRODUCTION

Gastric cancer is one of the most frequent causes of cancer-related mortality worldwide^[1,2]. Surgical resection after neoadjuvant chemotherapy in primary locally extended cases remains the mainstay for treating patients suffering from this disease. Surgery is limited by various factors: impaired general status, severe concomitant diseases, and distant metastases. One form is peritoneal dissemination of cancer cells within the abdominal cavity. Peritoneal carcinomatosis (PC) is detected in more than 30% of patients with advanced gastric cancer, and almost 60% of deaths are caused by peritoneal dissemination. In contrast to lymphatic and hematogenous metastasis, peritoneal carcinomatosis can be considered a local disease limited to the peritoneal cavity. Based on this rationale, cytoreductive surgery and intraabdominal chemotherapy have become a relevant treatment option for patients.

Various intraabdominal chemotherapy protocols have been established, varying from hyperthermic intraperitoneal chemotherapy (HIPEC), to early postoperative intraperitoneal chemotherapy, normothermic intraperitoneal chemotherapy, and delayed postoperative intraperitoneal chemotherapy^[3]. They differ in the heat of the administered agent, the chemotherapy dosage, and time of administration of the chemotherapy. HIPEC seems to have the most beneficial impact on overall survival^[3]. Retrospective analyses of patients treated with cytoreductive surgery plus HIPEC show a clear survival benefit when complete cytoreduction was possible. The randomized trial by Fujimoto *et al*^[4] in 141 gastric cancer patients, who were curatively resected, showed a significantly reduced peritoneal recurrence rate and improved long-term survival when HIPEC was part of the treatment as

compared to the “surgery alone” group. This observation was confirmed by Kim *et al*^[5], who showed a significantly lower peritoneal recurrence rate and an improvement in the five-year survival rate in the multimodally treated patients as compared to the “surgery alone” group.

Systemic chemotherapy is not as effective as surgery plus HIPEC because of the blood-peritoneal barrier^[6].

For metachronous peritoneal carcinomatosis from gastric cancer, there is no evidence to show which patient should be treated with the presented multimodal strategy. The dilemma arises when patients are very young and systemic chemotherapy is ineffective. In such cases, an individual approach with maximal tumor debulking may be an option and is justified in highly selected patients. However, in metachronous peritoneal carcinomatosis, the tumor often extensively involves the abdominal cavity with infiltration of the retroperitoneum, liver hilus, etc., which makes surgery impossible.

The aim of this article is to summarize the recent knowledge on patient selection for cytoreductive surgery and perioperative intraperitoneal chemotherapy for primary gastric cancer with peritoneal carcinomatosis or positive cytology.

GENERAL STATUS

Patients with limited peritoneal carcinomatosis from gastric cancer do not suffer from symptoms such as dysphagia or dysmotility, and PC is frequently found even in low T and negative N stages. Therefore, if the general status is acceptable, the option of radical surgical treatment should always be considered.

A detailed preoperative anesthesiological check-up is of importance and all patients should undergo a preoperative lung and cardiac function test. Concomitant diseases, that may influence surgical and anesthesiological risks, should be identified. As for most general elective operations, a low ASA score is mandatory. Age is still a matter of concern, because biological age does not always correlate with numerical age. However, most groups dealing with cytoreductive surgery and HIPEC restrict patient selection to an age below 65. Most importantly, informed consent with discussion of all alternative therapies must be obtained from the patients, and patients should be offered psychooncological support.

PREOPERATIVE DIAGNOSTICS

A high-end computed tomography is actually the standard and should be performed also to exclude extraabdominal spread and liver metastases. Recently, we demonstrated that positron emission tomography computed tomography (PET-CT) correlates well with intraoperative tumor load in peritoneal carcinomatosis^[7]. However, gastric cancer with PC is frequently of mucinous character; therefore, PET-CT is not helpful in selecting candidates for radical resection. Nodules smaller than 5-8 mm cannot be consistently detected^[8,9]. In particular, nodules on the small bowel and its mesentery are difficult to diagnose, but relevant for indication.

To date, there is no imaging method that can sufficiently predict intraoperative tumor load. Therefore, explorative laparoscopy is an invasive alternative for candidates in whom radiological work-up was not sufficient to determine operability.

Laparoscopy permits determination of the peritoneal carcinomatosis index (PCI) and cytology in locally advanced cases. Laparoscopy is highly accurate for the diagnosis of peritoneal carcinomatosis, with good correlation to the open surgical exploration found by Yonemura *et al*^[9].

Therefore, every patient should undergo explorative laparoscopy before neoadjuvant therapy or primary gastrectomy. As the first step of treatment, some groups even administer HIPEC *via* laparoscopy in patients with synchronous PC or positive cytology^[10,11].

PCI

PCI describes the tumor load in the abdomen and varies from 0 to 39, depending on the compartments involved^[12].

In contrast to colorectal cancer, where the PCI should be lower than 20 so that patients potentially profit in terms of overall survival^[13], in gastric cancer, the PCI should be much lower, because the biological behaviour of the tumor is more aggressive.

In a recent work by Yonemura *et al*^[14], complete cytoreduction was achieved in 91% of the patients when the PCI was lower than 6, but in only 42% of the patients with a PCI \leq 7. Overall survival was also better in the PCI \leq 6 group. In gastric cancer with peritoneal carcinomatosis, lymph nodes should be removed only if they are infiltrated; however, prophylactic D2 lymphadenectomy is unnecessary.

Patients with liver metastasis, involving para-aortic lymph nodes and extraabdominal metastases, are not candidates for cytoreductive surgery and HIPEC. The treatment of metachronous metastases remains controversial, and cancer masses tend to infiltrate the retroperitoneum and liver hilus with vascular structures, which makes surgery impossible.

COMPLETENESS OF CYTOREDUCTION SCORE

The completeness of cytoreduction score CC score describes the completeness of cytoreduction after operation. Ideally, all tumor nodules can be removed macroscopically (CC0). Otherwise, a CC1, CC2 or CC3 score describes non-resectable tumor nodules that vary in size and influence on prognosis. Non-resectability is caused either by diffuse peritoneal carcinomatosis with a high PCI, where surgical resection is oncologically not justified, or by diffuse infiltration of the small bowel or the mesenteric axis, and infiltration of the retroperitoneum.

NEW PROTOCOLS

Neoadjuvant intraperitoneal systemic chemotherapy pro-

tocol (NIPS) is a newly developed neoadjuvant intraperitoneal treatment modality developed by Yonemura *et al*^[15]. A good predictor of the possibility of achieving a CC0 status is preoperative cytology. Yonemura *et al*^[16] performed NIPS and achieved CC0 status in 27 of 52 patients with negative cytology, but only in four of 27 with positive cytology. Peritoneal wash cytology may, therefore, be a good predictor of the potential for CC0 status.

SUMMARY AND FUTURE PERSPECTIVES

Gastric cancer with peritoneal carcinomatosis is a biologically aggressive tumor, and surgery is still the gold standard of treatment if abdominal spread is limited and PCI is low, ideally < 10. HIPEC may have a potential impact on remaining free cancer cells, although it has not been proven in randomized trials. In metachronous peritoneal carcinomatosis, the surgical approach is often limited by the extensive intraabdominal tumor load and by the aggressive biological behaviour of the tumor itself. NIPS is a promising therapy, and may improve resectability and survival. Intense research is currently being done in experimental peritoneal carcinomatosis, which will eventually modulate current indications.

Concerning promising biomarkers, Phosphoglycerate-kinase 1 (PGK1), an adenosine-triphosphate (ATP)-generating enzyme of the glycolytic pathway, which also affects DNA replication and repair, seems to be an interesting enzyme that is significantly involved in the pathogenesis of gastric cancer and PC^[17-19]. Concerning tumorigenesis, it is assumed that genes involved in the glycolytic pathway are responsible for providing solid tumor cells with ATP. A newly discovered link between metabolic changes, including PGK1, and differentiation, has intriguing connections to an old hypothesis advocated by Otto Warburg for tumor metabolism. Further, recent *in vitro* and *in vivo* studies showed that PGK1 overexpression is associated with an elevated tumor invasion and metastatic rate in gastric cancer^[17-19]. Those results demonstrate that PGK1 might be a crucial enzyme enabling cancer cells to metastasize, and, therefore, may serve as a target molecule for therapy in gastric cancer in the near future.

CONCLUSION

Nowadays, a radical combined treatment should be considered for a motivated patient with good performance status and low-grade peritoneal carcinomatosis. In addition, the patient should be sent to a peritoneal surface malignancy center.

Abstract

Microscopic colitis (MC) is considered an “umbrella term”, comprising two subtypes, i.e., collagenous colitis (CC) and lymphocytic colitis (LC). They are classically associated with normal or unremarkable colonoscopy. In the last few years, reports have been published revealing findings that are thought to be characteristic or pathognomonic of MC, especially CC. A systematic electronic and manual search of PubMed and EMBASE (to December 2010), for publications on distinct endoscopic findings in MC, resulted in 42 relevant reports for inclusion in this review. Eighty eight patients with collagenous colitis were presented. Only one publication describing a distinct endoscopic pattern in LC was found. Typical findings in CC are alteration of the vascular mucosal pattern, mucosal nodularity, a sequence of change from mucosal defects to mucosal cicatricial lesions, and perhaps (although of doubtful relevance) mucosal pseudomembranes. A causal connection of

INTRODUCTION

Microscopic colitis (MC), regarded as a rare entity in the early 80s (and certainly overlooked), has now emerged as an increasingly common cause of chronic, non-bloody/watery diarrhea^[1].

MC is an “umbrella term”, comprising two entities/subtypes, i.e., collagenous colitis (CC) and lymphocytic colitis (LC)^[2]. The two entities are characterized by a variable, yet apparently benign, clinical course of protracted, non-bloody diarrhea and classically normal or unremarkable colonic mucosa on endoscopy^[3]. In 1984, Gledhill^[4] established that thickening of the colonic acellular basement membrane by > 15 µm is invariably associated with diarrhea.

The histological abnormalities in MC are discontinuous, subtle and often unequally located in the colon, making it necessary to take multiple biopsies from various

colonic regions for identification of the pathognomonic microscopy, i.e., thickened sub-epithelial collagen band and increased intraepithelial lymphocytes^[5] (Figure 1).

However, there are occasions where endoscopy reveals findings that are thought to be characteristic or pathognomonic of MC, and especially CC. Although the estimated prevalence of MC is up to 10% in patients with chronic diarrhea^[5], there are few reports of macroscopic findings in MC. This review attempts to describe the known characteristic endoscopy findings in MC and to categorize them in different types.

PATHOPHYSIOLOGICAL BACKGROUND

CC was first described in 1976, independently in Sweden by Lindström^[6] and in Canada by Freeman^[7], while LC was first described by Lazenby *et al*^[8] in 1989. An increase in their incidence has been recently reported, but this is most likely an artifact secondary to increased awareness and prompt diagnosis^[9]. In the absence of persistent endoscopic findings, diagnosis is based mainly on specific histological criteria^[9].

It is not clear whether CC and LC are separate entities or part of the spectrum of a single disease^[2]. With regard to pathogenesis, several hypotheses have been suggested, including inflammation secondary to medication, smoking, immune dysfunction, autoimmunity, and/or infection.

Studies of collagen typing in patients with CC have produced conflicting results. Electron microscopy findings have suggested that the collagen in CC appears similar to that found in granulation tissue, supporting the hypothesis that its presence would suggest a reparative response to injury^[10]. In fact, it is plausible to assume that overproduced, multiple, and different collagen types may deposit in the sub-epithelial layer of the colon and manifest clinically as CC^[11]. Günther *et al*^[12] showed that increased connective tissue growth factor expression might be the final mediator of local fibrosis in CC.

Non-steroidal anti-inflammatory drugs (NSAIDs) have been implicated as causative factors, through their ability to inhibit prostaglandin synthesis from the colonic mucosa. More recently, several reports have been published incriminating proton pump inhibitors (PPIs), especially lansoprazole, in the induction of CC. Most of the findings to support this came from the temporal relationship of resolution of symptoms with cessation of NSAID or PPI therapy. PPI-induced conformational changes in the cytoskeleton of epithelial cells may result in alterations in the function of the tight junction, leading to increased paracellular permeability. Keszthelyi *et al*^[13] postulated that this could allow the luminal contents to easily penetrate the lamina propria causing an immune and/or inflammatory reaction. On this basis, and in light of some recent reports^[14], which incriminate lansoprazole as the main cause of linear mucosal defects in CC, it may be plausible to suggest that CC is a syndrome with various causes and perhaps graded histopathology.

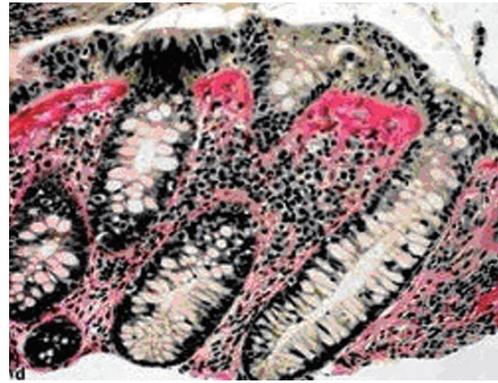

Figure 1 Van Gieson Stain, sub-epithelial collagen table.

The purpose of this review is to present the published experience on distinct endoscopic findings in MC and suggest a unifying lexicon for the reported lesions.

SEARCH STRATEGY

We conducted a PubMed and EMBASE computer search (to December 2010) in order to identify articles on microscopic colitis and endoscopic findings. Our search strategy for PubMed was [“Colitis, Microscopic” (MeSH) or “Colitis, Collagenous” (MeSH) or “Colitis, Lymphocytic” (MeSH)] and [“Endoscopy” (MeSH) or “colonoscopy” (MeSH) or “intestinal mucosa” (MeSH)]. We confined our search to articles in humans but we did not apply any language restriction. In order to search EMBASE we used the following key words: “collagenous colitis”, “microscopic colitis” or “lymphocytic colitis”, “endoscopy” or “colonoscopy”. A further search of electronic journals was undertaken.

Duplicate articles identified in PubMed or EMBASE were manually deleted. The first selection, based on the title and/or abstract was carried out by one of the authors (AK). From the outset, we agreed not to include for further review reports or studies on endoscopic technology, e.g., confocal laser endomicroscopy, which is not yet widely available or restricted to a small number of tertiary institutions. The full paper of each potentially relevant report was then obtained. Thereafter, the two authors independently assessed publications for inclusion in the review. In addition, the reference lists of relevant reports and review papers were cross-searched, in order to identify papers that our initial computer search may have missed.

The following data were extracted from each included publication: year of publication and first author, country of origin, number of cases reported, gender and age of the cases, described endoscopic findings, histopathological diagnosis, post-endoscopy/clinical complications and any important clinical associations (Table 1).

SEARCH FINDINGS

Our initial computational search returned 89 articles in

Table 1 Overview of reports of endoscopic findings/appearance of collagenous colitis

Year	Ref.	No. of cases, gender, age	Endoscopic findings	Lesion location collagen table thickness	Clinical associations	Complications
1990	Giardiello <i>et al</i> ^[15]	1, M, 60	Pseudomembranes	S colon 50-70 μ m	Watery diarrhea, received NSAIDs/antibiotics	None
1993	Richieri <i>et al</i> ^[16]	1, F, 43	Linear mucosal tears/lacerations Absent vascular mucosal pattern	R colon 30-40 μ m	Watery diarrhea, abdominal pain Successful therapy with steroids, some bloody stools	None
1993	Smiley <i>et al</i> ^[17]	1, F, 53	6 mo later; many linear cicatricial lesions Carpet-like patch with nodularity (5 cm)	R colon	Watery diarrhea	None
1995	Katanuma <i>et al</i> ^[18]	1, F, 72	Similar to sessile villous adenoma Diminished vascular pattern	20-40 μ m Pancolonial	Therapy with bulking agents RA on sulindac, diarrhea and wt loss	None
1997	Katsinelos <i>et al</i> ^[19]	1, M, 65	Edematous/red mucosa Multiple red mucosal spots Diminished vascular pattern	n/s R colon n/s	Treated by discontinuation of NSAID Watery diarrhea, Successful therapy with steroids	None
1997	Yabe <i>et al</i> ^[20]	1, F, 47	Multiple red mucosal spots Diminished vascular pattern	Pancolonial n/s	6 F/U colonoscopies showed no improvement	None
1998	Sato <i>et al</i> ^[21]	1, F, 78	Crowded/tortuous vascular pattern I/C spray: coarse/nodular surface	R + T colon n/s	Watery diarrhea	None
1999	Bermejo <i>et al</i> ^[22]	1, F, n/s	Pseudomembranes and aphthae	n/s	Watery diarrhea, received NSAIDs/antibiotics	None
2001	Freeman <i>et al</i> ^[23]	1, F, 37	Deep, elliptical mucosal defect/ulcer	S colon n/s	Watery diarrhea, acute abdomen Diagnostic laparotomy + IV antibiotics	Perforation
2001	Yagi <i>et al</i> ^[24]	1, F, 77	Mucous-covered lesions in R colon Ulcer in descending colon 2nd look: rectal pseudomembranes	R + T colon 30-60 μ m	Watery diarrhea, 4 colonoscopy linear lesions in rectum, ASA-associated	None
2002	Cruz-Correa <i>et al</i> ^[25]	2, F, (73/61) 1, M, 62	Deep lacerations/tears 0.5-4 cm long (to muscularis mucosa)	R and T colon n/s	All had hypothyroidism Therapy with tetracycline/5-ASA	None
2003	Kakar <i>et al</i> ^[26]	8, F, (a. r: 37-91) 1, M, 27	Linear ulcers or lacerations (5) Diminished vascular pattern (2)	R colon (5) S colon (3)	Aspirin and NSAID-associated CC Treated with discontinuation, bismuth	None
2003	Sato <i>et al</i> ^[27]	1, F, 78	Aphthae (2), pseudomembranes (1) 1st colonoscopy: 3 mm nodule 2nd look: crowded/tortuous vascular pattern I/C spray: coarse and nodular, uneven surface	n/s Pancolonial R: 40-70 μ m L: 20 μ m	Mesalamine or azathioprine/6-MP Watery diarrhea, wt loss ASA-associated	None
2003	Byrne <i>et al</i> ^[28]	1, F, 27	Erythematous mucosa Multiple pseudomembranes	S colon n/s	Watery diarrhea, common variable immunodeficiency (CVID)	None
2003	Yuan <i>et al</i> ^[29]	6, F, (a. r: 54-81)	Linear ulcers (1), R colon ulcers (2), inflamed rectum (1)	T colon n/s	Pseudomembranes in CC, only endoscopic cases included	None
2004	Buchman <i>et al</i> ^[30]	1, F, 58 1, F, 46	Hemorrhagic mucosal spots and erythema, granularity/ pseudomembranes	R colon	Prednisolone, antibiotics, TPN, PPI, hypoalbuminemia	None
2004	Sherman <i>et al</i> ^[31]	3, F, (a. r: 66-73) 1, M, 69	Mucosal tears and fractures Granularity of mucosa at places	R + T colon 40-50 μ m	Watery diarrhea, wt loss, hypoalbuminemia	Perforation in 3/4 cases

PubMed and 499 in EMBASE. Nineteen and 50 articles, from PubMed and EMBASE respectively, were included for further review. After obtaining the full papers, 35 papers were selected. Another seven publications were identified from references lists and included in the final analysis.

The terms mucosal break, defect, tear, fracture or laceration were used indiscriminately. For the purpose of this review and in order to standardize the terminology, we agreed to use the term “mucosal defect” as a collective one, under which there are two subtypes of lesions: (1) mucosal lacerations/tears which are the longitudinal (superficial or deep) and mainly fresh/hemorrhagic in appearance mucosal breaks (Figure 2); and (2) mucosal fractures describing the deeper (with occasional exposure of the muscularis mucosa) and white-based or more chronic looking mucosal defects (Figure 3).

Although to an extent arbitrary, we believe that this terminology will aid the introduction of a universal lexicon for future reports of similar lesions. It is obvious that in accordance with the above, the “cat scratch colon” belongs to the first category, i.e., mucosal lacerations or tears.

Eighty eight cases [65 females, 10 males, 13 not stated (n/s); median age: 67 years] were reported in 41 publications. Of these, 14 publications were from Japan^[18,20,24,27,37-41,44,45,47,50,51], 12 from the United States^[15,17,25,26,28-31,35-37,43], three from the United Kingdom^[33,48,52], two each from France^[16,34], Sweden^[21,32], and Greece^[19,54], and one each from Argentina^[55], Canada^[23], Italy^[42], the Netherlands^[49], Portugal^[46], and Spain^[22]. Where reported, the

submucosal collagen table thickness ranged from 14–70 μm . The only publication reporting endoscopic findings in LC described the presence of a subtle mucosal change in an 85-year-old female^[56].

Gardiello *et al*^[15] were the first to report distinct endoscopic findings in CC (i.e., pseudomembranes), but in fact it was Richieri *et al*^[16] who first described the presence of multiple linear mucosal lacerations with sharp edges in the right colon of a 43-year-old female, with sub-epithelial collagen table thickness of 30–40 μm . Eventually, on repeat colonoscopy 6 mo later the lesions had healed, resulting in fine cicatricial lines on an otherwise unremarkable colonic mucosa. Therefore, Richieri *et al*^[16] had effectively pointed to a pattern seen in some of the reports that followed, i.e., the continuum of laceration to cicatricial healing of the mucosa.

Since this report, 53 cases (34 females/6 males/13 n/s; median age: 69 years) of linear, long or shorter and finer (cat-scratch type) mucosal tears, fractures and ulcers have been reported^[25,26,29,31-42,45,46,49-54]. Sixteen patients with mucosal defects were on lansoprazole, and in the majority, discontinuation of the medication resulted in symptomatic, endoscopic and histopathological improvement.

On the other hand, only 11 (10 females/1 male) cases of mucosal cicatricial lesions have been reported to date, identified either during the index colonoscopy that revealed the mucosal defects, or at follow-up colonoscopic examinations^[16,32,38,41,43,45,46,48-50]. The lesions ranged from hypertrophic (celoid-type mucosal scars)^[32,38,41,43,45,46,48-50] to fine, cicatricial lines^[16,48] (Figure 4).

We did not manage to establish an association of any

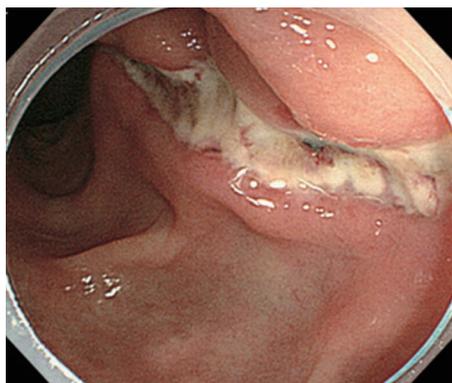

Figure 3 Colon mucosal fractures in collagenous colitis.

of these lesions either with the collagen table thickness or with symptom severity in the review cohort.

The right colon (for the purpose of this review defined as the area from the cecum to the hepatic flexure), irrespective of the type of findings, was affected in 32 cases, the transverse colon in 16 and the left (descending, sigmoid and rectum) colon in 32. Five reports presented cases with pancolonic mucosal involvement^[18,20,27,39,44].

Although the sign of a mosaic pattern or mucosa nodularity (“honeycomb mucosa”) was noted first by Smiley *et al*^[17] in 1993 in the ascending colon of a 53-year-old woman, a retrospective case-control study was only published in 2010^[55]. In the appropriate clinical context of watery diarrhea, the “honeycomb pattern” had an odds ratio of 19.4 with a specificity of > 99% for diagnosis of CC. The authors though pointed out that, due to both the retrospective nature of the study and the high possibility of under-reporting, this may be an over-estimation.

Dye spray (indigocarmine), for improved delineation of the identified lesions, was utilized in four reports^[21,27,50,55], and seems helpful in the context of subtle mucosal changes and/or disturbed vascular architecture. However, this should be balanced against the greater resource implications and procedure time.

With regard to complications, there were 17 recorded perforations/peritonitis in the review cohort^[23,31,35,37,45,49]. As expected, these were all associated with cases where mucosal defects (tears or fractures) were evident on colonoscopy^[52,57].

WHAT IS CURRENTLY KNOWN

We found four broad categories of distinct endoscopic findings in CC: (1) pseudomembranes^[15,22,24,26,28,30], (2) mucosal vascular pattern alteration which includes an indistinct appearance of the blood vessels and a variable degree of pruning of the mucosal vasculature, or a crowded, dilated and tortuous capillary network^[16,18-21,26,27,39,44,47]; (3) mucosal abnormalities such as red spots and some mucosal nodularity or textural alteration, evident with or without chromoendoscopy^[17,19-21,27,30,31,55]; and (4) a continuum of mucosal breaks/defects, i.e., mucosal lacera-

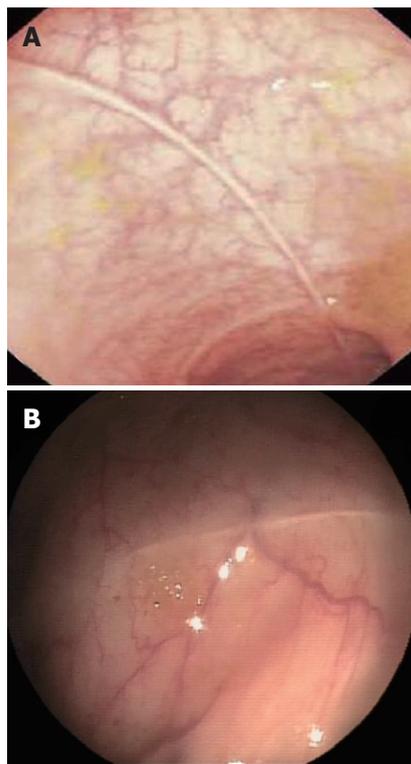

Figure 4 Cicatricial mucosal lesions in collagenous colitis (A and B).

tions/tears, including the so-called “cat scratch colon” pattern, or fractures usually along the long axis of the colonic wall^[16,25,26,29,31-42,45,46,49-54] to the fine linear cicatricial lines or thick scar-like ridges of the mucosal surface (effects of the mucosal healing process of mucosal defects)^[16,32,38,41,43,45,46,48-50]. There was only one publication describing a characteristic endoscopic pattern in LC^[56].

Hemorrhagic mucosal breaks have an appearance that could be liberally described as “colon craquelé”^[16]. The term mucosal fracture was introduced by Sherman *et al*^[31] in 2004 and it is admittedly a successful descriptive one. Thickened and abnormal sub-epithelial collagen table leads, at some areas, to loss of attachment with the epithelial component, and this in turn causes stretching of the mucosa over the deeper wall layers, and eventually tearing of the detached mucosal surface (in a “zip” fashion, hence the longitudinal lesions). The sharply demarcated margin of these mucosal defects, as if the mucosa has been slashed with a sharp knife, helps to differentiate them from ischemic colitis^[50].

Mucosal defects are more likely to be found in the right colon as a result of a colonic insult, i.e., instrumentation or air insufflation due to the abundant presence of a thicker and denser (hence dysfunctional) collagen type III table, in association with increased colon diameter on that side^[25,37,58]. The right colon thinner wall and its expansion to a greater diameter during fecal storage and transit, produce greater relative wall tension (Laplace’s law, i.e., tension on the wall of a cylinder is proportional to the radius). Therefore, a competent ileocecal valve and a deformed sigmoid are sufficient to cause colonic air

entrapment in a closed space^[59], and eventually “cracking” of the brittle colonic mucosa^[11,25,31,32,48,58]. Although the colon can not be seen as a simple cylinder^[37], we suggest that these breaks can occur spontaneously, and postulate that increased intra-colonic pressure during peristalsis and defecation leads to mucosal stretching and defects that will heal with time leaving behind various types of cicatricial lesions^[33,48].

McDonnell *et al*^[36] coined the term “cat scratch colon” to describe the red linear marks in the cecum or ascending colon seen in 21 of 8277 patients undergoing colonoscopy. They reported a 14% prevalence of CC of in their cohort. They also postulated that these marks were due to barotrauma from insufflation^[36,59-61]. However, it is unclear whether biopsies were taken in all patients undergoing the test for diarrhea, other than in those that had the “cat scratch” appearance. Furthermore, endoscopic findings are non-specific for CC and have been described in the normal colon (attributed to barotrauma from excessive insufflation during colonoscopy), in diversion colitis, and even in chronic cholestasis^[54,61,62].

The true prevalence of mucosal tears is unknown due to the rarity of reported cases, but it is estimated to be around 1%. Under the assumption that not all of the relevant cases have been reported, the true prevalence may be much higher. However, based on the type of publications included in this review, i.e., case reports or series, it is not possible to estimate prevalence. In addition, practices vary worldwide and up until recently flexible sigmoidoscopy was considered sufficient to diagnose MC (it is believed that left-sided biopsies probably miss less than 5% of MC cases, due to its patchy nature), and as lesion awareness rises, the incidence of macroscopic findings will increase^[63]. On the other hand, the increased frequency of reports published during the last decade show that there is an increased awareness of the distinct endoscopic appearances in MC, and perhaps endoscopist enthusiasm may result in over-diagnosis (as mucosal tears/scratches have been described in the normal colon, diversion colitis and in lansoprazole colitis^[36,64,65]) of an entity whose main hallmark remains histological confirmation.

It is also now known that mucosal defects in CC represent a marker of increased risk of colonic perforation^[52,54]. A recent review found 21 cases of perforation in CC. The majority of these were either colonoscopy-associated (15 cases) or barium enema-associated (four cases), while the rest seem to have occurred spontaneously^[57].

There are several reports of remission, including disappearance of the collagen layer on follow-up. This would indicate that an environmental factor such as medication may be responsible in susceptible individuals. NSAIDs or PPIs have been implicated. It has also been suggested that collagen plate thickness is greater with lansoprazole^[38]. The pathophysiologic mechanism by which lansoprazole induces microscopic colitis and mucosal defects is not well understood. Although a clear temporal correlation exists, it should be remembered

that, due to the fluctuating nature of CC^[66], it might simply represent a coincidence, as PPIs are one of the most commonly prescribed drug categories worldwide.

It has been postulated that this may be due to higher concentrations of drugs such as NSAIDs in the right colon^[26]. However, it is possible that more right sided biopsies are taken because of endoscopic abnormalities, more likely to be observed in the right colon, as mentioned above. More case control studies and multivariate analysis may provide the answer^[14].

In conclusion, the endoscopic appearances of CC are becoming more familiar amongst the endoscopic community. We recommend adoption of the proposed lesion description herein in order to improve homogeneity of future reports.

ACKNOWLEDGMENTS

We feel indebted to Ms Sarah Douglas, Senior Scientist and Dr. JN Plevris, Consultant and Reader in Gastroenterology, The Royal Infirmary of Edinburgh for their invaluable suggestions in proofreading. We are grateful to Dr. T Sekioka for allowing us to reproduce image (Figure 3) from Ref. 45. Figures 1, 2A and B from Koulaouzidis *et al*^[33], Endoscopy 2006, with permission. Abstract

The thiopurine drugs, 6-mercaptopurine (6-MP) and azathioprine, are efficacious in the arsenal of inflammatory bowel disease (IBD) therapy. Previous reports indicate that 6-thioguanine nucleotide (6-TGN) levels correlate with therapeutic efficacy, whereas high 6-methylmercaptopurine (6-MMP) levels are associated with hepatotoxicity and myelotoxicity. Due to their complex metabolism, there is wide individual variation in patient response therein, both in achieving therapeutic drug levels as well as in developing adverse reactions. Several strategies to optimize 6-TGN while minimizing 6-MMP levels have been adopted to administer the thiopurine class of drugs to patients who otherwise would not tolerate these drugs due to side-effects. In this report, we will review different approaches to administer the thiopurine medications, including the administration of 6-mercaptopurine in those unsuccessfully treated with azathioprine; co-administration of thiopurine with allopurinol; co-administration of thiopurine with anti-tumor necrosis factor α ; 6-TGN administration; desensitization trials; and split

INTRODUCTION

Inflammatory bowel disease (IBD) encompassing Crohn's disease (CD) and ulcerative colitis (UC), is a chronic inflammatory disorder caused by dysregulated immune responses in a genetically predisposed individual. Given the role that the immune system plays in IBD, the hallmark of therapy is immune modulation. The thiopurine drugs, 6-mercaptopurine (6-MP) and its prodrug azathioprine (AZA), remain the mainstay of immunomodulator therapy for IBD and are indicated in steroid-dependent and -refractory patients, as prophylaxis in CD^[1-3]. Chebli found that AZA maintained steroid-free clinical remission for three years in UC patients, previously steroid-dependent^[2]. Of note, however, AZA has not been shown to be effective in treating active UC flare^[4]. Rather, thiopurines have also been noted to induce and maintain remission in UC and CD patients, more effectively than 5-aminosalicylic acid^[1,5-10]. However efficacious, their use

is often limited, as an estimated 30% to 50% of patients discontinue these drugs due to either side-effects or lack of clinical efficacy^[11-13]. The lack of response to these immunomodulators has been attributed to differences in individual variations in drug metabolism^[14,15]. The 6-thioguanine nucleotide (6-TGN) metabolite of 6-MP and AZA appears to be the predominant active metabolite responsible for therapeutic efficacy, whereas 6-methylmercaptapurine (6-MMP) levels correlate with the risk of hepatotoxicity and possibly myelotoxicity^[15,16]. Theoretically, if the thiopurine metabolite profile can be shifted to 6-TGN, a greater percentage of IBD patients would benefit from immunomodulator therapy. A meta-analysis has confirmed that higher 6-TGN levels are associated with remission among IBD patients^[17]. In this review, we will discuss the thiopurine metabolic pathway, monitor the drug metabolite levels, and evaluate the different approaches that have been developed to enhance clinical efficacy and minimize the side-effects of AZA and 6-MP.

THIOPURINE METABOLIC PATHWAY

To achieve the active cytotoxic form, AZA is metabolized *via* a series of biochemical pathways summarized in Figure 1. Initially, approximately 90% is non-enzymatically cleaved to 6-MP in the liver^[18,19]. There are three competitive metabolic pathways in 6-MP metabolism. It can be inactivated to 6-thiouric acid (6-TU) *via* xanthine oxidase (XO), activated to 6-MMP *via* thiopurine methyltransferase (TPMT), or to the therapeutic 6-TGN *via* enzymes hypoxanthine phosphoribosyl transferase (HPRT), inosine monophosphate dehydrogenase (IMPDH), and guanosine monophosphate synthetase (GMPS)^[11,20,21]. A complete understanding of its mode of action is unknown^[19]; however, based on its structural similarity to the purine guanine, 6-TGN is a purine antagonist that inserts within the DNA of leukocytes^[22]. Intracellular build up of 6-TGN is thought to be the cytotoxic form that inhibits DNA synthesis and downstream T cell proliferation for its immunosuppressive activity^[20,23,24]. Using a genome-wide expression profiling approach, 6-TGN was found to inhibit several immune and inflammation-related genes including tumor necrosis factor-related apoptosis-inducing ligand, tumor necrosis factor receptor superfamily member 7, and $\alpha 4$ -integrin in activated but not resting T lymphocytes^[25]. Thus, 6-TGN may additionally exert its immunosuppressive effect by down-regulating the expression of pro-inflammatory and gut-homing factors. Another report found that the immunosuppressive role of thiopurine medications may in part be due to its metabolite 6-thioguanine triphosphate (6-TGTP) suppression of the Rac1 protein, which participates in T cell maturation and proliferation, thus inducing T lymphocyte apoptosis^[19,26].

MONITORING THIOPURINE METABOLITE LEVELS

Because AZA is 55% of 6-MP by molecular weight and

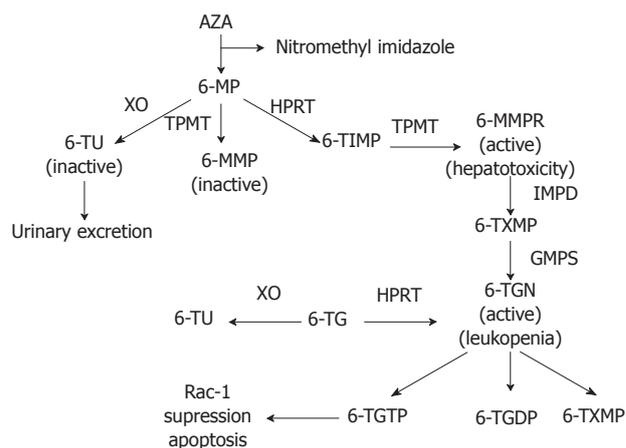

Figure 1 Thiopurine metabolic pathway. Metabolic pathway for AZA and 6MP is shown in the diagram. AZA: Azathioprine; 6-MP: 6-mercaptopurine; 6-TU: Thiouric acid; 6-MMP: 6-methylmercaptapurine; TIMT: Thiopurine methyltransferase; 6-MMPR: Methyl-mercaptapurine ribonucleotide; TXMP: 6-thioxanthosine monophosphate; 6-TGN: Thioguanine nucleotide; 6-TG: Thioguanine; 6-TGDP: 6-thioguanine diphosphate; 6-TGTP: 6-thioguanine triphosphate; XO: Xanthine oxidase; TPMT: Thiopurine methyltransferase; HPRT: Hypoxanthine phosphoribosyl transferase.

88% of AZA is converted to 6-MP, historically, thiopurines are dosed by the patient's weight; the maintenance dose of AZA is 2-2.5 mg/kg per day and 6-MP is dosed at half that of AZA, or 1-1.5 mg/kg per day in IBD patients^[1,22,7-29]. Individual variation in drug metabolism account for the differences in therapeutic efficacy and development of adverse reactions^[30,31]. Fortunately, advances in thiopurine metabolite monitoring can help predict which patients are more at risk of developing side effects, allowing for adjustments in drug dosages^[11,15].

TPMT is a key enzyme whose activity determines the level of 6-MMP as well as 6-TGN metabolite levels^[15,20,24,30]. TPMT methylates 6-MP to 6-MMP and 6-TIMP to 6-methylmercaptapurine ribonucleotide (MMPR) (Figure 1)^[15]. Elevated levels of 6-MMP (> 5700 pmol/ 8×10^8 erythrocytes) are associated with hepatotoxicity, whereas 6-TGN is the metabolite responsible for the therapeutic activity of thiopurines. Monitoring the thiopurine metabolite levels can help to optimize immunomodulator therapy and minimize adverse events. A retrospective study showed that patients who did not respond to AZA or 6-MP either had a high 6-MMP concentration or 6-MMP/6-TGN ratio^[12]. Furthermore, a subset of IBD patients preferentially metabolize thiopurines to the hepatotoxic 6-MMPR which explains why some patients develop toxic metabolite accumulation, side effects and ultimately cannot be maintained on thiopurine therapy^[30]. Even though 6-TGN is associated with therapeutic immunosuppressive activity, an excess amount of this metabolite poses an increased risk for myelosuppression^[32]. The therapeutic efficacy of 6-MP or AZA are correlated with 6-TGN levels between 235-450 pmol/ 8×10^8 erythrocytes^[15,22,33,34]. Because several studies have shown that weight-based dosing is poorly correlated with 6-TGN levels^[16,35,36], monitoring thiopurine metabolite levels can help optimize immunomodulatory therapy while mini-

mizing adverse effects^[15,30,34].

Differences in patient response to thiopurines may in part be due to patient-specific metabolism and genetic variation^[30]. TPMT activity is inversely related to clinical response to AZA^[11]. Different genetic polymorphisms code for the level of TPMT activity^[37]. 0.3% of the Caucasian population are homozygous for low enzyme activity; 11% are heterozygous and 89% are homozygous for high enzyme activity^[38]. Allelic frequency patterns vary among different ethnic groups. In Caucasian populations, intermediate or low TPMT activity is most frequently associated with TPMT*2, TPMT*3A or TPMT*3C alleles^[38], while in African-Americans, TPMT*3C is the most prevalent variant allele^[39]. Wild-type or heterozygous TPMT deficient patients have high TPMT activity > 14 units/mL RBC, which were associated with higher levels of 6-MMP and lower levels of 6-TGN, and thus a decreased likelihood of achieving complete remission (termed 6-MP resistance) and increased risk for hepatotoxicity^[11,13,30]. Dose escalation of thiopurine level may optimize 6-TGN levels, but must be done under caution given that TPMT also catalyzes the formation of the toxic metabolite 6-MMP^[40]. A meta-analysis found that TPMT polymorphisms are related to adverse drug reactions and myelotoxicity, but not hepatotoxicity or pancreatitis^[37]. It is thought that the higher level of TPMT activity may cause higher 6-MP catabolism resulting in higher 6-MMP and decreased 6-TGN levels^[11]. Low TPMT and thus high 6-TGN is associated with a higher risk for leukopenia^[13,15].

Studies have found that checking TPMT activity may be cost-effective as compared to standard therapeutic dose administration^[33,41]. Traditionally, AZA or 6-MP was started at a low dose and progressively titrated up because of safety concerns (bone marrow suppression, hepatotoxicity, etc.). Using this strategy, time to initial response is delayed and can take up to 6 mo to reach therapeutic response^[6,33,42,43]. Compared to traditional thiopurine dosing, monitoring TPMT can allow faster achievement of initial response (22.4 wk *vs* 18.9 wk) and lower costs at 1 year (\$7142 *vs* \$3861)^[33]. Thus, patients found to have normal TPMT could have dose escalation sooner therefore avoiding delay in achieving response^[33]. The cost-effectiveness of measuring TPMT activity was independently shown in a separate study^[41]. Furthermore, awareness of TPMT activity can help to avoid potential deleterious consequences of thiopurine therapy. For example, in patients with low TPMT activity, a lower initiation dose or avoidance of either 6-MP or AZA is recommended due to risks of leukopenia^[16,44]. Albeit, TPMT activity monitoring is not universally available to all practitioners; in these cases, thiopurine may be started at a low-dose (50 mg daily) and titrated up with weekly monitoring of CBC and liver function tests during the first 2 mo, and once every 3 mo thereafter^[20].

APPROACHES TO OPTIMIZING THIOPURINE METABOLITES

Use of 6-MP in patients who are intolerant of AZA

In addition to bone marrow suppression and hepatotoxicity,

early hypersensitivity reactions including fever and gastrointestinal side effects including diarrhea, nausea, and emesis can occur in as many as 10% of patients^[45]. These adverse reactions often cause IBD patients to discontinue thiopurine therapy. Several studies have shown that among patients intolerant of AZA, 6-MP may be a safe and effective alternative^[29,45,46]. One study showed that 20 of 29 (69%) IBD patients with a history of AZA hypersensitivity tolerated 6-MP^[46]. An AZA to 6-MP change appears to be more effective in UC compared to CD patients as by the end of the first year, none of the CD patients were maintained on 6-MP^[46]. In addition to hypersensitivity reactions, up to 60% of IBD patients with AZA intolerance due to nausea, emesis, and flu-like illness tolerated switching to 6-MP^[45]. In contrast, patients who discontinued AZA due to hepatotoxicity or pancreatitis were less likely to tolerate 6-MP^[45]. Another study found that 48% of patients previously intolerant to AZA due to myalgia and arthralgia were able to tolerate 6-MP^[46]. Another report showed that 11 of 15 (11 CD, 4 UC) patients (73.3%) who discontinued AZA due to epigastric pain, nausea and vomiting tolerated 6-MP and reached therapeutic goals^[47]. A retrospective study showed that 19 out of 140 patients discontinued AZA therapy (4 patients for clinical inefficacy, 13 due to side-effects, 2 due to leucopenia)^[48]. Of these 19 patients, 11 (58%) tolerated the switch to 6-MP^[48]. Consistent with the above findings, another report showed that 6 of 11 patients who initially could not tolerate AZA, were able to tolerate 6-MP and achieve response^[18]. The reasons behind the observation that 6-MP bypasses the adverse reactions caused by AZA are unclear, but may in part be due to the nitro-imidazole structure that is released as AZA is cleaved to 6-MP^[49].

Based upon the above studies, we propose that 6-MP should be considered in IBD patients who require continuing immunosuppressive therapy but are intolerant of AZA. We caution that there has been variable success among those who are switched to 6-MP (Table 1), and unfortunately many of the same reactions to AZA develop with 6-MP over time.

Use of AZA in 6-MP intolerant patients

The converse treatment strategy of administering AZA to patients who did not tolerate initial 6-MP therapy has not proved as effective^[48,50,51]. In a trial of AZA after 6-MP adverse reactions, similar side-effect profiles were seen^[18,48,50,51]. This is likely due to the fact that AZA is converted in the liver to 6-MP (Figure 1), thereby, yielding similar adverse reactions (Table 1). Based upon the lack of clinical efficacy, we do not recommend using AZA in patients who were previously intolerant of 6-MP.

Desensitization

Some investigators propose desensitization in the subset of patients who experience hypersensitivity reactions to AZA or 6-MP within the first month of treatment. Korrelitz *et al*^[51,52] retrospectively reviewed 591 charts of IBD

Table 1 Summary of strategies to optimize thiopurine metabolite levels

Method	Effectiveness (%)	Side effect
AZA to 6-MP	48-73 ^[45-48]	Nausea, vomiting, hepatotoxicity, neutropenia, pancreatitis
6-MP to AZA	Not effective ^[48,50,51]	Nausea, vomiting, hepatotoxicity, neutropenia, pancreatitis
Desensitization	25 ^[51]	Hypersensitivity reaction
Combination infliximab/thiopurine	25 ^[72,74]	Lymphoma, infection
6-TG	46-82 ^[50,58]	NRH, veno-occlusive disease and possible tumor
Allopurinol supplementation	25-75 ^[68,69]	Skin rash, renal impairment, leukopenia
Split-dosing	60 ^[75]	Reduces 6-MP, AZA associated adverse effects

AZA: Azathioprine; 6-MP: 6-mercaptopurine; NRH: Nodular regenerative hyperplasia; 6-TG: 6-thioguanine.

patients treated with 6-MP. Four of 16 patients who had early hypersensitivity reactions were successfully desensitized to 6-MP or AZA and achieved long-term clinical remission. One patient tolerated the direct switch from 6-MP to AZA. Of the remaining 11 patients, 5 needed surgery, 2 were changed to methotrexate (MTX), and 4 had chronic symptoms. In this study, desensitization began at one-quarter tablet per day, with an increase in the dose every 3 d for several weeks until a full dose was reached^[51,52]. A similar case report describes a CD patient who developed skin rash after 4 wk of treatment with AZA^[53]. Upon drug withdrawal, the rash resolved. A skin test was positive for AZA allergy, suggesting an IgE mediated hypersensitivity; and the patient was desensitized with AZA, with the patient's CD successfully in remission^[53]. Another case report describes a CD patient who developed a macular, erythematous truncal rash and fever after treatment with 6-MP^[54]. This patient was able to tolerate 6-MP after desensitization^[54]. The process of desensitization for patients with hypersensitivity reactions to AZA or 6-MP may be an empiric strategy for maintenance of immunomodulator therapy. However, we caution that more studies are needed to confirm the efficacy of this strategy.

6-thioguanine

As a possible alternative to those who cannot be maintained on 6-MP or AZA, treatment using 6-TG has been proposed. This drug has been used in children with acute lymphoblastic leukemia^[55]. Compared to AZA, 6-TG is directly converted to 6-TGN by HPRT (Figure 1)^[56,57]. Since 6-TG is a poor substrate for TPMT, hepatotoxic 6-MMP production would be low^[50,55]. Therefore, 6-TG bypasses several of the steps in thiopurine metabolism that are responsible for producing toxic metabolite

build-up and its association with the aforementioned potential adverse effects^[13,50]. One study found that of the 49 CD patients who were either resistant or intolerant to AZA or 6-MP, 46% of patients at 6 mo and 79% of patients at 12 mo were in remission and none of the patients developed pancreatitis or bone marrow toxicity^[58]. Although up to 82% of patients tolerated 6-TG^[50], this drug has been associated with several possible toxicities, notably nodular regenerative hyperplasia (NRH). One study found that the prevalence of NRH to be 16 out of 26 (62%) biopsies taken from patients treated with 6-TG^[59]. Several studies further found that the incidence of NRH associated with 6-TG use varied from 4%-27% among thiopurine naive patients (Table 1)^[60-62]. Other 6-TG associated adverse effects include secondary liver tumors, veno-occlusive disease, and other vascular liver pathologies^[50,58,63-65]. Formal dose-ranging studies for 6-TG are lacking and only limited data are available on the therapeutic efficacy and dosing regimens^[13]. As a general rule, dosage should not exceed 25 mg daily, as higher dosing has been associated with an increased risk of developing NRH^[13,66].

6-TG can be considered a rescue drug in IBD patients intolerant of or refractory to AZA or 6-MP. However, given the potential complications including NRH, and the small number of long-term safety monitoring and limited formal dose-range studies, we do not recommend 6-TG therapy at this time.

Allopurinol supplementation

In some patients, with AZA or 6-MP dose escalation, rather than achieving therapeutic levels of TGN, 6-MMP levels increase and resultant hepatotoxicity ensues^[67]. These patients are known as preferential 6-MMP metabolizers^[50]. Among IBD patients with high TPMT activity who favor 6-MMP production with reduced 6-TGN levels, adding the XO inhibitor allopurinol can favor the production of 6-TGN over 6-MMP^[68,69]. The addition of allopurinol to 6-MP or AZA resulted in improved disease activity as measured by the partial Harvey Bradshaw index in CD and Mayo scores in UC patients; decreased prednisone maintenance dose, and improved liver function laboratory values^[68,69]. However, at the 18 mo follow-up, 25% of these patients were escalated to anti-tumor necrosis factor (TNF) α therapy and 2 required surgery.

The exact mechanism of shifting thiopurine metabolites from 6-MMP to 6-TGN by the XO inhibitor is unknown, but may involve reduced production of the inactive thiouric acid (TU) metabolite in favor of the cytoactive metabolites 6-MMP and 6-TGN^[67,70,71]. However, if XO inhibition favors MMP and TGN production, then the toxic 6-MMP would also be expected to increase (Figure 1). Interestingly, allopurinol does not increase the level of 6-MMP or its associated hepatotoxicity, but mainly shifts the metabolite to 6-TGN.

Potential side effects of allopurinol include skin rash and renal impairment^[68]. In addition, the addition of allopurinol to thiopurine therapy may lead to supra-

therapeutic levels of 6-TGN, leading to leukopenia^[40,68]. Therefore, it is recommended that if allopurinol is used in combination with 6-MP or AZA, the dose of thiopurine medications should be reduced by at least 50% with close laboratory monitoring for leukopenia with weekly CBC monitoring during the first month, followed by every other week for the next month.

Combination therapy: Thiopurine and anti-TNF

Anti-TNF therapies are generally used for patients who are refractory to first-line medications^[72,73]. Colombel *et al.*^[72] conducted a randomized, double blind study of moderate-to-severe CD patients, comparing infliximab and AZA alone *vs* in combination and found that the primary endpoint, steroid-free remission at 26 wk, was achieved in a greater number among those treated in combination *vs* monotherapy. Mucosal healing, a secondary endpoint was also greater among patients who received combination therapy. These patients were immunosuppressant- and biologic therapy-naïve patients. Caution must be used, however, as studies have found an increased risk of non-Hodgkin's lymphoma in patients treated with anti-TNF with a history of thiopurine use^[74].

Split dose administration of thiopurines

As discussed above, patients who are preferential 6-MMP metabolizers exhibit high 6-MMP levels with subtherapeutic 6-TGN levels when thiopurines are dosed in the traditional weight-based, once-a-day fashion. 6-MP/AZA dose escalation in this subset of patients in an attempt to push the 6-TGN level into the "therapeutic range"-often results in dose-dependent leukopenia, transaminitis and/or flu-like symptoms (headache, nausea, myalgia, fatigue, general malaise). Overproduction of 6-MMP and side-effects resolve with dose reduction, but the lower dose often fails to adequately suppress IBD disease activity, resulting in suboptimal symptom control.

Anecdotally, we observed that simply splitting the daily dose of thiopurine (e.g., 50 mg *BID* rather than 100 mg once daily) can reduce the 6-MMP metabolites while maintaining 6-TGN levels. To confirm our observation, we performed a retrospective chart review of patients with baseline 6-MMP levels greater than $7000 \text{ pmol}/8 \times 10^8$ red blood cells (RBC) who underwent split dosing ($n = 20$). Dividing the daily thiopurine dose led to a significant reduction in 6-MMP levels ($11\,879 \text{ vs } 5955 \text{ pmol}/8 \times 10^8$ RBC; $P < 0.0001$) without adversely affecting clinical disease activity (HBI) or 6-TGN levels ($250 \text{ vs } 227 \text{ pmol}/8 \times 10^8$, $P = \text{NS}$)^[75]. Side-effects associated with 6-MMP, such as abnormal liver function test (LFT), leukopenia and flu-like symptoms, improved in seven of eight patients^[75]. After a mean follow-up of 42 mo, 12 of 20 patients were able to be maintained on a split dose of 6-MP with control of their IBD activity^[75]. To our knowledge, this is the first study to demonstrate the effectiveness of dose splitting on preferential metabolism. This approach has several advantages over other strategies. Dose splitting does not sacrifice potential efficacy associated with

dose reduction, and may even allow for further upward titration of thiopurine to efficacy if needed. It avoids the introduction of possible additional medication side effects as can be seen with co-administration of allopurinol and the potential cost burden of designer biologic inventions. This maneuver is relatively simple for both patients and practitioners alike.

Independent studies are needed to confirm that split-dose administration of thiopurine is an effective approach to manage 6-MMP preferential metabolizers. However, in an IBD patient who might otherwise not tolerate immunomodulator therapy and require ongoing steroid exposure and/or escalation of therapy to biologics, splitting the daily dose of 6MP or AZA may be attempted.

POTENTIAL RISK OF LYMPHOPROLIFERATIVE DISEASE

Thiopurines have been linked with chromosomal abnormalities and an increased risk of lymphoma among rheumatoid arthritis patients^[76]. Whether the same risk exists in IBD patients is controversial. A meta-analysis of six studies showed a four-fold increased risk of developing lymphoma among IBD patients treated with immunomodulators^[77]. Similarly, in the CESAME prospective cohort study by Beaugerie, a five-fold increased risk of lymphoproliferative diseases was shown among IBD patients on thiopurines^[78]. Whether this risk stems from underlying disease or iatrogenic medication is unclear. Studies have shown that the risk is greater in IBD patients who are male and between 15 to 40 years old^[79,80]. One study focused on hepatosplenic T-Cell lymphoma and noted cases among men younger than 35 years who had been treated with either anti-TNF and thiopurines or thiopurine monotherapy^[79]. In contrast, a study by Vos *et al.*^[81] found no increased risk of lymphoma among a nationwide study of 17 834 IBD patients. Interestingly, however, they did find an association between Epstein-Barr Virus-positive lymphoma and thiopurine use. EBV-positive lymphoma implies the effect of immunosuppression as a factor^[77,80,81]. Nevertheless, the consensus has been that the benefits of thiopurines outweigh the risk^[77,82]. Lewis *et al.*^[82] conducted a decision analysis and found that a 9.8-fold increase in lymphoma is needed to favor an alternative therapy over AZA. Further studies are needed, as it has yet to be determined how this risk changes with discontinuation of thiopurines^[77].

CONCLUSION

Given the complex metabolism of thiopurines and the individual variability among patients in response to this medication, various dosing strategies have been adopted. Several approaches have been promising among patients who develop toxicities to the initial strategy. However, no single strategy has proven completely effective in all patients. Further studies will inevitably provide more in-

formation to assist in optimizing administration of these vital IBD medications. This is significant given that there are a limited number of medications available in the IBD arsenal. In all dosing strategies, however, close monitoring of metabolites as well as determination of pharmacogenetics are pivotal for patient safety and medication efficacy.

Abstract

High-grade dysplasia (HGD) in Barrett's esophagus (BE) is the critical step before invasive esophageal adenocarcinoma. Although its natural history remains unclear, an aggressive therapeutic approach is usually indicated. Esophagectomy represents the only treatment able to reliably eradicate the neoplastic epithelium. In healthy patients with reasonable life expectancy, vagal-sparing esophagectomy, with associated low mortality and low early and late postoperative morbidity, is considered the treatment of choice for BE with HGD. Patients unfit for surgery should be managed in a less aggressive manner, using endoscopic ablation or endoscopic mucosal resection of the entire BE segment, followed by lifelong surveillance. Patients eligible for surgery who present with a long BE segment, multifocal dysplastic lesions, severe reflux symptoms, a large fixed hiatal hernia or dysphagia comprise a challenging group with regard to the appropriate treatment, either surgical or endoscopic.

INTRODUCTION

In the era of minimally invasive therapies, numerous treatment options for Barrett's esophagus (BE) with high-grade dysplasia (HGD) are available. Nevertheless, since therapy is individualized, the standard of care remains debatable for a large number of patients without clear-cut guidelines. The aim of this review is to briefly present and compare current therapeutic modalities with an emphasis on endoscopic approach, outline factors that can aid in the choice of the appropriate treatment (medical, endoscopic or surgical) and underline the lack of a properly designed study so far that compares the outcomes of these therapies.

BE is the result of chronic gastroesophageal reflux disease (GERD) and represents the end stage of the natural course of this disease. It has been estimated that 20% of the population in the United States suffers from gastroesophageal reflux^[1] and that about 10% of

these patients are diagnosed with BE^[2]. Commonly, BE is discovered during endoscopy for the evaluation of GERD symptoms. The severity of GERD symptoms is not considered an indicator of BE presence, whereas the chronicity of GERD symptoms may be related to the possibility of BE transformation^[3]. It is documented that longstanding exposure of esophageal mucosa to gastric acidity results in cellular damage of the stratified squamous epithelium and creates an abnormal environment, which stimulates repair in the form of intestinal epithelial metaplasia^[4,5]. Moreover, BE is related to a serious mechanical insufficiency of the lower esophageal sphincter, a functional derangement of the esophageal body, as well as an insufficient esophageal clearance^[6-8].

In BE it is possible to encounter three histologic types of columnar epithelium: (1) the specialized intestinal metaplasia type, in which the epithelium exhibits a villous surface and intestinal-type crypts lined by columnar cells that secrete mucous and goblet cells containing mucin; (2) the gastric fundus epithelial type; and (3) the junctional type. Among these three histological types, only the intestinal type represents an important premalignant state.

In BE, the stratified squamous epithelium, which physiologically lines the esophageal mucosa, is replaced by a pathological, specialized columnar epithelium which is neither of cardiac nor of stomach type, but exhibits features of the intestinal type of epithelium^[4]. This pathological type of epithelium usually demonstrates DNA alterations that predispose to malignancy^[2,9,10]. The alterations in BE are histologically classified into three categories, depending on whether or not they exhibit dysplasia: (1) BE without dysplasia; (2) BE with low-grade dysplasia; and (3) BE with HGD^[11-13]. In BE with HGD, dysplasia is confined to the mucosa without crossing the basement membrane. If dysplasia extends beyond the basement membrane into the lamina propria through the in-coming lymphatic network, it is defined as intramucosal (superficial) adenocarcinoma, whereas if it invades the muscularis mucosa layer it becomes invasive adenocarcinoma. Thus, **BE with HGD is considered a precursor of invasive adenocarcinoma**. Six to twenty percent of patients with BE and HGD are at greatest risk of developing adenocarcinoma within a short period of time, ranging from 17 to 35 mo at follow-up^[14]. Esophagectomy specimens from patients with BE and HGD revealed invasive adenocarcinoma in 30%-40% of cases^[15]. A recent meta-analysis demonstrated that patients with BE and HGD developed esophageal adenocarcinoma with an average incidence of 6 every 100 patients per year, during the first 1.5 to 7 years of endoscopic surveillance^[16]. Furthermore, the majority of esophageal adenocarcinoma is thought to have evolved from cells that have undergone Barrett's metaplasia^[17].

BE is also classified into two categories according to the extent of intestinal metaplasia above the gastroesophageal junction: (1) **long segment BE, if the extent of the intestinal epithelium is greater than 3 cm**; and (2)

short segment BE, if it is less than 3 cm^[18]. Among patients who undergo endoscopy for symptoms of GERD, the incidence of long segment BE is 3%-5%, whereas short segment BE occurs in 10%-15%^[4]. Whether long and short segment BE share the same pathogenetic alterations or the same predisposition to malignancy still remains unclear; however, both conditions are currently treated in the same manner^[19].

ENDOSCOPIC SURVEILLANCE IN PATIENTS WITH BE

Concerning the therapeutic management of BE, endoscopic follow-up of the patient at regular intervals, so-called endoscopic surveillance, plays a pivotal role. There is great difference of opinion when dealing with the problems of therapeutic management of BE. The value of endoscopic surveillance in patients with BE represents one of the many controversies that exist amongst gastroenterologists.

As aforementioned, BE represents a strong risk factor for developing adenocarcinoma, which is a particularly lethal malignancy^[19]. In order to diminish the risk of cancer development, the American College of Gastroenterology introduced the application of a surveillance protocol that is, in summary, as follows^[20]: (1) **patients who are diagnosed with BE at two consecutive endoscopies should undergo endoscopy every 3 years**; (2) **if Barrett's dysplasia is diagnosed, it should be confirmed by a second specialized pathologist**; (3) **patients who are definitely diagnosed with low-grade dysplasia after examination of sufficient biopsy specimen should undergo endoscopic surveillance every year**; (4) **patients diagnosed with HGD should undergo a new endoscopy with a second adequate biopsy specimen, to check the possible presence of invasive cancer**; (5) **if the results are positive, the biopsy specimen should be examined by a second specialized pathologist**; and (6) **if multiple HGD foci are confirmed, then the patient should undergo either surgical therapy (esophagectomy) or endoscopic surveillance every 3 mo**.

This protocol, concerning high-risk patients, is considered strict in various aspects. Many authors believe that surveillance is not justified in a cost-effectiveness analysis^[21-23]. Others compare endoscopic surveillance of patients with BE with the endoscopic follow-up of patients with ulcerative colitis for early detection of malignancy or mammography for early diagnosis of breast cancer and conclude that the former is lacking, in terms of cost-effectiveness, compared to the other two^[24,25].

Furthermore, many studies have shown that the survival of patients with BE is not different from that of the general population^[26]. This observation, as paradoxical as it may appear, can be explained by the low absolute number of adenocarcinoma cases in patients with BE^[19]. Current data demonstrate that patients with BE develop adenocarcinoma at a low rate of 0.5% which is, nevertheless, 30-40 times higher than that of the general population^[27,28]. The subgroup of patients with BE and HGD

develop esophageal adenocarcinoma at a higher rate of 6.58 per 100 patient-years, as shown in a recent meta-analysis^[16]. Moreover, survival studies in patients with BE primarily include elderly individuals, for whom the risk of death from other lethal co-morbid conditions is much higher than the annual 0.5% risk of death from esophageal adenocarcinoma^[29]. Apart from the above, a long-term prospective study involving young patients with BE demonstrating a decreased life span in these patients has not yet been published^[19].

Concerning the endoscopic surveillance of patients with BE, this is not a risk-free procedure. It is estimated that the risk of development of adenocarcinoma is one in every 200 or 300 patients with BE, whereas the risk of a major complication from an endoscopic procedure is one in 1000 esophagogastrosopies^[28-30]. The program of the American College of Gastroenterology also differs from that of the British Society of Gastroenterology^[31] and the NHS Technology Review^[32] in the value of endoscopic surveillance as a screening tool. Despite the previously mentioned contradictory views, many authors indicate a benefit of endoscopic surveillance in cost-effectiveness analyses for the early diagnosis of cancer^[33-36].

CURRENT MANAGEMENT OF BE WITH HGD

Controversy is also perpetuating between surgeons and gastroenterologists. BE with HGD carries a high risk of developing esophageal adenocarcinoma, at a rate of 6%-20%, within a short period of time (17-35 mo)^[14,16]. Therefore, in the presence of such risk, the traditional standard therapy was en bloc esophagectomy with regional lymph node dissection. This approach has been supported by the fact that invasive adenocarcinoma was previously diagnosed in patients with HGD at a rate of 30%-40%^[15], although more recent data have revealed a significantly lower incidence (12%)^[27]. Nevertheless, en bloc esophagectomy carries a high mortality (4%-19%)^[37], high postoperative morbidity (20%-47%)^[38] and unacceptable late postoperative quality of life^[39].

During the last few years, while surgeons try to improve their surgical technique and the results of esophageal resection (esophagectomy without lymph node dissection and/or without thoracotomy, esophagectomy with vagal preservation or laparoscopic esophagectomy), endoscopists have been developing minimally invasive therapeutic methods for the management of BE with HGD. It should be noted that the problem of GERD persists with these endoscopic methods and endoscopic surveillance is necessary for all endoscopic treatment options.

Management of gastroesophageal reflux disease

The therapeutic goal in patients with BE is similar to that of patients with GERD, i.e., relief of symptoms and reversal of the epithelial damage caused by increasing gastric reflux. In cases of BE with HGD, the question is whether medical or surgical management of GERD can

have beneficial effects on the dysplastic lesions. Therefore, the following questions come into play:

Can either surgical or medical antireflux therapy achieve regression of the epithelium in BE?

Evidence clearly indicates that medical therapy of GERD does not lead to acceptable results, with regard to the regression of dysplastic epithelial lesions^[40]. Surgical therapy may have better results than conservative therapy in terms of regression, but is far from being considered adequate. In a series of five publications that included 151 patients submitted to surgical management of gastroesophageal reflux (fundoplication), surgical therapy achieved full regression of these lesions in 6 patients only, whereas in 31 patients only a decrease in the length of BE lesions was observed and 6 patients developed invasive adenocarcinoma. Furthermore, other published data corroborate that antireflux surgery does not decrease the rate of adenocarcinoma in patients with gastroesophageal reflux^[41-43]. Data from the subgroup of patients with BE are also conflicting and pose an unsettled issue^[44].

Does antireflux surgery prevent the metaplastic evolution of the mucosa in BE?

Evidence suggests that surgery is superior to conservative therapy as it can abolish, at high rates, the progression of metaplastic mucosal lesions in BE^[45,46] and therefore protect from dysplasia and malignancy. On the other hand, systematic review indicates that antireflux surgery in patients with BE is associated with regression of BE lesions and/or dysplasia, but evidence supporting the assertion that surgery decreases the rate of adenocarcinoma comes from non-controlled studies^[47]. In a study from the Mayo Clinic in 118 patients who underwent antireflux surgery and follow-up for 18.5 years, it was stated that only 3 patients developed adenocarcinoma within the first three years postoperatively^[48]. This outcome suggested that the lesion probably existed during the operation^[49,50]. Encouraging data come from patients with low-grade dysplastic mucosa and antireflux surgery who, at endoscopic surveillance, showed conversion from a dysplastic to a non-dysplastic mucosa at a rate of about 70%^[51]. Concerning the endoscopic antireflux interventions (Stretta procedure, Bard EndoCinch, Wilson-Cook Endoscopic Suturing Device, NDO Plicator, Enteryx, Gatekeeper Reflux Repair System and Plexiglas), these are currently under evaluation and evidence is lacking to support their role in the therapy of BE with HGD^[52].

Should antireflux therapy accompany other treatment modalities when confronting metaplasia or dysplasia of BE epithelium?

The combination of medical or surgical antireflux therapy with endoscopic mucosal ablation has yielded promising results^[53,54]. These early observations concluded that the resected mucosa undergoes re-epithelialization by normal squamous epithelium and is preserved with the aid of antireflux therapy; usually proton pump inhibitors. Further research is nevertheless needed in this field.

Endoscopic treatment of BE with HGD

It is documented that BE with HGD or intramucosal adenocarcinoma constitute diseases amenable to cure in most cases. Data from high volume centers of esophageal surgery have indicated rare lymph node metastasis, ranging in incidence between 2%-6%^[36,49,55,56]. Newer, less invasive treatment modalities such as endoscopic therapies or less aggressive surgical operations are currently being evaluated in an effort to achieve the least postoperative morbidity and the best quality of life.

Current endoscopic methods include two major therapeutic categories: (1) endoscopic ablation of Barrett's mucosa that can be achieved by thermal, photodynamic and/or radiofrequency energy; and (2) endoscopic mucosal resection.

Thermal therapy

In methods implementing thermal energy, the endoscopic elimination or destruction of the diseased superficial esophageal mucosa is achieved by the administration of heat with one of the following specialized devices: (1) electrocoagulation; (2) argon plasma coagulation (APC); (3) heat probe; and (4) Nd: neodymium-doped yttrium aluminium garnet laser. Another version of thermal therapy consists of cryospray ablation, but experience with this method is limited^[57].

The more widely used first two methods of thermal therapy, probably due to greater availability in endoscopy units, provoke a superficial mucosal injury with a low rate of serious complications. APC has been evaluated at twelve independent centers in 444 patients with BE, making this technique by far the most commonly applied method^[55]. However, the significant variation in the regression of intestinal metaplasia and the formation of new squamous epithelium, together with the complications of this method, resulted in dismissal of APC as the method of choice^[55]. In published series, full regression of BE has ranged from 36%^[58] up to 98%^[59] in an average time frame of 36 and 12 mo, respectively.

Two studies have focused on the effect of APC on intestinal metaplasia in association with the amount of administered energy. In one, no recurrence of BE was noted, while in the other, recurrent disease occurred in 30% of cases. It is noted that in the patients of the first study ($n = 70$) a higher energy device (90 W) was utilized and higher doses of omeprazole (40 mg three times a day) were administered. In 69 patients (98.6%) complete BE eradication with associated squamous regeneration was achieved after a median of two APC sessions (range 1-5). During a median follow-up of 12 mo (range 2-51 mo) with continuous acid suppression, no case of dysplasia relapse was noted. Of these patients, only 3 developed stenosis (4.3%), for whom dilatation was advocated for therapy^[59]. In the second study, where low energy was administered in 27 patients, 70% showed regeneration of squamous epithelium with no persistent intestinal metaplasia and in 30%, areas of intestinal metaplasia were present under the new squamous epithelium, after a

median follow-up of 9 mo (range 6-18 mo). Overall, two cases of perforation were reported, one of which was fatal^[60]. In a third study of 33 patients treated with APC energy between 65 W and 70 W and 60 mg omeprazole daily, complete restoration of the normal squamous epithelium was noted in all cases after 1.96 sessions (range 1-4). Esophageal stenosis occurred in 3 patients, for whom dilatation was deemed necessary, 5 patients developed mediastinal syndrome (high fever and pleural effusion) and one patient pneumomediastinum. After a follow-up period of 10.6 mo, only one recurrence of BE was observed^[61]. Accordingly, the amount of energy administered with APC seems to be directly related to the recurrence rate of BE, favoring the use of high energy devices for a median follow-up of 9 to 12 mo, although data for long-term effectiveness are still lacking. It should be stated that the emergence of APC-related complications depends not only on the amount of energy, but also on other parameters such as mucosal contact at different pressures and repetitive therapy in the same area^[55].

Photodynamic therapy

Photodynamic therapy requires previous administration of a photosensitizer and selection of a specific wavelength of light that stimulates a specific target area or the whole of BE. As a result, singlet oxygen is formed that causes damage to the esophageal mucosa. 5-aminolevulinic acid (5-ALA) is an oral photosensitizing agent that incites severe superficial injury in the patients with HGD and superficial cancer. In the United States, intravenous porfimer sodium, which causes deeper injury, is used. Overholt *et al.*^[62] applied a technique of introducing a cylindrical inflatable balloon through which light was administered in 101 patients with HGD. After a follow-up of at least 4 years, the analysis of the therapeutic effect showed that in 54% of cases there were no residual BE lesions. Successful eradication of low- or high-grade dysplasia or cancer reached 93%, 78% and 48%, respectively. It is thus suggested that HGD and cancer exhibit the greatest resistance to therapy. The total rate of stenosis reached 30%, reflecting the effect of this therapy in deeper esophageal layers.

Great value to this type of therapy is attributed by a large multicentric, semi-blinded, randomized study by Overholt *et al.*^[62] in 208 patients with HGD. Patients were randomly divided, in a 2:1 ratio, into a study group treated with photodynamic therapy and omeprazole and a control group receiving only omeprazole. A statistically significant difference ($P < 0.0001$) regarding the complete eradication of HGD was noted in favor of photodynamic therapy (106/158, 77%), compared to the control group (27/70, 39%). The therapeutic response persisted even after 5 years of follow-up. It should be noted that endoscopic ablation was combined with a long-term follow-up and was, thus, more costly. Nevertheless, this approach has proved to be a better treatment option in terms of cost-effectiveness, compared to the standard follow-up and radical surgery for the treatment

of dysplasia, although clinical trials directly comparing these strategies are warranted^[63]. Additionally, esophagectomy provided 11.82 quality adjusted life years (QUALYs) compared to photodynamic therapy with 12.31 QUALYs and long-term follow-up^[63]. Furthermore, anecdotal time-life analysis of several cases has revealed that many patients with HGD and even early cancer could be controlled with ablative techniques and careful follow-up for 5-10 years^[39].

Radiofrequency energy ablation

This method is a novel therapeutic approach employing (1) energy emitted from a controlled radiofrequency (RF) source [Halo360 or Halo90 RFA (where A stands for ablation), BARRX Medical Inc, Sunnydale, CA]; (2) a sizer balloon catheter, that is introduced into the esophagus and measures esophageal width; and (3) an EFA balloon catheter. The controller of the RFA source is preset to deliver energy of 12 J/cm² which causes complete destruction beyond the lamina propria^[64]. The RFA balloon is 3 cm long and consists of 60 narrowly spaced electrode rings in a bipolar fashion. After the esophageal diameter is measured by the sizer balloon, the RFA balloon catheter is introduced in the esophagus and placed in its position. The balloon is then inflated and the RFA source releases energy circumferentially on the esophageal surface for 300 ms. The whole procedure is performed under general anesthesia^[65].

The use of radiofrequency for the ablation of the dysplastic epithelium in BE is more effective, posing less risk for damage beyond the desired limits, while also controlling the depth of the damage^[66]. In contrast to photodynamic therapy, radiofrequency mucosal ablation is not associated either with the development of esophageal strictures or with recurrent disease resulting from buried Barrett's glands. According to current opinion, the development of strictures after photodynamic or thermal therapy has been attributed to the circumferential destruction of the mucosa. Despite the fact that during RFA therapy destruction is also circumferential, no strictures are observed, as a result of better control of the depth of ablation attained by this method^[65,66]. In order to safely evaluate this method and its long-term effects, studies with larger series, longer duration of follow-up and endoscopic surveillance are expected, so as to document the recurrent dysplasia-free interval.

Recently, endoscopic radiofrequency ablation was evaluated in a study as the definitive treatment of 25 patients with ultralong-segment (≥ 8 cm) BE, using balloon- and/or plate-based devices (BARRX Medical Inc., Sunnydale, CA). Complications for all 25 patients included hemorrhage in one, stricture in two, and nausea and vomiting in two cases. The time from the initial procedure was such that 15 patients underwent at least one post-ablation biopsy. One patient was elected to undergo esophagectomy based on biopsies. Of these patients, 78.5% (11/14) had a complete response. The number of ablations in this group was 2-3 (median 2.5). The authors

concluded that the method is safe and feasible in patients with ultralong-segment BE and can be applied to the entire length of intestinal metaplasia during one session^[67]. Radiofrequency ablation has also been recommended as a single-modality therapy for flat type mucosa, or as a supplementary therapy after endoscopic resection of visible lesions. The treatment protocol consists of initial circumferential ablation, using a balloon-based electrode, followed by focal ablation of residual Barrett's epithelium. The authors believe that radiofrequency is less frequently associated with stenosis and buried glandular mucosa, in contrast to other ablation techniques. This method has been shown to be safe and effective in the treatment of patients with BE and early cancer^[68].

Endoscopic mucosal resection

Endoscopic mucosal resection (EMR) with a curative intent, beyond the scope of mucosal resection for biopsy, is being investigated more than any other endoscopic method for the treatment of HGD in BE. Since the first publication in 2000^[69], several other similar reports have emerged in the United States as well as in Europe^[56,70-76].

The landmark study by Ell *et al*^[69] included 35 low-risk patients with superficial cancer and well or moderately differentiated BE less than 2 cm in diameter who underwent EMR. With an average of 1.3 interventions and an average follow-up time of 1 year, complete regression was observed at a rate of 97% and local recurrence or metachronous cancer at a rate of 17%, with only one case of hemorrhage that was controlled endoscopically. In another study, a group of 70 patients with HGD or early cancer similarly underwent EMR, with an average follow-up interval of 34 mo, and demonstrated regression of lesions in 98% of cases, with a complication rate of 9.5%. Metachronous or recurrent disease occurred in 30% of cases^[77].

EMR has demonstrated satisfactory rates of complete regression; up to 82.5% in 550 patients with HGD or Barrett carcinoma, at an average follow-up interval of 12 mo. The best results were documented in patients with HGD and small (< 20 mm), well or moderately differentiated Barrett carcinomas, at a rate of 97%^[78]. Recently, in a retrospective, single center study from the University of Chicago, 49 patients, 33 with high-grade dysplasia and 16 with early carcinoma, underwent complete Barrett's eradication with the aid of EMR. The rate of stenosis was significant, but it resolved easily with endoscopic dilatation. The authors noticed the presence of Barrett's epithelium underneath the squamous resection margin (Z line) in 13 of 47 patients (28%) at initial mucosectomy. Based on their findings and surveillance biopsies, they concluded that ablative therapy should extend to 1 cm proximal to the endoscopically determined squamocolumnar junction. They also concluded that EMR, with close endoscopic surveillance, is an effective treatment modality for BE with HGD and intramucosal carcinoma^[79]. Another recent study, originating from two Australian academic hospitals, involved 75 patients; 89% with Barrett's HGD

and 11% with early esophageal cancer, who were treated by EMR over a 7-year period. The treatment resulted in complete Barrett's excision in 94% of cases with short segment BE. During the mean follow-up of 31 mo (range, 3-89) there was no recurrence although 11% developed metachronous lesions. Five patients underwent esophagectomy because the endoscopic resection specimen demonstrated submucosal invasion. The complications were one aspiration and six strictures, which were managed with endoscopic dilatation. This study concluded that EMR alters histological grade or local T stage in 48% of patients and dramatically reduces esophagectomy rate, thus providing a safe and effective therapy^[80].

The development of EMR allows full eradication of the neoplastic mucosal lesions and simultaneous accurate staging. Nevertheless, the greatest value of this method is focused on the ability to detect a metachronous lesion, in 50% of cases, in the residual portion of BE. From a therapeutic approach, EMR is promising but has been associated with persistent HGD, persistent Barrett's epithelium and serious recurrence rates of dysplasia or neoplasia in the residual Barrett's epithelium, thus necessitating endoscopic surveillance after resection. It is, therefore, obligatory to completely extirpate intestinal metaplasia at its whole extent, a target that can be accomplished with the combination of EMR with other therapeutic modalities. Combinations of EMR and photodynamic therapy with porfimer sodium, 5-ALA, or meta-tetrahydroxyphenylchlorine^[73,76,77] have been applied in selected patients and have yielded successful results with regard to the eradication of dysplastic lesions^[55].

Another novel therapeutic approach with the intent to eliminate local recurrence involves the use of circumferential mucosal resection with complete excision of the visible Barrett's epithelium^[81]. High success rates in eradication of Barrett's epithelium with a low rate of complications have been demonstrated^[82,83]. These findings suggest that this method could be beneficial for all patients with BE and HGD or intramucosal cancer. Larghi *et al*^[84] have used the technique of cylindrical mucosal excision in 26 patients with BE and HGD as a way to achieve complete excision of Barrett's mucosa. The technique utilized either endoscopic cap suction or endoscopic snare mucosectomy or a combination of both methods. The method of endoscopic cap suction was applied as previously described^[80,84], with the aid of commercially available kits (K001 and K002, Olympus America Inc.). The method of endoscopic snare mucosectomy was performed in the way described by Soehendra *et al*^[85], in which a single-channel therapeutic endoscope (type GIF-IT, Olympus America Inc.) and a single-channel mucosectomy snare (type D3422161 M-C, Endo-Flex GmbH, Voerde, Germany) were used. From the follow-up of 23 patients over an average period of 28 mo, complete eradication of lesions occurred in 21 patients (87.5%), whereas in one patient Barrett's epithelium developed underneath the neo-squamous epithelium three mo after excision, and in another an HGD nodule was detected and excised at

twelve mo during follow-up. Finally, many authors appreciate this method owing to its high therapeutic yield, but also stress the need for additional larger cohort studies, with longer duration of follow-up and endoscopic surveillance, in order to deduce definitive conclusions. It is also suggested that new equipment will aid in the en bloc resection and possibly prove more effective in completely excising the mucosa along with eliminating the possibility of residual Barrett's epithelium. Improvement in the skills needed to perform such techniques with optimal results is expected to accompany technological advances^[84,86,87].

CHOICE OF THERAPEUTIC APPROACH

The classical therapy of BE with HGD has been based on the well renowned, *en bloc* esophagectomy with thoracotomy, vagotomy and lymph node dissection; an operation that, as already mentioned, carries high perioperative mortality, morbidity and a poor quality of life. Considering these disadvantages, many patients are considered unfit for such an operation, whereas others fail to accept it as an option. Additionally, studies from high volume centers in esophageal surgery have demonstrated rare lymph node metastasis, in the region of about 5%, rendering lymph node dissection unnecessary^[36,88,89]. The above data have led surgeons as well as gastroenterologists to in-depth research regarding less invasive endoscopic procedures and operations with decreased mortality, morbidity and an acceptable quality of life, such as laparoscopic vagal-sparing esophagectomy. However, the decision for the appropriate therapeutic approach is often difficult and currently there is considerable controversy over which method is better, i.e., surgery or endotherapy (techniques involving endoscopy). Nevertheless, it must be noticed that a number of other parameters may affect the choice of the therapeutic method.

The histopathological diagnosis of HGD, or even the distinction between low- and high-grade dysplasia, remains alarmingly subjective. The kappa values for intra-observer and inter-observer variability are 0.64 and 0.45^[90] and the accordance for the diagnosis of dysplasia attains a rate of 94% and 88%, respectively. Furthermore, agreement between specialized and non-specialized pathologists as to the definition and the histopathological characteristics of HGD exists in only 50% of cases^[88]. When the need to distinguish HGD from intramucosal carcinoma arises, agreement is even poorer. It is also common knowledge that the natural course of dysplasia differs from patient to patient. Thus, some researchers announce cancer development in 60% of patients at 8 mo, while others report a cumulative cancer rate of 9% at 5 years and only 16% over a 15.9-year period, as documented by endoscopic surveillance^[91].

The presence of esophageal cancer in BE represents yet another diagnostic problem. With meticulous examination of esophagectomy specimens in an effort to detect invasion through the submucosal layer, the kappa values for intra-observer and inter-observer variability

are 0.56 and 0.42, respectively^[92]. There is also significant discrepancy between the prevalence of carcinoma in esophagectomy specimens of patients who are operated for HGD (0% up to 75%)^[93-95] and that of invasive adenocarcinoma in patients with HGD who are under endoscopic surveillance (16% up to 60%)^[88,93,95]. Further disagreement exists as to the presence of occult cancer in patients with BE and HGD. Cameron *et al*^[94] histologically mapped esophagectomy specimens from patients operated for early adenocarcinoma and depicted areas with occult cancer that are extremely small and can easily evade attention.

Obviously, current data are not sufficient to dictate clear-cut therapeutic indications for this specific patient population. The question in doubt is whether to choose endoscopic therapy, particularly EMR, over esophagectomy. Nevertheless, this does not apply to patients who reject surgical intervention or are considered unfit to undergo a major operation. The therapeutic indication for these patients is limited to the choice of an appropriate endoscopic method. Additionally, it must be pointed out that endoscopic therapy should probably be precluded for a group of patients with BE and HGD who are young (about 55 years old), otherwise healthy without significant co-morbidities, with a high risk of developing invasive adenocarcinoma^[95]. Therefore, the selection of the appropriate treatment is questionable for older patients who are eligible for esophagectomy.

Proponents of endoscopic treatment, even in the absence of comparative studies between surgical units and endoscopic departments, advocate that endoscopic therapy carries lower morbidity and mortality than esophagectomy. They also raise the argument that the FDA has already approved porfimer sodium for the photodynamic eradication of premalignant lesions in patients with BE who do not undergo esophageal resection. It seems that even technology works in favor of the endoscopic therapy argument. Recently, in the field of optical spectroscopy, a technique that allows detection of molecular degeneration and minute dysplastic alterations in real time was developed. This technique is expected to allow simultaneous detection and destruction in a single endoscopic session^[79,80].

On the other hand, surgeons argue that the patient is subject to the risk of being lost during the follow-up with endoscopic surveillance and may reappear later with inoperable disease. Moreover, the techniques of endoscopic destruction of the lesion may not provide adequate samples for histological examination. At EMR, residual foci of dysplastic cells remain deeper in the regenerated squamous epithelium; however, HGD is often multifocal and early reports of endoscopic excision have documented an unacceptably high rate of positive excision margins. The majority of studies evaluating endoscopic treatment of BE with HGD were neither randomized nor controlled, included small numbers of patients and the duration of follow-up was relatively short, thus unreliable for extraction of safe conclusions. From a surgeon's point of

view, before choosing a therapeutic approach, the severity of GERD as well as the gravity of symptoms should be taken into account. Thus, avoiding esophagectomy and implementing an endoscopic therapy should be considered for patients with few symptoms, normal esophageal function and short segment BE, with associated low risk of intramucosal cancer. Accordingly, esophagectomy is reserved for patients with BE and HGD or intramucosal cancer who present with severe symptoms of GERD or dysphagia, long segment BE, a large hiatal hernia and poor function of esophageal body^[96].

Currently, the optimal therapy of BE with HGD is, at best, controversial, despite the vast number of emerging new techniques in the fields of both surgery and endoscopy. No properly designed prospective randomized controlled trial, comparing the various therapeutic modalities, has yet been conducted, rendering the undertaking of such a study mandatory in order to elucidate the ideal therapy^[97].

CONCLUSION

The modern era surgeon is confronted with multiple dilemmas concerning the best therapeutic management of patients with BE and HGD, which represents an area of dispute between esophagogastric surgeons and gastroenterologists. The ideal therapy for BE with HGD is further perplexed by the unclear natural history of the disease, the discordance of histopathologic diagnosis and its relation to malignancy, i.e., coexistent disease or subsequent development of esophageal adenocarcinoma. When considering the best therapeutic approach for these patients, multifocality, extent and pretreatment staging of the disease, as well as patient's preference and performance status, should all be taken into account. Therefore, the ideal therapy should be individualized. Many advocate esophagectomy as the gold standard therapy for BE with HGD. Nevertheless, new and emerging minimally invasive, endoscopic and ablative techniques have more recently yielded significant results and gained popularity. Randomized controlled trials are still required to properly define their optimal role in the armamentarium against BE with HGD and current research is expected to lead to the incorporation of these techniques in standard clinical practice.

Abstract

AIM: To characterize the inductive effects of isoflurane (ISO) on hepatic heme oxygenase-1 (HO-1) in an animal model of hepatic steatosis.

METHODS: Lean (LEAN) and obese (FAT) Zucker rats were randomized into 4 groups: 1: LEAN + pentobarbital sodium (PEN); 2: LEAN + ISO; 3: FAT + PEN; 4: FAT + ISO. The animals were mechanically ventilated for 6 h. *In vitro* analyses of liver tissue included determination of HO-1 mRNA and protein expression as well as measurement of HO enzyme activity and immunohistochemical analyses.

RESULTS: Compared to PEN treatment, ISO administration profoundly induced hepatic HO-1 mRNA and protein expression and significantly increased HO enzyme activity in lean Zucker rats. In contrast, no difference in *HO-1* gene expression was observed after ISO or PEN anesthesia in obese Zucker rats.

CONCLUSION: The present study demonstrates that ISO is an inducer of hepatic *HO-1* gene expression in non-steatotic organs but failed to upregulate HO-1 in steatotic livers.

INTRODUCTION

The development of hepatic ischemia/reperfusion (I/R) injury is a fundamental problem in major hepatic surgery including liver transplantation, causing a higher rate of morbidity and mortality^[1,2]. Surgical interventions such as warm hepatic inflow occlusion (Pringle maneuver) or cold ischemia in the transplant setting followed by reperfusion are important and often unavoidable techniques used to reduce blood loss or preserve organs for subsequent transplantation. I/R injury frequently results in apoptosis and necrosis of hepatocytes, which could consequently lead to organ failure or graft dysfunction^[3,4]. In recent years liver surgery has become safer due to improvements in surgical techniques, anesthetic procedures

and postoperative care. However, due to the epidemic increase in obesity, the prevalence of hepatic steatosis has significantly increased during the last few decades. The Dallas Heart Study reported a prevalence of hepatic steatosis in their population of about 38% indicating the high relevance for today's health care system^[5]. It has been repeatedly shown that steatotic livers are especially vulnerable to I/R injury. Liver surgery in patients with severe hepatic steatosis is associated with higher morbidity and mortality rates due to the underlying pathogenic features affecting important mechanisms during I/R, liver regeneration and recovery^[6-8]. Various strategies have been proposed to improve the postoperative outcome of these patients including pharmacological approaches aiming at upregulation of cytoprotective genes.

Heme oxygenase-1 (HO-1) and its catalytic products have been identified as major players in cell protection in different organs^[9-12]. Whereas HO-1 represents the inducible form of the HO family, HO-2 is expressed constitutively. HO catabolizes the first and rate-limiting step in heme degradation producing carbon monoxide (CO), free iron and biliverdin, which is converted into bilirubin by biliverdin reductase^[13]. A multitude of HO-1 inducers are well known, but most of them are toxic which limit their therapeutic application in humans^[14,15]. We have previously shown that volatile anesthetics are potent non-toxic inducers of *HO-1* gene expression in the rat liver^[16]. Isoflurane (ISO) pretreatment induces hepatic HO-1 mRNA and protein followed by an increase in HO activity, thereby reducing portal resistance^[17]. Experimental and clinical evidence support the hypothesis that administration of volatile anesthetics could be a promising approach to limit I/R injury and to improve the outcome of patients undergoing liver surgery^[18,19]. To date, no data are available regarding the effects of anesthetics on hepatic HO-1 induction in steatotic livers. Therefore, the present study was designed to characterize the effects of ISO administration on hepatic *HO-1* gene expression in an established animal model of hepatic steatosis using genetically modified Zucker rats.

MATERIALS AND METHODS

Reagents

Isoflurane was obtained from Abbott (Wiesbaden, Germany) and pentobarbital sodium from Alvetra (Neumuenster, Germany). Pancuronium was purchased from Organon (BH Oss, Netherlands). All other reagents used were purchased from Sigma Aldrich (Deisenhofen, Germany), if not specified otherwise.

Animals

All animal experiments were approved by the local animal care and use committee and were in accordance with the Guide for the Care and Use of Laboratory Animals. Homozygous obese (FAT) male Zucker rats and heterozygous lean (LEAN) male Zucker rats aged 12 wk were obtained from Charles River (Sulzfeld, Germany). Animals were fasted for 6 h before the beginning of the

experiments but were allowed free access to water.

Experimental protocol

The animals were assigned to 4 groups: group 1, LEAN + PEN (pentobarbital sodium, 40 mg/kg per hour i.v.); group 2, LEAN + ISO; group 3, FAT + PEN; group 4, FAT + ISO. Animals treated with PEN received one initial intraperitoneal injection of pentobarbital sodium (40 mg/kg) followed by an intravenous infusion of 40 mg/kg per hour. For compensation of evaporative losses 10 mL/kg per hour of saline solution 0.9% were continuously infused. Rats in the ISO groups were anesthetized by inhalation of ISO (2.8-3.1 Vol%). After induction of anesthesia, a tail vein was cannulated and a tracheostomy was performed. Relaxation was achieved by injection of pancuronium (1 mg/kg i.v.) and all animals were mechanically ventilated (Rodent Ventilator UB 7025-10, Harvard Apparatus, March-Hugstetten, Germany). Doses of 0.5 mg/kg pancuronium were repeated every 3 h to maintain muscle paralysis. Cannulation of the left carotid artery with polyethylene (PE-50, Smith Medical, Ashford, United Kingdom) tubing was performed for arterial blood pressure monitoring and blood gas analysis. The right jugular vein was cannulated for fluid administration. Blood gas analyses were performed using an autoanalyzer ABL 800 Flex (Radiometer, Willich, Germany). At the end of the experiment (6 h after onset), the animals were killed and blood and liver tissue were removed for subsequent analyses.

Enzyme determination

Blood samples were collected at the end of each experiment and immediately centrifuged at 4 °C. Rat α -glutathione s-transferase (α -GST) serum concentration was evaluated using an anti-rat α -GST enzyme immunoassay (Argutus Medical, Dublin, Ireland). The procedures were performed according to the manufacturer's instructions.

RNA isolation

Total RNA was extracted from liver tissues using the TRIzol method (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's recommendation. RNA amounts were normalized to a concentration of 50 ng/ μ L diluted with RNase-free Water (Qiagen, Hilden, Germany).

Semi-quantitative real-time reverse transcriptase-polymerase chain reaction

Total RNA was reverse transcribed to single-stranded cDNA using a High Capacity cDNA Reverse Transcription Kit (Applied Biosystems Inc, Foster City, CA 94404 United States) according to the manufacturer's protocol. Briefly 250 ng of purified total RNA were subsequently used in 50 μ L reverse transcription reactions employing random hexamers. 50 ng of the resulting cDNA were used in semi-quantitative real-time polymerase chain reaction (PCR) analysis in a 50 μ L final volume. Reactions were performed on an ABI Prism 7000 (Applied Biosystems, Foster City, CA, United States) in duplicate for each animal using TaqMan Mastermix reagents (part number

4309169, Applied Biosystems, Foster City, CA, United States) with a specific TaqMan® Probe against HO-1 cDNA (Assay ID: Rn00561387_mL) as described in the manufacturer's protocol. Parameters for quantitative PCR were as follows: 10 min at 95 °C, followed by 40 cycles of amplification for 15 s at 95 °C, and 1 min at 60 °C. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene expression was used as endogenous control in all real time analyses using a VIC®/MGB labeled Probe (part number: 4352338E, Applied Biosystems, Foster City, CA, United States). The obtained data were analyzed by the $\Delta\Delta CT$ method.

Determination of heme oxygenase enzyme activity

The heme oxygenase (HO) enzyme activity assay was performed as previously described^[20]. Briefly, frozen liver tissue was homogenized and added to a reaction mixture containing NADPH, liver cytosol, glucose-6-phosphate, glucose-6-phosphate dehydrogenase and hemin. The reaction was performed at 37 °C for 1 h in the dark and stopped by the addition of chloroform. The extracted bilirubin was calculated by the difference in absorbance between 464 and 530 nm.

Hematoxylin-eosin staining of liver sections

For histological analysis, liver sections were fixed with 4% buffered formalin (pH 6.9) and embedded in paraffin. Livers were sliced (5 μ m) and stained with hematoxylin-eosin according to a standardized protocol.

Immunohistochemical staining

Liver tissue samples were formalin-fixed, paraffin embedded and cut in a microtome to 4 microns. The slides were deparaffinized with xylene, rehydrated and then rinsed with tap water. Antigen retrieval was performed by microwave irradiation in a sodium citrate buffer (pH 6) and slides were blocked with a ready-to-use peroxidase blocking reagent (Dako North America, Inc., CA 93013 United States) for 10 min at room temperature. After subsequent treatment with normal goat serum, slides were incubated with the primary antibody (dilution 1:50) as used in Western blotting for 1 h at room temperature. Following three washing steps with phosphate buffered saline (PBS) the slides were incubated with the HRP-conjugated secondary antibody (Goat A-rabbit-HRP, Dako, Denmark) diluted 1:200. The slides were again washed 3 times with PBS and then incubated with liquid diaminobenzidine and substrate (Dako North America, Inc., CA, United States) as the chromogen for 6 min and rinsed with deionized water. Finally the sections were counterstained with Mayer's hematoxylin (Merck KG, Darmstadt, Germany), dehydrated and mounted in an organic mounting media. For assessment of the severity of hepatic steatosis, hematoxylin and eosin-stained sections were evaluated without immunohistochemical treatment.

Western blotting analysis

Western blotting analysis was performed with total cell lysates as described previously^[19]. Briefly, frozen liver tissue was homogenized on ice in activated RIPA buffer (Santa

Cruz, CA, United States). Total protein concentration was determined in the supernatant using the Bradford assay (Bio-Rad Laboratories, Munich, Germany). Each lane of a 10% sodium dodecyl sulfate gel contained 100 μ g of total protein. After separation and electroblotting, HO-1 was detected by a rabbit polyclonal anti-HO-1 antibody (1:1000 dilution, SPA 895; Stress Gen Biotechnologies, Victoria, British Columbia, Canada) using the enhanced chemiluminescence detection kit (Amersham Pharmacia) according to the manufacturer's instructions.

Statistical analysis

Data are presented as mean \pm SE of the mean with $n = 5$ animals per group as indicated. Statistical differences within each group were determined using a one-way analysis of variance (ANOVA) for repeated measurements and between the different groups by one-way ANOVA followed by the post hoc Student-Newman-Keuls test for pairwise comparisons. When criteria for parametric tests were not met, Kruskal-Wallis ANOVA on ranks followed by Dunn's test was used. These data are presented as median (box: 25th and 75th percentiles; error bars: 5th and 95th percentiles) for $n = 5$ animals per group. Data were considered significant when $P < 0.05$. Statistical analysis was performed using the Sigma Stat and Sigma Plot 11 software package (Jandel Scientific, San Rafael, CA, United States).

RESULTS

Analysis of vital parameters and weight

The animals in the LEAN + PEN group had a significantly higher mean arterial pressure at the respective time points during the experiments (Table 1). There were no differences in heart rate between the different groups. Body temperature dropped during induction of anesthesia but returned to normal values after at least 2 h in all groups (Table 1). **Homozygous Zucker rats (FAT) had a higher body weight compared to the age-matched heterozygous controls (LEAN) (Table 2).** There were no significant differences in blood gas parameters.

Effect of ISO treatment on hepatic HO-1 mRNA expression

Semi-quantitative HO-1 mRNA real-time analysis of isolated liver extracts is shown in Figure 1A. ISO treatment over 6 h led to a significant increase in HO-1 mRNA in lean rats (4.81 ± 0.82) compared to all other groups. ISO inhalation in FAT Zucker rats (2.57 ± 0.22) did not lead to a significant induction of HO-1 compared to the respective PEN group (2.83 ± 0.39). A significant difference in HO-1 mRNA levels was detected between liver extracts of animals from the FAT+PEN and FAT + ISO group compared to rats assigned to the LEAN + PEN group (2.03 ± 0.38).

Effect of ISO administration on hepatic HO-1 protein levels and HO enzyme activity

In line with RT-analyses, representative Western blotting showed higher HO-1 protein levels in liver extracts

Table 1 Time course of mean arterial pressure, heart rate and temperature

	Time (h)	LEAN+PEN	LEAN+ISO	FAT+PEN	FAT+ISO
MAP (mmHg)	0	127 ^a ± 5	82 ± 11	106 ± 5	99 ± 5

pO ₂ (mmHg)	211 ± 52	279 ± 69	258 ± 33	308 ± 74

Data were obtained after induction of anesthesia. Data are presented as mean ± SE of the mean for $n = 5$ animals per group (^b $P < 0.001$ vs Lean + Pentobarbital sodium and Lean + Isoflurane). pCO₂: Arterial carbon dioxide partial pressure; pO₂: Arterial oxygen partial pressure; LEAN: Lean Zucker rats; FAT: Obese Zucker rats; ISO: Isoflurane; PEN: Pentobarbital sodium.

from animals in the LEAN + ISO group compared to the other groups (Figure 1B). Equal loading was verified by reprobing the membrane with a GAPDH antibody. In addition, HO enzyme activity was significantly higher in ISO treated lean Zucker rats (Figure 1C). Interestingly, we found no differences in HO activity between the FAT + PEN and FAT + ISO group.

Expression pattern of hepatic HO-1 protein after ISO treatment

HO-1 immunoreactive protein was restricted to spindle-shaped sinusoidal lining cells in PEN anesthetized control animals (Figure 2A). HO-1 protein was markedly upregulated in hepatocytes predominantly located in the perivenular area after ISO treatment in lean Zucker rats (Figure 2B). In sharp contrast, we did not detect any upregulation of HO-1 protein in hepatocytes of the perivenular area in obese Zucker rats after treatment with ISO (Figure 2C and D).

Hematoxylin-eosin staining

For confirmation of steatosis hepatis, hematoxylin-eosin staining was performed. Obese Zucker rats (FAT) showed

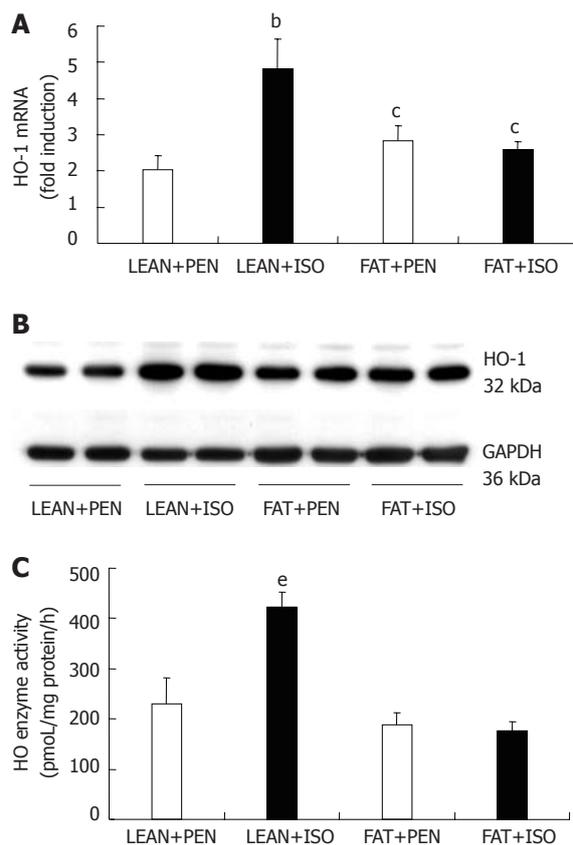

Figure 1 Hepatic heme oxygenase-1 gene expression and heme oxygenase enzyme activity in lean and obese Zucker rats after treatment with pentobarbital or isoflurane. A: Reverse transcriptase-polymerase chain reaction was performed for determination of HO-1 mRNA expression. Data are presented as mean ± SE of the mean for $n = 5$ per group. ^b $P < 0.01$ vs all other groups; ^c $P < 0.05$ vs LEAN + PEN; B: Western blotting analysis for determination of HO-1 protein expression in two representative animals from each group; C: Measurement of HO enzyme activity. severe macrovesicular and microvesicular fatty infiltration in hepatocytes (Figure 3C and D). In contrast, we did not detect any accumulation of lipid droplets in LEAN animals (Figure 3A and B).

Effect of ISO treatment on serum levels of α -glutathione S-transferase

As shown in Figure 4, α -GST, one of the most specific serum enzymes identifying hepatocyte injury did not differ between the groups.

DISCUSSION

In the present report we demonstrate that ISO induced upregulation of *HO-1* gene expression, which was reproducibly shown in normal livers and serves as a major protective mechanism against hepatic ischemia and reperfusion injury, is abrogated in the presence of hepatic steatosis. ISO treatment of heterozygous lean Zucker rats representing a normal phenotype led to a profound induction of HO-1 mRNA and protein with a subsequent

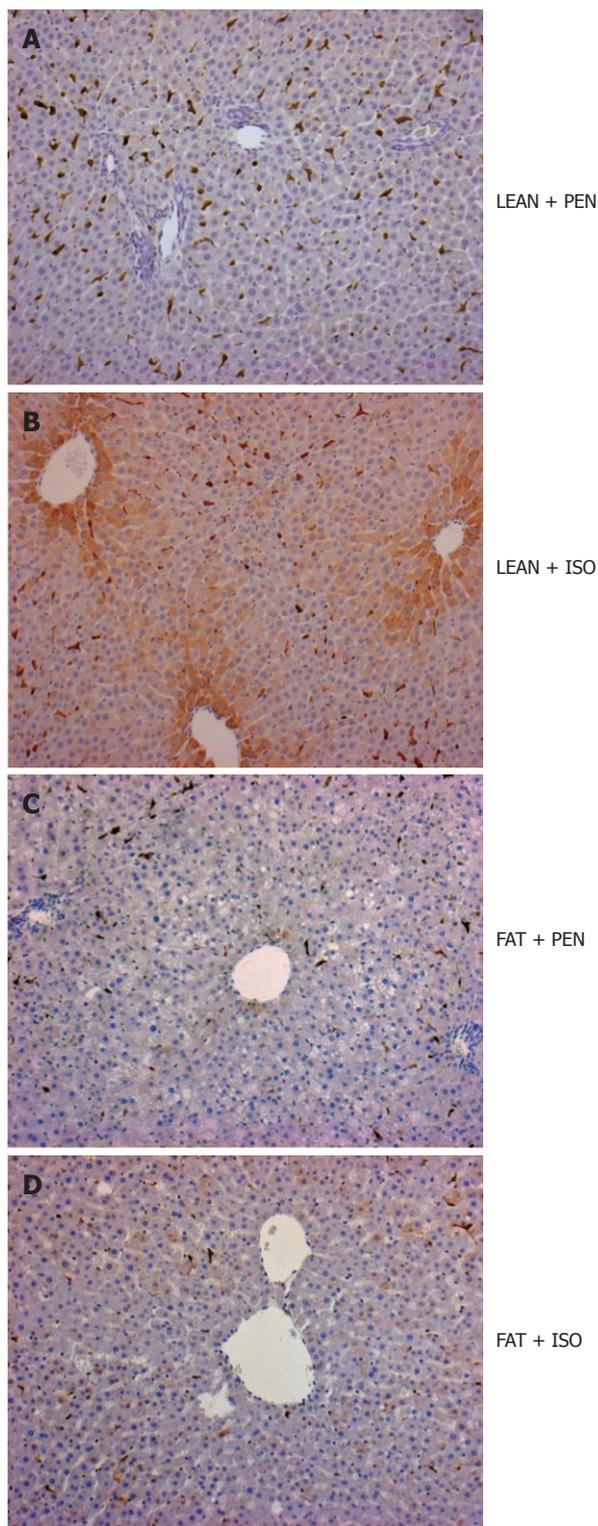

Figure 2 Heme oxygenase-1 protein expression pattern in liver sections from lean and obese Zucker rats after treatment with pentobarbital or isoflurane. A: Heme oxygenase-1 (HO-1) protein was restricted to spindle-shaped sinusoidal lining cells in pentobarbital treated animals; B: Isoflurane (ISO) administration led to markedly upregulated HO-1 protein expression in hepatocytes of the perivenular area; C and D: No detectable induction of HO-1 protein in hepatocytes of obese animals was detected after ISO treatment. expression in the liver of these animals.

Volatile anesthetics are non-toxic inducers of hepatic *HO-1* gene expression^[16,17,19,21]. We previously showed that pretreatment with ISO leads to an improvement in hepatic macro- and microvascular blood flow and reduces portal vascular resistance in the normal liver^[17]. Furthermore, ISO induced upregulation of hepatic HO-1 is an important hepatoprotective mechanism against I/R injury. It specifically upregulates HO-1 protein in hepatocytes of the perivenular area, the primary localization of cellular injury in low flow states like I/R. HO-1 induction improves microcirculation in the early reperfusion period, decreases the oxidative burst and significantly reduces serum levels of liver enzymes and morphological signs of hepatic injury after I/R^[19]. In addition to these experimental data, Beck-Schimmer and colleagues recently published the first randomized clinical study demonstrating the hepatoprotective effect of the volatile anesthetic, sevoflurane, in patients undergoing liver resection^[18]. Interestingly, they found an even more pronounced beneficial effect of sevoflurane in patients with steatotic livers. No information is available regarding sevoflurane treatment on *HO-1* gene expression in their study. However, we hypothesize that the protective effect of sevoflurane in this trial is independent of HO-1 since the duration of pretreatment (30 min) and the concentration applied (1.5 of minimal alveolar concentration) is most likely not sufficient to upregulate hepatic *HO-1* gene expression. Therefore, volatile anesthetics might mediate liver protection by at least two different mechanisms, one dependent and one independent of HO-1. To exclude the possibility that HO-1 upregulation in homozygous Zucker rats is generally prevented by genetic modifications in these animals, we screened the literature in this regard. It has been repeatedly shown by different authors that the administration of a variety of compounds can profoundly induce HO-1 in obese Zucker rats^[22,23]. Therefore, the inability to upregulate HO-1 by ISO seems to be substance specific rather than based on a general lack of inducibility

in these animals. As indicated in Figure 1A and B, hepatic HO-1 induction in obese animals was slightly but significantly higher than in the livers of lean controls. However, this did not affect HO enzyme activity in our experiments (Figure 1C).

To exclude hepatotoxic effects of the anesthetics in our experiments, we performed serum α -GST measurements. α -GST levels, which serve as a very specific marker of hepatocyte injury, did not differ between the respective groups indicating the non-toxic action of ISO.

Obese Zucker rats develop hypertensive blood pressure values accompanied by improper autoregulation caused by an impairment of sympathetic baroreceptor reflexes^[24-26]. Therefore, anesthetics (e.g., barbiturates) may have an even more pronounced effect on blood pressure in obese rather than lean Zucker rats. This could be an explanation for the higher blood pressure in the LEAN + PEN group compared to the other animals observed in the present study.

Patients with hepatic steatosis are at higher risk for postoperative complications after major hepatic surgery including liver transplantation, and adverse outcomes have been repeatedly documented^[8,27-30]. Due to the increasing gap between the number of available organs and the number of patients awaiting an organ, the amount of so-called “marginal livers” considered for transplantation is increasing. Based on this dilemma, it is important to develop protective strategies particularly for the above-mentioned type of organs comprising severely steatotic livers to expand the pool of available liver grafts.

The present study demonstrates that ISO is a potent inducer of *HO-1* gene expression in non-steatotic livers but failed to upregulate HO-1 in steatotic organs. If validated in humans, this observation may have an impact on the anesthetic regimen in patients undergoing liver surgery.

ACKNOWLEDGMENTS

The authors are grateful to Martina de Groot and Heide Marniga for their excellent technical assistance.

COMMENTS

Background

Experimental and clinical evidence support the hypothesis that administration of volatile anesthetics could be a promising approach to limit ischemia/reperfusion (I/R) injury and to improve the outcome of patients undergoing liver surgery. The volatile anesthetic isoflurane is a potent non-toxic inducer of heme oxygenase-1 (HO-1) gene expression in the normal liver. The authors previously showed that these livers are protected from I/R injury.

Research frontiers

There are no studies currently available characterizing the inductive effects of volatile anesthetics on steatotic livers which are especially vulnerable to I/R injury. Therefore, we examined the effects of isoflurane (ISO) on hepatic HO-1 induction in lean (non-steatotic livers) and obese (steatotic livers) Zucker rats.

Innovations and breakthroughs

The findings of the present study demonstrate that isoflurane is a potent inducer of HO-1 gene expression in non-steatotic livers but failed to upregulate HO-1 in steatotic livers.

Applications

If verified in humans, this observation may have a crucial impact on the anesthetic regimen in patients undergoing liver surgery.

Terminology

HO-1 also called heat shock protein-32 and its catalytic products were recently identified as major players in cell protection in different organs. Hepatic I/R injury is a fundamental problem in major hepatic surgery including liver transplantation. The Zucker rat is a genetic research model for obesity and hypertension named after Lois M Zucker. Homozygous Zucker rats have high levels of lipids in their blood and an increased size and number of fat cells. Therefore, these animals serve as a model for steatosis hepatis.

Peer review

In this manuscript, the authors compare the effects of the volatile anesthetic isoflurane in the induction of HO-1 among lean and obese rats. They measure HO-1 expression at the mRNA and protein level, and also assess the activity of this enzyme. The overall data suggest that isoflurane efficiently induces HO-1 in lean, but not in obese animals. The study is well designed, appropriate controls are included and the experiments are of high technical quality. The conclusion is fully supported by the presented data.

Abstract

AIM: To investigate the diagnosis of nonalcoholic steatohepatitis (NASH) using contrast ultrasonography in the NASH rat model.

METHODS: The liver in methionine choline-deficient diet (MCDD) rats, a NASH model constructed by feeding an MCDD, was examined by contrast ultrasonography at weeks 2, 4, 8, 12 and 16, with late phase images of contrast ultrasonography (Kupffer imaging) in which contrast enhancement was achieved by incorporation of a contrast agent by Kupffer cells (KCs), and images were compared to those in rats taking a regular chow.

RESULTS: Decrease in contrast enhancement was observed first in MCDD rats at week 2. KCs were counted based on immunohistochemistry, but their numbers were not reduced and it was assumed that attenuation of contrast enhancement was attributable to reduced phagocytic activity of the KCs.

CONCLUSION: It is suggested that clinical application

INTRODUCTION

Nonalcoholic steatohepatitis (NASH) is a relatively new disease entity, proposed by Ludwig in 1980^[1], which exhibits a clinical manifestation similar to that of alcoholic steatohepatitis in terms of liver histology, despite a lack of history of alcohol abuse causing hepatitis. The diagnosis of fatty liver without a history of drinking alcohol is generally termed nonalcoholic fatty liver disease (NAFLD), which is most simply fatty liver with an excellent prognosis, while NASH is a subtype of NAFLD^[2].

It is important to differentiate NASH from NAFLD at an early stage to start relevant treatment. Although there have been a number of reports aimed at differentiating NASH patients^[2], histological diagnosis based on liver biopsy is the only diagnostic method at present. However, liver biopsy is an invasive method, with a small risk of complications, and is too invasive for diagnosis of a benign disease, such as NASH.

It has been previously reported that liver-specific

Kupffer images of contrast ultrasound can be used for differential diagnosis between NASH and NAFLD^[3]. In this study, using a rat model of NASH, we carried out contrast ultrasonography to compare contrast enhancement between the NASH model and control rats that were fed a regular chow. LevovistTM (Schering AG, Berlin, Germany) and SonazoidTM (GE Healthcare, Oslo, Norway) were used as contrast ultrasonography agents. Microbubbles of LevovistTM and SonazoidTM are phagocytosed and incorporated by Kupffer cells (KCs) in the late contrast phase (Kupffer imaging)^[4]. There is a report that contrast enhancement by the contrast agent in the late contrast phase was decreased in patients diagnosed with NASH, compared to NAFLD patients^[3,5]. The reason for decreased microbubble accumulation in the NASH liver is presumed to be because phagocytosis of microbubbles by KCs is decreased.

We constructed a NASH model by feeding a methionine choline-deficient diet (MCDD, Oriental Yeast Co., Tokyo, Japan) to rats^[6-8]. Then, examining the liver using contrast ultrasonography, we compared the phagocytic activity by KCs in rats eating an MCDD and those given regular chow, using contrast enhancement in the late contrast phase.

MATERIALS AND METHODS

Animals and construction of a NASH model

Male Wistar rats weighing about 50 g at the time of purchase were used and kept in a room at 21 °C ± 2 °C with a 12-h cycle of light and darkness. The NASH model was constructed by feeding an MCDD to 15 rats, and the group was designated the MCDD group. Conversely, a diet of regular chow was fed to 5 rats and they were designated the control group. Rats were subjected to experiments at 2, 4, 8, 12 and 16 wk after beginning the diet, and three rats in the MCDD group and one in the control group were used for experiments at each time point. During the follow-up period, water and regular chow were given *ad libitum*. Body weight was measured in all rats in both groups at the designated time points. In addition, to observe the histological changes in liver tissue in MCDD rats at the designated time points, part of the resected liver was fixed in 10% formalin after the experiments, and paraffin slices were prepared and stained with hematoxylin and eosin for histological examination. All animals received humane care and the experimental protocols were approved by the Animal Ethical Committee of Tokyo Medical University.

Incorporation of the contrast ultrasonography agent

After rats were anesthetized at the designated time point by inhalation of diethyl ether (Wako Pure Chemical Industries, LTD., Tokyo, Japan), the abdomen and thighs were shaved and the fascia exposed by an excision of abdominal skin. At the same time, the thigh was incised to expose the femoral vein and a 24-gauge indwelling needle (TERUMO Corp., Tokyo, Japan) was inserted to secure

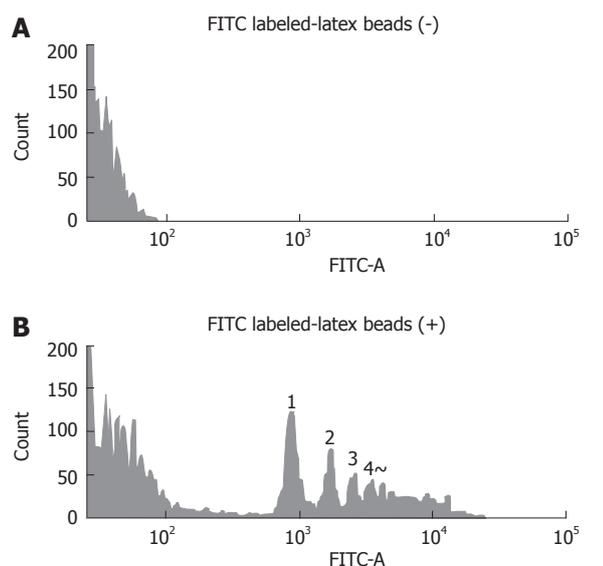

the vessel. From this site, a total of 500 µL of LevovistTM solution (10 µL/g body weight) with physiological saline was infused as a bolus. In both groups, the liver was scanned through the exposed fascia with an echo probe 10 min later. Images were scanned at mechanical index (MI) of 1.5 and then any LevovistTM remaining in the liver was destroyed by sweep scanning over the whole liver. Next, as for LevovistTM, a total of 500 µL of SonazoidTM 10 times diluted solution (1 µL/g of SonazoidTM solution/body weight) with physiological saline was infused intravenously as a bolus and, 10 min later, images were scanned and recorded at Advanced Dynamic FlowTM (ADF) ultrasound mode at MI of 1.5. An AplioTM (Toshiba Medical Systems, Tokyo, Japan) was used in this study. The frequency used was 7.5 MHz and the type of the transducer was linear. ADF was harmonic power Doppler mode from Toshiba Medical Systems.

A region of interest (ROI) was determined arbitrarily in the constant area of ultrasound images of the liver parenchyma obtained at 10 min, and contrast enhancement was quantified in the MCDD and control groups by intensity analysis software Image J (<http://rsb.info.nih.gov/ij/>). Quantified values in the MCDD group were expressed as relative values compared to those in the control group at each designated time point. An ROI was set in the region covering a wide area of the liver parenchyma, excluding large vessels as far as possible. The average intensity in the ROI was measured and relative values were compared.

In vivo administration of FITC-latex beads and isolation of KCs

After experiments using contrast ultrasound, 50 µL of FITC-latex beads (2 µm in diameter, Polyscience, Warrington, PA, United States) were mixed with 500 µL of physiological saline and infused from the tail vein to examine the phagocytic activity of KCs in rats in the MCDD and control groups. One hour later, KCs were isolated according to the following methods: Rats were anesthetized by inhalation of diethyl ether and a midline abdominal incision was made. A 20-G indwelling needle was inserted into the portal vein and after perfusion with Hanks Balanced Salt Solution (HBSS, Sigma, St. Louis, MO, United States), the portal vein was perfused with 100 mL of Dulbecco's Modified Eagle's Medium (DMEM/F-12, Sigma) containing 200 mg pronase (Roche Diagnostics Corp., Indianapolis, IN, United States), followed by 100 mL of DMEM/F-12 containing 25 mg collagenase (Nitta Gelatin Inc., Osaka, Japan). When collagenase leaked out of the blood vessel because of rupture during perfusion, and it was judged that the liver was not perfused, the procedure was stopped. After completion of perfusion, the digested liver was extracted carefully and incubated in DMEM/F-12 supplemented with 0.035% pronase and 62.5 units/mL of DNase (Sigma) for 20 min at 37 °C on a shaker incubator.

Next, the suspension was filtered through gauze and undigested liver tissue was discarded. The liver cell sus-

Figure 1 Measurement of Kupffer cells phagocytic activity by flow cytometry. A: The negative control, into which fluorescein isothiocyanate (FITC)-labeled latex beads were not injected; B: The positive control to which FITC-labeled latex beads were administered. Note the several peaks of the FITC from the beads in the positive control. The numbers on the peak show the number of latex beads phagocytosed. KC: Kupffer cell.

pension containing KCs was centrifuged for 1 min at 50 *g*/min and the supernatant collected. Then, the supernatant was centrifuged again at 50 *g*/min and parenchymal liver cells were removed as far as possible. Subsequently, the supernatant was centrifuged at 500 *g*/min for 8 min and a pellet of non-parenchymal cells was obtained. The supernatant was discarded and the pellet was resuspended with a small amount of washing buffer. The non-parenchymal liver cell suspension containing KCs was centrifuged at 900 *g*/min for 15 min with 50% and 25% Percoll (Pharmacia, Uppsala, Sweden) for density-gradient centrifugation, and the first layer from the top was collected. Next, the suspension was rinsed with 40 mL of HBSS and percentages of KCs that had phagocytosed FITC-latex beads were measured by flow cytometry. The purity of the KCs was examined by incorporation of latex beads 2 μm in size and confirmed to be always 96% or greater. Viability was examined by the trypan blue dye exclusion test and unstained cells accounted for 90% or more.

Changes in phagocytic activity of KCs

Phagocytosis by KCs isolated from each group was examined using a BD LSR-II flow cytometer (Becton Dickinson, Franklin Lakes, NJ, United States). First, in a preliminary experiment, it was determined whether FITC-latex beads phagocytosed by KCs were measurable by the flow cytometer. The flow cytometry histogram of KCs in the control group is shown in Figure 1. The upper panel shows the flow cytometry histogram of KCs in the control rat without adding FITC-latex beads and

the lower panel shows the flow cytometry histogram of KCs in the control rat given FITC-latex beads. The amount of FITC-latex beads added was the same as in the subsequent experiments. There were peaks representing the number of FITC-latex beads, but the number of KCs that phagocytosed five beads or more was not determined. Nevertheless, it was possible to detect phagocytosed FITC-latex beads. KCs isolated in the control group were used to determine the position of gating and the gates were set a little wider. After the flow of 10 000 counts of KCs, the percentage of cells positive for fluorescence of FITC-latex beads in all gated cells was calculated in the MCDD and control groups and taken as the phagocytic activity.

Changes in KCs

Because there was a possibility that microbubble accumulation in the liver was dependent on the number of KCs in the liver, the liver was removed from one rat in each group, embedded in O.C.T. compound (Sakura Finetechnical Co. LTD, Tokyo, Japan) and snap-frozen immediately in liquid nitrogen. Later, 5 μm frozen sections were cut with a cryostat. Sections were fixed with acetone and subjected to immunohistochemistry for KCs with anti-rat macrophage antibody (ED2, SEROTEC Ltd, Oxford, United Kingdom) to count positive cells under the same magnification in the MCDD and control groups. In addition, 5 μm frozen liver specimens were cut with the cryostat and immunofluorescent latex beads were observed.

Statistical analysis

Unpaired Student's *t* test was employed for all statistical analyses and a *P* value less than 0.01 was considered statistically significant.

RESULTS

Body weight changes and liver histology in the MCDD and control groups

Body weight initially was about 50 g and increased in the MCDD group to 270 g at week 9, but decreased slightly thereafter. Although body weight reduced, general conditions were stable. In the control group, body weight increased steadily to about 440 g at week 16. General conditions also were stable (data not shown). In terms of histological changes in the liver, large-droplet fat deposition was recognized in the entire liver lobules at week 2 and later. At week 8, necrotic inflammatory changes were observed around the central vein and inflammatory findings were evident. At week 16, fibrosis was observed extending from the central vein and the MCDD group was judged to be a NASH model. In contrast, no fatty liver, inflammation, or fibrosis was observed up to week 16 in the control group (Figure 2).

Changes in contrast ultrasonographic findings

Signal intensity of the liver obtained by contrast ultrasound with LevovistTM was compared between the two groups.

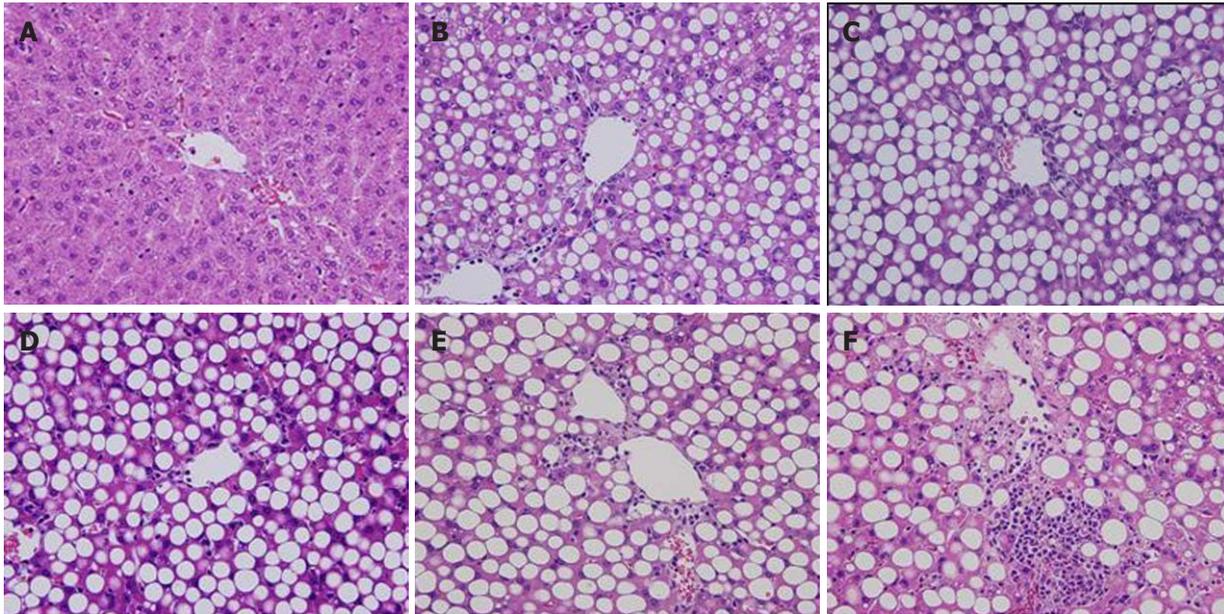

Figure 2 Histological changes of methionine choline-deficient diet-fed rat liver (hematoxylin eosin x 200). Extremely large vesicle fat deposits in almost the entire lobules were detected even as early as two weeks after the start of the methionine choline-deficient diet. By 8 wk, spotty necrosis was dispersed and by 16 wk, there was fibrosis extending from the central vein. A: Control; B: Two weeks methionine choline-deficient (MCD); C: Four weeks MCD; D: Eight weeks MCD; E: Twelve weeks MCD; F: Sixteen weeks MCD.

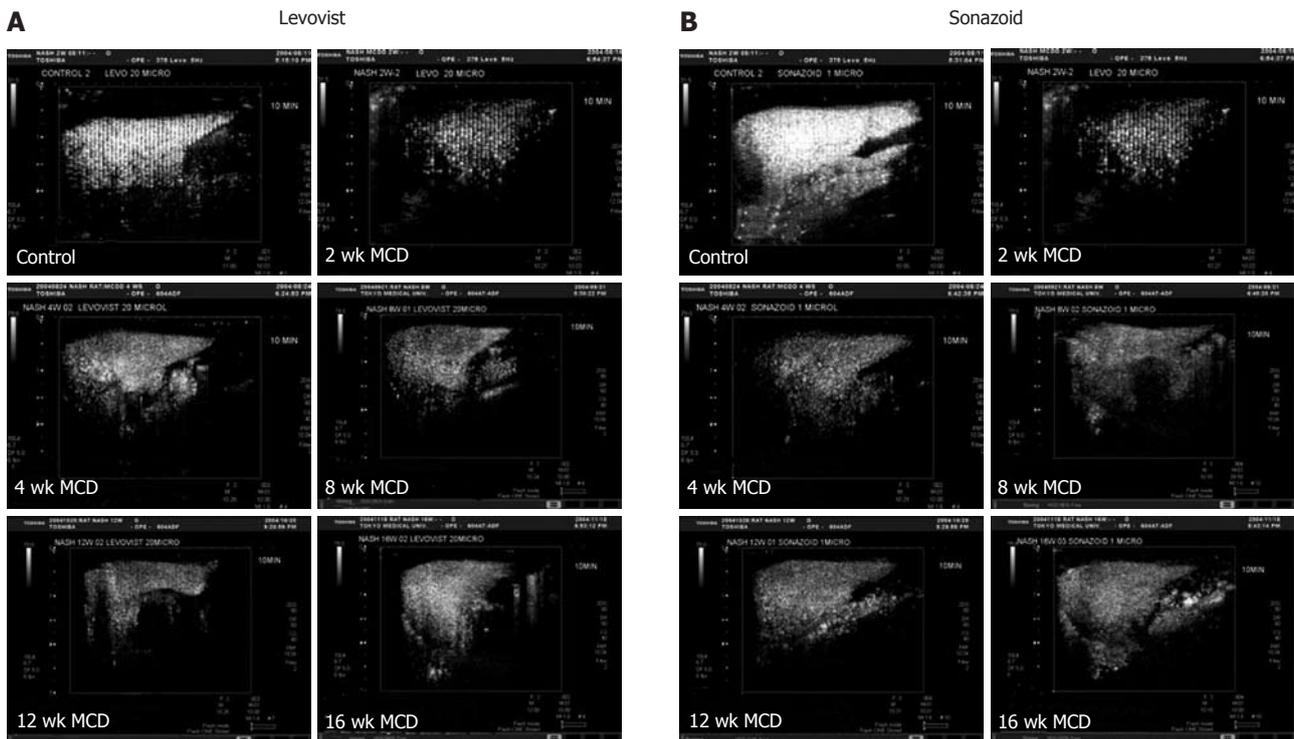

Figure 3 Ultrasound images of the liver 10 min after Levovist™ (A) and Sonazoid™ injection (B). Note signal intensity of the liver was lower in all methionine choline-deficient diet rats than in the controls. MCD: Methionine choline-deficient.

In the MCDD group, the intensity showed a significant decrease at weeks 2, 8 and 12, and a decrease, although not significant, at weeks 4 and 16 (Figures 3A and 4A). On the other hand, signal intensity of the liver obtained by contrast ultrasound with Sonazoid™ showed a significant decrease at all weekly time points in the MCDD group,

compared to the control group (Figures 3B and 4B).

Phagocytic activity of KCs in each group

Phagocytic activities (control *vs* MCDD) of KCs examined with fluorescent latex beads were 44.3% ± 12.6% *vs* 18.5% ± 9.8% (*P* < 0.01) at week 2, 55.1% ± 0.1% *vs*

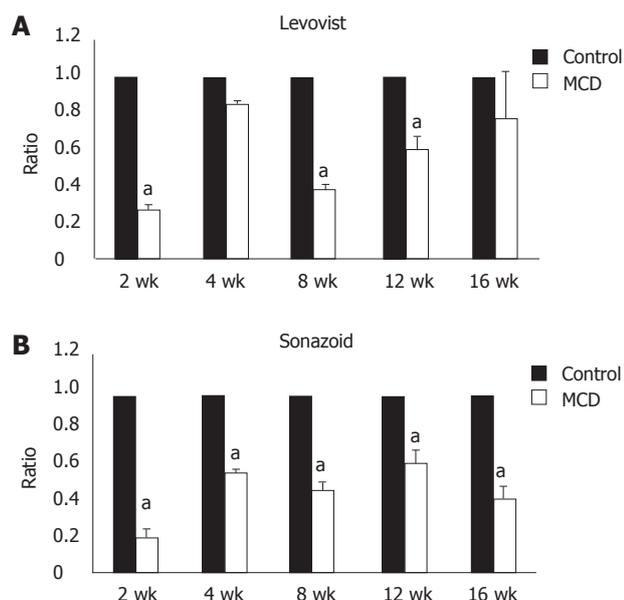

Figure 4 Changes in the signal intensity between control and methionine choline-deficient diet livers. A: Levovist™ contrast enhanced ultrasonography (CEUS). In the methionine choline-deficient diet (MCDD) liver, there was a significant decrease in Levovist™ signal intensity, compared to control livers at 2, 8 and 12 wk. While there was a lower tendency in signal intensity in MCDD liver than control liver at 4 and 16 wk, however, significance was not obtained; B: Sonazoid™ CEUS. In the MCDD liver, there was a significant decrease in Sonazoid™ signal intensity, compared to control livers at all time points. MCD: Methionine choline-deficient. ^a $P < 0.05$ vs control.

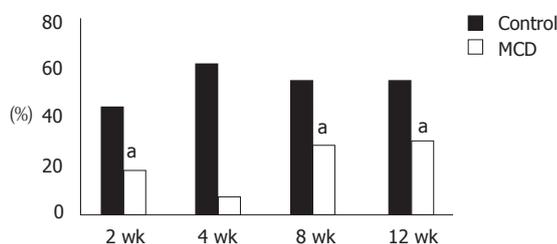

Figure 5 Decreased phagocytic activity in Kupffer cells from methionine choline-deficient diet rats compared to Kupffer cells from control rats. Control and methionine choline-deficient diet (MCDD) rats were injected with fluorescein-isothiocyanate (FITC)-labeled latex beads and Kupffer cells (KCs) were isolated 1 h later. KCs which had phagocytosed FITC-labeled latex beads were counted by flow cytometry and changes in the phagocytic activity were compared between control and MCDD KCs. Note that there was an almost 50% decrease in phagocytic activity in KCs from MCDD, compared to KCs from controls. ^a $P < 0.05$ vs control.

18.5% \pm 9.8% ($P < 0.01$) at week 8, and 57.4% \pm 3.4% *vs* 30.3% \pm 0.6% ($P < 0.01$) at week 12, and the activities in the MCDD group were about half those in the control group. At week 4, only one rat was examined but the activities were 61.9% in the control and 7.6% in the MCDD group, and again they tended to be lower in the MCDD group (Figure 5).

Counting of KCs and images of phagocytosed fluorescent latex beads

Because the decrease in the accumulation of the ultrasound contrast agent in the MCDD group potentially was

Group ($n = 10$)	¹ Total ED-2(+) cells
Control	122 \pm 14
MCDD	² 110 \pm 25

Numbers of Kupffer cells (KCs) in control and methionine choline-deficient diet (MCDD) livers were counted after immunostaining with ED-2 antibody, which recognizes residential macrophages or KCs in the liver. There was no significant difference in the numbers of KCs between controls and MCDD livers. ¹mean \pm SD; ²No significance.

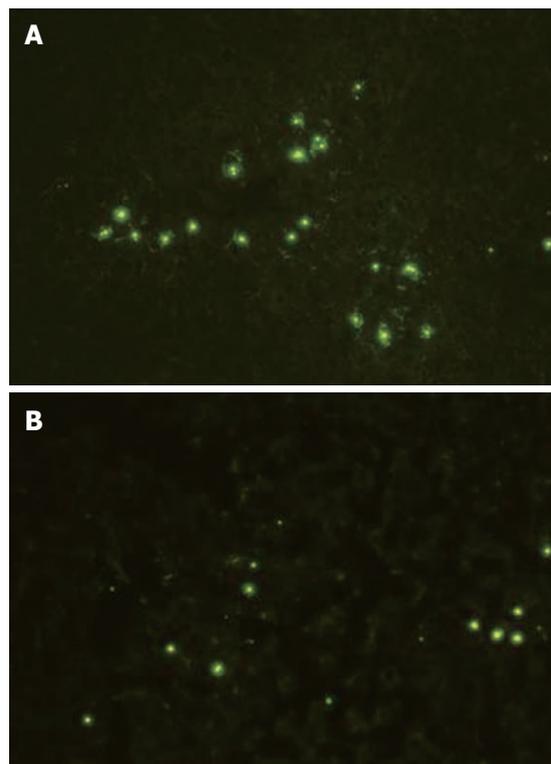

Figure 6 Fluorescein-isothiocyanate-labeled latex beads were injected through the tail veins of control and methionine choline-deficient diet rats. One hour later, small samples of the liver were snap frozen and sectioned using a cryostat. After immediate drying, unfixed tissues were observed by fluorescence microscopy. Note that there were fewer fluorescein-isothiocyanate-labeled latex beads in the livers from methionine choline-deficient diet (B) compared to the controls (A). Magnification: $\times 200$.

attributable to a decrease in the number of KCs compared to the control group, KCs were counted histologically based on immunohistochemistry with anti-rat macrophage antibody. As a result, there was no significant difference between the MCDD and control groups in the number of KCs (Table 1). In addition, fluorescence microscopy revealed a decrease in the accumulation of fluorescent latex beads in the MCDD group compared to the control group (Figure 6).

Serum leptin concentrations

Serum leptin concentrations (control *vs* MCDD) were 120.6 ng/L \pm 39.4 ng/L *vs* 31.5 ng/L \pm 77.6 ng/L ($P < 0.01$) at week 2, 396.7 ng/L \pm 95.0 ng/L *vs* 99.3 ng/L \pm

14.5 ng/L ($P < 0.01$) at week 4, 618.6 ng/L \pm 0 ng/L *vs* 79.2 ng/L \pm 7.0 ng/L ($P < 0.01$) at week 8, and 397.2 ng/L \pm 221.3 ng/L *vs* 93.7 ng/L \pm 21.5 ng/L ($P < 0.01$) at week 12, and were significantly lower in the MCDD group at all time points.

DISCUSSION

Fatty liver disease is a state in which triglycerides accumulate in hepatocytes. A manifestation of fat-related liver disease in non-drinkers is known as NAFLD, and consists of simple fatty liver and NASH accompanied by inflammatory changes. At present, it is difficult to differentiate NASH patients from a number of NAFLD patients by any diagnostic method other than liver biopsy. However, biopsy is invasive and potentially causes critical complications. Because it has been reported that 5% of NAFLD patients develop liver cirrhosis^[9], it is important to diagnose NASH at an early stage. There have been reports of differentiating NASH patients from NAFLD patients without the invasiveness of liver biopsy^[2,10]. It has been reported that contrast enhancement is decreased in the late contrast phase in NASH patients compared to healthy subjects^[3,5]. In this study, contrast enhancement was compared by injection of the contrast ultrasonography agent in a NASH model receiving MCDD and in controls taking a regular chow.

MCDD rats have been used in research to investigate the pathogenesis of NASH^[6,11,12]. We used MCDD rats as the most general NASH model developing steatohepatitis, which was induced quickly and easily by the administration of MCDD alone. In this study, the rats started to show fat deposition two weeks after the beginning of MCDD administration, steatohepatitis at week 8 and fibrosis at week 16.

LevovistTM is a first generation ultrasound contrast agent consisting of air as the inner gas within a lipid shell. SonoVueTM, OptisonTM, DefinityTM, ImagentTM and SonazoidTM are available commercially for liver imaging. LevovistTM and SonazoidTM are easily phagocytosed by KCs^[13] and have a liver-specific contrast phase. The ultrasound contrast agent LevovistTM, a high MI contrast agent consisting of microbubbles, is destroyed when exposed to ultrasound with a high acoustic pressure. Most Doppler signals are retrieved when all microbubbles in the scan volume are destroyed with high MI ultrasound. On the other hand, SonazoidTM is a new-generation ultrasound contrast agent, and develops resonance and vibration under the conditions of lower acoustic pressure than that for LevovistTM, because of an elastic phospholipid shell around the inner gas, perfluoro-butane. It is a low MI contrast agent to visualize harmonic signals. Compared to LevovistTM, SonazoidTM has the advantage of enabling evaluation of contrast enhancement in a real-time manner.

In order to quantify the accumulated microbubbles in the liver parenchyma, we destroyed microbubbles by exposing high MI ultrasound to both contrast agents, Levo-

vistTM and SonazoidTM. The period of about 2 min from the injection of the ultrasound contrast agent reflects the early vascular phase, while the time period from about 10 min later reflects the delayed parenchymal phase, or Kupffer imaging, representing the time for phagocytosis of microbubbles by KCs^[14,15]. Therefore, in the delayed parenchymal phase, it is possible to obtain information similar to that provided by superparamagnetic iron oxide (SPIO)-enhanced MRI^[16]. Clinically, about 25% of the ultrasound contrast agent injected from the peripheral vein is phagocytosed by KCs and visualized as the hepatic parenchyma-specific contrast^[17]. It has been reported that dysfunction of KCs is involved in NAFLD^[18].

In this study, images were scanned to measure the signal intensity 10 min after infusion of the ultrasound contrast agent, and accumulation of the medium by KCs was compared between the MCDD and control groups. As a result, contrast enhancement was decreased in MCDD rat livers, as in clinically diagnosed NASH patients. There are two potential mechanisms for the decrease of contrast enhancement in Kupffer imaging, which represents phagocytosis of microbubbles by KCs. These mechanisms are a reduction in phagocytosis by KCs and a decrease in the number of KCs despite normal phagocytic activity. To count the number of KCs, KCs were immunostained with anti-rat macrophage antibody, and it was found that there was no statistical difference in the number of KCs. Therefore, it was thought that decrease of contrast enhancement was attributable to a reduction in phagocytic activity of KCs, rather than a decrease in the number of KCs.

As for the pathogenesis of NASH, phagocytic activity of KCs and involvement of leptin have been suggested. Leptin is an adipocytokine produced by adipose tissue which interacts with a receptor in the hypothalamus. Leptin controls the amount of body fat by suppressing appetite and stimulating sympathetic nerve activity. NAFLD patients with obesity and insulin resistance exhibit leptin resistance and, thereby, serum leptin concentrations increase^[18].

In *ob/ob* mice defective in the leptin gene^[19], fatty liver is present in association with insulin resistance and obesity, and leptin administration improves fatty liver^[20]. In addition, *db/db* mice harboring an abnormality in the leptin receptor do not respond to leptin and develop obesity and fatty liver, as do *ob/ob* mice. Loffreda isolated and cultured macrophages from the peritoneum and bone marrow in *db/db* mice (with abnormality in the leptin receptor) and *ob/ob* mice (deficient in the leptin gene), added *Candida parapsilosis*, and examined the phagocytic activity of macrophages in the groups with and without addition of leptin. Phagocytic activity was augmented in the *ob/ob* mice but unchanged in the *db/db* mice by addition of leptin, which suggested the possibility that leptin interacted directly with KCs to regulate phagocytic activity^[21].

Sakaida *et al*^[22] examined lipopolysaccharide (LPS)-induced phagocytic activity and production of TNF- α in

the KCs isolated from *fa/fa* rats, with a mutation in the leptin receptor gene, and reported that both were reduced compared to the control (*fa/-* rats) and therefore leptin potentially affected the function of KCs. It has been presumed that leptin activated KCs and their phagocytic activity, and phagocytic activity of KCs and serum leptin concentrations were indeed decreased in MCDD rats in this study. In other words, because the amount of leptin secretion was low in MCDD rats, activation of KCs by leptin was attenuated and, thereby, the phagocytic activity of KCs was decreased. Although stimulation with leptin may be closely associated with the phagocytic activity of KCs, it is one of our experimental challenges to isolate and culture KCs from MCDD rats and determine whether addition of leptin will improve their phagocytic activity.

Although there is a report that contrast enhancement by contrast ultrasound was decreased in NASH patients compared to NAFLD and type C chronic hepatitis patients^[5], its pathogenesis has yet to be elucidated. By downregulating KCs and provoking leptin resistance, persistence of high concentrations of serum leptin levels decreases the activity of leptin and thereby reduces phagocytic activity in NASH patients. In this study, serum leptin concentrations were low and reduced leptin activity was one potential factor responsible for the pathogenesis. It should be possible to clinically diagnose NASH patients non-invasively, without liver biopsy, by quantifying contrast enhancement in contrast ultrasonography^[3]. Sensitivity and specificity for diagnosis of NASH differentiation from NAFLD are more than 90% and decrease in Levovist accumulation is the early stage of NASH.

In MCDD rats, pathological findings revealed fatty liver without inflammation or necrosis two weeks after the beginning of the MCDD, and the phagocytic activity of KCs was attenuated. These results suggest that it may be possible to diagnose NASH in human NASH patients at an early stage when inflammation, necrosis, and fibrosis specific for NASH have not developed. In addition, should early diagnosis of NASH be possible, early treatment would be feasible with prevention of progression to liver cirrhosis, and improvement of prognosis might be expected. It is necessary to accumulate clinical cases examined by a combination of contrast ultrasound and liver biopsy.

In conclusion, contrast enhancement in the late phase of contrast ultrasound was compared in MCDD rats and rats taking a regular chow. In the MCDD rats, accumulation of the contrast medium was attenuated compared to the control rats. As for the cause, a reduction in phagocytic activity by KCs was suspected, but activation by serum leptin might also be involved in the reduction of phagocytic activity.

COMMENTS

Background

Nonalcoholic steatohepatitis (NASH) is a disease that exhibits inflammation and fibrosis, and NASH may progress to liver cirrhosis and hepatocellular carcinoma. Early clinical diagnosis is important and difficult, and histological diagnosis based on liver biopsy is the only diagnostic method of NASH at the present time.

Research frontiers

Liver biopsy is somewhat invasive and may cause some complications, such as bleeding in the abdominal cavity or infection. Thus, a non-invasive method to diagnose NASH needs to be developed. It has been previously reported that liver-specific Kupffer images of contrast ultrasound can be used for differential diagnosis between NASH and nonalcoholic fatty liver disease (NAFLD).

Innovations and breakthroughs

The authors carried out a comparison of contrast ultrasonography between a NASH model and control rats. In the NASH model group, the intensity showed a significant decrease.

Applications

Contrast ultrasonography can be easily used to differentially diagnose NASH from NAFLD without liver biopsy.

Peer review

In the study, the authors demonstrated that phagocytic function of Kupffer cells from NASH liver is decreased. In this animal study, the authors also found that late phase contrast enhanced-ultrasound may be helpful in diagnosing NASH. Late phase contrast enhancement of NASH liver by ultrasound was lower compared to the simple fatty liver. The use of objective contrast quantification software appears promising. This might have implications in the diagnosis of NASH patients and in the evaluation of focal liver lesions in NASH patients; however further human studies are needed to evaluate this method.

Abstract

AIM: To prospectively assess the efficacy and safety of stapled trans-anal rectal resection (STARR) compared to standard conservative treatment, and whether preoperative symptoms and findings at defecography and anorectal manometry can predict the outcome of STARR.

METHODS: Thirty patients (Female, 28; age: 51 ± 9 years) with rectocele or rectal intussusception, a defecation disorder, and functional constipation were

submitted for STARR. Thirty comparable patients (Female, 30; age 53 ± 13 years), who presented with symptoms of rectocele or rectal intussusception and were treated with macrogol, were assessed. Patients were interviewed with a standardized questionnaire at study enrollment and 38 ± 18 mo after the STARR procedure or during macrogol treatment. A responder was defined as an absence of the Rome III diagnostic criteria for functional constipation. Defecography and rectoanal manometry were performed before and after the STARR procedure in 16 and 12 patients, respectively.

RESULTS: After STARR, 53% of patients were responders; during conservative treatment, 75% were responders. After STARR, 30% of the patients reported the use of laxatives, 17% had intermittent anal pain, 13% had anal leakage, 13% required digital facilitation, 6% experienced defecatory urgency, 6% experienced fecal incontinence, and 6% required re-intervention. During macrogol therapy, 23% of the patients complained of abdominal bloating and 13% of borborygmi, and 3% required digital facilitation. No preoperative symptom, defecographic, or manometric finding predicted the outcome of STARR. Post-operative defecography showed a statistically significant reduction ($P < 0.05$) of the rectal diameter and rectocele. The post-operative anorectal manometry showed that anal pressure and rectal sensitivity were not significantly modified, and that rectal compliance was reduced ($P = 0.01$).

CONCLUSION: STARR is not better and is less safe than macrogol in the treatment of defecation disorders. It could be considered as an alternative therapy in patients unresponsive to macrogol.

Comparative outcome of stapled trans-anal rectal resection and macrogol in the treatment of defecation disorders. *World J Gastroenterol* 2011; 17(37): 4199-4205 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i37/4199.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i37.4199>

INTRODUCTION

Functional constipation affects up to 20% of the population, and about 50% of constipated patients consulting a tertiary referral practice complain of difficult evacuation^[1,2], such as straining at stools, sensation of incomplete evacuation, or ano-rectal obstruction^[3,4], and may require digitation to facilitate defecation. Rectocele and intra-rectal intussusception are frequent findings in patients with functional constipation, and are thought to play a relevant role in defecatory alterations^[5]. Surgical repair of the recto pelvic anatomy has been proposed to improve defecation. Recently, an international consensus conference^[6] proposed that “the combination of the characteristic history of disordered defecation and the anatomical finding of one or more of the following: rectocele, rectal intussusception, perineal descent, mucosal prolapse may lead a surgeon to offer the stapled trans-anal rectal resection (STARR)^[7-9] procedure, provided that the individual has failed medical management”.

The STARR procedure consists of the trans-anal resection of the distal rectum using a double-stapler. Semi-circular purse-string sutures are applied on the prolapsed rectal wall, including mucosa, submucosa, and rectal muscle wall, at 2 cm above the hemorrhoidal apex so as to include the rectocele and the internal rectal prolapse.

So far both favorable^[10] and unfavorable results^[11] of the procedure have been reported. However, **no study** has assessed the efficacy and safety of the STARR procedure in comparison with evidence based conservative treatment for the management of functional constipation and defecatory disorders.

The main aim of the present study was to assess the efficacy and safety of the STARR procedure in the treatment of patients with chronic constipation complaining of defecatory disorders and with defecographic evidence of rectocele and intra-rectal intussusception. An additional aim of the study was to assess whether preoperative symptoms, and manometric or defecographic findings, can predict the long-term outcome of the STARR procedure.

MATERIALS AND METHODS

Population

Consecutive outpatients referred for refractory chronic

constipation in a 48-mo period by two surgical and one gastroenterological centers, underwent a diagnostic work up, including anorectal manometry and defecography. Patients with refractory chronic constipation were identified as those who did not respond to the usual conservative treatment and still complained of difficult and/or incomplete evacuation, despite the use of high daily doses of contact laxatives, enemas, or digital evacuation. Inclusion criteria were the following: (1) diagnosis of functional constipation according to the Rome III criteria during the preceding three months, with onset at least 6 mo prior to the diagnosis (in the absence of laxatives and/or enemas) of two or more of the following complaints: less than three bowel movements (BM) per week; straining at defecation and/or sense of incomplete evacuation and/or hard stools and/or sensation of anorectal obstruction/blockage and/or manual maneuvers to facilitate defecation on at least 25% of occasions; (2) difficult evacuation defined as either straining or sensation of obstruction/blockage; (3) age between 18 and 75 years; (4) no previous anorectal surgery; (5) no abnormality at barium enema or colonoscopy; (6) normal laboratory routine tests; (7) evidence of rectocele and/or intra-rectal intussusceptions at defecography; (8) no previous treatment with oral macrogol solution; (9) no pregnancy and efficacious birth control methods; (10) absence of systemic disease; and (11) absence of therapy affecting intestinal function. Chronic anxiolytic and antidepressive treatment were admitted provided the dosage was not modified during the study period. Exclusion criteria were the following: (1) no diagnosis of functional constipation; (2) previous anorectal surgery; (3) age less than 18 and above 75 years; (4) absence of rectocele and intra-rectal intussusception at defecography; (5) abnormality at barium enema or colonoscopy; (6) abnormal laboratory tests; (7) previous treatment with oral macrogol solution; (8) pregnancy and no use of efficacious birth control methods; (9) presence of systemic disease; and (10) presence of therapy affecting intestinal function.

Study protocol

At referral, all patients were interviewed with a standardized questionnaire, and had a physical examination. The questionnaire inquired about bowel habit: frequency of defecation, straining, stool consistency, sensation of incomplete evacuation, sensation of anal obstruction/blockage, digital facilitation to evacuate, anal pain, and anal incontinence.

On a different day, a colonoscopy was performed in patients over 50 years of age who had not had a colonoscopy or a barium enema in the previous five years. Patients were then submitted on different days for defecography and anorectal manometry.

Thirty consecutive patients, reporting an unsatisfactory response to the conservative treatment of constipation with different types of laxatives, were enrolled by the two surgical units; sixteen by AC and fourteen by

MM, and were then submitted to the STARR procedure according to a standardized and previously published method^[10]. In the same time period, thirty additional and consecutive patients referred to the gastrointestinal center were assigned conservative treatment with oral macrogol solution. These patients were instructed to consume 1 sachet (8.75 g) of macrogol dissolved in 125 mL of water *bid.*, with the option to either reduce the dose to *od* or increase it up to *qid.* to obtain evacuation of soft stools.

After the STARR procedure patients, were subjected to a second rectoanal manometry and defecography.

All patients were re-assessed at least 24 mo after the surgical procedure or the medical prescription.

At follow-up, the patients were interviewed, either face to face or by telephone, with the same standardized questionnaire used at referral, which included additional items related to treatment satisfaction and adverse events. Patients were invited to declare whether they were “totally dissatisfied with the treatment”, or “partially satisfied with the treatment” when at least one symptom of constipation and/or side effects were present, or “fully satisfied with the treatment”.

The degree of constipation was evaluated with the Wexner score^[12]. The study was approved by the local ethics committee.

Defecography

A cleansing non-medicated water enema was performed the night before the radiological examination. About 200 milliliters of barium paste were injected into the rectum, through an anal catheter. Continuous injection of the contrast during slow withdrawal of the catheter rendered the anal canal opaque. Patients were then seated on a radiolucent commode. The entire evacuation sequence was recorded on videotape (JVC SR-VS30E Mini DV/S-VHS). Latero-lateral radiograms were taken at rest and during mid-evacuation, as previously reported^[13].

Anorectal manometry

After a cleansing enema, rectal sensitivity and anorectal manometry were evaluated using a multilumen polyethylene catheter with four open tips disposed radially, and 0.5 mm apart longitudinally, continuously perfused (0.5 mL/min) with bubble-free distilled water by means of a pneumo-hydraulic infusion system (Arndorfer, Milwaukee, Wisconsin, United States), and connected to Beckman 611 external transducers. A fifth lumen ended in a latex balloon attached to the tip of the catheter. Intraluminal pressure variations were transmitted from the transducers to a polygraph (R612 Dynograph Recorder Sensor-Medics Italia srl) for recording.

The resting pressure profile of the anal canal was recorded with a pull-through technique. Thereafter, the manometric probe was positioned in the anal canal with the recording holes and the deflated balloon in the rectum. The patient was then asked to squeeze and to strain. Lastly the intra-rectal balloon was intermittently inflated

with progressive volumes of air to elicit the recto-anal inhibitory reflex (RAIR). To assess the threshold of rectal sensitivity, patients were instructed to refer the first sensation of rectal distension and/or the urge to defecate during the incremental intrarectal balloon inflations^[14].

Analysis of data

The primary endpoint of the study was relief of constipation, i.e., when the patient no longer met the Rome III criteria for functional constipation and was considered a responder.

Secondary endpoints were: the assessment of (1) the constipation improvement by means of the Wexner score; and (2) symptoms, defecographic, and manometric findings in predicting the outcome of the STARR procedure.

Analysis of defecographic data: **Frame by frame** analysis of the sequences recorded on the videotape assessed timing and dynamics of evacuation, rectal emptying, and presence of anatomical alterations of the rectal wall. Anorectal angle (ARA) widening, anal canal opening, pelvic floor (PF) location at rest, and its mobility were assessed on the latero-lateral radiograms. Rectocele was defined as an outpouching of the anterior rectal wall into or across the rectovaginal septum, rectal intussusception was defined as an enfolding of the rectal wall, which may (intra-anal) or may not (intra-rectal) protrude through the anal canal. Pelvic floor dyssynergia was defined as: anorectal angle (ARA) widening $< 10^\circ$ and/or the opening of anal canal < 10 mm, and/or anal canal opening > 10 mm in more than 30 s or interrupted by repetitive squeezing contractions. Contrast rectal residue was assessed by a semi-quantitative evaluation of the rectal residue as small ($< 40\%$), intermediate (40% - 70%), and abundant ($> 70\%$).

Analysis of manometric data: **Maximal resting and squeezing pressures** were identified as the maximal steady value observed for 20 s in basal condition and during maximal voluntary anal contraction. The thresholds of RAIR and rectal sensitivity were defined as the smallest inflated volumes of the intrarectal balloon inducing, respectively, a fall in anal pressure of at least 12 mmHg^[14], and the urge to evacuate. Rectal compliance was calculated as the ratio between intrarectal balloon volume inflated with 100 mL of air and intrarectal pressure. During straining, a decrease of anal pressure of more than 20% was considered a normal relaxing pattern; the absence of a decrease of less than 20%, or the increase, of the anal pressure were considered as dyssynergic patterns.

Statistical analysis

Results are reported as means and standard deviation (mean \pm SD). Descriptive statistical techniques were used to compare the two groups of patients. A χ^2 test and Fisher's exact test were used to compare the frequency of symptoms in the different study groups; Student's *t* test was used to compare the two groups for

continuous variables.

RESULTS

Sixty patients were enrolled: 30 patients underwent STARR, and 30 patients were treated with macrogol. The two study groups were comparable for gender, age, and symptom presentation (Table 1).

Macrogol group: The follow up period was 44 ± 11 mo. Twenty-two (75%) patients were classified as responders; constipation by the Wexner score decreased significantly (13.9 ± 1.5 vs 5.9 ± 4.5 ; $P < 0.001$). Seven patients (27%) had discontinued macrogol and were using either contact or other osmotic laxatives; two patients still required digital facilitation (Figure 1).

STARR group: The follow up period was 38 ± 18 mo. Sixteen (53%) patients were classified as responders. No outcome difference was observed between patients of the two surgical units (responders: 8/16 vs 6/14). Constipation by the Wexner score decreased significantly (13.4 ± 3.2 vs 7.32 ± 5.76 ; $P < 0.001$); nine (30%) patients still used laxatives and four (13%) digital facilitation (Figure 1). After the surgical procedure, 14 patients reported at least one side effect and two (6%) required re-intervention; the first for relapse of rectocele and the second for fecal incontinence. The presenting symptoms at referral did not differ between responders and non-responders (Table 2).

Comparison between the study groups: The two groups did not differ statistically for response to the treatment according to the Rome criteria for functional constipation, for improvement of constipation evaluated by means of the Wexner score, and for degree of satisfaction (Table 3). Bowel symptoms at follow-up were similar in the two study groups (Figure 1).

Adverse events in the STARR procedure group, at the end of follow up, were: staining/leakage (13%), fecal incontinence (6%), urgency (6%), intermittent anal pain (17%), and re-intervention (6%). Adverse effects in the macrogol therapy group were abdominal bloating (23%), and borborygmi (13%).

Defecography

Defecography was performed at referral and at 7 ± 4 mo after STARR in 16 patients. In comparison to the pre-surgical condition, defecographic variables did not vary after surgery, except for a significant reduction in rectal diameter (7.5 ± 1.2 cm vs 5.6 ± 1.2 cm; $P < 0.001$), and size of rectocele (3.9 ± 1.3 cm vs 1.4 ± 1.5 cm; $P < 0.001$). The size of intussusceptions was reduced, but the variation was not statistically significant (3.2 ± 1.7 cm vs 2.4 ± 1.3 cm; ns).

Responders and non-responders did not statistically differ for any defecographic variable assessed before surgery (Table 3). Before the operation, the mean ARA variation during evacuation was not statistically different between non-responders and responders (Table 4).

After the operation, it was significantly less in the non-responders compared to the responders (28 ± 16 vs 8 ± 20 degrees; $P < 0.05$).

Before STARR, defecographic evidence of pelvic floor dyssynergia was detected in three patients; equally represented in responders (one patient) and non-responders (two patients). After STARR, defecographic evidence of pelvic floor dyssynergia was detected in three patients; equally represented in responders (one patient) and non responders (two patients).

Ano-rectal manometry

Ano-rectal manometry was performed at referral and 24 ± 4 mo after STARR in 12 patients. After STARR, rectal compliance was significantly reduced (5.4 ± 1.9 vs $3.7 \pm$

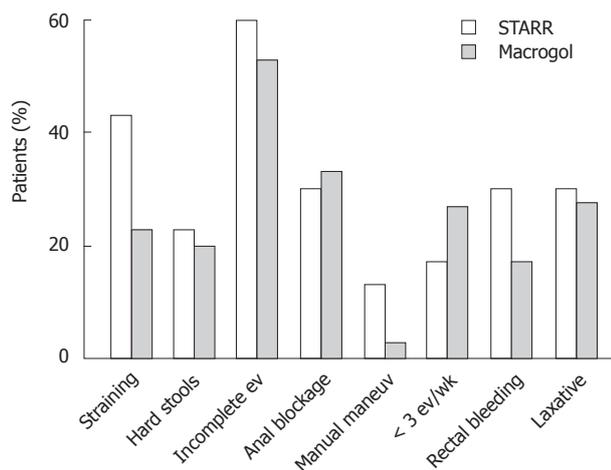

Figure 1 Percentage of patients with constipation symptoms, rectal bleeding, and use of laxatives (other than macrogol in the macrogol treatment group) after stapled trans-anal rectal resection and during macrogol treatment. No statistical difference was observed between the two study groups. STARR: Stapled trans-anal rectal resection. ev: Evacuations.

1.2 mL/mmHg; $P = 0.01$), all other manometric variables did not vary. Responders and non-responders did not differ for any manometric findings before and after the procedure.

Before STARR, manometric evidence of pelvic floor dyssynergia was detected in four patients, equally represented in responders (two patients) and non-responders (two patients). After STARR, manometric evidence of pelvic floor dyssynergia was detected in seven patients, equally represented in responders (four patients) and non-responders (three patients).

DISCUSSION

No previous study has compared the STARR procedure with conservative pharmacological therapy. This study evaluated, over a long time period, the outcome of STARR treatment for constipation, defined with standardized and validated criteria. The surgical procedure was performed following the standardized and previously published procedure^[9] by two experienced coloproctology units that obtained comparable postsurgical outcomes. The patients submitted to the STARR procedure reported an unsatisfactory response to a usual, but not standardized, laxative treatment.

Previous studies have reported the postsurgical outcomes of the STARR procedure or of other modified techniques, but no study has compared the efficacy and safety of STARR procedure versus the standardized conservative treatment.

In the present investigation, we compared the outcome of STARR procedure with the gold standard treatment of constipation based on macrogol in a prospective, parallel group, longitudinal study. This therapy for functional constipation is supported by level 1 evidence and grade A recommendation^[15]. This is a high molecular weight (3350 or 4000) non-absorbable, non-metabolized soluble

polyethylene, which forms hydrogen bonds with water in the gut; it is used with orthograde whole-gut irrigation in preparing for colon investigation, and in small-volume daily doses (125-250 mL) to treat functional constipation. Macrologol therapy is reported to be effective in about 80% of constipated patients, is well tolerated, and devoid of serious side effects, even in long term treatment^[16,17].

All the patients of these study groups met the Rome III criteria for functional constipation and had defecographic evidence of rectocele and or intrarectal intussusception. Patients were evaluated with a standardized questionnaire before and after treatment, with a mean follow-up of 38 mo, which is, to our knowledge, one of the longest reporting STARR outcome^[18-31]. Some long-term studies reported sustained improvement of defecation score, but provided conflicting results about side effects, relapse, and complications^[32-34].

The present study demonstrated that the surgical treatment was less, but not statistically so, efficacious than the conservative one, as indicated by the finding that 75% of the macrogol group and 53% of the STARR group did not present any Rome criteria for functional constipation. In addition, after the STARR operation, about 30% of the patients still consumed laxatives and 13% were using digital manipulation to evacuate.

Of note is that during a mean follow up of three years after the STARR operation, intermittent bleeding was present in 24% of the patients, anal pain in 17%, and anal incontinence of variable severity in 25%. Furthermore, two patients required a re-intervention. The observed prevalence of these complications in the present study is similar to that reported in other studies^[11,25]. The European STARR register reports perioperative and postoperative complications in about 36% of the patients, and defecatory urgency in 20% of the cases at one year of follow-up^[35]. In our study, a few adverse events of STARR persisted in this long-term follow up with possible detrimental effects on daily living.

The degree of satisfaction expressed by patients parallels that of the improvement of constipation achieved by the two treatments. Only 15% of the patients were

not satisfied with the STARR procedure, despite the presence of some persistent symptoms or the previously mentioned complications.

Defecography was performed in all patients before and, in a subgroup of them, after the STARR procedure. No defecographic finding before surgery predicted the outcome of the STARR operation. As expected, after surgery there was a significant reduction of rectal diameter and the size of the rectocele, but such variations were no different between responders and non-responders.

After STARR, the mean value of ARA variation during evacuation in non-responders was significantly reduced in comparison to the preoperative value, and was significantly less than in responders. This finding indicates that the STARR procedure may affect the relaxation pattern of the puborectalis muscle during evacuation. It remains to be established how the STARR procedure induces this effect on the puborectalis. It is reasonable to assume that a reduced ARA variation during defecation may negatively affect evacuation, nonetheless it is not possible to conclude from this study whether it has any role in the poor clinical outcome of non-responders.

According to the STARR consensus conference, the inclusion criteria for surgical treatment are based on clinical presentation of difficult evacuation and/or straining, in the presence of rectocele and/or intussusception. In this study, the inclusion criteria were based on the consensus conference recommendations; however, no presenting symptom was predictive of the outcome of STARR, nor of the procedure adverse events.

In addition, anorectal manometry was not useful in predicting the outcome of STARR. A previous study reported that altered compliance could be predictive of positive outcome^[10]. This observation was not confirmed by the present study; the discordance could be due to the small sample in this study or to the different method used to evaluate compliance. In the previous study, compliance was assessed by the ratio between volume and pressure at the threshold of rectal sensitivity, whereas in this study, it was calculated using the fixed volume of 100 mL of air, to avoid possible subjective differences of rectal sensitivity. However, a study designed to investigate whether rectal compliance is altered in females with obstructed defecation, showed that the compliance of the rectal wall is normal^[36].

Several structural and functional alterations of the rectum and/or pelvic floor are considered to markedly impair the act of defecation; however, the findings of this study indicate that stool consistency is a major factor in chronic constipation. Indeed, the favorable response to macrogol treatment in the non-surgical group indicated that reducing stool consistency, reported at referral to be hard by more than 90% of the patients, effects resolution of constipation, despite the persistence of the structural and functional alterations. Thus, it seems reasonable to consider a surgical procedure only after the failure of a standardized macrogol treatment.

In conclusion, the results of this prospective study

suggest that STARR is not better and is less safe than conservative therapy in the treatment of defecation disorders in functional constipation patients. Preoperatively, no presenting symptom, or defecographic, and manometric variables were useful to indicate STARR and predict its results. Postoperatively, a reduced widening of ARA during evacuation was associated with an unfavorable outcome of the procedure. The STARR procedure could be considered as an alternative treatment in patients with constipation and defecatory disorders who are unresponsive to conservative macrogol treatment.

COMMENTS

Background

Constipation is a common problem. It is not clear whether a defecation disorder commonly known as obstructed defecation syndrome (ODS) is due to anatomical abnormalities. However, some surgeons propose a new type of surgery [stapled trans-anal rectal resection (STARR)], which, by correcting the anatomical changes, should solve the constipation. Surgery should be considered for those patients who do not benefit from conservative treatment. The gold standard pharmacological treatment of constipation is based on macrogol, which is also effective in patients with altered defecation.

Research frontiers

Ideally, a randomized double blind clinical trial would have more properly assessed the efficacy and safety of the STARR procedure, but the comparison between a non-invasive treatment and an invasive procedure is an objective obstacle to plan a proper protocol, and such studies have not been previously performed. No previous study has so far compared the STARR procedure with conservative pharmacological therapy.

Innovations and breakthroughs

This study evaluated, over a long time period, the outcome of STARR treatment for constipation in comparison with macrogol therapy. The study has shown that STARR is not better, and is less safe, than macrogol therapy. In addition, no preoperative findings could predict the outcome of surgery.

Applications

The authors believe that macrogol should be used before considering surgery in cases of lack of response to conservative treatment

Terminology

Rectocele is a protrusion of part of the rectum into the vagina. Rectal intussusception is a protrusion of the rectal mucous membrane into the lower rectum.

Peer review

The manuscripts reports the comparative analysis of two strategies in managing functional constipation. The authors have compared outcomes of patients that underwent treatment with a conservative regimen that consisted of macrogol and patients that underwent the STARR procedure. This is a well done study; despite not being randomized it provides useful information and should be published.

Abstract

AIM: To assess the validity of the Milan and University of California San Francisco (UCSF) criteria and examine the long-term outcome of orthotopic liver transplantation (OLT) in patients with hepatocellular carcinoma (HCC) in a single-center study.

METHODS: This study is a retrospective review of prospectively collected data. Between 1998 and 2009, 56 of 356 OLTs were performed in patients with HCC. Based on pathological examination of liver explants,

patients were retrospectively categorized into 3 groups: Milan + ($n = 34$), Milan -/UCSF + ($n = 7$) and UCSF - ($n = 14$).

RESULTS: Median follow-up period was 39.5 (1-124) mo. The 5-year overall survival rates in the Milan +, Milan -/UCSF + and UCSF-groups were 87.7%, 53.6% and 33.3%, respectively ($P < 0.000$). Within these groups, tumor recurrence was determined in 5.8%, 14.3% and 40% of patients, respectively ($P < 0.011$). Additionally, the presence of microvascular invasion within the explanted liver had a negative effect on the 5-year disease free survival (74.7% vs 46.7%, $P < 0.044$).

CONCLUSION: The Milan criteria are reliable in the selection of suitable candidates for OLT for the treatment of HCC. For cases of OLT involving living donors, the UCSF criteria may be applied.

Comparison of Milan and UCSF criteria for liver transplantation to treat hepatocellular carcinoma. *World J Gastroenterol* 2011; 17(37): 4206-4212 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i37/4206.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i37.4206>

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy in the world, and is associated with the third highest number of cancer-related deaths^[1]. Moreover, for 70%-90% of HCC cases, HCC develops on a background of cirrhosis or chronic liver inflammation^[2]. Currently, there are three potentially curative therapeutic options for HCC, liver resection, orthotopic liver transplantation (OLT), and local ablative therapies^[3]. Although liver resection treats localized HCC, it is not optimal for treating multifocal HCC, and has no efficacy in preventing *de novo* HCC that can develop in the remnants of a cirrhotic liver. Alternatively, liver transplantation is an established therapy which offers the potential advantage of removing both the tumor and the organ at risk for developing future malignancies^[4].

In order to identify the best candidates for OLT, a set of criteria were proposed, referred to as the "Milan" criteria. According to these guidelines, patients with cirrhosis and a solitary tumor with a diameter less than 5 cm, or patients who have up to 3 tumor nodules, each of which is smaller than 3 cm and are not characterized by vascular invasion or extrahepatic metastasis (according to preoperative radiologic findings), are patients that have a higher probability of obtaining a successful outcome following OLT. For example, the 5-year recurrence-free survival rate for a set of patients who fulfilled the Milan criteria was reported to be 83%^[5]. The "Milan criteria" were subsequently adopted by the United Network for Organ Sharing (UNOS) in 2002 as the optimal criteria for determining the use of OLT to treat HCC^[6]. However, an expanded set of criteria proposed by the University of California San Francisco (UCSF), referred to here as the "UCSF" criteria, allows patients with a solitary tumor smaller than 6.5 cm, or patients having 3 or fewer nodules, with the largest lesion being smaller than 4.5 cm or having a total tumor diameter less than 8.5 cm without vascular invasion, to undergo OLT. Based on the comparable success of this set of criteria in selecting patients for OLT, it has been suggested that the Milan criteria may be too stringent^[7]. Therefore, the aim of this study was to examine the long-term outcome of patients undergoing liver transplantation to treat HCC, and to compare the use of the current criteria (both the Milan and UCSF) for the selection of HCC patients for possible OLT.

MATERIALS AND METHODS

Between 1998 and 2009, 56 of 356 (15.7%) OLTs were performed in patients with HCC at the Dokuz Eylul University Hospital (Izmir, Turkey). Of these, 50 were diagnosed with HCC prior to transplantation, and 6 (10.7%) were diagnosed during OLT. According to pre-OLT imaging and post-OLT pathological evaluation, 56 patients were retrospectively classified into 3 groups: Milan +, Milan -/UCSF + and UCSF - (Table 1).

Following the pathological examination of liver ex-

Table 1 Number of patients associated with each criteria depending on pre-orthotopic liver transplantation imaging and post-orthotopic liver transplantation pathology results *n* (%)

Diagnostic approaches	Milan +	Milan -/UCSF +	UCSF -
pre-OLT imaging	44 (78.0)	5 (8.9)	7 (12.5)
post-OLT pathology	34 (60.7)	7 (12.5) ¹	15 (26.8) ²

¹6/7 patients were classified as "Milan +" based on pre-OLT imaging; ²4 patients each were classified as "UCSF +/Milan -" and "Milan +" based on pre-OLT imaging. UCSF: University of California San Francisco; OLT: Orthotopic liver transplantation.

plant specimens, 14 (25.0%) patients were reclassified due to underestimates of tumor size, and 7 (12.5%) patients were reclassified due to the tumor number being greater than expected (false negative rate: 25%) (Table 1). For the applied Milan and UCSF criteria, false negative rates of pre-OLT radiological evaluations were 22.7% (10/44) and 16.3% (8/49), respectively. In summary, 8 patients met the UCSF criteria prior to undergoing OLT, and exceeded the UCSF criteria following pathologic evaluation of the explants obtained.

Pre-OLT workup

All patients included in this study had cirrhosis due to various etiologies. A pre-operative diagnosis of HCC was based on a patient's medical history, a physical examination, laboratory studies, α -fetoprotein (AFP) levels, and the results of one or more imaging studies [i.e., abdominal ultrasonography, contrast-enhanced computed tomography (CT), angiographic CT, or abdominal magnetic resonance imaging (MRI)]. Tumor biopsies were not performed to confirm each diagnosis. Chest CT, cranial CT, and technetium-99 m bone scintigraphy were used to detect the potential incidence of extrahepatic disease, and distant or lymph node metastases were not detected in any of the patients. Pre-OLT adjuvant therapies, including radiofrequency ablation (RFA), transarterial hepatic chemoembolization (TACE), percutaneous ethanol injection (PEI), and liver resection were performed in selected patients. In the absence of medical contraindications, patients who fulfilled the Milan criteria in pre-OLT evaluations were qualified to receive a transplant from either a living or deceased donor. Alternatively, for patients who did not fulfill the Milan criteria, these patients were qualified to receive organs from living donors only. In our series, 31 (55.3%) living and 25 (44.7%) deceased donor liver grafts were utilized. In the latter group, 3 marginal liver grafts from deceased donors were transplanted to recipients who did not fulfill the Milan criteria.

Pre-OLT locoregional therapy

Thirteen out of 50 (26%) patients received locoregional treatment prior to OLT, which included either TACE (*n* = 9), liver resection (*n* = 2), PEI (*n* = 1), or RFA (*n* = 1). Moreover, complete radiological regression was associated with all patients who underwent TACE, PEI, or RFA.

Table 2 Patient characteristics according to Milan and University of California San Francisco criteria determined from post-orthotopic liver transplantation imaging and post-orthotopic liver transplantation pathological evaluations *n* (%)

Variables	Milan +	Milan -/UCSF +	UCSF -	<i>P</i> value

Furthermore, two patients were successfully downstaged to the Milan criteria following treatment with TACE. For the two patients who underwent curative resection for HCC, both suffered intrahepatic recurrences one year later and were scheduled to undergo OLT. Due to the use of local ablative procedures, the incidence of major morbidity was 0%.

Immunosuppressive regimen and antiviral prophylaxis

OLTs involving deceased or living donors were performed by the same surgical team, and standard techniques were used. Briefly, patients received an immunosuppressive regimen of calcineurin inhibitors (i.e., cyclosporine A or tacrolimus), mycophenolic acid, and corticosteroids in the early post-operative period. The latter were tapered and eventually discontinued during the second month following each OLT. For patients with hepatitis B virus (HBV), peri- and post-operative hepatitis B immunoglobulin and an antiviral were administered. Lamivudine-resistant patients were treated with tenofovir. During the follow-up period, serum hepatitis B antibody levels were kept above 200 IU/L, and interferon and ribavirin treatments were initiated if hepatitis C recurred.

Pathological evaluation

All explants were examined by an experienced hepatopathologist (Sagol O), and were categorized depending on the size, number, distribution, HCC histologic grade, and vascular invasion associated with each tumor.

Post-OLT monitoring

Post-operative death was defined as death within 3 mo post-OLT. All patients underwent regular follow-up examinations in the outpatient clinic. Both the surgical

team and an experienced hepatologist maintained surveillance for tumor recurrence or metastasis based on AFP levels and chest CT scans, as well as by contrast-enhanced abdominal CT scans performed once every 3 mo for the first year post-OLT, then once a year thereafter. The minimum follow-up period was 12 mo.

Statistical analyses were performed using SPSS 15.0 for Windows (SPSS, Chicago, Illinois, United States). Data are expressed as the mean ± SD, and median and range values are provided when appropriate. Quantitative variables were compared using the Kruskal-Wallis test. Comparisons between groups with regard to qualitative variables were performed using the chi-square test and Fisher's exact test, if necessary. Survival was calculated using Kaplan-Meier estimates, with comparisons made using the log rank test. *P* < 0.05 was considered statistically significant.

RESULTS

The demographic characteristics of the patients included in this study are presented in Table 2. OLT was performed for patients who had been on a waiting list for a median of 62 d. Furthermore, the interval between when the patients were listed for transplantation and when the patients underwent transplantation was similar for both deceased and living donor transplantations (i.e., 60 vs 68 d, respectively). The average rates of graft weight/body weight for both OLT groups were also 1.09% (range, 0.69-1.8) and 1.82% (range, 0.76-2.58), respectively.

The mean hospital stay for patients was 31.2 ± 21.5 d, and complications associated with surgery were experienced by 10 (17.8%) recipients. Four (7%) recipients presented with biliary leak, with two of the cases resolving and two of the cases resulting in death due to sepsis. In addition, 3 (5.3%) recipients acquired pneumonia post-operatively. Two of these patients recovered, while the other died from respiratory arrest. One recipient died due to intra-abdominal sepsis and another developed intra-abdominal hemorrhage post-operatively and underwent a second operation. Only one patient experienced a wound infection. In contrast, a total of 4 (7%) patients died due to surgical complications, while another patient died from duodenal ulcer perforation with sepsis. The overall mortality for this study was 8.9% (5/56).

Pre-operative AFP levels ranged from 1.72 to 3630 ng/dL (median, 158.7 ng/dL), with the normal range being 0.5-5 U/L. Only 6/56 (10.7%) patients had an AFP level greater than 200 ng/dL. Furthermore, the mean AFP levels during the pre-OLT period for patients with incidental HCC was 15.5 ± 26.6 ng/dL (range, 2.45-63.1).

Tumor characteristics are described in Table 2. In particular, the number of nodules per patient and the diameter of the largest nodule were significantly lower in the Milan + group compared to the Milan -/UCSF + and UCSF-groups, respectively (*P* < 0.000).

Adjuvant chemotherapy was an option for 13 (23.2%) patients who were medically eligible for chemotherapy

Table 3 Follow-up data for patients who underwent orthotopic liver transplantation for hepatocellular carcinoma *n* (%)

Variables	Milan +	Milan -/UCSF +	UCSF -
No. of patients	34	7	15
Post-operative death	2 (5.9)	-	1 (4.5)
Death	5 (14.7)	2 (28.6)	11 (73.3)
HCC recurrence	2 (5.8)	1 (14.3)	6 (40.0)
Median follow-up	51.5 (1:124)	32 (1:66)	14 (3:66)

UCSF: University of California San Francisco; HCC: Hepatocellular carcinoma.

Table 4 Causes of mortality associated with cases in this study

Causes of death	<i>n</i> (%)
Sepsis (late postoperative period)	7 (36.8)
Lung metastasis	5 (26.3)
Sepsis (early postoperative period)	3 (15.8)
Recurrent fulminant hepatitis B	2 (10.5)
Duodenal ulcer perforation	1 (5.3)
Intracranial hemorrhage	1 (5.3)

and was administered post-OLT according to pathological tumors with a diameter of > 2 cm and/or microvascular invasion or post-OLT in case of recurrence. These patients received 5-fluorouracil in combination with epirubicin, mitomycin C, or cisplatin. None of the patients died as a result of chemotherapy-related complications. However, for three patients, grade 4 hematologic toxicity was reported, two patients experienced grade 3 gastrointestinal toxicity (i.e., excessive nausea and vomiting), and one patient exhibited grade 3 neurotoxicity.

Recurrence

Tumor recurrence was experienced by 9 (16%) patients (Table 3). Recurrence rates were 5.8%, 14.3% and 40% in the Milan +, Milan -/UCSF + and UCSF-groups, respectively. Five patients presented solely with distant metastasis in the lung (*n* = 3), in both the lung and bone (*n* = 1), and in the bone and skin (*n* = 1). The remaining 4 patients suffered intrahepatic tumor recurrence with (*n* = 2) or without (*n* = 2) extrahepatic metastasis (i.e., lung, adrenal gland, bone). None of the 6 recipients with incidental HCC recurred. For the treatment of tumor recurrence, chemotherapy was the only therapeutic option administered.

Survival

The median follow-up period was 39.5 mo (range, 1-124), and at this point, 19 (33.9%) patients had died. Causes of death are listed in Table 4. Correspondingly, the 1-, 3- and 5-year overall survival (OS) rates of the whole series were 80.4%, 68.9% and 65.3%, respectively. The disease-free survival rates for the same categories were 78.6%, 67.1% and 67.1%, respectively.

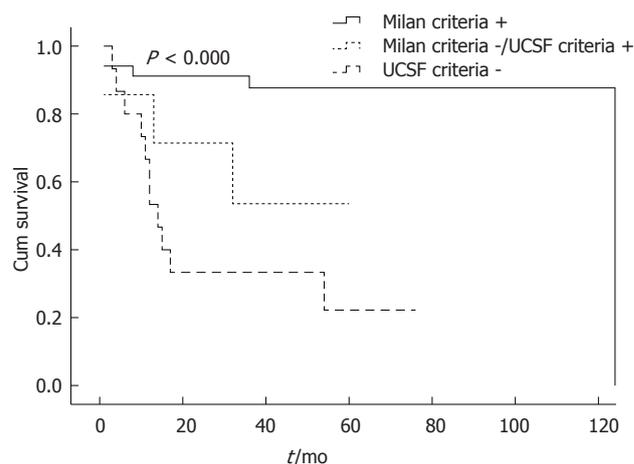

Figure 1 Kaplan-Meier overall survival curves for Milan +, Milan -/UCSF + and UCSF-patients (post-orthotopic liver transplantation). UCSF: University of California San Francisco.

Overall survival in the groups

When OS rates were calculated according to the criteria used, the 1-, 3- and 5-year OS rates for the Milan + group were 91.2%, 87.7% and 87.7%, respectively. The mean survival time was 110.3 ± 7.2 mo (95% CI: 96.1-124.4) for this group. In contrast, the 1-, 3- and 5-year OS rates for Milan -/UCSF + patients were 85.7%, 53.6% and 53.6%, respectively. The mean OS period was 39.8 ± 9.1 mo (95% CI: 22.1-57.6). The OS rates for UCSF-patients were 66.7%, 33.3% and 22.2%, respectively, with a mean survival time of 29.8 ± 7.4 mo (95% CI: 15.3-44.4) ($P < 0.000$) (Figure 1).

Disease-free survival in the groups

The rates of disease-free survival at 1-, 3- and 5-years post-OLT were 91.2%, 87.7% and 87.7%, respectively, for Milan + patients. Furthermore, the mean disease-free survival period was 109.3 ± 7.2 mo (95% CI: 95.2-123.1). In contrast, the 1- and 3-, and 5-year disease-free survival rates for Milan -/UCSF + patients were 71.4%, 53.6% and 53.6%, respectively, and the mean disease-free survival period was 39.6 ± 9.2 mo (95% CI: 21.6-57.5). The disease-free survival rates for the UCSF-group were 33.3%, 25.0% and 25.0%, respectively, and the mean disease-free survival period was 26.1 ± 7.8 mo (95% CI: 10.9-41.4) ($P < 0.000$) (Figure 2).

Microvascular invasion

When OS rates were calculated for patients with and without microvascular invasion, the 1-, 3- and 5-year OS rates for each category were 87.8%, 74.7% and 74.7%, and 73.3%, 53.3% and 35.6%, respectively ($P < 0.029$) (Figure 3). Furthermore, disease-free survival rates were 82.9%, 74.7% and 74.7% for patients without microvascular invasion, and 53.3%, 46.7% and 46.7% for patients with microvascular invasion ($P < 0.044$) (Figure 4). Moreover, we found that the presence of microvascular invasion was significantly higher in UCSF - than Milan +

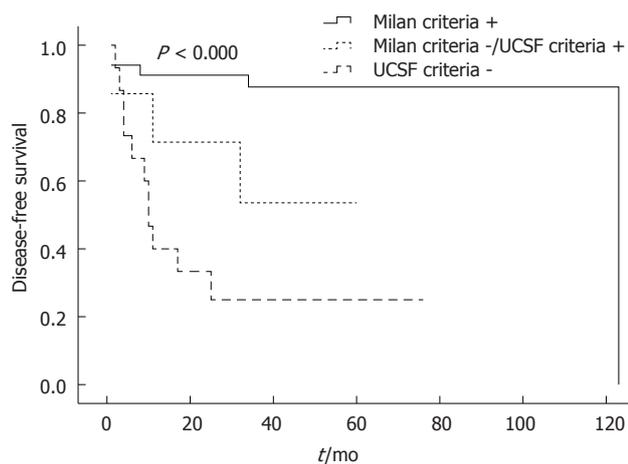

Figure 2 Kaplan-Meier disease-free survival curves for Milan +, Milan -/UCSF + and UCSF-patients (post-orthotopic liver transplantation). UCSF: University of California San Francisco.

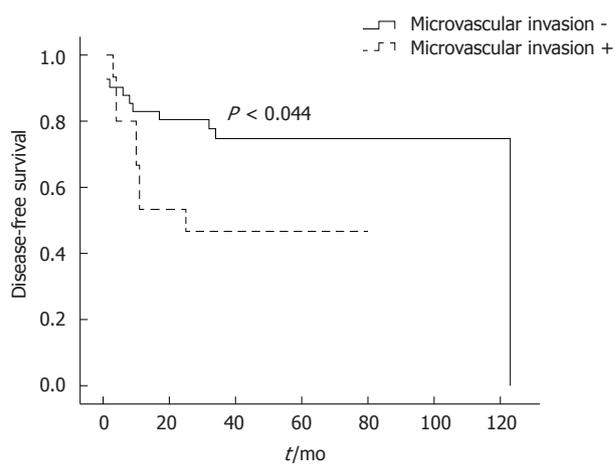

Figure 4 Kaplan-Meier disease-free survival curves for patients with microvascular invasion (post-orthotopic liver transplantation).

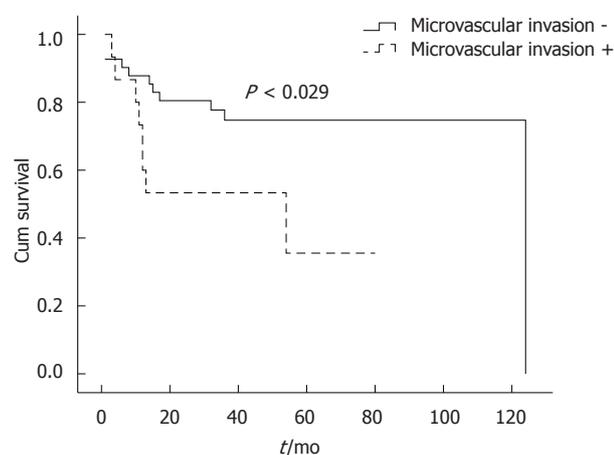

Figure 3 Kaplan-Meier overall survival curves for patients with microvascular invasion (post-orthotopic liver transplantation).

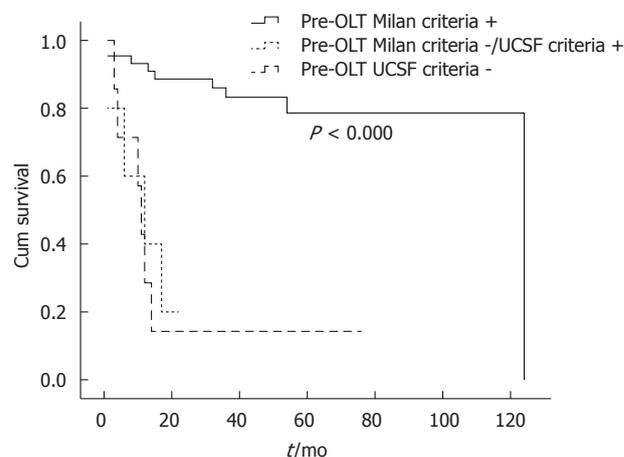

Figure 5 Kaplan-Meier overall survival curves for Milan +, Milan -/UCSF + and UCSF-patients based on pre-orthotopic liver transplantation imaging results. UCSF: University of California San Francisco. OLT: Orthotopic liver transplantation.

patients ($P < 0.034$).

Survival analysis based on pre-OLT imaging

In the three groups which were classified based pre-OLT imaging, OS rates are shown in Figure 5. Among these, the 1-, 3- and 5-year OS rates for Milan + patients were 93.2%, 83.3%, and 78.6%, respectively. The mean survival period was 102.7 ± 7.2 mo (95% CI: 88.5-116.9 mo). In contrast, the OS rates for UCSF-patients were 28.6%, 14.3%, and 14.3%, respectively, with a mean survival period of 18.6 ± 8.9 mo (95% CI: 1.0-36.2 mo) ($P < 0.000$). When the same evaluations were made for Milan -/UCSF + patients ($n = 5$), only the 1-, and 2-year OS rates were available and were 40% and 20%, respectively, and the mean survival period was 11.6 ± 3.4 mo (95% CI: 5.0-18.2 mo) (Figure 5).

DISCUSSION

This retrospective study sought to examine the overall reliability of the Milan and UCSF criteria as clinical tools

for the selection of HCC patients to be treated with OLT. Currently, the best liver transplant outcomes for HCC are obtained using the Milan criteria. For these patients, the 5-year survival rates are greater than 70% and the recurrence rate is 15%^[8-10]. In 2002, UNOS adopted the “Milan criteria” as the optimal criteria for selecting patients for possible OLT due to HCC^[6]. However, it was subsequently proposed that the Milan guidelines be expanded based on the comparable survival rates that were being achieved for patients undergoing selection based on the UCSF criteria^[7]. Therefore, to investigate whether the Milan criteria are too restrictive for the selection of patients who could otherwise benefit from OLT, a series of HCC cases, who were confirmed by pathology studies of explanted liver specimens, were analyzed. In particular, Milan + patients had significantly better 5-year OS rates than both Milan -/UCSF + and UCSF-patients (87.7% *vs* 53.6% and 33.3%; $P < 0.039$ and $P < 0.000$, respectively). Additionally, Milan -/UCSF + patients who would be expected to obtain the maximum benefit from the proposed expanded criteria had

no significant difference in survival rates compared to UCSF-patients (53.6% *vs* 33.3%, $P < 0.239$).

In most cases, patient selection criteria are based on radiological imaging performed to assess the extent of intrahepatic disease present, and to exclude extrahepatic spread. However, pre-OLT imaging studies have been shown to underestimate tumor stage in 20%-30% of cases^[4,11,12]. Consistent with these results, pre-OLT imaging associated with the series of cases evaluated in this study underestimated either the size, or the number, of tumors present in 14/56 (25%) patients. As a result, 80% of patients identified as Milan -/UCSF + prior to OLT were reclassified as UCSF-following pathological evaluations of the explants obtained. In addition, the 5-year survival rate of these reclassified patients was 25%. Thus, the Milan criteria appear to provide a wider “safe” margin and reduce the negative influence of underestimates of tumor stage by pre-OLT imaging.

As the interval between imaging studies performed and the date of transplantation increases, the patient undergoing transplantation is potentially at a higher risk for tumor recurrence. This could be avoided by shortening the waiting time for a transplant by increasing the number of organ donors, or better utilization of living donors. In this series, OLT was performed a median of 62 d after the patient was placed on a waiting list. In addition, due to the limited number of deceased donors available in Turkey, transplant centers have agreed to allocate deceased donor liver grafts to HCC patients who meet the Milan criteria. Although living donors are currently utilized as a source of liver grafts for the treatment of HCC, the primary concern for transplant programs is minimization of donor morbidity and mortality. Today, living donor hepatectomies are performed safely, and for countries experiencing a shortage in deceased donors, OLTs from living donors shorten the time that patients spend on a waiting list^[13]. In our study, 55.4% of the grafts used were obtained from living donors. However, despite all efforts, the morbidity and mortality of living donors following resection of the right lobe of the liver is approximately 0.5% and 35.0%, respectively^[14-15]. Thus, considering the safety of living donors and the poor long-term survival rates associated with recipients exceeding the UCSF criteria, it is recommended that the UCSF criteria be followed in order to select HCC patients with the highest likelihood of survival following OLT.

Overall, the recurrence rate (16%) associated with this study was consistent with previous reports^[16]. According to the patient groups, the recurrence rates were 5.8%, 14.3% and 40.0% for the Milan +, Milan -/UCSF +, and UCSF-patients, respectively. We hypothesize that these low recurrence rates are associated with the use of the Milan criteria in patient selection and especially for the allocation of deceased donor grafts.

Microvascular invasion is a key step in HCC metastasis. However, as a characteristic of tumor growth that must be determined pathologically, it is impossible to

know pre-operatively if it exists. According to previous studies, the presence of microvascular invasion is considered a negative factor for OLT in the treatment of HCC. Correspondingly, in our study microvascular invasion was associated with a significant decrease in 5-year OS rates from 74.7% to 35.6% ($P < 0.029$). Moreover, we found that the presence of microvascular invasion was significantly higher in UCSF -than Milan + patients ($P < 0.034$).

There are cases where HCC is detected in explanted livers incidentally, and transplant centers worldwide have reported variable incidences of this situation. In particular, Chui *et al*^[17] and Loinaz *et al*^[18] reported the unexpected incidence of HCC to be 1.4% and 2.8%, respectively. In other series, slightly higher incidences of 7% and 8% have been reported^[19,20]. This discrepancy could be partly due to the thickness of the liver sections used for pathologic examination. In the present series, the rate of unexpected HCC incidence was 10.7% (6/56). The mean tumor diameter associated with these cases was 14.7 mm, and the maximum nodule size was less than 20 mm. Furthermore, none of these tumors exhibited radiological features that are typically associated with HCC. Serum AFP levels for 5/6 of these patients were also within the normal range, while one patient had an AFP level of 63.1 ng/dL. However, previous studies have demonstrated that AFP levels are not a reliable indicator for the diagnosis of HCC^[8], and this was consistent with our results. In addition, confirmatory biopsies were not performed for these cases since almost all of the patients had diagnostic findings identified in the imaging studies conducted. Therefore, our results indicate that the current guidelines of the American Association for the Study of Liver disease can provide a reliable diagnosis of HCC^[8].

In conclusion, pre-OLT imaging continues to have a relatively high false negative rate for HCC patients considered for transplantation. The inaccuracy of imaging modalities for identification of tumor characteristics such as size and number may result in the selection of patients with unfavourable survival outcome for OLT. Based on the cases analyzed in this study, it would appear that the Milan criteria are very useful and safe in selecting recipients who will benefit from OLT. Therefore, given the limited number of deceased liver grafts available, the Milan criteria should be followed in the selection of suitable candidates for OLT for the treatment of HCC. In contrast, for cases of OLT involving living donors, the UCSF criteria may be applied. In addition, future advancement in imaging modalities may further improve the reliability and applicability of these selection criteria.

COMMENTS

Background

Liver transplantation offers the best long-term effective treatment for patients with hepatocellular carcinoma (HCC) in cirrhosis. Patients who fulfill the Milan criteria may have a 5-year survival of up to 88%. However, application of the

Milan criteria might lead to the exclusion of patients who otherwise would benefit from orthotopic liver transplantation (OLT). Several studies have evaluated more liberal criteria for tumor staging which could be adopted without significant impairment of patient survival or tumor recurrence. However, the expansion of tumor-specific criteria for transplantation raises concerns about rational use of scarce deceased donor organs and safety issues in living donation.

Research frontiers

The role of OLT in patients with HCC beyond the Milan criteria is a matter of debate. Several different selection criteria have been proposed to reach an optimum survival outcome after OLT. Improvements in imaging modalities and markers of aggressive tumor biology may help in selecting patients with better outcome after OLT.

Innovations and breakthroughs

In a substantial portion of HCC patients, pre-OLT imaging studies underestimate the extent of the disease. Patients who were reclassified to higher tumor stages after pathological evaluations of the explants had poor survival after OLT. The Milan criteria appear to provide a wider safe margin and reduce the negative influence of underestimates of tumor stage by pre-OLT imaging.

Applications

In the face of low deceased donor organ availability and safety issues in living donation, transplanting patients with HCC who meet the Milan criteria appears to have optimum benefit on patient survival. Better understanding of tumor behavior may help in selecting patients who may benefit from OLT even with higher tumor burden (expanded selection criteria).

Peer review

Despite several studies in the literature about the Milan and University of California San Francisco (UCSF) criteria, this study for the first time suggests Milan criteria for safer preoperative radiological staging over the UCSF criteria.

Abstract

AIM: To assess the efficacy of N-acetylcysteine (NAC) and activated Dimethicone in improving endoscopic mucosal visibility.

METHODS: A total of 148 patients were randomly allocated into four groups to receive one of the following premedications: group A: 100 mL water alone; group B: activated Dimethicone plus water (up to 100 mL); group C: NAC plus water (up to 100 mL); and group D: activated Dimethicone and NAC plus water (up to 100 mL). A single endoscopist blinded to the patients group assessed the gastric mucosal visibility scores (range 1-4) at four sites. The sum of the scores from the four sites was considered as the total mucosal visibility score (TMVS).

RESULTS: The patients in group B showed a significantly lower TMVS than those of groups A and C ($P < 0.001$). The TMVS in patients of group D was significantly lower than that of groups A and C ($P < 0.001$). The TMVS did not significantly differ between groups B and D ($P > 0.05$). The difference between TMVS of groups C and A was not significant ($P > 0.05$).

CONCLUSION: Premedication with activated Dimethicone 20 min prior to the upper endoscopy leads to the best visibility. NAC does not improve visualization by itself.

INTRODUCTION

Studies recently demonstrated a declining trend in gastric cancer incidence throughout the world; yet, it is still the second most common cause of mortality due to malignant diseases^[1]. As detecting the cancer at the early stage has a great impact on its potential curability, mass screening programs are implementing in Japan with the highest rate of the disease. Although the real effect of this approach on mortality is said to be little by some, studies conducted in Japan favor endoscopic mass screening especially by the advent of new minimally invasive procedures such as endoscopic mucosal resection for cancers detected at early stages^[2-5].

Foam, bubbles, and mucus accumulated in the upper gastrointestinal tract can interfere with clear mucosal visualization and pose potential risk of missing early or subtle lesions. That is why anti-foam and bubble-bursting

agents are widely used in gastrointestinal endoscopic centers particularly in Japan where it is common. This is a routine practice neither in the country where this study was conducted nor in the West, probably in fear of some presumed risk of pulmonary aspiration^[6].

Simethicone [Dimethylpolysiloxane (DMPS) or activated Dimethicone] was proved to be a good defoaming agent for pre-endoscopic usage to remove bubble and mucus^[7,8]. Pronase, a proteolytic enzyme isolated in 1962 from the culture filtrate of *Streptomyces griseus*, is another agent whose efficiency as a premedication for improving the visual field of endoscopy devoid of foam and mucus has been investigated and is now being used routinely in Japan's endoscopic centers. It is better to be used in combination with DMPS and bicarbonate to yield more improvement in visibility^[9,10].

Other than upper endoscopy, Simethicone has been studied to be used in colonoscopy as an additive to other bowel preparations to eliminate bubbles^[11,12], in capsule endoscopy as small bowel preparation for the same goal^[13,14], and in endoscopic ultrasonography to reduce artefacts and increase the accuracy of the modality^[15,16].

Currently, N-acetylcysteine (NAC), a mucolytic agent, in combination with DMPS has shown to be effective in elimination of gastric mucus and bubbles when used 20 min prior to endoscopy, improving visualization of the gastric mucosa^[17]. Owing to the lack of any study surveying the efficiency of NAC independently, the present study aimed to compare the effect of this compound and activated Dimethicone (Simethicone) with placebo and together as premedications for gastroscopy.

MATERIALS AND METHODS

This double-blind, randomized, placebo-controlled study was carried out from April to August 2010. Amongst all the consecutive patients referred to our out-patient endoscopy clinic, 148 patients were enrolled in the study after giving a written informed consent. The patients with a history of upper gastrointestinal surgery, gastric cancer, gastrointestinal bleeding, caustic ingestion, pregnancy, diabetes mellitus, asthma, and allergic reactions were excluded from the study. This study was approved in the ethics committee of the local university.

The patients were randomly allocated into four different groups (using random blocks) with peculiar liquid premedication for each one: (1) group A, 100 mL water; (2) group B, 100 mg, 2.5 mL, activated Dimethicone (Dimetin, Tolid Daru co., Tehran, Iran) plus water up to 100 mL; (3) group C, 600 mg N-acetylcysteine (ACC, Hexal AG, Holzkirchen, Germany) in water up to 100 mL; and (4) group D, 100 mg, 2.5 mL, activated Dimethicone and 600 mg N-acetylcysteine plus water up to 100 mL.

All the liquid solutions were prepared in the same opaque bottles and taken about 20 min prior to endoscopic procedure under supervision of an informed attendant nurse. All patients were unaware of their groups and the type of liquid solutions. Then the patient awaited

endoscopy in sitting position in the endoscopy waiting room.

All the endoscopic procedures were performed by a single, experienced endoscopist blinded to the patient's group and premedication. The endoscopies were done at a relatively fixed period of time in a clinic affiliated with Shiraz University of Medical Sciences, using a video endoscope (EPK 1000 PENTAX, Japan).

During endoscopy, four distinct domains of the stomach including the antrum, the upper part of the greater curvature, the lower part of the greater curvature, and the gastric fundus were evaluated separately for mucosal visibility. Scoring from 1 to 4 for each domain, known as visibility score, was defined based on the modified form of Kuo *et al.*^[9] scoring system like the one used by Chang *et al.*^[17] as follows: (1) score 1, no adherent mucus on the gastric mucosa; (2) score 2, little amount of mucus on the gastric mucosa, but no obscuring vision; (3) score 3, large amount of mucus on the gastric mucosa, with less than 50 mL of water to clear; and (4) score 4, large amount of mucus on the gastric mucosa, with more than 50 mL of water to clear.

The sum of visibility scores of all four domains is considered as the TMVS for each patient.

Statistical analysis

The demographic characteristics were assessed using a χ^2 test, ANOVA, or one-way analysis of variance. The visibility scores of all the four groups were analyzed using Kruskal-Wallis and Mann-Whitney pairwise comparisons. *P* value < 0.05 was considered statistically significant.

RESULTS

From a total of 148 patients enrolled in the study, 77 (52%) were male and 71 (48%) female. Then, 38, 37, 37 and 36 patients were randomly assigned to groups A, B, C and D, respectively. The mean (\pm SD) age was 42.2 ± 13.9 in group A, 44.3 ± 18 in group B, 44.6 ± 16.4 in group C, and 41.8 ± 17.5 in group D. The mean age in the whole study population was 43.2 ± 16.4 . The most common reason for endoscopy in all the groups and also in the total population was dyspepsia (65.5% in total). Moreover, the second most common cause in all the patients was acid reflux (12.8%). All demographic data encompassing sex distribution per group and reason for endoscopy are shown in Table 1. There was no statistically significant difference (*P* > 0.05) among groups regarding age and gender.

The mean of TMVS in group A was 9.50 ± 2.55 , in group B 5.11 ± 1.28 , in group C 8.41 ± 2.10 , and in group D 5.39 ± 1.71 . The total mean ranks in groups A, B, C and D were 109.96, 41.69, 98.39 and 46.24, respectively (the lower the rank, the better the visibility). The difference among the mean ranks was statistically significant (*P* < 0.001). Group B showed the least visibility scores at different locations of the stomach and also the least

Lower part of the greater curvature	2.26 ± 0.89	1.14 ± 0.34 ^{a,b}	1.89 ± 0.87	1.19 ± 0.46 ^{c,d}
Upper part of the greater curvature	2.47 ± 0.79	1.38 ± 0.54 ^{a,b}	2.35 ± 0.94	1.53 ± 0.69 ^{c,d}
Fundus	2.37 ± 0.75	1.38 ± 0.54 ^{a,b}	2.11 ± 0.65	1.39 ± 0.54 ^{c,d}
Total (TMVS)	9.50 ± 2.55	5.11 ± 1.28 ^{a,b}	8.41 ± 2.10	5.39 ± 1.71 ^{a,b}

^a*P* < 0.001 vs group A; ^b*P* < 0.001 vs group C; ^c*P* < 0.05 vs group A; ^d*P* < 0.05 vs group C; a, b, c, d: Kruskal-Wallis and Mann-Whitney pairwise comparisons. TMVS: Total mucosal visibility score.

mean TMVS which were all significantly lower than those of groups A and C (*P* < 0.001). The patients in group D had significantly lower visibility scores for separate gastric domains (*P* < 0.05) and showed lower mean TMVS than group A and C too (*P* < 0.001). Groups B and D did not differ significantly in scores (*P* > 0.05). Despite the fact that patients in group C achieved lower scores than group A patients, the difference was not significant at all (*P* > 0.05). The mean rank, the mean mucosal visibility scores at separate sites, and the mean TMV scores in distinct groups are depicted in Table 2 and 3, respectively. No adverse reaction was detected during the study in any group.

DISCUSSION

Esophagogastroduodenoscopy or upper endoscopy re-

mains commonplace for the evaluation of upper gastrointestinal tract disorders. One of the major applications of this modality is to discern gastric cancer at early stages. This is of paramount importance because of the direct effect of early diagnosis of gastric cancer on patients' future survival, quality of life, and management. A case series from Britain, reported by Sue-Ling *et al*^[18] showed a 5 year survival rate of 98% for patients detected at early stages of gastric cancer and survived operation. On the other hand, rapid diagnosis is not guaranteed by doing upper endoscopy alone even in a wide range. Suvakovic *et al*^[19] in 1997 remarked that open-access gastroscopy by itself was not sufficient to increase early gastric cancer pick-up; moreover, more awareness from general practitioners, more experience in endoscopy, and high sensitivity for biopsying are important among others too. Besides, foam, bubbles, and mucus accumulated on gastric mucosa are postulated to play a role by blurring visual field during endoscopy. So, it seems prudent to make use of some agents before endoscopy to eliminate these troubles and enhance the precision and accuracy of endoscopy in showing subtle abnormalities.

Simethicone (activated Dimethicone or activated Methylpolysiloxane), commonly used for relief of bloating and gas with no significant adverse reaction or interaction^[20], is a safe adjunct to endoscopic premedications. It works via decreasing the surface tension of bubbles of air and dispersing them without remarkable absorption in the gastrointestinal system^[20]. The effectiveness of Simethicone has already been proved in some other trials as a defoaming agent^[7,8]. Recently, Keeratchananont *et al*^[22], though using a different grading scale and including the esophagus and duodenum in their study, concluded that 133.3 mg (2 mL) of liquid Simethicone in 60 mL water 15-30 min prior to procedure could improve the visibility and reduce the number of flushings required for removing the mucus significantly. They also showed that using Simethicone prior to endoscopy would cut down the duration of the procedure and consequently lead to more satisfaction to both physician and patient. Similarly in our study, those patients in group B who received 100 mg activated Dimethicone in water showed better visualization compared to group A that received only simple water as placebo. The amount of water to be given with Simethicone had been a matter of debate. We used of a fixed volume of water in all our patient groups to remove the possible role thereof; however, in two clinical trials it was shown that there was no significant difference in visibility between those who received Simethicone alone or with 100 mL water^[9,17].

Pronase is a proteolytic enzyme commonly used in Japan as a premedication in combination with bicarbonate and Gascon (Simethicone)^[6]. Fujii *et al*^[10] came to the conclusion that the solution of 100 mL water, 20 000 units Pronase, 1 gm bicarbonate, and 80 mg DMPS was more effective than DMPS alone in improving visibility during conventional endoscopy and chromoendoscopy. They showed that this would decrease duration of endoscopy. Kou *et al*^[9] in a similar study proved that Pronase would

improve visualization much better than DMPS only when used in combination with bicarbonate and DMPS. They vividly concluded that Pronase without DMPS was of no use. Pronase is not routinely used in this country and was not the scope of the study.

NAC is a mucolytic and antioxidant agent acting via its free sulfhydryl group to lower the mucus viscosity^[21]. Nor significant interaction neither adverse reaction has been reported with oral preparations. In this study, those patients with a history of asthma and Diabetes Mellitus were excluded. This study is the only one in which the effect of NAC alone has been investigated and compared to Dimethicone and placebo. The patients in group C who received 600 mg NAC in 100 mL water did not show any betterment in visibility scores (8.41 ± 2.10 vs 9.50 ± 2.55 in group A). Combination of NAC and Dimethicone in group D demonstrated better visualization than simple water in group A. But this combination was not superior to Dimethicone alone in group B. We supposed that this was the effect of Dimethicone appearing in group D as in group B and NAC had no effect. In contrast to our results, Chang *et al*^[17] concluded that the mixture of 400 mg NAC and 100 mg DMPS plus water up to 100 mL is more effective than DMPS alone or DMPS in water in a significant manner. They also recommended that NAC could be a substitute for Pronase where it was unavailable. In their study, the mean of the total visibility score in the patients who received NAC plus DMPS was 6.5 ± 2.2 (vs 5.39 ± 1.71 in this study) and in those receiving DMPS with water 7.6 ± 2.6 (vs 5.11 ± 1.28 in this study). The scoring system was exactly similar in the two studies though performed by different endoscopists. All these compounds were proved not to affect the result of rapid urease tests using Campylobacter-like organism tests^[9,17].

In conclusion, regarding the lower cost of Dimethicone (activated) (one third that of NAC per patient herein) and lack of Pronase, we suggest the routine use of 100 mg activated Dimethicone in water up to 100 mL twenty min prior to upper endoscopy here and all other areas where Pronase is not available. To clarify the exact benefits of NAC requires further trials.

COMMENTS

Background

Upper endoscopy is a routine and widely-used procedure to evaluate upper gastrointestinal tract. Since foam and air bubbles can impair visibility, some anti-foam agents such as Simethicone and Pronase are used as premedications prior to endoscopy.

Research frontiers

Activated Dimethicone (Simethicone) has been shown to be effective in reducing

foam and bubbles in the stomach. N-acetylcysteine (NAC) is a mucolytic drug that is supposed to be efficacious too. This study aims to compare the efficacy of these agents in improving visibility.

Innovations and breakthroughs

Activated Dimethicone was shown to be effective. In contrast to prior findings our study showed that NAC was not able to improve visibility when used alone. Furthermore, combination of NAC and Dimethicone did not differ from Dimethicone alone in providing more clear visualization. This is the first study in which the efficacy of NAC was investigated independently as a premedication.

Applications

Usage of activated Dimethicone prior to upper endoscopy is of benefit for improving mucosal visibility; however, N-acetylcysteine seems not to be effective if used alone. Thus, activated Dimethicone should be considered as a premedication before upper endoscopy especially in areas where other agents are lacking.

Peer review

This is a nice study. It is well composed, balanced, documented and the English spelling is good.

ranging from 3 mo to 10 years in age were enrolled, and one to three stool samples from each subject were collected. Certain parameters, including white blood cells /differential count, C-reactive protein, fecal mucus, fecal pus cells, duration of fever, vomiting, diarrhea and severity (indicated by Clark and Vesikari scores), were recorded and analyzed. Fecal lactoferrin was determined by enzyme-linked immunosorbent assay and compared in different pathogen and disease activity. Generalized estimating equations (GEE) were also used for analysis.

RESULTS: Data included 226 evaluations for 117 individuals across three different time points. Fecal lactoferrin was higher in patients with *Salmonella* ($11.17 \mu\text{g/g} \pm 2.73 \mu\text{g/g}$) or *Campylobacter* ($10.32 \mu\text{g/g} \pm 2.94 \mu\text{g/g}$) infections and lower in patients with *rotavirus* ($2.82 \mu\text{g/g} \pm 1.27 \mu\text{g/g}$) or *norovirus* ($3.16 \mu\text{g/g} \pm 1.18 \mu\text{g/g}$) infections. Concentrations of fecal lactoferrin were significantly elevated in patients with severe ($11.32 \mu\text{g/g} \pm 3.29 \mu\text{g/g}$) or moderate ($3.77 \mu\text{g/g} \pm 2.08 \mu\text{g/g}$) disease activity compared with subjects with mild ($1.51 \mu\text{g/g} \pm 1.36 \mu\text{g/g}$) disease activity ($P < 0.05$). GEE analysis suggests that this marker could be used to monitor the severity and course of gastrointestinal infections and may provide information for disease management.

CONCLUSION: Fecal lactoferrin increased during bacterial infection and with greater disease severity and may be a good marker for predicting and monitoring intestinal inflammation in children with infectious diarrhea.

Abstract

AIM: To explore the value of fecal lactoferrin in predicting and monitoring the clinical severity of infectious diarrhea.

METHODS: Patients with acute infectious diarrhea

Chen CC, Chang CJ, Lin TY, Lai MW, Chao HC, Kong MS. Usefulness of fecal lactoferrin in predicting and monitoring the clinical severity of infectious diarrhea. *World J Gastroenterol* 2011; 17(37): 4218-4224 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i37/4218.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i37.4218>

INTRODUCTION

Infectious diarrhea caused by pathogens may induce gastroenteritis, bloody stool, or severe intraabdominal infections, which spreads disease, especially among infant and child populations, and increases the economic burden. Viral infection is a leading cause of diarrhea among children in developed and developing countries. Moreover, several bacterial pathogens, including *Salmonella spp.*, *Campylobacter spp.*, and *Shigella spp.*, can cause invasive diarrhea. These pathogens have the capacity to invade the mucosa of the distal small intestine and colon, stimulate local and systemic inflammatory responses, and may sometimes cause hemorrhaging and ulceration of the mucosa. Although acute infectious diarrhea is a common clinical disease in children, few reliable and noninvasive diagnostic tools have been used as biological markers in patients with acute infectious diarrhea or persistent digestive symptoms.

Lactoferrin, an 80 kDa iron-binding glycoprotein produced by many exocrine glands, is a major whey protein with a major constituent in the secondary granules of neutrophilic leukocytes. Lactoferrin displays diverse biological activities, ranging from the activation of innate immunity^[1,2], microbicidal effects^[3], and anti-cancer cell responses^[4]. Exposure of host cells to lactoferrin may modulate subsequent cellular functions, such as cytokine gene activation^[5], cytotoxicity^[6], and T cell^[7] or B cell^[8] maturation. Lactoferrin may affect innate immunity by stimulating macrophages through interaction with toll-like receptor pathways^[2]. Because diarrheal illnesses are extremely common in communities and hospitals throughout the world, a noninvasive inflammatory marker may be helpful for disease management. The presence of lactoferrin in bodily fluids, including intestinal lumen, is proportional to the flux of neutrophils, and its assessment can provide a reliable biomarker for inflammation. Neutrophils have been shown to be involved in the perpetuation of inflammation in the gut in acute infections caused by *Shigella* and *Salmonella* and inflammatory bowel disease (IBD)^[9-11]. Guerrant *et al.*^[12] confirmed increased fecal lactoferrin in 96% (25/26) of samples from patients with shigellosis and concluded that fecal lactoferrin was a useful marker for fecal leukocytes.

Few scales are available for evaluating gastroenteritis disease severity. The most commonly used scoring scales are the Vesikari 20-point scale, in which an episode of gastroenteritis with a score ≥ 11 is considered severe^[13] (≥ 11 moderate, ≥ 16 severe), and the Clark 24-point scale, in which an episode of gastroenteritis with a score

≥ 16 is considered severe^[14]. Our present prospective study was conducted to explore the role of fecal lactoferrin in gastrointestinal infection, including (1) predicting bacterial or viral infection; (2) ascertaining the extent to which values may be associated with the severity of gastroenteritis in the above scales; and (3) monitoring the severity and course of gastrointestinal infection, which may provide information for disease management.

MATERIALS AND METHODS

This prospective study enrolled and analyzed children being treated in Chang Gung Children's Hospital located in Northern Taiwan. All subjects provided written informed consent, and three fecal samples were collected from each subject.

Enrollment was conducted between September 2008 and May 2010. Diarrhea was defined as three or more outputs of loose or liquid stools per day. Inclusion criteria were 3 mo to 10 years of age and hospitalization with infectious diarrhea. Exclusion criteria were immunodeficiency and history of IBD or gastrointestinal tract surgery. The study protocol was approved by the Institutional Review Board of Chang Gung Memorial Hospital. Informed consent was obtained from the parents of all eligible children. The study was performed in accordance with the Declaration of Helsinki.

Upon entering the study, hospitalized patients received treatment consisting of intravenous fluid and oral rice water or half-strength formula. The severity of diarrhea was evaluated according to the following parameters: volume of stools, fecal consistency and frequency. Other clinical symptoms, including fever, vomiting, abdominal pain, daily intake, and appetite, were also assessed. All participants underwent first-step hematology and biochemistry tests [including blood cell counts, serum C-reactive protein (CRP), and electrolytes] as well as fecal pus cell and mucus analysis. Disease severity was recorded using the severity scoring methods of the Vesikari 20-point scale and Clark 24-point scale. In the Vesikari 20-point scale, an episode of gastroenteritis with a score ≥ 11 is considered moderate or severe (< 11 mild, ≥ 11 moderate, ≥ 16 severe)^[5], and in the Clark 24-point scale, an episode of gastroenteritis with a score ≥ 16 is considered severe. Fecal samples of some patients were collected at three different time points, including the initial stage of infectious diarrhea, 3-5 d later and 7-10 d later. Series follow-ups of fecal lactoferrin were measured by enzyme-linked immunosorbent assay. Their control group comprised 15 children (mean age, 3.7 years; range, 1-10 years) without diarrhea. We compared and analyzed the levels of fecal lactoferrin collected from the different patients at the same time point.

Identifying pathogens

To assess the etiology of infectious diarrhea, fecal specimens were collected to detect *Salmonella*, *Shigella* or *Campylobacter* colonies on specifically prepared agar plates.

Table 1 Patient characteristics

Gender	
Female	52
Male	65
Age (mean), yr	3.23 (3 mo-10 yr)
Pathogen identified	
Rotavirus	41
Norovirus	28
Salmonella	31
Campylobacter	17
Disease severity (Vesikari scoring scale)	
Mild	42
Moderate	50
Severe	25
Duration of diarrhea (median), h	73.8 (14-169)
Vomiting, (d)	2.1 (0-5)
Fever, (d)	2.9 (0-7)
WBC counts (10 ⁶ /L)	12 658 ± 2364
CRP (mg/L)	34.7 ± 22.1
Hemoglobin (g/dL, n = 117)	11.6 (8.2-15.3)
Platelets (10 ⁹ /L, n = 117)	232 (134-585)

Range in brackets. WBC: White blood cells; CRP: C-reactive protein.

The fecal specimens were also sent for evaluating *rotavirus* antigen levels by ELISA and *norovirus* RNA by real-time polymerase chain reaction.

Lactoferrin assay

The stool samples were prepared and analyzed for lactoferrin according to the manufacturer's instructions (AssayMax Human Lactoferrin ELISA Kit, St. Charles, MO, United States). This assay employs a quantitative sandwich enzyme immunoassay technique that measures lactoferrin in 4 h. A polyclonal antibody specific for lactoferrin was pre-coated onto a microplate. Lactoferrin standards and samples were sandwiched by the immobilized antibody and a biotinylated polyclonal antibody specific for lactoferrin recognized by a streptavidin-peroxidase conjugate. Absorbance was read at 450 nm. Lactoferrin was expressed as µg/g of feces.

Statistical analysis

Simple univariate correlation coefficients (Spearman rank correlation) were calculated using baseline data only. Independent associations between the variables of interest were investigated by generalized estimating equations (GEE). GEE is a regression technique that allows the investigation of longitudinal data while adjusting for within-patient correlations. GEE requires a predefined working correlation structure for the dependent variable (lactoferrin), and based on first level and follow-up data, an exchangeable correlation structure was chosen here. The GEE approach was developed to correct for repeated outcomes within the same subject^[15]. When using data from more than two time points, the GEE analysis was employed for longitudinal analysis (associations).

A univariate comparison between groups was performed with a *t* test for repeated measures, and the χ^2 test

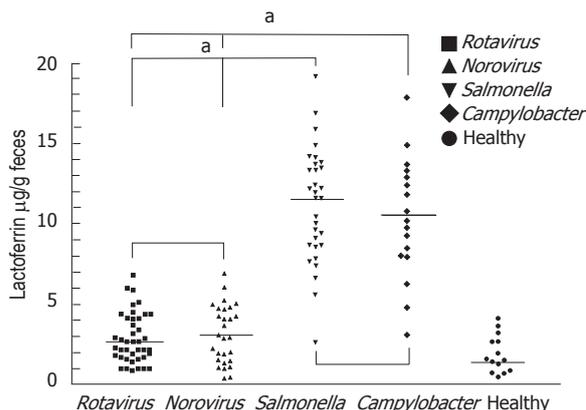

Figure 1 Grouped samples of fecal lactoferrin (µg/g feces) in healthy children and children with gastroenteritis caused by different pathogens, including rotavirus, norovirus, Salmonella and Campylobacter infection. The mean level of fecal lactoferrin was higher in patients with *Salmonella* or *Campylobacter* infections but lower in patients with *rotavirus* or *norovirus* infections. Horizontal line: Mean; ^a*P* < 0.05.

and Fisher's exact test were used with categorical data. Analyses were performed on the intention-to-treat population. A *P* value less than 0.05 was considered significant, and the statistical tests were two-tailed. The GraphPad Software Prism 3.03 (GraphPad Software, Inc., San Diego, CA, United States) and SPSS Software, version 15.0 (SPSS Inc., Chicago, IL, United States), were used for the statistical analysis.

RESULTS

Description of samples

A total of 154 participants were screened between September 2008 and May 2010. From that cohort, 37 patients were excluded from further study because no definite pathogen was identified from the stool examination. Among the individuals included in the study, *rotavirus* infection was diagnosed in 41 patients, and *norovirus* infection was diagnosed in 28 patients. In addition, *Salmonella* infection was diagnosed in 31 patients and *Campylobacter* infection in 17 patients. Demographic details are shown in Table 1.

The data include a total of 226 evaluations for 117 individuals across three different time points. The pattern of assessment was as follows: 43 subjects (36.9%) had three assessments, 23 (19.6%) had two assessments, and 51 (43.5%) had one assessment. The mean age of the subjects was 3.23 years (SD 2.15, range 3 m/o-10 y/o), and 65 (55.5%) were male.

Fecal lactoferrin

The mean ± SD of the fecal lactoferrin concentration was 11.17 µg/g ± 2.73 µg/g in patients with *Salmonella* infections, 10.32 µg/g ± 2.94 µg/g in patients with *Campylobacter* infections, 2.82 µg/g ± 1.27 µg/g in patients with *rotavirus* infections and 3.16 µg/g ± 1.18 µg/g in patients with *norovirus* infections (Figure 1). Concentrations of each fecal marker for patients with either form of bacterial infection were significantly elevated compared

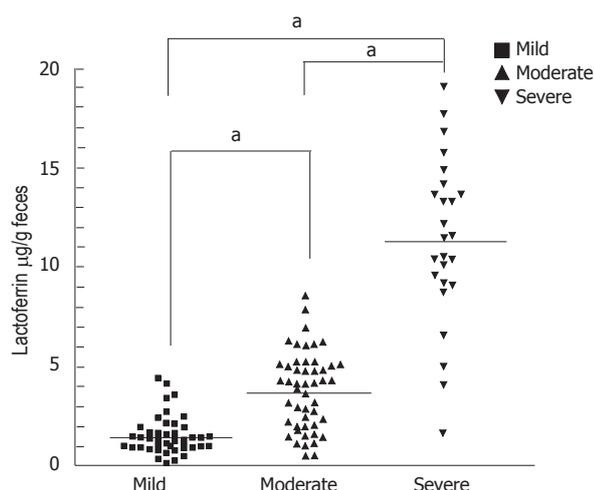

Figure 2 Fecal lactoferrin level ($\mu\text{g/g}$ feces) in children with mild, moderate or severe disease activity according to the Vesikari score (< 11 mild, ≥ 11 moderate, ≥ 16 severe). Levels of fecal lactoferrin were elevated in moderate and severe disease activities. Horizontal line: Mean; ^a $P < 0.05$.

with those of virus-infected patients. The P values for lactoferrin were < 0.05 . No statistical differences were observed in fecal lactoferrin concentrations between the clinically confirmed *Salmonella* and *Campylobacter* infections. The P values for lactoferrin was 0.71.

The mean \pm SD of fecal lactoferrin concentration was $11.32 \mu\text{g/g} \pm 3.29 \mu\text{g/g}$ in patients with severe disease activity (Vesikari score ≥ 16 , Table 2), $3.77 \mu\text{g/g} \pm 2.08 \mu\text{g/g}$ in patients with moderate disease activity (Vesikari score ≥ 11) and $1.51 \mu\text{g/g} \pm 1.36 \mu\text{g/g}$ in patients with mild disease activity (Vesikari score < 11 , Figure 2). Concentrations of each fecal marker for patients with either form (viral or bacterial) of severe or moderate disease activity were significantly elevated compared with those of mild

disease activity. The P values for lactoferrin were < 0.05 .

Univariate linear regression analysis

Certain parameters associated with the level of fecal lactoferrin, including white blood cells/differential count, C-reactive protein, fecal mucus, fecal pus cells, duration of fever, vomiting, diarrhea and severity (as indicated by Clark and Vesikari scores), were recorded and analyzed. To determine the correlation between these parameters and fecal inflammatory markers, we performed a univariate linear regression analysis.

The univariate linear regression analysis revealed that the Vesikari score, Clark score, fecal pus cells, CRP, vomiting and dehydration were all correlated with lactoferrin level (Table 3).

GEE analysis results

Table 4 reveals the results of the multivariate analysis of the predictive value of fecal lactoferrin with time variations. Subjects with higher Vesikari severity scores had higher fecal lactoferrin levels initially (when time = 0), and the levels of fecal lactoferrin may have decreased when followed-up at different time points (when time > 0).

(Lactoferrin = $3.9289 + 3.2257 \times \text{Vesikari score} - 0.1835 \times \text{time} - 0.1575 \times \text{time} \times \text{Vesikari score}$)

However, there was no significant relationship between fecal lactoferrin and the Clark score with time variations. On the contrary, subjects with higher band form (%) had higher fecal lactoferrin levels initially (when time = 0), and the levels of fecal lactoferrin may have decreased when followed-up at different time points (when time > 0).

(Lactoferrin = $3.6654 + 1.9759 \times \text{Band} + 1.627 \times \text{time} - 1.5261 \times \text{Band} \times \text{time}$)

DISCUSSION

An intense intestinal infection involves intense infiltration of neutrophils, macrophages, mast cells, lymphocytes, natural killer cells, other inflammatory cells in the epithelial lining and the lamina propria of the colonic mucosa^[16]. Cells in the innate immune system secrete various enzymes and metabolites, including myeloperoxidase and lactoferrin, produced by activated neutrophils. Lactoferrin is found mainly in the oral cavity and intestinal tract where it can come into direct contact with pathogens, such as viruses and bacteria. The noninvasive fecal marker lactoferrin may prove useful in screening for inflammation in patients with abdominal pain and diarrhea^[17]. Our study demonstrates the usefulness of fecal lactoferrin for detecting colonic inflammation in children with gastrointestinal symptoms, such as enteritis or enterocolitis.

The most significant function of lactoferrin in mucosal defense is its antimicrobial activity. Lactoferrin can also amplify the actions of lysozyme and secretory immunoglobulin A^[18]. *In vitro* studies have shown lactoferrin's bactericidal effects on *V. cholerae*, *Salmonella enterica* subsp. *enterica* serovar mutants, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Candida albicans*^[19]. Thus, increased stool levels of lac-

toferrin in acute shigellosis may suggest increased degranulation of neutrophils upon stimulation that may promote the killing of *Shigella* in the colonic mucosa. Interaction of lactoferrin with immune system cells induces a regulated release of cytokines, such as interleukin 6 and tumor necrosis factor alpha^[19], which has also been observed during acute *Shigella* infection in adults^[20,21] and children.

Fecal lactoferrin has been reported as a promising biomarker in active Crohn's disease^[22] and ulcerative colitis^[23], requiring the exclusion of patients enrolled with a history of the above IBDs. Indeed, in patients without known IBDs suspected of having a bacterial diarrheal illness, fecal lactoferrin may be useful in evaluating bacterial gastrointestinal infections in which antimicrobial therapy may be prescribed (e.g., *Salmonella*, *Shigella*, *Campylobacter*, and pathogenic *Escherichia coli* spp.) and aid in following the inflammatory activity of bacterial infection. Previous study has suggested that fecal lactoferrin could serve as a screening tool for deciding when to perform a stool culture^[24]. Fifty-five patients were enrolled in the Choi *et al*^[24] study, and the researchers reported that fecal lactoferrin was higher in invasive bacterial pathogens and might greatly enhance a cost-effective approach for evaluating infectious diarrhea^[24]. Fecal lactoferrin could be a more sensitive test than fecal leukocytes for evaluating patients with acute diarrhea. Scerpella *et al*^[25] reported that 94% of travelers with invasive pathogens had positive fecal lactoferrin, while only 69% had fecal leukocytes. The other study has also found that fecal lactoferrin was better than methylene blue for detecting invasive pathogens^[26]. According to our study, the fecal lactoferrin level is higher in bacterial gastrointestinal infections, such as *Salmonella* and *Campylobacter*, but lower in patients with rotavirus or norovirus infections. The above results are similar to the findings of Choi *et al*^[24] (higher fecal lactoferrin in *Salmonella*, *Campylobacter* and *Shigella* infections but lower in rotavirus infections).

In some meta-analyses of the sensitivity and specific-

ity of different markers of intestinal inflammation associated with invasive pathogens (e.g., fecal leukocytes, occult blood in stool, and fecal lactoferrin), fecal lactoferrin was recommended as having the best diagnostic accuracy^[27-29]. In enteroaggregative *Escherichia coli* infectious diarrhea, mucosal inflammation included heavy mucus formation, intimate cell adherence, and secretion of toxins, and the common finding was higher fecal lactoferrin, which suggests a diffuse colonic inflammatory process^[30,31]. Our study has demonstrated that fecal lactoferrin is higher in infections caused by *Salmonella* and *Campylobacter* and in moderate or severe disease severity.

In our study, the data include 226 evaluations for 117 individuals across three different time points. Concentrations of fecal lactoferrin were significantly elevated in patients with severe or moderate disease activity compared with those with mild disease activity ($P < 0.05$ for each marker). Univariate linear regression analysis revealed that the Vesikari and Clark scores, fecal pus cells, CRP, vomiting and dehydration were all correlated with the lactoferrin level. The parameters of the Vesikari and Clark scores included body temperature, severity of dehydration, and the number of instances and duration of diarrhea and vomiting. Fecal pus cells are usually positive in bacterial infection. Increased CRP may be related to intestinal mucosal inflammation caused by pathogens. Taken together, fecal lactoferrin might correlate with disease activity, which may include the number of instances and duration of diarrhea or vomiting, severity of fever or dehydration, fecal pus cells and CRP.

GEE is a regression technique that allows the investigation of longitudinal data and corrects for the repeated outcomes within the same subject. GEE requires a pre-defined working correlation structure for the dependent variable (lactoferrin) and is based on first level and follow-up data. In our study, we found that fecal lactoferrin on the first evaluation and follow-up levels were highly associated with Vesikari scores. The above results indicate that fecal lactoferrin may be useful in monitoring the severity of infectious diarrhea during the course of the disease and may provide information for the management of gastrointestinal infection. In addition, fecal lactoferrin levels at the first evaluation and at follow-up were also associated with the band-form percentile. This result suggests that fecal lactoferrin may play a role in monitoring the disease activity and providing guidance for treating infectious diarrhea. According to our study, the measurement of fecal lactoferrin may be a useful noninvasive test for evaluating intestinal infectious or inflammatory situations. For children with persistent diarrhea or recurrent digestive symptoms after one episode of gastrointestinal infection, fecal lactoferrin could be a helpful tool for providing treatment and management information for physicians.

In conclusion, the non-invasive marker fecal lactoferrin was able to predict bacterial or viral infection, and the relative values may be associated with the severity of gastroenteritis, corresponding to Vesikari and Clark scores. Furthermore, fecal lactoferrin may be useful in monitor-

ing the severity and course of gastrointestinal infections, which may provide information for disease management and follow-up.

COMMENTS

Background

This study provides increasing evidence that acute gastrointestinal infection is a common clinical disease in children. Few reliable, noninvasive and painless diagnostic tools have been used as biological markers in patients with acute gastroenteritis.

Research frontiers

How to predict the infectious pathogens (virus or bacteria) that caused acute diarrhea has not been fully clarified. The use of fecal leukocytes, pus cells and serum C-reactive protein has been attempted but was not fully effective. Fecal lactoferrin could be involved in the inflammation caused by the intestinal infectious pathogen. We attempt to investigate a useful noninvasive fecal marker for predicting and monitoring intestinal inflammation in children with infectious diarrhea.

Innovations and breakthroughs

The study design measures the level of fecal lactoferrin during acute infectious diarrhea. The authors also investigated the clinical information and certain parameters of patients, as well as used univariate linear regression analysis and generalized estimating equations to (1) predict bacterial or viral infection; (2) ascertain the extent to which values may be associated with the severity of gastroenteritis; and (3) monitor the severity and course of gastrointestinal infection, which may provide information for disease management.

Applications

This study found that fecal lactoferrin is higher in patients with *Salmonella* infection or *Campylobacter* infections but lower in patients with *rotavirus* infection or *norovirus* infections. Fecal lactoferrin increased during bacterial infection and with greater disease severity and may be a good marker for predicting and monitoring intestinal inflammation in children with infectious diarrhea.

Peer review

The study by Chen and colleagues presents the value of using fecal lactoferrin to predict and monitor the clinical severity of infectious diarrhea. The study is well planned, includes a robust sample size, is well controlled and the results are clearly interpretable. Perhaps, one benefit, which they argue for the approach in using fecal lactoferrin is that it allows for diagnosis and monitoring without using invasive approaches.

Abstract

AIM: To identify the novel methylation-silenced gene *pentraxin 3 (PTX3)* in esophageal squamous cell carcinoma (ESCC).

METHODS: *PTX3* mRNA expression was examined in six human ESCC cell lines, one human immortalized normal esophageal epithelial cell line, primary ESCC tumor tissue, and paired adjacent nontumor tissue using reverse transcription polymerase chain reaction (RT-PCR). Semi-quantitative immunohistochemistry was used to examine cellular localisation and protein levels. Methylation specific PCR and bisulphite genomic se-

quencing were employed to investigate the methylation of the candidate gene.

RESULTS: In the majority of ESCC cell lines, we found that *PTX3* expression was down-regulated due to gene promoter hypermethylation, which was further confirmed by bisulphite genomic sequencing. Demethylation treatment with 5-aza-2'-deoxycytidine restored *PTX3* mRNA expression in ESCC cell lines. Methylation was more common in tumor tissues (85%) than in adjacent nontumor tissues (25%) ($P < 0.01$).

CONCLUSION: *PTX3* is down-regulated through promoter hypermethylation in ESCC, and could potentially serve as a biomarker of ESCC.

INTRODUCTION

Esophageal cancer is the sixth most common cause of cancer death worldwide, with over 400 000 new cases diagnosed each year^[1]. Esophageal squamous cell carcinoma (ESCC) has a high morbidity and mortality rate in

China. However, the molecular mechanisms underlying ESCC development remain poorly understood.

Human carcinogenesis is a multi-stage process in which genetic and epigenetic changes lead to oncogene activation and tumor suppressor gene inactivation^[2]. Epigenetic changes, such as promoter DNA methylation, can induce the inactivation of tumor suppressor genes. DNA methylation plays a crucial role in the development of nearly all types of cancer^[3]. Recently, a growing list of aberrantly methylated genes has been reported in ESCC, including esophageal cancer related gene 4^[4], p16^[5], adenomatous polyposis coli^[6], transmembrane protein endothelial factor^[7], deleted in liver cancer 1^[8], ubiquitin carboxy-terminal hydrolase 1^[9], testis-specific Y-like protein 5, and human protein phosphatase-1 regulatory subunit-14A^[10]. Nevertheless, most of these tumor suppressor genes exhibit a relatively low frequency of methylation in ESCC. Thus, further studies of a greater number of genes involved in the disease pathogenesis and progression are needed to identify putative epigenetic biomarkers for this tumor type.

The *pentraxin 3 (PTX3)* gene at 3q25 is a member of the pentraxin superfamily. PTX3 expression is induced in response to inflammatory signals, and is produced at the site of inflammation by several cell types, primarily monocytes/macrophages, dendritic cells (DCs), endothelial cells, smooth muscle cells (SMCs), and fibroblasts. PTX3 can combine with a variety of soluble receptor ligands, and plays multiple biological roles, such as immune defense, female reproductive fertility, atherosclerosis, apoptosis, and the regulation of angiogenesis^[11-14]. To date, there has been no reported study concerning *PTX3* gene promoter methylation.

In the present study, we examined reactivation of epigenetically silenced genes using an oligonucleotide microarray in ESCC cell lines. We also investigated the gene expression profiles of tumor tissue and nontumor tissue in ESCC. The genes markedly up-regulated by 5-aza-2'-deoxycytidine (5-Aza-dC) treatment in an ESCC cell line and markedly decreased in tumor tissue compared with nontumor tissue were considered genes of interest. Bisulphite sequencing and methylation-specific polymerase chain reaction (MSP) analyses were carried out on these genes to confirm the presence of aberrantly methylated CpG dinucleotides. Using the methods mentioned above, we successfully identified PTX3 as a new epigenetically silenced hypermethylated gene in ESCC.

MATERIALS AND METHODS

Cell lines and tissue samples

Six human ESCC cell lines were utilized in this study (TE-11, KYSE-30, KYSE-410, KYSE-510, EC-109, and EC-9706) [from American type culture collection (ATCC) and Sciencell]. One human immortalized normal esophageal epithelial cell line (Het-1A) (from ATCC) was used as the "normal" control for ESCC. The ESCC cell lines were cultured in Roswell Park Memorial Institute 1640

supplemented with 10% fetal bovine serum (Hyclone, United States) and antibiotics (100 U/mL penicillin G and 100 µg/mL streptomycin) at 37 °C in a humidified 5% CO₂ incubator. Het-1A cells were maintained in bronchial epithelial basal media with growth supplements (Clonetics, United States).

Twenty primary ESCC and paired adjacent nontumor tissues were obtained from the Beijing Friendship Hospital, Beijing, China. Specimens were snap-frozen in liquid nitrogen and subsequently stored at -80 °C. Formalin-fixed, paraffin-embedded samples of 79 primary ESCC cancer tissue specimens and paired adjacent nontumor tissues were also obtained from the Beijing Friendship Hospital. All patients from whom we obtained the study specimens gave informed consent to participate in this study. All case samples were collected from the primary surgical resection in patients with no prior history of ESCC and adjuvant therapy. Pathological diagnosis was performed and confirmed in the Pathology Department. Tumors were histopathologically classified according to TNM (tumor node metastasis) criteria.

Treatments with 5-aza-2'-deoxycytidine

ESCC cell lines and Het-1A were treated with 10 µmol/L of the DNA demethylating agent 5-Aza-dC (Sigma-Aldrich, United States) for 4 d.

RNA extraction and reverse transcription-PCR

Total RNA was extracted from cell line pellets and tissues using Trizol (Invitrogen, United States). Reverse transcription was performed using total RNA (1 µg) with Reverse Transcription System (Applied Biosystems, United States). The PTX3 mRNA expression levels were detected by conventional RT-PCR with Taq polymerase (Takara, Japan). RT-PCR was performed for 35 cycles at an annealing temperature of 55 °C. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal control of RNA integrity. Primer sequences for PTX3 are as follows: (1) PTX3-F: 5'-TCTCTGGTCTGCAGTGTGG-3'; (2) PTX3-R: 5'-TGAAGAGCTTGTCCCATTC-3'; (3) GAPDH-F: 5'-CGGAGTCAACGGATTGGTCGTAT-3'; and (4) GAPDH-R: 5'-AGCCTTCTCCATGGTGGTGAAGAC-3'.

Isolation and bisulphite modification of genomic DNA

Genomic DNA was extracted from cells and tissues by standard phenol-chloroform extraction. Bisulphite modification of DNA was produced with a Zymo DNA Modification Kit (Zymo Research, United States) according to the manufacturer's protocol.

MSP

Bisulphite-treated DNA was amplified with the methylation-specific primer set, PTX3-MF: 5'-CGTTTGCGGT-TAGGAGTATTC-3', and PTX3-MR: 5'-CAAAACGTC-GTCCGTAACCTTA-3', or the unmethylation-specific primer set, PTX3-UF: 5'-TGTGTTTGTGGTTAGGAG-TATTTG-3' and GPX3-UR: 5'-CAAAACATCATC-

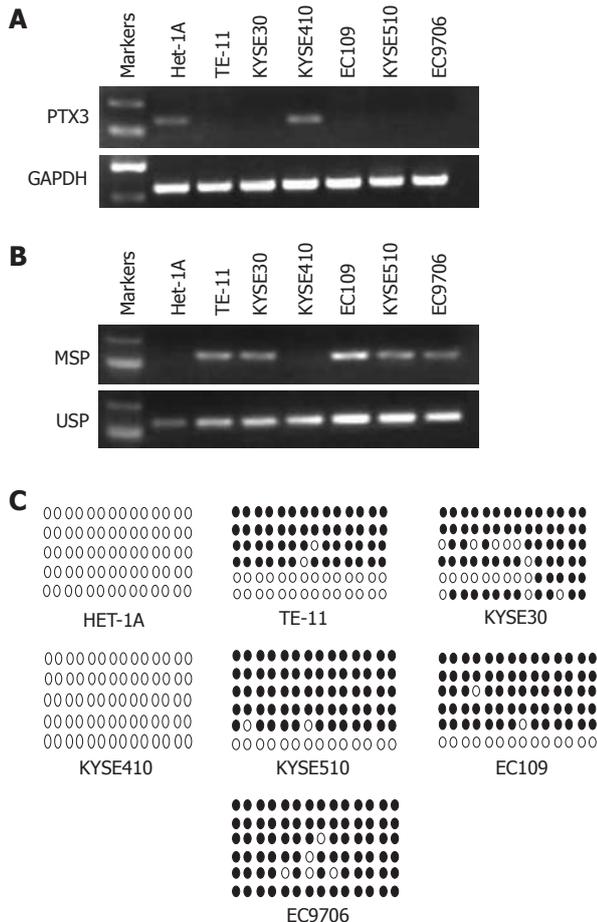

Figure 1 Promoter methylation contributes to pentraxin 3 downregulation in esophageal squamous cell carcinoma cell lines. **A:** Pentraxin 3 (PTX3) mRNA expression was detected by reverse transcription polymerase chain reaction; **B:** The methylation status of PTX3 promoter was determined by methylation-specific polymerase chain reaction. **C:** Representative high-resolution analyses of the methylation status of individual CpG sites in the PTX3 promoter by bisulphite genomic sequencing. Each row represents one bacterial clone with one circle symbolizing one CpG site. Methylated and unmethylated CpG sites were indicated by black and white circles, respectively. **PTX3:** Pentraxin 3; **GAPDH:** Glyceraldehyde-3-phosphate dehydrogenase; **MSP:** Methylation-specific polymerase chain reaction; **USP:** Unmethylation.

CATAACTTA-3', in a total volume of 20 μ L using a 0.5 unit of hot-start Taq-polymerase (Takara, Japan) per reaction. The size of the unmethylated amplicon is 105 bp, and the methylated amplicon is 103 bp. Cycle conditions were: initial denaturation and hot start for 10 min at 95 $^{\circ}$ C, then 35 cycles consisting of 30 s at 94 $^{\circ}$ C, 30 s at 59 $^{\circ}$ C (for methylated reactions) or 50 $^{\circ}$ C (for unmethylated reactions), and 45 s at 72 $^{\circ}$ C, and a final extension of 10 min at 72 $^{\circ}$ C.

Bisulphite genomic sequencing

For the bisulphite genomic sequencing technique, the targeted fragment was amplified from bisulphite-treated DNA, cloned, and sequenced to obtain an accurate map of the distribution of CpG methylation. Forward: 5' TTTTGTGAGATATTTATATGTTGTTTTT-3' and Reverse: 5'AAACACTAATCAACCTAACCTCTAC-3'.

PCR was performed for 40 cycles at an annealing temperature of 54 $^{\circ}$ C. The PCR products were then cloned into the pEasy-T1 vector (Transgene, China), and eight to ten colonies were randomly chosen and sequenced.

Immunohistochemistry

Expression of PTX3 was investigated in 79 primary ESCC cancer tissue specimens and in paired adjacent nontumor tissues using immunohistochemistry. The immunohistochemical expression of PTX3 was examined with light microscopy. The percentage of positive tumor cells was determined semi-quantitatively by assessing the entire tumor section, and each sample was assigned to one of the following categories: 0 (0%-4%), 1 (5%-24%), 2 (25%-49%), 3 (50%-74%), or 4 (75%-100%)^[15]. The intensity of the immunostain was categorised as 0 (no stain), 1+ (weak stain), 2+ (medium stain), and 3+ (strong stain). Additionally, an immunoreactive score was calculated by multiplying the percentage of positive cells and the stain intensity. In instances of heterogeneous staining intensity within one sample, each component was scored independently and the results were summed. Using this system, the maximum score was 12. For statistical analysis, the criteria were combined as follows: 0, negative; 1 to 4, weakly positive; 5 to 8, moderately positive; and 9 to 12, strongly positive^[16].

Statistical analysis

Statistical analysis was performed using the Student's *t* test and the χ^2 test; a value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Transcriptional silencing of PTX3 in most ESCC cell lines

Using RT-PCR with glyceraldehyde 3-phosphate dehydrogenase as a control, we tested the mRNA expression of PTX3 in the immortalized normal esophageal epithelial cell line Het-1A, and in 6 ESCC cell lines (TE-11, KYSE-30, KYSE-410, KYSE-510, EC-109, and EC-9706). The PTX3 transcript was silenced in 5 ESCC cell lines (TE-11, EC109, EC9706, KYSE30, and KYSE510), but not in KYSE-410 and Het-1A (Figure 1A).

As DNA methylation is an important regulator at the transcription level, we hypothesized that the silencing of PTX3 could be caused by methylation. Thus, we performed the MSP assay to measure the methylation level in these ESCC cell lines. The MSP results indicated that partial methylation was observed in the ESCC cell lines TE-11, EC109, EC9706, KYSE30, and KYSE510, whereas the unmethylated promoter was detected in KYSE-410 and in the immortalized normal esophageal epithelial cell line (Het-1A) (Figure 1B). The methylation results were in concordance with the transcription results of these ESCC cell lines.

We performed bisulphite genomic sequencing analysis to confirm the MSP result, and as shown in Figure 1C,

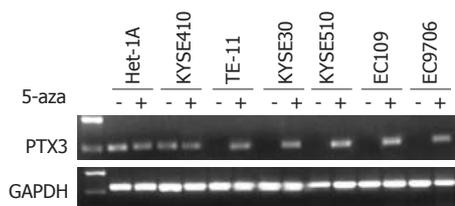

Figure 2 The mRNA expression of pentraxin 3 was restored after treatment with demethylation agent 5-aza-2'-deoxycytidine in esophageal squamous cell carcinoma cell lines. PTX3: Pentraxin 3; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Figure 3 Representative methylation-specific polymerase chain reaction results of esophageal squamous cell carcinoma primary tumors (T) and paired adjacent nontumor tissues (N). Numbers 1-8: Sample number. M: Methylation; U: Unmethylation.

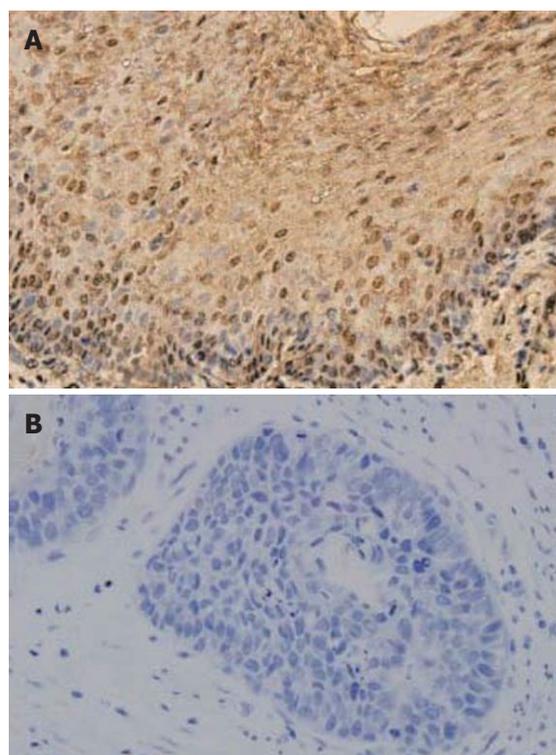

Figure 4 Pentraxin 3 expression assessed by immunohistochemistry staining in esophageal squamous cell carcinoma tumor tissues and adjacent nontumor tissues. A: Significant expression of PTX3 was detected in adjacent nontumor tissues (x 40); B: Negative or weak expression of pentraxin 3 was observed in esophageal squamous cell carcinoma (x 40).

the BGS result was consistent with our MSP data: no methylated CpG sites detected in KYSE-410 and Het-1A, but methylated CpG sites in the other ESCC cell lines (TE-11, EC109, EC9706, KYSE30 and KYSE510). The results indicated that transcriptional silencing of PTX3 was associated with methylation in ESCC cells.

PTX3 expression is up-regulated in ESCC cell lines treated with 5-aza-2-deoxycytidine

The results of RT-PCR indicated that five ESCC cell lines did not express PTX3 mRNA (Figure 1A). As mentioned above, there was a correlation between PTX3 silencing and DNA methylation in ESCC cell lines. To determine whether PTX3 expression could be reactivated by pharmacological demethylation of genomic DNA, all cell lines above were treated with the demethylating agent 5-Aza-dC. After treatment with 5-Aza-dC at 10 μmol/L for 4 d, the five silenced ESCC cell lines resulted in an obvious increase in PTX3 expression (Figure 2), further supporting the role of methylation as a primary mechanism of PTX3 silencing.

Methylation of PTX3 promoter is observed in most ESCC tumor tissues

To assess whether the PTX3 promoter hypermethylation observed in cell lines was relevant to ESCC, we further examined PTX3 methylation in 20 primary ESCC tumors with paired adjacent nontumor tissues using MSP. We found that 80% of ESCC tumor samples (16 of 20) exhibited statistically different methylation within the PTX3 promoter region, whereas the paired nontumor tissues exhibited only 20% (5 of 20) ($P < 0.001$).

The MSP results of ESCC primary tumors (T) and paired adjacent nontumor tissues (N) are shown in Figure 3.

Decreased expression of PTX3 protein in ESCC

We then analyzed 79 primary ESCC specimens and their corresponding adjacent nontumor tissues using immunohistochemical staining. PTX3 protein was detected in 24 of 79 (30.38%) ESCC specimens. In the non-malignant tissues, 67 of 79 (84.81%) samples showed positive detection of PTX3 protein.

In adjacent nontumor tissues, intense immunostaining for PTX3 was observed consistent with cytoplasmic distribution (Figure 4), whereas absent or weak immunostaining was detected in tumor tissues. Immunohistochemical results revealed that the expression of PTX3 protein in ESCC tumor tissues was significantly lower compared to adjacent nontumor tissues ($P < 0.01$).

The clinicopathological features of these patients and the results of PTX3 expression are summarized in Table 1. Statistical analysis indicated that PTX3 protein expression exhibited no correlation with the patients' age, gender, smoking habit, depth of invasion, or lymph node metastasis ($P > 0.05$). However, we found a higher frequency of promoter hypermethylation of PTX3 in the early stages of cancer (I and II) compared to advanced stages, suggesting that PTX3 hypermethylation occurs during a relatively early stage of the multi-step esophageal carcinogenesis.

DISCUSSION

Tumorigenesis is a multistep process caused by the accumulation and interplay of genetic and epigenetic alterations. DNA methylation is a key regulator of gene

Table 1 Clinical features of esophageal squamous cell carcinoma patients and their expression status for pentraxin 3 *n* (%)

transcription and genomic stability. Alteration of DNA methylation is one of the most consistent epigenetic changes that silence tumor suppressor genes in human cancers^[17]. Additionally, aberrant methylation results in increased gene mutagenicity, due to the deamination of 5-methylcytosine to thymine^[17].

We have previously analyzed expression microarray data prior to and post treatment using a demethylating agent in the EC9706 cell line, and we speculated that the *PTX3* gene is potentially down-regulated by promoter hypermethylation. *PTX3* is involved in the regulation of innate resistance to pathogens, the inflammatory reaction, and possibly the clearance of self-components and female fertility. Transfection of *PTX3* into breast cancer cells lacking expression led to a reduction in endothelial cell invasion and capillary tube formation, as well as prevention of tumor formation in athymic nude mice^[18]. In this study, we examined the methylation status of the *PTX3* promoter region in ESCC. As far as we understand, this is the first study to report on *PTX3* gene promoter methylation in ESCC.

Silencing of *PTX3* in ESCC

Down-regulation of *PTX3* mRNA and protein was detected by RT-PCR and immunostaining. We found that *PTX3* was silenced in most ESCC cell lines (5 of 6 ESCC cell lines that we tested) and also silenced in tumor tissues. Reduced expression of *PTX3* suggests that *PTX3* plays a tumor suppressive role in ESCC.

Methylation of *PTX3* promoter

PTX3 promoter hypermethylation was confirmed by

methylation specific PCR and bisulphate genomic sequencing methylation in 83.3% of ESCC cell lines (5/6) and 80% of primary esophageal squamous cell carcinoma tissues (16/20), suggesting that promoter hypermethylation is a major, if not the only, mechanism for *PTX3* down-regulation in ESCC.

Up-regulation of *PTX3* expression after treatment with 5-Aza-dC

Treatment of ESCC cell lines *in vitro* with 5-Aza-dC, a nucleoside analogue inhibitor of DNA methyltransferase, reversed *PTX3* CpG island hypermethylation and restored *PTX3* expression; this confirmed that *PTX3* hypermethylation serves as the principal mechanism for *PTX3* downregulation in ESCC. *PTX3* hypermethylation is involved in the development and progression of esophageal cancer.

Clinico-pathological significance of *PTX3* protein expression

In our study, *PTX3* protein expression was not associated with patients' age, gender, smoking habit, depth of invasion, and lymph node metastasis. We found a high frequency of promoter hypermethylation of *PTX3* in the early tumor stages (I and II) of ESCC, indicating that aberrant methylation is a relatively early event in esophageal carcinogenesis.

Methylation-mediated inactivation is reversible, and up-regulation of *PTX3* by 5-aza-dC may reverse the malignant phenotype of tumor cells. Therefore, *PTX3* could serve as a novel target for gene therapy in ESCC treatment. In the future, further studies to elucidate the function of *PTX3* in ESCC are warranted.

In summary, our study provides the first documentation that *PTX3* is a novel tumor suppressor gene epigenetically silenced in most ESCC tumors. Our results suggest that methylation of the *PTX3* promoter region occurs at an early stage of ESCC pathogenesis and may provide a suitable biomarker for ESCC diagnosis.

COMMENTS

Background

Esophageal cancer is the sixth most common cause of cancer death worldwide, with > 400 000 new cases diagnosed each year. The molecular mechanisms underlying esophageal squamous cell carcinoma (ESCC) development remain poorly understood. DNA methylation plays a crucial role in the development of ESCC.

Research frontiers

Oligonucleotide Microarray Analysis can be used to identify novel genes that are aberrantly methylated in ESCC. Genes that were significantly upregulated after 5-aza-2'-deoxycytidine (5-Aza-dC) treatment in ESCC cells and significantly downregulated in tumor tissue compared with paired nontumor tissue were selected as hypermethylated candidate genes. Subsequently, bisulphite sequencing and methylation-specific PCR were performed to confirm the presence of aberrantly methylated CpG dinucleotides. In this study, the authors successfully identified *pentraxin 3* (*PTX3*) as a new methylation-silenced gene in ESCC.

Innovations and breakthroughs

The study provides the first documentation that *PTX3* is a novel candidate tumor suppressor gene epigenetically silenced in most ESCC tumors. The results

suggest that methylation of the PTX3 promoter region occurs at an early stage of ESCC pathogenesis and may be used as a biomarker for ESCC diagnosis.

Applications

Up-regulating PTX3 by 5-aza-dC may reverse the malignant phenotype of tumor cells. Therefore, PTX3 could be used as a novel target for gene therapy in ESCC treatment. PTX3 functions extracellularly as a secreted protein. PTX3 plays a tumor suppressive role in ESCC; thus, PTX3 protein could potentially be used directly as an anticancer drug therapy.

Terminology

PTX3 gene at 3q25 is a member of the pentraxin super-family. PTX3 expression is induced in response to inflammatory signals. PTX3 is able to combine with a variety of soluble receptor ligands and play multiple biological roles, such as immune defense, female reproductive fertility, atherosclerosis, apoptosis, and regulation of angiogenesis.

Peer review

This study reports the newly recognized tumor suppressor features of the gene *PTX3*, a gene that encodes a protein referred to as pentraxin 3 that serves as a protector against pathogens in tissues and aids in the control of autoimmunity. As an acute phase reactant, its blood level increases significantly during sepsis and severe inflammation, correlating with the severity of the disease and making the protein a useful biomarker for many inflammatory diseases. The authors of this study suggest that PTX3 could also be utilized as a tumor marker in ESCC.

Abstract

AIM: To assess the application of the Kasai procedure in the surgical management of hilar bile duct strictures.

METHODS: Ten consecutive patients between 2005 and 2011 with hilar bile duct strictures who underwent the Kasai procedure were retrospectively analyzed. Kasai portoenterostomy with the placement of biliary stents was performed in all patients. Clinical characteristics, postoperative complications, and long-term outcomes were analyzed. All patients were followed up for 2-60 mo postoperatively.

RESULTS: Patients were classified according to the Bismuth classification of biliary strictures. There were two Bismuth III and eight Bismuth IV lesions. Six lesions were benign and four were malignant. Of the benign lesions, three were due to post-cholecystectomy injury, one to trauma, one to inflammation, and one to inflammatory pseudotumor. Of the malignant lesions, four were due to hilar cholangiocarcinoma. All patients underwent Kasai portoenterostomy with the placement of biliary stents. There were no perioperative deaths.

One patient experienced anastomotic leak and was managed conservatively. No other complications occurred perioperatively. During the follow-up period, all patients reported a good quality of life.

CONCLUSION: The Kasai procedure combined with biliary stents may be appropriate for patients with hilar biliary stricture that cannot be managed by standard surgical methods.

INTRODUCTION

Surgical management of hilar biliary strictures remains a great challenge. The etiology of hilar biliary stricture is diverse, including benign and malignant lesions. The most common benign lesion associated with hilar biliary stricture is secondary to intraoperative injury; most commonly after laparoscopic cholecystectomy. Benign biliary strictures can also occur after hilar bile duct trauma and cholangitis. Malignant hilar biliary stricture can be caused by primary hilar cholangiocarcinoma; a cancer that involves confluence by contiguous spread (e.g., gallbladder and liver cancer), and metastatic cancer

to hilar lymphatic nodes^[1]. Surgery for hilar bile duct stricture is difficult and not without risk. Several repair procedures have been described; none of which are fully satisfactory. Surgical complications are frequent and life-threatening, primarily related to anastomotic leak in the early postoperative period, and biliary strictures in the long term^[2-4]. We therefore recently implemented the Kasai procedure with the use of biliary stents to repair hilar bile duct strictures. We report our experience of using this approach for hilar biliary strictures.

MATERIALS AND METHODS

Patients

We retrospectively analyzed 10 patients (five male, five female) with hilar bile duct strictures who underwent the Kasai procedure in our department from January 2005 to January 2011. The mean age was 52 years (range: 37-64 years). Clinical characteristics are shown in Table 1. Postoperative variables included complications and mortality. Long-term outcomes were retrieved from follow-up visit information.

Operative technique

Radical resections were performed for all malignant hilar lesions. For benign lesions, hilar bile duct dissection was performed, and healthy, non-scarred ducts were exposed for reconstruction. The hepatic quadrate lobule was removed at the level of the hilar plate to expose adequately the bile ducts. A Roux-en-Y portoenterostomy was performed. The afferent limb was approximately 50 cm, which was secured to the hepatic parenchyma, which surrounded the transected hepatic ducts, with 4-0 absorbable braided suture. Fine silicone catheters were used as intrahepatic duct stents to minimize the risk of bile duct restenosis. These were externalized through the stump of the intestinal Roux-en-Y loop and left *in situ* for 5 mo. Intra-abdominal drainage catheters were routinely placed at the anastomosis.

RESULTS

Two lesions were classified as Bismuth III, and eight as Bismuth IV^[5]. Four patients had biliary strictures secondary to bile duct injury: three due to cholecystectomy, and one secondary to abdominal trauma. Four patients had malignant biliary strictures caused by hilar cholangiocarcinoma: one had an inflammatory hilar bile duct stricture secondary to cholangitis; and one had a hilar inflammatory pseudotumor (Table 2).

Of 10 patients, four underwent one or two prior biliary operations. Radiological modalities for evaluation of these patients included ultrasonography ($n = 7$), contrast-enhanced computed tomography ($n = 1$), magnetic resonance cholangiopancreatography (MRCP) ($n = 10$), and endoscopic retrograde cholangiopancreatography ($n = 1$, Figure 1). All patients underwent Kasai portoenterostomy with biliary stenting. Other surgical operations

were performed simultaneously, including hepatic quadrate lobectomy in 10 patients and hepatic left lobectomy in one.

There were no perioperative deaths. One patient experienced a postoperative anastomotic leak and was successfully managed conservatively with drainage and antibiotics. The liver functions of patients were returned to normal postoperatively. Surgical margins at the bile duct cut surfaces were clear in all four patients with hilar cholangiocarcinoma. No other complications such as hemorrhage, abdominal abscess, and wound infection were noted during the perioperative period.

All patients were followed up for a median period of 25.3 mo (range: 2-60 mo). All patients reported a good quality of life. No recurrence or metastasis was found in patients who underwent the Kasai procedure for malignant lesions. Moreover, cholangitis, anastomotic stricture, and cholelithiasis were not observed in any patients.

DISCUSSION

Surgical treatment of hilar bile duct strictures is one of the most challenging areas for hepatobiliary surgeons due to the anatomic complexity and diversity of lesions. Moreover, inappropriately managed biliary strictures can predispose patients to recurrent cholangitis, jaundice, and biliary cirrhosis, which requires additional surgical procedures^[6].

Roux-en-Y hepaticojejunostomy is the most common method for repairing hilar biliary strictures. The

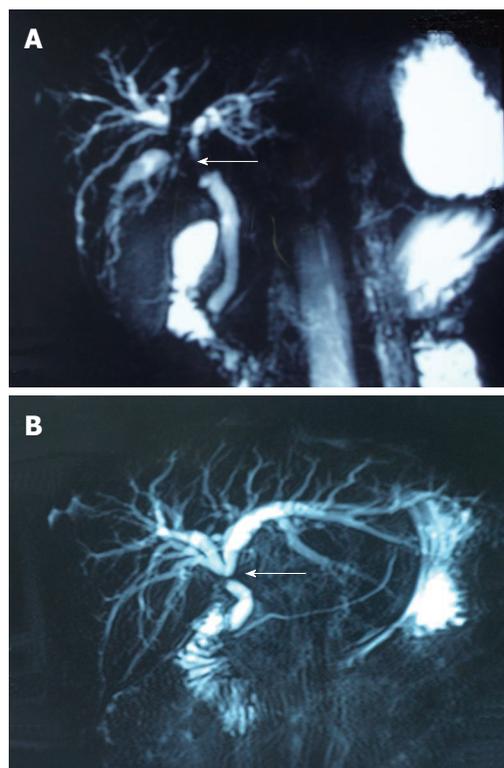

Figure 1 Magnetic resonance cholangiopancreatography images. A: Magnetic resonance cholangiopancreatography (MRCP) showing the hilar bile duct stricture (arrow) caused by cholangiocarcinoma; B: MRCP showing stricture at the hepatic duct confluence (arrow), due to post-laparoscopic cholecystectomy injury.

fundamental principle for repairing a biliary stricture at the hepatic hilum includes identification of healthy bile ducts proximal to the stricture, direct mucosa-to-mucosa anastomosis, a tension-free and wide anastomosis, and a 40-60 cm Roux-en-Y loop^[7]. However, in some circumstances, it is difficult and risky to perform a standard Roux-en-Y hepaticojejunostomy due to the presence of edematous and fragile biliary wall tissues, or the presence of more than one small and thin duct, which cannot be reconstructed to one anastomotic opening. The Kasai procedure has been used extensively for infants with congenital biliary atresia since 1968^[8]. However, there are few reports about the Kasai procedure performed in adults. Schlitt *et al.*^[9] performed the Kasai procedure for three adult patients with high ischemic-type biliary stricture after liver transplantation, but did not achieve satisfactory results. Pickleman *et al.*^[10] have reported five patients with bile duct injuries during laparoscopic cholecystectomy. These patients were managed by the Kasai procedure. All patients were symptom free and functioning normally for a follow-up period of 7-90 mo. In the present study, we applied the Kasai procedure to repair hilar biliary strictures in 10 patients. All patients had an uneventful recovery and have a good quality of life. Therefore, the Kasai procedure may be a good choice for the management of complex hilar biliary strictures that cannot be addressed by standard surgical methods.

Exposure of the proximal bile duct of hilar stricture remains the key to success in the repair of hilar biliary strictures. Some approaches are recommended to expose the hilar bile ducts, such as the hilar and transhepatic approaches^[11,12]. The hilar approach involves lowering the hilar plate to expose the bile duct confluence, to manage the lesion extrahepatically. It is very difficult to expose the second- and third-order branches of the intrahepatic bile duct. The transhepatic approach involves exposing the hilar bile ducts by transecting the liver parenchyma between the left and right lobes of the liver. Although this approach can provide excellent surgical visualization, it requires more elaborate and complex skills, and is high risk. In this study, we performed a concomitant quadrate lobectomy to expose the hilar bile duct. We first dissected the hilar plate and hepatoduodenal ligament to evaluate the lower margin of the lesion, and assessed the portal vein and hepatic artery for tumor invasion. We routinely resected the base of quadrate lobe to visualize the bile duct confluence. Lastly, adequate exposure of the bile ducts could not be obtained, therefore, we resected more of the quadrate lobe between the gallbladder bed and the round ligament, to improve exposure of the hilar ducts, including the second- and third-order branches. Adequate exposure of the hilar bile ducts was obtained in all patients.

In recent years, biliary stenting has become a new technique for the treatment of biliary strictures. The major advantages are that the procedure used to place them is minimally invasive and well tolerated. It was first applied as palliative treatment in patients with unresectable malignant strictures. Previous studies have shown that patients undergoing stent placement for malignant strictures have a significant improvement in abdominal comfort, jaundice, and quality of life. The application of biliary stents as palliative treatment of biliary malignancies is a widely accepted practice^[13,14]. With advances in stent material and the technical process of stent placement, many reports have described their use for treatment of benign biliary strictures^[15-17]. However, complications of stent placement, such as stent occlusion and cholangitis limit their use in benign strictures. Both the requirement for and duration of stenting for benign strictures have been controversial for many years. Siriwardana and Siriwardana have reported a systematic appraisal of the current status of the use of metallic endobiliary stents in the treatment of benign biliary strictures^[18]. They have demonstrated that, although stents can be deployed endoscopically or radiologically with relative ease and with a low procedure-related complication rate, there is a critical lack of data on long-term patency. Thus, currently, metallic endobiliary stents should not be used for benign strictures in patients with a predicted life expectancy of > 2 years. In our study, six patients with benign hilar strictures underwent the Kasai procedure. All patients had a good outcome during follow-up. Therefore, the Kasai procedure may be a good alternative for patients with benign hilar strictures.

The Kasai procedure is a portoenterostomy performed by suturing a jejunal loop to the hepatic parenchyma that surrounds the transected hepatic ducts. Direct mucosa-to-mucosa anastomosis is not required. Anastomotic leak and stricture are the most common postoperative complications. To prevent or lessen the probability of postoperative stricture and bile leak, we routinely placed transanastomotic catheters in the bile ducts, which were externalized through the intestinal Roux-en-Y loop. In our study, all 10 patients underwent the Kasai procedure with transanastomotic stents, and no anastomotic stricture was observed during follow-up. Transanastomotic catheters not only limit the tendency to stricture, but also serve to decompress the biliary system and provide access for radiographic imaging in the perioperative period^[19]. Innes *et al.*^[20] have suggested that a bilioenteric anastomosis to manage benign stenosis of the biliary tract might be undertaken without placing stents, which promises low postoperative morbidity and excellent obstruction-free long-term results. Although the use of postoperative transanastomotic stenting tubes is controversial, we recommend their use when the Kasai procedure is being performed.

In conclusion, the management of hilar biliary strictures is challenging. Surgical repair has been the preferred approach. A Roux-en-Y hepaticojejunostomy is a standard procedure to repair hilar stricture for most patients. The Kasai procedure may be a good choice for a small subset of patients who suffer from complex hilar biliary strictures that cannot be managed by standard surgical methods.

COMMENTS

Background

Surgical management of hilar bile duct stricture is a great challenge because of the complexity of the perihilar anatomy and the diversity of the lesions.

Research frontiers

The appropriate management of hilar bile duct strictures depends on the cause, type, and level of stricture. Roux-en-Y hepaticojejunostomy is a conventional procedure used to repair hilar bile duct stricture. However, in some circumstances, it is very difficult and high risk to perform a standard Roux-en-Y hepaticojejunostomy.

Innovations and breakthroughs

The authors investigated the role of the Kasai procedure in the surgical management of hilar bile duct strictures and demonstrated that the Kasai procedure is a successful method to treat complex hilar biliary strictures.

Applications

This study may help surgeons to choose the Kasai procedure as an appropriate procedure to deal with complicated hilar bile duct strictures.

Terminology

The Kasai procedure is a hepaticportoenterostomy, which is performed by suturing a jejunal loop to the hepatic parenchyma that surrounds the transected hepatic ducts.

Peer review

This is a small case series that describes the use of hepatic portoenterostomy in adults for the reconstitution of biliary-enteric continuity when mucosal to mucosal hepaticojejunostomy is not feasible. Although this is not a new concept, it is an important technique that is occasionally used by hepatobiliary surgeons. Because the literature describing this technique is scarce, this article should be published.

Abstract

AIM: To compare non-liquid and clear-liquid diets, and to assess whether the latter is the optimal treatment for mild acute pancreatitis.

METHODS: The Cochrane Library, PUBMED, EMBASE, EBM review databases, Science Citation Index Expanded, and several Chinese databases were searched up to March 2011. Randomized controlled trials (RCTs) that compared non-liquid with clear-liquid diets in patients with mild acute pancreatitis were included. A meta-analysis was performed using available evidence from RCTs.

RESULTS: Three RCTs of adequate quality involving a total of 362 participants were included in the final analysis. Compared to liquid diet, non-liquid diet significantly decreased the length of hospitalization [mean difference (MD): 1.18, 95% CI: 0.82-1.55; $P < 0.00001$] and total length of hospitalization (MD: 1.31, 95% CI: 0.45-2.17; $P = 0.003$). The subgroup analysis showed

solid diet was more favorable than clear liquid diet in the length of hospitalization, with a pooled MD being -1.05 (95% CI: -1.43 to -0.66; $P < 0.00001$). However, compared with clear liquid diet, both soft and solid diets did not show any significant differences for recurrence of pain after re-feeding, either alone [relative risk (RR): 0.95; 95% CI: 0.51-1.87; $P = 0.88$] and (RR: 1.22; 95% CI: 0.69-2.16; $P = 0.49$), respectively, or analyzed together as non-liquid diet (RR: 0.80; 95% CI: 0.47-1.36; $P = 0.41$).

CONCLUSION: The non-liquid soft or solid diet did not increase pain recurrence after re-feeding, compared with the clear-liquid diet. The non-liquid diet reduced hospitalization.

INTRODUCTION

Early enteral nutrition therapy is important for management of severe as well as mild acute pancreatitis^[1]. The initial part of the necessity is to prevent bacterial infection, as well as energy supplementation^[2]. This kind of nutrition is always preferable *via* the nasojejunal route with a nasal bowel nutrition tube^[3]. However, it is not necessary for mild acute pancreatitis patients because of

longer length of hospitalization and discomfort^[4,5].

In daily clinical care, 80%-90% of patients with acute pancreatitis demonstrate a mild clinical course of the disease^[6]. The traditional initial treatment in mild acute pancreatitis has included: (1) fasting for the first few days; and (2) administration of parenteral fluids followed by clear-liquid-diet intake, orally until the abdominal pain has resolved and the levels of pancreatic enzymes have decreased^[7-9]. It sounds reasonable that clear-liquid diet intake will shorten the presence of food in the duodenum, which reduces cholecystokinin release that stimulates pancreatic enzyme secretion^[10]. Hospital discharge is usually planned on the basis of the patient's tolerance to solid diet^[11].

Oral re-feeding has been recommended to start with small amounts of clear-liquid diet, rich in carbohydrates and proteins and low in fat, gradually increasing or shifting the intake to soft or solid diet during 3-7 d, to avoid abdominal pain and pancreatitis relapse^[12,13]. Unfortunately, to date, evidence is sparse concerning when one kind of diet should be shifted to another, and what kind of diet is definitely optimal re-feeding^[14].

Some recent studies have suggested that oral re-feeding with soft or solid diet instead of clear liquids can be considered safe for pain recurrence, and shorten the length of hospitalization. Some randomized trials in patients with mild acute pancreatitis have shown that non-liquid diets are feasible and safe^[15-17]. However, the results of these studies were inconclusive. The aim of the present study was to perform a meta-analysis of current randomized controlled trials (RCTs) to evaluate non-liquid diet (including soft and solid diets) as an initial treatment in mild acute pancreatitis.

MATERIALS AND METHODS

Study selection criteria

The titles and abstracts of all citations identified by the literature search were reviewed. Selection criteria were then applied to all potentially relevant studies. Editorials and expert opinions, reviews without original data, case reports and studies lacking control groups were excluded. The selection criteria for inclusion in the meta-analysis were as follows: (1) only RCTs that compared non-liquid diet, including soft and solid diet, with clear-liquid diet were included; (2) diagnosis of mild acute pancreatitis was confirmed according to computed tomography scores, APACHE II scores, and basic laboratory examination; (3) outcomes of length of hospitalization (LOH), total length of hospitalization (TLOH), and recurrence of pain after re-feeding were reported; and (4) no other nutritious supplement treatment was given to patients.

Search strategy for identification of studies

Trials were identified by searching the Cochrane Library (Issue 1 2011), PubMed (March 2011), EMBASE (March 2011), Science Citation Index Expanded, and CBM (Chinese Biomedical Literature Database). The query was constructed by using the combination of the following keywords: (mild pancreatitis or acute pancreatitis)

and (diet or nutritious supplement or nutrition). Articles published in any language were considered. Reference lists from the trials selected by electronic searching were hand-searched to identify further relevant trials. Abstracts of the articles selected from each of these multiple searches were reviewed and those meeting the criteria were recorded. In the case of duplicate reports, or studies obviously reporting results from the same study population, only the latest published results were used.

Assessment of study quality

The quality of included studies was assessed independently by two authors (Meng WB and Li YM) without blinding to authorship or journal. Discrepancies were resolved by involving the third author, Xun Li. The quality of the studies was assessed using the scores proposed by Cochrane handbook 5 standards: randomization, allocation, concealment, blinding (participants, investigators, outcomes assessors, and data analysis), and completeness of follow-up.

Data extraction

Two investigators (Meng WB and Li YM) extracted the data from the studies that met the selection criteria (Tables 1-3). The outcomes were totalled from the three studies. There was > 98% agreement for data extraction between the two investigators.

Statistical analysis

We analyzed the data using Review Manager (version 5.0)^[18] and pooled data for summary estimates. We expressed results for dichotomous outcomes as relative risk (RR), and mean difference (MD) with 95% CIs for continuous outcomes. We used the χ^2 test to assess heterogeneity between trials and the I^2 statistic to assess the extent of inconsistency. Statistical significance cut-off for the test of heterogeneity was set at 0.10. We used a fixed-effect model for calculations of summary estimates unless there was significant heterogeneity, in which case, results were confirmed using a random-effects statistical model.

RESULTS

Search results

The flowchart of reviews shows the detailed process of study selection (Figure 1). The comparison was made between non-liquid and clear-liquid diets^[15-17]. Three trials fulfilled the inclusion criteria.

Quality and characteristics of included studies

Data regarding characteristics of the studies, including patients, baseline characteristics and quality assessment of the studies are summarized in Tables 1-3, respectively.

Group and subgroup arrangement

Groups for non-liquid diet *vs* clear-liquid diet were established first. We deemed both solid and soft diets as non-liquid diets to perform the analysis. In the study of Moraes *et al*^[15] in Table 1, there were three arms with solid diet, soft diet, and clear-liquid diet, which were

compared with each other simultaneously. We extracted the solid arm and placed it into the non-liquid diet group, and excluded the soft diet arm for good balance of the statistics. According to the type of control group compared, all the included studies were divided into two subgroups: subgroup A, soft diet *vs* liquid diet; and subgroup B, solid diet *vs* liquid diet.

Meta-analysis

Recurrence of pain: As shown in Figures 2-4, meta-analysis did not show any statistically significant difference between 174 patients in the non-liquid diet group and 188 in the clear-liquid diet group with regard to pain recurrence (RR: 0.80, 95% CI: 0.47-1.36; $P = 0.41$). There was no significant heterogeneity between them ($P = 0.74$, $I^2 = 0\%$). In the subcategory analysis, there was no difference between soft diet and clear-liquid diet (RR: 0.95, 95% CI: 0.51-1.87; $P = 0.88$), nor was heterogeneity ($P = 0.54$, $I^2 = 0\%$). Similarly, in subgroup B, RR was 1.22 (95% CI: 0.69-2.16, $P = 0.49$), and no significant heterogeneity was observed ($P = 0.46$, $I^2 = 0\%$).

LOH: Three trials comprising a total of 174 patients in the non-liquid diet group and 188 in the clear-liquid diet group reported LOH. There was a significant difference

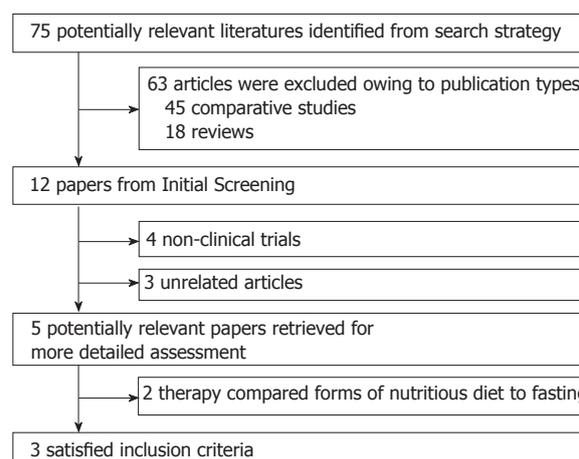

Figure 1 Flowchart of study selection.

between the non-liquid and clear-liquid diet groups (Figure 2), with a pooled MD of 1.18 (95% CI: 0.82-1.55; $P < 0.00001$). There was significant heterogeneity between them ($P = 0.0001$, $I^2 = 89\%$). In subgroup A, there was heterogeneity between two trials ($P < 0.0001$, $I^2 = 94\%$), although a pooled MD was -0.30 (95% CI: -0.78 to 0.17, $P = 0.21$). In subgroup B, MD was -1.05 (95% CI: -1.43 to -0.66; $P < 0.00001$); However, significant heterogeneity was observed ($P = 0.0003$, $I^2 = 92\%$).

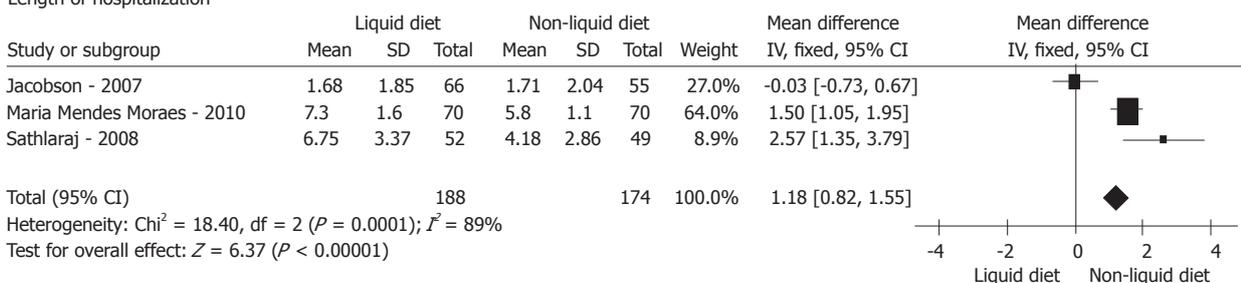

TLOH: TLOH was reported by three trials comprising a total of 119 patients on non-liquid diet and 122 on clear-liquid diet. There was a significant difference between the two groups (MD: 1.31, 95% CI: 0.45-2.17; $P = 0.003$) (Figure 2). The subgroup analyses showed no significant difference for subgroup A (MD: -0.59, 95% CI: -1.33 to 0.14; $P = 0.11$) and subgroup B (MD: -0.70, 95% CI: -1.71 to 0.31; $P = 0.17$). No significant heterogeneity was found between the non-liquid and clear-liquid diet groups

($P = 0.03$, $I^2 = 79\%$). However, significant heterogeneity was seen in subgroup A ($P = 0.002$, $I^2 = 89\%$).

DISCUSSION

The current meta-analysis demonstrated that, compared with clear-liquid diet, non-liquid diet did not increase the recurrence of pain after re-feeding in mild acute pancreatitis, and this finding was supported by the subgroup analyses. These outcomes totally challenged our belief that solid diet, even soft diet, would definitely induce the recurrence of abdominal pain and increase pancreatic enzyme secretion^[19-21]. Physicians had previously hypothesized that oral re-feeding could promote inflammatory

processes in the pancreas and increase production of enteral hormones (such as cholecystokinin, motilin and serotonin), which have a negative trophic effect on the pancreatic tissue, thus decreasing pancreatic blood flow and gastrointestinal motility^[22-25]. However, the meta-analysis did not show any significant difference between non-liquid and clear-liquid diets (RR: 1.22, 95% CI: 0.69-2.16; $P = 0.49$), as well as the two subgroups. There have only been a few studies on diet in acute pancreatitis thus far, therefore, it is possible to speculate that most of the patients could tolerate non-liquid diet successfully. Another key point was that our analysis only selected data from mild acute pancreatitis, with potentially severe types being excluded. The inclusion criteria of the three

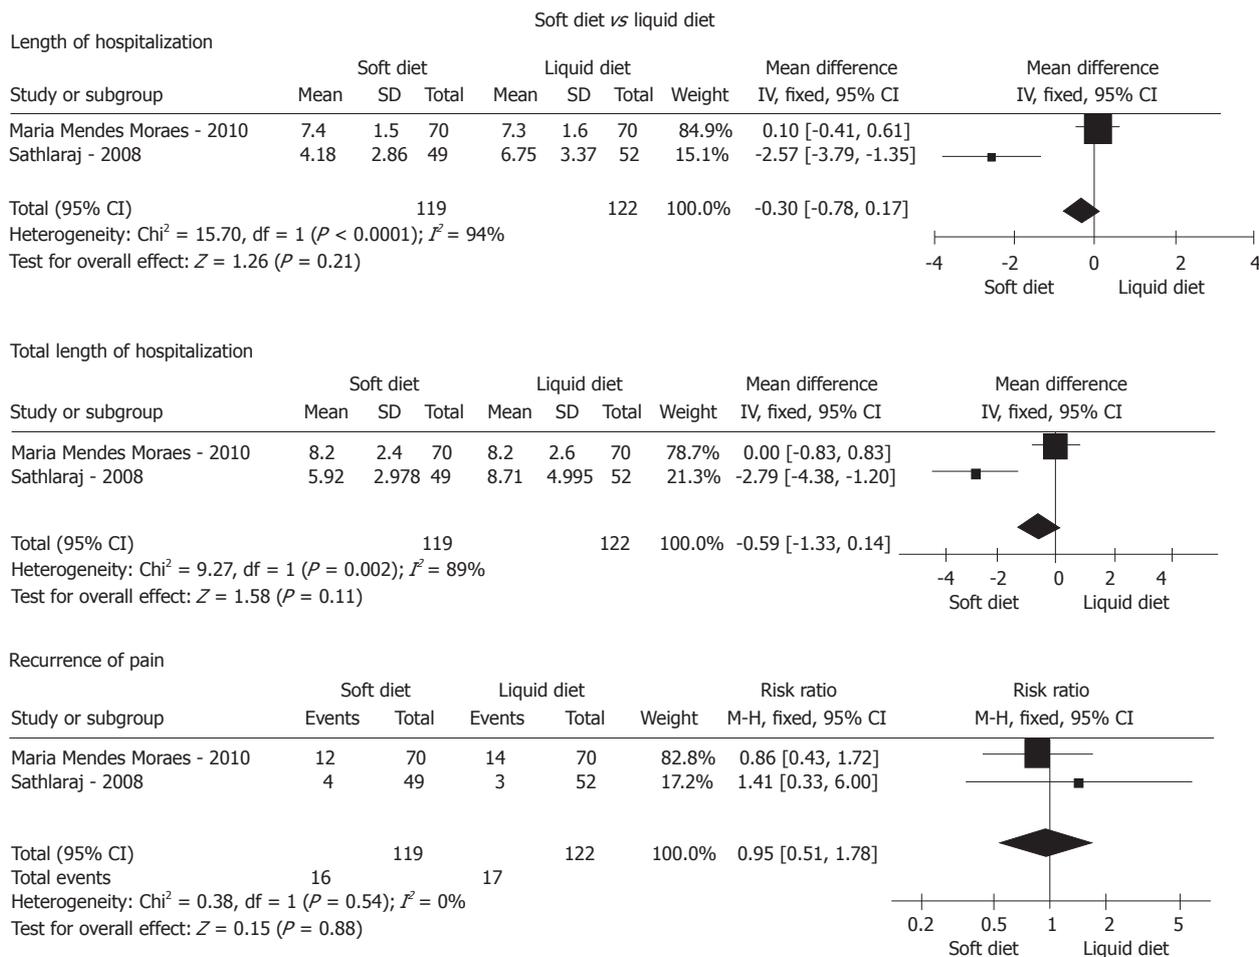

Figure 3 Outcomes in subgroup A: soft diet vs liquid diet with length of hospitalization, total length of hospitalization and recurrence of pain. IV: Inverse-Variance; M-H: Mantel-Haenszel.

RCTs were similar. There was no significant heterogeneity between any of the groups.

Non-liquid diet, especially solid diet, showed superiority over clear-liquid diet on the LOH in the meta-analysis. Consequently, as compared to soft diet, solid diet supplement showed significant beneficial effects on both LOH and TLOH in patients with mild acute pancreatitis. Significant heterogeneity was found in the non-liquid diet vs the clear-liquid diet groups ($P = 0.0001$, $I^2 = 89\%$) and in the comparison of solid diet vs clear-liquid diet ($P = 0.0003$, $I^2 = 92\%$). This heterogeneity could have originated from discrepancies in the criteria for hospital discharge and the limited number of RCTs. Although practice management guidelines have presented detailed information concerning the appropriate timing and form of nutrition in severe acute pancreatitis, little attention has been paid to optimizing the dietary management of mild pancreatitis^[4,14,26,27]. Earlier studies were not able to explain the benefits of soft or solid diet with fat re-feeding, or the patients' tolerance. There is a viewpoint that the pancreas may be less responsive to stimulation by nutrients in normal digestive tract than when patients are suffering from pancreatitis^[20,27].

With the respect to TLOH, a significant difference was only seen in the non-liquid diet vs the clear-liquid

diet group. In the subgroup study, although outcomes favored the soft and solid diet, there was no significant difference. Significant heterogeneity was found in the non-liquid diet vs clear-liquid diet groups ($P = 0.03$, $I^2 = 79\%$) and soft diet vs clear-liquid diet groups ($P = 0.002$, $I^2 = 89\%$). Due to the lack of exact data on TLOH, the heterogeneity analysis could not be performed. The heterogeneity would also have derived from discrepancies in the criteria of discharge and the time zone difference from being hospitalized to re-feeding.

One of the disadvantages of this meta-analysis was that only three RCTs were included. All three studies had high methodological quality and generalizability, nonetheless, there may still have been bias in the final results. There was one study from Brazil^[15] for which we could not obtain accurate data for TLOH. Additionally, another study^[16] that showed shorter LOH may have been related to the fast discharge protocol, which could have led to heterogeneity. Therefore, more multicenter cooperative studies with prospective design are needed.

To the best of our knowledge, many diseases can cause mild acute pancreatitis. The tolerant form of the different diets should be projected separately by disease. That is probably why there are always some patients who cannot tolerate re-feeding, hence prolonging LOH

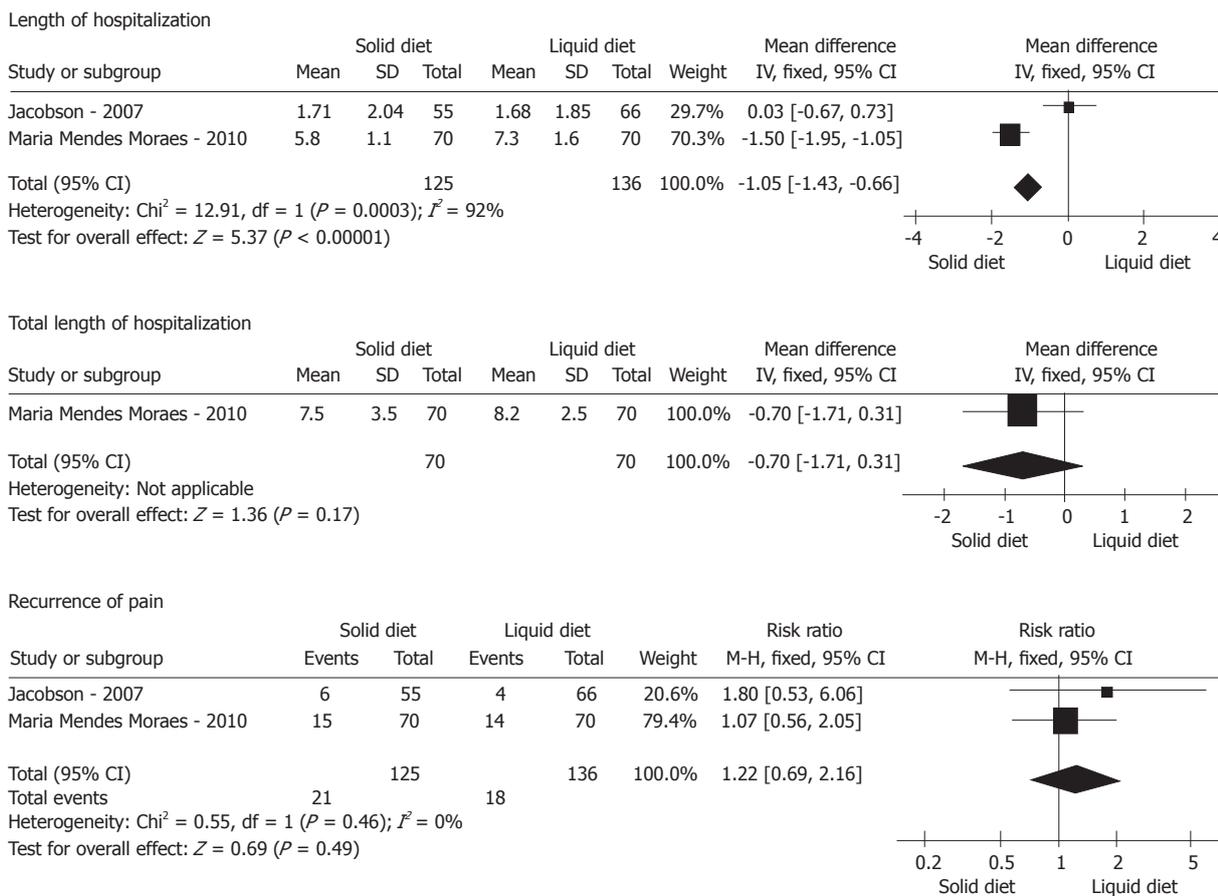

Figure 4 Outcomes in subgroup B: solid diet vs liquid diet with length of hospitalization, total length of hospitalization and recurrence of pain. IV: Inverse-Variance; M-H: Mantel-Haenszel.

in patients with mild pancreatitis^[28]. For example, if patients suffer from bile duct obstruction or infection, high pressure in the bile duct can cause deterioration of pancreatitis by increasing inflammation if the pressure is not released immediately^[29-31]. In that situation, even a small load with any kind of diet could lead to serious consequences^[32-34]. Therefore, treatment directed against the causes of pancreatitis is still an essential step. It is advisable to try and cure pancreatitis as soon as possible after the cause has been established, therefore, we should focus therapeutic options on the pathogenesis, in addition to the necessary supporting treatments; not only to ameliorate abdominal pain, but also to recover the whole function of the gastrointestinal tract. This will in turn improve the tolerance of the patients to earlier application of enteral nutritional therapy, thus reducing LOH. According to our meta-analysis, we obtained novel results that will encourage us to promote further new protocols with regard to dietary management of pancreatitis secondary to different protopathies. Also, more multicenter cooperative studies with prospective design are needed for ultimate conclusions about this issue.

In conclusion, the encouraging outcomes in this analysis may demonstrate a different notion from our previous experience in nutritional supplementation of the patients who are diagnosed with mild acute pancreatitis. None of the soft or solid non-liquid diets showed greater recur-

rence of pain after re-feeding, compared to the clear-liquid diet. Non-liquid diet nutritional supplementation, especially with solid diet, could reduce LOH and TLOH. At this point, we cannot explain our findings with previous pathophysiological experiments performed on acute pancreatitis. One possibility is that the upper digestive tract is less responsive to stimulation by nutrients than we assumed. However, new dietary experiments with animal models of acute pancreatitis and more RCTs comparing roles of different diet forms in the recovery of mild acute pancreatitis are expected to resolve these issues.

COMMENTS

Background

Early enteral nutrition therapy is important for management of mild acute pancreatitis. Initial treatment includes fasting in the first few days and administration of parenteral fluids, followed by gradual clear-liquid diet intake until abdominal pain has resolved and levels of pancreatic enzymes have decreased. Hospital discharge is usually planned on the basis of the patients' tolerance to solid diet.

Research frontiers

Some recent studies have suggested that oral re-feeding with soft or solid diet instead of clear liquids can be considered safe for recurrence of pain, but it inconsistently shortens length of hospitalization (LOH). Some randomized trials in mild acute pancreatitis have shown that non-liquid diets are both feasible and safe.

Innovations and breakthroughs

To review systematically the outcomes of non-liquid diet including soft and solid diet compared with clear-liquid diet in mild acute pancreatitis. The meta-analysis demonstrated that none of the non-liquid soft and solid diets increased

recurrence of pain after re-feeding, compared with clear-liquid diet. Surprisingly, non-liquid diet nutritious supplement re-feeding reduced LOH and total length of hospitalization (TLOH). Furthermore, solid diet decreased LOH.

Applications

With the encouraging outcomes, non-liquid diet nutritional supplementation, especially solid diet, could reduce LOH and TLOH. It might potentially improve the management of mild acute pancreatitis. However more randomized controlled studies on dietary experiments comparing roles of different diet forms in the recovery of mild acute pancreatitis are expected.

Terminology

LOH means the minimum number of days that patients stay in hospital. TLOH is the total length of hospitalization.

Peer review

Nutrition management of mild acute pancreatitis was the focus of the study. In the literature, comparison between total parenteral and enteral nutrition have been performed but not among different types of oral feeding. This study was unique in describing a carefully conducted meta-analysis comparing liquid, soft and solid diets. The conclusions are intriguing but sound. It potentially can improve the management of mild acute pancreatitis as well as further understanding of gastrointestinal physiology.

Abstract

AIM: To detect human papillomavirus (HPV) DNA in esophageal carcinoma (EC) 109 cells and investigate the relationship between HPV and EC.

METHODS: Genomic DNA and total RNA from EC109 cells were isolated. HPV DNA was detected by polymerase chain reaction (PCR) with the general primer sets of My09/11 and GP5 +/6 + for the *HPV L1* gene and type-specific primer sets for HPV18 E6 and HPV18 E6-E7. Reverse transcription (RT) of mRNA isolated from EC109 cells was performed to produce a cDNA.

And then a PCR-based protocol for the amplification of papillomavirus oncogene transcripts was used to analyze HPV18 DNA and integrated transcripts of HPV18 in the chromosomes of EC109 cells. The final nested PCR products were cloned into a pMD-18T vector and sequenced to analyze the chromosomal location of HPV integration.

RESULTS: HPV18 DNA was detected in EC109 cells by PCR using the general primer sets of My09/11 and GP5 +/6 + for HPV L1 and the type-specific primer sets for HPV18 E6 and E6-E7 to generate products of 450 bp, 150 bp, 335 bp and 944 bp, respectively. Approximately 600 bp of integrated HPV18-specific transcript was identified. The final nested PCR product of integrated HPV18 DNA was cloned into a pMD-18T vector and sequenced to analyze the chromosomal location of HPV integration. Sequence alignment showed that the HPV18 sequence from EC109 cells was identical to that of the encoded early protein E7-E1 of the standard HPV18 strain X05015, and another partial gene sequence was identical to a partial sequence of human chromosome 8.

CONCLUSION: Integration of the HPV genome into the host cell chromosome suggests that persistent HPV infection is vital for malignant cell transformation and carcinogenesis.

INTRODUCTION

The esophageal carcinoma (EC) cell line EC109 was established in 1976 by the Cell Biology Research Group at the Chinese Academy of Medical Sciences Institute of Cancer Research. The cell line was derived from esophageal cells that were surgically removed from a patient with a pathological diagnosis of EC^[1]. The cells were determined to be positive for human papillomavirus (HPV) type 18^[2].

EC is one of the major cancers in China. The etiology of EC has yet to be established despite extensive investigation of the contribution of environmental factors, lifestyle, and low levels of chemical elements. In 1982, Syrjanen formulated a hypothesis on the relationship between HPV infection and the development of EC; the hypothesis was based on the presence of papilloma-like tissues in EC specimens and other molecular evidence^[3]. Thereafter, numerous clinical studies have supported this hypothesis^[4-13]. However, the link between HPV infection and the etiology of EC remains inconclusive.

A link between HPV infection and squamous cell cancer of the cervix has been identified^[14]. Currently, several oncogenic types of HPV are regarded as the etiological agents responsible for the development of cervical squamous cell carcinoma^[15,16].

We further studied the association between HPV infection and carcinogenesis using HPV18 E6-E7-transfected stable cell lines derived from fetal esophageal epithelial tissue. Our results strongly supported the conclusion that the expression of HPV18 proteins E6 and E7 induced the transformation of the esophageal cells^[17]. HPV18 was also detected in EC109 cells^[2]. These results support a link between HPV infection and esophageal carcinogenesis.

Persistent infection with high-risk HPV and the integration of viral genomes into the host genome have been implicated in the etiology of malignant and pre-malignant disease of the female lower genital tract^[18,19]. HPV is divided into low-risk (LR) and high-risk (HR) types according to the presumed degree of risk for the development of cancer. HR HPV types such as HPV16, HPV18, and HPV31 are associated with cancer, while LR HPV types such as HPV6, HPV11, and HPV40 are the causative agents of benign warts^[20]. Episomal and integrated HPV can be distinguished using a polymerase chain reaction (PCR)-based protocol for the amplification of papillomavirus oncogene transcripts (APOT), developed by Klaes and his colleagues^[21]. The same

group hypothesized that HPV transcripts derived from the integrated HPV genome represent suitable molecular markers for a pre-neoplastic lesion at risk for progression to carcinoma. For EC, however, few data are available concerning HPV status and integration patterns. The aim of the present study was to assess high-risk HPV infection and HPV18 DNA integration into the host cell genome in EC.

MATERIALS AND METHODS

Cell lines

EC109 cells, the human embryonic kidney (HEK) 293 cell line, and the HeLa cell line were maintained by our laboratory. HeLa cells served as the HPV18-positive control, and HEK293 cells served as the human glyceraldehyde-3-phosphate dehydrogenase (GAPDH)-positive control. The cell lines were cultivated in Dulbecco's modified Eagle medium supplemented with 10% fetal bovine serum and antibiotics (penicillin and streptomycin, the concentration of each antibiotic was 100 U/mL) under standard conditions. Cells were maintained as a subconfluent monolayer at 37 °C in a humidified atmosphere of 5% CO₂/95% air. Exponentially proliferating cells were harvested with 0.25% trypsin and 0.02% EDTA, resuspended in fresh medium, and seeded in new flasks. The cells (2 × 10⁶) were collected and washed with phosphate-buffered saline. Then, the cells were separated into two cryotubes, immediately frozen in liquid nitrogen, or stored at -70 °C until further use.

Detection of HPV DNA

Genomic DNA was isolated from each cell line using the Easy-DNA kit ("BioTake", China) according to the supplier's instructions. HPV DNA was detected by PCR with the general primer sets of My09/11 (My09: 5'-CGTCCMARRGGAWACTGATC-3', MY11: 5'-GC-MCAGGGWCATAAAYAATGG-3', amplicon size 450 bp) and GP5 +/6 + (GP5 +: 5'-TTTGTACTGTG-GTAGATACTAC-3', GP6 +: 5'-GAAAAATAAACT-GTAAATCATATTC-3', amplicon size 150 bp) for the *HPV L1* gene^[22] and type-specific primer sets for HPV18 E6 (forward: 5'-GCGCTTTGAGGATCCAACAC-3', reverse: 5'-ATTCAACGGTTTCTGGCAC-3', amplicon size 335 bp) and HPV18 E6-E7 (forward: 5'-AACACAC-CACAATACTATGGCGCG-3', reverse: 5'-GCATTTTC-GTCCCTCGTCATCTG-3', amplicon size 944 bp). The type-specific primer sets for HPV18 E6 and HPV18 E6-E7 were designed according to the GenBank-provided *HPV18* gene sequences of X05015 (<http://www.ncbi.nlm.nih.gov/nuccore/X05015>).

PCR was conducted in a final volume of 25 µL containing 1× PCR buffer ("BioTake", China), 0.2 mmol/L dNTPs, 1 µL complexed recombinant Taq DNA polymerase, 0.2 mmol/L of each primer, and 100 ng DNA. An initial 5-min denaturation step at 95 °C was followed by 30 amplification cycles of 30 s at 95 °C, 30 s at 55 °C,

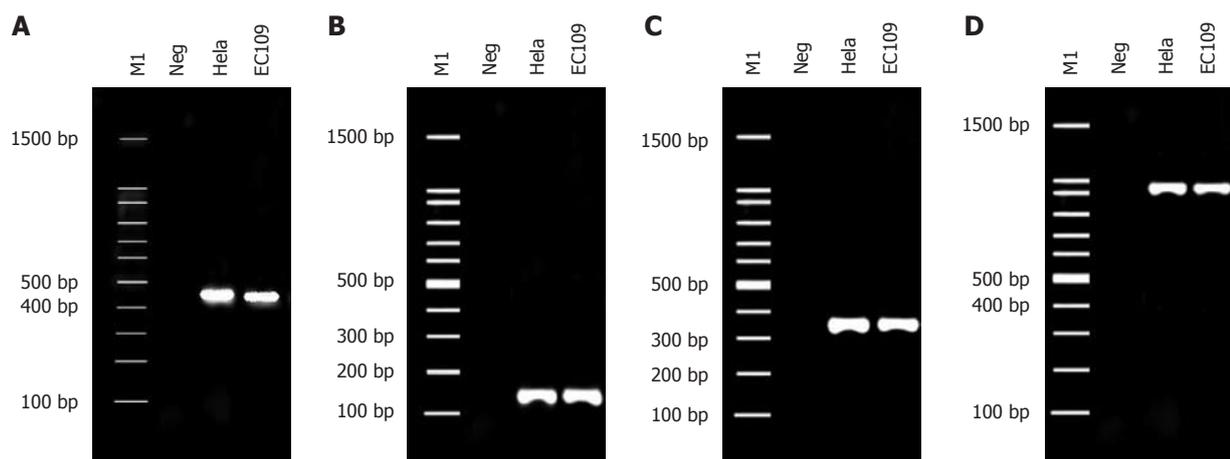

Figure 1 Detection of HPV18 DNA in EC109 cells. A-D: HPV18 DNA detection in EC109 cells using the primer pairs Y09/11, GP5 +/6 +, HPV18E6, and HPV18E6-E7, respectively. M1: 100 bp DNA ladder; Neg: Negative control (template of HEK 293 cell DNA); HeLa: Positive control (template of HPV18-infected cervical cancer cells); EC109: DNA from EC109 cells. HPV: Human papillomavirus; EC: Esophageal carcinoma.

and 1 min at 72 °C, with a final extension step of 5 min at 72 °C using a block thermocycler (PeQLab Biotechnology, Germany). A negative control (HEK293 cell DNA template) was included in each amplification step. DNA from HeLa cells was included as an HPV18-positive control. The PCR products were resolved on a 1.0% agarose gel.

Reverse transcription

Total RNA from the cell lines was isolated using the Micro-to-Midi Total RNA Purification System kit (“Bio-Take”, China) according to the manufacturer’s instructions. The RNA was quantified by spectrophotometry. Reverse transcription (RT) of mRNA isolated from EC109 cells was performed to produce a double-stranded DNA product that was then amplified by PCR. The final concentrations for the RT reaction were RNase-free H₂O (9.2 μL), 0.2 mmol/L dNTP mixture (1 μL), 10 pmol (dT)17-p3 (oligonucleotide primer: GACTCGAGTC-GACATCGATTTTTTTTTTTTTTTTTTTTTT; 1 μL), 5 × first-strand buffer (“BioTake”, China; 4 μL), 200 U SuperScript reverse transcriptase (“BioTake”, China; 1 μL), 40 U RNase inhibitor (1 μL), and total RNA (1-2 μg) in a total volume of 20 μL. The RNA in each reaction was reverse transcribed by heating at 42 °C for 50 min and inactivated by heating at 70 °C for 15 min. Samples were stored at 4 °C.

To confirm that EC109 cells with detectable HPV18 E7 mRNA were indeed harboring HPV, mRNA for a human housekeeping gene was amplified by RT-PCR to ensure that mRNA isolated from EC109 cells was of sufficient integrity to be amplified by PCR. mRNA encoding human GAPDH was used as a target for the RT-PCR. PCR was carried out as described previously^[19], using 10 pmol/L of each GAPDH primer (forward 5’-CATCACCATCTTCCAGGA-3’; reverse 5’-GTCTAC-CACCCTATTGCA-3’) and 2 μL cDNA at a 52 °C annealing temperature for 30 s to generate a GAPDH product of 500 bp.

Detection of viral-cell fusion transcripts by nested PCR

HPV18 PCR reactions were prepared as described by Klaes *et al.*^[21] using forward primer p1-18 specific for HPV18 E7 (5’-TAGAAAGCTCAGCAGACGACC-3’) and p3 (5’-GACTCGAGTCGACATCG-3’) as reverse primer, 1 × buffer, 2.5 mmol/L MgCl₂, 0.2 mmol/L dNTPs, 10 pmol/L primers, 1 U Ex Taq DNA polymerase, 3 μL cDNA product in a total volume of 25 μL. PCR was conducted as follows: 95 °C for 5 min, followed by 30 cycles of denaturation at 95 °C for 1 min, annealing at 56 °C for 1 min, and elongation at 72 °C for 3 min. The last cycle was followed by a final extension step at 72 °C for 5 min.

The amplification product (5 μL) was used for nested PCR under identical conditions using forward primers p2-18 specific for HPV18 E7 (5’-ACGACCTTCGAG-CATTCCAGCAG-3’) and (dT)₁₇-p3 as reverse primer, except that the annealing temperature was 67 °C. The positions of the two primers were 814-835 for p1-18 and 830-853 for p2-18. To control for false-positives, a negative control (HEK293 cell DNA template) was included in each amplification. Electrophoresis was performed using a 1.2% agarose gel.

Cloning and sequence analysis

To confirm specific HPV18 oncogene transcription in EC109 cells, the final nested PCR products were cloned into a pMD-18T vector and sequenced to analyze the chromosomal location of HPV integration.

RESULTS

Detection of HPV DNA in EC109 cells

HPV18 DNA was detected in EC109 cells by PCR using the general primer sets of My09/11 and GP5 +/6 + for HPV L1 and the type-specific primer sets for HPV18 E6 and E6-E7 to generate products of 450 bp, 150 bp, 335 bp and 944 bp respectively (Figure 1).

HPV infection and the development of EC. However, the role of HPV in the carcinogenesis of EC remains unclear. In this study, the authors demonstrate the integration of HPV DNA into host chromosomes, which could be a potential mechanism where by HPV infection leads to the development of EC.

Innovations and breakthroughs

Recent reports have highlighted the importance of HPV infection in EC. This paper is the first study to report that HPV18 integrated into one part of chromosome 8 in a cell line, EC109, derived from human EC cells. This study further suggests that HPV infection may be the cause of EC.

Applications

By understanding how EC is induced after HPV infection, this study may provide a future strategy for the diagnosis and prevention of EC.

Peer review

The authors examined HPV18 integration into one part of chromosome 8 in EC109 cells. Integration of the HPV genome into the host cell chromosome suggests that persistent HPV infection is a key factor in malignant cell transformation and carcinogenesis. The results may represent a molecular mechanism for the development of EC.

Abstract

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive disease characterized by exocrine pancreatic insufficiency, hypoplastic or aplastic nasal alae, cutis aplasia on the scalp, and other features including developmental delay, failure to thrive, hearing loss, mental retardation, hypothyroidism, dental abnormalities, and anomalies in cardiac and genitourinary systems. More than 60 cases of this syndrome have been reported to date. We describe the case of a male infant with typical symptoms of JBS. In addition, a new clinical feature which has not previously been documented, that is anemia requiring frequent blood transfusions and mild to moderate thrombocytopenia was observed. A molecular study was performed which revealed a novel homozygous UBR1 mutation. Possible explanations for this new association are discussed.

INTRODUCTION

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive disorder, first described in 1971 by Johanson and Blizzard^[1]. The genetic defect causing the disease was unknown until 2005, when it was shown to result from mutations of the *UBR1* gene located on chromosome 15q15-21. *UBR1* encodes one of at least four functionally overlapping E3 ubiquitin ligases of the N-end rule pathway, a conserved proteolytic system whose substrates include proteins with destabilizing N-terminal residues 20^[2]. The precise pathophysiological link between altered protein degradation and the clinical anomalies observed in JBS remains to be determined.

The reported cases of JBS showed no difference in gender. Parental consanguinity is frequently observed. The typical clinical features of JBS are the following (with decreasing frequency): exocrine pancreatic insufficiency, hypoplasia/aplasia of the alae nasi, dental anomalies, congenital scalp defects, sensorineural hearing loss, growth retardation, psychomotor retardation, hypothyroidism, imperforate anus and genitourinary anomalies. A detailed list of observed clinical features is given in Table 1.

CASE REPORT

A 5-mo-old male infant of consanguineous Yemeni par-

Table 1 Clinical features of Johanson-Blizzard syndrome

<i>Exocrine pancreatic insufficiency</i> ^[1,3-5]
<i>Hypoplasia/aplasia of alae nasi</i> ^[1,4,6-8]
<i>Scalp defect/aplasia cutis</i> ^[1,6,8]
<i>Sensory neural hearing loss</i> ^[1,3,8,9]
<i>Bilateral cystic dilation of cochlea, low set ears, and temporal bone defect</i> ^[10]
<i>Growth retardation, short stature</i> ^[1,11]
<i>Dental anomalies: oligodontia and absence of permanent teeth</i> ^[1,6,7,11]
<i>Anorectal anomalies: imperforate anus</i> ^[4,11,12]
<i>Hypotonia, microcephaly, and mental retardation sometimes normal intelligence</i> ^[3,7,11]
<i>lacrima duct anomalies, coloboma of the lids, superior puncta absence, lacrima cutaneous fistula, and congenital cataract</i> ^[13]
<i>Abnormal frontal hair pattern (upsweep)</i> ^[7]
<i>Vesicoureteric reflux, hypospadias, and duplex of uterine and vagina</i> ^[8]
<i>Congenital heart diseases such as myxomatous mitral valve, PDA, VSD, ASD, dextrocardia, complex congenital heart disease, and cardiomyopathy</i> ^[13,14]
<i>Cholestatic liver disease (one case)</i> ^[15]
<i>Café au lait spots</i> ^[16]
<i>Hypothyroidism</i> ^[1]
<i>Growth hormone deficiency</i> ^[5]
<i>Hypopituitarism</i> ^[17]
<i>Impaired glucagon secretion response to insulin induced hypoglycemia</i> ^[18]
<i>Diabetes mellitus</i> ^[19,20]

Italic letters show common features. PDA: Patent ductus arteriosus; VSD: Ventricular septal defect; ASD: Atrial septal defect.

Figure 1 Typical facial appearance of this patient with Johanson-Blizzard syndrome, showing aplasia of alae nasi, scalp defect, and sparse hair.

ents was referred because of poor feeding. The history started when he was 2-mo old with recurrent attacks of pallor and edema in the feet and hands. In addition, the infant showed failure to thrive and greasy stools. He received 3 blood transfusions. There was a family history of two previous male siblings with the same facial features as the index case, who also received several blood transfusions and expired at 4 and 4 ½ mo, respectively

On physical examination, the patient was lethargic, hypotonic, and pale. His body weight was 3.3 kg (< 5% percentile), and body length was 52 cm (< 5% percentile). Head circumference was 37 cm (microcephaly), and the anterior fontanel was wide (6 cm × 3 cm). There was aplasia of the alae nasi, midline cutis aplasia and a small scalp defect on the occiput, the scalp hair was sparse with areas of alopecia (Figure 1), and eye lashes and eyebrows were sparse. Hypospadias was detected, and the anus was narrow and displaced anteriorly. There was also pitting edema on the feet and hands.

Routine laboratory tests revealed the following re-

sults: hemoglobin (Hb) was 4 g/dL, with reticulocytes 7%, mean corpuscular volume 85 fl and mildly decreased platelets (75 000/μL). Erythrocyte morphology showed anisocytosis and normochromia. Hb electrophoresis and bone marrow aspiration were normal (Table 2).

Serum pancreatic enzymes (amylase, lipase) were low. Total protein and albumin were low, and other liver function tests, renal function tests, serum electrolytes and blood sugar were within the normal range (Table 2).

Thyroid function tests revealed low free T4 and slightly increased thyroid-stimulating hormone. These results indicated hypothyroidism.

Echocardiography showed a small atrial septal defect. Whole body X-ray, abdominal ultrasound, brain computed tomography (CT) scan, and temporal bone CT scan were normal.

The patient received oral thyroxine, pancreatic enzyme replacement, multivitamins and strict monitoring to avoid complications. When the patient was seen last time at the age of 9 mo, his overall condition had significantly improved. He has gained weight, although still below the 3rd centile, and blood cell counts had normalized (Table 2). The child still showed muscular hypotonia and delay in motor milestones.

Genetic studies

After obtaining informed written consent from the parents for the genetic investigation, venous blood samples were taken from the index patient and his parents. DNA was extracted from blood leukocytes according to standard procedures. All 47 exons of the *UBR1* gene including the flanking intronic regions were analyzed by direct bidirectional sequencing as described previously^[19]. Sequencing in the index patient revealed a homozygous mutation in exon 19. The nucleotide substitution c.2089 C > T predicts a missense change (p.S700P) affecting an

	At presentation (5 mo)	At 9 mo	Normal range

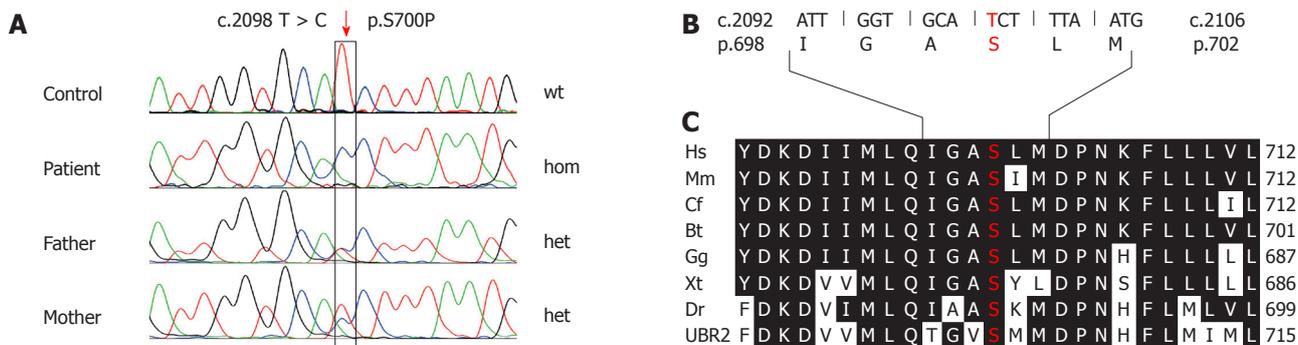

Figure 2 Demonstration and characterization of the familial mutation. A: Comparison of electropherograms around the T > C transition at position c.2098; B: Nucleotide and amino acid sequence; C: Multiple protein alignment (<http://www.ebi.ac.uk/Tools/msa/clustalw2>) of vertebrate UBR1. Black shading indicates identical residues. wt: Wild-type; Hom: Homozygous; Het: heterozygous; Hs: Homo sapiens; Mm: Mus musculus; Cf: Canis familiaris; Bt: Bos taurus; Gg: Gallus gallus; Xt: Xenopus tropicalis; Dr: Danio rerio; UBR2: Human UBR2 protein.

amino acid residue that is 100% conserved throughout vertebrate UBR1 and UBR2 proteins (Figure 2). To date, this change has not been known as a mutation or polymorphism. PolyPhen-2 (<http://genetics.bwh.harvard.edu/pph2/>) predicts that this mutation is probably damaging with a score of 0.992 (sensitivity: 0.59; specificity: 0.96). Both parents were found to be heterozygous for the mutation. Based on this evidence we regarded p.S700P as the disease-causing mutation in this family.

DISCUSSION

JBS is a rare autosomal recessive disorder that affects many systems with a wide range of congenital abnormalities. A small beak-like nose (due to aplasia or hypoplasia of the alae nasi), and exocrine pancreatic insufficiency are considered the most consistent manifestations, while others features (Table 1) occur at varying frequencies in the affected patients. The patient presented here had typ-

ical facial features and exocrine pancreatic insufficiency, this combination is pathognomonic for JBS. Our patient also presented with scalp defects, developmental delay, and generalized hypotonia, which have been described in reported cases of JBS. Remarkably, our patient presented with an additional phenotypic feature, namely significant anemia, and required frequent blood transfusions from the age of 2 mo. The hematologic abnormalities also included thrombocytopenia and mild leukopenia. No definite etiology could be established. This feature has not been described in previous reports of JBS. Remarkably, two previous male siblings, who were assumed to have the same disease based on the report of similar facial features, also had significant anemia (Hb: 4 g/dL) and received frequent blood transfusions.

In addition, there was also mild to moderate thrombocytopenia in the other affected children of this family. The unusual and consistent association of JBS with a hematologic phenotype in this family may raise different speculations, such as a second autosomal recessive condition that might segregate JBS in this family or a specific function of the UBR1 protein carrying the novel missense mutation.

In infants, anemia caused by iron, vitamins and trace element deficiencies are unusual before the age of 6 mo, but in this patient the nutritional consequences of malabsorption might have appeared earlier due to many factors such as low birth weight, malnutrition in the mother and hypothyroidism in which normochromic, normocytic anemia may be secondary to reduced red blood cell production and reduced red cell survival.

Although we cannot exclude these possibilities, the fact that the hematologic disease resolved after efficient pancreatic enzyme and vitamin supplementation suggests a major contribution of malnutrition.

ACKNOWLEDGMENTS

We thank the family for their kind cooperation.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copy-right" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D,

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Systematic review of modulators of benzodiazepine receptors in irritable bowel syndrome: Is there hope? *World J Gastroenterol* 2011; 17(38): 4251-4257 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i38/4251.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i38.4251>

Abstract

Several drugs are used in the treatment of irritable bowel syndrome (IBS) but all have side effects and variable efficacy. Considering the role of the gut-brain axis, immune, neural, and endocrine pathways in the pathogenesis of IBS and possible beneficial effects of benzodiazepines (BZD) in this axis, the present systematic review focuses on the efficacy of BZD receptor modulators in human IBS. For the years 1966 to February 2011, all literature was searched for any articles on the use of BZD receptor modulators and IBS. After thorough evaluation and omission of duplicate data, 10 out of 69 articles were included. BZD receptor modulators can be helpful, especially in the diarrhea-dominant form of IBS, by affecting the inflammatory, neural, and psychologic pathways, however, controversies still exist. Recently, a new BZD receptor modulator, dextofisopam was synthesized and studied in human subjects, but the studies are limited to phase II b clinical trials. None of the existing trials considered the neuroimmunomodulatory effect

PRESENT KNOWLEDGE ON IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is well-defined as a functional abdominal disorder categorized by intestinal pain or distress, and changes in bowel habits without recognizable malefactor^[1]. The symptoms are either constant or intermittent and vary from diarrhea or constipation, hypersecretion of colonic mucus, flatulence, to the sensation of weakness or depression^[2]. The pathophysiology of IBS is in some ways multifaceted, yet no consistent biomarker, anatomic, or biochemical alteration has been found^[3]. Several pathophysiologic paths have been deliberated for elucidation leading symptoms such as motor and sensory dysfunction, neuroimmune mechanisms, dysregulation of mucus secretion, emotions, colonic motility, enteric nervous system, changes in intraluminal situation and visceral feeling^[4]. Gut motility turbulence creates

different bowel behaviors and IBS subtypes, according to these outlines they are presented as IBS-D (diarrhea-predominant), IBS-C (constipation-predominant) and IBS-M (mixed)^[5].

Earlier, the role of parasympathetic and hormonal provocations in motor activity of some portions of the gut was demonstrated^[2]. The most important observation is well-thought-out visceral hypersensitivity as a substantial element in combination with fluctuations in gastrointestinal (GI) motility and secretory activity^[6]. Recent epidemiological findings further underline the central and peripheral disease activators or exacerbations as psychosomatic contributions^[7-9] and gastroenteric infections^[10]. In addition, the brain-gut axis endorses the strong relationship between the brain and the gut *via* neural, immune and endocrine paths which is affected by neuroimmunological or neuroendocrinological stressors^[11,12]. A summary of the pathophysiological mechanisms involved in IBS are presented in Table 1.

Contemporary treatment approaches depend on patients' signs and symptoms as well as comorbid conditions. Other than lifestyle and dietary changes, psychotherapy and psychopharmacological treatment, prokinetics (dopamine antagonists, 5-HT₃ antagonists and/or 5-HT₄ agonists), antispasmodics, sedatives and tranquilizers, antibiotics^[13], probiotics^[14], fecal bulking agents and complementary and alternative therapies are now considered as symptomatic treatment^[2,15]. Prokinetics and antispasmodics^[16] are usually used in IBS-C type, while patients with IBS-D benefit from opioid agonists, anticholinergics, and 5-HT₃ antagonists. Treatment options are summarized in Table 2.

Despite the wide range of medications and the high prevalence of the disease, to date no completely effective remedy is available. Therefore, investigations in this area should be continued. Pain relief is one of the challenges in the management of IBS as existing visceral analgesics have significant adverse effects and there is a balance to be struck between their usage and side effect profiles. Although various classes of drugs are used for visceral analgesia or other symptoms of IBS such as 5-HT₃ antagonists^[17], tricyclic antidepressants (TCAs)^[18], selective serotonin reuptake inhibitors (SSRIs)^[19,20], gabapentinoids, corticotrophin-releasing factor receptor-1 antagonists^[21], β_3 adrenoceptor agonists^[21], somatostatin, and N-methyl d-aspartate receptor antagonists, melatonin^[22], and sildenafil^[23], there are hopes for new drug investigations. In accordance with this idea, the efficacy of benzodiazepines (BZD) receptor modulators is being determined in ongoing phase III clinical trials^[24].

Bearing in mind the new advances in drug classes, and the special attention paid to new BZDs, we intend to study the promising advantageous effects of BZDs from diverse themes including neuroimmunology, anxiolytic, and visceral pain.

In the present review, the most relevant articles on the subject were searched using PubMed, Scopus, Web of Science, and Google Scholar databases up to February 2011. MeSH terms including irritable bowel syndrome,

Table 1 A summary of the pathophysiological mechanisms of irritable bowel syndrome

Mechanism	Description
Visceral hypersensitivity	↓ Threshold of visceral perception, hyperalgesia; ↑ Viscerosomatic referral areas
Modulation of CNS	Altered activation in reaction to rectosigmoid stimuli; fail to inhibit pain perception; activation of pain facilitatory pathways
Stress	Changes in visceral perception and neuro-endocrine responses to stressor
Infection	↑ Incidence after bacterial, viral, parasitic infections
Inflammation	Increased inflammatory cytokines; decreased anti-inflammatory cytokines
Serotonin	Influencing gut motility, sensation and secretion; altered serotonin signaling in IBS
Genetic factors	Familial clustering

CNS: Central nervous system; IBS: Irritable bowel syndrome.

benzodiazepines, benzodiazepine receptor modulators, and gabamimetics were used as search terms. The search was limited to English articles only. All non-clinical and clinical studies were included. The search resulted in 69 papers on the role of benzodiazepines in IBS; of these, after thorough evaluation and the omission of duplicate or non-relevant articles, 10 papers were included and evaluated in detail.

FINDINGS

Visceral pain

Visceral sensitivity and abdominal pain are dual warning signs of IBS but are not present in all patients^[25,26]. These patients show diminished visceral perceptual edges, augmented viscerosomatic referral area and larger sensory scores^[26]. The regulation of sensory neurotransmission in the gut is indicative of a satisfactory goal in the treatment of IBS. Incidentally, sensory afferents from the intestine have been examined in preclinical and clinical models.

New approaches in brain imaging provided new understandings of the likeness between IBS symptoms and different non-gastrointestinal disorders which pointed to the reformed sense of visceral drive in the central nervous system (CNS) in IBS^[27-29]. There is the possibility that the CNS fails to excite pain inhibitory pathways or activates pain facilitatory trails in patients with IBS^[30]. As a consequence of the convenient connection between the brain and gut *via* neural, immune, and endocrine pathways (Figure 1), the involvement of the CNS in the pathophysiology of IBS is prominent^[8,11,31-36]. Several parts of the CNS including cerebral regions, dorsal vagal nuclei, as well as the enteric nervous system contain γ -amino butyric acid (GABA) receptors^[37,38]. Vagal fibers influence migrating motor complex activity *via* the enteric nervous system^[38]. With the intention of reducing visceral hypersensitivity and the consequential pain, different pathological and pharmacological tactics have been used, for instance motility modulators (SSRIs), and special receptors or ion channels on visceral afferent pathways.

Table 2 Common therapeutic modalities

Therapeutic approach	Mechanism	Example of drugs	Therapeutic issues
Cholinergic system	Muscarinic receptor antagonists	Hyoscine, cimetropium, zamifenacin, solifenacin	Limited value, limited side effects, no interaction
Serotonin system	5-HT receptor antagonists	Alosetron, tegaserod, renzapride	Safe on cardiovascular system, anxiolytic, psychological side effects, adverse effects
Antidepressants (SSRIs, TCAs, SNRIs)	Neurotransmitter reuptake inhibitor	Paroxetine, desipramine, venlafaxine	Limited use, serious side effects, limited efficacy
Adrenergic agents	α , β adrenergic agents	Clonidine, solabegron	Limited use, side effects, limited efficacy
Corticoid system	CRF antagonists	A-Helical CRH9-41	Limited use, under investigation
Cholecystokinin		Loxiglumide, dexloxiglumide	Limited use, under investigation
Neurotrophins	Enhance neuron survival and development	NT3	Expensive, under investigation, limited use
Sleeping process	Sleep regulator	Melatonin	Limited use
BZD receptor modulators		Gabapentin, dextofisopam, pregabalin	Side effects, limited use, under investigation
Guanylate cyclase-c agonists	Activates guanylate cyclase-c receptor in enterocytes	Linaclotide	Limited use, well toleration, minimal side effects, under investigation
Opioid system	Modulating visceral nociception	Asimadoline, naloxone, naltrexone	Limited central side effects, good efficacy
Neurokinin antagonists	Affect colonic motility	Ezlopitant, nepadutant	Under investigation

SSRIs: Selective serotonin reuptake inhibitors; TCAs: Tricyclic antidepressants; SNRIs: Serotonin norepinephrine reuptake inhibitors; NT3: Neurotrophin-3; BZD: Benzodiazepine; 5-HT: 5-hydroxytryptamine; CRF: Corticotrophin-releasing factor.

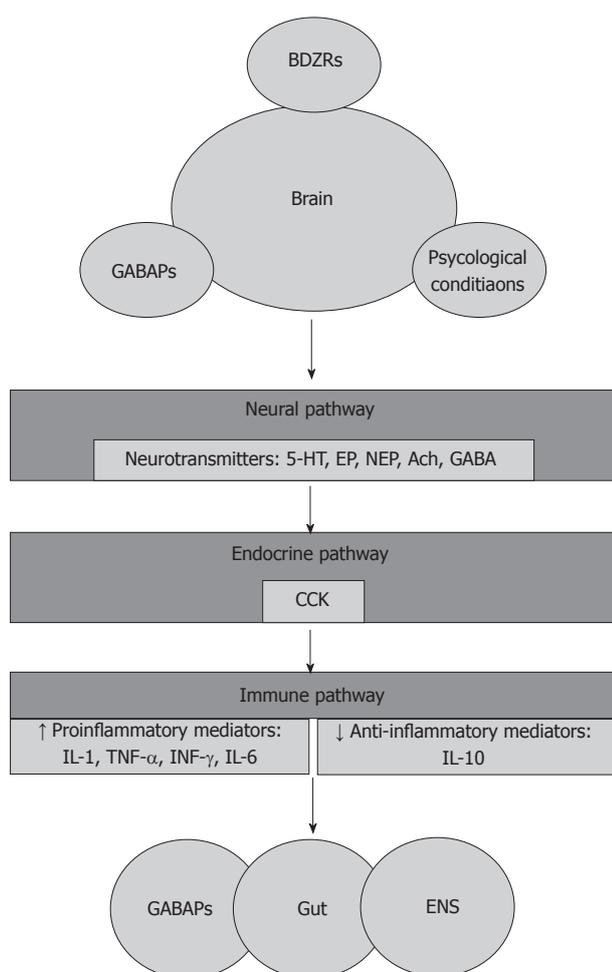

Figure 1 The brain-gut axis. BDZRs: Benzodiazepine receptors; GABARs: γ -aminobutyric acid receptors; 5-HT: 5-hydroxytryptamine; EP: Epinephrine; NEP: Norepinephrine; GABA: γ -aminobutyric acid; Ach: Acetylcholine; CCK: Cholecystokinin; IL-1: Interleukin-1; IL-6: Interleukin-6; TNF- α : Tumor necrosis factor- α ; IFN- γ : Interferon- γ ; IL-10: Interleukin-10; ENS: Enteric nervous system.

One of the newly targeted classes of drugs for the treatment of visceral pain, BZD receptor modulators, reduce sensitivity and ache perception. Consistent with the promising effects of these modulators, dextofisopam the R enantiomer of tofisopam was developed for the management of IBS-D^[39].

BZDs interact with GABA receptors which exist in the CNS and influence the autonomic nervous system, dorsal vagal nuclei, and the enteric nervous system. Vagal fibers affect migrating motor complex movement by the enteric nervous system^[40].

BZD receptors were identified in subcortical and hypothalamic regions and appear important in controlling autonomic function^[41], such as motor and sensory activity of the gut^[42]; nevertheless they do not exist in the gut^[43]. Animal studies on the R-enantiomer of tofisopam (the non-sedating anxiolytic), dextofisopam, showed encouraging results in reducing colonic motility and visceral sensitivity with little effect beneath basal conditions^[44]. Leventer *et al*^[45] in a phase II b study of dextofisopam for 12 wk in 140 patients with IBS observed overall symptom relief (primary end point) in 57% of patients as compared with placebo (43% of patients). Although dextofisopam improved stool consistency in men and women, the recurrence rate was only decreased in females. This occurred within one week. The most common side effects were headache and abdominal pain (in 12% of patients in comparison with 4% in the placebo group) which was comparable to placebo. No benefit on bloating, partial defecation, or hospital anxiety and depression scale scores was observed^[45]. Interestingly, dextofisopam showed a slight influence on basal GI movement in animals, while after induction of hypermotility, it showed more efficacy^[46].

There are a few studies on other BZDs in IBS patients. Castedal *et al*^[40] showed a small effect of midazol-

am on small bowel motility using manometry, however, phase III related retroperistalsis did not work.

Other than the anxiolytic effect of BZDs, their effect on GABA may be constructive. Two antiepileptic drugs, gabapentin and pregabalin are effective in neuropathic pain. They equally affect GABA receptors in the CNS and increase their binding affinity for endogenous GABA ligand and elevate chloride ion efflux. In this regard, numerous studies assessed the beneficial influence of pregabalin and gabapentin on visceral pain.

Gabapentin, an amplifier of GABA transmission, prevents central neurotransmitter release by impeding $\alpha_2\delta$ subunits of voltage-dependent calcium channels^[47,48]. Gabapentin has favorable effects on neuropathic pain and hyperalgesia^[49,50]. Lee *et al*^[51] demonstrated the effect of gabapentin in reducing human experimental hyperalgesia. They randomized 40 IBS-D patients to receive gabapentin 300 mg/d and then 600 mg/d for 5 d. Gabapentin reduced rectal sensory thresholds by decreasing rectal sensitivity to expansion and improving rectal compliance.

Although the structure of pregabalin is related to GABA, it is inactive at GABA and BZD receptors. It strongly attaches to the $\alpha_2\delta$ subunit of voltage-dependent calcium channels and reduces calcium arrival at nerve endings^[52] and results in the release of excitatory neurotransmitters (noradrenaline, glutamate, substance P, and calcitonin gene-related peptide) decreasing their involvement in pain pathogenesis^[53]. Accordingly, pregabalin reduces normal colonic pain responses and colonic hyperalgesia in a dose-dependent manner in animal studies^[54,55]. In animal studies, pregabalin reduced viscerosomatic and autonomic responses caused by colorectal distension resulting in visceral pain relief^[56]. In addition, the effect of GABA_B receptors in visceral pain was confirmed^[57]. In another preclinical study, pregabalin reduced both visceral allodynia and hyperalgesia with no change in basal sensitivity. Houghton *et al*^[58] randomized 26 hypersensitive IBS patients to increasing doses of pregabalin for 3 wk or placebo. They reported significant increases in sensory thresholds from baseline for first defecation and pain, and rectal compliance. In IBS patients, pregabalin restored sensory thresholds to normal levels^[58].

Neuroimmunology

Recent approaches to the pathophysiology of IBS have changed from spastic colitis to mucosal immune activation^[59,60] and inflammation^[61] which is supported by animal studies^[62,63]. Generally, in 7%-30% of patients, there is a history of recent bacterial gastroenteritis^[64]. Failure to reduce the inflammatory reaction to infection may increase cytokines or special inflammatory cells^[65]. There is a discrepancy between pro-inflammatory and anti-inflammatory cytokines in IBS. The influence of the neuroimmune system in the pathogenesis can be elucidated by an augmented number of activated mast cells in the vicinity of colonic nerves, decreased interleukin-10/interleukin-12 (IL10/IL12) ratio and changes in local defense mechanisms in the sigmoid and colonic mucosa

in IBS^[65-67]. In fact, a number of investigators have proposed low-grade inflammation in IBS which is defined as infiltration of T lymphocytes, mast cells, and enteroendocrine cells into colonic mucosa with mast cells priority^[68]. Excessive production of tumor necrosis factor- α (TNF- α), and interferon- γ (IFN- γ), a trend toward excessive production of interleukin-6 (IL-6), and a defect in the production of interleukin-10 (IL-10) were reported in IBS^[15,69]. In accordance with cellular infiltrations, increased levels of interleukin-1 β (IL-1 β), IL-6, INF- γ and TNF- α , and an abnormal ratio of IL-10/IL-12 in IBS patients were observed^[68].

There is a counteraction between the endocrine, central and autonomic nervous and immune systems which is mediated by signal transduction, cytokines and mediators^[70]. BZD receptors in both central and peripheral forms and their ligands create a regulatory network between anxiety and the immune system^[71]. Central BZD receptors located in the CNS and their activation affects GABA binding to GABA_A receptors which regulates chloride flux^[72]. The peripheral receptors are located in peripheral tissues and are involved in cell proliferation, heme biosynthesis, cholesterol transport and immunomodulation^[73]. Peripheral BZD receptors **have been identified on immune cells such as macrophages, neutrophils, leukocytes, and lymphocytes** and may have a crucial role in the relationship between the CNS, behavior and immunity^[74-78]. Activation of cell growth and DNA synthesis requires nanomolar concentrations of BZDs, thus inhibition of cell proliferation is subject to micromolar concentrations of these compounds^[79]. Of BZDs, diazepam and tofizopam bind to both types of receptors^[80,81]. Kalashnikov *et al*^[70] in an *in vitro* study confirmed the inhibitory effect of diazepam on cell proliferation at high doses, while tofizopam enhanced cell proliferation at low and moderate doses. In addition, they found dose-dependent suppression of TNF- α production with both diazepam and tofizopam and a wide range of effects of tofizopam on IL-2 production (enhancement to suppression), **while diazepam suppressed IL-2 production**^[70].

Psychotherapy

A history of psychiatric complaints or mental instabilities in patients is a key factor in IBS and some studies have indicated extensive occurrence of psychiatric disorders in IBS^[82,83]. Similarly, the mental state of the patient affects bowel symptoms and may relieve symptoms^[84]. The most dominant psychological features of IBS patients are hypochondriasis, depression, anxiety, obsession, and neuroticism^[84]. Whitehead *et al*^[85] demonstrated higher scores of psychopathology in IBS patients. High comorbidity exists between functional bowel and stress-related psychiatric disorders^[86,87]. **Stress precipitates or exacerbates IBS**^[88].

Since the possibility of comorbidity with mood disturbances such as depression and anxiety is high in IBS, almost all patients with IBS may benefit from TCAs or BZDs. These agents may also decrease pain perception.

Guidelines of the Britain Society of Gastroenterol-

ogy and the American Gastroenterology Association endorse psychotherapeutic interventions for severe forms of IBS^[89,90] to relieve psychological, visceral, and somatic symptoms. Overall benefit was found in IBS patients following psychological treatments in a meta-analysis^[91]. In these conditions, combining psychotherapy with psychopharmacological treatment is effective^[92]. Studies show that the two most common antidepressant and anxiolytic classes of drugs, TCAs and SSRIs, are effective in symptom relief^[93]. Compared to TCAs, SSRIs have fewer side effects but do not improve bloating or visceral pain^[93,94]. BZDs are used routinely in anxiety disorders but their efficacy in symptom relief of IBS is under debate^[90].

Clouse *et al.*^[95] studied the effect of antidepressants in a retrospective study in 138 IBS patients. They evaluated patients' response to a wide range of antidepressants such as TCA (amitriptyline, doxepin, *etc.*), trazodone, amoxapine, alprazolam and thioridazine at lower doses than used for affective disorders. They reported significant responses regardless of the presence or absence of psychiatric illness.

CONCLUSION

In the present work, all possible beneficial effects of BZD receptor modulators in IBS from the view points of visceral pain, psychopharmacologic effects, and immunologic properties were reviewed. It seems that these BZDs influence IBS symptoms *via* different mechanisms, and these mechanisms are under investigation. There are a small number of studies examining the effects of dexetofisopam on patient's symptoms, however, we are still waiting for the results of phase III trials. In addition, none of these trials have considered the neuroimmunomodulatory effect of BZDs in IBS. Moreover, bearing in mind the concentration-dependent effect of BZDs on cytokines and cell proliferation, future studies using pharmacodynamic and pharmacokinetic approaches are highly recommended.

Abstract

Primary liver cancer is an important cause of cancer death, and hepatocellular carcinoma (HCC) accounts for 70%-85% of total liver cancer worldwide. Chronic hepatitis B virus (HBV) infection contributes to > 75% of HCC cases. High serum viral load is the most reliable indicator of viral replication in predicting development of HCC. HBV genotype C is closely associated with HCC in cirrhotic patients aged > 50 years, whereas genotype B is associated with development of HCC in non-cirrhotic young patients and postoperative relapse of HCC. Different HBV subgenotypes have distinct patterns of mutations, which are clearly associated with increased risk of HCC. Mutations accumulate during chronic HBV infection and predict occurrence of HCC. Chronic inflammation leads to increased frequency of viral mutation *via* cellular cytidine deaminase induction.

Mutations are negatively selected by host immunity, whereas some immuno-escaped HBV mutants are active in hepatocarcinogenesis. Inflammatory pathways contribute to the inflammation-necrosis-regeneration process, ultimately HCC. Their hallmark molecules can predict malignancy in HBV-infected subjects. Continuing inflammation is involved in hepatocarcinogenesis and closely related to recurrence and metastasis. HBV load, genotype C, viral mutations and expression of inflammatory molecules in HBV-related HCC tissues are significantly associated with poor prognosis. Imbalance between intratumoral CD8⁺ T cells and regulatory T cells or Th1 and Th2 cytokines in peritumoral tissues can predict prognosis of HBV-related HCC. These factors are important for developing active prevention and surveillance of HBV-infected subjects who are more likely to develop HCC, or for tailoring suitable treatment to improve survival or postpone postoperative recurrence of HCC.

INTRODUCTION

Liver cancer in men is the fifth most frequently diagnosed

cancer worldwide but the second most frequent cause of cancer death. It is the seventh most commonly diagnosed cancer and the sixth leading cause of cancer death in women. Globally, liver cancer rates are more than twice as high in men as in women. An estimated 748 300 new liver cancer cases and 695 900 cancer deaths occurred worldwide in 2008^[1]. The highest liver cancer rates are found in East and South-East Asia and in Central and Western Africa. Developing countries contribute more than 80% of cases. About half of these cases and deaths occur in China, due to the endemicity of hepatitis B virus (HBV) infection. Chronic HBV infection accounts for about 60% of the total liver cancer in developing countries and for about 23% of the cancer in developed countries, while hepatitis C virus (HCV) infection accounts for about 33% of the total liver cancer in developing countries and for about 20% in developed countries^[2]. Recently, the incidence of liver cancer has been increasing in some western countries due to the increasing prevalence of HCV infection and immigration of people from countries with high endemicity for HBV infection^[3]. Among primary liver cancers, hepatocellular carcinoma (HCC) accounts for 70%-85% of the total liver cancer burden worldwide^[1]. Chronic HBV infection results in approximately one-third of all cases of liver cirrhosis and more than three-quarters of all cases of HCC worldwide^[4]. The relative risks of HCC among people infected with HBV ranges from 5 to 49 in case-control studies and from 7 to 98 in cohort studies, and the incidence of HCC (per 100 000 person/years) among people with chronic HBV infection ranges from 400 to 800 in men and from 120 to 180 in women^[5]. Standard HBV vaccination dramatically decreases HCC prevalence among vaccinees aged 6-19 years in Taiwan^[6]. In Mainland China, the prevalence of hepatitis B surface antigen (HBsAg) in people born after 1992 has dramatically decreased, possibly due to expanded program of immunization of HBV vaccination, however, the rate in those born before 1992 is around 8%-9%^[7,8]. Thus, HCC will remain one of the major public health problems in Mainland China in next 40-50 years.

The patients with HCC usually present late and have mostly developed serious liver cirrhosis. The life expectancy of patients with newly diagnosed HCC is measured in terms of weeks to months with a mortality to incidence ratio close to 1^[3]. Therefore, it is critical to clarify some risk factors that can be clinically applied for the prediction of this malignancy in the HBV-infected population. Viral characteristics of HBV and hepatic inflammation status are not only associated with the occurrence, but also with the recurrence and metastasis of HCC after surgical treatment. Prognostic factors for predicting survival probability are invaluable to tailor suitable treatment options.

In this paper, we characterize viral properties of HBV and inflammatory factors that have been recently proven to be significantly associated with the occurrence and the prognosis of HCC, and summarize a group of viral

and inflammatory factors (Table 1) that can be of significance for active prevention and surveillance of the HBV-infected subjects who are more likely to develop HCC, and for tailoring suitable treatment options like antiviral treatment to improve the survival or postpone the recurrence of HBV-related HCC.

ROLES OF VIRAL AND INFLAMMATORY FACTORS IN PREDICTING OCCURRENCE OF HBV-ASSOCIATED HCC

HBV replication status and viral variations

Association of viral replication status with HCC: HBV precore region encodes the precore protein, which is processed in the endoplasmic reticulum to produce secreted hepatitis B e antigen (HBeAg). HBeAg expression indicates active viral replication. In community-based HBV-infected subjects, HBeAg-positive rates and viral loads are high in the young, and decrease with age^[8]. Continuing high viral load and/or HBeAg expression have been significantly associated with increased risk of HCC in prospective studies^[9-11]. With reference to the low serum HBV DNA level ($\leq 10^{4.5}$ copies/mL), the hazard ratio (HR) for HCC of the intermediate HBV DNA level ($10^{4.5-6.5}$ copies/mL) is 1.62 (95% CI: 1.05-2.48) and that of the high HBV DNA level ($> 10^{6.5}$ copies/mL) is 2.73 (95% CI: 1.76-4.25)^[12], indicating viral load predicts the risk of developing HCC dose-dependently. In another group of prospective studies, HBV viral load rather than HBeAg has been documented to be independently associated with an increased risk of HCC^[13,14]. In cross-sectional case-control studies, high viral load ($\geq 10^4$ copies/mL) is independently associated with an increased risk of HCC^[15-17]. However, HBeAg expression is not usually high in patients with HCC, and is not significantly associated with an increased risk of HCC in some case-control studies^[16,17]. Ongoing high levels of HBV replication in patients seronegative for HBeAg are strongly associated with poor prognosis of patients with chronic hepatitis B (CHB)^[18]. Thus, serum viral load is the most reliable indicator in predicating the development of HCC. HBeAg seroconversion reflects viral mutations in the HBV genome, especially in the precore and core promoter regions^[19], and this usually happen during the natural course of chronic HBV infection, possibly caused by cytotoxic T-lymphocyte (CTL)-mediated clearance.

Association of HBV genotypes/subgenotypes with HCC: HBV genotypes and subgenotypes have distinct geographical distributions and have been shown to differ with regard to HBeAg seroconversion, clinical outcome, prognosis, and response to antiviral treatment^[20-22]. HBV genotypes A, B, D and F are associated with earlier spontaneous seroconversion of HBeAg than genotype C. HBV subgenotype B2 is more likely to cause acute hepatitis B, while subgenotype C2 is more prone to caus-

Table 1 Viral and inflammatory factors associated with the occurrence and prognosis of hepatitis-B-virus-related hepatocellular carcinoma

Factor	Occurrence	Ref.	Prognosis	Ref.
Viral load				
Sera	≥ 10 ⁴ copies/mL	[9,11,12,15-17]	> 10 ⁴ copies/mL (poor survival)	[99,100]
Non-cancerous liver tissues	-	-	> 3 × 10 ⁷ copies/g (poor survival)	[101]
HBV genotype/subgenotype	C2 > B2 C2: cirrhotic patients ≥ 50 yr B2: non-cirrhotic ones < 50 yr	[15,24-26]	C > B (poor survival) B2 in the young (recurrence)	[15,104]
HBV mutation				
Individual	C1653T, T1753V, T1674C/G A1762T/G1764A, C1766T, T1768A; G1899A, C2002T, A2159G, A2189C, G2203A/T; T53C, preS2 start codon mutation, preS1 deletion, C2964A, A2962G, C3116T, C7A	[17,27-29]	A1762T/G1764A and short stretch (< 100 bp) pre-S deletions in non-cancerous liver tissue of the HCC patients (poor survival)	[101]
Combined	2964C-3116T-preS2 start codon wildtype-7A; 2964C-3116T-7A-76C; 2964A-3116T-7C-76A/T; 2962G-preS2 start codon wildtype-105C-1762T/1764A	[30,31]	-	-
Intratumoral immune cells	M2 macrophage (risk), CD8 + T cells (protective); Imbalance between CD8 + T cells and Treg or between Th1 and Th2	[52-58]	NK and CD8 + T cell (good prognosis); Treg cells (poor prognosis)	[106,107]
Inflammatory pathways and cytokine	Pathway: NF-κB, STAT3, Wnt/β-catenin, IGF-α1, RAF/MEK/ERK, PI3K/AKT/mTOR, p53, VEGF Cytokine: IL-6, TNF-α	[60-81]	IL-2 and IL-15 (good prognosis); G-CSF (poor prognosis); Wnt-1 protein (poor prognosis); LI-cadherin (short survival); ErbB-2 (short survival); Cyclooxygenase-2 (recurrence); Low miR-199-3p (poor survival)	[108-113,116]
Genetic polymorphism of inflammatory molecules	HLA, TGF-β1, IL-β1, IL-18, IL-12, KIF1B-, UBE4B- or PGD-related pathways, NF-κB1, IκBα	[82-88]	VEGF	
ALT	> 45 U/L	[17,28,31]	> 50 U/L (poor survival)	[104]

HBV: Hepatitis-B-virus; HCC: Hepatocellular carcinoma; NF: Nuclear factor; TNF: Tumor necrosis factor; IL: Interleukin; STAT: Signal transducer and activator of transcription; TGF: Transforming growth factor; RAF: Raf protein kinases; PI3K: Phosphatidylinositol-3 kinase; MEK: Mitogen-activated protein kinase; ERK: Extracellular-signal-regulated kinase; mTOR: Mammalian target of rapamycin; AKT: Protein kinase B; HLA: Human leukocyte antigen; ALT: Alanine aminotransferase; VEGF: Vascular endothelial growth factor; G-CSF: Granulocyte-colony stimulating factor; LI: Liver intestine; NK: Natural killer.

ing chronic infection than is subgenotype B2 following an acute course^[23]. Chronic infection with genotype C is more likely to cause liver cirrhosis and HCC, as compared with chronic infection with genotype B^[24,25]. Chronic infection with genotype C (C2) is closely associated with an increased risk of HCC in the HBV-infected subjects, especially in cirrhotic patients aged > 50 years, whereas infection with genotype B (B2) has been found to be associated with development of HCC in non-cirrhotic young patients and relapse of HCC after surgical treatment^[15,26].

Association of HBV mutations with HCC: Different HBV subgenotypes have distinct patterns of mutations. We and others have found that HBV mutations including C1653T, T1753V, A1762T/G1764A, T1674C/G and C1766T/T1768A in the enhancer II/basal core promoter (Enh II/BCP) regions; G1899A, C2002T, A2159G, A2189C, and G2203A/T in the precore/core gene; and T53C, preS2 start codon mutation, preS1 deletion, C2964A, A2962G, C3116T, and C7A in the preS region are significantly associated with an increased risk of HCC^[17,27-29]. Of the HCC-associated mutations, combined rather than single mutations are significantly associated with the risk of HCC. In the preS region, the frequencies of combined mutations (haplotypic carriage) including 2964C-3116T-preS2 start codon wildtype-7A, 2964C-3116T-7A-76C, and 2964A-3116T-7C-76A/T are sig-

nificantly higher in the patients with HCC than in those without HCC, whereas the haplotypic carriage with single mutation and other three wild types are inversely associated with HCC^[30]. In the preS and Enh II/BCP regions, a haplotypic carriage with 105C and 2962G is significantly more frequent in the patients with HCC than in those without HCC, and the frequency of 2962G-preS2 start codon wild type-105C-1762T/1764A is 47.9% in the patients with HCC and 4.3% in those without HCC^[31]. Interestingly, the HBV mutations, either in the preS or in the core promoter region, are significantly associated with HCC, whereas the wild-type nucleotides in these regions are mostly associated with liver cirrhosis^[17,28]. HBV mutations can be used as indicators for the prediction of end-stage liver diseases including HCC. Although these mutations and the combinations are specific for HCC to some extent, it will be more practicable if they can predict this malignancy in the HBV-infected subjects before the occurrence of HCC.

Role of viral mutations in prediction of HCC: The majority of patients with chronic HBV infection are believed to be infected *via* perinatal transmission, especially in HBV-endemic areas. The HCC-associated HBV mutants may not transmit *via* mother-to-child transmission because the children whose mothers carry both HBV mutants and wild-type virus are mostly found to be in-

ected with wild-type virus alone^[32]. In the early stage of HBV infection, serum viral load is high and HBeAg is frequently positive because immune selection is weak. Immune selection may increase during HBeAg seroconversion. HBV mutations tend to be gradually generated during a chronic immunopathological course after infection. Recent studies have shown that accumulation of HBV mutations in the core region in children with HCC differ from those in HBV-infected children without HCC, and the frequencies of the HCC-associated mutations do not increase with increasing age of HCC patients, in contrast to patients without HCC^[17,33]. These data support that the frequencies of HBV mutations might increase to high levels during malignant transformation, no matter how old the HBV-infected subjects are. However, HCC mostly occurs in HBV-infected subjects between 45 and 65 years of age. The HBV mutations mostly experience long-term processes of immune selection. A1762T/G1764A occurs up to 10 years before the onset of HCC and is a valuable indicator of HBV-infected men who are more likely to develop HCC^[13,34,35]. The mutations in the BCP region accumulate sequentially during the development of HCC^[36]. Some of the mutations including the preS deletion, C1653T, T1753V and A1762T/G1764A accumulate during the course of HBV infection from asymptomatic HBsAg carrier state to cirrhosis or HCC^[27]. Thus, these viral mutations might accumulate before the diagnosis of HCC and predict the occurrence of HCC.

Possible mechanisms of viral mutation/selection: The HCC-associated HBV mutations are probably generated *via* an evolutionary process on two aspects: increased frequencies of the viral mutations and directional selection of the mutations by the host immune system. As a result of the spontaneous error rate of viral reverse transcriptase, HBV genome might exhibit higher frequencies of mutations than other DNA viruses. This kind of HBV mutation may be considered as a random mutation. In addition, HBV is highly vulnerable to the editing activity of an endogenous human cytidine deaminase activated by proinflammatory cytokines such as tumor necrosis factor (TNF)- α *via* nuclear factor (NF)- κ B activation, especially in late-stage liver diseases in which up to 35% of genomes can be edited^[37,38]. The majority of the newly synthesized HBV DNA genomes displayed extensive G-to-A mutations in the presence of APOBEC3C, an important member of cellular cytidine deaminases, contributing to innate anti-HBV host responses^[39]. Some of the cytidine deaminases play a role in the carcinogenesis of HCC through the generation of HBVx mutants, providing preneoplastic and neoplastic hepatocytes with a selective clonal growth advantage^[40]. The cytidine-deaminase-driven HBV mutations may be classified as “semi-directional mutations”. Either random or semi-directional mutations might be responsible for HBV mutagenesis during viral replication and inflammatory processes. Moreover, the direction of the mutations should be negatively selected

by host immune responses. Reduction of CD8⁺ T cell epitopes in HBV is one of the common means to evade immune clearance. HBV accumulates escape mutations *via* reduction in the epitopes number, eventually leading to the removal of epitopes in HBVx and surface proteins^[41,42]. The preS1 and preS2 play an essential role in the interaction with host immune responses because they contain several epitopes for T and/or B cells^[43]. The preS deletion is one of the most frequent HCC-associated HBV mutations, even in children with HCC^[27,28,30,44]. These mutations might facilitate immune escape of HBV.

Potential function of HBV mutations: Currently, the HCC-associated HBV mutations are mainly found in the preS and Enh II /BCP/precure regions. Two functional viral proteins coded by these regions are preS2 and truncated HBVx. HBVx protein may increase the expression of telomerase reverse transcriptase (TERT) and telomerase activity, prolonging the lifespan of hepatocytes and contributing to malignant transformation. A1762T has introduced a translation initiation site ATG at the C-terminal of HBVx protein. HBVx mutations, especially the C-terminal deletions, have been frequently found in tumor tissues of HCC^[45]. Most of the C-terminally truncated HBVx proteins lose their inhibitory effects on cell proliferation and transformation, retain their ability to bind to p53, and attenuate DNA repair and p53-mediated apoptosis, which may provide a selective clonal advantage for preneoplastic or neoplastic hepatocytes and contribute to hepatocarcinogenesis^[46,47]. HBVx and the preS2 activators exert a tumor-promoter-like function, resulting in positive selection of cells that produce functional regulatory proteins^[48]. HBV preS2 also promotes HCC development *via* activation of human TERT^[49]. However, the role of the mutated preS2 on hepatocarcinogenesis remains unknown. HBV mutations in the BCP region may alter viral replication ability. *In vitro* transfection of HBV mutants has indicated that high-replication clones with 1762/1764/1766 or 1753/1762/1764/1766 mutations expressed very low levels of HBeAg, whereas high-replication clones with 1753/1762/1764 triple mutations expressed high levels of HBeAg, and both 1762/1764/1766 and 1753/1762/1764/1766 mutations conferred significantly higher viral replication and lower HBeAg expression than 1762/1764 mutation alone^[50]. In addition, HBV mutations usually accompany high viral load in patients with HCC^[17]. These results indicate that some HBV mutations might promote hepatocarcinogenesis.

Taken together, HBV mutagenesis might be augmented in hepatic inflammatory microenvironment due to induction of activated cytidine deaminases. Host immune selection might differ in determining the distinctive outcomes of chronic HBV infection. Upon negative and incomplete immune selection, the mutations facilitate viral replication in the hepatocytes. The escaped HBV accumulates mutations that might predict

the occurrence of HCC and in turn play an active role in hepatocarcinogenesis.

Inflammatory signaling pathways and hallmark cytokines

The liver is the primary organ in which mammals metabolize nutrients, environmental toxins, and drugs. The liver also comprises enrichment of innate immune cells (such as macrophages, natural killer, natural killer T, and $\gamma\delta$ T cells), $CD8^+$ cytotoxic T cells, $CD4^+$ T helper cells (such as Th1, Th2, Th17 and Treg) and B cells, playing an important role not only in host defenses against invading microorganisms and tumor transformation, but also in liver injury and repair^[51]. Liver injuries caused by HBV are traditionally considered to be immuno-mediated and are mainly due to the activity of HBV-specific T cells. Liver-infiltrating neutrophils, natural killer cells and activated bystander lymphocytes also play important roles in causing HBV-related liver damage. These inflammatory cells release cytokines and chemokines which may favor cancer growth.

Liver immune cells: Macrophages can be divided schematically into two main classes in line with the Th1/Th2 dichotomy: M1 and M2. M1 macrophages (classically activated) originate upon encounter with interferon (IFN)- γ and microbial stimuli and are characterized by interleukin (IL)-12 and IL-23 production and consequent activation of polarized type I T cell response, defending the host from viral infections, fighting against tumors, producing high amounts of inflammatory cytokines, and activating the immune response. Monocytes may differentiate into M2 macrophages upon stimulation with IL-4, IL-10 and IL-13. M2 macrophages are responsible for scavenging debris, angiogenesis, remodeling and repair of wounded/damaged tissues, and promote carcinogenesis and downregulate M1 function and adoptive immunity. Tumor-associated macrophages (TAMs) resemble M2-polarized macrophages^[52]. $CD8^+$ T cells recognize viral peptides derived from phagocytosed and proteolytically cleaved HBV proteins, activate and differentiate B cells, and secrete IFN- γ and TNF- α , which inhibit the replication and gene expression of HBV. As discussed before, HBV mutations within T-cell epitopes have been documented during chronic HBV infection. These viral mutations may downregulate T-cell functions, such as proliferation or cytokine secretion, and completely or partially inhibit the immune response against the original epitope. Effective $CD8^+$ T-cell-mediated cytotoxic killing may play a crucial role in the control of cancer development. Although tumor-reactive CTL responses are evident in HCC patients, tumor regression is rarely seen, implying that tumor microenvironment inactivates antitumor effector cells, or induces immune tolerance. Macrophages in liver (also called Kupffer cells) function as M2 and suppress $CD8^+$ T cells in human HCC *via* B7-H1/programmed death-1 interactions and favor HCC growth^[53]. Depletion of TAMs in HCC enhances the therapeutic

effect of sorafenib on HCC^[54]. Treg cells serve as critical gatekeepers in immune homeostasis. Increased Treg cells ($CD4^+CD25^+FoxP3^+$) in HCC may impair the effector function of $CD8^+$ T cells and promote HCC progression^[55]. Th17 cells elicit a highly inflammatory immune response. The frequency of IL-17⁺ cells is significantly elevated in the patients with chronic liver diseases including viral hepatitis and HCC, and the tumor-derived Th17 cells may promote tumor growth and inflammation, and tumor-activated monocytes secrete a set of key proinflammatory cytokines that trigger proliferation of functional Th17 cells^[56,57]. Th17 cells promote angiogenesis, tumor growth and inflammation, while Treg cells appear to have counter-regulatory effects on Th17 cells and can inhibit their function. Therefore, an imbalance between Th17 and Treg cell function may be central in some inflammation-associated malignancies, possibly including HBV-associated HCC. The same is true for the imbalance between Th1 and Th2 functions in the microenvironment of HBV-related HCC^[58]. These immune imbalances caused by chronic HBV infection contribute to chronic inflammation, hepatic necrosis and subsequent regeneration, accumulated mutagenesis in hepatocytes and ultimately HCC. Multiple signaling pathways are involved in this inflammation-necrosis-regeneration process and in human HCC development. Hallmark cytokines and related molecules in these pathways might be candidate biomarkers for the prediction of the occurrence of HCC in the HBV-infected population.

NF- κ B pathway and hallmark cytokines: NF- κ B, a collection of dimeric transcription factors including NF- κ B1 (p105 and p50), NF- κ B2 (p100 and p52), RelA (p65), RelB and c-Rel, is present in all cells in inactive form. In non-stimulated cells, most NF- κ B dimers are retained in the cytoplasm by binding to inhibitory I κ B proteins. In response to proinflammatory stimuli, such as TNF- α or IL-1 β , the I κ B kinase (IKK) complex, composed of the IKK α and IKK β catalytic subunits and the IKK γ regulatory subunit, is activated, resulting in I κ B phosphorylation and eventual ubiquitin-mediated degradation^[59], leading to the nuclear entry of freed NF- κ B dimers. Of the two catalytic subunits, IKK β is the most critical for I κ B degradation, forming the core of what is known as the classical NF- κ B activation pathway^[60]. The classical IKK β -dependent NF- κ B signaling pathway promotes hepatocyte survival in both developing and adult livers. NF- κ B activation is often observed in human HCC, particularly following hepatitis. It plays a crucial role in liver inflammatory responses by controlling the expression of an array of growth factors and cytokines. One of the most important NF- κ B-dependent cytokines that is produced by activated Kupffer cells is IL-6. IL-6 released by Kupffer cells after NF- κ B activation also controls HBV gene expression and replication in hepatocytes at the level of transcription shortly after infection^[60]. HBVx protein also stimulates IL-6 expression in hepatocytes *via* a MyD88-dependent pathway^[61]. Hepatocyte IKK/NF- κ B promotes

HCC development by maintaining liver inflammatory responses^[62]. The inflammatory process triggers hepatocyte NF- κ B through upregulation of TNF- α in adjacent endothelial and inflammatory cells. NF- κ B inhibition through anti-TNF- α treatment or induction of I κ B super repressor in later stages of tumor development results in apoptosis of transformed hepatocytes and failure to progress to HCC^[63]. Serum levels of IL-6 and TNF- α have been found to be significantly higher in HBV-infected patients with liver cirrhosis and HCC than those without or in accordance with the progress of the disease phases^[64,65]. In this pathway, IL-6 and TNF- α are hallmark cytokines whose expression might indicate the risk of HCC in HBV-infected population.

Signal transducer and activator of transcription 3 pathway and hallmark cytokines: Signal transducer and activator of transcription (STAT)3 is inactive in non-stimulated cells, but is rapidly activated by various cytokines and growth factors, such as IL-6 and epithelial growth factor family members, as well as hepatocyte growth factor (HGF)^[61]. STAT3 activation requires phosphorylation of a critical tyrosine residue, Tyr705, which mediates its dimerization that is a prerequisite for nucleus entry and DNA binding. The phosphorylation of STAT3 at Tyr705 is most commonly mediated by Janus kinases (JAKs), especially JAK2. C-Jun N-terminal kinase (JNK) plays a dual role in the development of HCC. JNK promotes an inflammatory hepatic environment that supports tumor development, but also functions in hepatocytes to reduce tumor development^[66]. Activation of STAT3 also turns on strong negative feedback loops involving suppressor of cytokine signaling 3 (SOCS3). STAT3 is activated in the majority of HCCs with poor prognosis and not in surrounding non-tumor tissue or in normal liver. HBVx expression *in vitro* has a significant inverse correlation with the expression of the highly expressed members of the let-7 miRNA family in HCC patients, while the most highly expressed let-7 family member, let-7a, negatively regulates cellular proliferation partly through targeting STAT3, indicating that HBVx upregulates STAT3^[67]. HBVx mutant proteins express an atypical nuclear and perinuclear localization in HCC samples, and the effect of HBVx mutants on STAT/SOCS signaling demonstrates a significant upregulation of STAT3 activation in comparison to wild-type HBVx^[68]. These data indicate an active role of HBVx mutants in hepatocarcinogenesis that involves dysregulation of STAT/SOCS signaling. Hepatocyte-specific STAT3 ablation prevents HCC development^[69]. Other reasons like obesity-promoted HCC development is dependent on enhanced production of the tumor-promoting cytokines IL-6 and TNF- α , which cause hepatic inflammation and activation of STAT3^[70]. The main cause of STAT3 activation in human HCC could simply be the elevated expression of IL-6 and related cytokines, such as TNF- α , IL-11 and IL-23. One of the most critical tumor-promoting cytokines in HCC is IL-6. High serum level of IL-6 predicts future occur-

rence of HCC in patients with CHB^[65].

Wnt/ β -catenin signaling pathway: A hallmark of Wnt signaling is the stabilization of cytoplasmic β -catenin. Wnt/ β -catenin signaling regulates cytokine-induced human inducible nitric oxide synthase expression through interaction with NF- κ B, and plays an important role in the pathophysiology of inflammation-associated carcinogenesis^[71]. β -catenin was first identified on the basis of its association with cadherin adhesion molecules, and is widely recognized as a key molecule of the Wnt signaling cascade. Mutations of β -catenin, specifically stabilizing mutations in exon 3, are detected in approximately 30% of primary HCCs, raising the possibility that activation of Wnt/ β -catenin signaling contributes to hepatocarcinogenesis^[72]. Aberrant activation of the Wnt signaling pathway together with transforming growth factor (TGF)- β has been used for gene expression profiling-based classification of HCC^[73]. Wnt/ β -catenin signaling is activated relatively early during hepatocyte regeneration, mostly through post-translational modifications. Once activated, β -catenin signaling drives the expression of target genes that are critical for cell cycle progression and contribute to initiation of the regeneration process. Wnt-1 is a survival factor for HCC cells. The blockade of Wnt-1-mediated signaling may offer a potential pathway-specific therapeutic strategy for the treatment of a subgroup of HCC that over-expresses Wnt-1^[74]. Wnt/ β -catenin signaling is particularly activated by ectopic expression of Wnt-1 in HBV-infected HCC cells. Wnt-1 is necessary but insufficient to activate Wnt/ β -catenin signaling in HCC. The enhanced stabilization of β -catenin by HBVx, in addition to Wnt-1, is essential for the activation of Wnt/ β -catenin signaling in HCC^[75]. However, it should be clarified if HBVx mutant and other HBV mutants play a distinct role in activating this pathway.

TGF- β 1 pathway: The balance between death and survival is dysregulated in HCC mainly due to overactivation of antiapoptotic pathways^[76]. TGF- β signaling involves both tumor suppression and oncogenesis. TGF- β 1 is an important regulatory suppressor factor in hepatocytes, inhibiting proliferation and inducing cell death, however, it may also modulate other pro-tumorigenic processes, such as cell invasion^[77]. Elevated TGF- β 1 may accelerate hepatic fibrosis through increased TGF- β 1-induced proinflammatory signaling pathways in hepatic stellate cells^[78]. TGF- β activates TGF- β type I receptor (T β R I) and JNK, which differentially phosphorylate the mediator Smad3 to become C-terminally phosphorylated Smad3 (pSmad3C) and linker-phosphorylated Smad3 (pSmad3L). Reversible shifting of Smad3-mediated signaling between tumor suppression and oncogenesis in HBVx-expressing hepatocytes indicates that T β R I-dependent pSmad3C transmits a tumor-suppressive TGF- β signal, while JNK-dependent pSmad3L promotes cell growth. HBVx shifts hepatocytic TGF- β signaling from

the tumor-suppressive pSmad3C pathway to the oncogenic pSmad3L pathway in early carcinogenesis^[79]. Hepatocytic pSmad3L and pSmad3C assessment in HBV-infected liver specimens should prove clinically useful for predicting risk of HCC.

Other inflammatory pathways: Apart from above described pathways, raf protein kinases (RAF)/mitogen-activated protein kinase (MEK)/extracellular-signal-regulated kinase (ERK) pathway, phosphatidylinositol-3 kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin (mTOR) pathway, insulin-like growth factor pathway, HGF/c-Met pathway, the p53 pathway, and growth factor-regulated angiogenic signaling are implicated in hepatocarcinogenesis^[76]. These pathways are of interest for a therapeutic perspective, because targeting them may help to reverse, delay or prevent hepatocarcinogenesis^[80]. For example, the antitumor effect of sorafenib on HCC can be improved by vertical blockade of RAF/MEK/ERK signaling with CI-1040^[81].

Genetic susceptibility of inflammatory factors

The imbalances in inflammation reactions play an important role in HBV-induced hepatocarcinogenesis, therefore, it is necessary to clarify the role of key inflammatory molecule germline mutations, which influence the expression and function of those molecules, on the susceptibility of HCC. Human leukocyte antigen-DR13 polymorphism has been shown to be strongly associated with the clearance of HBV^[82]. A study in Japan has evaluated the association of genetic polymorphism in the cytokines TNF- α , IFN- γ , TGF- β 1, IL-6 and IL-10 with the risk of HCC in HBV-infected subjects and has found that the risk of HCC was significantly lower in HBV carriers with C/C genotype than in those with T/C or T/T genotype in position +29 of the TGF- β 1 gene, but was not associated with genetic polymorphism of other molecules^[83]. It has been demonstrated that in the presence of the IL-1 receptor antagonist *2 allele, the IL- β 1-31 polymorphism T/C and T/T genotypes in Taiwan are significantly associated with HBV-related HCC, with adjusted odds ratios (ORs) of 2.93 (95% CI: 1.07-8.07) and 5.76 (95% CI: 1.79-18.53), respectively^[84]. A study in Korea has documented that the -148C, +8925G, and +13925C alleles of the IL-18 gene are associated with HBV-related HCC and the 148G > C single nucleotide polymorphism is functionally important in determining disease outcome^[85]. IL-12 polymorphisms have been recently associated with HBV-related HCC in the Chinese population^[86]. A recent genome-wide association study (GWAS) in Mainland China has shown that the 1p36.22 locus confers susceptibility to HBV-related HCC, and suggests that KIF1B-, UBE4B- or PGD-related pathways might be involved in the pathogenesis of this malignancy^[87]. Our recent data have demonstrated that NF- κ B1 gene promoter NFKB1-94ATTG2 allelic carriage and IKK β gene promoter NFKBIA-826T and NFKBIA-881AG allelic carriage, which are related to upregulation

of NF- κ B function, are significantly associated with an increased risk of HCC in patients infected with genotype C HBV, while the estimated haplotype frequency of NFKBIA promoter -881G-826T-519C is significantly higher in patients with HCC than in HBV-infected subjects without HCC^[88]. Problems in current studies on genetic susceptibility of HBV-associated HCC are: (1) GWAS with enough samples has limited coverage, resulting in loss of data; (2) individual case-control studies lack sufficient samples and strict controls; and (3) significant polymorphisms found by GWAS and individual case-control studies have few loci in common. Nevertheless, the contribution of genetic polymorphisms to the occurrence of HCC may be limited because of low ORs obtained both in current GWAS and in case-control studies.

Other parameters

Family history is one of the major risk factors for HCC^[89,90]. First-degree relatives of patients with HCC are associated with an increased risk of HBV-related HCC in Taiwan and with HCC in United States independently of HBV and HCV infection. In HBV-endemic regions, family clustering of HCC is, to some extent, related to family clustering of HBV infection *via* perinatal transmission. Apart from HBV and HCV infection, exposure to aflatoxin B1, alcoholic abuse, and diabetes are well-established risk factors for HCC. Regular consumption of coffee or green tea is significantly associated with a decreased risk of HCC in subjects with or without HBV and/or HCV infection^[91,92]. Old age, male sex and poor socioeconomic status are also related to the occurrence of HCC in the HBV-infected subjects.

Poor liver function, as indicated by low serum level of albumin and high level of bilirubin, favor HBV-induced hepatocarcinogenesis. Persistent or intermittent increase in serum alanine aminotransferase (ALT) level reflects persistent liver damage. CHB patients with ALT levels 0.5-1 times the upper limit of normal (ULN) and 1-2 \times ULN have an increased risk for the development of complications compared with patients with ALT levels < 0.5 \times ULN ($P < 0.0001$ for both)^[93]. In HBeAg-negative subjects, high viral load is frequently associated with abnormal ALT level, while ALT abnormality is more frequent in those with liver cirrhosis than those without (19.5% *vs* 7.8%, $P = 0.001$)^[24]. Abnormal ALT level (> 45 U/L) has been frequently shown to be an independent risk factor for HCC in HBV-infected subjects^[17,28,31]. Liver cirrhosis is a well-established important risk factor of HCC^[94]. Older age, higher total bilirubin, ALT, and HBV DNA levels, and HBV preS deletion, A1846T and/or T1768A mutations are major independent determinants of progression to cirrhosis in HBeAg-negative patients^[17,24,28,95].

Clinical scoring system for prediction of HCC occurrence

A research group in Hong Kong prospectively evaluated 1005 HBV carriers and found that age, albumin, bilirubin,

bin, HBV DNA, and cirrhosis independently predicted the development of HCC. They used these variables to construct a prediction score ranging from 0 to 44.5 and then validated the score in a different cohort of 424 HBV carriers. In the training cohort, they found cutoff values of 5 and 20 best discriminated HCC risk. In the validation cohort, the 5-year HCC-free survival rates were 98.3%, 90.5% and 78.9% in the low-, medium- and high-risk groups, respectively. HR for HCC in the medium- and high-risk groups was 12.8 and 14.6, respectively. This simple prediction score constructed from routine clinical and laboratory parameters is accurate in predicting HCC development in HBV carriers^[96]. To set up a scoring system for the prediction of HCC from CHB patients, 820 CHB patients have been followed up for a mean duration of 76.8 mo in a prospective study. It has been found that male [relative risk (RR) = 2.98], increasing age (RR = 1.07), higher HBV DNA levels (RR = 1.28), core promoter mutations (RR = 3.66), and presence of cirrhosis (RR = 7.31) are independent risks for the development of HCC. A risk score is derived and validated with sensitivity > 84% and specificity > 76% to predict the 5- and 10-year risks for the development of HCC^[97]. The two scoring systems can accurately predict HBV carriers and CHB patients who will more likely develop HCC in the near future, and have important implications for treatment allocation and strategic screening for HCC in CHB patients and HBV carriers.

ROLE OF VIRAL AND INFLAMMATORY FACTORS IN PREDICTING PROGNOSIS OF HBV-ASSOCIATED HCC

Viral load

In a study carried out in Japan, a total of 74 patients with HBV-associated HCC who had received either conventional treatment or not were followed up for survival analysis. In multivariate regression analysis, it has been found that serum level of HBV DNA and tumor size at diagnosis are independent and significant prognostic factors ($P = 0.0022$ and $P = 0.0106$, respectively), and a low level of viremia is associated with longer survival ($P = 0.0057$), even in patients seronegative for HBeAg^[98]. In another study, a total of 62 HBV-related HCC patients who had achieved complete necrosis with transarterial chemolipiodolization were followed up for analysis of recurrence. Multivariate analysis has established that high viral load ($> 10^5$ copies/mL) at complete necrosis is among the most important risk factors for post-treatment recurrence^[99]. Seventy-two patients who underwent liver resection for HBV-related HCC were followed up. By multivariate analysis, high viral load ($> 10^4$ copies/mL) (OR = 22.3, $P = 0.001$), α -fetoprotein > 1 mg/mL (OR = 7.4, $P = 0.02$), tumor size > 5 cm (OR = 5.1, $P = 0.02$), and age > 60 years (OR = 4, $P = 0.01$) at the time of tumor resection are independently associated with HCC recurrence after resection. Of those,

high viral load ($> 10^4$ copies/mL) is the most important correctable risk factor^[100]. In a Taiwan study, HBV DNA $> 3 \times 10^7$ copies/g in the non-cancerous liver tissues of patients with HCC was found to be independently associated with shorter overall survival^[101]. Lamivudine therapy is beneficial for patients after initial treatment for HBV-related HCC because it contributes to improving remnant liver function, decreasing the risk of liver failure, and increasing the chances of receiving available treatment modalities for recurrent HCC^[102]. Treatment of the HBV-infected HCC patients with IFN- α after curative resection efficiently prevents early recurrence and improves overall survival^[103]. These data indicate that high viral load is the most reliable factor in predicting poor prognosis of the patients with HBV-related HCC, therefore, antiviral treatment after surgical resection is highly recommended.

HBV genotype and viral mutations

A Taiwan study enrolled 64 patients who underwent liver resection for HBV-related HCC. During a mean follow-up of 26.6 ± 13.2 mo, patients with genotype C had worse disease-free survival rate ($P = 0.028$) than those with genotype B. By univariate analysis, genotype C, ALT > 50 U/L, tumor size ≥ 5 cm, and microvascular invasion were associated with tumor recurrence. Multivariate analysis indicated that genotype C was a risk factor independently associated with poor prognosis ($P = 0.034$)^[104]. Recently, the core gene of HBV isolated from HCC tissues has been found to have fewer mutations compared with those isolated from adjacent non-tumor tissues from the same patients ($P < 0.05$)^[105], implying that active immune selection of viral mutation most likely happens in the peritumoral liver tissues. In a study carried out in Taiwan, the association of virological characteristics with the prognosis of the patients was investigated by using the non-cancerous part of surgically removed HBV-associated HCC tissues from 185 patients. All virological and clinicopathological factors were subjected to Cox proportional hazard model analysis to estimate postoperative survival. After adjusting for other confounding factors, multivariate analysis revealed that age older than 50 years, bilirubin > 1.4 mg/dL, and A1762T/G1764A mutation were independently associated with shorter overall survival. Kaplan-Meier survival analysis indicated that in-frame, short stretch (< 100 bp) preS deletions, but not large fragment (> 100 bp) preS deletions, were significantly associated with poorer disease-free ($P = 0.005$) and overall ($P = 0.020$) survival. A hot deletion region located between codons 107 and 141 of the preS sequence was identified for the short stretch preS deletion mutants^[101]. The result of viral load in the inflammatory liver tissues seems to be consistent with that of serum viral load. It remains unknown if the mutations of HBV in the tissues are consistent with those in the sera.

Inflammatory cells and molecules

Inflammatory cells: Immune cells infiltrated into HCC

tissues and adjacent non-cancerous tissues have various roles in conducting inflammatory responses. NK and T cells are present in tumors of HCC patients with longer survival, and exclusively in areas devoid of proliferating tumor cells. NK and CD8⁺ T cell densities are correlated positively with tumor apoptosis, and negatively with tumor proliferation^[106]. On the other hand, higher density of intratumoral Treg cells and lower density of intratumoral CD8⁺ T cells are independently associated with poor prognosis of HCC. In addition, high Treg cell density is associated with both absence of tumor encapsulation and presence of tumor vascular invasion^[107]. Intratumoral balance of regulatory and cytotoxic T cells is a promising independent predictor for recurrence and survival in the HBV-infected patients with HCC.

Th1/Th2-like cytokines: Peritumoral hepatic tissues of patients with HCC have been used for investigating the association of inflammatory cytokines with prognosis in Mainland China. Higher levels of IL-2 and IL-15 in peritumoral liver tissues, but not in tumor tissues, are significantly associated with decreased incidence of recurrence of intrahepatic tumor and prolonged overall survival, whereas peritumoral expression of granulocyte-colony stimulating factor, a Th2-like cytokine, is significantly associated with poor prognosis^[108,109]. This reflects that the imbalance of Th1/Th2-like cytokines affects inflammation status, which later determines the malignant phenotype of HCC. Peritumoral levels of Th1/Th2-like cytokines are useful for stratifying patients, even those with early-stage HCC, into subgroups with different prognoses after curative resection. Treatment with Th1 cytokine IFN- α benefits HBV-related HCC patients after curative resection^[103], possibly *via* correcting the imbalances.

Other inflammatory molecules: Up-regulation of Wnt-1 protein has been reported in HBV-related HCC tissues. High Wnt-1 expression in HBV-related HCC tissues correlates with enhanced nuclear β -catenin accumulation, diminished membranous E-cadherin expression, and increased HCC recurrence after curative resection^[110]. Liver-intestine cadherin (LI-cadherin; CDH-17) is a new member of the cadherin superfamily with distinct structural and functional features. Overexpression of LI-cadherin is well correlated with microvascular invasion in HBV-positive HCC tissues and strongly associated with shorter overall survival as well as higher incidence of tumor recurrence^[111]. Thus, LI-cadherin should be a candidate target for HCC intervention. ErbB-2 is strongly upregulated in HBV-infected liver and correlated with HBVx expression. ErbB-2 contributes to the stabilization of β -catenin. Strong ErbB-2 staining in liver tissues of patients with HCC is associated with dysplasia and a shorter survival after tumor diagnosis^[112]. Cyclooxygenase-2 is a proinflammatory factor whose expression in non-cancerous liver tissue increases the postoperative recurrence of HCC in patients with HBV-related cirrhosis^[113]. These inflammatory molecules may serve as

prognostic markers and/or candidate therapeutic targets of HBV-related HCC after surgical treatment.

Signaling-associated miRNAs: miRNAs are a class of small non-coding RNAs that modulate gene function at the post-transcriptional level and act as fine tuners of various processes including cell signaling and apoptosis. miRNAs are associated with different types and stages of cancer, and are involved in liver diseases caused by various factors, including HBV^[114]. Some miRNAs are specifically found in HCC tumors and sera of patients. Serum miRNAs including miR-25, miR-375 and let-7f have been recently identified as biomarkers and clearly separate HCC cases from controls, and miR-375 and miR-92a have been identified as HBV-specific^[115]. miR-199a/b-3p exhibits its biological activity *via* inhibiting the Raf/MEK/ERK pathway, and is the most consistently decreased miRNA in HCC. Low miR-199-3p expression correlates with poor survival of HCC patients^[116]. Current problems of developing miRNAs as diagnostic and prognostic markers are their stability in sera and selection of internal controls. It will be a great challenge to search for miRNA markers, especially for those that target some existing inflammatory signaling pathways involved in the recurrence and metastasis of HBV-associated HCC.

Clinical scoring systems for prediction of HCC prognosis

Clinical scoring systems have been developed not only for the prediction of HCC occurrence, but also for its prognosis. Nathan *et al.*^[117] have prospectively evaluated survival of HCC patients with small tumors, and have found that tumor size > 2 cm (HR = 1.51), multifocal tumors (HR = 1.51), and vascular invasion (HR = 1.44) remained independent predictors of poor survival (all $P < 0.05$) after adjusting for demographic factors and histological grade. Based on these findings, they developed a prognostic scoring system by allotting 1 point each for these factors. Patients with early HCC could be stratified into three distinct prognostic groups (median and 5-year survival, respectively): 0 point (70 mo, 55%), 1 point (52 mo, 42%), and ≥ 2 points (24 mo, 29%) ($P < 0.001$). However, this scoring system has not been validated using an independent cohort. Hsu *et al.*^[118] have prospectively investigated the prognostic ability of the five currently used staging systems with 1713 enrolled HCC patients, and have concluded that the CLIP staging system is the best long-term prognostic model for HCC in a cohort of patients with early to advanced stage HCC. Current scoring systems for the prediction of HCC prognosis lack useful viral and inflammatory markers like serum HBV load and expression of inflammatory molecules in tumors and/or non-cancerous liver tissues. Inclusion of viral and inflammatory factors that are closely related to malignant phenotype and poor prognosis will make current scoring systems more accurate in predicting the prognosis of HBV-related HCC after surgical resection.

In summary, continuing inflammation caused by chronic HBV infection is not only involved in hepatocarcinogenesis, but also plays critical roles in the recurrence and metastasis of HCC after surgical treatment. Viral load, genotype/subgenotype, and a subset of viral mutations are major viral factors that may predict the occurrence of HCC. Inflammatory microenvironment may increase the frequency of viral mutation *via* induction of cellular cytidine deaminases, whereas HBV mutations selected by inflammation reaction might in turn promote hepatocarcinogenesis. Imbalance either between peritumoral Th1 and Th2 cytokines or between intratumoral CD8+ T cells and Treg cells contributes, at least partially, to inflammation-necrosis-regeneration response, ultimately HCC. Inflammatory pathways including NF- κ B, STAT3, Wnt/ β -catenin, and TGF- β 1 signaling pathways contribute to the development of HCC, and their hallmark molecules including IL-6, TNF- α and Wnt-1 can predict the occurrence or recurrence of this malignancy. HBV load, viral mutations and imbalance between infiltrating immune cells or between Th1 and Th2 cytokines can predict the prognosis of HBV-related HCC. These factors are of significance for developing active prevention and surveillance of the HBV-infected subjects who are more likely to develop HCC, or tailoring suitable treatment options for HBV-related HCC patients to improve the survival or postpone recurrence after surgical resection.

Abstract

Over the last few years, improvements in endoscopic imaging technology have enabled identification of dysplasia and early cancer in Barrett's oesophagus. New techniques should exhibit high sensitivities and specificities and have good interobserver agreement. They should also be affordable and easily applicable to the community gastroenterologist. Ideally, these modalities must exhibit the capability of imaging wide areas in real time whilst enabling the endoscopist to specifically target abnormal areas. This review will specifically focus on some of the novel endoscopic imaging modalities currently available in routine practice which includes chromoendoscopy, autofluorescence imaging and narrow band imaging.

CHROMOENDOSCOPY

Chromoendoscopy involves topical application of various dyes during endoscopy which improves the visualisation of mucosal surfaces. The stains can be divided into three main classes: contrast, absorptive and reactive. Contrast stains, for example indigo carmine (IC), accumulate in the mucosal fissures thereby accentuating surface topology. In contrast, absorptive stains such as Lugol's iodine (LI), crystal violet and methylene blue (MB) are absorbed into components of the cellular structure in the mucosa. Differences in the uptake of these stains can therefore be used to elucidate different types of mucosa. Reactive stains such as Congo red and Phenol red are pH-dependent. Congo red turns dark blue or black in acidic conditions, while phenol is yellow in an acidic environment and turns red in the presence of alkaline substances. These stains are, however, not used routinely in the oesophagus. There are two essential steps in chromoendoscopy - firstly, removal of mucous which is then followed by dye application. The former is achieved by using water, or occasionally some centres have advocated the use of a mucolytic agent; N-Acetylcysteine^[1,2]. This can be achieved by flushing the agent through the working channel, using a spray catheter or even administering it as an oral solution before the endoscopic procedure^[3]. Once the mucous is cleared, the dye can then be applied. The volume, concentration and the dye contact time varies considerably. Canto's group^[4,5] used 10-20 mL of 0.5% MB for every 5 cm of Barrett's mucosa, while Raganath *et al*^[6] used 4 mL of 0.5% MB for every 1 cm.

LUGOL'S IODINE

LI is a compound iodine solution that is absorbed by the glycogen containing squamous epithelium and stains it brown. The demarcation between squamous epithelium of the oesophagus and columnar epithelium of the stomach can therefore be clearly delineated. Damaged mucosa due to oesophagitis or malignant infiltration does not stain as well as normal mucosa. In BE, specialised intestinal metaplasia does not stain after application of LI. Woolf *et al*^[7] used LI to improve demarcation of squamous from columnar mucosa in patients with BE.

Toluidine blue

This is an absorptive stain taken up by the nuclei of columnar cells. Chobanian and colleagues used 1% toluidine blue to aid in the endoscopic detection of BE and reported improved sensitivity compared to standard endoscopy alone^[8]. The main limitation of this technique is that the dye stains all columnar cells, hence distinguishing between the intestinal and non intestinal epithelial subtypes of BE is not feasible especially since intestinal metaplasia can be patchy in BE.

Methylene blue

MB, an absorptive dye, is probably the most investigated stain for evaluation of BE and also the most controversial. It is a vital stain taken up by actively absorbing epithelial cells after topical application at a concentration of 0.5%-1.0%^[9,10]. The dye is absorbed by goblet cells present in specialised intestinal metaplastic epithelium. Initial work done by Canto's group revealed that MB can distinguish IM and dysplasia in BE with high precision. However, these results were not reproducible. Various other subsequent studies have revealed mixed findings. The main contention with MB in BE is that dysplastic areas do not stain, but the problem with that is that even areas which do not harbour IM do not absorb the dye. This makes it difficult for the endoscopist to decide on which areas to target the biopsies during the procedure. There were also some issues with the uniformity of the dye and recently even toxicity with MB. It has been examined in both long and short segment BE^[11,12,13]. Two patterns of staining have been documented - diffuse and focal. Canto *et al*^[5,11] found that most patients with long segment BE exhibited diffuse staining, whereas Wo *et al*^[14] observed focal staining in their cohort of patients with long segment BE. Similar discrepancies have been reported in short segment BE. Sharma *et al*^[13] found that the majority of their patients with short segment BE stained diffusely. In contrast, in 30 patients with short segment BE assessed by Kiesslich's group^[12], 80% demonstrated staining in a focal pattern.

The published data for biopsy related sensitivity of MB in detecting specialised intestinal metaplasia (SIM) vary considerably. Some studies reported high sensitivities ranging from 81% to 98%^[3,11,12], while others show markedly less favourable sensitivities ranging from 37% to 61%^[6,13-16]. The reasons for this variation in results are

not clear. Differences in stain concentration^[4,11,12] and the volume used^[4,6,14] may have influenced results. The biopsy protocol used in specific studies has also varied. Some investigators performed random 4 quadrant biopsies irrespective of the staining pattern^[4,6,15], while others obtained equal numbers of stained and unstained mucosa^[11] or biopsied stained mucosa only^[3]. Another possible explanation for the inconsistent published data is the discrepancy in operator skill and experience. Most procedures were performed by a single expert endoscopist in a "tertiary centre"^[4,5,11,15], hence the generalisability of the procedure itself has to be questioned. The role of MB in the detection of foci of dysplasia in BE is even more unclear. Early studies by Canto *et al*^[4,11] showed that dysplastic tissue did stain with MB, although histology revealed predominantly low grade dysplasia. Subsequent work suggested that lack of staining was more predictive of dysplasia, attributed to the loss of goblet cells with progression of dysplasia^[5]. A focal non-staining area in a sea of blue has been found to be highly predictive of dysplastic change. However, investigators continue to report dysplasia and carcinoma occurring in stained biopsies^[12,14]. The inter-observer variability in differentiating between shades of blue has not been determined, and the interpretation of deeply *vs* lightly stained mucosa is largely subjective. As a result of all these controversies and confusion, MB has hence not really gained widespread acceptance in the gastrointestinal fraternity.

A recent meta-analysis assessing the diagnostic yield of MB in detecting SIM and dysplasia in BE looked at 9 published studies that included 450 patients. Despite controlling for differences in technique and quality of published data, the meta-analysis showed no significant benefit of MB chromoendoscopy compared with random biopsies in detecting SIM, dysplasia or early oesophageal cancer^[17].

Crystal violet

Crystal violet has been used as an absorptive stain to evaluate colonic polyps since it is preferentially taken up by the crypts of Lieberkuhn^[18,19]. Its role in the assessment of BE is less clear. A case report using a combination of crystal violet and Methylene blue has been described to be useful for the detection of a minute focus of adenocarcinoma in BE^[20]. These investigators found that 0.05% crystal violet directly dyes the surface of BE, thereby enhancing MB stained mucosa.

Indigo carmine

This dye is not absorbed when applied topically to the mucosa. Instead it augments mucosal details and is therefore used as a contrast stain to delineate irregularities of the mucosal surface. Since it provides a clearer definition of the mucosal pattern in BE, evaluation of IC is best considered in conjunction with magnification endoscopy. Sharma *et al*^[21] showed that IC magnification endoscopy may improve mucosal imaging and the detection of dysplasia in BE. However, Kara *et al*^[22] showed that when a

high resolution endoscope is used, the adjunctive use of IC chromoendoscopy is of limited use for the primary detection of lesions.

High resolution magnification endoscopy

Standard video endoscopes are tailored to view the mucosa from a focal distance of 1-2 cm from the endoscope tip. With a pixel density of 200 000, detailed inspection is limited especially if the tip of the scope is advanced closer to the area of interest. The focused area tends to exhibit a blurred view. Coupled with low resolution monitors, the quality of images obtained in real time can be compromised. As technology improves, the pixel density and resolution of monitors has increased tremendously, and this has resulted in improved image quality with high resolution (> 850 000 pixel density) and high magnification (115X) systems. This phenomenon is especially crucial in BE surveillance as early, subtle lesions harbouring dysplasia or cancer should not be missed.

Recent advancements in endoscopic technology have produced high magnification endoscopes with electronically moveable lenses which allow real time visualisation of mucosal morphology in greater detail. Magnification enlarges the endoscopic image, while better resolution improves the ability to discriminate detail by enabling two closely approximated points to be better appreciated. The clinical utility of this modality had been limited by the size of the endoscope in the past. However, improvement in the design of the charged-couple device, an electronic light sensing apparatus located at the tip of the endoscope, has given rise to less bulky and more manageable instruments. High resolution magnification endoscopy (HRME) has been evaluated in coeliac disease where it was found to be valuable in assessing the degree of villous atrophy^[23]. Inoue's group used HRME to characterise the blood vessel morphology, hence facilitate the diagnosis of superficial oesophageal cancer^[24]. The morphology of intrapapillary loops became progressively more tortuous and disorganised with the evolution of dysplasia to cancer. HRME has also been assessed in the stomach, where the authors have shown that it can reliably identify normal gastric mucosa, *Helicobacter pylori*-associated gastritis and gastric atrophy^[25]. In the colon, magnification endoscopy has been used to assess colonic polyps^[26,27] and colon cancer^[28,29].

Magnification endoscopy has been proposed as a diagnostic tool to improve the sensitivity of standard endoscopy in the detection of specialised intestinal metaplasia and dysplasia. Stevens *et al*^[30] used IC as a contrast stain to assess BE using magnification endoscopy and noted a villiform appearance correlated with the histological finding of specialised intestinal metaplasia. Endo and colleagues^[31] characterised the pit pattern of BE using magnification endoscopy and MB staining and found that specialised intestinal metaplasia was detected in patients who exhibited a tubular/villous pattern in their BE segment. Similarly, Sharma's group found that 97% of their cohort of patients with a ridged/villous pattern on magnification chromoendoscopy using IC had specialised intestinal

metaplasia, and 100% with an irregular and distorted pattern exhibited high grade dysplasia^[21]. Fortun and colleagues reported that enhanced magnification endoscopy with acetic acid (Figure 1A) allows clear visualisation of the epithelial pit patterns within BE, and targeted biopsy resulted in a high yield of specialised intestinal metaplasia and dysplasia^[32]. However, despite the increasing availability of high resolution magnification endoscopes, there is a lack of diagnostic criteria for magnified endoscopic images.

Autofluorescence imaging

When tissues are exposed to short wave length light, endogenous biological substances (i.e., fluorophores) are excited, leading to emission of fluorescent light of a longer wavelength. This phenomenon is known as autofluorescence^[33]. Autofluorescence imaging (AFI) is a technique that can potentially differentiate tissue types based on their differences in fluorescence emission. Normal and neoplastic tissue have different autofluorescence spectra which may enable their distinction. This is due to the various different compositions of the endogenous fluorophores which includes collagen, NADH, aromatic amino acids and porphyrins in these tissues. Until recently, AFI has been restricted to either autofluorescence spectroscopy or autofluorescence endoscopy using the older generation fibre optic endoscopes^[34-36]. The main limitation of AFI using this modality is that the quality of the images produced was inferior. Recently, video AFI which incorporates high resolution endoscopy has been evaluated^[37]. In an uncontrolled feasibility study, AFI led to the detection of a significant number of patients with high grade dysplasia/early cancer in Barrett's oesophagus (BE). There was, however, a very high false positive rate (51%) using this modality.

Narrow band imaging

The quest for a simpler technique which would obviate the complexity of chromoendoscopy led to the development of narrow band imaging (NBI) (Figure 1B-G: HRME and corresponding images on NBI). Termed "electronic chromoendoscopy" by some quarters, this unique technology was first described by Gono *et al*^[38]. Standard white light endoscopy consists of 3 light waves: blue, green and red. The principles behind NBI technology are that the bandwidths of blue (440-460 nm) and green (540-560 nm) wave light are narrowed whilst the contribution of red wave light is totally negated out of the emitted light. This is achieved by a special filter which is electronically activated once the endoscopist presses a switch on the endoscope. The whole process takes less than 1 s and is practical during any endoscopy procedure provided the system is equipped with NBI. The narrowed bandwidths of green and blue light lead to superficial penetration of the mucosa accentuating the microvasculature pattern as haemoglobin has a peak absorption spectrum towards both these wave lengths. The quality of the surface pit pattern morphology is also clearly enhanced by this technology. It enables the endoscopist to

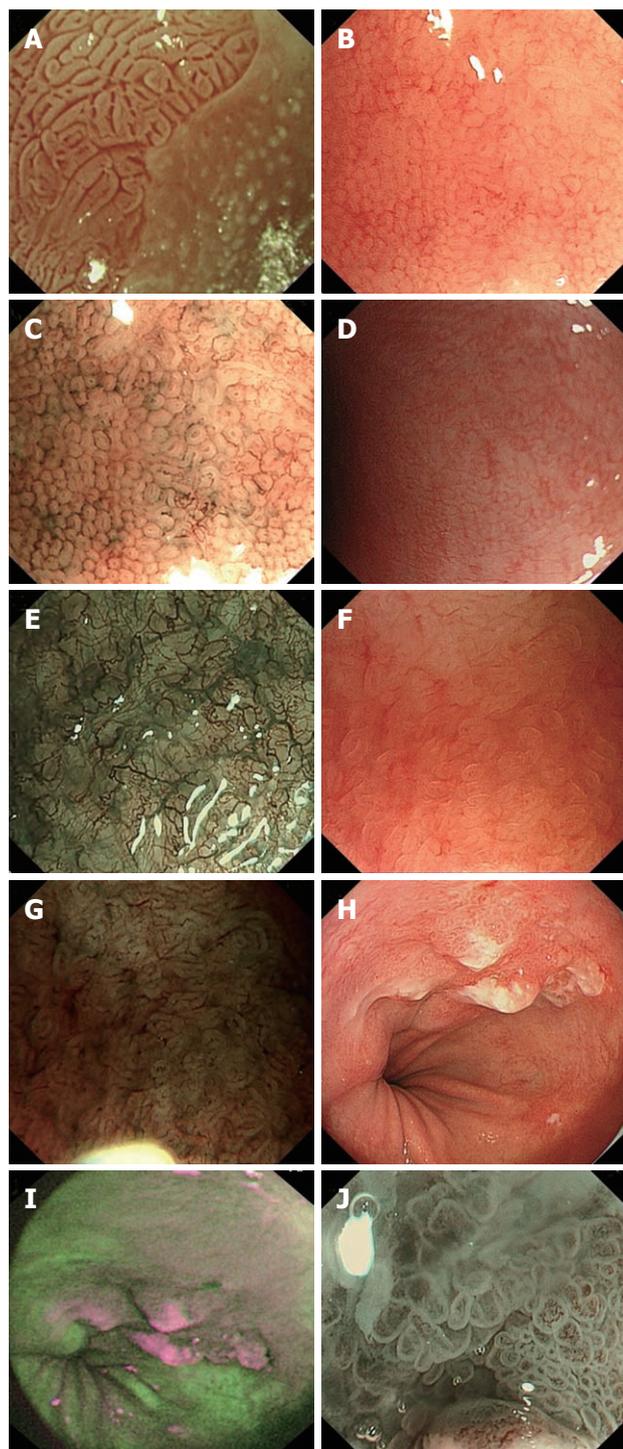

Figure 1 Images of various advanced imaging modalities in Barrett's oesophagus. A: Acetic acid used to visualise Barrett's oesophagus, ridge pattern signifying Intestinal metaplasia; B: High magnification white light endoscopy-round pits in keeping with columnar mucosa without intestinal metaplasia; C: Corresponding area on image B seen with narrow band imaging (NBI) and magnification; D: High magnification white light endoscopy - absent pits in keeping with columnar mucosa with intestinal metaplasia; E: Corresponding area on image D seen with NBI and magnification; F: High magnification white light endoscopy - villous/ridge pits in keeping with columnar mucosa with intestinal metaplasia; G: Corresponding area on image F seen with NBI and magnification; H: White light endoscopy of Barrett's cancer; I: Corresponding area on autofluorescence imaging; J: Abnormal area on NBI with magnification showing total distortion of the pit pattern.

switch between conventional white light and NBI views easily and quickly during the procedure, thus making the procedure itself less messy and cumbersome compared to chromoendoscopy. By depressing a lever on the endoscope, the focal distance of the lens at the tip of the endoscope can be adjusted electronically thus enabling the endoscopist to achieve a maximal magnification of 115X in real time. NBI has been evaluated in BE with very promising results^[39-43]. A recent meta-analysis of 8 published studies which included 446 patients with 2194 lesions showed that NBI-Z has high diagnostic precision in detecting high grade dysplasia with a sensitivity and specificity of 96% and 94%, respectively^[44]. However, the results of NBI-Z in characterising SIM were inferior with a sensitivity of 95% and a specificity of 65%.

Trimodal imaging

With various new technologies available, it was inevitable that combining them into a single system was the next step forward, hence the introduction of the novel concept of trimodal imaging. This modality incorporates three advanced endoscopy imaging techniques into a single endoscope: HRME (Figure 1H), AFI (Figure 1I) and NBI (Figure 1J), thereby enabling the endoscopist to use all 3 modalities during a single procedure. Promising early results have been reported in a multicentre feasibility study^[45] and more recently in a multicentre randomised cross-over study^[46].

CONCLUSION

Although chromoendoscopy has been available for more than 20 years, the lack of standardisation of the technique is one major reason for the indifference towards it. The dearth of well controlled studies that determine its clinical utility, cost efficacy, patient acceptance and tolerability in terms of the additional time needed are amongst the other reasons why chromoendoscopy has not truly caught on. With the rapid development of various novel technologies, it seems that the ideal endoscopy system could very well be on the horizon. It would incorporate a "red flag" technique similar to the AFI system but with hopefully a lower rate of false positives followed on by further detailed interrogation of the suspicious area detected by the technique with either NBI or a confocal probe to obtain "optical biopsies". This may enable the endoscopist to ascertain the histopathological diagnosis in real time. There are, however, numerous issues which would need to be overcome. Standardisation of the various classification systems as well as incorporation of all these techniques into a single easily managed, less bulky unit which is financially viable and less time consuming could eventually lead to widespread availability of a technique in the community.

Abstract

The emergence of endoscopy for the diagnosis of gastrointestinal diseases and the treatment of gastrointestinal diseases has brought great changes. The mere observation of anatomy with the imaging mode using modern endoscopy has played a significant role in this regard. However, increasing numbers of endoscopies have exposed additional deficiencies and defects such as anatomically similar diseases. Endoscopy can be used to examine lesions that are difficult to identify and diagnose. Early disease detection requires that substantive changes in biological function should be observed, but in the absence of marked morphological changes, endoscopic detection and diagnosis are difficult. Disease detection requires not only anatomic but also functional imaging to achieve a comprehensive interpretation and understanding. Therefore, we must ask if endoscopic examination can be integrated with both anatomic imaging and functional imaging. In recent years, as molecular biology and medical imaging technology have further developed, more functional imaging methods have emerged. This paper is a review of the literature related to endoscopic optical imaging methods in the hopes of initiating integration of functional imaging and anatomical imaging to yield a new and more effective type of endoscopy.

INTRODUCTION

Traditional endoscopic imaging of anatomical lesions has mainly been used for disease diagnosis. This imaging modality for diagnosing gastrointestinal diseases has been very successful, but the use of only anatomic imaging as an endoscopic imaging modality has exposed a number of shortcomings. Many diseases show not only anatomical abnormalities, but also dysfunction, which can be difficult to diagnose based solely on anatomical observations and differential diagnosis. Thus, it seems important to combine endoscopy with anatomical and functional imaging. In recent years, as molecular biology and medical imaging have rapidly developed, more functional imaging methods have emerged and may be the future of endoscopy. This paper will focus on the latest imaging methods, especially those closely related to endoscopic methods for optical imaging. We hope a combination of functional imaging and anatomical imaging will be developed for endoscopy.

OPTICAL COHERENCE TOMOGRAPHY

In 1990, the Austrian scientist Fercher first reported the

use of low-time coherent optical interferometric techniques (low time_coherence interferometry) to observe the topology of the human retina^[1]. The following year, Huang *et al.*^[1] at the Massachusetts Institute of Technology used optical coherence tomography (OCT) technology to image microstructure of the coronary artery. OCT technology has since developed rapidly^[2,3]. OCT technology as a low-coherence interferometer has been used together with confocal scanning microscopy and heterodyne detection techniques to non-invasively obtain internal information on living structures and physiological functions. The imaging depth is in the millimeter range, and the spatial resolution is in the micrometer range. Thus, OCT technology has quickly become a focus in biomedical imaging research. It is now considered a promising, non-destructive, high-resolution, real-time imaging technique and is the next most promising technique for optical imaging^[4,5].

OCT technology provides micrometer-scale images of opaque or translucent tissue superficial cross-sectional imaging. OCT imaging and ultrasound imaging are similar, except that OCT uses near-infrared light instead of ultrasound, and is aptly called “light ultrasound imaging”^[2]. OCT is generally composed of five parameters: the light source, beam splitter, reference mirror, detector and image sample. First, given the low temporal coherence light source, exposure to the beam splitter causes part of the sample to be exposed to light through the spectroscope. Another portion of light is reflected to the reference beam splitter mirror and generates a Doppler shift effect. Then, the beam from the reference mirror and different depths of the sample are reflected back together and are received by the detector. When the optical path between the two beams is less than the low-coherent light coherence length of time, it will produce more obvious interference, which is called the “coherence gate”. With the use of coherent gate technology, OCT can differentiate sample depths due to separation of the reflected light to reveal structural information and thus the direction of imaging^[6].

Currently, OCT technology has developed into a new, cutting-edge diagnostic technique and plays an important role in examining the eye, heart, gastrointestinal tract and skin and in diagnosing cancer and other diseases. In 2005, Evans *et al.*^[7] described technical monitoring and diagnosis using OCT to examine Barrett’s esophagus and reported that this technology can be used to view a certain depth of the digestive tract with cross-sectional imaging and can reliably identify high-level changes and intestinal tumors of Barrett’s esophagus. In 2010, Woitkowski^[8] reported basic and applied research reports describing high-speed OCT imaging. OCT technology has the potential to distinguish between metabolism and function to achieve functional imaging^[9-13]. In the same year, Fercher^[4] published reports showing that endoscopic OCT technology can not overcome the traditional shortcomings of the depth of imaging. However it is very good for examining the mu-

cosa, lamina propria, mucosal primary and submucosa and can accurately assess the esophagus, stomach, duodenum, pancreas and bile duct, and diagnose colorectal and other diseases, especially atypical hyperplasia, intestinal metaplasia, Barrett’s esophagus and pancreatic duct diseases. In 2011, Srinivasan *et al.*^[14] reported the use of OCT technology to examine cerebral blood flow and removed the quantitative determination of hydrogen ions. This study showed the huge potential of using cerebral vascular imaging to examine physiological functions, thus confirming OCT technology as a non-invasive method for quantitative determination of cerebral blood flow and metabolism.

Currently, OCT technology is carried out first for digestive diseases and reports of functional imaging studies are increasing. Given the non-invasive, high resolution, multi-level, real-time imaging and functional imaging features, as well as many other advantages, OCT technology will likely play an increasingly important role in the diagnosis of gastrointestinal diseases

FLUORESCENCE MOLECULAR IMAGING

Fluorescence molecular imaging (FMI) is an important branch of optical molecular imaging. FMI is non-invasive, uses non-ionizing radiation, has high resolution and sensitivity, is quick, easy and inexpensive, has relatively high access, and has many other advantages, which have developed rapidly in recent years^[15]. The 2008 Nobel Prize in Chemistry was awarded for discovering uses for green fluorescent protein, which is widely used in the scientific community. Green fluorescent protein is a molecular probe in FMI technology, and the clinical application of imaging methods has great potential in the field of optical imaging.

Molecules in different states and at different energy levels absorb photons of different wavelengths. Molecular absorption of light involves upward transitions from ground state molecules to the excited state, called the excitation light. When molecules are excited, they transition from the excited state to the ground state and emit light. When a molecule absorbs a photon of energy and transitions from one electronic state to another low-energy electronic state, the luminescence is called fluorescence^[15]. In short, the production of fluorescent molecular probes involves the process of absorbing fluorescent energy to the excited state after the transition, which occurs after a short stay and returns to the ground state emitting fluorescence^[16]. According to different fluorescent substances, FMI can be divided into two broad categories: direct fluorescence imaging and indirect fluorescence imaging. In the direct fluorescence imaging mode, a fluorescent substance is injected. Exogenous dyes or fluorescent probes then target specific molecules. For example, such probes are currently used for fluorescence imaging of human breast tissue. In the indirect fluorescence imaging mode, the fluorescent material is fluorescent protein. In this imaging mode,

no fluorescent substances are injected to find the target. Due to the need for genetic modification for indirect fluorescence imaging, this technology can not be applied to the human body. Currently, FMI technology can be divided into a two-dimensional technique and three-dimensional space-oriented fluorescence molecular tomography (FMT) technology^[13-18]. Charge-coupled device (CCD) cameras are used in the two-dimensional FMI system by directly inducing the tissue imaging surface to fluoresce. The fluorescent image is added to the white image, which shows the general distribution of fluorescence in the body. However, because of high scattering in biological tissue, fluorescence images obtained this way do not accurately reflect the organization or spatial distribution of fluorescent material. Furthermore, FMI is difficult to use for quantitative analysis, and therefore, its application in some studies is limited. Three-dimensional FMT utilizes optical imaging to analyze absorption and scattering in the sample and the receiving surface of the light intensity. Mathematical methods are used to reconstruct the distribution in body tissue and the concentration of fluorescent material. Thus, three-dimensional FMT provides relatively accurate quantitative analysis.

In 2007, Montet^[19] used FMT in experimental animals to examine tumor blood vessels and thus demonstrated the success of functional imaging. In the same year, Corlu *et al.*^[20] reported the use of FMT technology in human breast cancer and showed clear imaging. Using indocyanine green (ICG) as a fluorescent dye and magnetic resonance imaging, diffuse optical tomography images were compared showing the accuracy of FMT imaging, the optical FMT image and the high contrast ratio of diffuse optical tomography^[20]. In 2008, Willmann^[21] and others used FMI imaging technology in the field of drug discovery. Currently, reports of the use of FMI technology for human body imaging are few, partly because only ICG is approved for use in humans and because fluorescence spreads a short distance, limiting its application in the human body. AS FMI technology continues to improve, its application will be further expanded.

PHOTOACOUSTIC TOMOGRAPHY

As early as 1880, workers at Bell Labs discovered the photoacoustic phenomenon. Over the last century, combinations of the photoacoustic effect, modern laser technology and weak signal monitoring technology have developed rapidly. In the 1970s, the photoacoustic effect was used to develop photoacoustic spectroscopy. In the 1980s, photoacoustic imaging of biological tissues was introduced. Currently, photoacoustic tomography (PAT) technology represents a new generation of biomedical imaging technology. Combined with the optical advantages of imaging and ultrasound imaging, PAT can provide high resolution and high contrast imaging and can provide structural and functional imaging of biological tissues to study tissue morphology, physiological characteristics, pathological characteristics and metabolic

functions^[22-24].

Beam irradiation occurs with a varying absorber that cause thermal expansion of ultrasound, a phenomenon known as the photoacoustic effect, which is the "light" produced by the ultrasonic acoustic signal^[25]. PAT imaging involves a beam of pulsed light that shines on a sample. Multiple ultrasonic detectors detect the light emitted by the acoustic signal, and then mathematical methods are used to reconstruct the photoacoustic signals to produce a three-dimensional image. An advantage of traditional optical imaging is that the image is better. However, a significant limitation involves the depth and spatial resolution. Thus, the light diffusion caused by the strong high spatial resolution is accompanied by a sharp drop in the imaging depth, and vice versa. Ultrasound imaging increases the depth of tissue that can be examined and has the advantages of larger, higher spatial resolution, but has the disadvantage of an image with poor contrast between the different types of tissues. PAT is a hybrid type of imaging technology, which combines optical imaging and ultrasound imaging with the advantages of both, utilizing the absorption properties of biological tissues to obtain an image with higher image contrast and higher resolution^[26].

For early diagnosis of disease, PAT light absorption for tissue imaging, and the optical absorption properties to examine biological tissues, tissue function and pathological features of a structure are closely related to differences in the parameters of optical imaging. In recent years, research on the application of PAT imaging has increased. Oraevsky *et al.*^[27] used PAT technology to examine hamster buccal squamous cell carcinoma at different stages of capsule imaging, using a wavelength of 532 nm and 12 ns of YAG (Yttrium aluminum garnet) pulsed laser excitation to clearly show photoacoustic images of pre-cancerous tissue. Wang *et al.*^[28] used three-dimensional PAT to show clear images of rat brain structures such as blood vessels, cerebellum and hippocampal processes. Further photoacoustic images of optical information reflected in the quantitative analysis and calibration were obtained with a photoacoustic signal corresponding to physiological parameters to achieve functional imaging of the rat brain. Esenaliev *et al.*^[29] performed a photoacoustic imaging study of brain structure and blood vessel dynamics in the brain by monitoring dynamic changes in cerebral blood oxygenation. Ku *et al.*^[30] used PAT to image blood vessels, to more clearly distinguish the location of a tumor. Several groups took advantage of the nature of differences in absorption and PAT to image tumor tissue and surrounding normal tissue for early diagnosis of breast cancer, showing that this technology can be combined with traditional techniques such as X-radiography and breast ultrasound imaging to produce high contrast, high resolution, non-ionizing images^[31-33]. Li *et al.*^[34] reported a molecular probe that was used as a PAT contrast agent, to show that the absorption spectra of hemoglobin are different in specific molecules in biological tissue. After calibra-

tion, an imaging experiment with multi-wavelength PAT and mathematical modeling of the contribution of the molecular probe to the optical image was used to subtract the background to achieve specific photoacoustic imaging.

Currently, despite high-resolution three-dimensional optical imaging modes, including confocal microscopy and two-photon microscopy, OCT has become fundamentally embedded in bio-medical research. However, these imaging methods cannot image deeper tissues. Photoacoustic imaging in the same signal mode, combined with a powerful optical joint ultrasound contrast and resolution, results in exceeding previous depth limits, resulting in deep tissue high-resolution optical images. At the same time, use of this technology can provide functional imaging, including analysis of oxygen use, blood flow, tumor blood vessels, and many other functions. In the future, photoacoustic imaging is expected to become the mainstream optical imaging mode and should result in development of this technology for endoscopic examination^[35].

CERENKOV LUMINESCENCE TOMOGRAPHY

Cerenkov luminescence Tomography (CLT) technology has progressed from the emergence of modern physics and detectors resulting in technological progress. In 1901, Kelvin proposed that the speed of particle radiation may exceed the speed of light^[36]. In 1933, Soviet scientist Vavilov Cerenkov used photometric technology in guided research and accidentally discovered faint blue fluorescence^[37]. In 1934, Cerenkov and colleagues confirmed that this faint blue Cerenkov radiation was fluorescence and was a new physical phenomenon. A charged particle moves in medium faster than the speed of light and emits electromagnetic radiation, known as Cerenkov radiation. In 1958 Cerenkov, Frank and Tamm won the Nobel Prize in Physics for this discovery. Since then, research involving Cerenkov radiation has been widely performed.

CLT technology is based on the principles of Cerenkov radiation physics. Small amounts of high-speed charged particles are emitted following *in vivo* injection of radioactive molecular probes. The use of low-light imaging devices in the body provides non-invasive detection of fluorescent molecular probes due to the release of Cerenkov signals. These signals are detected with a computer, which is used for data processing to produce Cerenkov luminescence imaging (CLI). Recently, *in vivo* molecular imaging probes and systems technology have been developed for CLT. ¹⁸F-FDG is a molecular probe in nuclear medicine and has played an increasingly important role in the development of low-light CCD imaging in both basic and clinical research.

In 2009, Cho *et al.*^[38] used the blue spectrum, its highly sensitive quantum effects and a dominant photomultiplier tube to detect a microchip with weak ¹⁸F-FDG-

induced fluorescence. Robertson *et al.*^[39] used a highly sensitive CCD and semiconductor cooling to detect *in vivo*-induced weak fluorescence in animals. Spinelli *et al.*^[40] used a multi-spectrum fluorescent light source in the body to successfully obtain the deep information. The essence of these experiments is the Cerenkov effect. CLT technologies employ commonly available optical detectors to observe the release of high-speed charged particles with the high sensitivity of radionuclide isotope imaging. These probes that are used in such studies in molecular nuclear medicine and functional imaging are new tools. In 2010, at the Sloan-Kettering Cancer Center in the United States Ruggiero *et al.*^[41] suggested that neither the CLI value nor positron emission is adopted to achieve gamma-ray radionuclide imaging, which can be achieved with radioactive tracers. CLI optical imaging technology is a potential new imaging mode because it can be used for quantitative assessment of exposure. In 2011, Boschi *et al.*^[42] used Cerenkov radiation in small animals *in vivo* to measure ¹⁸F-FDG uptake in tumors. This experiment showed the feasibility of using a traditional optical imaging device to study the metabolism of tumor tissue *in vivo* and that ¹⁸F-FDG PET and conventional optical imaging could be used as a dual-mode device.

Although CLT technology is still in the exploratory stage and has not been used for functional imaging in humans, functional imaging experiments in animals have shown excellent potential. In the future, the use of CLT technology combined with traditional endoscopic techniques for functional imaging may be meaningful.

ANALYSIS AND PERSPECTIVES

Endoscopy was invented 100 years ago, and has gone from hard to soft endoscopy, from endoscopy to the electronic endoscope, from ordinary white light endoscopy to new types of endoscopy, such as magnifying endoscopy, FICE endoscopy, NBI endoscopy, i-scan endoscopy, fluorescence endoscopy, confocal endoscopy, *etc.* and today's doctors are almost overwhelmed by the different types of endoscope. However, looking at the history of endoscopy over the last hundred years highlights both changing and unchanging eternal themes. One change is that high magnification endoscopy is gradually moving towards the micro-microscopic world, and endoscopy continues to develop with the unchanging goal of observing anatomic morphology. Diagnosis of gastrointestinal disease has greatly improved with endoscopy over the past 45 years. During this time, we have discovered approximately 200 types of gastrointestinal diseases. Abandoning endoscopy will be almost impossible. Therefore, the past 45 years have been a brilliant era in endoscopy^[43].

However, endoscopic diagnosis at this stage is also facing many challenges including the following: (1) early diagnosis of digestive tract cancer, because endoscopic intervention has not significantly increased; (2) the deep

mucosa and submucosa and lesions of the mucous membrane are difficult to imaging and assess; (3) microvascular imaging of the mucosa and submucosa is difficult to assess; and (4) anatomic lesions with similar endoscopic images are difficult to distinguish, etc. For these problems, the existing endoscopic imaging of morphology as the only mode has deficiencies and shortcomings. Using only gastrointestinal endoscopy for early cancer diagnosis, for example, may require introduction of new endoscopic techniques. Many experts have attempted to develop advanced endoscopic procedures to find cancer earlier despite the economic concerns and the fact that awareness of the public concerning their health has significantly improved. Today, more and more people undergo endoscopy, even though all the external conditions are favorable for developing endoscopic techniques for early diagnosis of cancer. The rate of early diagnosis of gastric cancer in China still hovers around 10%. Little has changed over the last 10 years, even with a focus on early endoscopic diagnosis of carcinoma in the top domestic endoscopy center. Similar results are seen in most of the rest of the world. Indeed, early diagnosis of cancer is a very complex issue, and in addition to endoscopy, there are many other factors. However, other factors aside, what role does endoscopy play in the early diagnosis of digestive tract cancer? Can endoscopic morphology be used solely to identify early cancer? In addition to anatomical observation, can functional endoscopic imaging also be used? Although endoscopic diagnosis of only early cancer has been discussed, other diseases, including Crohn's disease, intestinal tuberculosis, and other gastrointestinal diseases, can be diagnosed relying on existing morphology-based imaging. Endoscopic identification and diagnosis will be very difficult and challenging. Changes to the existing single anatomic endoscopic imaging modality are necessary and may include the integration of a functional imaging mode. The new Multimode endoscopy with functional imaging and anatomical imaging integration may be an effective way to solve these problems. These changes will allow earlier examination of morphological changes. In addition, functional imaging of the organism, metabolism, blood flow, and many other biological parameters offer a more comprehensive interpretation of lesions. Combined with anatomical imaging, functional imaging may permit a view of shape and function of living tissue. Changing the present single form of endoscopic morphology to include functional imaging will be a revolutionary change in modern endoscopy.

Currently, multi-modal fusion of modern medical imaging technology has become a major technology trend^[44]. Positron Emission Computed Tomography (PET-CT) is an example of this idea. Recently, multi-modal integration of new imaging technologies has emerged, such as development of Optical PET (O-PET) detectors at the University of California, Los Angeles by Prout *et al*^[45]. O-PET can detect spontaneous and gamma-ray fluorescence signals, enabling optical signals and

the integration of PET imaging. Undoubtedly, future research and development of endoscopic techniques provides a new way of thinking. A critical moment for the future of endoscopy has occurred. Should anatomical imaging continue or should it conform to multi-modal fusion imaging trends with the integration of a bolder change? Careful consideration is required. In our opinion, the future should involve functional imaging, anatomical imaging, two-dimensional imaging, and three-dimensional imaging combined with a variety of newly integrated imaging and endoscopic technologies.

CONCLUSION

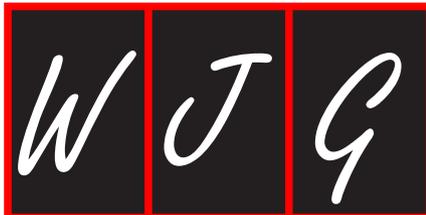

The basic anatomical observation available with existing endoscopy is a brilliant achievement, but it has also exposed many shortcomings. Development of more powerful endoscopic techniques in the future is an important issue. New optical imaging technology may soon be available for us to learn from. The future involves actively developing a set of functional imaging and anatomical imaging techniques which result in a multi-modal fusion of endoscopic techniques.

Abstract

Heme oxygenase-1 (HO-1) system catalyzes heme to biologically active products: carbon monoxide, biliverdin/bilirubin and free iron. It is involved in maintaining cellular homeostasis and many physiological and pathophysiological processes. A growing body of evidence indicates that HO-1 activation may play an important protective role in acute and chronic inflammation of gastrointestinal tract. This review focuses on the current understanding of the physiological significance of HO-1 induction and its possible roles in

the gastrointestinal inflammation studied to date. The ability to upregulate HO-1 by pharmacological means or using gene therapy may offer therapeutic strategies for gastrointestinal inflammation in the future.

INTRODUCTION

Heme oxygenase (HO) is the rate-limiting enzyme in heme catabolism, a process which leads to the generation of equimolar quantities of carbon monoxide (CO), Fe²⁺ and biliverdin. Three distinct HO isoforms (HO-1, HO-2 and HO-3) have been identified to date, which are the products of different genes. HO-2 is constitutively and most highly expressed in neuronal tissues contributing to cell homeostasis, whereas HO-1, also referred to as heat shock protein-32 (Hsp32), is an inducible enzyme and expressed at a relatively low level in most tissues^[1]. HO-3 has been found only in the rat brain, but no activity in humans^[2].

Unlike the constitutively expressed HO-2, HO-1 is exquisitely sensitive, not only to heavy metals^[3], but also to all kinds of stimuli and agents that cause oxidative stress and pathological conditions. Induction of the HO-1 protein has been reported to protect against a variety of stress conditions such as ischemia^[4], hemorrhagic shock^[5], heat

shock^[6], hypoxia^[7], and reactive oxygen species (ROS)^[8].

In fact, there has been no other enzyme described to date that is affected by so many stimuli of diverse nature as HO-1^[1]. The strong adaptive response of HO-1 to various stimuli suggests that pharmacologic modulation of HO-1 system may represent an effective and cooperative strategy to intervene in protection against inflammatory processes and oxidative tissue injury. HO-1 is expressed constitutively in normal gastric, intestinal and colonic mucosa^[9,10] and up-regulated in their inflamed tissues^[10]. What implications of HO-1 are in gastrointestinal inflammation and injury? In this review, we focus on this subject, and elucidated the mechanisms and some potential clinical applications to gastrointestinal inflammation.

UPREGULATION OF HO-1 IN GASTROINTESTINAL TRACT

Interestingly, expression of HO-1 is usually increased in gastrointestinal inflammation and injury. This was shown in gastric ulcers^[11], colitis^[12,13], radiation enteritis^[14], inflammatory bowel disease (IBD)^[15] of animal models or patients. Moreover, HO-1 is expressed constitutively in normal gastrointestinal tract (GIT)^[9,10].

The GIT is lined by a simple epithelium that separates the hostile processes of digestion and absorption that occur in the intestinal lumen from the aseptic environment of the internal milieu by defensive mechanisms.^[16] GIT undergoes constant oxidative stress, inflammation and cell cycle/apoptosis. The normal expression and up-regulation of HO-1 indicate that activation of HO-1 could act as a natural defensive mechanism to alleviate inflammation and tissue injury in the GIT^[13,17,18].

ROLE OF HO-1 IN GASTROINTESTINAL INFLAMMATION AND INJURY

HO-1 is commonly regarded as a potent anti-inflammatory enzyme and has anti-inflammatory properties. For example, HO-1 upregulated by hemin^[19], heme^[20] and cobalt-protoporphyrin^[21] can ameliorate experimental colitis. Conversely, administration with HO inhibitor (tin mesoporphyrin, SnMP) results in exacerbation of experimental colitis along with a reduction in HO-1 activity^[12].

In addition, the mechanism of action of 5-aminosalicylic acid (5-ASA, an anti-colitis agent used clinically) is attributed in part to the up-regulation of HO-1 enzyme expression and activity^[22]. Moreover, some agents including glutamine^[9,23], tranilast^[24], RDP58^[25], Octreotide^[26,27], lansoprazole^[28-30], Ketamine^[31] Polaprezinc (PZ, an anti-ulcer drug)^[32] and gliotoxin^[33] may contribute to the preservation of gastrointestinal mucosa in some experimental models, such as colitis, radiation enteritis, and acute gastric mucosal lesions. This protective effect is partly mediated by the induction of HO-1 expression.

Nuclear factor-erythroid 2-related factor 2 (Nrf2) has

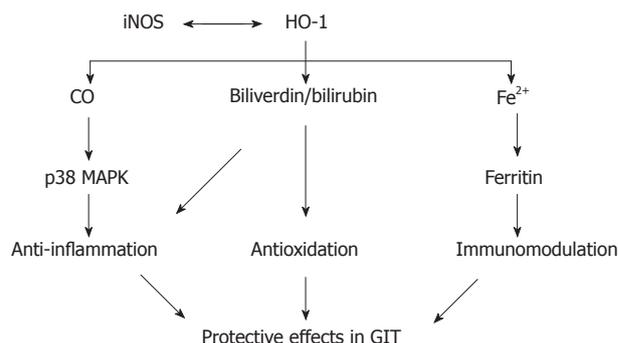

Figure 1 Cytoprotective effects of heme oxygenase-1 pathway in gastrointestinal inflammation. CO: Carbon monoxide; GIT: Gastrointestinal tract; HO-1: Heme oxygenase-1; iNOS: Inducible nitric oxide synthase; MAPK: Mitogen-activated protein kinase.

been known to be a transcriptional factor which plays a crucial role in cytoprotection against inflammation. The severity of colitis induced by dextran sulphate sodium (DSS) in Nrf2-deficient mice is found to be associated with decreased expression of HO-1^[34].

These results demonstrate that HO-1 may be implicated in cytoprotection and may be an effective agent for the treatment of diseases characterized by mucosal inflammation in GIT.

MECHANISMS OF ACTION

HO-1 seems to have an important protective role in acute and chronic inflammation of GIT. HO-1 is the key enzyme in heme degradation and plays a key role in regulating the intracellular heme level. HO-1 activity means rapid removal of free heme, which is shown to be cytotoxic. Thus, HO-1 is associated with a protective response and contributes to the preservation of GIT mucosa (Figure 1).

CO AND GASTROINTESTINAL INFLAMMATION

Almost all CO produced *in vivo* comes from the degradation of heme by HO. Evidences indicate that CO mediates many of the biological actions of HO-1^[35]. Otterbein *et al*^[36] demonstrate that CO can inhibit the production of proinflammatory cytokines [tumor necrosis factor (TNF)- α , interleukin (IL)-1 β , and macrophage inflammatory protein-1 β] and stimulate the synthesis of the anti-inflammatory cytokine interleukin-10. Other studies also suggest that CO implicates in mediating the anti-inflammatory actions^[37,38].

Hegazi *et al*^[39] have shown that CO at a low concentration mitigates chronic intestinal inflammation in a T helper-type-1 cell-mediated mouse model of murine colitis in IL 10-deficient mice and protect against the development of postoperative ileus (POI) and necrotising enterocolitis in rodents and swine^[40-42]. Moreover, Scott *et al*^[43] demonstrate that low-dose inhaled CO selectively attenuates the remote intestinal inflammatory response

elicited by hindlimb ischemia-reperfusion. And pre-treatment with CO-releasing molecules (CO-RMs) markedly reduced intestinal muscularis inflammation induced by surgical manipulation of the small intestine^[44]. The anti-inflammatory actions of CO can be in large measure mediated through p38 mitogen-activated protein kinase (MAPK) pathway^[36,37].

The knowledge of the role of CO in gastrointestinal inflammation is limited, but such a mechanism could be operative in GIT. Recently, **Chin *et al*^[45] pointed out that CO has been ascribed an additional novel role as a host defense molecule agent against microbes (bactericidal agent).**

BILIVERDIN/BILIRUBIN AND GASTROINTESTINAL INFLAMMATION

HO-1 catalyzes the rate-limiting step in heme degradation to biliverdin. Biliverdin is, in turn, converted into bilirubin by biliverdin reductase at the expense of nicotinamide adenine dinucleotide phosphate (NADPH). Biliverdin and bilirubin are reducing species and hence potential **antioxidants**^[46,47]. Several studies have demonstrated that the administration of biliverdin and/or bilirubin is potently cytoprotective in a variety of pathophysiological events, including ischemia-reperfusion injury, and **transplant rejection**^[48,49]. In addition, bilirubin is also known to modulate immune effector functions and suppress inflammatory response^[50].

Treatment with biliverdin can significantly decrease mRNA expression of inducible nitric oxide synthase (iNOS), cyclooxygenase 2, and intercellular adhesion molecule-1 as well as the inflammatory cytokines IL-6 and IL-1 β , and decreased neutrophil infiltration into the jejunal muscularis in rat syngeneic small intestinal transplants^[51]. Hayashi *et al*^[52] demonstrate that the effects of HO-1 induction on leukocyte adhesion could be mimicked by bilirubin. In addition, the study of Lee *et al*^[53] show that bilirubin exerts anti-inflammatory effects *in vitro*.

The data indicate that this product of HO reaction play an important role in the anti-inflammatory effects of HO-1. However, there has been **no report about the measurement of tissue levels of biliverdin/bilirubin in human GIT, and even the role of the biliverdin/bilirubin pathway has not been clarified in experimental model of gastrointestinal inflammation.**

Fe²⁺ AND GASTROINTESTINAL INFLAMMATION

Fe²⁺, the third product of heme decomposition, can be potentially toxic, but it **can upregulate an iron-transporter pump that removes intracellular Fe²⁺ from the cell**^[54] and induces the expression of ferritin, an iron storing protein^[55]. Expression of ferritin is originally reported to protect endothelial cells **against oxidant damage *in vitro***^[55]. In addition, over-expression of H-ferritin (heavy

chain ferritin) has also been shown to protect cultured endothelial cells from undergoing apoptosis and protect livers from transplant-associated ischemia-reperfusion injury^[56]. Increased ferritin protein levels induced by lansoprazole in endothelial cells and macrophages can reduce NADPH-dependent ROS formation, indicating that **ferritin may account for the gastric protection of lansoprazole**^[30].

Although the roles of the iron and ferritin in the overall cytoprotective effect of HO-1 are not clear, presumably both contribute in a crucial manner to the overall antioxidant effect following increased HO-1 expression in a variety of situations^[57]. Further work is clearly needed in this area.

The exact mechanisms underlying the anti-inflammatory functions of the HO-1 in gastrointestinal inflammation have not been fully elucidated. However, the signaling action of CO combined/or complemented by the antioxidant properties of biliverdin/bilirubin and the sequestration of iron by ferritin could all contribute to suppression of inflammation^[58]. It becomes **clear that upregulation of HO-1 and/or exogenous administration of one or more of its products would be therapeutic strategies for gastrointestinal inflammation.**

HO-1 AND iNOS

The inducible isoform of nitric oxide synthase (iNOS) can produce sustained high quantities of nitric oxide (NO), which may be involved in the mucosal injury associated with IBD. Indeed, upregulation of iNOS or NO release has been demonstrated in **both ulcerative colitis and Crohn's disease**^[59,60]. HO-1 inducers, cadmium and bismuth salts, heme, and nitric oxide (NO) donors, act at the transcriptional level inhibiting iNOS mRNA expression *in vitro*^[61]. Wang *et al*^[12] investigated the **possible role of HO-1 in experimental colitis in rats.** Their data show that HO-1 plays a protective role in the colonic damage, and this **effect probably result in part from inhibition of iNOS expression in colonic tissues.** Moreover, Dijkstra *et al*^[62] demonstrate opposite regulation of iNOS and HO-1 in intestinal epithelial cells in response to cytokine exposure and oxidative stress. These findings suggest that HO-1/CO and iNOS/NO system may act together in a complex, dynamic, and adaptable association in gastrointestinal inflammation, which remain to be elucidated further.

HO-1 PROMOTER POLYMORPHISM

HO-1 is known as an oxidative stress responsive protein that is upregulated by multiple stimuli, **which has been proposed to provide an important cellular response that protects cells against oxidative damage.** However, humans differ quantitatively in their ability to mount an HO-1 response.

An *HO-1* gene promoter microsatellite (GT)(*n*) dinucleotide repeat polymorphism is associated with

regulation of HO-1 in response to inflammatory stimuli. Short GT repeats (< 25) are associated with highly significant up-regulation of HO-1 in response to inflammatory stimuli^[63,64]. The investigators have studied the association between the HO-1 genotype and gastrointestinal inflammation. They investigated the variants of the HO-1 promoter region in 179 patients with Crohn's disease, 110 with ulcerative colitis and 56 control patients without inflammation. The data show that (GT)_(n) dinucleotide repeats of the HO-1 promoter region have no significance for the pathophysiology and disease course of IBD^[65]. In gastrointestinal tumors, a potential impact of the (GT)_(n) repeat polymorphism has been demonstrated^[66]. But in gastrointestinal inflammation diseases which usually associate tumors, it remains to be verified.

CONCLUSION

Chronic inflammatory disorders in GIT have been linked with an increased risk of the development of gastrointestinal tumors^[66]. It is well known that HO-1 is involved in inflammation and have protective effects in GIT against inflammation and oxidative injury; thus, the modulation of HO-1 through pharmacological means or the use of gene therapy may offer therapeutic strategies for gastrointestinal inflammation and more importantly, to prevent gastrointestinal cancer. A comprehensive understanding of the underlying mechanisms for the observed effects of HO-1 in gastrointestinal inflammation will be necessary in the future.

Abstract

AIM: To investigate potential antitumor effects of rAd-p53 by determining if it enhanced sensitivity of gastric cancer cells to chemotherapy.

METHODS: Three gastric cancer cell lines with distinct levels of differentiation were treated with various doses of rAd-p53 alone, oxaliplatin (OXA) alone, or a combination of both. Cell growth was assessed with an 3-(4,5)-dimethylthiazoliazol-2-yl-4-methylcarbazole (MTT) assay and the expression levels of p53, Bax and Bcl-2 were determined by immunohistochemistry. The presence of apoptosis and the expression of caspase-3 were determined using flow cytometry.

RESULTS: Treatment with rAd-p53 or OXA alone inhibited gastric cancer cell growth in a time- and dose-dependent manner; moreover, significant synergistic effects were observed when these treatments were combined. Immunohistochemical analysis demonstrated that treatment with rAd-p53 alone, OXA alone or combined treatment led to decreased Bcl-2 expression and increased Bax expression in gastric cancer cells.

Furthermore, flow cytometry showed that rAd-p53 alone, OXA alone or combination treatment induced apoptosis of gastric cancer cells, which was accompanied by increased expression of caspase-3.

CONCLUSION: rAd-p53 enhances the sensitivity of gastric cancer cells to chemotherapy by promoting apoptosis. Thus, our results suggest that p53 gene therapy combined with chemotherapy represents a novel avenue for gastric cancer treatment.

INTRODUCTION

Gastric cancer is the most common malignant tumor of the digestive system. Currently, the major therapeutic methods for the treatment of gastric cancer are surgery, radiotherapy and chemotherapy. Despite recent improvements in these treatments, the 5-year survival rate for gastric cancer patients is only 45%. Thus, the development of new therapeutic approaches for gastric cancer, such as gene therapy, is urgently needed.

p53 is known as the "genome guard" and plays important roles in various cellular processes, including cell cycle regulation, DNA damage repair and apop-

tosis. Genetic mutations in p53 are present in > 50% of human tumor tissues, and it is the most commonly detected genetic mutation in cancer^[1]. Therefore, a gene therapy strategy has been developed that employs rAd-p53, a weakened adenovirus carrying the wild-type p53 gene. rAd-p53 has been shown to inhibit tumor growth, promote apoptosis by inducing the expression of Puma, Bax, Bak and Fas, and to sensitize tumor cells to radiotherapy and chemotherapy^[2]. Clinical application of rAd-p53 has been used to treat lung cancer, breast cancer, oophoroma, liver cancer, and bladder carcinoma. However, few studies have investigated the therapeutic effects of rAd-p53 in gastric cancer.

Genetic mutation of p53 is found in > 60% of gastric cancer cases and has been shown to correlate not only with the onset and prognosis of gastric cancer, but also with the chemosensitivity of gastric cancer^[3]. Thus, we speculated that rAd-p53 could be a potential treatment for gastric cancer. In this study, we investigated the effects of rAd-p53 treatment alone or in combination with oxaliplatin (OXA) on the growth and chemosensitivity of gastric cancer cells. Our results demonstrate that rAd-p53 has antitumor properties in gastric cancer.

MATERIALS AND METHODS

Reagents

rAd-p53 was purchased from Shenzhen Saibainuo Gene Technology Co. Ltd. (Shenzhen, China); OXA was purchased from Jiangsu Hengrui Medicine Co. Ltd. (Lianyungang, China). rAd-p53 was diluted to 5×10^8 virus particles vp/mL or 5×10^{10} vp/mL in saline, and OXA was diluted to 2.5 mg/mL in 5% glucose and stored at -80 °C.

Cell culture

The human gastric cancer lines SGC-7901 (moderately differentiated), BGC-823 (poorly differentiated), and HGC-27 (undifferentiated) were purchased from the Chinese Academy of Sciences (Beijing, China). The cells were cultured in XX media containing 10% fetal bovine serum, 10^5 U/L penicillin, and 100 ng/L streptomycin at 37 °C in 5% CO₂.

MTT assay

Cells were seeded in 96-well plates at 10^4 cells/well and treated with rAd-p53 or OXA for 24, 48 or 72 h at 37 °C. Next, 150 µL MTT was added to each well and incubated for 4 h at 37 °C, followed by addition of 200 µL dimethyl sulfoxide to each well, and 10 min incubation to dissolve the formazan crystals. The absorbance was measured using an ELISA reader (EXL800; Bio-Tek, United States) at 450 nm. The data are presented as mean ± SD of triplicate samples from at least three independent experiments.

The cell growth inhibition ratio was calculated using the following formula: cell growth inhibition ratio (%) = $1 - [(A_s - A_b)/(A_c - A_b)] \times 100\%$, where A_s represents the A value of the experimental well, A_c represents the A value in the control well, and A_b represents the A

value of the blank well.

To determine whether rAd-p53 and OXA had synergistic effects, the following formula was used: $q = (E_a + b)/[(E_a + E_b) - E_a \times E_b]$, where E_a represent the inhibition ratio of rAd-p53, E_b represents the inhibition ratio of OXA, and $E_a + b$ represents the inhibition ratio of the associated group. A q value > 1.15 was considered to indicate a synergistic effect, whereas a q value < 0.85 was considered to indicate a lack of a synergistic effect, and a q value between 0.85 and 1.15 was considered to indicate an additive effect.

Immunohistochemistry

Cells were seeded in six-well plates at 10^6 cells/well and then treated with rAd-p53 or OXA for 24 h. The cells were fixed with acetone for 20 min and then stained using an SP immunohistochemistry kit (Zhongshanqiao, Beijing, China) according to the manufacturer's protocol. In the gastric cancer cells examined, p53 expression was nuclear, whereas Bcl-2 and Bax expression were located in the cytoplasm.

Flow cytometry analysis

Cells were seeded in six-well plates at 5×10^5 cells/well and then treated with rAd-p53 or OXA for 24 h. Apoptotic cells were detected with an apoptosis detection kit (Invitrogen, Eugene, OR, United States).

Statistical analysis

All data were presented as mean ± SD. Statistical analysis was performed using SPSS 13.0. Single factor analysis of variance, least significant difference methods, and Q tests were used for inside group comparisons, group comparisons, and multiple comparisons, respectively. For all analyses, the test size was set to $\alpha = 0.05$. $P < 0.05$ was considered statistically significant.

RESULTS

Treatment with rAd-p53 or OXA inhibits the growth of gastric cancer cells in a time- and dose-dependent manner

The MTT assay results showed that rAd-p53 could inhibit the growth of the gastric cancer cell lines SGC-7901 (moderately differentiated), BGC-823 (poorly differentiated) and HGC-27 (undifferentiated) in a time- and dose-dependent manner (Figure 1A-C). A similar result was observed for OXA treatment (Figure 1D-F). Among the three cell lines, we found that the inhibitory effects of rAd-p53 and OXA were both strongest in SGC-7901 and weakest in HGC-27 when treatment dose and time were kept constant, suggesting that more differentiated gastric cancer cells are more sensitive to rAd-p53 and OXA treatments.

Combined treatment with rAd-p53 and OXA shows a synergistic effect on the inhibition of gastric cancer cell growth

We next used treated the three gastric cancer cell lines

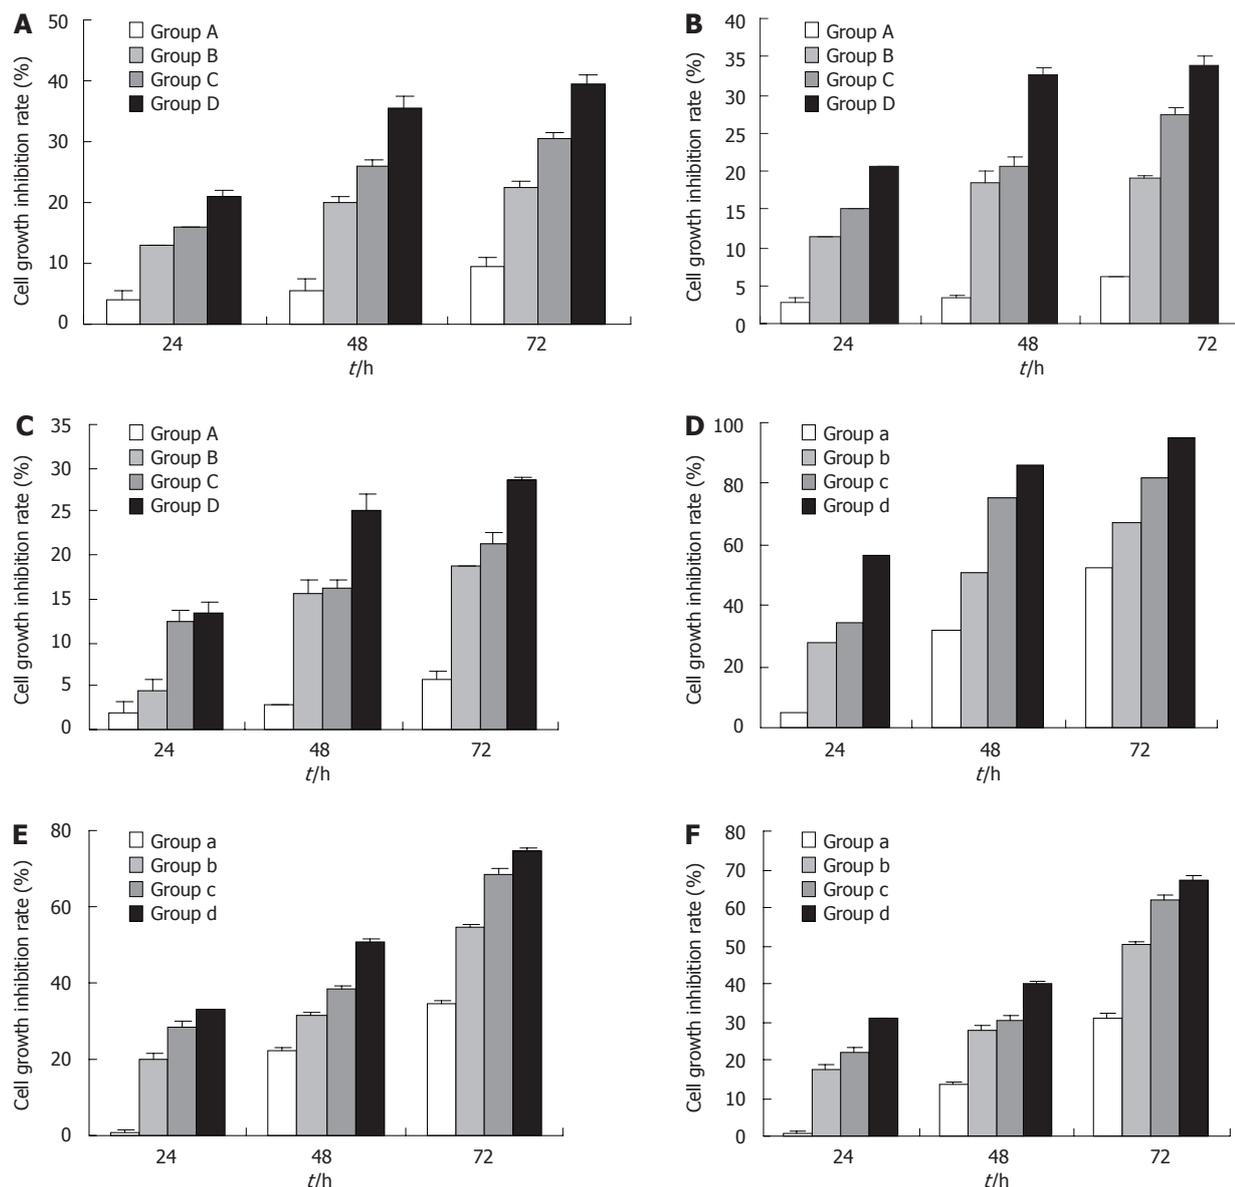

Figure 1 Treatment with rAd-p53 or oxaliplatin alone inhibits the growth of gastric cancer cells in a time- and dose-dependent manner. SGC-7910 (A), BGC-823 (B) and HGC-27 (C) cells were treated with rAd-p53 followed by the determination of cell growth inhibition rates. Groups A, B, C and D were treated with the indicated rAd-p53 dose (vp/mL) of 5×10^6 , 5×10^7 , 5×10^8 and 5×10^9 , respectively. SGC-7910 (D), BGC-823 (E) and HGC-27 (F) cells were treated with oxaliplatin (OXA), and cell growth inhibition rates were determined. Groups a, b, c and d were treated with the indicated OXA dose ($\mu\text{g/mL}$) of 3.2, 6.4, 12.8 and 25.6, respectively.

with a combination of rAd-53 and OXA and found that the inhibition of cell growth was markedly stronger at a relatively low combined dose and with a short treatment time (Figure 2), compared to treatment with rAd-p53 or OXA alone (Figure 1). A q value > 1.15 indicated that rAd-p53 and OXA had synergistic effects on the inhibition of gastric cancer cell growth.

Expression of p53 in gastric cancer cells treated with rAd-p53 or OXA alone or with rAd-p53 in combination with OXA

As expected, when the gastric cancer cell lines were treated with rAd-p53 for 48 h, immunohistochemical staining showed that p53 expression increased gradually

with respect to dose (Figure 3, Table 1). Moreover, when the same treatment doses were used, p53 expression was stronger in more differentiated gastric cancer cells. However, the combined use of OXA at 3.2 $\mu\text{g/mL}$ and rAd-p53 had no obvious, additional effects on p53 expression, indicating that the antitumor effects of OXA were not related to the upregulation of p53 expression in tumor cells.

Expression of Bax and Bcl-2 in gastric cancer cells treated with rAd-p53 or OXA alone, or rAd-p53 in combination with OXA

Immunohistochemical staining also showed that the expression of the pro-apoptotic protein Bax increased

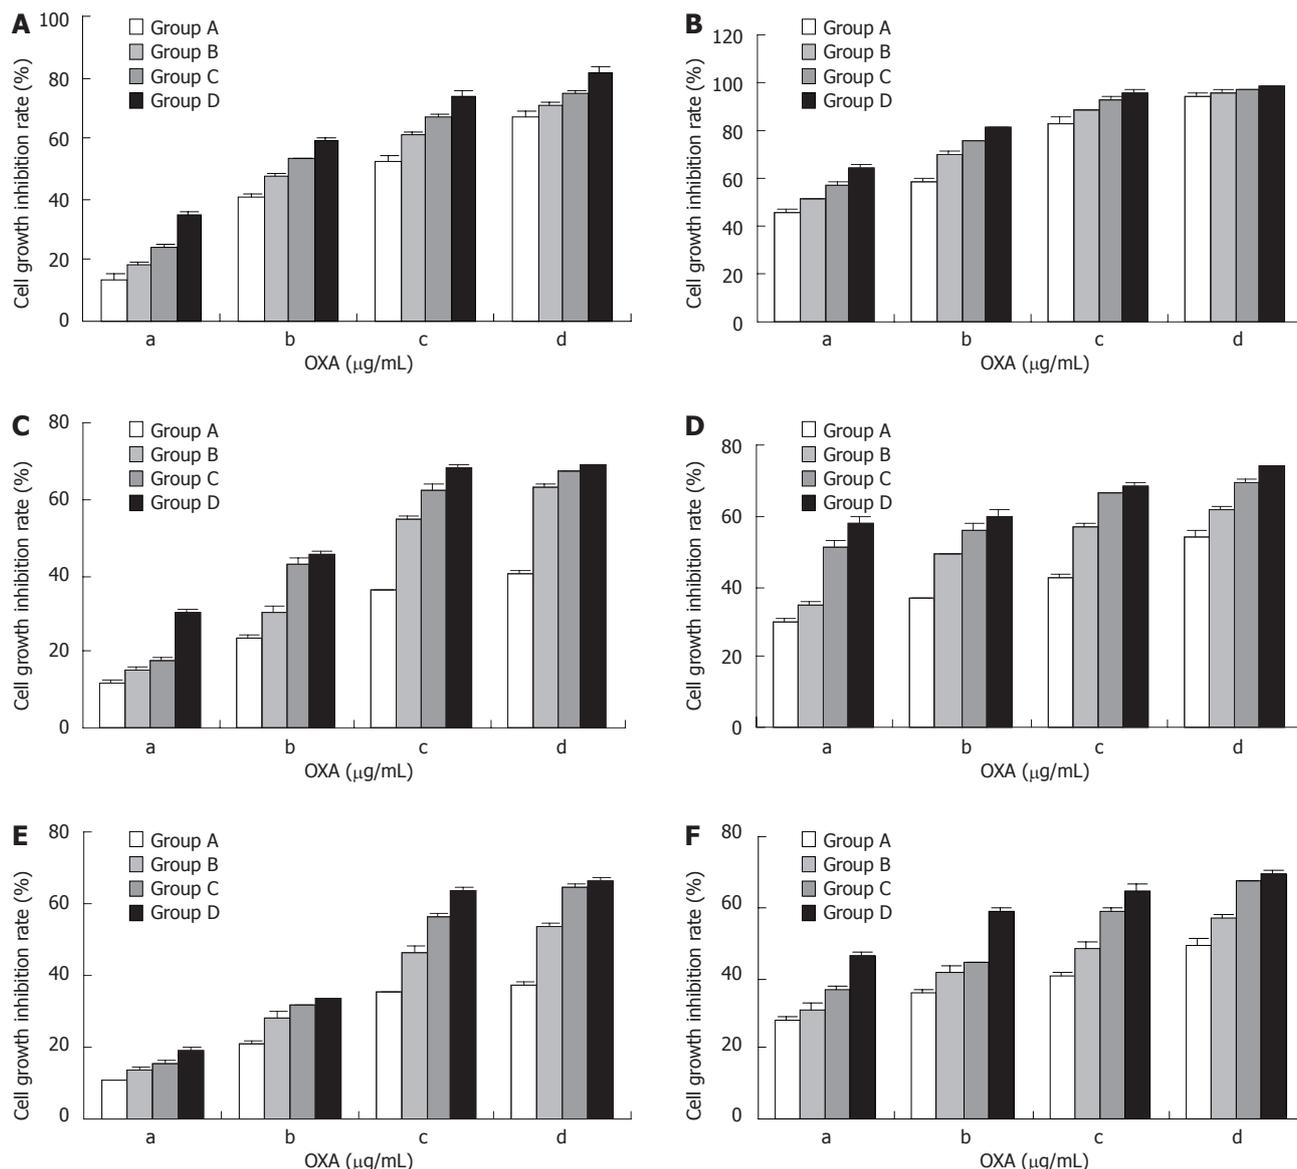

Figure 2 Combination treatment with rAd-p53 and oxaliplatin has synergistic effects on the inhibition of gastric cancer cell growth. SGC-7910 (A, B), BGC-823 (C, D) and HGC-27 (E, F) cells were treated with rAd-p53 plus oxaliplatin (OXA), and cell growth inhibition rates were determined at 24 h (A, C, E) or 48 h (B, D, F). Groups A, B, C and D were treated with the indicated rAd-p53 dose (vp/mL) of 5×10^6 , 5×10^7 , 5×10^8 and 5×10^9 , respectively. Groups a, b, c and d were treated with the indicated OXA dose (μg/mL) of 3.2, 6.4, 12.8 and 25.6, respectively.

gradually in gastric cancer cells treated with increasing doses of rAd-p53 for 48 h (Figure 4, Table 2), whereas the expression of the anti-apoptotic protein Bcl-2 decreased gradually (Figure 5, Table 3). Combination treatment with OXA at 3.2 μg/mL and rAd-p53 had modest effects on the levels of Bax and Bcl-2 expression, indicating that the antitumor effects of rAd-p53 and OXA were mediated by a mechanism that promoted gastric cancer cell apoptosis.

Apoptotic ratio and expression of caspase-3 in gastric cancer cells treated with rAd-p53 or OXA alone or with rAd-p53 in combination with OXA

To confirm that the antitumor effects of rAd-p53 and OXA were associated with induction of apoptosis in gastric cancer cells, we examined the expression of caspase-3

and the apoptotic rate in the three different gastric cancer cell lines by flow cytometric analysis. We found that caspase-3 expression was higher in treated gastric cancer cells compared to untreated cells ($P < 0.05$). Moreover, the combined treatment with rAd-p53 and OXA presented synergistic effects in the upregulation of caspase-3 expression and induction of apoptosis ($P < 0.05$) (Tables 4 and 5).

DISCUSSION

As the most important tumor suppressor gene, p53 plays an important role in the induction of apoptosis. However, the mutation rate of p53 gene is approximately 50% in human cancers^[4], leading to the loss of p53 function, including its induction of apoptosis. Available data sug-

gest that p53 mutations are linked to the development of multiple malignant tumors, such as liver cancer, breast cancer, bladder carcinoma, gastric cancer, colon carcinoma, prostatic carcinoma, ovarian cancer, brain cancer, esophageal cancer, lung cancer, lymphocyte tumor, soft tissue sarcoma, and osteogenic sarcoma^[5-20].

rAd-53, which is an adenovirus carrier containing the p53 tumor suppressor gene, is the first gene therapy drug. In this therapy, the adenovirus is used to deliver the p53 gene to target cells; restoration of p53 expression in the targeted cells results in antitumor effects. The mechanisms of p53 action include: (1) inhibition of cell cycle progression and induction of apoptosis in tumor cells through the modulation of the expression of apoptosis- and cell-cycle-related genes; (2) sensitization of tumor cells to radiotherapy and chemotherapy;

and (3) stimulation of antitumor immunity through the bystander effect. Clinical application studies have demonstrated that rAd-p53 not only strengthens tumor cell sensitivity to radiotherapy and chemotherapy, but also reduces side effects of chemotherapy. For these reasons, a combination of p53 gene therapy and chemotherapy has been successfully applied to cure a variety of cancers, including lung adenocarcinoma, liver cancer and oophoroma^[21,22].

In the present study, we treated three different gastric cancer cell lines with a combination of rAd-p53 and OXA and found that these agents had significant inhibitory effects on cancer cell growth that were dependent on treatment time and dose. In addition, we observed that more differentiated cells were more sensitive to rAd-p53 and OXA treatment. To investigate whether

the antitumor effects of rAd-p53 and OXA are related to the induction of apoptosis in gastric cancer cells, we examined the expression of apoptosis-related proteins. Bcl-2 is the most important anti-apoptotic protein^[23,24], whereas Bax is a pro-apoptotic protein^[25]. Furthermore, it is well known that caspase-3 is critical in chemotherapy-induced apoptosis of cancer cells^[26-30]. Therefore, we examined the expression of Bcl-2, Bax and caspase-3 in gastric cancer cells treated with rAd-p53. As expected, our results demonstrated that the expression Bax and caspase-3 was increased, whereas the expression of Bcl-2 was decreased in a dose-dependent manner. Consistent with these data, we found that the apoptosis of gastric cancer cells was increased.

In conclusion, in the present study, we demonstrated that rAd-p53 inhibited gastric cancer cell growth and sensitized these cells to the chemotherapeutic agent OXA. The underlying mechanisms of these effects involved the induction of apoptosis, which was achieved via downregulation of Bcl-2 and upregulation of Bax and caspase-3. Our results suggest that the combination of p53 gene therapy and chemotherapy represents a novel avenue for gastric cancer treatment.

COMMENTS

Background

Gastric cancer is the most common malignant tumor of the digestive system. Current major therapeutic methods for gastric cancer are surgery, radiotherapy and chemotherapy. Despite recent improvements in these treatments, the > 5-year survival rate for gastric cancer patients is only up to 45%. Thus, it is urgent to develop new therapeutic approaches such as gene therapy for gastric cancer.

Research frontiers

p53 is known as the "genome guard" that plays important roles in various cellular processes, including cell cycle regulation, DNA damage repair and apoptosis. p53 genetic mutation exists in > 50% human tumor tissues and it is the most common detected genetic mutation in cancer. Therefore, a gene therapy strategy has been developed to employ rAd-p53, a weakened adenovirus that carries the wild-type p53 gene, to make tumor cells sensitive to radiotherapy and chemotherapy. Clinical application of rAd-p53 has been carried out on lung cancer, breast cancer, oophoroma, liver cancer, and bladder carcinoma. However, few studies have investigated the therapeutic effects of rAd-p53 on gastric cancer.

Innovations and breakthroughs

In the present study, the authors demonstrated that rAd-p53 inhibited gastric cancer cell growth and sensitized them to chemotherapy by oxaliplatin (OXA). The underlying mechanisms were concerned with induction of apoptosis achieved via downregulation of bcl-2 and upregulation of Bax and caspase-3.

Applications

Given that p53 genetic mutation exists in > 60% of gastric cancers and is correlated with onset and prognosis of gastric cancer, and with chemosensitivity of gastric cancer, the authors' findings that rAd-p53 had antitumor effects in gastric cancer is important for the application of rAd-p53 to clinical treatment of gastric cancer.

Terminology

Apoptosis is a process of programmed cell death that occurs in multicellular organisms. In contrast to necrosis, which is a form of traumatic cell death that results from acute cellular injury, apoptosis confers advantages during an organism's life cycle by maintaining the balance of cell survival and death. However, an insufficient amount of apoptosis results in uncontrolled cell proliferation, such as cancer. Apoptosis is regulated by a balance between pro-apoptotic and anti-apoptotic molecules.

Peer review

In this paper, the authors reported that rAd-p53 enhanced the sensitivity of

gastric cancer cells to chemotherapy by promoting apoptosis. These results suggest that p53 gene therapy combined with chemotherapy is more effective for gastric cancer treatment than regular chemotherapy.

Abstract

AIM: To investigate the apoptotic activities of casticin in hepatocellular carcinoma (HCC) cells and its molecular mechanisms.

METHODS: PLC/PRF/5 and Hep G2 cell lines were cultured *in vitro* and the inhibitory effect of casticin on the growth of cells was detected by 3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyl tetrazolium bromide (MTT) assay. The apoptotic cell death was examined using the cell apoptosis enzyme linked immunosorbent assay (ELISA) detection kit, flow cytometry (FCM) after propidium iodide (PI) staining and DNA agarose gel electrophoresis. The caspase activities were measured using ELISA. Reactive oxygen species (ROS) production was evalu-

ated by FCM after dichlorodihydrofluorescein diacetate (DCFH-DA) probe labeling. Intracellular glutathione (GSH) content was measured using a glutathione assay kit. The expression of death receptor (DR)4 and DR5 proteins was analyzed by Western blotting and FCM.

RESULTS: Casticin significantly inhibited the growth of human HCC (PLC/PRF/5 and Hep G2) cells in a dose-dependent manner ($P < 0.05$). Casticin increased the percentage of the sub-G1 population in HCC cells in a concentration-dependent manner. The potency of casticin to PLC/PRF/5 cells was higher than that of 5-fluorouracil ($26.8\% \pm 4.8\%$ vs $17.4\% \pm 5.1\%$) at $10 \mu\text{mol/L}$ for 24 h. Casticin increased the levels of Histone/DNA fragmentation and the levels of active caspase-3, -8 and -9 in a concentration-dependent manner ($P < 0.05$). Treatment with $30 \mu\text{mol/L}$ casticin for 24 h resulted in the formation of a DNA ladder. Casticin reduced the GSH content ($P < 0.05$), but did not affect the level of intracellular ROS in PLC/PRF/5 and Hep G2 cells. The thiol antioxidants, acetylcysteine (NAC) and GSH restored GSH content and attenuated casticin-induced apoptosis. In contrast, the nonthiol antioxidants, butylated hydroxyanisole and mannitol failed to do so. In the HCC cells treated with casticin for 24 h, DR5 protein level was increased. The expression of DR5 protein induced by casticin was inhibited by NAC. Pretreatment with DR5/Fc chimera protein, a blocking antibody, effectively attenuated the induction of apoptosis by casticin.

CONCLUSION: Casticin-induced apoptosis of HCC cells is involved in GSH depletion and DR5 upregulation.

Casticin-induced apoptosis involves death receptor 5 upregulation in hepatocellular carcinoma cells. *World J Gastroenterol* 2011; 17(38): 4298-4307 Available from: URL: <http://www.wjnet.com/1007-9327/full/v17/i38/4298.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i38.4298>

INTRODUCTION

Hepatocellular carcinoma (HCC) is currently the fifth most common malignant neoplasm in the world^[1], causing over 600 000 deaths each year^[2]. HCC is prevalent in Asia and Africa and its incidence has steadily increased in European and American populations^[3,4]. The majority of patients with HCC die within one year after the diagnosis was established. Unfortunately, HCC is often diagnosed at its late stage when potentially curative therapies are least effective. The 5-year relative survival rate is only 7%^[5]. Patients with surgically resectable localized HCC have a better prognosis, but their 5-year survival rate is only 15%-39%^[6], thus, new therapeutic agents for this malignant disease are urgently needed.

Casticin is one of the main components from *Fructus Viticis* (Manjingzi in Chinese name), a traditional Chinese medicine prepared from the fruit of *Vitex trifolia* L. (family *Verbenaceae*) that is also used as an anti-inflammatory agent and for the treatment of certain cancers in China^[7]. Its chemical structure is shown in Figure 1. Casticin has been shown to inhibit lymphocyte proliferation *in vitro*^[8] and has an anti-inflammatory effect *in vivo*^[9]. In recent years, many studies have demonstrated its anti-carcinogenic activity in breast cancer^[10], lung cancer and colon cancer^[11]. Casticin was also reported to inhibit the growth of human myelogenous leukemia cells^[12] and induce cell death of leukemia cells through induction of apoptosis or mitotic catastrophe^[13]. However, the precise mechanisms underlying casticin inducing apoptosis of HCC cells are still unclear. In the present study, we investigated the effects and molecular mechanism of casticin on the apoptotic cell death of HCC cells *in vitro*. We found that casticin significantly induced apoptosis of HCC cells by glutathione (GSH) depletion and upregulation of DR5.

MATERIALS AND METHODS

Cell culture and reagents

PLC/PRF/5 (*p53* mutant) and Hep G2 (*p53* wild type) human HCC cells were obtained from American Type Culture Collection (Rockville, MD, United States) and cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, penicillin 100 U/mL and streptomycin 100 µg/mL (Life Technologies, Inc., Shanghai, China) in an incubator containing 50 mL/L CO₂ at 37 °C. Casticin was purchased from Chengdu Biopurify Phytochemicals Ltd. (Chengdu, China), and has a molecular weight

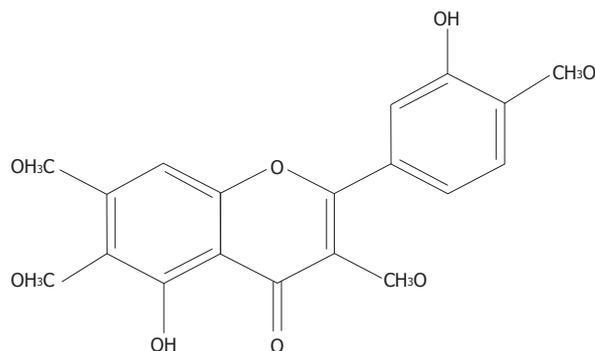

Figure 1 Chemical constitution of casticin.

of 374.3 kDa, appears as yellow crystals and has a purity of 98.0%. Casticin was prepared in dimethyl-sulfoxide (DMSO) as a 10 mmol/L stock solution and diluted in a medium to the indicated concentration before use. The followings were purchased from Hunan Clonetimes Biotech Co., Ltd. (Changsha, China): RPMI-1640 medium (Invitrogen, CA, United States), fetal bovine serum (Invitrogen), Cell Apoptosis enzyme linked immunosorbent assay (ELISA) Detection Kit (Roche), N-acetylcysteine (NAC; Sigma, MO, United States), glutathione (GSH; Sigma), propidium iodide [propidium iodide (PI); Sigma], ethidium bromide (EB; Sigma), N-(4-hydroxyphenyl) retinamide (4HPR; Sigma), butylated hydroxyanisole [butylated hydroxyanisole (BHA); Sigma], mannitol (Sigma), Glutathione Assay kit (Calbiochem, Darmstadt, Germany), Apoptotic DNA Ladder Detection Kit (Bodataike Company, Beijing, China), Caspase 3 Activity Detection Kit (Millipore, MA, United States), Caspase 8 Colorimetric Activity Assay Kit 25 (Millipore), Caspase 9 Colorimetric Activity Assay Kit (Millipore), zVAD-fmk (R and D Systems, MN, United States), zIETD-fmk (R and D Systems), zLEHD-fmk (R and D Systems), 5-fluorouracil (5-FU; Sigma), death receptor (DR)5/Fc chimera protein (R and D Systems), 2',7'-dichlorofluorescein diacetate (DCFH-DA; Molecular Probes Inc., OR, United States), mouse anti-human DR5 and DR4 (Santa Cruz Biotechnology, CA, United States), Fluorescein isothiocyanate (FITC)-conjugated anti-mouse IgG (Zymed Laboratories, CA, United States), mouse IgG1 immunoglobulin (Dako Cytomation, CA, United States).

MTT assay

Cells were seeded in a 96-well plate at a density of 0.5×10^4 cells/well and incubated for 24 h, followed by treatment with various concentrations of casticin or 5-fluorouracil for 24 h. 3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyl tetrazolium bromide (MTT) colorimetric analysis was performed as described previously^[14]. The IC₅₀ value, i.e., 50% of the cell growth inhibition compared with (DMSO) control, was calculated by nonlinear regression analysis using GraphPad Prism software (San Diego, CA).

Flow cytometry using PI staining

Cells were seeded at a density of 4×10^6 cells/mL in

100 mL culture flasks for 24 h and then treated with the medium containing various concentrations of casticin or 5-fluorouracil for the indicated time. Propidium iodide staining for DNA content analysis was performed as described previously^[15].

Histone/DNA fragment ELISA

The cell apoptosis ELISA detection kit was used to detect apoptosis in cells treated with casticin according to the manufacturer's protocol. Briefly, cells were seeded in a 96-well plate at a density of 1×10^4 cells/well for 24 h, added with the medium containing various concentrations of casticin. After 24 h, we transferred the cytoplasm of the control and treatment group to the 96-well plate peridumed by the streptavidin, incubated with the biotinylated histone antibody and peroxidase-tagged mouse anti-human DNA for 2h at room temperature. The absorbance at 405 nm was measured with EXL-800 type Enzyme-Linked Immunosorbent apparatus.

DNA fragmentation assay

Cells were seeded at a density of 4×10^6 cells/mL in 100 mL culture flasks for 24 h and treated with medium containing various concentrations of casticin for 24 h. This assay was performed as described previously^[15].

Analysis of caspase-3, -8 and -9 activities

To evaluate caspase activity, cell lysates were prepared after their respective treatment with the testing agents. Assays were performed in 96-well plates by incubating 20 μ g cell lysates in 100 μ L reaction buffer (1% NP-40, 20 mmol/L Tris-HCl (pH 7.5), 137 mmol/L NaCl, 10% glycerol) containing a 5 μ mol/L caspase-3 substrate Ac-DEVD-*p*NA or caspase-8 substrate Ac-IETD-*p*NA or caspase-9 substrate Ac-LEHD-*p*NA. Lysates were incubated at 37 °C for 2 h. Thereafter, the absorbance at 405 nm was measured with an enzyme-labeling instrument (ELX-800 type). In the caspase inhibitor assay, cells were pretreated with a caspase inhibitor (20 μ mol/L zVAD-fmk or zIETD-fmk or zLEHD-fmk) for 1 h prior to the addition of casticin.

Determination of reactive oxygen species

Intracellular reactive oxygen species (ROS) accumulation was measured by flow cytometry using the fluorescent probe DCFH-DA^[15]. Cells were incubated with 10 μ mol/L DCFH-DA for 30 min at 37 °C in dark. After incubation, the cells were washed with phosphate buffered saline (PBS) and analyzed within 30 min using FACScan (Becton Dickinson, San Jose, CA, United States) equipped with an air-cooled argon laser tuned to 488 nm. The specific fluorescence signals corresponding to DCFH-DA were collected with a 525-nm band pass filter. As a rule, 10 000 cells were counted in each determination.

Measurement of intracellular glutathione

Intracellular GSH contents were measured using a Glutathione Assay kit. In brief, 5×10^6 cells were homogenized in 5% metaphosphoric acid using a Teflon

pestle (Racine, WI). Particulate matter was separated by centrifugation at $4000 \times g$. The supernatant solution was used for GSH measurement according to the manufacturer's instructions. The GSH content was expressed as nmol/106 cells.

Analysis of cell surface receptor expression

Cells were cultured at an indicated concentration for 24 h, and then collected. Five hundred thousand cells for each receptor analysis were transferred to polystyrene tubes, washed twice with PBS and resuspended in PBS containing 0.5% bovine serum albumin (BSA) (Sigma). A specific monoclonal antibody to either DR5, DR4 or unspecific mouse IgG1 as isotype control was applied at 5 μ g/mL. Cells were incubated for 20 min with gentle rocking at room temperature. Cells were washed twice in PBS, and secondary fluorescein isothiocyanate-conjugated polyclonal goat antibody to mouse IgG1 (1:200 in PBS containing 0.5% BSA) was added, followed by incubation protected from light for 30 min with gentle rocking at room temperature. Cells were then washed and resuspended in PBS containing 0.5% BSA. All analyses were carried out on FACScan using CellQuest software (Pharmingen BD Biosciences, CA, United States).

Western blotting analysis

Total cell extracts were obtained as described previously^[15]. Cell lysate containing 50 μ g of protein was separated on a 10% SDS-polyacrylamide gel for electrophoresis and then blotted onto polyvinylidene difluoride (PVDF) membranes (Millipore, Bedford, MA, United States). Anti-DR5, -DR4 and - β -actin (1:1000 dilutions for each) were used as primary antibodies. Signals were detected using an ECL kit (Amersham Pharmacia Biotech, Piscataway, NJ, United States). Images were scanned followed by densitometric analysis with Alphazmager 2200 software (Silk Scientific Inc., Utah, United States). The ratios of DR5 or DR4/ β -actin were determined for the expression level of DR5 or DR4.

Statistical analysis

The database was set up with the SPSS 15.0 software package (SPSS Inc, Chicago, IL, United States) for analysis. Data were presented as mean \pm SD. The means of multiple groups were compared with one-way analysis of variance (ANOVA), after the equal check of variance, and the two-two comparisons among the means were performed using the least-significant difference (LSD) method. Statistical comparison was also performed with two-tailed *t* test when appropriate. *P* < 0.05 was considered statistically significant.

RESULTS

Effects of casticin on growth of hepatocellular carcinoma lines

To characterize the effect of casticin on cell growth, two kinds of cell lines, including PLC/PRF/5 (*p53* mutant) and Hep G2 (*p53* wild type) cells, were treated with various

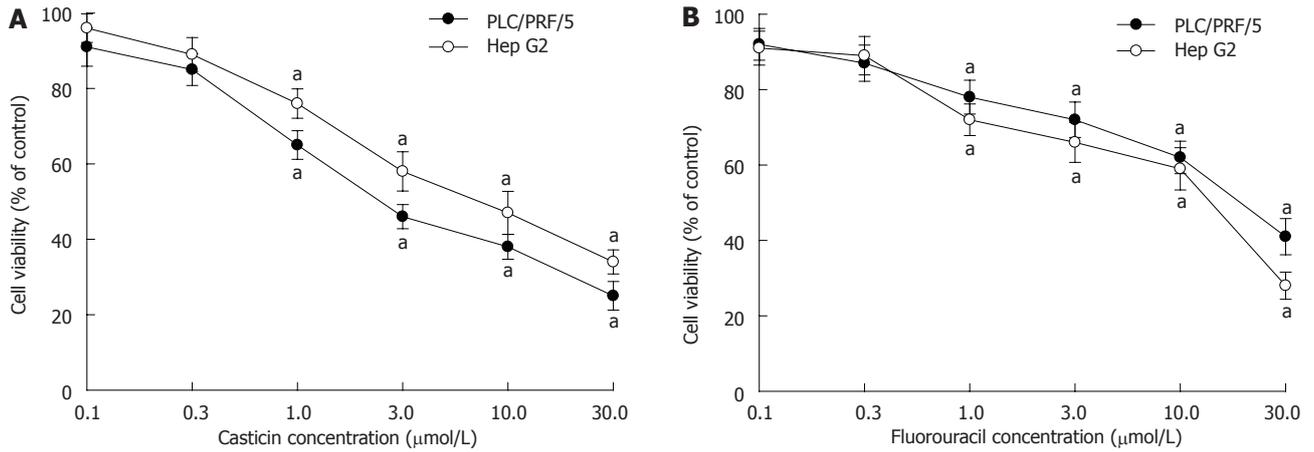

Figure 2 Effects of casticin (A) and fluorouracil (B) on the growth of hepatocellular carcinoma cells using 3-(4,5)-dimethylthiaziazolo (2,4)-bis(4-methyl-5-pyridyl) tetrazolium bromide assay (mean \pm SD, $n = 9$). ^a $P < 0.05$ vs treatment with dimethyl-sulfoxide.

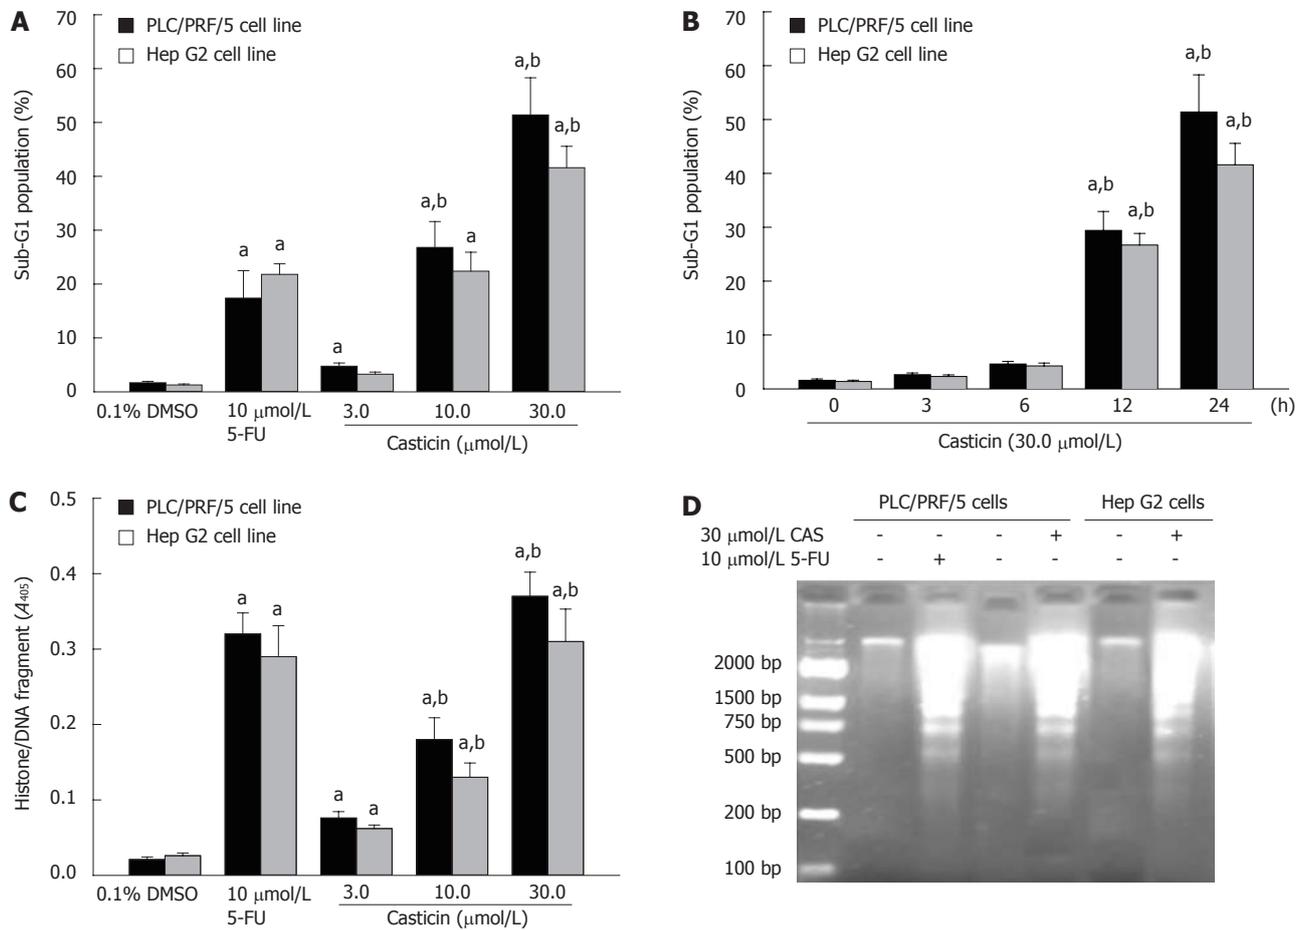

Figure 3 Effects of casticin on the percentage sub-G1 cell population (A and B), histone/DNA fragment (C) and DNA fragmentation (D) in PLC/PRF/5 and Hep G2 cells (mean \pm SD, $n = 3$). ^a $P < 0.05$ vs treatment with dimethyl-sulfoxide (DMSO) or 0 h; ^b $P < 0.05$ vs treatment with 3 μ mol/L casticin or 6 h. 5-FU: 5-fluorouracil.

concentrations of casticin for 24 h, and cell viability was assessed by MTT assay. Figure 2A shows that casticin significantly inhibited the growth of human HCC (PLC/PRF/5 and Hep G2) cells in a dose-dependent manner. When the IC₅₀ for 24 h was 9.4 and 13.6 μ mol/L, respectively, the potency of casticin to PLC/PRF/5 cells was stronger than that of 5-FU with an IC₅₀ of 16.8 μ mol/L (Figure 2B).

Effects of casticin on apoptosis of hepatocellular carcinoma cells

To investigate whether apoptosis was involved in cell growth inhibition by casticin, we detected apoptosis increase using flow cytometric analysis in hypodiploid cell populations. Figure 3A shows that casticin increased the percentage of the sub-G1 cell population in PLC/PRF/5

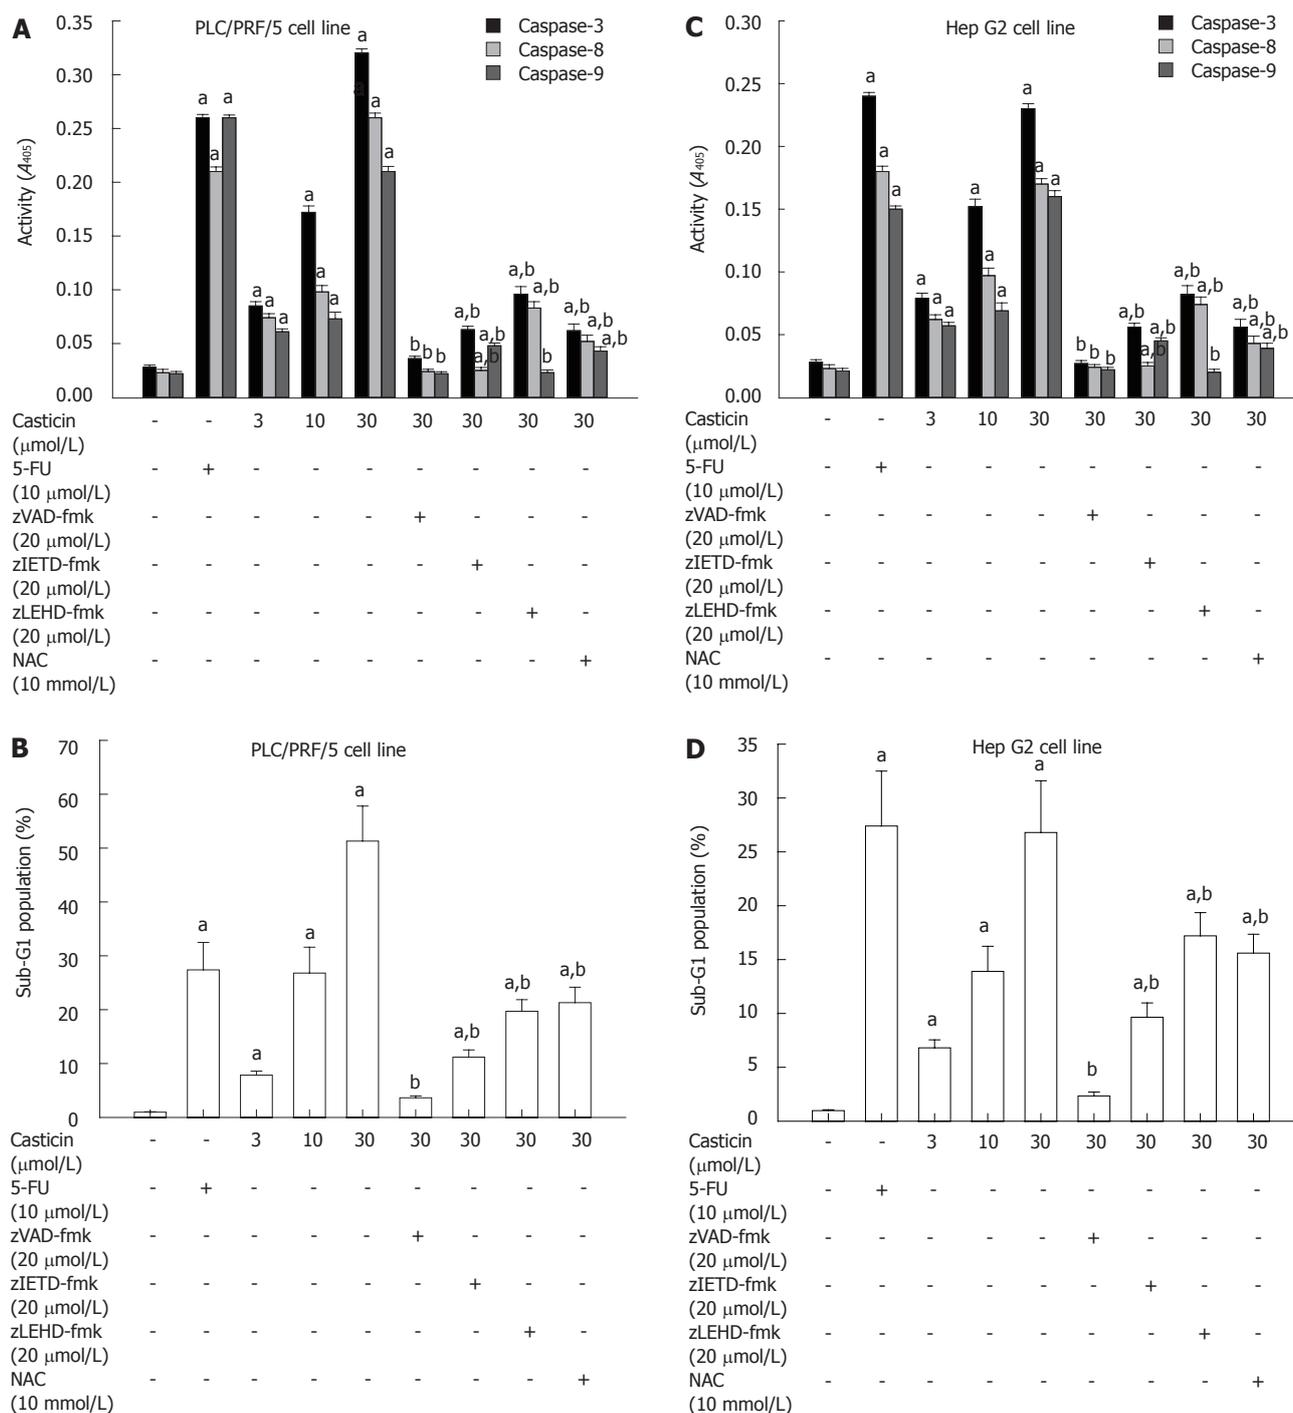

Figure 4 Effects of casticin on the activities of caspases (A and C) and the percentage sub-G1 cell population (B and D) in PLC/PRF/5 and Hep G2 cells (mean \pm SD, $n = 3$). ^a $P < 0.05$ vs treatment with dimethyl-sulfoxide (DMSO); ^b $P < 0.05$ vs treatment with 30 μ mol/L casticin alone. 5-FU: 5-fluorouracil; NAC: N-acetyl-cysteine.

and Hep G2 cells in a concentration-dependent manner ($P < 0.05$). The potency of casticin to PLC/PRF/5 cells was higher than that of 5-fluorouracil (26.8% \pm 4.8% *vs* 17.4% \pm 5.1%) at 10 μ mol/L for 24 h. The sub-G1 population in PLC/PRF/5 and Hep G2 cells by casticin was increased at 12 h and peaked at 24 h (Figure 3B). Histone/DNA fragment of PLC/PRF/5 and Hep G2 cells, as measured by the cell apoptosis ELISA detection kit, was increased in a dose-dependent manner ($P < 0.05$) after treatment with casticin (Figure 3C). Furthermore, DNA fragmentation analysis by agarose gel electrophoresis showed a typical ladder pattern of internucleosomal DNA

fragments in PLC/PRF/5 and Hep G2 cells treated with 30 μ mol/L casticin for 24 h (Figure 3D). These results suggested that casticin inhibited HCC cell growth through a mechanism involving the induction of apoptosis.

Effects of casticin on caspases activities of hepatocellular carcinoma cells

To determine the effectors active in casticin-induced apoptotic pathways, we examined whether caspases were actually activated during casticin-induced cell death of HCC cells. Figure 4A shows that treatment of PLC/PRF/5 cells with casticin for 24 h increased the levels of

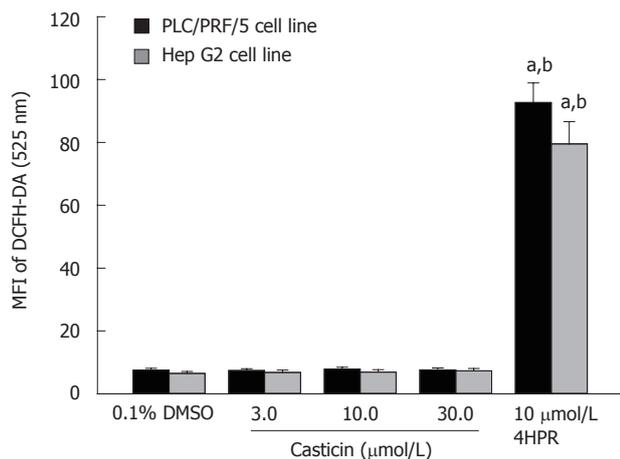

Figure 5 Effects of casticin on the production of reactive oxygen species in PLC/PRF/5 and Hep G2 cells (mean \pm SD, $n = 3$). ^a $P < 0.05$ vs treatment with dimethyl-sulfoxide (DMSO); ^b $P < 0.05$ vs treatment with 30 $\mu\text{mol/L}$ casticin. 4HPR: N-(4-hydroxyphenyl) retinamide.

active caspase-3, -8 and -9 ($P < 0.05$) in a concentration-dependent manner ($P < 0.05$).

We further examined the role of caspases activated during apoptosis induced by casticin treatment using the pan-caspase inhibitor zVAD-fmk, the caspase-8 inhibitor zIETD-fmk and the caspase-9 inhibitor zLEHD-fmk. Figure 4B shows that zVAD-fmk abrogated apoptosis induced by casticin and zIETD-fmk and zLEHD-fmk attenuated casticin-induced apoptosis. The similar findings were observed in the Hep G2 cell line (Figure 4C and D). These data indicate that casticin-induced apoptosis was essentially dependent on the activation of caspase-3, -8 and -9.

Effects of casticin on reactive oxygen species generation of hepatocellular carcinoma cells

Because NAC, an antioxidant, could attenuate induction of apoptosis by casticin (Figure 4B and D), it was plausible to speculate that casticin-induced apoptosis by promoting intracellular ROS generation. Thus, we examined whether casticin promoted ROS generation in HCC cells. Unexpectedly, we failed to detect any increase of intracellular ROS generation in PLC/PRF/5 and Hep G2 cells treated with casticin, at concentrations ranging from 3.0 to 30.0 $\mu\text{mol/L}$. 4HPR, an agent known to promote ROS generation in cancer cells^[16,17], did increase the ROS generation in HCC cell lines (Figure 5).

Effects of casticin on intracellular glutathione content of hepatocellular carcinoma cells

Earlier studies demonstrated that flavonoid toxicity was strictly dependent on the intracellular GSH content^[18,19]. We measured the intracellular GSH in cells treated with casticin. In PLC/PRF/5 cells treated with casticin (3.0, 10.0 and 30.0 $\mu\text{mol/L}$) for 24 h, the intracellular GSH content significantly was decreased in a concentration-dependent manner (Figure 6A). In addition, time-course studies indicated that casticin caused a progressive decrease in GSH content from 1 h onwards (Figure 6B).

Importantly, the pan-caspase inhibitor z-VAD-fmk, which successfully prevented apoptosis execution, failed to prevent GSH decrease (Figures 4A and B, 6A and C). This excludes the possibility that GSH depletion in casticin-treated cells could be a trivial, secondary consequence of cell death.

To shed light on the mechanisms accounting for GSH depletion as well as on the relationship between GSH depletion and apoptosis induction, we determined the effects of thiol antioxidants including NAC and GSH, and nonthiol antioxidants including butylated hydroxyanisole (BHA) and mannitol on GSH content and apoptosis by casticin treatment. Figure 6A and C show that thiol antioxidants, NAC and GSH, restored GSH content and attenuated casticin-induced apoptosis. In contrast, nonthiol antioxidants, BHA and mannitol, failed to do so (Figure 6A and C). The similar findings were observed in Hep G2 cell line (Figure 6D-F). The results suggest that casticin-induced apoptosis of HCC cells is at least partially dependent on GSH depletion.

Effects of casticin on DR5 expression of hepatocellular carcinoma cells

Because casticin induced caspase-8 activation (Figure 4A), we wondered whether casticin induced DR5 upregulation. Therefore, we compared the effects of casticin on the expression of DR4 and DR5 using Western blotting. In PLC/PRF/5 cell line, casticin increased the expression of DR5 at protein levels, but not affected the expression of DR4 protein; however, it failed to do so in the presence of NAC (Figure 7A). In addition, flow cytometry (FCM) analysis showed that casticin increased DR5 protein levels on the surface of Hep G2 cells by casticin treatment, but DR4 expression levels were not obviously altered (Figure 7 C).

To further define the role of DR5 upregulation in casticin-induced apoptotic cell death, we examined the effects of DR5/Fc chimera protein, a blocking antibody on induction of apoptosis by casticin. Figure 7B shows that the pretreatment with 1 $\mu\text{g/mL}$ DR5/Fc chimera protein effectively attenuated induction of apoptosis by casticin in PLC/PRF/5 and Hep G2 cells. Our findings suggest that casticin-induced apoptosis of HCC cells is involved in upregulation of DR5.

DISCUSSION

The polymethoxyflavone from *Fructus Vitis*, casticin is a potent novel molecule with a wide range of actions, many of which are potentially useful for cancer prevention or treatment^[20-23]. In the present study, we investigated the effects of casticin on the cell growth using two kinds of human HCC (PLC/PRF/5 with *p53* mutant and HepG2 with *p53* wild type) cell lines. We have demonstrated that casticin was a potent agent in inhibiting the growth of human HCC cells. The cancer suppressor *p53* is an important factor that affects the cell response to drug effects on growth inhibition and

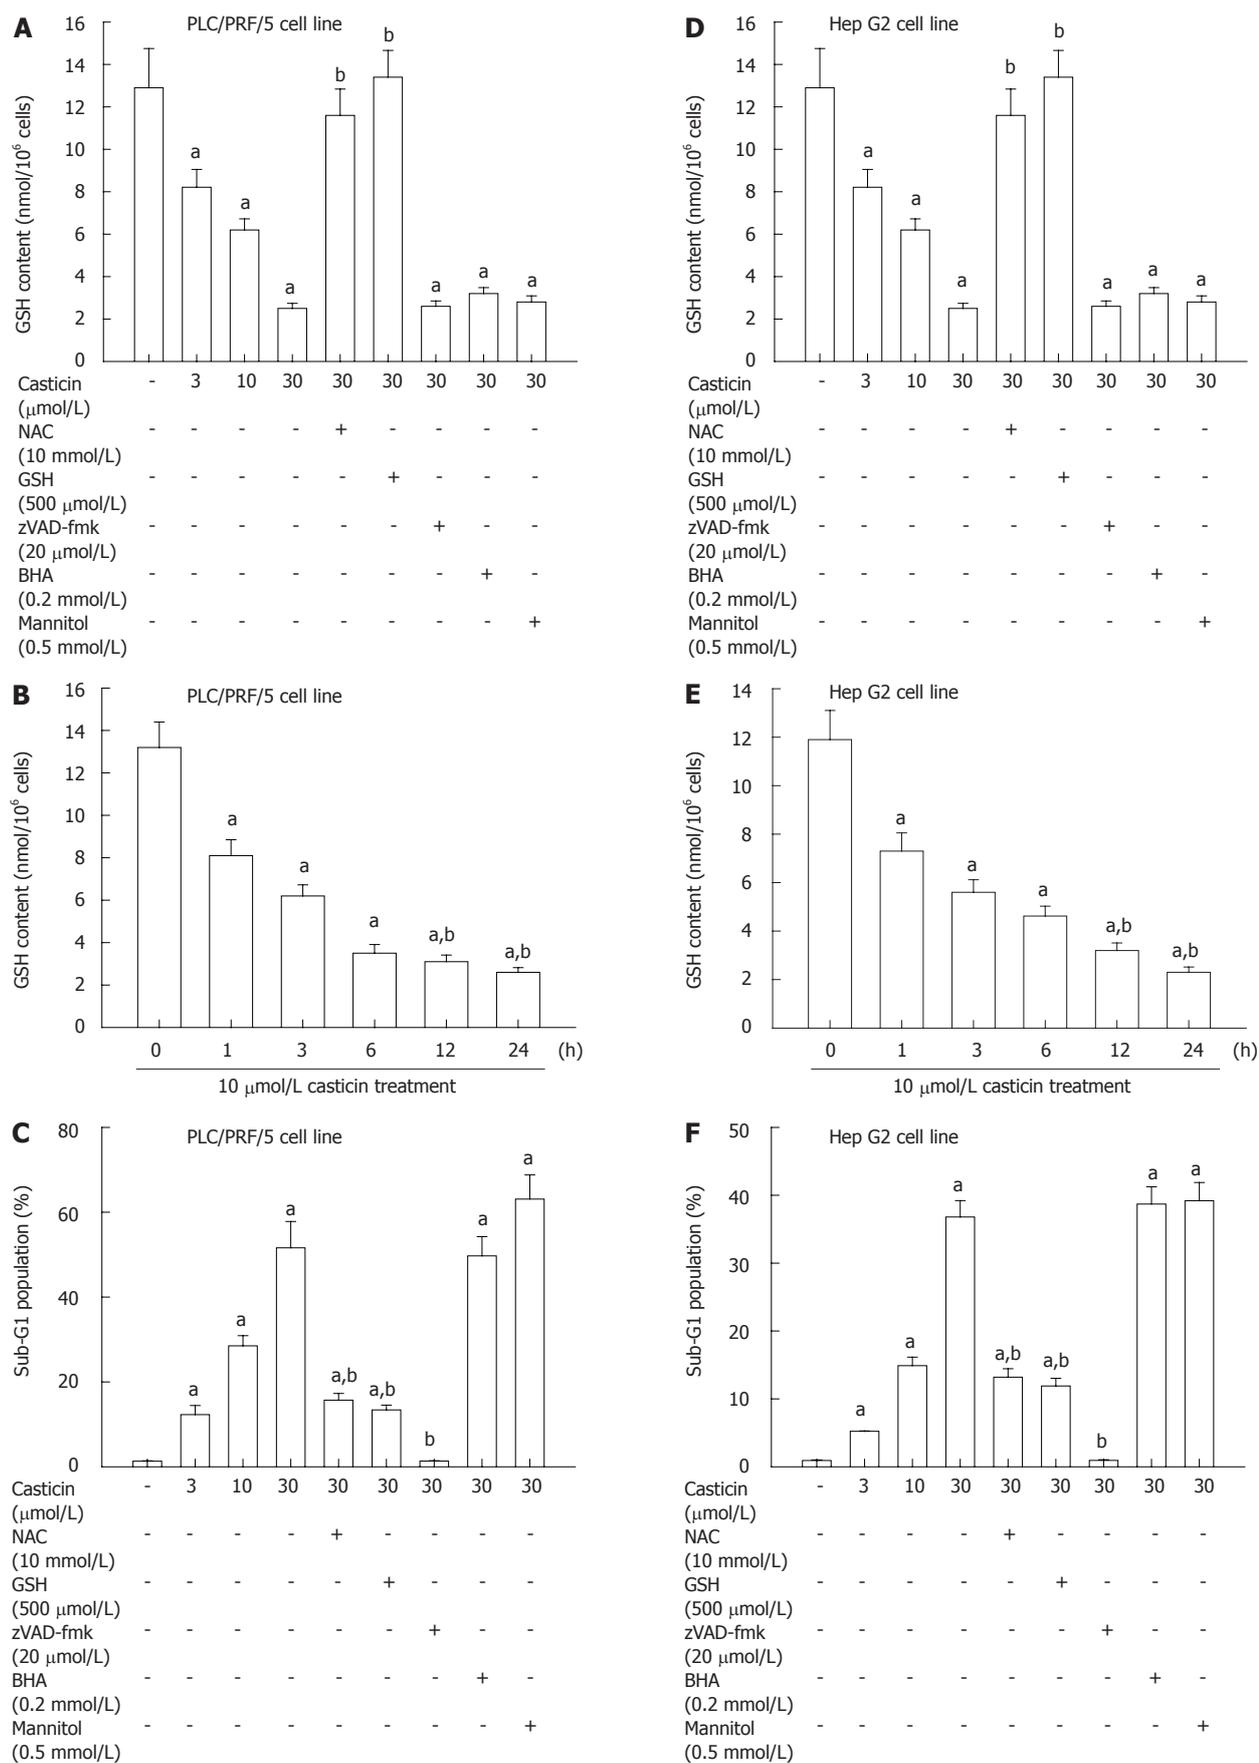

Figure 6 Effects of casticin on intracellular glutathione content (A, B and D, E) and the percentage sub-G1 cell population (C and F) in PLC/PRF/5 and Hep G2 cells (mean \pm SD, $n = 3$). ^a $P < 0.05$ vs treatment with dimethyl-sulfoxide (DMSO) or 0 h; ^b $P < 0.05$ vs treatment with 30 $\mu\text{mol/L}$ casticin alone or treatment with 10 $\mu\text{mol/L}$ casticin for 1 h. GSH: Glutathione; BHA: Butylated hydroxyanisole; NAC: N-acetyl-cysteine.

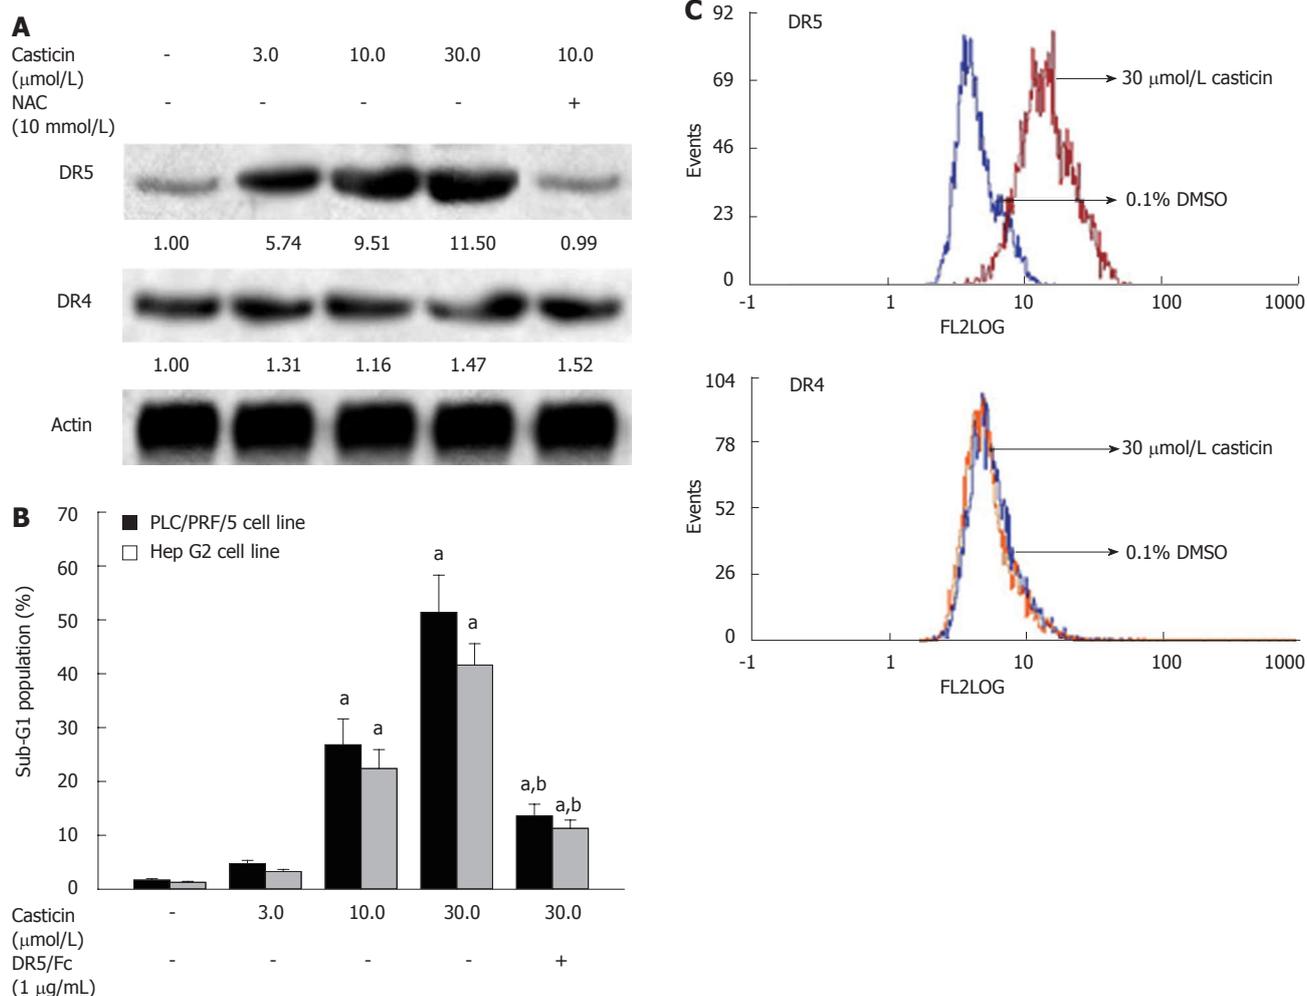

Figure 7 Effects of casticin on the levels of death receptors (DR4 and DR5) expression(A) using Western blotting and the percentage sub-G1 cell population (B) in PLC/PRF/5 cells (mean ± SD, n = 3). ^aP < 0.05 vs treatment with dimethyl-sulfoxide (DMSO); ^bP < 0.05 vs treatment with 30 μmol/L casticin alone. C: Effects of casticin on the levels of death receptor (DR)4 and DR5 protein levels on the surface of Hep G2 cells using flow cytometry. NAC: N-acetyl-cysteine.

apoptosis induction^[24,25]. The majority of evidence supports the notion that cells with wild-type *p53* exhibit increased sensitivity to radiation or chemotherapeutic agents, whereas cells lacking wild-type *p53* expression still undergo apoptosis but need a relatively high dose of radiation or chemotherapeutic drugs^[24,25]. The study by Häidara *et al*^[10] demonstrated the apoptotic effect of casticin in *p53* mutant breast cancer cell lines. Our results indicated that casticin inhibited cell growth and induced apoptosis regardless of *p53* status in human HCC cells. Therefore, we conclude that casticin-induced apoptosis in human cancer cells is *p53*-independent.

Apoptotic cells presented some common characteristics. In the stage of apoptosis, activation of a cascade of various caspases, was followed by DNA fragmentation, nuclear fragmentation, the appearance of apoptotic bodies and cellular shrinkage. Hence, caspase-3 activation, sub-G1 cell population, Histon/DNA fragment and DNA ladder were regarded as the characters specific for apoptosis. Our present study showed activation of caspase-3, increase of the percentage of sub-G1 population and Histone/DNA fragment and presentation of DNA

ladder in casticin-treated HCC cells, demonstrating that casticin inhibited HCC cell growth through induction of apoptosis.

We also demonstrated that casticin induced apoptosis by depleting intracellular GSH content, rather than by promoting ROS generation, in HCC cells. Our findings are supported by the following lines of evidence: (1) casticin did not promote intracellular ROS generation although it decreased intracellular GSH content; and (2) Thiol-containing antioxidants rather than nonthiol antioxidants reduced casticin-induced apoptosis; this suppression correlated with their ability to prevent a casticin-induced decrease of GSH content. NAC, an aminothiols and synthetic precursor of intracellular cysteine and GSH, functions through either its antioxidative/radical scavenging properties as an antioxidant or its thiol-disulfide exchange activity as a reductant^[26,27]. We found that only thiol containing antioxidants with reducing activity, including NAC and GSH, rather than nonthiol antioxidants, including BHA and mannitol, suppressed casticin-induced apoptosis. Therefore, it is likely that NAC and GSH inhibit casticin-induced apoptosis *via* their reducing activ-

ity. It appears that our findings have clinical implications regarding the rational use of casticin in combination with other agents for cancer prevention and/or treatment. The polymethoxyflavone should not be used in combination with the agents with reducing activity, such as NAC, in order to avoid the potential contradictory interaction.

The activation of caspases plays an important role in apoptosis triggered by various proapoptotic signals^[28,29]. It is generally recognized that there are two major apoptotic pathways: one involves death signals transduced through death receptors, and the other relies on a signal from the mitochondria^[22,28]. Both pathways are involved in an ordered activation of a set of caspases, which in turn cleave cellular substrates leading to the morphological and biochemical changes of apoptosis. The activation of caspase-8 and caspase-9 has been documented to play central roles in mediating apoptosis signaled by death receptors and by mitochondria, respectively^[15,28]. However, caspase-8 can activate the caspase-9-mediated apoptotic pathway *via* activating or cleaving the Bid protein^[28,29]. We found that casticin activated caspase-8 and -9. The presence of the caspase-8 inhibitor z-IETD-fmk and the caspase-9 inhibitor zLEHD-fmk attenuated the apoptosis induced by casticin, indicating that caspase-8 and -9 activation were required for the apoptosis induced by casticin in PLC/PRF/5 cells. Moreover, casticin up-regulated DR5 expression, and DR5/Fc chimera protein reduced casticin-induced apoptosis, which shows that DR5 upregulation is required for casticin-induced apoptosis. Therefore, our results, for the first time, highlight a novel simultaneous both death receptor and mitochondria-mediated mechanism by casticin-induced apoptosis in HCC cells. The study by Zou *et al.*^[30] demonstrated that the synthetic triterpenoid methyl-2-cyano-3,12-dioxoolean-1,9-dien-28-oate induced upregulation of DR5 expression by activation of the CCAAT/enhancer binding protein homologous protein (CHOP) *via* intracellular GSH depletion-induced the endoplasmic reticulum stress. Quercetin, a flavonoid compound decreases intracellular GSH content and potentiates the apoptotic action of the antileukemic drug, arsenic trioxide, in human leukemia cell lines^[31]. However, why and how the intracellular GSH depletion induces DR5 expression up-regulation need to be further investigated.

In summary, our studies have demonstrated that the polymethoxyflavone from *Fructus viticis*, casticin is a potent apoptosis-inducing agent in human HCC cells, which acts through depleting intracellular GSH content and upregulating DR5, and subsequent activation of caspase-3, -8 and -9. Moreover, casticin inhibited the growth of HCC cells independent of *p53* status. For this reason, we suggest that casticin may be a good candidate for additional evaluation as a cancer therapeutic agent for human HCC as well as other types of cancer.

neoplasm in the world, leading to over 600 000 deaths each year. HCC is prevalent in Asia and Africa and its incidence has steadily increased in European and American populations. New therapeutic agents for this malignant disease are urgently needed.

Research frontiers

Casticin is one of the main components from *Fructus Viticis* (Manjingzi in Chinese name), a traditional Chinese medicine prepared from the fruit of *Vitex trifolia* L. (family *Verbenaceae*) that is also used as an anti-inflammatory agent and for the treatment of certain cancers in China. In recent years, many studies have demonstrated its anti-carcinogenic activity in breast cancer, lung cancer and colon cancer. However, the precise mechanisms underlying casticin-induced apoptosis of HCC cells is still not clear.

Innovations and breakthroughs

In this study, the effects and molecular mechanism of casticin on apoptotic cell death of HCC cells *in vitro* were studied. Casticin significantly induced apoptosis of HCC cells by glutathione (GSH) depletion and upregulation of reactive oxygen species.

Applications

Casticin is a potent apoptosis-inducing agent in human HCC cells, which acts through depleting intracellular GSH content and upregulating DR5, and subsequent activation of caspase-3, -8 and -9. Moreover, casticin inhibited the growth of HCC cells independent of *p53* status. The authors suggested that casticin may be a good candidate for additional evaluation as a cancer therapeutic agent for human HCC as well as other types of cancer.

Terminology

Casticin is one of the main components from *Fructus Viticis* (Manjingzi in Chinese name), a traditional Chinese medicine prepared from the fruit of *Vitex trifolia* L. (family *Verbenaceae*).

Peer review

In this manuscript, the authors demonstrate that the treatment with casticin, main components from *Fructus Viticis*, induced apoptosis through the depletion of glutathione DR5 up-regulation in HCC cells. A series of experiments were well planned and well performed, and the manuscript is well written. The findings are important to those with closely related research interest.

Abstract

AIM: To compare high resolution colonoscopy (Olympus Lucera) with a megapixel high resolution system (Pentax HiLine) as an in-service evaluation.

METHODS: Polyp detection rates and measures of performance were collected for 269 colonoscopy procedures. Five colonoscopists conducted the study over a three month period, as part of the United Kingdom bowel cancer screening program.

RESULTS: There were no differences in procedure du-

ration ($\chi^2 P = 0.98$), caecal intubation rates ($\chi^2 P = 0.67$), or depth of sedation ($\chi^2 P = 0.64$). Mild discomfort was more common in the Pentax group ($\chi^2 P = 0.036$). Adenoma detection rate was significantly higher in the Pentax group (χ^2 test for trend $P = 0.01$). Most of the extra polyps detected were flat or sessile adenomas.

CONCLUSION: Megapixel definition colonoscopes improve adenoma detection without compromising other measures of endoscope performance. Increased polyp detection rates may improve future outcomes in bowel cancer screening programs.

INTRODUCTION

Colorectal cancer is one of the most common cancers worldwide, particularly in Europe and the United States^[1]. Detection of cancer at an early stage, as well as detection and removal of polyps, is likely to decrease mortality from the disease. Colonoscopy is now established as the gold standard for the identification of both colorectal cancer and

polyps^[2]; therefore, the accuracy of the procedure is very important. The UK bowel cancer screening program has been established to reduce deaths from colorectal cancer utilising colonoscopy for patients screened positive by faecal occult blood tests. However, the colonoscopic miss rate of adenomas is as high as 24%^[3] and the false negative colonoscopy rate for colorectal cancers appears to be up to 6%^[4]. It is therefore desirable to investigate methods that could improve the accuracy of colonoscopy, particularly as a higher adenoma detection rate is associated with lower rates of subsequent development of colon cancer^[5]. It has been suggested that screening efficacy requires a high quality examination and removal of all visible neoplastic lesions. It is plausible that higher image resolution will help achieve these aims^[6-8]. For bowel cancer screening, we currently use Olympus Lucera colonoscopes and Scope Guide system for colorectal cancer screening. The new Pentax HiLine colonoscopes have a higher image resolution and might, therefore, provide better detection of visible polyps and early cancers. Pentax scope handling is different to Olympus scopes, and patient comfort and procedure performance may therefore be altered. This in-service evaluation of the new Pentax HiLine colonoscopes aimed to compare procedure duration, caecal intubation rates, patient comfort, and polyp detection with those obtained by the Olympus Lucera system.

MATERIALS AND METHODS

All patients undergoing colonoscopy in the bowel cancer screening program at University College London Hospitals NHS Foundation Trust between August and November 2009 were included in this prospective study. Routine bowel cancer screening colonoscopies are usually performed in our unit with the Olympus Lucera series of colonoscopes (CF-Q260DL colonoscopes and CLV 260-SL processor). There are five bowel cancer screening colonoscopy lists per week. During the study period, one of the screening lists was allocated to be performed with a Pentax HiLine colonoscopy (EC-3890i).

A specialist bowel cancer screening nurse collected data on completeness of insertion to caecum or terminal ileum, duration of insertion, withdrawal of colonoscopy, and total length of procedure in real time. In addition, the nurse noted the amount of sedation used, the level of conscious sedation (awake, drowsy, asleep), and degree of discomfort suffered by the patient during the procedure. This was classified as minimal, mild, moderate, or severe using a nurse-evaluated score in line with the National Bowel Cancer Screening standards. The location and size of polyps, as well as removal and retrieval rates, were collected. Polyps were classified by the histopathologist in charge of running the bowel cancer screening program at UCLH.

Statistical analysis was performed using non parametric Mann Whitney tests, where Gaussian approximation did not occur, and unpaired *t* tests where it did, for ex-

ample in comparing polyp sizes. Linear regression analysis was used to assess learning curves, and χ^2 contingency tests were used to compare patient parameters between scope types.

The University College London hospitals research ethics committee considered this study to be an in-service evaluation. Ethical approval was therefore not required.

RESULTS

A total of 269 procedures were recorded. Forty-four were performed with the new Pentax HiLine colonoscopes and the rest were performed with Olympus Lucera series colonoscopes. Five colonoscopists performed the procedures. An important limitation to our in-service evaluation was that most of the procedures performed with the Pentax Scopes were completed by a single colonoscopist. This colonoscopist also performed a significant number of colonoscopies with the Olympus Lucera scopes. We therefore analysed all parameters for this single endoscopist between the two scopes, as well as for all procedures performed by all endoscopists. We found no difference between these analyses and therefore present the overall findings only. All the study colonoscopists are accredited for the UK bowel cancer screening programme and during the study, all detected adenomas in at least 40% of procedures, demonstrating their competence^[5,9].

The Pentax HiLine colonoscopes were new in our unit, and these have different handling characteristics to the Olympus Lucera Scopes; therefore, we analysed the learning curve, as measured by duration of procedure and time to reach the caecum, as none of the endoscopists in this study had used this colonoscopy before. There was no significant change in either of these parameters throughout the study, suggesting that there was no significant learning curve. There was no difference in caecal intubation time, duration of withdrawal, or in total procedure duration with either type of scope or between endoscopists.

No statistically significant difference was found in the caecal intubation rate, which was 100% with Olympus Scopes and 95% with the Pentax Scopes [$\chi^2 P = 0.67$, not significant (NS)]. Terminal ileal intubation was 54% with Olympus and 55% with Pentax scopes ($\chi^2 P = 0.38$, NS).

Equivalent doses of midazolam or fentanyl were used with both types of scope, with a median dose of 2 mg midazolam and 50 μ g fentanyl. The depth of sedation was equivalent ($\chi^2 P = 0.64$) and the majority of patients were drowsy in both groups. More patients suffered mild discomfort with Pentax scopes (44%) compared to Olympus colonoscopies (16%), ($\chi^2 P = 0.036$). There was no increase in moderate discomfort, and no patients in either group suffered severe discomfort during the procedures (Figure 1).

Although all colonoscopists demonstrated a high pick up rate of adenomas with both colonoscopes; a higher proportion of patients had polyps picked up when examined with the Pentax scopes (66%) compared to

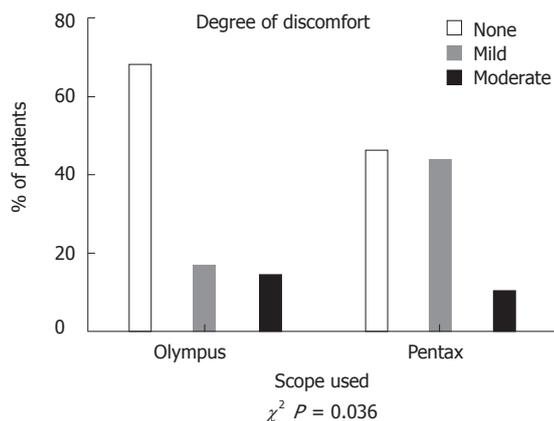

Figure 1 Discomfort scores during colonoscopy. The degree of mild discomfort was worse for patients undergoing colonoscopy with Pentax scopes; however, there was no increase in moderate discomfort and no patients suffered severe discomfort with either scope.

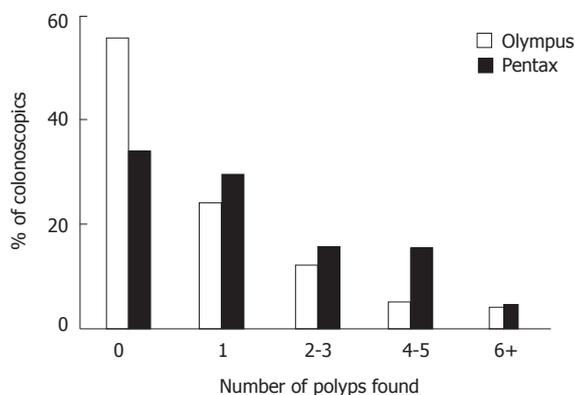

Figure 2 Polyp detection rates. More polyps were found with Pentax HiLine colonoscopes than with Olympus Lucera colonoscopes. χ^2 test for trend $P = 0.01$.

Olympus scopes (44%). The median number of polyps detected per procedure was also higher at one (IQR 0-3) for Pentax compared to zero (IQR 0-1) for Olympus (χ^2 for trend $P = 0.01$) (Figure 2). The median size of polyps was identical at 4 mm in the Olympus group (IQR 2-8) and 3 mm in the Pentax group (IQR 2-8) ($\chi^2 P = 0.98$) (Figure 3). In both groups, approximately one quarter of the polyps were pedunculated and the other three quarters were sessile in nature (Fisher exact test $P = 0.74$. NS). More importantly, the majority of polyps found with both colonoscopes were adenomas. Although smaller polyps were more likely to be hyperplastic, there was no statistically significant difference in polyp histology whichever scope was used.

DISCUSSION

The principal aim of the bowel cancer screening programme in the United Kingdom is to reduce the mortality from colorectal cancer by the early detection of cancerous or pre-cancerous lesions. The accuracy of colonoscopy in identifying these lesions is vital to the success of the program. Factors important in the optimisation of the test

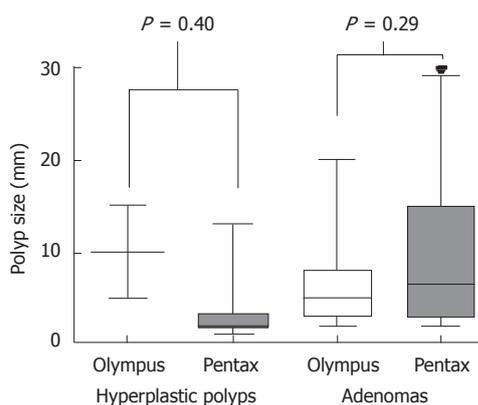

Figure 3 Sizes of polyps. Box plot demonstrating that the median size of polyps was identical for both hyperplastic and adenomatous polyps for both type of colonoscope. Median, interquartile range, and minimum and maximum polyp sizes are shown for each polyp type and colonoscope.

include the bowel preparation, operator skill, withdrawal time, and the image quality^[5,7-11]. On the basis of prevalence of adenomas and caecal intubation rates in studies of screening colonoscopy, threshold values for rates of adenoma detection of 15% amongst women and 25% amongst men over the age of 50 have been proposed in the United States^[7,12]. These have received support from a recent European Study^[5]. All endoscopists taking part in the United Kingdom bowel cancer screening services must demonstrate a minimum level of competence that exceeds these thresholds.

Several studies have demonstrated the potential advantage of utilising additional optical technology, such as narrow band imaging in Olympus scopes, to improve polyp detection, although results are conflicting^[13-16]. Pentax HiLine colonoscopes also have enhanced optical imaging capability, using the iScan surface and contrast enhancements^[17]; however, our aims were to investigate whether white light colonoscopy with increased image resolution alone may be sufficient to improve detection, as neither narrow band imaging nor iScan enhancements are used routinely.

The quality of the final endoscopy image viewed on the screen is dependent upon all the components in the system, including the charge coupled device (CCD) chip within the scope, the processor, the cables, and the screen. CCD chips in the newer “high resolution” scopes contain more pixels, and have increased by an order of magnitude from 100 000 pixels in the older standard definition scopes to 1.3 million pixels in the latest scopes^[18]. The current displays are “high definition” displaying 1080 lines, thereby further improving image quality. The Olympus Lucera colonoscope series has been available in the United Kingdom since 2003 and were the first high resolution endoscopes. The Pentax HiLine series has been marketed since 2009. The images from both video systems are viewed on a high-definition TV screen (1080 lines), but the Olympus colonoscopes have a resolution range from 400 000 to 700 000 pixels whereas the Pentax Scopes have a much higher resolution at 1.3 megapixels. It is therefore expected that the new Scopes would have

a better detection rate for colonic polyps. This study has confirmed this finding, showing that there is a significantly increased chance of detecting polyps with the HiLine system compared to the Lucera system. More importantly, these polyps are significant in that they are adenomas and of a similar size to those detected with the Olympus Lucera Scopes.

The American Gastroenterological Association “Guidelines on screening and surveillance for colorectal cancer”^[19] consider any adenomatous polyp, irrespective of size, to be a significant risk factor for the development of further high risk polyps or colorectal cancer. The prevalence in one large study reporting on 4967 patients identified that the majority (69%) of advanced adenomas detected were < 10 mm size. Even among polyps \leq 5 mm, there was an appreciable prevalence of advanced adenomas (10%)^[20]. Combining this with the ability to now accurately predict polyp type *in vivo* with the modified Kudo pit pattern and vascular colour intensity (VCI) analysis^[21], enables colonoscopists to decide on which polyps to remove *in vivo*, irrespective of size. Consistent with this, most polyps removed in this paper were adenomas on histology.

The estimated 10-year CRC risk for unresected diminutive (< 5 mm), small (5-9 mm), and large (\geq 10 mm) polyps in a decision analysis for CT colonography (CTC) in the United States was 0.08%, 0.7%, and 15.7%, respectively; however, this analysis considered all polyps detected at CTC for these estimations. With modified Kudo pit pattern classification and VCI, accurate *in vivo* characterisation of polyps < 10mm can be predicted with 94% sensitivity and 89% specificity^[22]. This allows non-adenomatous polyps to be resected and discarded without the need for histological assessment. Full economic modelling would be needed to assess the overall cost savings; however, the potential cost savings of not sending diminutive polyps for formal histopathology is thought to exceed 95 million dollars per year in the United States alone^[23].

Rembacken and colleagues^[24] have demonstrated that flat and depressed polyps are more likely to contain high grade dysplasia or invasive cancer than polypoid lesions; however, they are less easily identified and, therefore, are more likely to be missed on colonoscopy. Moreover, it is suggested that the advanced cancers appearing within three years of a negative colonoscopy may have developed from these subtle lesions^[24,25]. A recent population-based study showed that 8% of colorectal cancers were missed by colonoscopy performed within the previous three years^[26]. The improved overall polyp detection rate of megapixel high resolution colonoscopies demonstrated by our study, particularly for small flat adenomas could significantly improve outcomes of the bowel cancer screening program, although this hypothesis clearly needs to be formally tested in a prospective randomised controlled trial.

The Lucera colonoscopes have variable stiffness and are the standard scopes used by the majority of endoscopists in United Kingdom. The Pentax colonoscopes do not have a variable stiffness feature and feedback from in-

dividual endoscopists prior to the start of the study suggested that patients may find these scopes more uncomfortable than the Lucera Scopes. This study confirmed this finding, although the degree of added discomfort was only mild and only occurs in one quarter of patients. For the majority therefore, there was no difference in discomfort score between the two types of colonoscope. Importantly, patients did not require any more sedation. We routinely use ScopeGuide with our Lucera colonoscopes, which helps us to manage scope looping. We do not have this feature with the Pentax scopes and this might also explain the increase in mild discomfort in this group of patients.

Operators also suggested that endoscopists’ performance with the new Pentax scopes may be reduced due to changes in handling from the Olympus scopes. The performance, as measured by caecal intubation rates and procedural times, were no different between the two scopes. Moreover, no performance learning curve was detected.

Missing polyps when performing a colonoscopy is a serious problem. Several advanced imaging techniques have therefore been developed, including dye sprays, narrow band imaging, and endomicroscopy, amongst others. However, these techniques can be time consuming and require training and experience. Only techniques that are easy to perform and can be done without “high end” expertise by all appropriately trained endoscopists are suitable for screening programs. For this reason, the introduction of better image quality may be a simple solution to the problem of missed polyps at colonoscopy.

It is worth remembering that all colonoscopists who are accredited for bowel cancer screening have to demonstrate very high standards of caecal intubation and polyp detection. The fact that scope handling was no different between the scopes may not be generally applicable to all endoscopists, but it is likely to be applicable to all colonoscopists who are accredited to do bowel cancer screening, even if they are not trained to use enhanced optical detection techniques.

There are obvious limitations to this study. Although the data were collected prospectively, this is a single site study and most of the Pentax HiLine procedures were performed by a single endoscopist. All analyses, however, were carried out between the two types of endoscope for all five colonoscopists taking part in the bowel cancer screening programme, and also for the individual colonoscopists who performed procedures with both Pentax and Olympus colonoscopes. No difference was found between the two types of analysis, suggesting that the findings are robust. Nonetheless, it would be wise to confirm these findings with a multicentre, prospective, randomised controlled study involving multiple endoscopists. In addition, it would be optimal to have assessed either endoscopy system in the same patient performed by the same operator to test for a significant difference in the measured outcomes, but this would not be ethically viable. Finally, it is not certain that detecting more small

polyps would actually translate to better outcomes from a national bowel cancer screening programme. It would take a very large study to prove this. Nonetheless, if the procedure takes no more time, carries minimal extra discomfort, and detects significantly more polyps, it seems reasonable to consider using this in routine practice. A prospective trial to compare the performance of these two colonoscopes for bowel cancer screening is therefore required.

COMMENTS

Background

Colorectal cancer is one of the most common cancers worldwide, particularly in Europe and the United States, and is the 7th most common cause of death worldwide in high earning countries. To reduce the number of deaths from this disease, strategies have been designed to detect cancer at an earlier stage, and detect and remove polyps, thought to be the precursors for a large proportion of future colorectal cancers.

Research frontiers

In the United Kingdom, the national bowel cancer screening program was established to reduce deaths from colorectal cancer, utilising colonoscopy for patients screened positive with tests designed to detect minute quantities of blood in their stool. Colonoscopy was chosen as the screening modality, as it is now established as the gold standard both for the identification of colorectal cancer and polyps. The miss rate during colonoscopy, however, is unsuitably high for both the detection of significant polyps, known as adenomas (24%) and colorectal cancers (up to 6%). It is therefore desirable to investigate methods that may improve the accuracy of colonoscopy, particularly as a higher adenoma detection rate is associated with lower rates of colon cancer developing later.

Innovations and breakthroughs

Although colonoscopy is now accepted as the gold standard for the detection of colorectal cancer, a number of colonoscopes with varying technologies are now available in the market. Previous studies have compared high definition (HD) with standard video colonoscopy to show how high definition colonoscopy could detect significantly more patients with colorectal neoplasia (38% vs 13%), and significantly more adenomatous and cancerous polyps. Furthermore high definition endoscopy with surface enhancement could also predict the final histology with high accuracy (98.6%) within the HD+ group. There are few studies comparing different high definition systems that have varying resolutions.

Applications

This study demonstrates that higher definition colonoscopes improve adenoma detection without compromising other measures of endoscope performance. Increased polyp detection rates may improve the outcomes of bowel cancer screening programs in the future. Future research is still needed to identify the cost effectiveness of megapixel high-resolution endoscopy systems in larger clinical studies.

Terminology

Polyps: a polyp is an abnormal growth of tissue arising from the lining of the bowel; Adenoma: an adenoma is benign tumour arising from glands inside the lining of the bowel; Histology: the microscopic study of cells and tissues.

Peer review

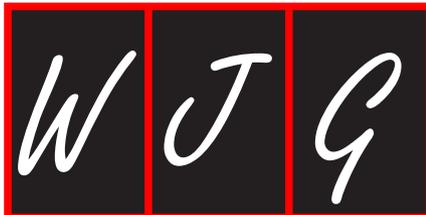

This article addresses the very important issue of investigating the best equipment available to endoscopist in order to adequately equip them to perform their duties to the best of their abilities. Historically, studies have concentrated on comparing groups or individuals practicing procedures. This study is unique and important as it compared two independently available endoscopy systems that are used in the United Kingdom. It demonstrates that the Pentax system is superior to the Olympus system when specifically looking at the question of polyp detection. Although the Olympus scopes are widely used and have other excellent qualities that have made them very popular in the United Kingdom, it is vital that, as endoscopists and practitioners, the authors question the quality of their equipment. This study allows bowel cancer colonoscopists to make a better and more informed decision about which endoscopy system is best for allowing them to accurately detect these pre-cancerous polyps, in their practice.

Abstract

AIM: To investigate the clinicopathological characteristics of late-stage lung cancer patients with gastrointestinal (GI)-tract metastases, focusing on therapeutic options and outcomes.

METHODS: Our institution (the National Taiwan University Hospital) diagnosed 8159 patients with lung cancer between 1987 and 2008, of which 21 developed symptomatic GI metastases. This study reviewed all of the patients' information, including survival data, pathological reports, and surgical notes.

RESULTS: The most common histological type of lung cancer was adenocarcinoma, and 0.26% of patients with lung cancer developed GI metastases. The median duration from lung cancer diagnosis to GI metastases was three months (range, 0-108 mo), and the average time

from diagnosis of GI metastasis to death was 2.8 mo. Most patients with symptomatic gastric and/or duodenal metastases exhibited GI bleeding and were diagnosed by panendoscopy. In contrast, small bowel metastases typically presented as an acute abdomen and were not diagnosed until laparotomy. All patients with small bowel or colonic metastases underwent surgical intervention, and their perioperative mortality was 22%. Our data revealed a therapeutic effect in patients with solitary GI metastasis and a favorable palliative effect on survival when metastases were diagnosed preoperatively. In patients with multiple GI metastases, the presentation varied according to the locations of the metastases.

CONCLUSION: Surgical treatment is worthwhile in a select group of patients with bowel perforation or obstruction. Physicians should be more alert to symptoms or signs indicating GI metastases.

Role of surgical intervention in managing gastrointestinal metastases from lung cancer. *World J Gastroenterol* 2011; 17(38): 4314-4320 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i38/4314.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i38.4314>

INTRODUCTION

Lung cancer is a major cause of cancer-related death worldwide. In Taiwan, it is the second leading cause of cancer death, with nearly 8700 new cases and 7500 deaths per year^[1]. Approximately one-half of lung cancer pa-

tients develop metastases^[2,3], the most common sites of which are the lymph nodes, liver, adrenal glands, bone, and brain^[2]. Symptomatic gastrointestinal (GI) tract metastases are not uncommon^[4,5], although GI metastases from lung cancer are rare. The reported incidence of GI metastasis from lung cancer varies from 0.5%-10%, and mainly depends on the evaluation method used (endoscopy, surgical specimens, or autopsy)^[2,5-7]. The typical presentations of GI metastases are abdominal pain, bleeding, obstruction, and perforation, of which perforation is the most serious complication, necessitating surgical intervention to prevent a life-threatening event. GI tract involvement with lung cancer is generally considered to be associated with a late or advanced stage of the disease. Therefore, the question of how to manage patients with symptomatic GI metastases from lung cancer is important; however, management of the disease remains a controversial topic^[2,3,6].

The present study describes the clinicopathological features of a large series of primary lung cancers manifesting GI metastases and discusses therapeutic options, with a particular focus on the role of surgeons in this uncommon oncological setting.

MATERIALS AND METHODS

This research reviewed the surgical pathology reports of patients diagnosed with GI metastases from 1987 to 2008 at the National Taiwan University Hospital. Only those cases in which the primary source of the metastases was documented as lung cancer were included in our analysis. The diagnostic criteria were (1) radiological demonstration of a primary lung tumor and exclusion of tumors elsewhere, and (2) the morphology and immunohistochemical profiles were consistent with a primary pulmonary tumor. Of 8159 patients diagnosed with lung cancer, 21 were found to have GI metastases. Metastatic disease originating from a lung primary tumor was confirmed from biopsy specimens or from surgical resection of the GI tract in patients.

Patient information, including age, sex, pathology, initial lung cancer stage, interval between lung tumor diagnosis and discovery of GI involvement, clinical presentation, other metastatic site locations at the time of GI metastases, and patient survival, was recorded and reviewed retrospectively. Clinical and other follow-up data were obtained in all cases from patient records and referring physicians. Analysis of the survival data was performed by the Kaplan-Meier method. Differences between subgroups were compared for statistical significance using the log-rank test. *P* values were two-sided and the significance level was set at 0.05.

RESULTS

Patient characteristics

Table 1 summarizes the patient data, including clinical manifestations, diagnosis, treatment, and follow-up.

The patients ranged in age from 40 to 81 years (median, 69 years), and of the five women and 16 men, 14 had a smoking history. Nine patients (one woman, eight men) developed symptomatic gastric and/or duodenal metastases. Six patients (all male) had symptomatic small bowel metastases. Three patients (two women, one man) had symptomatic colonic metastases. The other three patients (two women, one man) had multiple GI tract metastases.

Interval between lung cancer diagnosis and gastrointestinal metastasis

Studies have reported GI tract metastasis to occur in the later stages of lung cancer^[1]. In our study, the median duration from lung cancer diagnosis to GI tract metastasis in the eight patients with initial stage I to III disease was 8 mo (ranging from 2 to 108 mo). In contrast, 5 of the 13 patients with stage IV lung cancer developed simultaneous GI metastases, and the median duration of the other eight patients with GI metastases was 3.5 mo (ranging from 1 to 17 mo). The average time from GI metastasis diagnosis to death was 2.8 mo, similar to the 130.3 d reported by Yang *et al*^[8].

Clinical presentations and diagnosis

Gastrointestinal hemorrhage was the most common symptom of GI metastasis (11 of 21, 52.4%). Panendoscopic biopsy easily diagnosed nine patients with gastric or duodenal metastases. Three of the six patients with small bowel metastases exhibited intestinal perforations and the others exhibited GI obstructions. Of these patients, 67% (4/6) were diagnosed by laparotomy, including three cases of intestinal perforation, which could reflect the fact that small bowel metastases are more difficult to diagnose before surgery, and the typical clinical manifestations are an acute abdomen or peritonitis. In contrast to patients with colonic metastases, the diagnosis of patients with GI metastasis could be made before surgery by computed tomography (CT) or colonoscopy. This result is possibly attributable to the slow progression of clinical manifestations and physician awareness. Clinical presentations of multiple GI involvements were variable, and depended on the major location of the metastatic GI tumors. For example, patient #19 had stage IV lung cancer and experienced mild abdominal pain for weeks. She did not pay attention to the pain, thinking it was an adverse effect of chemotherapy. Her symptoms progressed rapidly to poor appetite and little oral intake; therefore, she was admitted for further management. A CT scan revealed multiple intra-abdominal tumors involving the ovaries, pancreas, and stomach. After discussing the options with the patient and her family, they all agreed to hospice care, and the patient passed away three months later.

Histological subtypes and other metastatic sites

Half of the patients in this series (12 of 21) had primary lung adenocarcinoma and five had squamous cell carcinoma; the other four included one pleomorphic carcinoma, one small cell carcinoma, one undifferentiated carcinoma,

¹Patient still alive. M: Male; F: Female; pTNM: Pathological tumor-lymph node-metastasis; GI: Gastrointestinal; PES: Panendoscopy; CT: Computed tomography.

and one adenosquamous carcinoma.

All but two of the patients (19/21, 90.5%) had metastases to other locations at the time of GI metastasis diagnosis. The most common extrathoracic metastatic sites were the liver, brain, bone, adrenal glands, spleen, and pancreas. The two cases (patients #12 and #16) with only one GI metastasis underwent surgical resection with therapeutic intent and one was still alive at the time of writing.

Surgical procedures and clinical outcomes

Upon diagnosis of stomach or duodenal involvement, conservative treatment was prescribed for symptoms, and imaging studies were performed to evaluate other possible metastatic sites. All nine patients in this subgroup had other simultaneous metastases that were considered to represent the late stage of lung cancer. If the symptoms (GI bleeding or abdominal pain) could be controlled by medication, supportive treatment was continued. Two

patients underwent surgical intervention due to massive hemorrhage; patient #5 received a proximal gastrectomy for a 6.7-cm ulcerative mass over the body of the stomach with direct invasion of the spleen, and patient #7 received a wedge resection for an ulcerative lesion over the cardia of the stomach. Unfortunately, these two patients died within one month of surgery owing to postoperative complications. The other seven patients received only supportive treatment, and the median survival was one month (range, 1 to 15 mo). We observed that patients treated with conservative therapy exhibited a significant survival benefit in comparison with those who received surgical treatment ($P = 0.005$).

Nine patients with small bowel or colonic metastases underwent laparotomy. As mentioned above, four patients were not diagnosed until laparotomy. Patients who required immediate surgical intervention exhibited an acute abdomen, such as perforation or peritonitis. Survival comparisons of these patients, based on the timing

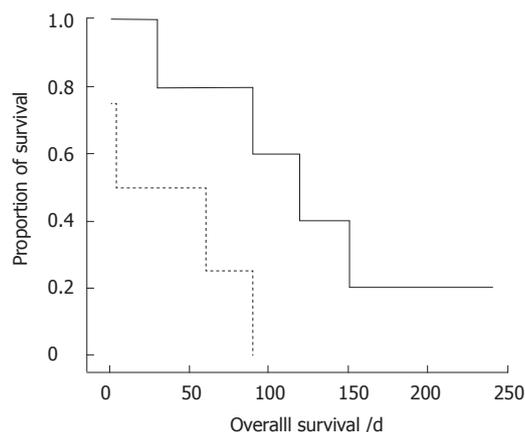

Figure 1 Kaplan-Meier plot of the survival curve for nine patients according to the diagnostic time of gastrointestinal metastasis before surgery (solid line) or after surgery (dashed line).

of diagnosis, showed that the survival benefit was significantly increased in the subgroup with GI metastases diagnosed before surgery ($P = 0.032$, Figure 1). Accordingly, early GI metastasis detection and timely surgical intervention are important for lung cancer patients. Of the three patients with multiple GI tract metastases, all received palliative treatment and died of the disease.

As an example, one patient (case #16 in Table 1) was diagnosed with lung adenocarcinoma in October of 2003. At that time, chest radiography showed massive left pleural effusion. A chest CT revealed a patchy consolidation with pleural thickening in the left upper lung lobe. Adenocarcinoma was confirmed by CT-guided biopsy and pleural effusion collected *via* aspiration for cytological analysis. After a complete staging work-up, stage IIIb lung cancer was confirmed and the patient underwent multiple courses of chemotherapy. However, the patient began experiencing abdominal pain, which was aggravated after meals, in March of 2008. A physical examination revealed diffuse abdominal tenderness without rebounding pain, and an abdominal and pelvic CT showed a single ill-defined mass with local infiltration into the ascending colon (Figure 2A). Colonoscopy revealed a circular tumor with luminal obstruction (Figure 2B), and a biopsy indicated adenoma with malignant change. Colon cancer was the tentative diagnosis; however, the actual origin of the tumor could not be confirmed. After surgical intervention, a 4-cm irregular-shaped mass invading the adjacent small bowel in the ascending colon was noted during the laparotomy, and a right hemicolectomy with a segmental resection of the small bowel was performed without complications. The pathological report revealed that the tumor involving the colon was mainly located in the pericolonic soft tissue and invaded inwards into the colonic muscular layer (Figure 3A). The morphology of the tumor was distinct, characterized by pleomorphic oval nuclei, scant cytoplasm, and an irregular glandular pattern. Immunohistochemical staining revealed the tumor cells to be positive for thyroid transcription factor-1 (TTF-1) and cytokeratin 7 (CK7), but negative for CK20

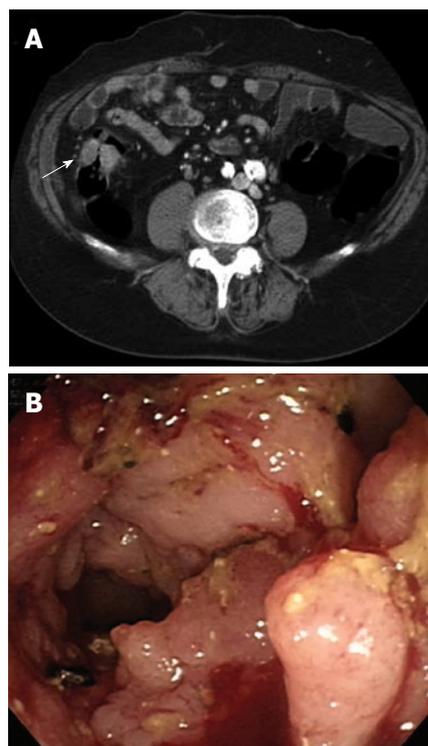

Figure 2 Imaging study of one patient with colonic metastases from lung cancer. A: An abdominal computed tomography showed a 4-cm ill-defined tumor at the ascending colon (arrow); B: Colonoscopic feature of a circular mass with luminal stenosis and easy-touch bleeding.

(Figure 3B-D). The diagnosis of a metastatic adenocarcinoma of pulmonary origin was confirmed.

DISCUSSION

Lung cancer is the leading cause of death from cancer worldwide, and about one-half of lung cancer patients have metastatic disease at the initial diagnosis^[2,3]. The most common sites of metastatic disease are the lymph nodes (48%), liver (45%), adrenal glands (41%), bone (31%), and brain (25%)^[2]. Before the 1980s, GI tract involvement was considered an unusual metastasis site from lung cancer^[9,10], and the pathogenesis of bowel metastases was considered to be due to tumor-cell spreading via the hematogenous or lymphatic routes. A review of autopsy data by Antler *et al*^[7] reported the incidence of GI metastasis to be 14%; however, 14% may be higher than the true incidence of GI metastasis, because a large number of esophageal metastases in their study were the result of direct invasion. The incidence of symptomatic small bowel metastasis has been reported to be 0.4%-0.5%^[4,5]. In our series, there were 21 cases of symptomatic gastrointestinal metastases among the 8159 lung cancer patients (0.26%). The disparity between subclinical and clinical GI metastases is still high.

Gastric and/or duodenal metastases from lung cancer are very rare, and there are only a few cases of varying malignant cell types reported in the literature^[11-13]. These cases exhibited symptoms of abdominal pain, chronic

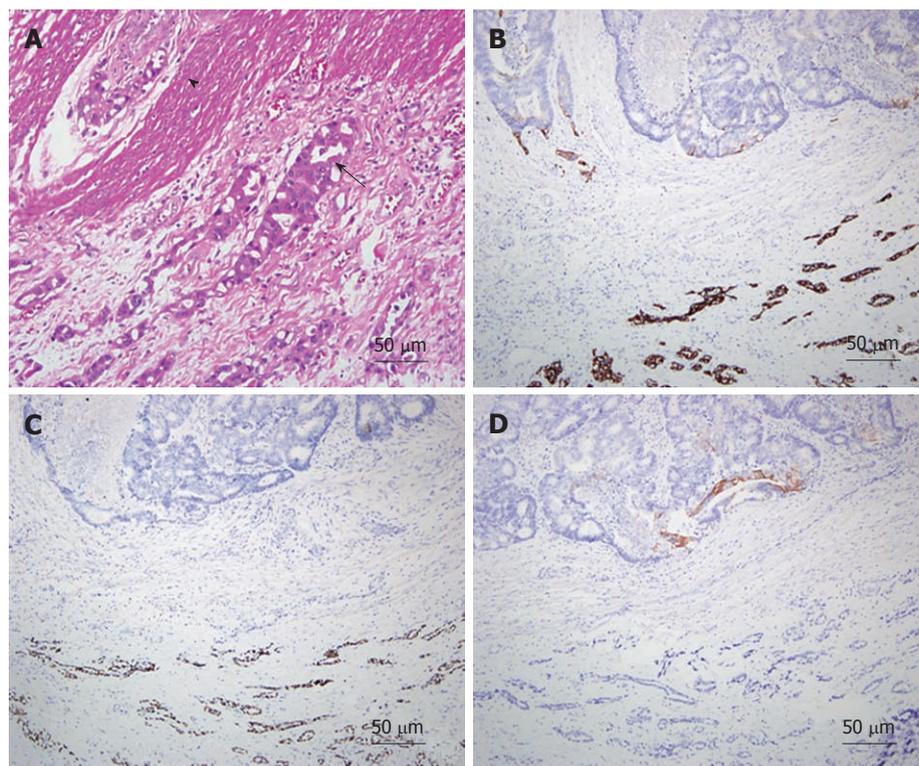

Figure 3 Microscopic findings of metastatic lung adenocarcinoma in the colon. A: Hematoxylin-eosin staining; $\times 200$. This tumor was characterized by pleomorphic oval nuclei, scant cytoplasm, an irregular glandular pattern (arrow), and invasion of the muscle layer (arrow head) of the colon; B-D: Staining for thyroid transcription factor (TTF)-1 (B), cytokeratin (CK)7 (C), CK20 (D); $\times 100$. In general, CK20 positive means that the tumor originates from the gastrointestinal tract. By immunohistochemistry, the tumor cells located in the lower part of the figure were found to be positive for TTF-1 (B) and CK7 (C), but negative for CK20 (D). The glandular structures in the upper part belong to the colon mucosa.

bleeding, anemia, or hematemesis, and the pathological results of panendoscopic biopsy provided accurate diagnoses. In contrast to the small bowel, the most common metastatic site of lung cancer in the GI tract^[4,5,14,15], there have been few reports of lung cancer metastases to the colon, appendix, or anus^[16-19]. Small intestine involvement often leads to an acute abdomen as a result of perforation or obstruction^[4,5,15], whereas colon metastases usually result in vague symptoms. In our cases of small bowel or colon metastases, all patients required surgery to relieve the obstruction or control peritonitis. In general, the use of CT, abdominal sonography, or endoscopy plays an important role in identifying lesions.

Even with endoscopy, lung cancer involving the GI tract has no specific features, appearing as a diffuse involvement of the mucosa and multiple nodules with or without mucosa ulceration^[20,21]. An experienced pathologist might be able to conclude a metastatic tumor based on morphological study of tumor tissue from surgical resection. However, in most cases histological examination with staining using cell type-specific markers is the only way to identify metastatic tumors of the GI tract. Several different CK and other protein markers are widely used to distinguish carcinomas of different origins. Rossi *et al.*^[21] concluded that lung carcinomas usually demonstrate a CK7+/CK20- immunoprofile, whereas intestinal carcinomas have a different CK7-/CK20+ pattern. Thus, CK7 is a good marker for distinguishing those cell types. In gen-

eral, primary lung tumors can be identified by CK7; however, studies have demonstrated that primary adenocarcinomas of the rectum or small intestine may also express CK7 in a significant number of cases, and may even lose CK20 expression^[22,23]. Therefore, to exclude a possibility like this, employing a more specific marker of lung tumor origin, such as TTF-1^[24], together with CK7 and CK20 could more effectively differentiate metastatic GI tumors from lung cancer.

Every type of lung cancer can result in GI metastasis. McNeill *et al.*^[2] and Berger *et al.*^[5] reported that squamous cell carcinoma causes small bowel metastases more frequently than other lung tumor cell types. In the series of Antler *et al.*^[7], small cell carcinoma and large cell carcinoma were more likely to result in GI metastases. However, in our series, adenocarcinoma was the most frequent type resulting in GI metastases. In accordance with our results, Garwood *et al.*^[4] reported that adenocarcinoma (23.7%) and squamous cell carcinoma (22.7%) were the most common histological types causing small bowel perforations.

Our results showed that the median time from lung cancer diagnosis to GI metastasis was three months and the longest period of time was 108 mo (patient #7). Observations of previous data show that, in patients with lung metastases from colon cancer, a longer interval between colon cancer diagnosis and lung metastasis was associated with a significantly longer survival^[25]. However, our findings did not show a similar survival difference

when patients with an interval greater than 1 year were compared with those with an interval less than 1 year ($P = 0.79$). Our results also revealed no significant difference in overall survival in patients with initial stage I–III lung cancer upon GI metastasis diagnosis in comparison with those with stage IV disease. Taken together, these findings indicate that patients with GI metastases from lung cancer have a poor prognosis.

The perioperative mortality rate reported in the literature ranges from 60% to 100%^[2,15]. The series of Berger *et al.*^[5] indicated no perioperative mortality in patients with small bowel metastases who underwent resection. However, in our experience, the perioperative mortality rate was 100% in the two patients with gastric and/or duodenal metastases and 22% (2/9) in patients with small bowel or colon metastases. We observed longer survival in patients with gastric and/or duodenal metastases that were managed by supportive treatment without surgery ($P = 0.005$). However, the relatively small sample size in this retrospective subgroup analysis and the nature of the different underlying conditions (these nine patients had other metastases at the same time) may limit the conclusion that surgical treatment is not suitable for patients with gastric or duodenal metastases from lung cancer. On the other hand, in two of our patients, radiological work-up did not show other metastases. These patients then underwent surgical resection and one is still alive. Although surgery for localized extrathoracic metastasis from lung cancer still has a palliative intent^[21], some authors have reported prolonged survival in cases of surgically-resected isolated bone^[26], brain^[27], or small bowel^[14] metastasis from lung cancer. Our results (Figure 1) are the first to show a longer survival or more favorable outcome in patients diagnosed with GI metastasis before surgery. Consequently, surgical treatment still plays an important role in lung cancer patients with GI metastases that cause bowel obstruction, perforation, or massive hemorrhage.

In summary, patients with GI metastases from lung cancer are in the latter stages of the disease. However, physicians and surgeons should be aware that surgical intervention is typically required for patients exhibiting bowel perforation or an acute abdomen. Therefore, early detection of GI metastasis in lung cancer patients and timely surgical management may provide symptom palliation in patients with a life-threatening GI event and long-term survival in those with only a solitary GI metastasis.

COMMENTS

Background

Lung cancer is a major cause of cancer-related death worldwide. Lung cancer patients with gastrointestinal (GI)-tract metastases are generally considered to be at a late or advanced stage of the disease. Management of the disease remains controversial. Study of the management in patients with symptomatic GI metastases from lung cancer is important.

Research frontiers

Histological examination using cell type-specific markers is the best way to identify the origin of metastatic tumors of the GI tract. Staining using thyroid transcription factor-1 (TTF-1) as a specific marker of lung tumor origin, together with cytokeratin 7 (CK7) and CK20, could more effectively differentiate meta-

static GI tumors from lung cancer.

Innovations and breakthroughs

Surgical treatment plays an important role in lung cancer patients with a GI metastasis that causes bowel obstruction, perforation, or massive hemorrhage. The results of this study were the first to show a longer survival or more favorable outcome in patients diagnosed with GI metastasis before surgery.

Applications

Surgical intervention is typically required for patients exhibiting bowel perforation or an acute abdomen. Therefore, early detection of GI metastasis in lung cancer patients and timely surgical management may provide symptom palliation in patients with a life-threatening GI event and improve long-term survival in those with only solitary GI metastasis.

Terminology

CK7 and CK20 are low molecular weight cytokeratins. Their distribution is generally restricted to epithelia and neoplasms. The specific expression patterns of CKs are correlated with different pathways of epithelial differentiation, and therefore can be used to classify epithelial cells into different subtypes or origins. TTF-1 is a 38-kDa nuclear transcription protein that influences organogenesis and the maintenance of the differentiated phenotypes of various tissues, including thyroid, lung and brain.

Peer review

The paper was well written and it is enhanced by the photomicrographs, radiological and endoscopic images.

Abstract

AIM: To determine the therapeutic effect of lamivudine in late pregnancy for the interruption of mother-to-child transmission (MTCT) of hepatitis B virus (HBV).

METHODS: Studies were identified by searching available databases up to January 2011. Inclusive criteria were HBV-carrier mothers who had been involved in randomized controlled clinical trials (RCTs) with lamivudine treatment in late pregnancy, and newborns or infants whose serum hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg) or HBV DNA had been documented. The relative risks (RRs) for interruption of MTCT as indicated by HBsAg, HBV DNA or HBeAg of newborns or infants were calculated with 95% confidence interval (CI) to estimate the efficacy of lamivudine treatment.

RESULTS: Fifteen RCTs including 1693 HBV-carrier

mothers were included in this meta-analysis. The overall RR was 0.43 (95% CI, 0.25-0.76; 8 RCTs; $P_{\text{heterogeneity}} = 0.04$) and 0.33 (95% CI, 0.23-0.47; 6 RCTs; $P_{\text{heterogeneity}} = 0.93$) indicated by newborn HBsAg or HBV DNA. The RR was 0.33 (95% CI, 0.21-0.50; 6 RCTs; $P_{\text{heterogeneity}} = 0.46$) and 0.32 (95% CI, 0.20-0.50; 4 RCTs; $P_{\text{heterogeneity}} = 0.33$) indicated by serum HBsAg or HBV DNA of infants 6-12 mo after birth. The RR (lamivudine vs hepatitis B immunoglobulin) was 0.27 (95% CI, 0.16-0.46; 5 RCTs; $P_{\text{heterogeneity}} = 0.94$) and 0.24 (95% CI, 0.07-0.79; 3 RCTs; $P_{\text{heterogeneity}} = 0.60$) indicated by newborn HBsAg or HBV DNA, respectively. In the mothers with viral load $< 10^6$ copies/mL after lamivudine treatment, the efficacy (RR, 95% CI) was 0.33, 0.21-0.53 (5 RCTs; $P_{\text{heterogeneity}} = 0.82$) for the interruption of MTCT, however, this value was not significant if maternal viral load was $> 10^6$ copies/mL after lamivudine treatment ($P = 0.45$, 2 RCTs), as indicated by newborn serum HBsAg. The RR (lamivudine initiated from 28 wk of gestation vs control) was 0.34 (95% CI, 0.22-0.52; 7 RCTs; $P_{\text{heterogeneity}} = 0.92$) and 0.33 (95% CI, 0.22-0.50; 5 RCTs; $P_{\text{heterogeneity}} = 0.86$) indicated by newborn HBsAg or HBV DNA. The incidence of adverse effects of lamivudine was not higher in the mothers than in controls ($P = 0.97$). Only one study reported side effects of lamivudine in newborns.

CONCLUSION: Lamivudine treatment in HBV carrier-mothers from 28 wk of gestation may interrupt MTCT of HBV efficiently. Lamivudine is safe and more efficient than hepatitis B immunoglobulin in interrupting MTCT. HBV MTCT might be interrupted efficiently if maternal viral load is reduced to $< 10^6$ copies/mL by lamivudine treatment.

INTRODUCTION

Hepatitis B virus (HBV) infection is a global issue of public health. More than 350 million people suffer from chronic HBV infection, the commonest cause of hepatocellular carcinoma^[1]. Mother-to-child transmission (MTCT) of HBV, the commonest mode of transmission worldwide, may occur either in utero or perinatally. In East and Southeast Asia, in utero transmission of HBV is rare, whereas perinatal transmission is common. MTCT of HBV is associated with a very high rate of chronicity, especially in countries where HBV is endemic. This is attributed to the high rate of hepatitis B e antigen (HBeAg)-positive infection in women of child-bearing age in these areas and the efficient transmission of HBV from mothers to their newborns^[2-4]. Therefore, prevention of MTCT is the most important strategy in the eradication of HBV infection.

Joint immunoprophylaxis with hepatitis B immunoglobulin (HBIG) and three doses of hepatitis B vaccines to infants born to hepatitis B surface antigen (HBsAg)-positive mothers are known to be safe and effective. However, 5%-10% of infants of HBV-positive mothers become infected even with proper vaccination^[5]. Very high maternal viremia, in utero infection, or escape mutants are possible reasons for vaccination failure, while immunocompromised hosts also risk vaccination failure^[6]. Of those, maternal high viral load and HBeAg positivity contribute greatly to MTCT despite the use of passive-active immunoprophylaxis in newborns. A meta-analysis of individual patient data of the three randomized trials indicated that the passive-active immunoprophylaxis had 100% protective efficacy if maternal serum HBV DNA was lower than 150 pg/mL compared with 68% if maternal serum HBV DNA was higher than 150 pg/mL^[7]. The recommended dose of HBIG may be insufficient to neutralize the huge virus load that the infants are exposed to at the time of birth in cases whose mothers have very high serum HBV DNA levels^[8]. In addition, immunized children born to genotype C HBV-infected mothers may have a higher rate of breakthrough infection than those born to genotype B-infected mothers in Southeast Asia^[9]. Thus, administration of antiviral therapy to lower the maternal serum HBV DNA levels may reduce the rate of perinatal infection in newborns born to mothers who have high serum HBV DNA levels or who are infected with HBV genotype C, the major HBV

genotype endemic in mainland China^[10].

The antiviral drug with a record of safe use in pregnant women is lamivudine^[11]. In HBeAg-positive mothers who had serum HBV DNA > 10⁹ copies/mL, lamivudine treatment started between weeks 34 and 38 of pregnancy until delivery might greatly decrease the perinatal infection of their newborns who routinely received the combined immunoprophylaxis, as compared with historical controls^[12]. However, some studies have demonstrated that treatment with lamivudine or HBIG did not reduce the perinatal infection rate significantly among women with an extremely high HBV DNA load, and among those with reduced maternal HBV DNA, even with undetectable status, this treatment could not guarantee exemption of their newborns' HBV infection in late pregnancy^[13,14]. These controversial results necessitate meta-analyses by pooling data of the available studies to address the following questions^[8]. (1) At which maternal serum HBV DNA level does the antiviral therapy have a clear beneficial effect? (2) How early in pregnancy should antiviral therapy be initiated? (3) Is lamivudine safe in pregnancy or in nursing mothers? A recent meta-analysis of randomized controlled trials (RCTs) using the data up to October 2009 has demonstrated that lamivudine treatment in HBV-infected mothers with a high degree of infectiousness in late pregnancy effectively prevented MTCT^[15]. However, the first two questions have not been fully answered. In this study, we performed a meta-analysis of the randomized, placebo controlled trials up to January 2011, evaluated the efficacy of lamivudine in late pregnancy as compared with placebo or control in interruption of MTCT of HBV and determined the maternal HBV DNA level that lamivudine treatment has a clear beneficial effect. We also investigated the safety of lamivudine treatment in mothers and their newborns in an attempt to provide useful data for interrupting MTCT of HBV.

MATERIALS AND METHODS

Search strategy and selection criteria

We searched MEDLINE, EMBASE, the Cochrane controlled trials register, the Cochrane Library, and China Biological Medicine Database for publications (including abstracts) in English or Chinese, up to January 2011. The keywords used for searching were "MTCT (vertical transmission, perinatal transmission or intrauterine transmission)" and "hepatitis B virus (HBV or hepatitis B)" and "antiviral treatment (lamivudine)". We also did a full manual search from bibliographies of selected studies to identify additional studies. We contacted some of the authors to collect further information.

The following studies were included: RCTs; lamivudine treatment for HBV-carrier mothers in late pregnancy; passive-active immunoprophylaxis for newborns after birth; MTCT; MTCT diagnosed based on the serum parameters including HBsAg, HBeAg and HBV DNA; and relative risks (RRs) with the 95% confidence intervals (CIs). The following studies were excluded: unclear his-

tory of the immunoprophylaxis of newborns or infants; the patients co-infected with hepatitis C or hepatitis D virus or human immunodeficiency virus; participants who had received antiviral treatment before pregnancy or without control subjects. We only included the most recent studies or studies with a larger number of participants when more than one studies were published by the same authors.

Data extraction

Data were independently extracted by two investigators (Han L and Zhang HW) and checked by the other authors. The concordance rate between the two investigators was more than 90%. Discrepancies were resolved by consensus. The following information was extracted using a standardized form: the details of the study (study design, citation, publication date); the characteristics of the subjects (number of included mothers, maternal serum HBV HBsAg and HBeAg); the interventions on mothers (lamivudine treatment and comparative treatment regimen used for each arm, dosage, and duration) and the outcomes (serum HBsAg, HBeAg and HBV DNA of newborns within 24 h and infants within 6-12 mo after birth) and adverse events.

Quality assessment

Two investigators (Han L and Zhang HW) independently rated the quality of each retrieved study. Disagreement was resolved by discussion among the investigators. Trials of high quality (with low risk of bias) should fulfil two or three of the following elements: adequate generation of the allocation sequence, adequate allocation concealment, and adequate blindness. Trials of low quality (with high risk of bias) were those having one or none of these elements^[16,17].

Statistical analysis

Freeware program Review Manager (Version 5.0 for Windows, Cochrane Collaboration, Oxford, United Kingdom, 2010) was applied to conduct statistical analysis. The effect measures of interest were RRs and the corresponding 95% CIs. Statistical heterogeneity among studies was evaluated using χ^2 test, P values, and I^2 statistics^[18]. Statistical heterogeneity was defined as $P < 0.10$ or $I^2 > 50\%$. A random-effect model was used to obtain summary RRs. The random-effect model adjusted for variability of results among trials provided a more conservative estimate of an effect using wider CI^[19]. Publication bias was evaluated using funnel plots which displayed the studies in a plot of effect size against sample size, which mapped the log standard error against the log RR of individual studies^[20]. All statistical tests were two-sided.

RESULTS

We identified 106 citations from the literature. The relevant trials are shown in Figure 1. Eighteen irrelevant ci-

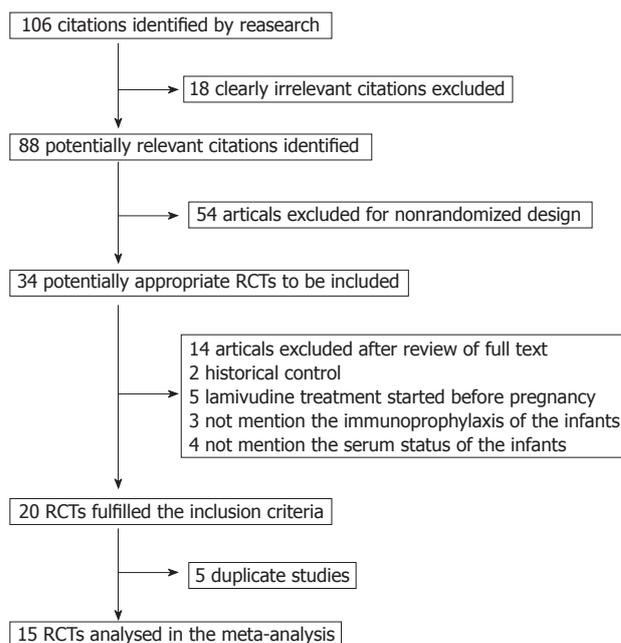

Figure 1 Flow chart of study recruitment. RCTs: Randomized controlled clinical trials.

tations were excluded after abstract preview. Among the remaining 88 articles, 54 were excluded because of non-randomized design after the full text review. Of the remaining 34 potentially appropriate RCTs, 2 were excluded because of historical controls, 5 were excluded because the lamivudine treatment started before pregnancy, 3 were excluded for not having detailed information on the immunoprophylaxis of newborns, and 4 were excluded because the serum HBV parameters of the infants were not mentioned. After removing the 5 duplicate studies, a total of 15 RCTs were included eventually^[21-35]. Of the 15 RCTs, 2 were from PubMed^[25,35], 12 from China Biological Medicine Database published in Chinese^[21-24,27-34], and 1 from reference lists^[26]. Of those, 10 investigated MTCT by measuring the newborn's blood within 24 h after birth^[21-23,25,26,28-30,34-35], 11 investigated MTCT by measuring the infant's sera 6-12 mo after birth^[21-25,27-28,30-33], 11 measured maternal HBV DNA levels when they were enrolled in the trials before lamivudine treatment^[21,23,25-27,29-31,33-35], 10 measured maternal HBV DNA levels after treatment before delivery^[21,25-27,29-31,33-35]. The regimen of lamivudine treatment varied and some RCTs had several intervention groups such as HBIG or lamivudine plus HBIG groups. Three articles reported adverse events in mothers with lamivudine treatment^[25,26,34], only one article reported adverse events in the infant whose mother received lamivudine treatment^[25]. A total of 1693 HBV-carrier mothers were included. The characteristics of the included studies are summarized in Table 1. Of the 15 trials, 6 adequately described the generation of the allocation sequence^[26-29,34,35], 2 concealed treatment allocation and double blinded methods were described^[25,26]. The remaining trials did not report the methodological quality.

As a result, 2 trials were classified as of high quality and the remaining 13 trials were of low quality (Table 2).

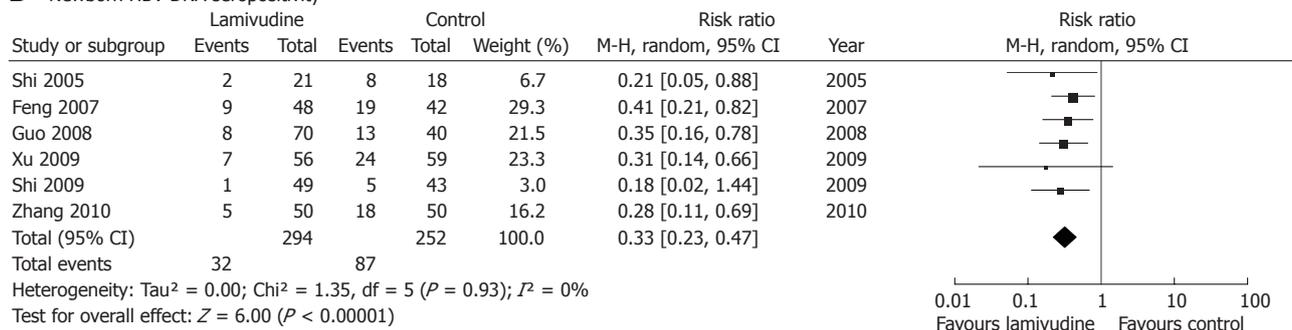

Effects of lamivudine on interruption of MTCT indicated by serum HBsAg, HBeAg or HBV DNA of newborns within 24 h after birth

Compared with controls (placebo or no treatment), lamivudine treatment for the HBV-carrier mothers significantly interrupted MTCT. The efficacy (RR, 95% CI) of lamivudine treatment *vs* control in 8 RCTs was 0.43, 0.25-0.76; *P* < 0.01, with significant heterogeneity (*P* = 0.04, *I*² = 52%) as indicated by serum HBsAg (Figure 2A). It was 0.33, 0.23-0.47 in 6 RCTs; *P* < 0.01, with minimum heterogeneity (*P* = 0.93, *I*² = 0) indicated by serum HBV DNA (Figure 2B). However, the corresponding values shown by HBeAg was not significant in 3 RCTs (0.86, 0.43-1.69; *P* = 0.65) with minimum heterogeneity (*P* = 0.87, *I*² = 0) (Figure 2C). The funnel

0.01, with minimum heterogeneity (*P* = 0.33, *I*² = 13%) as shown by serum HBV DNA (Figure 4B). The funnel plots showed possible publication bias (Figure 4C).

Two RCTs evaluated the effect of lamivudine treatment *vs* HBIG in late pregnancy on the interruption of MTCT^[22,23]. The efficacy of lamivudine *vs* HBIG in interruption of MTCT indicated by serum HBsAg or HBV DNA in 2 RCTs was 0.05, 0.01-0.41; *P* < 0.01, with minimum heterogeneity (*P* = 0.95, *I*² = 0); and 0.06, 0.01-0.47; *P* < 0.01, with minimum heterogeneity (*P* = 0.95, *I*² = 0), respectively. Two RCTs evaluated the efficacy of lamivudine plus HBIG *vs* HBIG alone in the interruption of MTCT indicated by serum HBsAg^[24,32]. The corresponding value was 0.28, 0.13-0.65, *P* < 0.01, with minimum heterogeneity (*P* = 0.41, *I*² = 0).

Influence of maternal viral load before or after lamivudine treatment on MTCT indicated by serum HBsAg or HBV DNA of newborns

To determine the effect of viral load of mothers before or after lamivudine treatment on interruption of MTCT, we stratified the included mothers into subgroups with different viral loads and compared with the controls. MTCT was indicated by newborn serum HBsAg. In the mothers with a viral load of 10⁶-10⁸ copies/mL before lamivudine treatment, the efficacy (RR, 95% CI) of lamivudine *vs* controls was 0.30, 0.15-0.57 in 3 RCTs, *P* < 0.01, with minimum heterogeneity (*P* = 0.73, *I*² = 0), however, in the mothers with a viral load > 10⁸ copies/mL before lamivudine treatment, the corresponding value in lamivudine *vs* controls was 0.61, 0.25-1.52 in 4 RCTs, *P* = 0.29, with

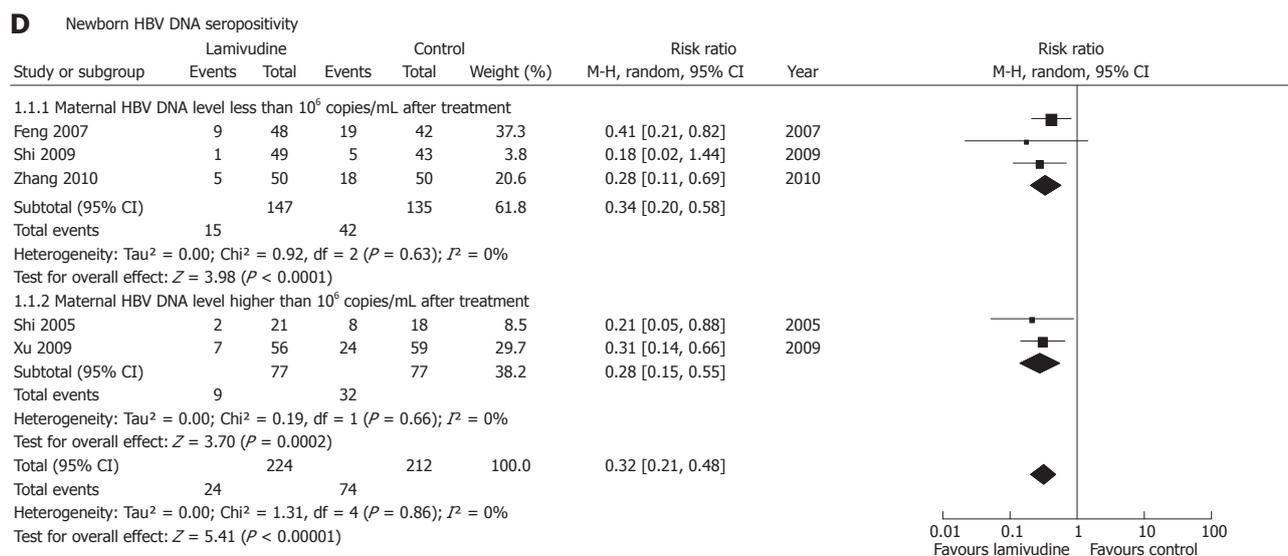

Figure 5 Influence of maternal viral load before or after lamivudine treatment on hepatitis B virus mother-to-child transmission as indicated by serum hepatitis B surface antigen or hepatitis B virus DNA of newborns within 24 h after birth. Vertical line indicates no difference between compared treatments. Horizontal lines show 95% CIs. Squares indicate point estimates, and the size of the squares indicates the weight of each study in the meta-analysis. CI: Confidence interval; HBV: Hepatitis B virus; M-H random: Mantel-Haenszel random-effects model; RR: Risk ratio; HBsAg: Hepatitis B surface antigen.

significant heterogeneity (*P* = 0.05, *I*² = 61%) (Figure 5A). In the mothers with a viral load < 10⁶ copies/mL after lamivudine treatment, the efficacy of lamivudine treatment *vs* controls was 0.33, 0.21-0.53 in 5 RCTs, *P* < 0.01, with minimum heterogeneity (*P* = 0.82, *I*² = 0), however, in the mothers with a viral load > 10⁶ copies/mL after lamivudine treatment, the corresponding value was 1.26, 0.70-2.27 in 2 RCTs, *P* = 0.45, with minimum heterogeneity (*P* = 0.78, *I*² = 0%) (Figure 5B). When MTCT was indicated by newborn serum HBV DNA, lamivudine treatment significantly interrupted MTCT in groups with various maternal viral loads before or after lamivudine treatment (*P* < 0.01) (Figure 5C and D).

Effect of lamivudine treatment starting time on interruption of MTCT indicated by serum HBsAg or HBV DNA of newborns within 24h after birth

Lamivudine treatment was initiated from week 28 of gestation in most of the included studies. The treatment was initiated from week 32 of gestation in one study^[25]. The efficacy of lamivudine treatment initiated at week 28 of gestation *vs* controls in interruption of MTCT indicated by serum HBsAg or HBV DNA (RR, 95% CI) was 0.34, 0.22-0.52 in 7 RCTs; *P* < 0.01, with minimum heterogeneity (*P* = 0.92, *I*² = 0); and 0.33, 0.22-0.50 in 5 RCTs; *P* < 0.01, with minimum heterogeneity (*P* = 0.86, *I*² = 0), respectively. When lamivudine treatment was initiated at week 32 of gestation, MTCT was not significantly interrupted as indicated by serum HBsAg, however, lamivudine significantly interrupt MTCT as shown by serum HBV DNA (Figure 6).

Efficacy of lamivudine treatment in interruption of MTCT indicated by serum HBsAg or HBV DNA of newborns within 24h after birth among different studies

We stratified the included studies into high and low

qualities and evaluated the efficacy of lamivudine in interruption of MTCT. Using pooled data of “low-quality” studies, the efficacy of lamivudine *vs* controls was 0.35, 0.23-0.55 in 6 RCTs; *P* < 0.01, with minimum heterogeneity (*P* = 0.88, *I*² = 0%) indicated by serum HBsAg. It was 0.34, 0.22-0.52 in 4 RCTs; *P* < 0.01, with minimum heterogeneity (*P* = 0.81, *I*² = 0) indicated by serum HBV DNA. Using pooled data of the 2 “high-quality” studies, the corresponding value was 0.63, 0.13-3.04, *P* = 0.57, with significant heterogeneity (*P* = 0.02, *I*² = 81%) as shown by serum HBsAg. However, the corresponding value was 0.29, 0.14-0.59, *P* < 0.01 with minimum heterogeneity (*P* = 0.93, *I*² = 0) as indicated by serum HBV DNA. These results are shown in Figure 7.

Side effects of lamivudine treatment

Three RCTs reported adverse effects of lamivudine in mothers^[25,26,34]. The incidence of adverse effects was not significantly different as compared with the control. Only one trial reported adverse event in the newborns^[25]. Among the ten major adverse events, only one was considered drug-related, with a symptom of jaundice.

DISCUSSION

This meta-analysis included 15 RCTs published up to January 2011, including a total of 1693 HBV-carrier mothers. We demonstrated that lamivudine treatment in the HBV-carrier mothers, as compared with controls, significantly interrupted MTCT as indicated by serum HBsAg or HBV DNA of newborns or infants. And lamivudine treatment *vs* HBIG in the HBV-carrier mothers significantly interrupted MTCT as indicated by serum HBsAg or HBV DNA of newborns or infants. This is also true for lamivudine plus HBIG *vs* HBIG. In a recent meta-analysis, advantage of lamivudine treat-

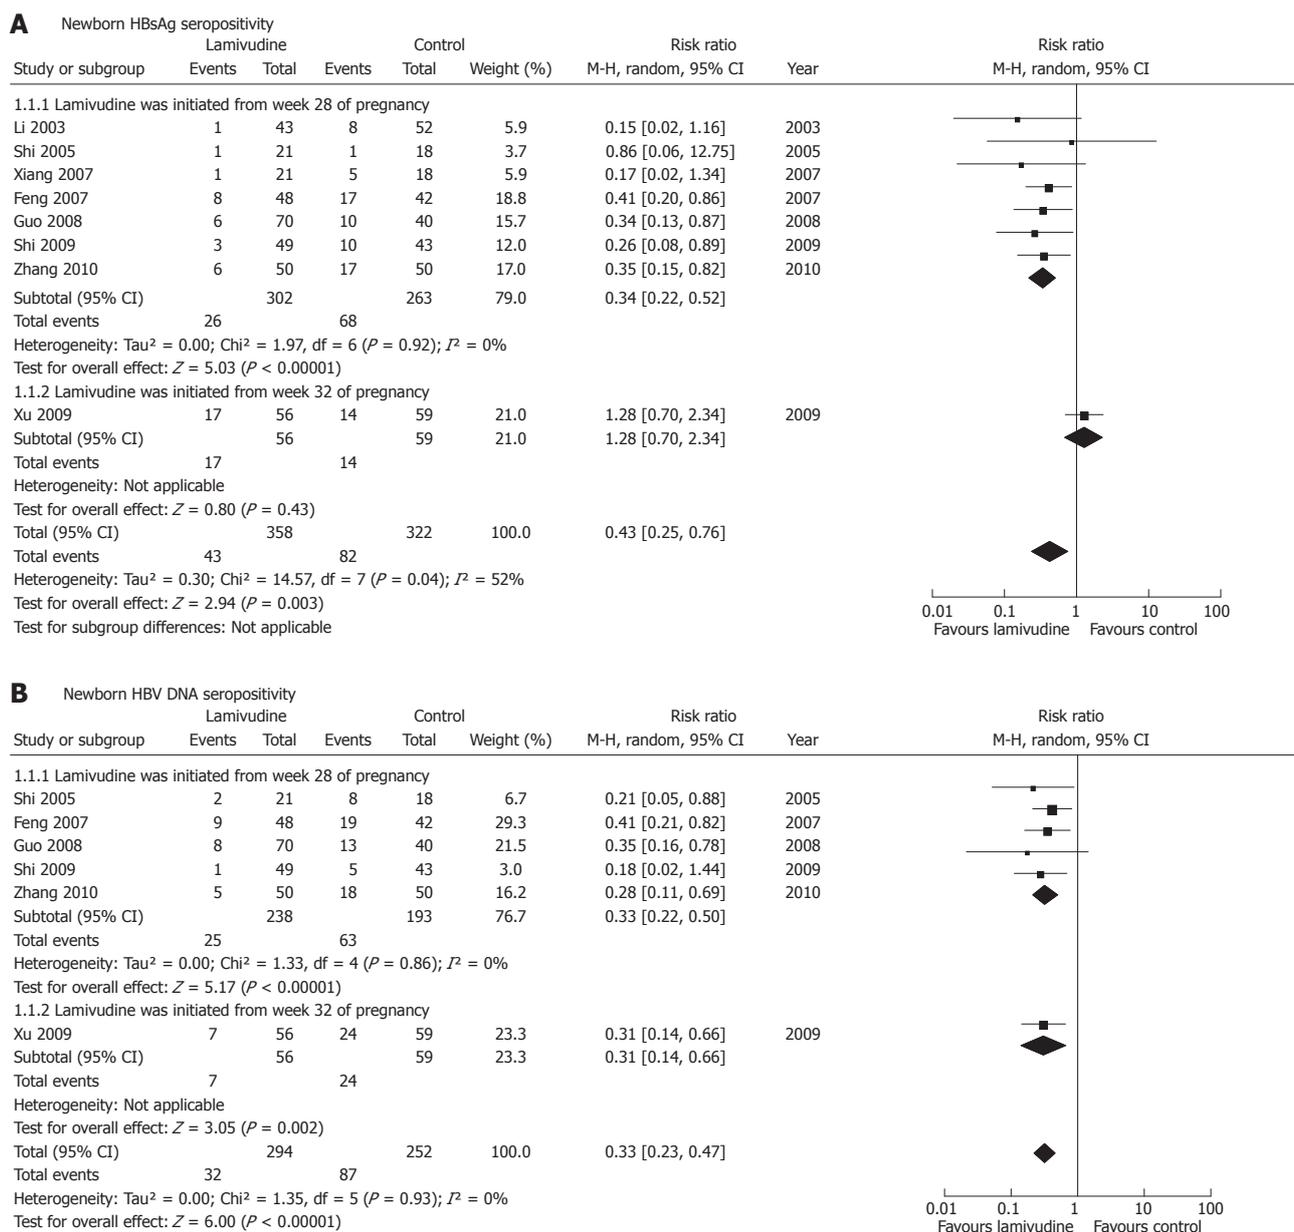

Figure 6 Effect of lamivudine treatment starting time on interruption of mother-to-child transmission indicated by newborn hepatitis B surface antigen or hepatitis B virus DNA. Vertical line indicates no difference between compared treatments. Horizontal lines show 95% CIs. Squares indicate point estimates, and the size of the squares indicates the weight of each study in the meta-analysis. CI: Confidence interval; HBV: Hepatitis B virus; M-H random: Mantel-Haenszel random-effects model; RR: Risk ratio; HBsAg: Hepatitis B surface antigen.

ment was not found over HBIG because two important papers were not included^[15]. This result is quite reasonable because the recommended dose of HBIG might be insufficient to neutralize the huge virus load in HBV-carrier mothers at late pregnancy, although HBIG to HBeAg-seropositive mothers from week 28 of gestation significantly decreased the seropositivity of HBV DNA in newborns^[36]. Thus, lamivudine can be used for the pregnant women with a high degree of infectiousness.

Serum HBsAg, HBeAg, and/or HBV DNA in newborns or infants born to HBV-carrier mothers are routine indicators of MTCT. Of these indicators, HBsAg is a reliable and widely used one. Beasley *et al*^[37] suggested two criteria for HBV perinatal infection: (1) high titers of

HBsAg within 24 h after birth; and (2) after the joint immunoprophylaxis, infants developed into HBsAg carriers. In addition, continuous monitoring of HBeAg and/or HBV DNA is also suggested, because HBeAg from the mother through the placenta will disappear within 7 mo after birth and peripheral blood HBV DNA testing is more reliable and sensitive than other HBV markers^[38,39]. In this study, although the results using HBsAg or HBV DNA as an indicator were mostly consistent, there were some inconsistencies in indicating MTCT. If indicated solely by HBsAg, lamivudine treatment in the mothers with a viral load > 10⁸ copies/mL before the treatment or in those with a viral load > 10⁶ copies/mL after the treatment could not significantly interrupt MTCT. How-

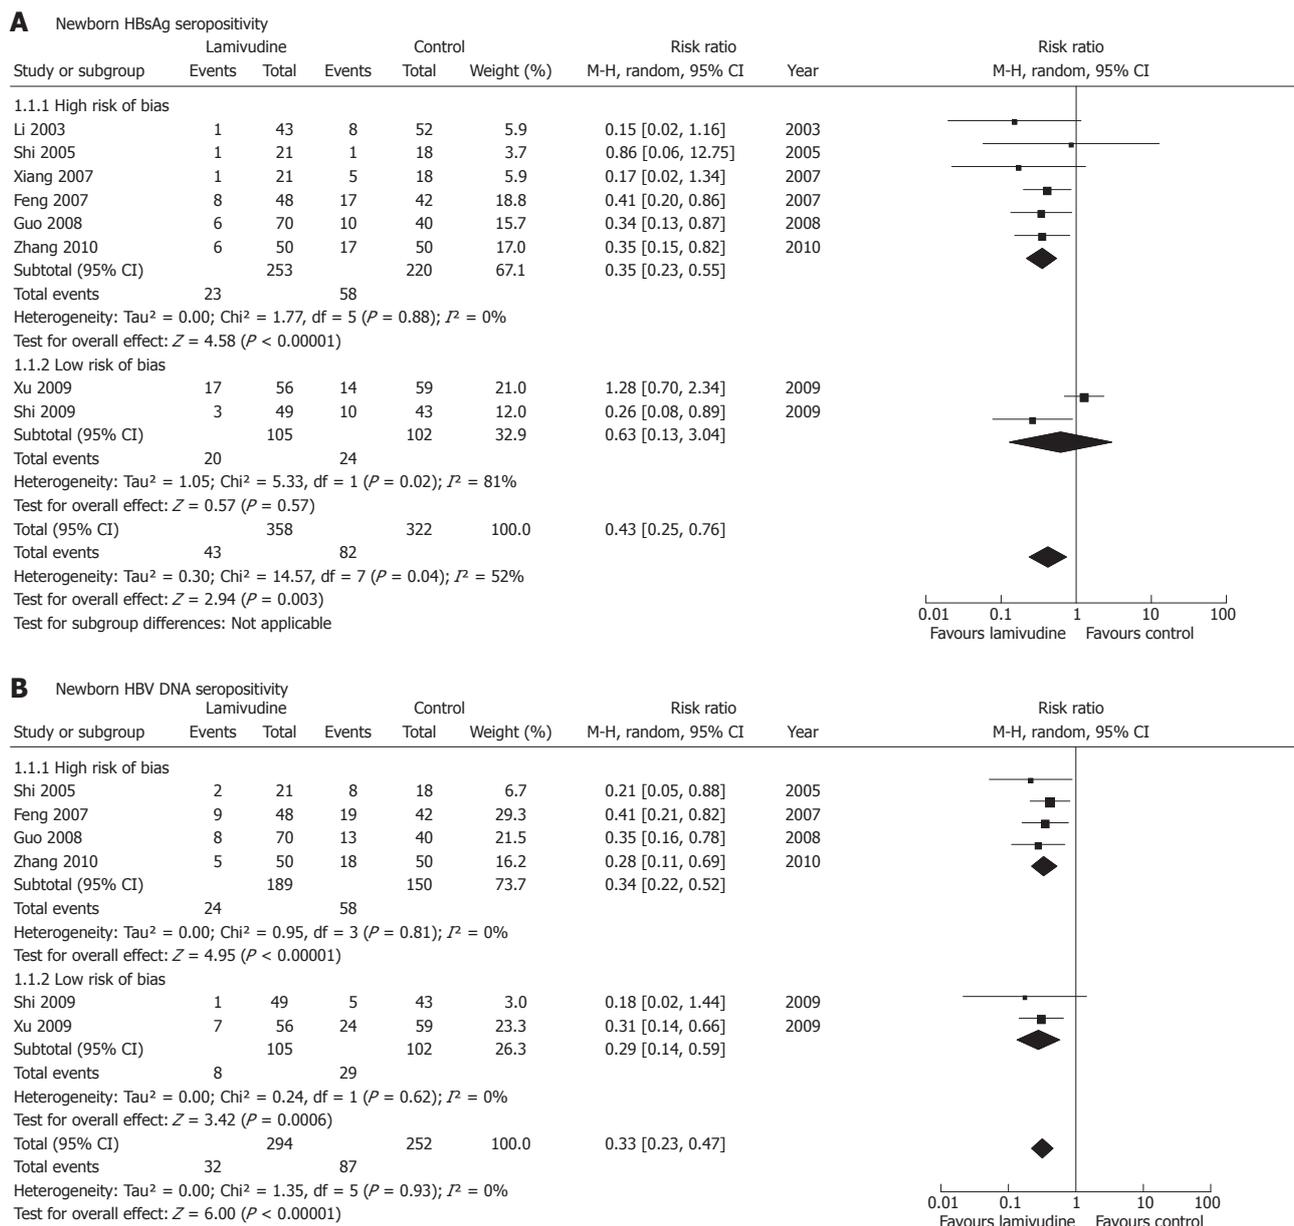

Figure 7 Efficacy of lamivudine treatment in “high-quality” studies or “low-quality” studies in interruption of mother-to-child transmission indicated by serum hepatitis B surface antigen or hepatitis B virus DNA of newborns. Vertical line indicates no difference between compared treatments. Horizontal lines show 95% CIs. Squares indicate point estimates, and the size of the squares indicates the weight of each study in the meta-analysis. CI: Confidence interval; HBV: Hepatitis B virus; M-H random: Mantel-Haenszel random-effects model; RR: Risk ratio; HBsAg: Hepatitis B surface antigen.

ever, if indicated by newborn HBV DNA, lamivudine treatment in the mothers with a viral load > 10⁸ copies/mL before the treatment or in those with a viral load > 10⁶ copies/mL after the treatment significantly interrupted MTCT. The same results were found in the pooled analysis of “low quality” and “high quality” studies. These controversial evidences reflect the validity and reliability of the indicators. In the included studies, HBV DNA was measured by quantitative PCR method. However, a viral load ≤ 5 × 10² copies/mL is usually undetected using commercially available reagents in mainland China. HBV DNA is frequently negative in HBsAg seropositive subjects, especially in asymptomatic HBsAg carriers^[40-42]. Thus, efficacy of lamivudine treatment in

interruption of MTCT might be over-estimated by using newborn HBV DNA alone. Serial examination of HBV DNA and HBsAg from newborns to infants 6-12 mo after birth is highly suggested. In this study, we also found that lamivudine treatment was unable to interrupt transmission of HBeAg from mothers to newborns. HBeAg, a small soluble protein, might pass through the placenta during gestation and disappear within 6-7 mo after birth, indicating that HBeAg is unsuitable for indicating MTCT for newborns, but can be used for the confirmation of MTCT 6-12 mo after birth.

In this study, we confirmed that lamivudine treatment from week 28 of gestation was efficient in interrupting MTCT as indicated by serum HBsAg or HBV DNA of

newborns within 24 h after birth. However, only one study reported that lamivudine treatment from week 32 of gestation was inefficient in interrupting MTCT as indicated by serum HBsAg, although newborn HBV DNA could be significantly decreased. Thus, we suggest that lamivudine treatment should be initiated from week 28 of gestation.

The incidence of adverse effects was not significantly different in HBV carrier mothers with and without lamivudine treatment. Lamivudine treatment in HBV carrier-mothers in late pregnancy has been inversely associated with the complications of HBV-infected pregnant patients^[43]. Thus, lamivudine treatment is well-tolerated and safe for the HBV-carrier mothers at the late stage of pregnancy. However, long-term treatment with lamivudine might generate the treatment-escape mutations like V173L in the B domain and M204V or I substitution in the C domain of the polymerase/reverse transcriptase^[44]. Generation of lamivudine treatment-escape mutations might prevent future treatment of the HBV carrier mothers.

Our meta-analysis has several potential limitations. Firstly, some analysis included few trials so that the subgroup analysis could not be conducted appropriately. Secondly, HBeAg status of mothers was not evaluated because the data was incomplete in the original studies. Thirdly, the majority of included RCTs were of low quality and had high risk of bias in design, and funnel plot showed possible publication bias. The results from this meta-analysis should be discreetly interpreted.

In conclusion, lamivudine treatment in HBV carrier-mothers from 28 wk of gestation efficiently interrupts MTCT as indicated by newborn or infant serum HBsAg or HBV DNA. Lamivudine treatment is safe for the HBV-carrier mothers in late pregnancy and more efficient than HBIG in interrupting MTCT. If maternal viral load is reduced to $< 10^6$ copies/mL by lamivudine treatment, HBV MTCT can be prevented more efficiently as indicated by newborn serum HBsAg.

COMMENTS

Background

Mother-to-child transmission (MTCT) of hepatitis B virus (HBV) is associated with a very high rate of chronicity, especially in countries where HBV is endemic. Prevention of MTCT is the most important strategy in the global eradication of HBV infection. Apart from the joint immunoprophylaxis to infants born to HBV-carrier mothers, lamivudine treatment in late pregnancy has been reported to be effective in interrupting MTCT and safe in pregnant women. However, the sample sizes of these studies were small and results were controversial, which necessitates a meta-analysis by pooling data of more available studies.

Research frontiers

Compared with placebo controls or hepatitis B immunoglobulin (HBIG), lamivudine treatment in late pregnancy significantly interrupted MTCT as indicated by serum hepatitis surface antigen (HBsAg) or HBV DNA of newborns 24h or infants 6-12 mo after birth. In the mothers with viral load $< 10^8$ copies/mL, lamivudine treatment has a clear beneficial effect, as indicated by newborn serum HBsAg. Lamivudine treatment initiated at week 28 of gestation is efficient in interruption of MTCT as indicated by serum HBsAg or HBV DNA of newborns.

Innovations and breakthroughs

A recent meta-analysis of randomized controlled trials using data up to October 2009 has demonstrated that lamivudine treatment in HBV-infected mothers in

late pregnancy effectively prevented MTCT. However, difference in interruption of MTCT between lamivudine treatment and HBIG was not found.

Applications

Lamivudine treatment for HBV carrier mothers should be initiated at week 28 of gestation. For the HBV carrier mothers with viral load $> 10^8$ copies/mL, antiviral treatment with lamivudine alone might be not enough to interrupt MTCT. MTCT might be efficiently interrupted if maternal viral load is decreased to the level of $< 10^6$ copies/mL by lamivudine treatment.

Terminology

MTCT of HBV includes in utero transmission and perinatal transmission of HBV. In East and Southeast Asia, in utero transmission of HBV is rare, whereas perinatal transmission is common.

Peer review

The study determines the effect of lamivudine treatment in hepatitis B virus-carrier mothers in late pregnancy on interruption of MTCT by means of meta-analysis.

Abstract

AIM: To investigate the role of 64-slice computed tomography (CT) in portal vein cavernous transformation to determine surgical strategy.

METHODS: The site of lesions and extent of collateral circulation in 12 pediatric cases of cavernous transformation of the portal vein with surgical treatment were analyzed.

RESULTS: Eleven of 12 children had esophageal varices and were treated with lower esophageal and gastric devascularization and splenectomy, and the other case was only treated with splenectomy. There were eight cases with spontaneous spleen/stomach-renal shunt, four with Retzius vein opening, which was reserved during surgery. Three cases of lesions involving the intrahepatic portal vein (PV) were treated with living

donor liver transplantation. One patient died from PV thrombosis after liver transplantation, and the rest had no significant complications.

CONCLUSION: The PV, its branches and collateral circulation were clearly seen by 64-slice spiral CT angiography, which helped with preoperative surgical planning.

Sixty-four-slice computed tomography in surgical strategy of portal vein cavernous transformation. *World J Gastroenterol* 2011; 17(38): 4334-4338 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i38/4334.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i38.4334>

INTRODUCTION

Cavernous transformation of the portal vein (CTPV) is a rare disease in children. The location of the cavernous transformation determines the clinical manifestation of the patients and the treatment procedures^[1]. Computed tomography (CT) can be utilized for angiography of CTPV and has distinct advantages in locating the position and assessing the severity of the cavernous transformation^[2]. Few people have reported using 64-slice CT for the diagnosis of CTPV or its impact on surgical procedures. The current study retrospectively analyzed the angiographic performance of 64-slice CT in 12 cases

and evaluated whether it affects surgical procedures by comparing the corresponding surgical results.

MATERIALS AND METHODS

Clinical information

Eighteen pediatric cases of CTPV were admitted to our department between June 1999 and December 2007. Among these 12 patients (nine male and three female) received 64-slice CT and surgical treatment after 2004. The patient ages were between 3 and 8 years, with an average of 5 years and 3 mo. The clinical records of the patients were thoroughly analyzed, and the location of the thrombus in the portal vein (PV), the pathology of the hepatic lesions, surgical procedures, findings during surgery, and the corresponding treatment were recorded. The symptoms of CTPV were reviewed and analyzed along with the surgical results.

Imaging examination

All the cases in this group were first diagnosed with CTPV and portal hypertension using color Doppler ultrasound. After 2004, they were all further examined with 64-slice CT. The choice of surgical procedures was determined by the range, degree and location of cavernous transformation in the hepatic hilar area, as well as the condition of thrombus in the vein and establishment of collateral circulation in the surrounding tissue.

Selection of surgical procedures

Infants with little bleeding and no obvious symptoms were subjected to conservative treatment. The surgical procedures were determined based on the clinical manifestation, the location of the cavernous transformation and the condition of the varices. Surgical vascular disconnection was performed in the gastric fundus and the lower esophagus for the children with symptoms of CTPV with little bleeding (less than twice). No significant damage of hepatic function, cavernous transformation outside the liver, or varices in the lower esophagus and gastric fundus was observed. Surgery should completely disconnect the variceal veins. Splenectomy was only performed in children who showed splenomegaly and hypersplenism, but who did not have gastrointestinal bleeding or varices in the lower esophagus and gastric fundus. Living-donor liver transplantation was performed in children with cavernous transformation in intrahepatic veins, which was accompanied by liver dysfunction. Patients in this group were younger and had smaller vein diameters and thinner venous walls, which led to difficulties in anastomosis and risk of obstruction at the anastomosis, therefore, we did not perform shunt surgery on these patients.

Follow-up management

Information on clinical, laboratory and imaging examinations, as well as treatment procedures and prognosis, was recorded for all patients. The treatments and their effectiveness were evaluated for each patient. For those

A: Illustration of cavernous transformation of the portal vein (PV); B: Sixty-four-slice computed tomography angiography of cavernous transformation in the extrahepatic PV indicates varices in the esophagus and gastrosplenic area.

patients treated with surgery, the results were considered good if the clinical symptoms disappeared after surgery. The longest follow-up time was 5 years. The follow-up content included the inquiry of the incidence of hematemesis and melena after surgery, as well as liver function examination and type B ultrasound examination.

RESULTS

Location of CTPV

For all 12 cases of CTPV, a large amount of collateral circulation was found around the PV. The normal PV structure disappeared at the hepatic hilar area, and nodular vessels, with anfractuosity, hemangiectasis and different diameters were instead detected on the angiogram and were accompanied by an apparently enhanced venous phase. The patients exhibited typical symptoms of cavernous transformation. Occlusion in the PV trunk was found in nine cases, and complete occlusion was found in three. Four cases had occlusion in the PV trunk, in combination with occlusion of the superior mesenteric vein or proximal splenic vein. Five cases had occlusion of the large part of the superior mesenteric vein and splenic vein (Figure 1). Three cases had liver laceration with obvious narrowing or occlusion, or unclear angiograms in both the left and right branches of the intrahepatic PV. Cavernous transformation in the intrahepatic PV frequently compressed the biliary system and led to occlusion, infec-

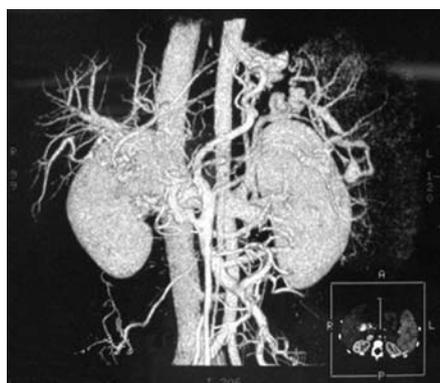

Figure 3 Splenorenal shunt.

tion and other complications, resulting in liver dysfunction, which is an indication for liver transplantation.

Portal hypertension

Among the 12 pediatric patients with CTPV, nine had splenomegaly and six had ascites. The major branches of the PV showed different degrees of dilation (Figure 2). Five cases exhibited severe dilation, showing lumpy, tortuous, dilated blood vessels in the lower esophagus and under the gastric fundic mucosa, narrowing of the lumen of the lower esophagus and lumpy protuberance in the gastric cavity (Figure 1). Eight cases had spontaneous splenorenal/gastrorenal shunt, showing highly tortuous, dilated blood vessel structure in disorderly directions. The blood vessels originated from the short gastric vein, posterior gastric vein or blood vessels at the splenic hilum,

and connected to the left renal vein through the tortuous, dilated retroperitoneal venous plexus (Figure 3). Seven cases had paraumbilical vein patefaction, showing tortuous dilation with spiral-shaped changes in the ligamentum teres hepatis. The blood vessels were in a radial pattern at the upper and lower end of the structure and connected to chest wall veins as well as the deep and superficial veins of the abdominal wall. Four cases had open retroperitoneal communicating branches (venous plexus of Retzius), showing tortuous disordered retroperitoneal blood vessels, which were dilated in a bundle shape or cirroid shape or connected to the inferior vena cava in a radial shape. Except for the collateral circulation in the lower esophagus and gastric fundal varices, which can lead to bleeding in the digestive tract, collateral circulation formed at other locations can help to reduce PV pressure and were thus preserved during surgery. When selecting surgical procedures, collateral circulation formation should be considered, which can help estimate prognosis on postoperative recurrence of gastrointestinal bleeding.

Impact of severity of CTPV on surgical procedure

Surgical procedure selection was based on the severity of vascular dilation in the lower esophagus and gastric fundic mucosa, whether CTPV was located inside the liver and the extent of liver dysfunction. Surgical vascular disconnection in the gastric fundus and lower esophagus in combination with splenectomy was performed in 5 cases with severe dilation in the lower esophagus and gastric fundic mucosa. Among them, surgical removal of the thrombus and end-to-end anastomosis of the PV were performed in one case with occlusion of the PV trunk. Splenectomy was performed for four cases without obvious lumpy, tortuous dilation of the veins in the lower esophagus and gastric fundus, but with apparent splenomegaly. Two of these four cases had occlusion of the PV trunk, and surgical removal of the thrombus and end-to-end anastomosis of the PV were performed along with splenectomy. The findings from intraoperative exploration were completely consistent with the results from the preoperative angiography using 64-slice CT. Three children were diagnosed with cavernous transformation involving the inside of the intrahepatic portal vein using 64-slice CT, and all three patients had damaged liver function. Therefore, living-donor liver transplantation was performed on these patients. Due to the lack of collateral vessels, the great saphenous vein of the donor was used as the vascular bypass graft for anastomosis between the PV and the superior mesenteric vein in one case (Figure 4). The findings from the intraoperative exploration were consistent with the preoperative imaging results.

Postoperative recovery and follow-up

The average follow-up time was 2 years (from 3 mo to 5 years). During the follow-up, no recurrence of severe hematemesis or obvious black tarry feces was observed in the 9 pediatric patients who received gastric fundic and lower esophageal vascular disconnection and splenec-

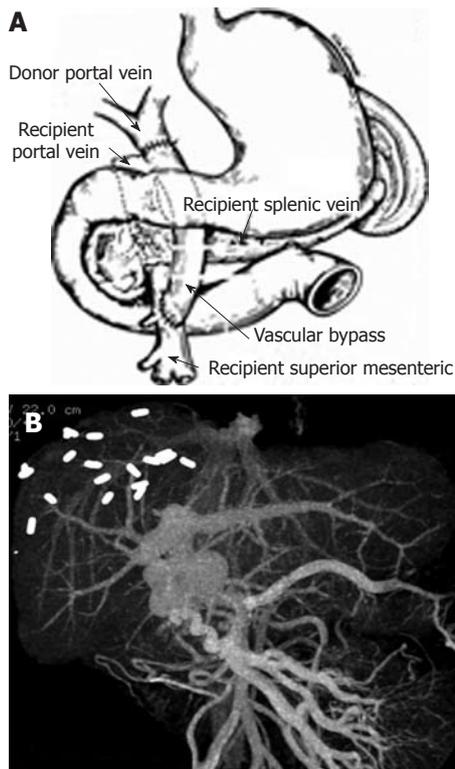

Figure 4 Vascular bypass and sixty-four-slice computed tomography angiography. A: Illustration of vascular bypass between the donor portal vein and the recipient superior mesenteric vein for liver transplantation; B: Sixty-four-slice computed tomography angiography after liver transplantation.

tomy. Three of the patients had liver transplantation; one of them died of portal thrombosis 5 d after surgery. The other two patients did not experience more hematemesis, melena or lower esophageal stenosis, and their liver function completely recovered. One of the patients was already back in elementary school with good performance, and the other went to kindergarten with normal body development (body weight and height) compared to the average values of the children of the same age. Two wk after surgery, one patient had adhesive ileus, which was cured after another operation. Six months after surgery, barium meal examination showed that esophageal varices disappeared in 10 cases, were relieved in one, and one patient was lost to follow-up.

DISCUSSION

The degree and size of CTPV have an apparent impact on the difficulty level, operative duration and incidence of postoperative complications. Therefore, preoperative understanding of the condition of the CTPV is very important for the surgical process^[5]. Ultrasound is a routine clinical examination for CTPV. However, color Doppler ultrasound cannot provide sufficient information on the formation of collateral circulation. Apart from B-type ultrasound, magnetic resonance angiography and 64-slice CT, portal angiography is the ideal examination method for angiogram. However, the former is limited by breath-

holding time and it cannot finish a comprehensive examination for the abdominal wall, paraumbilical area and retroperitoneal varices at one time. Because 64-slice CT can clearly demonstrate the anatomy of the PV system and collateral circulation, sub-millimeter thin-layer volume scan was performed with 64-slice spiral CT for the patients in this study, with 3D reconstitution to display in high resolution the anatomical morphology of the PV system in three dimensions and a clear relationship with the adjacent structures. Sixty-four-slice CT has a positive influence on surgical planning, locating blood vessels and preventing intraoperative injuries. Sixty-four-slice CT can also visualize the veins surrounding and those adjacent to the esophagus. The former are the smaller veins attached to the outer membrane of the esophagus, and the latter are the larger veins that are separated from the outer membrane of the esophagus. Previously, examination of these veins has required left gastric angiography or esophageal ultrasound examination. Collateral vessels in the patients in the present study were mainly located in the lower esophagus and gastric fundus, which was consistent with the clinical symptoms of upper gastrointestinal bleeding such as hematemesis and melena. All five cases were treated with surgical venous disconnection in the gastric fundus and esophagus and did not experience any recurrence during postoperative follow-up. Vascular disconnection was performed for the four cases in this study that did not show obvious gastric fundic and esophageal varices. Only splenectomy was carried out in these patients to reduce PV pressure and relieve reduce esophageal and gastric fundic varices. The findings from intraoperative exploration were completely consistent with the results from the preoperative imaging examination. No gastrointestinal bleeding occurred in these patients for 5 years after surgery.

Angiography of the left gastric vein indicates the existence of coronary venous reflux. Coronary venous reflux is an important pathological symptom of portal hypertension. It is also an indicator of esophageal variceal rupture and bleeding. Measures should be taken to prevent this bleeding^[4,5]. In the present study, the patients with the most severe symptoms all had dilated and tortuous left gastric veins in 64-slice CT, showing stiffness and irregularity in the running direction of the blood vessels. In addition, to reduce the pressure of the gastric coronary vein, part of the blood in the PV with hypertension can shunt from the open umbilical vein and splenorenal vein to the superior and inferior vena cava. Upper gastrointestinal bleeding is diagnosed based on analysis of the open extent of RVs using 64-slice spiral CT for PV angiography^[6]. In the present study, open RV was found in four cases, and spontaneous portosystemic shunt was found in five, which were all conserved during surgery. None of the patients displayed upper gastrointestinal bleeding after surgery. This is similar to reports from other countries^[7]. Cavernous transformation in the intrahepatic PV frequently compresses the biliary system and leads to occlusion, infection and other complications, resulting in damage to

liver function, which is an indication for liver transplantation. In the present study, three cases had deformed blood vessels and hemangioma-like symptoms in the intrahepatic portal system, which were accompanied by damaged liver function and hypersplenism. All of these patients were at the late stage of portal hypertension. Studies have shown that intrahepatic CTPV is one of the indications for liver transplantation^[8]. Three of our patients received liver transplantation. Due to the difficulties in anastomosis resulting from a large lesioned area, the great saphenous vein of the donor was used as a vascular bypass graft for anastomosis between the PV and superior mesenteric vein in one case. The findings from intraoperative exploration were consistent with the preoperative imaging results. From the follow-up, the symptoms of portal hypertension in the three patients were all remarkably relieved, demonstrating excellent short-term clinical results. However, liver transplantation has not been widely used to treat CTPV. Long-term follow-up is still necessary for the assessment of its long-term therapeutic effects and to compare it with other surgical procedures.

In summary, many changes occur in the portal venous system following CTPV. Sixty-four-slice spiral CT portal angiography and the 3D reconstitution technique can effectively demonstrate the pathological changes in the PV system, clearly showing the major branches of the PV as well as the running direction and distribution of collateral circulation, precisely locating the pathological lesions, demonstrating the space relationship between the lesions and the blood vessels and providing accurate information for clinical assessment and surgery planning. Sixty-four-slice CT is an optimal diagnostic method. However, it requires corresponding equipment and facilities. In addition, its cost is relatively high, which not all young patients can afford.

ACKNOWLEDGMENTS

We wish to express our gratitude to all our transplant coordinators, nursing staff, and administrative personnel, without whom this work would not have been possible. In particular, Lin Mo, Zhi-Mei Ren, Yuan Shi, Lin Bo, Ying-Liang Li, Qi-Lin Li, Yi Tang and Qiao Wang. We would also like to thank our previous and current transplant fellows for their diligent and tireless work: Xiao-Ke Dai, Qiang Xiong, Kai Chen and Xiao-Mei Zhu.

COMMENTS

Background

Portal venography by 64-slice computed tomography (CT) can depict the anatomical characteristics of portosystemic collateral vessels in pediatric patients with cavernous transformation of the portal vein (CTPV). Sixty-four slice CT has been used widely in collateral circulation studies of esophageal and gastric varices. The drainage veins of esophageal varices can be clearly displayed by 64-slice CT.

Research frontiers

Diagnosing and treatment of this complicated disease is problematic mostly due

to the absence of more accurate data on the position and severity of the disease features in such patients. Recent technical advances offer us increasingly greater imaging clarity of CTPV for its diagnosis. Few people have reported the impact of 64-slice CT on surgical strategy planning. This study focused on the utilization of 64-slice CT to provide referable information for clinical management selection and prognosis evaluation.

Innovations and breakthroughs

Recent reports have highlighted the importance of 64-slice CT in the diagnosis of CTPV or its impact on prognosis evaluation. However, this is the first study to report that 64-slice CT is also valuable in the selection of surgical procedures. This studies suggest that 64-slice CT is a useful method for the assessment of therapeutic effect following treatment of gastric varices. In the majority of cases in the present study, the collateral circulation pattern and the morphological characteristics of CTPV were revealed as a result of the high spatial resolution images of 64-slice CT and the appropriate images post-processing.

Applications

Displaying the morphological characteristics of the PV system and collateral circulation, 64-slice CT portal angiography may represent a future strategy for therapeutic management of patients with CTPV. It would seem that 64-slice CT has a valuable role in this situation.

Terminology

Faster scanning with 64-slice CT, combined with rapid intravenous administration of contrast material, allows visualization of the more distal branches of the portosystemic vessels. CTPV is a relatively rare condition resulting from extrahepatic PV obstruction with recanalization or collateral vein formation to bypass the obstruction. Paraesophageal varices are the varices that exist outside the esophagus. The subphrenic vein is the bilateral vessel that ends up at the inferior vena cava at the diaphragm level.

Peer review

The authors demonstrated that 64-slice CT portal angiography could provide accurate information for clinical assessment, especially surgical planning. This is a good paper with excellent images. The results are interesting and may represent the optimal selection of clinical therapy and evaluation of prognosis.

Abstract

AIM: To investigate the feasibility and therapeutic effect of laparoscopic surgery for pyogenic liver abscess (PLA) with biliary pathology.

METHODS: From January 2004 to October 2010, 31 patients with PLA combined with biliary pathology meeting entry criteria received surgical management in our hospital. Of the 31 patients, 13 underwent laparoscopic surgery (LS group) and 18 underwent open surgery (OS group). Clinical data including operation time, intraoperative blood loss, postoperative complication rate, length of postoperative hospital stay, and abscess recurrence rate were retrospectively analyzed and compared between the two groups.

RESULTS: All patients received systemic antibiotic therapy. Four patients underwent ultrasound-guided percutaneous catheter drainage before operation. Postoperative complications occurred in 5 patients (16.1%, 5/31) including 2 in the LS group and 3 in the OS group. One patient had retained calculus in the common bile duct and another had liver abscess recurrence in the OS group. No retained calculus and liver abscess

recurrence occurred in the LS group. In the two groups, there was no mortality during the perioperative period. There were no significant differences in operation time, intraoperative blood loss and transfusion, postoperative complication rate and abscess recurrence rate between the two groups. Oral intake was earlier (1.9 ± 0.4 d vs 3.1 ± 0.7 d, $P < 0.05$) and length of postoperative hospital stay was shorter (11.3 ± 2.9 d vs 14.5 ± 3.7 d, $P < 0.05$) in the LS group than in the OS group.

CONCLUSION: Laparoscopic surgery for simultaneous treatment of PLA and biliary pathology is feasible in selected patients and the therapeutic effect is similar to that of open surgery.

Comparison of laparoscopic and open surgery for pyogenic liver abscess with biliary pathology. *World J Gastroenterol* 2011; 17(38): 4339-4343 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i38/4339.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i38.4339>

INTRODUCTION

Pyogenic liver abscess (PLA) is a potentially fatal disease. Before the 1970s open surgical drainage was often adopted for the treatment of PLA. With the development of imaging techniques, ultrasound or computed tomography (CT)-guided percutaneous catheter drainage combined with systemic antibiotics has become the preferred treatment, and mortality has significantly decreased^[1-3]. In

some conditions such as percutaneous drainage failure or underlying biliary pathology, surgery is still required^[4-6]. With the development of laparoscopic instruments and techniques, laparoscopic liver abscess drainage has become popular^[7-11]. Compared with conventional open liver abscess drainage, laparoscopic drainage has some advantages in operation time, postoperative recovery and length of hospital stay^[10,11]. However, little research has been done on laparoscopic surgery (LS) for simultaneous treatment of both PLA and biliary pathology. The purpose of this study was to explore the safety and feasibility of laparoscopic or open surgery (OS) for simultaneous treatment of both PLA and biliary pathology, and to compare the therapeutic effects of the two methods through retrospective analysis of 31 patients with PLA meeting entry criteria.

MATERIALS AND METHODS

Patients

From January 2004 to October 2010, 348 patients with PLA were treated in our hospital. Of the 348 patients, 31 met entry criteria. The entry criteria included (1) ultrasound, CT, surgery or pathogen culture-diagnosed PLA combined with biliary pathology including gallstone, choledocholith, hepatolith, biliary stricture and biliary tract neoplasms; (2) simultaneous surgical treatment for both PLA and underlying biliary pathology. Patients undergoing drainage of liver abscess alone were excluded. Of the 31 patients with PLA, 13 underwent LS (LS group) and 18 OS (OS group). In the 13 patients in the LS group, 5 patients were men and 8 women, with a mean age of 57.5 years (range 37-69). In the 18 patients in the OS group, 8 patients were men and 10 women, with a mean age of 55.8 years (range 35-73). Fever and/or chills were common, then abdominal pain. Most patients had right upper quadrant tenderness. Symptoms and signs of patients are shown in Table 1.

Routine blood analysis, liver function tests and blood coagulation assays were performed in all patients. Increased white blood cell count was the most common laboratory abnormality in these patients (Table 2). Abdominal ultrasound examination was performed in 31 patients, and indicated liver abscess in 30 patients and biliary pathology in 28 patients. CT scan and contrast-enhanced CT scan were performed in 30 patients, and indicated liver abscess in 30 patients and biliary pathology in 26 patients. Magnetic resonance imaging (MRI) was performed in 5 patients, and indicated liver abscess in 5 patients, choledocholith in 3 patients and cholecystolithiasis in 2 patients. In the 13 patients from the LS group, 5 patients had right liver abscess, 7 left liver abscess and one both right and left liver abscess; 11 patients had single liver abscess and 2 multiple liver abscesses; and 5 patients had > 5 cm diameter liver abscess. In the 18 patients from the OS group, 9 patients had right liver abscess, 7 left liver abscess and 2 both right and left liver abscess; 15 patients had single liver abscess and 3 multiple liver abscesses; and 10 patients had > 5 cm-diameter liver abscess. In the 13

patients from the LS group, 6 patients had cholecystolithiasis combined with acute cholecystitis; 3 patients had choledocholith cholangitis (2 also had cholecystolithiasis); 3 patients had left multiple hepatolithiasis (one also had choledocholith); one patient had left intrahepatic biliary stricture. In the 18 patients from the OS group, 7 patients had cholecystolithiasis combined with acute cholecystitis (one also had primary gallbladder cancer); 5 patients had choledocholith cholangitis (2 also had cholecystolithiasis and one right hepatolithiasis); 4 patients had left multiple hepatolithiasis (one also had choledocholith); one patient had left intrahepatic biliary stricture; and another one had intrahepatic bile duct cystadenoma combined with hepatolithiasis (Table 3). Among the 31 patients, aerobic bacterium culture was positive in 21 patients. The common bacteria were colibacillus, then *Klebsiella pneumoniae*. Three of the 13 patients in the LS group had diabetes mellitus. Four of the 18 patients in the OS group had diabetes mellitus, 2 patients had hypertensive disease, one patient had a history of biliary surgery and another patient had a history of two-time biliary surgery. There were no statistical differences in age, sex, clinical manifestations, characteristics of liver abscess and underlying biliary pathology between the two groups.

Operative techniques

Laparoscopic liver abscess drainage: After general anesthesia, a small cut below the umbilicus was made followed by establishing pneumoperitoneum and placing a laparoscope into the peritoneal cavity. The pore site positions were determined according to the size and position of liver abscess. Under laparoscopy, the adhesions of the liver with the abdominal wall or diaphragm were separated using electrocautery. In large and superficial liver abscess, the surface of the liver was locally elevated with gray-and-white or yellowish-white color. After aspirating pus from the liver abscess through paracentesis, a small hole was made on the elevated or thinnest surface of the liver abscess. The abscess cavity was then unroofed using electrocautery, and samples were routinely obtained for bacterial culture and drug sensitivity testing. Debridement and irrigation of the abscess cavity were performed. Laparoscopic cholecystectomy or common bile duct exploration for calculus removed was routinely carried out. Laparoscopic left hepatectomy was performed as previously described^[12]. Thick latex drainage tubes were left in the abscess cavity and subhepatic space, respectively. When B-ultrasonic image or CT confirmed abscess cavity collapse or closure 6-9 d after operation, and 24-hour drainage liquid was less than 20 mL, drainage tubes might be removed.

Open surgery: A right subcostal incision or a superior median abdominal incision was made to explore abdominal lesions. The position of the liver abscess was determined through paracentesis, and then hemostatic forceps entered the abscess cavity along the paracentetic needle to remove pus and separate fibrous septa. A latex drainage tube was left. At the same time, biliary pathology was also treated.

Clinical data including operation time, intraoperative

Table 1 Clinical manifestation of patients with pyogenic liver abscesses

Variables	LS group (n = 13)	OS group (n = 18)

blood loss, postoperative complication rate, length of postoperative hospital stay, and abscess recurrence rate were compared between the two groups.

Statistical analysis

Categorical parameters in each group were compared by the chi-square test, and continuous parameters were compared using independent sample *t* test. All analyses were performed using SPSS 12.0, and *P* < 0.05 was considered statistically significant.

RESULTS

All patients received systemic antibiotic therapy. Four patients (one patient in the LS group and 3 patients in the OS group) underwent ultrasound-guided percutaneous catheter drainage before surgery. Preoperative drainage lasted 2-8 d. After percutaneous catheter drainage, diameters of liver abscesses were decreased by 2-5 cm in 3 patients, while in another patient, the diameter of

liver abscess was unchanged due to inadequate drainage. In 7 patients with diabetes mellitus, blood glucose levels were all controlled under 10 mmol/L by administration of insulin. General anesthesia was performed in 31 patients through endotracheal intubation. In the LS group, 6/13 patients received laparoscopic liver abscess drainage and cholecystectomy; 3 patients received liver abscess drainage, cholecystectomy, common bile duct exploration and T tube drainage; 2 patients with hepatolithiasis limited to the left lateral segment combined with liver abscess received left lateral segmentectomy, and of these 2 patients, one also received cholecystectomy, common bile duct exploration and T tube drainage; one patient with left hepatic duct stenostomia and another patient with hepatolithiasis limited in left hepatic lobe received laparoscopic left hemihepatectomy. In the OS group, 7/18 patients received laparoscopic liver abscess drainage and cholecystectomy, and of these 7 patients, one with gallbladder cancer also received radical cholecystectomy; 5 patients received liver abscess drainage and common bile duct exploration, and of these 5 patients, primary closure of the bile duct was performed in 2 patients and T tube drainage in 3 patients, and 4 patients also received cholecystectomy; 4 patients received left lateral segmentectomy, and of these 4 patients, two also received cholecystectomy, common bile duct exploration and T tube drainage; 2 patients received hemihepatectomy, and one of these patients also received cholecystectomy, common bile duct exploration and T tube drainage (Table 4).

Postoperative complications occurred in 5 patients (2 patients in the LS group and 3 in the OS group, 16.1%). In the LS group, one patient had biliary leakage (100-200 mL of bile per day), and it automatically healed 7 d after drainage; another patient had right hydrothorax, and it was relieved 4 d after closed drainage. In the OS group, early postoperative inflammatory ileus occurred in one patient who recovered 10 d after conservative treatment; subphrenic abscess occurred in one patient and was relieved 8 d after ultrasound-guided puncture; and incision infection occurred in one patient who showed second-class healing after changing dressings. In the OS group, one patient had retained calculus in the common bile duct and left hospital with T tube, the retained calculus were removed using fibercholedochoscope 58 d after operation; liver abscess recurrence occurred in one patient 20 d after surgery and were relieved a week after systemic use of antibiotics and ultrasound-guided percutaneous cath-

eter drainage. In the LS group, no retained calculus and liver abscess recurrence occurred. In the LS group, one patient was given 2U of concentrated red cells intravenously while in the OS group, one patient was given 4U of concentrated red cell intravenously. In the two groups, there was no mortality during the perioperative period. There were no significant differences in operation time, intraoperative blood loss and transfusion, postoperative complication rate and abscess recurrence rate between the two groups. Oral intake was earlier (1.9 ± 0.4 d *vs* 3.1 ± 0.7 d, $P < 0.05$) and length of postoperative hospital stay was shorter (11.3 ± 2.9 d *vs* 14.5 ± 3.7 d, $P < 0.05$) in the LS group than in the OS group (Table 5).

DISCUSSION

In the early 20th century, PLA was commonly secondary to pyelophlebitis caused by acute appendicitis. Since the mid 20th century, PLA has been mainly due to benign or malignant biliary pathology, accounting for about 40%-65%^[1,13,14]. These common biliary lesions include cholecystolithiasis, intrahepatic and extrahepatic cholangiolithiasis, ascariasis of the biliary tract, biliary stricture and biliary tumor. When these biliary lesions lead to acute suppurative cholecystitis, acute suppurative cholangitis, and intrahepatic and extrahepatic cholangitis, bacteria may enter intrahepatic bile ducts and cholangioles to cause PLA. Perforation of gallbladder may also result in PLA^[15]. Mezhir *et al*^[5] have reported that 88% of patients with PLA have a history of malignant tumor including pancreatic cancer (36%), cholangiocarcinoma (17%), colon carcinoma (12%) and gallbladder cancer (10%) in 58 patients between 1998 and 2009. However, in India^[14] and China^[16], the main cause of PLA is still biliary calculi. Since the 1980s, the incidence of hepatolithiasis has been decreased and the incidence of cholecystolithiasis has been significantly increased. In China, cholecystolithiasis is increasingly becoming a main cause of PLA. In this study, the main causes of PLA were cholecystolithiasis and cholangiolithiasis.

Before the 1970s, conservative treatment or open surgical drainage was mainly adopted for the treatment of PLA, but the mortality rate was as high as 65%^[1]. With the development of imaging techniques and effective

broad-spectrum antibiotics, image-guided percutaneous catheter drainage combined with systemic antibiotics have become preferred for the treatment of PLA, and the mortality rate is under 10%^[2,3,17]. Image-guided percutaneous catheter drainage is suitable not only to unilocular abscess, but also to multiple unilocular abscesses and multiloculated abscess^[2], and has some advantages including simple procedures, low cost and good therapeutic effect. However, percutaneous catheter drainage has some disadvantages. For example, multiple percutaneous drainages are required due to drainage tube block or inadequate drainage; it has the possibility of hepatic hemorrhage or pneumothorax; and it cannot simultaneously treat PLA with underlying hepatobiliary pathology.

Liver abscess surgical drainage and percutaneous drainage are complementary techniques. In this study, 4 patients received percutaneous drainage before operation, and following improvement of pathogenetic condition, underwent surgical management. Liver abscess open surgical drainage is suitable after percutaneous drainage failure or for patients having primary diseases such as biliary PLA, abscess rupture and so on^[4-6]. Surgical drainage has some advantages including positioning accuracy, and simultaneous treatment of both abscess and primary diseases^[4,14,18]. In this study, as well as liver abscess drainage laparoscopic cholecystectomy was also performed in 6 patients, open cholecystectomy was performed in 7 patients, laparoscopic common bile duct exploration for calculus removed was performed in 3 patients and open common bile duct exploration for calculus removed was performed in 5 patients. Hepatolobectomy is suitable for hepatolithiasis or hepatobiliary tumor combined with PLA^[6,19]. In this study, 7 patients with hepatolithiasis combined with PLA underwent left lateral segmentectomy or left hemihepatectomy. Hepatolobectomy can achieve radical treatment results, because of removal of not only the abscess but also biliary stones, biliary stricture and hepatic lesions. Moreover, hepatolobectomy for treatment of hepatolithiasis combined with PLA is conducive to long-term prevention of biliary carcinogenesis. With the development of laparoscopic techniques, laparoscopic drainage may replace traditional open drainage in the treatment of PLA. A laparoscopic drainage group is better than an open drainage group in operation time, blood loss and length of hospital stay, and laparoscopic drainage is safe and feasible in patients who have no response to conservative treatment^[10,11]. In this study, LS or OS were used to treat PLA combined with biliary pathology in 31 patients with a postoperative complication rate of 16.1%. In the two groups, there was no mortality during the perioperative period. There were no significant differences in operation time, intraoperative blood loss and transfusion, postoperative complication rate and abscess recurrence rate between the two groups. Oral intake was earlier and length of postoperative hospital stay was shorter in the LS group than in the OS group.

LS or OS for the concomitant treatment of both PLA and biliary pathology is suitable for (1) cholecystolithiasis, common bile duct calculi, ascariasis of biliary

tract, biliary stricture or biliary tumor-caused PLA; (2) vital signs stable, and tolerable anesthesia and surgery for the important organs such as heart, lung, liver and kidney. In patients with diabetes mellitus, the preoperative blood glucose level should be controlled under 10 mmol/L and sensitive broad-spectrum antibiotics should be given before and after operation. Preoperative ultrasound, CT and MRI indicate the conditions including abscess liquefaction, size of abscess cavity, pus volume, fibrous septa, abscess number and biliary pathology. If preoperative images indicate that the abscess cavity is deep, in order to prevent pus spill, fine needle aspiration is performed first, and thick needle puncture is done to remove pus. Radial incision from the porta hepatic may avoid the damage to intrahepatic bile ducts and blood vessels. If aspirated pus is significantly less than expected pus, there may be fibrous septa in the abscess and the incision should be extended to explore abscess cavities. During separation of fibrous septa of the abscess cavity, the hepatic frame structure cannot be transected and the separated stick should not enter normal tissue through the abscess cavity wall. Pulse-like arterial hemorrhage can be stopped by occlusion with titanium clips. Since adhesions are often severe in the cystohepatic triangle, cholecystectomy requires careful separation to avoid damage to the bile ducts. The key of laparoscopic hepatectomy is to prevent and control intraoperative hemorrhage^[12].

In summary, for the treatment of most PLA, ultrasound-guided percutaneous catheter drainage combined with systemic antibiotics is preferred. In selected patients with biliary PLA, laparoscopic or open surgery for simultaneous treatment of PLA with underlying biliary pathology is safe and feasible. Laparoscopic surgery has advantages in postoperative recovery of gastrointestinal function and length of postoperative hospital stay.

COMMENTS

Background

Pyogenic liver abscess (PLA) is a potentially fatal disease. Before the 1970s, open surgical drainage was often adopted for the treatment of PLA. With the development of imaging techniques, ultrasound or computed tomography-guided percutaneous catheter drainage combined with systemic antibiotics has become preferred, and the mortality has been significantly decreased. In some conditions such as percutaneous drainage failure or underlying biliary pathology, surgery is still required. With the development of laparoscopic instruments and techniques, laparoscopic liver abscess drainage has become popular. Compared with conventional open liver abscess drainage, laparoscopic drainage has some advantages in operation time, postoperative recovery and length of hospital stay. However, little research has been done on laparoscopic surgery for simultaneous treatment of both PLA and biliary pathology.

Research frontiers

The feasibility and therapeutic effect of laparoscopic surgery for simultaneous treatment of both PLA and biliary pathology is a hotspot.

Innovations and breakthroughs

This study was performed to explore the safety and feasibility of laparoscopic or open surgery for simultaneous treatment of both PLA and biliary pathology, and to compare the therapeutic effects of the two methods through retrospective analysis of 31 patients with PLA meeting entry criteria

Applications

In selected patients with biliary PLA, laparoscopic or open surgery for simultaneous treatment of PLA and biliary pathology is safe and feasible. Laparoscopic surgery has advantages in postoperative recovery of gastrointestinal function

and length of postoperative hospital stay.

Terminology

PLA is the result of bacterial infection of the liver parenchyma, with subsequent infiltration by inflammatory cells and formation of a collection of pus.

Peer review

This is a nice case series. The numbers of patients are obviously small, and meaningful comparisons between the 2 groups are difficult.

Abstract

Inflammatory bowel disease (IBD) is often associated with extraintestinal manifestations (EIMs) such as optic neuritis (ON), although this has been described in only a few adult patients so far, all of whom were affected with Crohn's disease (CD). Furthermore, ON and demyelinating diseases have been demonstrated to be more frequent in IBD patients than in control populations. In our current case report, we describe a child with active CD who developed sudden blindness due to bilateral ON that was not related to any known cause, and that promptly responded to a high dose of steroids. Investigations and a clinical follow-up have so far ruled out the development of demyelinating diseases in this patient. To our knowledge, this is the first report of ON in a pediatric patient with CD. Possible explanations for this case include an episodic EIM of an active bowel disease, an associated autoimmune disorder such as a recurrent isolated ON, the first manifestation of multiple sclerosis, or another demyelinating disease that could appear in a later follow-up.

INTRODUCTION

Joint, skin, eye and biliary tract disorders are frequently associated with inflammatory bowel disease (IBD) as an extraintestinal manifestation (EIM), although nearly every organ may be involved in this disorder. Some EIMs are clearly related to intestinal disease activity, whereas others occur independently. Ophthalmologic complications are independent of the extent of bowel involvement, usually occurring during the early years of IBD. In rare cases, eye manifestations precede the IBD diagnosis and their course tends to parallel that of the underlying bowel disease. Several ophthalmologic manifestations from the anterior and the posterior segment have now been described^[1]. Among the known posterior segment manifestations, optic neuritis (ON) may be present in up to 4% of adult IBD patients^[2,3]. When ON is diagnosed, a thorough differential diagnosis has to be applied as it can be an isolated condition or a manifestation of neurologic or systemic disease. In particular, ON may be the sign of an autoimmune demyelinating disease.

A possible association between multiple sclerosis (MS) and IBD has been hypothesized for decades and

an approximately 3-fold increased risk of MS in IBD patients has been suggested^[4]. On the other hand anti-tumor necrosis factor (TNF)- α therapies may trigger the new onset of MS, ON and other demyelinating diseases in IBD patients. However, because of the small number of controlled clinical trials with anti-TNF- α medications conducted to date, it is not possible to state with certainty whether a causal association exists between these drugs and demyelinating disorders. Nevertheless, a recent study conducted in the era before anti-TNF therapies^[4], has demonstrated that patients with Crohn's disease (CD) and ulcerative colitis were 54% and 75% more likely, respectively, than community controls to have been diagnosed with MS, ON or other demyelinating conditions^[5]. The results of this study have given credence to the emerging concept that patients with immune-mediated conditions are more likely than the general population to have another autoimmune disease. Thus, ON in IBD patients can signify an EIM of the underlying bowel disease or a demyelinating condition that seems more frequent in this population.

CASE REPORT

An 11-year-old boy presented with a recent history of severe and bloody diarrhea, abdominal pain and vomiting. The abdomen was meteoric and tender. His weight was 26 kg and height was 138 cm, which were, respectively, less than the 5th and the 10th-25th percentile for his age. Laboratory tests revealed hemoglobin 11 g/dL, platelets 507 000/m³, erythrocyte sedimentation rate 38 mm/h, C-reactive protein 9.5 mg/dL (normal < 0.45 mg/dL), and albumin 2.4 g/dL (normal > 3.5 g/dL). Thorough stool investigations ruled out infection or infestation. An abdominal ultrasonogram demonstrated thickened (9 mm) and hyperemic colonic walls. The patient was given iv albumin, metronidazole, ampicillin + sulbactam, and omeprazole without subsequent improvement. Pancolonoscopy with a terminal ileoscopy showed skip areas of deep ulcerations with a cobblestone pattern in the transverse and descending colon, and focal aphthous ulcers in the rectum. Esophagogastroduodenoscopy revealed patchy duodenal erosions and deep, wide ulcerations of the stomach. Owing to endoscopic findings that were consistent with severe CD fasting, a regimen of total parenteral nutrition (TPN) and iv methylprednisolone (20 mg bid) was started, and resulted in a slow clinical improvement. On histology, a chronic-active, patchy, erosive-ulcerative inflammation of the colon, stomach and duodenum, without evidence of granulomata, was seen. A barium meal and follow-through did not reveal small bowel lesions. On hospitalization day 20, at 14 d after the commencement of this treatment, steroids were tapered (5 mg/wk) and the antibiotics and TPN were discontinued.

On hospitalization day 25, on which 35 mg/d of iv steroids was given, the patient suddenly complained of bilateral visual loss. Diffuse and severe bilateral papilledema was detected (Figure 1). Magnetic resonance imaging (MRI) of the head, with paramagnetic iv contrast, and cytologi-

Figure 1 Papilledema of the right eye.

cal and chemical analysis of the cerebrospinal fluid (CSF) showed no abnormalities. A diagnosis of ON was made and three iv pulses of methylprednisolone (30 mg/kg on alternate days) were administered. At the end of this treatment course, visual acuity completely recovered and the optic disc appearance improved. Steroid treatment was prolonged orally. MRI of the spine, visual and brainstem auditory and somatosensory-evoked potentials, motor and sensory nerve conduction velocity, blood and CSF polymerase chain reaction analysis for viruses, CSF monoclonal band and the B₁₂ blood level showed normal or negative results. On hospitalization day 40, the child was eventually discharged and was in clinical remission on prednisone (25 mg/d to be tapered to 5 mg weekly until discontinuation) and azathioprine (1 mg/kg per day). Eighteen days after the ON diagnosis, the optic nerve edema had resolved and optical coherence tomography revealed decreased thickness of the retinal nerve fiber layer (RNFL) in the temporal superior quadrant of both eyes. The child was then regularly followed-up and at 20 mo after diagnosis is still in clinical remission with normal growth.

DISCUSSION

IBDs are often associated with EIMs which occur in approximately one third of patients^[6]. Little has been published, however, on their frequency in pediatric patients and most of the current data are from studies in adults^[7,8]. The incidence of ocular manifestations ranges from 3.5% to 43% according to previous reports^[1-3,9-11] and seems to occur more frequently in colonic CD cases. The most common complications of IBDs are episcleritis, scleritis, and uveitis occurring in up to 29%, 18% and 17% of patients, respectively. The reported incidence of posterior segment manifestations ranges between less than 1% to 30% depending upon the series^[1,2,12]. ON as an ophthalmologic manifestation of IBD has been described in only a few adult patients so far^[1,12,13], all affected with CD. The term ON is used to describe any inflammation, demyelination, or degeneration of the optic nerve with attendant impairment of function^[14]. The disease process for ON is usually acute, with a rapid and progressive loss of vision, and may be unilateral or bilateral. In childhood, ON may

occur as an isolated condition or as a manifestation of a neurologic or systemic disease. ON may also be secondary to inflammatory disease, infections, toxic causes or a vitamin B₁₂ deficiency and may signify a demyelinating disease of childhood such as MS, Devic disease or acute diffuse encephalomyelitis. Patients who experience an isolated episode of ON can develop other symptoms later on associated with a demyelinating disorder. High-dose iv methylprednisolone may help to speed the visual recovery in young adults^[14].

We here present a case report of a child with severe acute gastrointestinal symptoms in which our investigations, in accordance with the Porto criteria^[15], led to the diagnosis of diffuse CD. This disease was difficult to treat and required iv steroids, antibiotics and TPN. The patient subsequently developed a sudden loss of visual acuity consistent with a bilateral ON and not due to any known cause. This vision loss was promptly responsive to a high dose of steroids. Nevertheless after resolution, a residual segmental decrease of RNFL thickness was detected in both eyes. An extensive diagnostic work-up was required and investigations and clinical follow-up, that have not shown any recurrence, have ruled out demyelinating diseases thus far in this patient.

Reports of MS, demyelination (D), and ON associated with anti-TNF- α therapy have resulted in warnings in the instructions for prescribing of infliximab and adalimumab. However, the underlying relationship between IBD and these neurologic conditions has not been established. A previous retrospective cohort and retrospective cross-sectional study, performed in the era before TNF- α blockers were in clinical use, has reported that the incidence and prevalence of MS/D/ON is higher in patients with IBD compared with their matched controls. In particular, ON was recorded in 6 of 7988 CD patients (0.08%) and in 17 of 12 185 ulcerative colitis patients (0.14%) in this study, in comparison with 50 of 80 666 controls (0.06%)^[4].

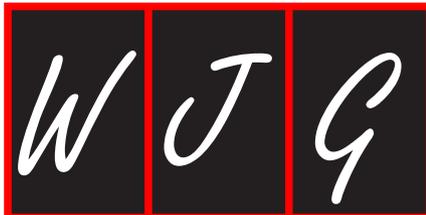

To our knowledge, our current report represents the first description of ON in a pediatric patient with CD. A correlation between ON and CD is possible in this case but, taking into account the current literature, a clear relationship cannot yet be argued. Our current case may represent an episodic EIM of the active bowel disease or an associated autoimmune disorder, such as recurrent isolated ON. It could also be a first manifestation of MS or other demyelinating diseases that are more frequent in IBD patients and could be clarified in a later follow-up of our current patient. We conclude from this case study

that, although extremely rare, ON should be considered by pediatric gastroenterologists and ophthalmologists as a possible IBD complication. In patients with IBD presenting with ON, a thorough diagnostic work-up and strict long-term follow-up are recommended.

Abstract

This article discusses the adequate treatment of early gallbladder cancer (T1a, T1b) and is based on published studies extending over nearly 3 decades. Randomized studies and meta analyses comparing different surgical treatments do not exist. The literature shows that in up to 20% of patients lymph node metastasis are found in T1b gallbladder cancer. Due to high malignancy with early angiolymphatic spread and resistance to chemotherapy and radiation on the one hand, and the relative low operative risk of extended cholecystectomy (cholecystectomy and regional lymphadenectomy) on the other hand, we believe that this procedure is mandatory in early gallbladder cancer.

TO THE EDITOR

We read with interest the systematic review by Lee and colleagues, which compares the results of surgical treatment of T1a and T1b gallbladder cancer with cholecystectomy alone or by extended cholecystectomy^[1]. In this study, the published results of 1266 patients were evaluated. The authors conclude that there is no evidence to show that extended cholecystectomy is advantageous over simple cholecystectomy for T1b cancer. However, they recommend performing regional lymphadenectomy in T1b gallbladder cancer. The argument for extended cholecystectomy was mentioned at the end of the discussion: via lymphadenectomy material can be obtained for correct staging which is the basis for possible re-resection.

In fact, the debate on adequate treatment of so-called early gallbladder cancer has extended over nearly 3 decades^[2]. Randomized controlled studies and consecutive meta-analyses comparing different surgical treatment strategies for T1a and T1b gallbladder cancer do not exist.

The general accepted opinion of visceral surgeons - as the leading physicians for this disease- is to perform regional lymphadenectomy in patients with T1b status on^[3].

In their retrospective evaluation, Lee and colleagues found that 10.8% of patients had lymph node metastasis in T1b gallbladder cancer, and 9.3% of patients with T1b gallbladder cancer died due to tumour recurrence. 12.5% of T1b patients had recurrence after simple cholecystectomy, and only 2.7% had recurrence after extended cholecystectomy. These data are consistent with recent studies.

In contrast, the rate of postoperative morbidity was 28% and postoperative mortality was 1.5% after extended cholecystectomy in the evaluation by Lee *et al*^[1] which, in our opinion, may not be representative^[4].

The detection rate of early gallbladder carcinoma has increased in recent years, due to the high frequency of laparoscopic cholecystectomy. Currently, the detection rate of T1a and T1b tumours exceeds more than the 10% as cited by Lee and colleagues, who evaluated data from 1991 on. The high rate of open cholecystectomy (e.g., 54.4% in T1a gallbladder carcinoma) argues for a past era in the treatment of benign gallbladder disease.

In the debate on surgical strategies for early gallbladder cancer, an exact comparison of operating procedures is mandatory as there is a wide variation in the procedures carried out by surgeons during “regional lymphadenectomy”.

Regional lymphadenectomy in our group consists of lymphadenectomy in the hepatoduodenal ligament, pericholedochal, periportal and along the celiac axis.

When considering current experience in the interdisciplinary treatment of solid gastrointestinal cancer, abandonment of lymphadenectomy in submucosal T1b-esophageal-, gastric-, and colorectal cancer is no longer defensible^[3].

The characteristics of gallbladder cancer are high malignancy with aggressive direct, lymphatic and hemato-

gen-venous spread, and extensive resistance to chemotherapy and radiation^[6]. Combined with the low morbidity and mortality of regional lymphadenectomy, this procedure is mandatory in T1b cancer of the gallbladder^[4].

The study by Lee and colleagues is important and commendable. It shows that oncosurgical treatment recommendations for patients with highly malignant cancer are not only based on literature studies.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copy-right" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ABOUT COVER Pezzilli R, Santini D, Calculli L, Casadei R, Morselli-Labate AM, Imbrogno A, Fabbri D, Taffurelli G, Ricci C, Corinaldesi R. Cystic dystrophy of the duodenal wall is not always associated with chronic pancreatitis.
World J Gastroenterol 2011; 17(39): 4349-4364
<http://www.wjgnet.com/1007-9327/full/v17/i39/4349.htm>

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Cystic dystrophy of the duodenal wall is a rare form of the disease which was described in 1970 by French authors who reported the presence of focal pancreatic disease localized in an area comprising the C-loop of the duodenum and the head of the pancreas. German authors have defined this area as a "groove". We report our recent experience on cystic dystrophy of the paraduodenal space and systematically review the data in the literature regarding the alterations of this space. A MEDLINE search of papers published between 1966 and 2010 was carried out and 59 papers

were considered for the present study; there were 19 cohort studies and 40 case reports. The majority of patients having groove pancreatitis were middle aged. Mean age was significantly higher in patients having groove carcinoma. The diagnosis of cystic dystrophy of the duodenal wall can now be assessed by multi-detector computer tomography, magnetic resonance imaging and endoscopic ultrasonography. These latter two techniques may also add more information on the involvement of the remaining pancreatic gland not involved by the duodenal malformation and they may help in differentiating "groove pancreatitis" from "groove adenocarcinoma". In conclusion, chronic pancreatitis involving the entire pancreatic gland was present in half of the patients with cystic dystrophy of the duodenal wall and, in the majority of them, the pancreatitis had calcifications.

INTRODUCTION

Cystic dystrophy of the duodenal wall is a rare form of the

disease which was described for the first time in 1970 by Potet and Duclert^[1]. Potet and Duclert and other French authors^[2,3] described the presence of focal pancreatic disease localized in an area comprising the C-loop of the duodenum and the head of the pancreas (Figure 1A). In 1991, Becker and Mischke^[4] defined this area as a “groove” and pointed out that it serves as a bed for the large vessels, lymph nodes, common bile duct (CBD) and main pancreatic duct. These authors also reported that pancreatitis can be found in this area and they suggested the term “groove pancreatitis” which was well received. They also classified groove pancreatitis as “pure groove pancreatitis” (Figure 1B), **segmental pancreatitis of the head and chronic pancreatitis with groove involvement** (Figure 1C). **In addition, in recent years, Adsay and Zamboni^[5] proposed the term “paraduodenal pancreatitis” in patients classified as having “cystic dystrophy of the heterotopic pancreas” or “paraduodenal wall cyst” or “groove pancreatitis”; they also recognized two types of pancreatitis: one characterized by cystic changes and the other characterized by solid lesions. These authors pointed out that the latter type of pancreatitis is difficult to distinguish from an adenocarcinoma originating in this area. Finally, the presence of cystic dystrophy of the duodeno-pancreatic space together with chronic pancreatitis of the remaining pancreas is not always true because there is also the possibility of disease limited to the CBD^[6]. Thus, in this review, we report our recent experience on cystic dystrophy of the space from the C-loop of the duodenum and the pancreas by reporting three cases observed in the last year, and also systematically review and discuss the data in the literature on the alteration of the groove space.**

OUR EXPERIENCE ON THREE RECENT OBSERVED CASES OF CYSTIC DYSTROPHY OF THE DUODENAL WALL

We report our experience on three recently observed cases of cystic dystrophy of duodenal wall. Patients were one female and two males aged 49-65 years having persistent abdominal pain and weight loss. One male patient was a drinker and the diagnosis in all 3 patients was confirmed at laparotomy. The pathological examination in two cases confirmed cystic dystrophy of duodenal wall associated with chronic pancreatitis in one case and autoimmune pancreatitis and pancreatic carcinoma in the remaining one.

Case 1

A 65-year-old female was admitted to our department in April 2009 for persistent abdominal discomfort and progressive weight loss (about 5 kg in two months). Before this admission, she had had a one-year history of recurrent epigastric pain; an ultrasonographic (US) examination showed gallstones and the patient had been cholecystectomized in another hospital. After surgery, she

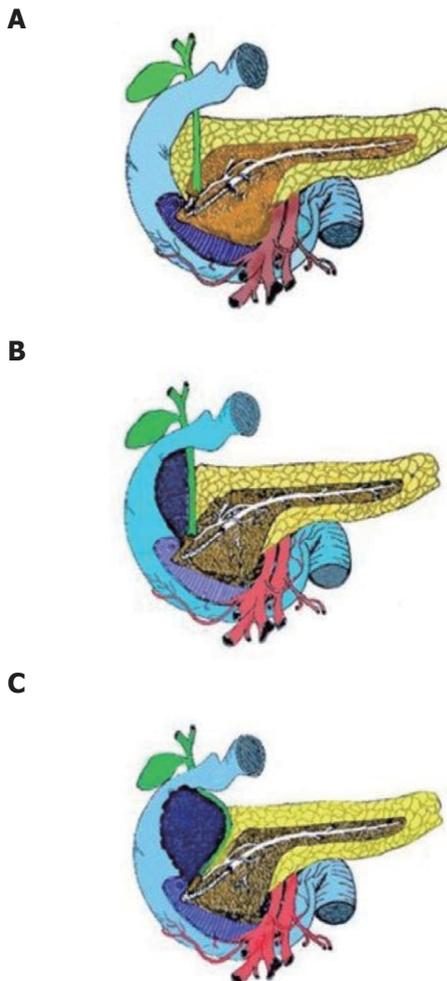

Figure 1 Classification of the various types of groove pancreatitis. A: Typical finding of groove pancreatitis (purple area); B: Segmental head pancreatitis: the scar tissue (dark blue) expands towards the duodenum; C: Pancreatitis of the head: the scar tissue (dark blue) expands to the duodenal area, determining duodenal stenosis and displacement of the common bile duct.

continued to have recurrent and frequent episodes of epigastric pain; US showed a dilation of the CBD and, two months after surgery, she underwent an endoscopic sphincterotomy. One month after this procedure, epigastric pain reappeared and, due to the presence of scleral jaundice (total bilirubin 3.2 mg/dL), the patient underwent another endoscopic retrograde cholangiopancreatography (ERCP). The papilla of Vater was substenotic and another sphincterotomy was carried out without any clinical improvement. On admission to our department, physical examination was unremarkable as was a routine blood examination; her body temperature was 37.2 °C, her arterial pressure was 110/60 mmHg and her cardiac rate was 73 bpm. Contrast-enhanced multidetector computer tomography (MDCT) was carried out. This examination showed the presence of multiple hypodense lesions in the liver (Figure 2); a US fine needle biopsy of one of these lesions was carried out and the pathological specimen was compatible with an abscess; the liver tissue was also cultured and the patient was treated with a spe-

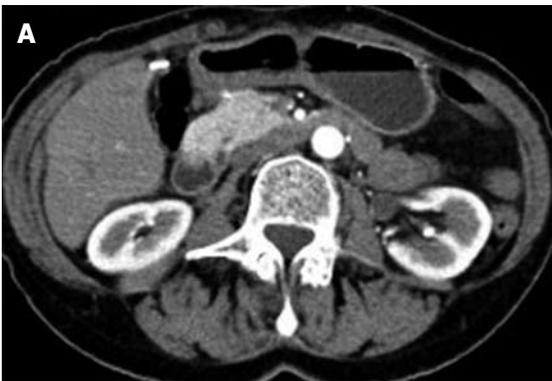

Figure 3 Case No. 1 computer tomography duodenal and pancreatic gland evaluation. A: Presence of duodenal bulging; B: Normal appearance of the pancreatic gland.

cific antibiotic. At computer tomography (CT) examination, there was the presence of biliary sludge and a dilation of the left intrahepatic biliary tree. There was also the presence of duodenal bulging (Figure 3A) while the pancreatic gland was normal (Figure 3B). An endoscopic US (EUS) was finally carried out. It confirmed the presence of duodenal bulging (Figure 4A) and showed CBD sludge; in addition, cysts in the duodenal wall were seen (Figure 4B) and a diagnosis of cystic dystrophy of duodenal wall was made. The patient refused surgery, and conservative treatment with ursodeoxycholic acid was carried out. Twenty months after discharge, the patient

Figure 4 Case No. 1 computer tomography duodenal and pancreatic gland evaluation. A: Presence of duodenal bulging; B: Presence of cysts in the duodenal wall.

was free of abdominal discomfort and regained her lost weight.

Case 2

A 49-year-old male patient with a history of chronic alcoholic consumption (about 40 g of pure alcohol intake per day) was admitted to our Department in May 2010 with persistent epigastric pain of seven months duration associated with nausea and biliary vomiting; there was also weight loss of 13 kg. The following biochemical tests were carried out: Hb 11.9 g/dL, MCV 85.8; amylase 156 U/L (upper reference value 100), CA 19-9: 52 U/mL (upper reference value 37). The patient underwent an upper gastrointestinal endoscopy which was normal. Ultrasonographic examination did not show alterations of the abdominal parenchyma. MDCT showed an enlarged pancreatic head and the presence of multiple cysts between the enlarged pancreatic head and the duodenum (Figure 5A); the remaining pancreas was normal as was demonstrated by magnetic resonance imaging (MRI) (Figure 5B). The patient was operated on and a pancreatic head resection was performed. The pathology of the resected specimen showed cystic dystrophy of the duodenal wall with hypertrophy of the Brunner glands and the presence of an ectopic pancreas (Figure 6A), showing chronic pancreatitis (Figure 6B). Seven months after surgery, the patient was symptom free and in good general health.

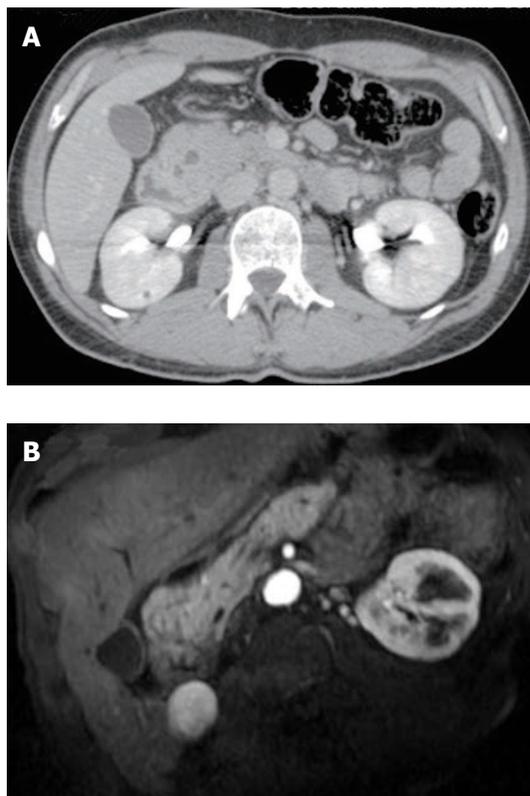

Figure 5 Case No. 2 computer tomography duodenal and pancreatic gland evaluation. A: Enlarged pancreatic head and the presence of multiple cysts between the enlarged pancreatic head and the duodenum (multidetector computer tomography); B: The remaining pancreas was normal as demonstrated by the magnetic resonance imaging.

Case 3

A 56-year-old male affected by Crohn's disease was seen in August 2010 with persistent epigastric pain of one month duration associated with jaundice, weight loss, nausea and intermittent vomiting. The patient was not an alcohol drinker. The following biochemical tests were carried out: total bilirubin, 25.4 mg/dL, AST, 63 U/L (upper normal limit 38), ALT, 66 U/L (upper normal limit 40), alkaline phosphatases, 1105 U/L (normal value 98-280), amylase, 108 U/L (upper normal limit 100), lipase, 293 U/L (upper normal limit 60), CA, 19-9 2345 U/mL (upper reference value 37). The patient underwent US which showed a dilated CBD and a mass of 2.5 cm in the head of the pancreas. The MDCT showed the pancreatic head focally enlarged with a 2.5 cm heterogeneous area extending to and involving the wall of the posterior bulbar duodenum. The main pancreatic duct was uniformly dilated in caliber and appearance with no changes in the pancreatic body or tail. The patient underwent a pancreaticoduodenectomy and surgical pathology showed the presence of cystic dystrophy of the duodenal wall (Figure 7A) with aspects of chronic pancreatitis in the heterotopic pancreas (Figure 7A), aspects of autoimmune pancreatitis (Figure 7B) and, finally, groove adenocarcinoma extending to the pancreatic head (Figure 7C). At present, the patient is still alive and is in adjuvant chemotherapy

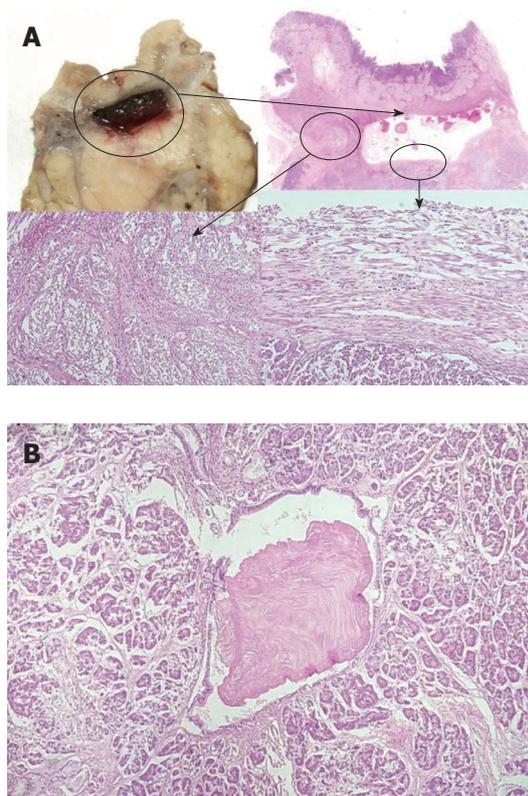

Figure 6 Case No. 2 pancreatic and duodenal surgical specimens. A: Resected specimen showing cystic dystrophy of the duodenal wall with hyperplasia of the Brunner glands and the presence of an ectopic pancreas (arrows); B: Chronic pancreatitis in the remaining pancreas together with cystic dystrophy of the duodenal wall.

with gemcitabine.

CLINICAL CONSIDERATIONS AND AIMS

The present report involving three cases of cystic dystrophy of the duodenal wall represents one of the few case series published concerning this rare entity. All of our patients presented with symptoms consistent with chronic pancreatitis; however, pancreatic diseases were found in two and these two patients improved dramatically after surgical head pancreatic resection while one is symptom free after medical treatment. It is important to diagnose the pathological involvement of the proximal duodenum in order to detect the presence of malignancy and to evaluate the prognosis of these subjects. In order to better establish the features of this rare entity we also undertook a systematic review of the literature.

LITERATURE SEARCH AND DATA EXTRACTION

A search was carried out on December 18, 2010 using the MEDLINE/PubMed database (United States National Library of Medicine National Institutes of Health) in order to select the data existing in the literature under the headings of pancreatitis and groove

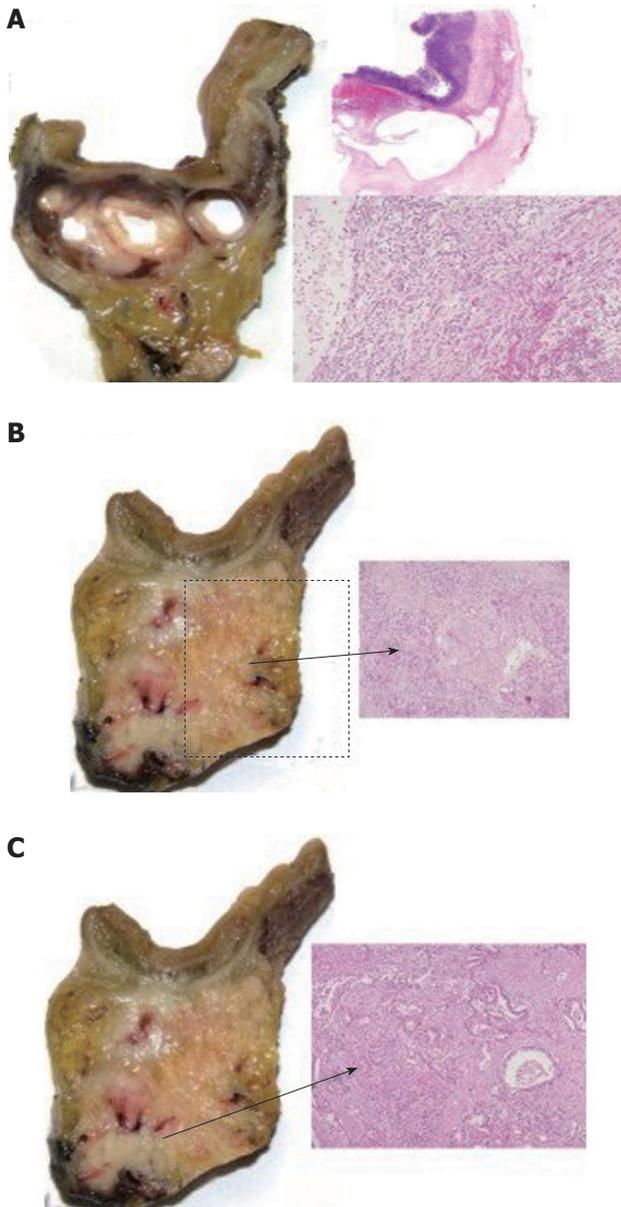

Figure 7 Case No. 3 pancreatic and duodenal pathological specimens. A: Cystic dystrophy of the duodenal wall with aspects of chronic pancreatitis in the heterotopic pancreas; B: Aspects of autoimmune pancreatitis (arrow); C: Groove adenocarcinoma extending to the pancreatic head (arrow).

pancreatitis. The terms used were “groove pancreatitis” or “duodenal cystic dystrophy” (explanatory variables) and “pancreatic diseases” (outcome variable). The search was limited to human studies written in English. We identified additional studies by means of a hand search of the bibliographies from the primary studies, review articles and key journals. A total of 70 citations were found in MEDLINE/PubMed^[4-73]. Four investigators (Pezzilli R, Morselli-Labate AM, Fabbri D, and Imbrogno A) independently screened all articles for those meeting the broad inclusion criteria. Of the 70 papers, 4 were excluded because they contained data regarding diseases other than those searched for^[8,15,48,71]. Of the remaining 66 papers, 10 were excluded because they

were review articles not containing data useful for the analyses^[4,5,24,41,42,45,56,58,60,68] and one because it was a comment on an article^[19] without new data/cases; therefore, 55 papers with available data remained. Of these 55 papers, 4 were also excluded for the following reasons: 1 because it was a duplicated publication^[55] and 3 because it was not possible to extract useful data^[49,57,73]. Eight papers were added to these 51 papers because they were extracted from the references^[74-81]. Thus, 59 papers were considered for the present study; there were 19 cohort studies^[6,7,10-13,16,18,23,30,36,37,39,40,46,47,52,63,81] and 40 case reports^[9,14,17,20-22,25-29,31-35,38,43,44,50,51,53,54,59,61,62,64-67,69,70,72,74-80].

For each study, the following information was recorded: gender, mean age for the cohort studies or age of the subjects studied in the case reports, interval time from the appearance of the symptoms to diagnosis, alcoholism, the presence of clinical variables (such as abdominal pain, weight loss and jaundice, hyperamylasemia, CBD stenosis, duodenal stenosis), the need for surgery and the type of surgery, the possible presence of chronic pancreatitis in the pancreas together with cystic dystrophy as well as the presence of pseudocysts, the possible presence of pancreatic neoplasms, the time of follow-up and death.

Data are presented as absolute numbers and relative frequencies, mean \pm SD, medians, ranges, and interquartile ranges (IQR); follow-up data are also presented as crude survival.

EVALUATION OF THE SELECTED STUDIES

Due to the low frequency of diseases, such as groove pancreatitis and groove carcinomas, there is a limited number of cohort studies (No. 19) and a large number of case reports (No. 40). All the cohort studies were retrospective and patients were enrolled from 1959^[11] to 2008^[6]. Thus, the changes in diagnostic techniques with the appearance of MRI and EUS in clinical practice render the studies not comparable as to what is the best technique for diagnosing groove diseases. Furthermore, the mean follow-ups vary greatly and the longest follow-up is about 8 years which is that reported by Casetti *et al.*^[63]. As shown in Tables 1-8, we found no substantial differences between the data reported in the cohort studies and those we calculated when grouping the series of case reports by gender, age at diagnosis, alcoholism, presence of pain, weight loss, jaundice, hyperamylasemia, CBD stenosis, duodenal stenosis and the need for surgery. The presence of chronic pancreatitis and deaths were more frequently reported in the cohort studies than in the case reports while associated adenocarcinoma and pseudocysts were more frequently reported in the case reports than in the cohort studies.

EPIDEMIOLOGY

We have no epidemiological data regarding the preva-

lence and incidence of cystic dystrophy of the duodenal wall in the general population. The data regarding this anomaly mainly describes patients with associated chronic pancreatitis. A recent Italian survey which reviewed the data on chronic pancreatitis in Italy in mixed medical/surgical cases from 2000 to 2005^[57] reported that the frequency of groove pancreatitis was 6.2% (55

out of 893 patients) with a higher frequency in males (7.6%, 50/660) than in females (2.1%, 5/233). In a surgical setting, groove pancreatitis ranges from 2.7% to 24.5%^[4,7,10,63]; in these cases, the frequency in males is also higher than that in females. We have no epidemiological data regarding groove carcinomas or biliary involvement without pancreatitis or pancreatic adenocar-

cinoma. In all these studies, the patients having groove pancreatitis were middle aged (about 45 years of age), having a wide range from 20 mo^[76] to 75 years of age^[40]. Only two of the patients described were children (a

20-mo-old girl and a 15-year-old boy)^[51,76]. Mean age was significantly higher in patients having groove carcinoma than in those having groove pancreatitis, namely 70 years of age (range 57 to 80 years)^[51].

CLINICAL AND BIOCHEMICAL FEATURES

As shown in Tables 1-8, the main symptoms of cystic dystrophy of the duodenal wall were epigastric pain, weight loss and jaundice. These symptoms were similar in those patients having associated chronic groove pancreatitis and in those patients having groove carcinoma. All these symptoms can be present, further complicating

the differential diagnosis with ampullary and periampullary cancers. Pain may be persistent or recurrent, and nausea and vomiting are usually present as accompanying symptoms. The majority of these patients are heavy alcohol drinkers (275/341, 80.6%), and this may explain the fact that most of the patients with groove pancreatitis are males. In addition, in the 18 patients with groove adenocarcinoma, the majority of cases were males (11/18, 61.1%) (Tables 9-12).

Regarding the laboratory examinations, serum amylase activity was usually abnormally high in these patients (38/59, 64.4%) (Tables 1-8), but the magnitude of this elevation varied greatly. An increase in bilirubin may have also been present, along with an increase in alkaline phosphatases in patients with jaundice. Finally, it has also been reported in the literature that tumor markers, such as serum CA 19-9, are usually within the normal limits^[10,58].

ASSOCIATED DISEASES

The majority of patients with cystic dystrophy of the duodenal wall have been reported to have chronic groove pancreatitis or groove carcinoma. However, the lesions in the remaining pancreatic gland not affected by groove pancreatitis have not been fully evaluated. As shown in Tables 1-12, in patients with groove pancreatitis as well as in those with groove carcinoma, the pancreatic gland above the groove lesion is generally not affected by chronic pancreatitis. Chronic pancreatitis of the entire pancreas was reported in 166 of the 302 (55.1%) patients and there were pancreatic calcifications in 125 of these 166 patients (75.3%) (Tables 1-8). The presence of pancreatic pseudocysts was usually rare (13 out of 378, 3.4%) (Tables 1-8), and, in most cases, they were localized in the head of the pancreas (7/13, 53.8%). In addition, some authors have reported that groove pancreatitis is associated with the occasional findings of neuroendocrine tumors^[63] or pancreatic cystadenoma^[54].

IMAGING ASSESSMENT

As shown in Tables 3, 7, 8 and 11, the imaging diagnosis of dystrophy of the duodenal wall is rarely assessed using a single radiological modality. Even if US is the first line imaging modality in these patients, it is rarely diagnostic. ERCP, which was frequently used in the past, is feasible and in typical cases it demonstrates smooth tubular stenosis at the distal part of the CBD without abnormality of the main pancreatic duct or, occasionally, with only slight irregularities^[44,65]. ERCP may also demonstrate irregularity, tapering obstruction or dilatation of the Santorini duct and its branches, sometimes with intraductal stones or protein plugs^[44]. At present, ERCP is used mainly for endoscopic therapy^[33]; in fact, successful treatment for groove pancreatitis by endoscopic drainage *via* the minor papilla was carried out in only one patient^[33].

CBD: Common bile duct; NR: not reported.

For many years, CT has been an excellent imaging modality for diagnosing chronic pancreatitis or adenocarcinoma associated with cystic dystrophy of the duodenal wall^[6,16]. In the pure form of groove pancreatitis, it may be visualized as a poorly enhancing hypodense lesion between the pancreatic head and the duodenum, near the minor papilla, reflecting the pathological characteristics of the mass. The delayed enhancement is mainly

due to delayed blood circulation caused by fibrous tissue proliferation and artery constriction^[12]. In addition, CT may reveal the presence of duodenal stenosis with wall thickening and cystic lesions in the duodenal wall or in the groove area. The cysts may be tiny even if multilocular cystic lesions may be observed. The main pancreatic duct may be mildly dilated above the lesion while, in the pure form, paraduodenal pancreatitis can be expected.

Table 7 Epidemiological and clinical characteristics of patients in the 38 case report papers involving 46 subjects with a benign cystic duodenal wall (a paper may report more than one patient), the three cases reported in the present paper are also shown (continues from Table 6)

CBD: Common bile duct; NR: Not reported; PD: Pancreaticoduodenectomy; WP: Whipple procedure.

In groove pancreatitis and in groove carcinoma, the CBD may be stenosed in its distal part and a dilation of the extra- and intra-hepatic biliary system can be observed^[6,16].

The same CT findings can also be observed when utilizing MRI which may reveal a mass between the head of the pancreas and the duodenum associated with duodenal wall thickening. The mass visualized in the groove

and/or in the adjacent head of the gland is hypointense

to the pancreatic parenchyma. Delayed enhancement may also be seen in the thickened duodenal wall. These imaging features reflect the fibrous involvement of the lesions of groove pancreatitis. Cysts, which may be present in the groove area and the duodenal wall, have high signal intensity. An important diagnostic aspect of MRI, which cannot be evaluated by CT, is the fact that MRI can be followed by magnetic resonance cholangiopancreatography (MRCP); this additional evaluation provides images similar to those of ERCP without the morbidity of this latter technique. In addition, MRCP may visualize those lesions which are not seen in ERCP in the case of serrated duodenal stenosis^[18]. The diagnostic value of MRI is superior to CT in evaluating biliary ducts in paraduodenal pancreatitis as well as in groove carcinomas. The stricture, or narrowing of the CBD, may be better approached by using MRCP rather than CT and/or ERCP. The dilation of the space comprising the main pancreatic duct, the CBD and the duodenum is another sign which can be observed in patients with groove pancreatitis or groove carcinoma when using MRCP^[47].

In the last few years, EUS has emerged as a useful technique for diagnosing pancreatic diseases because of the accurate evaluation of the biliopancreatic structures through the gastro-duodenal lumen without interference of the abdominal wall or other organs^[82]. EUS can easily demonstrate the hypoechoic area between the duodenal wall and the pancreatic parenchyma, narrowing of the duodenal lumen and stenosis of the CBD and/or pancreatic duct in both groove pancreatitis and groove carcinomas^[50]. Furthermore, the diagnosis can be confirmed by EUS-guided fine-needle aspiration of the mass visualized.

PATHOLOGY

Macroscopically, groove pancreatitis is associated with an absent or narrow Santorini duct or the presence of pancreas divisum^[17], and the difficult outflow of pancreatic fluid may be hypothesized for lesions of the groove similar to those of chronic pancreatitis^[17]. The duodenal wall contains dilated ducts, in the majority of cases with thickened secretions, pseudocystic changes as well as adjacent stromal reactions, foreign-body type giant cell reaction engulfing mucoprotein material and myofibroblastic proliferation. Brunner gland hyperplasia is usually present as is dense myoid stromal proliferation, with intervening rounded lobules of pancreatic acinar

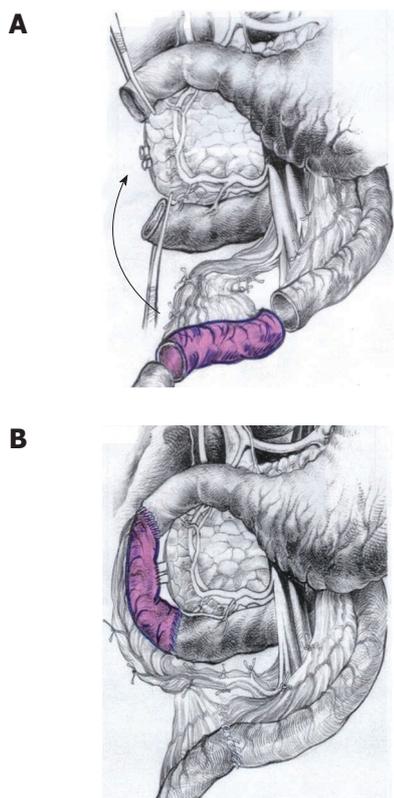

Figure 8 New surgical option for patients having cystic dystrophy of duodenal wall. A: Scheme of the pancreas-preserving resection of the second portion of the duodenum. The second part of the duodenum, including the main papilla, is removed and the segment of the proximal jejunum supplied by the artery and vein is cut out and prepared for transposition between the 1st and 3rd portions of the duodenum; B: The shifted segment is interposed between the 1st and the 3rd parts of the duodenum. Jejunum-jejunum- and duodeno-jejunum-anastomoses are performed. The bile and the pancreatic ducts were implanted in the neoduodenum 4 cm below the proximal duodeno-jejunum-anastomosis (from Egorov *et al*^[70] with the kind permission of the authors).

tissue. Fibrosis into the adjacent pancreas and soft tissue occurs, especially in the groove area which involves the CBD^[5].

In groove carcinoma, the macroscopic pathology is similar to that of groove pancreatitis while the pancreatic tissue has the same histology as that of pancreatic adenocarcinoma^[6,20,30,38].

TREATMENT

Conservative treatment is the main option in the acute phase of the disease, including analgesia and parenteral nutrition. In some patients, enteral nutrition is not always possible due to the presence of duodenal stenosis^[17]. The main therapeutic option for these patients is a surgical approach in benign as well as in malignant diseases of the groove, as shown in Tables 1-12. **The most frequent** surgical approach is a pylorus-preserving pancreaticoduodenectomy or a Whipple procedure; in a limited number of patients, a gastrointestinal by-pass, with or without biliary by-pass, has been carried out. More recently, a new approach has been reported by Egorov *et al*^[70];

these authors have described a new surgical approach carried out on two patients who were successfully treated by two modifications of a pancreas-preserving duodenal resection with reimplantation of the bile and pancreatic ducts into the neoduodenum (Figure 8). The authors have claimed that these two cases are a good example of a pancreas-preserving approach to duodenal dystrophy treatment and that the technique may be an alternative to the Whipple procedure in cases of mild changes of the orthotopic gland.

Only in a few cases was a medical approach carried out (see Case 1 of our three patients), mainly because the patients refused surgery, and also in one patient in whom successful treatment for groove pancreatitis was carried out by endoscopic drainage *via* the minor papilla^[33].

THE FATE OF PATIENTS

The first important question arising from the studies analyzed is the extreme length of time necessary from the onset of the symptoms to reach a diagnosis in patients with groove pancreatitis: it varies from a few days to ten years (Tables 1-8). **In one of the larger studies in this field**, such as that of Rebours *et al*^[40], the mean time from the appearance of the symptoms and the diagnosis is 1 year with a range of 0 to 24 mo. This long time period is similar to that previously reported in chronic pancreatitis^[83]. In patients with groove adenocarcinoma, we have no information on time to diagnosis. The perioperative mortality rate seems to be negligible, the only death being reported by Babál *et al*^[79]. In the only study reporting this information (Tables 1-8), **the mortality rate was 8.9%** (9/101) in the follow-up period in patients with benign disease. However, this information should be taken with caution because, as previously stated, the follow-up period is not quite as long in the majority of studies.

CONCLUSION

The diagnosis of cystic dystrophy of the duodenal wall can be easily assessed by MDCT, MRI and EUS. These latter two techniques may also add more information on the involvement of the part of the pancreatic gland not involved in the duodenal malformation.

Chronic pancreatitis involving the entire pancreatic gland is present in half the patients with cystic dystrophy of the duodenal wall, and the pancreatitis has calcifications in the majority of them. We have no information about exocrine function in these patients and this topic requires additional study. In subjects without pancreatitis, the patients with cystic dystrophy of the duodenal wall are usually in satisfactory general condition after surgical treatment and they regain weight after surgery.

The fact that only two children have been reported to have cystic dystrophy of the duodenal wall confirms the hypothesis that pancreatic and biliary diseases develop over a long period of time.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Paolo Bassi of the Surgical Department, Dr. Maurizio Zani and Dr. Maurizio Iorio of the University of Bologna Clinical Library at Sant'Orsola-Malpighi Hospital for their technical assistance.

Abstract

Extraction of large pancreatic and common bile duct (CBD) calculi has always challenged the therapeutic endoscopist. Extracorporeal shockwave lithotripsy (ESWL) is an excellent tool for patients with large pancreatic and CBD calculi that are not amenable to routine endotherapy. Pancreatic calculi in the head and body are targeted by ESWL, with an aim to fragment them to < 3 mm diameter so that they can be extracted by subsequent endoscopic retrograde cholangiopancreatography (ERCP). In our experience, complete clearance of the pancreatic duct was achieved in 76% and partial clearance in 17% of 1006 patients. Short-term pain relief with reduction in the number of analgesics ingested was seen in 84% of these patients. For large CBD calculi, a nasobiliary tube is placed to help target the calculi, as well as bathe the calculi in saline - a simple maneuver which helps to facilitate fragmentation. The aim is to fragment calculi to < 5 mm size and clear the same during ERCP. Complete clearance of the CBD was achieved in 84.4% of and partial clearance in 12.3% of 283 patients. More than 90% of the patients with pancreatic and biliary calculi needed three or fewer sessions of ESWL with 5000 shocks being delivered at each session. The use of epidural anesthesia helped in reducing patient movement. This, together with the better focus achieved with newer third-gen-

eration lithotripters, prevents collateral tissue damage and minimizes the complications. Complications in our experience with nearly 1300 patients were minimal, and no extension of hospital stay was required. Similar rates of clearance of pancreatic and biliary calculi with minimal adverse effects have been reported from the centers where ESWL is performed regularly. In view of its high efficiency, non-invasive nature and low complication rates, ESWL can be offered as the first-line therapy for selected patients with large pancreatic and CBD calculi.

INTRODUCTION

Extracorporeal shock wave lithotripsy (ESWL) was first introduced in the 1980s for the fragmentation of renal and ureteric calculi^[1]. Its application was quickly extended to include large biliary and pancreatic calculi. Over the past three decades, it has been utilized at many centers worldwide for fragmentation of biliary and pancreatic calculi that are not amenable to routine endotherapy^[2-16]. In this review, we briefly highlight the principles of ESWL as well as its place in therapy of biliary and pancreatic calculi.

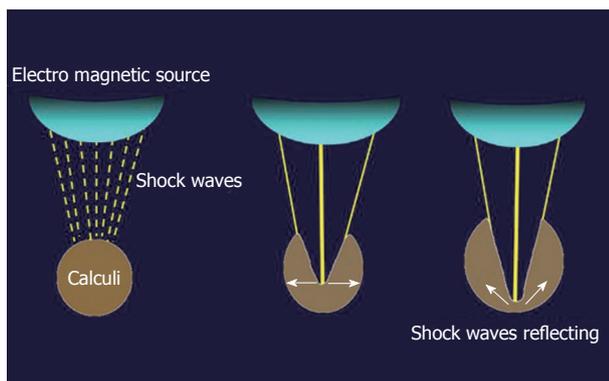

Figure 1 Principle of extracorporeal shockwave lithotripsy. Shockwaves from the source are targeted on the calculi and these induce fragmentation.

PRINCIPLES OF ESWL

ESWL is based on the principle of shock wave energy. Whenever energy is abruptly released in an enclosed space, shock waves are generated. The passage of these shock waves through substances of different acoustic impedance generates compressive stress on the boundary surface. This stress eventually overcomes the tensile strength of the object (in the present case, biliary and pancreatic calculi) and the anterior surface of the calculi crumbles as a result. The shock waves cross to the posterior surface of the calculi and some of them are reflected back and cause further fragmentation^[7] (Figure 1). Modern lithotripsy machines consist of the following basic components.

Shock wave generator

The earlier generation lithotripter utilized electrohydraulic energy or piezoelectric crystals for shock wave generation. The newer third-generation lithotripter utilizes the principle of electromagnetic shock wave generation from an electromagnetic coil. These shock waves are focused on a target (calculi) using an acoustic lens or cylindrical reflector.

Focusing system

Shock waves are focused to the focal point or target in the body. This focal path is conical in shape and all the waves are concentrated at the apex of the cone, which is called the focal point. During ESWL, the focal point targets the calculi. Targeted focusing reduces collateral tissue damage and minimizes the complications.

Localization

Localization of the calculi is basically done by fluoroscopy or ultrasound. All the newer lithotripters are equipped with both these facilities.

Coupling device

The generated shockwaves are transmitted *via* a coupling device, to the skin surface and then through the body tissue to the calculi. The earlier lithotripters used a “water

bath” for this purpose. The newer machines use a small water-filled cushion covered with a silicone membrane to transmit the shock waves to the patient’s skin.

ESWL FOR PANCREATIC CALCULI

Chronic calcific pancreatitis (CCP) is a disease of varied etiology that is associated with the development of pancreatic ductal calculi, which result in upstream hypertension, increased parenchymal pressure, and ischemia. Pain is the dominant feature of both alcoholic and non-alcoholic CCP. Decompression of the duct by clearing the stones leads to relief of pain in many patients. Small pancreatic duct (PD) stones can be extracted by the routine technique of endoscopic pancreatic sphincterotomy and basketing. Stones > 5 mm in diameter are often impacted in the main pancreatic duct and require fragmentation to facilitate their expulsion^[15]. ESWL has been successfully used at many centers for fragmentation of large PD calculi followed by spontaneous or endoscopic clearance with resultant relief in pain^[7-15].

Indications and contraindications

ESWL is indicated in all patients of CCP with large PD calculi (> 5 mm) that are not amenable to routine endotherapy - where pain is the predominant symptom. The aim is to break the calculi to fragments of ≤ 3 mm, so that they can be removed by subsequent endoscopic retrograde cholangiopancreatography (ERCP). Calculi in the head and body are targeted during ESWL.

ESWL is not indicated in patients with extensive calculi in the head, body and tail of the pancreas, or in patients with isolated calculi in the tail area because of increased chance of collateral damage to the spleen are high. Patients with multiple stricture, head mass, pancreatic ascites or pseudocysts are not treated by ESWL. Cholangitis or coagulopathy due to biliary stricture are treated before subjecting the patient to ESWL.

Procedure protocol

The protocol followed for ESWL of pancreatic calculi at our institute is depicted in Figure 2.

A third-generation electromagnetic lithotripter (Delta Compact; Dornier Med Tech, Weissling, Germany.) (Figure 3) is used to deliver a maximum of 5000 shocks are delivered per session. Repeat sessions are carried out on successive days until the stone fragments are < 3 mm in diameter. An intensity of 5-6 (15 000-16 000 kV) on a scale of 1-6 with a frequency of 90 shocks per minute is used for fragmentation^[7,8].

A few centers have advocated ESWL alone without any subsequent endotherapy for large PD calculi, stating that good fragmentation is followed by spontaneous expulsion of the fragments^[18,19]. At our center, ERCP, pancreatic sphincterotomy and pancreatic ductal clearance is always performed after ESWL because of the dense nature of the calculi present in patients with idiopathic chronic pancreatitis^[7]. Pancreatic sphincterotomy prior to

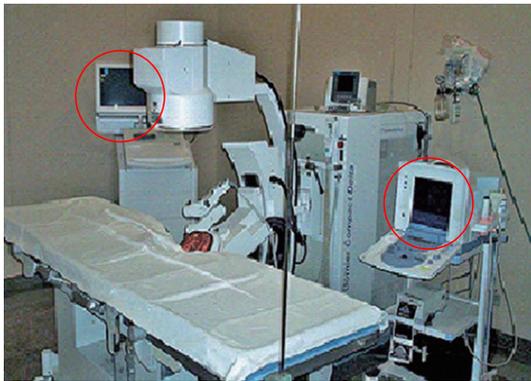

Figure 3 Third-generation lithotripter with fluoroscopic and ultrasound imaging facility.

ESWL is technically challenging because these dense calculi tend to obstruct the pancreatic duct completely and prevent deep cannulation. In our study, the majority of ESWL procedures were carried out under epidural anesthesia (EA)^[20]. However, general anesthesia or total intravenous analgesia has also been used for this procedure.

Efficacy and pain relief

Over 95% of our patients require three sessions or fewer of ESWL for adequate fragmentation. In 76% of patients, the PD cleared completely, in 17% partially, and there was clearance failure in the remaining 7%^[7] (Table 1 and Figures 4 and 5). Similar results for clearance of the PD, ranging from 37% to 100% have been reported earlier^[9]. Comparative efficacy of ESWL for pancreatic calculi is shown in Table 2. Short-term pain relief was seen in 84% of our patients. This experience is also similar to others who have reported short-term pain in 82%-94% of the patients^[9,10,21-23]. The results of a large meta-analysis have indicated that ESWL has a significant impact on improvement of pain. The mechanism of pain relief is due to decompression of the main PD following clearance of the

obstruction^[9]. Pain relief was reflected by decreased use of analgesics and of number of hospitalizations during the follow-up period^[7,14] (Table 3). Failure of pain relief, despite adequate clearance could be because of multiple mechanisms of pain in patients of chronic pancreatitis. These include pancreatic inflammation, ischemia, and associated lesions such as duodenal and biliary strictures. Surgery is often considered as the gold standard in the management of chronic pancreatitis. However, even after duodenum-preserving resection of the head of the pancreas, which is considered to be the best surgical approach for chronic pancreatitis, almost 25% of patients experience recurrence of pain^[21]. In addition, there is considerable procedure-related morbidity and mortality. ESWL followed by PD clearance on ERCP is therefore increasingly used in the management of CCP, with results that

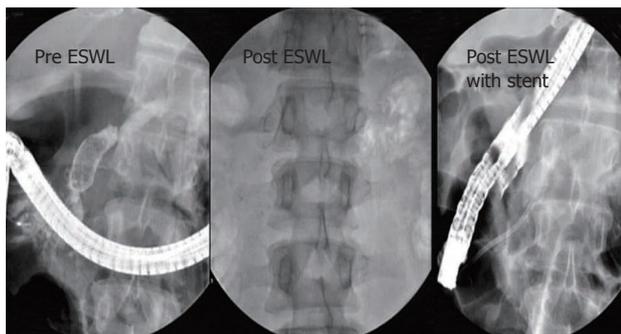

Figure 4 Large pancreatic calculi in head and genu, cleared by extracorporeal shockwave lithotripsy followed by pancreatic stenting. ESWL: Extracorporeal shockwave lithotripsy.

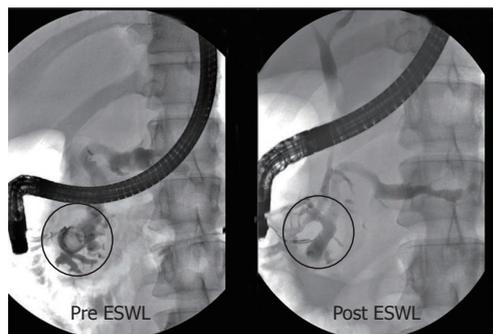

Figure 5 Large pancreatic calculi in head. Post extracorporeal shockwave lithotripsy (ESWL) reduction in diameter of main pancreatic duct.

are comparable to surgery^[10-12,19].

Limitations of ESWL in CCP

Long-term follow-up is necessary to evaluate the role of ESWL in PD clearance of patients with CCP. Data on this issue are conflicting. Although no benefit on glandular function and pain has been reported by some workers^[16,24], others have shown a definite improvement in exocrine and endocrine functions^[23]. We feel that more long-term follow-up studies are required to define the role of ESWL in pain and exocrine or endocrine dysfunction, as well as the possibility of carcinoma development, which are all potential sequelae of CCP. This is especially true in tropical regions and in patients with idiopathic chronic pancreatitis in whom the disease begins at a young age.

Although the numbers are small, failure of complete fragmentation has been reported at most centers. It would be ideal to identify this set of patients, so that they can be subjected to surgery directly. Yet another limitation is the failure to prevent recurrence following ESWL, which has been reported in 22%-35% of patients^[22,24].

In conclusion, ESWL is a good technique for extraction of large PD calculi in patients with CCP and offers good pain relief. It is conceivable that ESWL done at a young age, followed by intensive medical therapy could alter the course of the patients with CCP, besides obviating the need for surgery^[8].

ESWL FOR LARGE COMMON BILE DUCT STONES

Conventional therapy for common bile duct (CBD) stones involves endoscopic sphincterotomy and extraction by balloon catheter or Dormia basket. Between 80% and 90% of CBD stones can be extracted using these techniques^[4,5,25]. The rest are categorized as difficult CBD stones and include large stones (> 15 mm diameter), impacted stones in patients with narrow distal CBD and/or difficult anatomy. Large stones can either be fragmented or the CBD passage dilated to facilitate extraction. Fragmentation of large CBD stones can be carried out by me-

chanical lithotripsy, electro hydraulic lithotripsy (EHL)^[26], intraductal laser lithotripsy (ILL)^[27], spy scope and holmium laser^[28], and ESWL. The narrow distal CBD can be subjected to balloon dilatation to facilitate extraction of large calculi^[29-31]. Sauerbruch and colleagues first demonstrated the efficacy in achieving CBD stone disintegration successfully and with minimal side effects^[8].

Indications and contraindications

ESWL is indicated all patients with large CBD calculi that are not extractable by routine techniques of sphincterotomy followed by basket or balloon tawl. It is especially useful for patients with post-cholecystectomy retained stones, isolated or primary CBD stones, and in those who refuse or are unfit for surgery.

Acute cholangitis and coagulopathy are relative contraindications and ESWL can be performed once these conditions are treated.

Procedure protocol

The majority of CBD calculi are radiolucent. An initial ERCP is performed and a nasobiliary tube (NBT) is placed in the CBD. This is used to opacify the calculi for targeting and fragmentation. It is also used to bathe the stones in saline - a simple technique that aids fragmentation. ESWL is carried out at an intensity of 4 (in a scale of 1-6) corresponding to 11 000-16 000 kV) at a rate of 90 shocks/min. A maximum of 5000 shocks are given per session. The aim is to break the calculi into fragments < 5 mm in diameter for extraction by subsequent ERCP. Stenting is done if clearance is partial or an associated stricture is present. The protocol followed at our institute is shown in Figure 6.

Efficacy

In our experience, complete clearance was achieved in 84.4%, partial in 12.3%, and failure in 3.1% of patients^[3] (Figure 7). ESWL was useful in clearing intrahepatic calculi also. Similar successful clearance has been reported at other centers (Table 4). Over 75% of our patients needed ≤ 3 less sessions of ESWL. Clearance of the CBD in patients with post-cholecystectomy calculi or primary CBD calculi by ESWL and subsequent ERCP

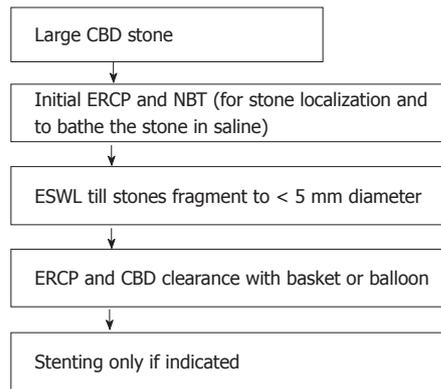

Figure 6 Protocol for extracorporeal shockwave lithotripsy of large common bile duct calculi. CBD: Common bile duct; ERCP: Endoscopic retrograde cholangiopancreatography; NBT: Nasobiliary tube; ESWL: Extracorporeal shockwave lithotripsy.

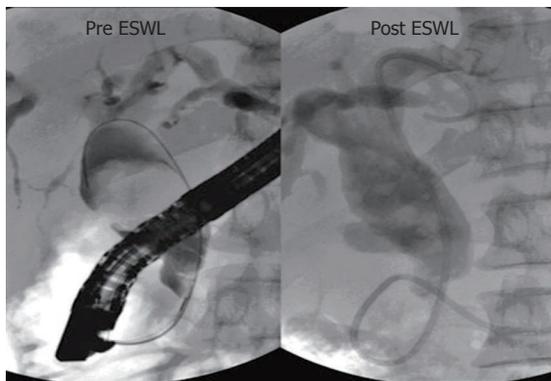

Figure 7 Large common bile duct calculi with narrow distal common bile duct. Good fragmentation achieved with extracorporeal shockwave lithotripsy (ESWL).

obviates the need for surgery^[3]. ESWL was successful in patients in whom mechanical lithotripsy or surgical extraction of CBD stones was unsuccessful^[5]. Non-operative options for removing large CBD calculi include laser lithotripsy, EHL or ESWL. The success rates are similar at between 80% and 95%^[6]. No significant differences in CBD clearance was seen in comparison of ESWL with EHL^[25]. Laparoscopic CBD exploration (LCBDE) is a well-established technique for management of large CBD stones. Despite several studies supporting LCBDE, current surgical practice suggests an overwhelming preference for preoperative ERCP^[33]. Potential explanations for this preference include the challenging nature of LCBDE, lack of necessary equipment, lack of formal training in LCBDE, and increased operative time^[34,35].

Factors that influence fragmentation of CBD stones

Factors that promote better fragmentation and patient compliance have been analyzed at our center^[3]: (1) Use of EA. EA provides good sensory block and reduces patient movement^[20]. This helps with better targeting and reduces the total number of shocks. The same catheter can be used for three sessions of ESWL, which is

Table 4 Efficacy of extracorporeal shockwave lithotripsy for large common bile duct calculi

Author	No. of patients	Complete clearance (%)
Adamek <i>et al</i> ^[27]	79	78.5
Neuhaus <i>et al</i> ^[29]	30	73
Binmoeller <i>et al</i> ^[28]	10	70
Ellis <i>et al</i> ^[5]	83	83
Tandan <i>et al</i> ^[3]	283	84
Kocdor <i>et al</i> ^[32]	20	85

often adequate to fragment calculi in the majority of patients; (2) Frequency of shocks at 90/min. At a higher frequency, the ongoing shock waves and those reflected from the surface of the calculus tend to cancel each other out^[17]; (3) The presence of fluid around the calculi aids better fragmentation. Saline irrigation *via* the NBT is carried out during ESWL; and (4) Radiolucent calculi fragment easier compared to radio-opaque ones.

At our center, patients with large CBD calculi undergo ESWL, under EA, at a shock wave frequency of 90/min, with saline irrigation *via* an NBT. Limitations include failure to prevent recurrence, which is reported around 14% at 1 year following ESWL^[36]. The other limitation is failure to identify the calculi that are not amenable to fragmentation, prior to ESWL.

COMPARISON WITH COMPETING STRATEGIES

Mechanical lithotripsy, ILL, EHL and Spy Glass are the other modalities of stone fragmentation for large CBD calculi. Neuhaus *et al*^[27] have reported better clearance with ILL as compared with ESWL, whereas Adamek and colleagues have found no difference between these modalities^[25]. The availability of instrumentation and expertise at a center often determines the choice of the procedure adopted at that center. Very few studies have compared different strategies for fragmentation of large CBD stones.

COMPLICATIONS OF ESWL

A number of rare and serious complications have been reported following ESWL^[37-40]. These occur infrequently and appear to be limited in number. The complications include perirenal hematoma, biliary obstruction, bowel perforation, splenic rupture, lung trauma, and necrotizing pancreatitis. In our experience, as well as in most of the other centers with high patient volume, complications are minimal and mild, and are managed conservatively without extension of hospital stay^[3,7,25,27]. Pain at the site of shock wave delivery, skin ecchymosis, abdominal pain, occasional fever, and hemobilia were observed in some of our patients. No blood transfusion or intervention was required in any of these cases. There is no increased incidence of pancreatitis following ESWL and ERCP. Accurate targeting achieved by the

third-generation lithotripter, as well as reduced patient movements with EA, are responsible for reducing collateral tissue damage and minimizing complications^[3,7].

AREAS OF FUTURE RESEARCH

Although fragmentation of pancreatic and biliary calculi by ESWL is satisfactory, there is ample scope for future research to improve results and minimize complications. The long-term results of ESWL in CCP, especially in young patients, are yet to be determined. Data on post-ESWL long-term follow-up are conflicting, with no benefit being shown in some studies^[16], whereas others have revealed good long-term results^[23]. Can intervention at an early age change the course of CCP and help avoid surgery and long-term sequelae^[7]? A long term prospective study in this regard would give us a clearer insight. Another focus of research would be to identify the small percentage of pancreatic and biliary calculi that do not respond to ESWL, so that they can be subjected to alternate modes of endoscopic therapy or surgery. An improvement in the focusing and intensity of shock waves would minimize the failure rate as well as help target pancreatic calculi in the tail region while avoiding splenic complications^[38,39]. Recurrence of pancreatic and biliary calculi after initial successful clearance is known to occur^[22,36]. Identification of this subset of patients and prevention of such recurrences using pharmacological agents would be ideal.

CONCLUSION

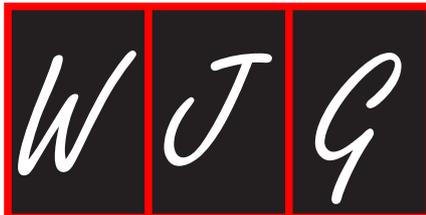

ESWL is an excellent therapeutic modality for large pancreatic and CBD calculi. The high efficacy, non-invasive nature of the procedure, along with the low complication rate make it a procedure of choice and can be offered as first-line therapy for selected patients with large pancreatic and CBD calculi.

Abstract

In the last decades, with the development of biological therapy, the treatment paradigms in patients with Crohn's disease have continuously evolved. Several studies focusing on the optimal use of both traditional immunosuppressants and biological therapy have been published, investigating conventional, accelerated step-up and top-down approaches. In addition, much emphasis has been placed in recent years on the determination of important predictive factors that could enable early patient stratification, which would lead to a tailored management strategy. In this review, the authors try to highlight new evidence on the optimal timing, benefits, and risks of immunosuppressants alone, or in combination, in patients with Crohn's disease.

INTRODUCTION

Inflammatory bowel disease (IBD) is a multifactorial disease with probable genetic heterogeneity^[1]. In addition, several environmental risk factors (e.g., diet, smoking, measles or appendectomy) may contribute to its pathogenesis. During the past several decades, the incidence pattern of both forms of disease, Crohn's disease (CD) and ulcerative colitis, has changed significantly^[2], showing some common characteristics yet also quite distinct features between the two disorders.

The phenotypic classification of CD plays an important role in determining the treatment, and may assist in predicting the likely clinical course of disease. In 2005, the Montreal revision of the Vienna classification system was introduced^[3]. Using the Vienna classification system, it has been shown in clinic-based cohorts that there can be a significant change in disease behavior over time, whereas disease location remains relatively constant^[4]. Population-based studies have demonstrated that up to one-third of the patients had evidence of a stricturing or penetrating intestinal complication at diagnosis, and half of all patients experienced an intestinal complication within 20 years after diagnosis^[4,5]. Similarly, these complications occurred in more than 50% of children, after a median follow-up of 84 mo^[6]. Half of the adult patients required surgery within 10 years after diagnosis, while in children, 34% of patients required surgery within 5 years of diagnosis. The risk of postoperative recurrence was approximately 44%-55% after 10 years. These data suggest that Crohn's disease is a chronic progressive disease,

where effective intervention prior to the onset of bowel damage (stricture, fistula, abscess) is required in order to improve the outcome. Of note, however, not all patients with CD will show disease progression. Thus, recognizing patients at the highest risk of developing a disabling disease or complications at an early stage is crucial. In CD cohorts from referral centers, an initial need for steroids, an age below 40 years, the presence of perianal or stricturing disease and a significant weight loss were associated with the development of disabling disease^[7,8].

A systematic review published in 2004, which analyzed population-based studies in CD with a complete follow-up, failed to demonstrate a significant improvement in disease outcome during the past four decades^[9]. Of note, disease activity, occurrence of complications, and need for surgery did not significantly change during that period. For example, time to intestinal surgery did not change despite the more frequent use of immunosuppressants in CD patients from the end of the 1990s^[10]. According to the authors' conclusion, the timing of immunosuppressants use might have been inappropriate. Nevertheless, data support that azathioprine (AZA) allows not only for the maintenance of remission and weaning off steroids in approximately two-thirds of patients with steroid-dependent CD, but may lead to complete or near-complete mucosal healing and histological remission in a significant proportion of CD patients^[11].

More recently, Peyrin-Biroulet *et al.*^[12] published a systematic review on the natural history of CD in population-based cohorts. The authors conclude that the impact of changing treatment paradigms with the increasing use of immunosuppressants and biological agents on the natural history of CD is poorly understood. To investigate this question, two approaches may be appropriate; (1) to conduct a disease-modification trial using the newly proposed definition of "early Crohn's disease"^[13]; (2) to investigate the evolution of the disease phenotype and complications in population-based cohorts with unified patient management. The limitation of the first approach is that only the relatively short-term outcomes (e.g., clinical remission, endoscopic healing, short-term risk of hospitalization and/or surgery) can be investigated with adequate statistical power. In contrast, in the second setting, the follow-up is complete in every patient; however, patient management is more individualized and variable.

Treatment paradigms have been evolving in the last two decades, with the inclusion of biological therapy. In the last several years, numerous studies focusing on the optimal use of traditional immunosuppressants and biological therapy have been published. In addition, much emphasis has been placed in recent years on the determination of important predictive factors to identify patients at risk for disease progression as soon as possible, in order to enable a tailored management strategy^[14]. In this review, the authors try to highlight some of the new, available evidence on the benefits, timing, and risks of immunosuppressants alone, or in combination, in pa-

tients with CD.

NEW DATA AND NEW STRATEGIES ON THE USE OF THIOPURINE ANALOGUES: ALONE OR IN COMBINATION?

Efficacy of conventional immunosuppressants

In CD, the efficacy of immunosuppressive therapy with purine analogues has been established in controlled trials, which assessed the role of AZA/6-mercaptopurine (6-MP), both as induction agents and as steroid-sparing agents in a withdrawal study^[15,16]. The study reported by Present *et al.*^[15] in 1980, was the first to demonstrate with certainty the efficacy of 6-MP in the induction of remission in CD. By using a dose of 1.5 mg/kg per day, 67% of patients responded to therapy as compared to only 8% of patients who received placebo. However, not all controlled trials report such a positive clinical response to thiopurines in the induction of disease remission in CD. The notion of the delayed onset of action of 6-MP also stems from the study by Present *et al.*^[15], which reported that the mean time to response was 3.1 mo, with 89% of responders doing so within 4 mo of initiating therapy. However, it should be noted that the first clinical evaluation in this study was not performed until the 12-wk mark. Thus, it is likely that a proportion of patients were already responding before the first assessment. It is important to note that if therapy is started relatively late in the disease course, when the anatomical damage is irreversible, these medications will not prevent the occurrence of complications. Until recently, immunosuppressants were introduced relatively late during the disease course, mainly in steroid-dependent/resistant or postoperative patients^[17]. Thiopurines were started in the majority of patients years after the diagnosis. Even so, in clinical cohorts, the efficacy of thiopurine therapy was defined as optimal in approximately 47% of the patients. Similar results were published by the Oxford clinic^[18], where the mean remission rate was 45% and the proportion of patients remaining in remission at one-, three-, and five-years was 95%, 69% and 55%, respectively. In general, it is recommended that thiopurines be added to the therapeutic regime in patients failing to wean off corticosteroids during their first attempt at tapering the dose or alternatively after a second attempt.

The most convincing data to support a benefit from early use of AZA, however, come from the pediatric literature^[19], where in a randomized controlled trial involving 55 children, the early use of 6-MP was associated with a significantly lower relapse rate (only 9%) compared with 47% in controls ($P = 0.007$). Moreover, the duration of steroid use was shorter ($P < 0.001$) and the cumulative steroid dose was lower at 6, 12 and 18 mo ($P < 0.01$). The benefit of an early aggressive treatment was also demonstrated in another pediatric study^[20], where 80.5% of children with newly diagnosed moderate-to-severe CD were treated with immunomodulators within

the first year. Early immunomodulator use was associated with reduced corticosteroid exposure and fewer hospitalizations per patient. Candy *et al*^[21] similarly showed that AZA offers a therapeutic advantage over placebo (47% *vs* 7% remission rate at 15 mo; $P < 0.001$) in the maintenance of remission in CD patients. Both studies showed no difference in the proportion of patients who had achieved remission at 12 wk, since corticosteroids served as the induction therapy for both groups. These results highlight the steroid-sparing benefits of thiopurines and suggest that the short-term use of corticosteroids for the induction of remission can serve as a bridge to the more long-term maintenance of a steroid-free remission with thiopurines.

The benefit of thiopurines was also demonstrated in cohort studies. In the pediatric setting, since the year 2000, the more systematic introduction of AZA at the time of diagnosis led to a 2-fold longer first remission period^[22]. Similarly, the long-term beneficial effect of early AZA treatment was demonstrated in an adult referral cohort study from Hungary, where early AZA treatment was independently associated with a decreased risk for disease behavior change and resective surgery. It also prevented the deleterious effects of smoking^[23,24]. Similarly, a lower risk of surgery (HR: 0.41; 95% CI: 0.21-0.81) in non-penetrating non-stricturing CD patients with an immunomodulator use lasting more than 6 mo was also reported from the United States^[25]. An important clinical question is of course, patient adherence to treatment. A wide range of non-adherence was reported in Germany, for patients taking AZA and in long-term remission, ranging from 7.1% to 74.3%^[26]. Limited data are available with regards to factors predicting effectiveness and failure of long-term thiopurine use in IBD patients. There is evidence to suggest that 6-methylmercaptopurine (6-MMP) concentration and the 6-MMP/6-thioguanine nucleotides (6-TGN) ratio may be associated with therapeutic failure^[27]. In patients with suboptimal response on AZA and high 6-MMP levels, the addition of allopurinol was effective and safe in optimizing 6-TGN production, leading to improved disease activity scores, reduced corticosteroid requirements, and normalization of liver enzymes, but careful monitoring for adverse effects and profiling of thiopurine metabolites is essential^[28].

The efficacy of thiopurine analogues for the induction of maintenance was also proven in recent reviews by the COCHRANE group^[29,30]. The odds ratio (OR) of a response to AZA or 6-MP therapy compared with placebo in active CD was 2.43 (95% CI: 1.62-3.64), 54% in AZA-treated patients and 34% in the placebo arms. This corresponded with a number needed to treat (NNT) equaling about five. When the two trials using 6-MP in active disease were excluded from the analysis, the OR was 2.06 (95% CI: 1.25-3.39). Treatment for longer than 17 wk resulted in an OR of 2.61 (95% CI: 1.69-4.03); however, a significant benefit was not observed for a shorter treatment period. A steroid-sparing effect was seen with an OR of 3.69 (95% CI: 2.12-6.42),

corresponding to a NNT of about three, in order to observe steroid-sparing in one patient. Similarly, AZA was effective in maintaining remission in the seven trials with AZA and one with 6-MP. AZA and 6-MP had a positive effect on maintaining remission (OR: 2.32; 95% CI: 1.55-3.49) with a NNT of six. The OR for the maintenance of remission with 6-MP was 3.32 (95% CI: 1.40-7.87) with a NNT of four. Higher doses of AZA improved response (AZA 1 mg/kg, OR: 1.20; 2 mg/kg, OR: 3.01; 2.5 mg/kg, OR: 4.13). A steroid-sparing effect with AZA was noted, with an OR of 5.22 (95% CI: 1.06-25.68) and a NNT of three. The Cochrane analysis reported a response rate of 55% with thiopurine therapy *vs* 29% for placebo, a pooled OR of 4.58 (95% CI: 0.49-42.82) also favored fistula healing. It should be noted that there was only a small number of patients evaluable for this analysis, and with the confidence interval crossing 1 this result is statistically insignificant.

In clinical practice, it is still uncertain if and when immunosuppressive therapy should be interrupted in patients in long-term (4-6 years) remission on thiopurines. In a recent withdrawal study by the GETAID group^[31], the authors have provided evidence for the benefit of long-term AZA therapy beyond 5 years in patients with prolonged clinical remission. The cumulative probabilities of relapse at 1, 3, and 5 years were 14.0%, 52.8%, and 62.7%, respectively. A C-reactive protein (CRP) concentration of 20 mg/L or greater (risk: 58.6), a hemoglobin level of less than 12 g/dL (risk: 4.8), and a neutrophil count 4×10^9 /L or greater (risk, 3.2) were independently associated with an increased risk of relapse. Among the 32 relapsing patients, 23 were retreated by AZA alone, with all but one leading to a successful remission.

Finally, in adults, a recently published clinical strategy trial from Belgium and the Netherlands^[32] randomized 133 patients with active CD, naïve to both steroids and AZA, to either a conventional step-up strategy [with full courses of steroids (prednisolone or budesonide) and introduction of AZA when the patients experienced a flare-up after tapering off or became dependent on steroids] or top-down (infliximab induction therapy and AZA at the first presentation). From week 6, AZA was continued as monotherapy, thus, a long-term combination was not administered. Up to the one-year mark after the initiation of therapy, steroid-free remission was more frequent in the early combined immunosuppressive group (61.5% *vs* 42.2%, difference: 19.4%, 95% CI: 2.4-36.3, $P < 0.05$). The median time to relapse was also longer in the early combined immunosuppressive - the "top-down" group [329.0 d, interquartile range (IQR) 91.0-∞ *vs* 174.5 d, IQR 78.5-274.0, $P < 0.03$]. In contrast, the difference was not significant after 52 wk. This open-label trial was liable to the intrinsic observer bias. Furthermore, patients in the conventional group had to fail two courses of steroids before the start of the immunosuppressant, which added a delay of appropriate treatment in at least one-third of the patients. None-

theless, a significant difference was found concerning complete ulcer healing during endoscopy, with 73.1% of evaluated patients (19/26) in the early combined immunosuppressants group *vs* 30.4% (7/23) in the controls, in a subgroup of patients who underwent ileocolonoscopy at week 104. In addition, the majority of patients (15/17) with mucosal healing in the early combined immunosuppressive group, after two years of therapy, remained in remission off steroids and did not need further infliximab (IFX) therapy in the subsequent two years of follow-up^[33]. The authors concluded that CD can be effectively treated without steroids, if patients are offered an early combined therapy of immunosuppressants. An interesting secondary result of the study was that approximately 10%-20% of patients required IFX after the induction period.

Current use of thiopurines and anti-TNF blockers: Alone or in combination?

There is no consensus on the appropriateness of concomitant immunomodulators with anti-tumor necrosis factor (anti-TNF) therapy for CD. Some patients benefit from concomitant immunomodulators, but there are increasing concerns related to infections and the risk of lymphoma. Until recently, anti-TNF antibodies have usually been initiated as second or third line immunosuppressants in patients failing or dependent on steroids and/or AZA. In 2003, immunosuppressants were shown to inhibit the development of neutralizing anti-infliximab antibodies, when this drug was used in an episodic, on-flare strategy^[34]. Moreover, IFX serum levels were also significantly higher in patients with concomitant immunosuppressive therapy^[35]. Therefore, theoretically, combined therapy may have synergistic immunosuppressive effects resulting in increased efficacy, but it may also increase the long-term toxicity. However, in randomized controlled trials (discussed previously in detail) in CD patients with long disease duration, often after multiple surgical interventions, a synergistic effect was not observed. Concomitant immunosuppressive and/or steroid therapy was not more efficacious compared to the anti-TNF agent alone in patients on scheduled maintenance therapy^[36]. Thirty to seventy percent of patients in these trials received either of the drugs. In PRECISE 1, for example, 23% of patients on certolizumab with concomitant immunosuppressants *vs* 23% without immunosuppressants, showed a drop of more than 100 points at weeks 6 and 26 in the Crohn's disease activity index (CDAI). The numbers were identical for patients with and without concomitant steroid therapy^[37]. Similarly, in PRECISE 2, at week 26, 61% of patients receiving concomitant immunosuppressive agent and 64% without demonstrated a clinical response. A similar tendency was also reported for adalimumab in CHARM. Clinical remission rates with or without concomitant immunosuppression were not significantly different either at week 26 or 52 [37% *vs* 33% for adalimumab every other week (EOW) and 39% *vs* 50% for adalimumab every

week (EW)]. In addition, similar to certolizumab, the clinical efficacy was significantly different based on the disease duration. This tendency was also similar for IFX in the ACCENT I and II trials, although the rate of infusion reactions was lower (12.5%) in patients receiving concomitant immunosuppression compared to those without (22.0%), and the rate of formation of antibodies was higher^[37]. In contrast, reported IFX concentrations were not different over time. Although significance was not reported, in ACCENT I, the clinical response and remission rate in the 5 mg/kg group was reported as 54% and 38%, respectively, in patients with an immunosuppressant, and was 34% and 26% without immunosuppressant therapy.

Additionally, a recent, prospective, open-label study demonstrated that withdrawing immunosuppressants in patients with CD on a combined maintenance schedule of IFX and immunosuppressive therapy for at least six months did not affect efficacy over two years of follow-up, but tended to decrease IFX trough levels and CRP elevation^[38]. This indicates that the impact of withdrawing antimetabolites in patients treated with biologicals has no, or only limited, risk of loss of efficacy, although the impact on IFX trough levels warrants further long-term follow-up. Noteworthy, however, is that most patients had been failing AZA therapy before having entered the trial. As a final point, in a recent large Belgian cohort study^[39], concomitant AZA or methotrexate (MTX) therapy did not influence the outcome of IFX treatment during a median follow-up of five years. Importantly, 49.7% of patients were on AZA and 9.4% on MTX at the time of anti-TNF induction therapy. 34.1% of those on AZA at baseline stopped its use after a median of 15 mo; however, in 41.3% of these patients MTX was started later during the follow-up, based on the clinical indication. Moreover, 26% of the patients needed one intervention (increasing the dose to 10 mg/kg or decreasing the interval) during IFX maintenance therapy, while 10% and 14% needed two or three modifications, respectively. Therefore, the results should be interpreted with caution, since an alternative conclusion might be that patients with more aggressive disease course were able to maintain similar clinical benefit with a combination therapy and/or modifications in the dose or interval of the biological therapy.

More recently, however, anti-TNF agents have been used earlier in the disease course, including in patients naïve to AZA. The first piece of evidence arises from the pediatric literature^[40]. In 112 children with moderate-to-severe disease, IFX induction and scheduled maintenance therapy, every 8 wk, in the REACH study was associated with 63.5% and 55.8% clinical response and clinical remission rates, respectively. All patients were required to have started concomitant immunomodulators (AZA, 6-MP or MTX) at least 8 wk prior to study entry and approximately one third of the patients were also simultaneously receiving steroids. The average disease duration was as low as two years. Although the defini-

tion of remission was different (instead of CDAI, the pediatric index, PCDAI, was used) and disease duration was short, these were among the highest remission rates reported for anti-TNF agents.

In adult CD patients with early disease (< 2 years) naïve to purine analogues and MTX, the outcome was similar to that found in the pediatric population. The large, blinded, double-dummy, controlled SONIC trial compared AZA monotherapy (2.5 mg/kg per day), IFX monotherapy, and combined IFX and AZA therapy^[41]. The average disease duration was 2.3 years (range 0-43 years). At 26 wk, the steroid-free remission rates in patients receiving combined immunosuppressive therapy with IFX and AZA were higher than with IFX monotherapy (56.8% *vs* 44.4%, $P < 0.05$). In turn, these were also higher than remission rates in patients receiving AZA monotherapy (30.0%, $P < 0.01$). A course of steroids was allowed in all patients until week 12, to compensate for the slow onset of the therapeutic effect of AZA. The proportion of patients receiving systemic steroids at baseline in combination with AZA, IFX or in the combination group was similar ($n = 40, 52$ and 47 patients, respectively); however, the dose used was below that recommended for induction therapy (mean dose of 24 mg/d). It is even more difficult to explain the large difference in clinical remission off steroids at week 26, since the number of patients receiving steroids at this time point ($n = 60, 60$ and 58 , respectively) and the mean dose were virtually identical (range: 9.4-11.6 mg/d) in all three groups. Therefore, the lower clinical efficacy is not reflected by differences in steroid use. Moreover, steroids should have been tapered off by week 12, where possible. As a consequence, the end result in at least one-third of the patients reflects an insufficient steroid induction therapy in combination with either AZA, IFX or the combination of the two drugs. Nevertheless, the total disappearance of mucosal ulcers was also higher in the combined IFX-AZA group (43.9% IFX and AZA *vs* 16.5% AZA, $P < 0.001$). Nonetheless, a significant bias cannot be excluded, since patients with lesions at baseline who did not undergo endoscopy at week 26, or who had results that could not be evaluated were assumed to have a lesion. These patients numbered 50 of 109 (45.9%) in the AZA group, 29 of 93 (31.2%) in the IFX group, and 31 of 107 (29.0%) in the combination-therapy group. In addition, it is difficult to interpret the data since a significant proportion of the patients had negative ileocolonoscopy at inclusion.

At week 50, assuming that patients not entering the study extension would not be in a steroid-free remission, the overall proportion of patients in steroid-free remission was 46.2% with the IFX-AZA combination, 34.9% under IFX monotherapy, and 24.1% with AZA monotherapy ($P < 0.03$). To select patients with objective signs of inflammation (an elevated C-reactive protein and/or active disease at endoscopy) seems to be important, since in a subgroup analysis, benefit from more aggressive combination therapy was restricted to patients with

objective signs of active inflammation.

Whether these results would affect the management of non-immunosuppressive-naïve patients remains debated. Of note, in a very recent cohort study by Sokol *et al*^[42] IBD flare-ups, perianal complications, and a switch to adalimumab were less frequently observed in patient-semester with combined immunosuppressant and biological use than in those without immunosuppressives (19.3% *vs* 32.0%, $P = 0.003$; 4.1% *vs* 11.8%, $P = 0.03$; 1.1% *vs* 5.3%, $P = 0.006$). Maximal C-reactive protein (CRP) level and IFX dose/kg observed during the semesters were lower in semesters with immunosuppressives. In a multivariate analysis, immunosuppressive co-treatment was associated with a decreased risk of disease flare-up (OR: 0.52; 95% CI: 0.35-0.79). Moreover, the effectiveness of co-treatment with immunosuppressants was time-independent.

POSTOPERATIVE MANAGEMENT: IMMUNOSUPPRESSANTS OR MORE?

Early postoperative use of AZA at a dose of 2-2.5 mg/kg per day) seemed to delay endoscopic postoperative recurrence in comparison to historical series or placebo groups in randomized controlled trials^[43]. Furthermore, in a recent controlled, randomized, prospective trial, AZA administered for 12 mo together with metronidazole for 3 mo was more effective in preventing endoscopic postoperative recurrence assessed at 12 mo, compared to metronidazole alone in patients previously only minimally exposed to AZA^[44]. In a meta-analysis, Peyrin-Biroulet *et al*^[45] have shown that purine analogues were more effective than control arms in preventing clinical recurrence at 1 year (mean difference: 8%, NNT = 13 and 2 years, respectively (mean difference: 13%, NNT = 8)). The efficacy of purine analogues was also superior to that of placebo for the prevention of clinical and endoscopic recurrence at 1- and 2-years (mean differences: 13%, NNT = 7, and 23%, NNT = 4), respectively. At 1-year, purine analogues were more effective than control arms in preventing severe (≥2-4) endoscopic recurrence (mean difference: 15%, NNT = 7); however, the rate of adverse events leading to drug withdrawal was higher in thiopurine-treated patients.

In a more recent study from Austria,^[46] the authors evaluated the impact of thiopurine treatment on surgical recurrence in patients after the first intestinal resection for CD. In a Cox regression analysis, treatment with thiopurines for no more than 36 mo (HR: 0.41; 95% CI: 0.23-0.76, $P = 0.004$) and smoking (HR: 1.6; 95% CI: 1.14-2.4, $P = 0.008$) were identified as independent predictors for surgical recurrence. In addition, a multicenter study led by Reinisch *et al*^[47] investigated the efficacy of AZA therapy for the prevention of clinical relapse in patients with endoscopic recurrence (≥2-4, but CDAI < 200). Treatment failure-defined as a CDAI score > 200 and an increase of > 60 points from baseline, or study drug discontinuation due to lack of efficacy or intolerable adverse drug reaction-occurred in 22.0% (9/41) of

AZA-treated patients and 10.8% (4/37) of mesalazine-treated patients. The difference was mainly due to the discontinuation of AZA and the adverse drug reactions that only occurred in AZA-treated patients [9/41 (22.0%) *vs* 0%, $P = 0.002$]. In contrast, clinical recurrence was significantly less frequent in patient treated with AZA *versus* mesalazine [0/41 (0%) *vs* 4/37 (10.8%), $P = 0.031$]. Hence, the efficacy of AZA, while clearly established, must be balanced against its side-effect profile, resulting in a high rate of discontinuation. Finally, preliminary data support biological therapy as a possible therapeutic option, at least in selected patient populations^[48].

ADVERSE EVENTS

6-Mercaptopurine (predominantly used as a chemotherapeutic agent) and its pro-drug, AZA (an immune modifier agent), are purine analogues that competitively interfere with nucleic acid metabolism by acting as substrate competitive antagonists for the hypoxanthine-guanine phosphoribosyl transferase enzyme (anti-metabolite activity)^[49]. Consequently, both drugs reduce cell proliferation and have immune-modifier properties. Adverse events are frequent and lead to cessation of therapy in 9% to 25% of patients^[50]. Adverse events associated with AZA and 6-MP include nausea, allergic reactions, flu-like illness, malaise, fevers, rash, abdominal pain, pancreatitis, hepatotoxicity, myelosuppression, and an increased risk of lymphoma^[51]. Classically, AZA-related adverse events have been categorized into two types: allergic, idiosyncratic or non-dose-dependent and dose-dependent.

Advances in the understanding of AZA and 6-MP drug metabolism have led to genetic and metabolite tests that help clinicians optimize the use of these drugs. A deficiency of the thiopurine methyltransferase (TPMT) enzyme appears to account for some dose- and metabolism-dependent toxicities, such as leukopenia (and possible subsequent infection), thrombocytopenia, and malignancy. TPMT exerts these side effects by limiting the production of 6-TGNs by converting 6-MP to 6-thiouric acid and 6-MMP^[52], and major 6TGN accumulation may lead to profound, potentially life-threatening myelotoxicity. Population studies have shown that the distribution of TPMT activity is trimodal: 0.3%-0.5% of the population have low to absent activity (TPMTL/TPMTL), around 10% have intermediate activity (TPMTL/TPMTH), and approximately 90% inherit normal to high enzyme activity (TPMTH/TPMTH)^[52]. In this regard, a correlation between the TPMT genotype and enzyme activity has been proven. Approximately 5% of the white population carries one or more variant TPMT alleles, with more than ten variant alleles reported^[53]. The functional consequences of alleles *2, *2A, *3B and *3C, accounting together for more than 90% of mutant alleles, have been extensively characterized.

Nevertheless, it is clear that there are many other causes of myelotoxicity. This was accurately demon-

strated by Colombel *et al.*^[54], who found that only 27% of CD patients with myelosuppression had a documented low TPMT activity. Other confounding genetic and environmental factors include, for instance, the patient's age, renal function, AZA formulation, co-administration of mesalazine (a reversible TPMT inhibitor) and allopurinol (XO inhibitor). Thus, the determination of TPMT activity is not an exclusive test to rely on when predicting the risk of myelotoxicity. It may only be helpful in identifying a certain group of high-risk patients but as the negative predictive value is rather low, it is not beneficial in ruling out possible side effects. Also, as the prevalence of double carriage of variant TPMT alleles is as low as 1/300, continuous monitoring of red blood cell counts remains mandatory in clinical practice.

Other toxicities such as rash-fever-arthralgias (2.3%), pancreatitis (1.4%), hepatitis, nausea (1.4%), non-pancreatic abdominal pain, and diarrhea appear to be hypersensitivity reactions^[55]. Mercaptopurine may be tolerated in up to 60% of AZA-intolerant patients, and treatment should be considered, particularly if intolerance was due to hepatotoxicity, arthralgia, nausea, vomiting, flu-like illness or rash^[56,57]. A less well-known, and relatively rare, side-effect of AZA is nodular regenerative hyperplasia (NRH). In a recent French study^[58], the cumulative risk calculated was 0.5% at 5-years and 1.25% at 10-years in patients on a median AZA dose of 2 mg/kg per day.

According to a recent review by the Cochrane group, adverse events requiring withdrawal from an induction trial, principally allergy, leukopenia, pancreatitis, and nausea, were increased with active therapy with an odds ratio of 3.44 (95% CI: 1.52-7.77), and were observed in 9.3% of treated patients and in 2.3% of patients in the placebo arms^[50]. The NNT to observe one adverse event on AZA or 6-MP was 14.

In 2005, Kandiel *et al.*^[59] performed a meta-analysis utilizing data from six of these cohort studies. The authors were able to pool calculated standardized incidence ratios (SIR) from all studies. When data were pooled across all studies, there were 11 observed lymphomas compared to the expected 2.63 cases, resulting in an SIR of 4.18 (95% CI: 2.07-7.51). Due to significant variability in SIR estimates amongst the studies, sensitivity analyses were performed, where each study was excluded from the group and SIR was recalculated (SIR range: 3.49-5.21). The authors concluded that IBD patients on thiopurines seemed to have a 4-fold increased risk of lymphoma, but whether this risk was due to the medications themselves or the underlying disease severity has not yet been elucidated. Nevertheless, there may be a small but real risk of lymphoma. Interestingly, treatment with AZA or 6-MP appeared to be associated with a small increased risk of Epstein-Barr virus (EBV)-positive lymphoma^[60]. Of note, EBV is a hallmark of lymphomas and lymphoproliferative disorders that arise in patients on immunosuppressive agents, which are used to limit rejection of bone marrow or solid organ transplants [post-transplant lymphoproliferative dis-

Table 1 Current status of thiopurine analogues in the treatment in Crohn's disease: Take home messages

Based on recent data, the determination of TPMT activity may be helpful in identifying high-risk patients for developing major complications, especially myelosuppression. In contrast, the negative predictive value is rather low, and it is not beneficial in ruling out the possibility of a side effect. Similarly, there is no established rationale to use TPMT activity for adjusting the dose of azathioprine to enhance therapeutic efficacy. For general practice, regular, frequent monitoring of clinical symptoms and laboratory check-ups continue to be recommended</p> <p>Combination therapy with infliximab-azathioprine may have an added benefit in inducing steroid-free remission and mucosal healing compared to either infliximab or azathioprine alone, in azathioprine-naïve patients with early onset of disease</p> <p>At present, the risks and benefits of combination therapy should be assessed on a per-case basis and should be discussed with the patient in the everyday clinical practice</p>

order (PTLD)]. More recently, the CESAME group^[61] confirmed the above findings, through a study involving 19 486 IBD patients. The incidence rate of lymphoproliferative disorders were 0.90 per 1000 (95% CI: 0.50-1.49) patient-years in those receiving thiopurines, 0.20/1000 (95% CI: 0.02-0.72) patient-years in those who had discontinued therapy, and 0.26/1000 (95% CI: 0.10-0.57) patient-years in those who had never received thiopurines ($P = 0.0054$). The multivariate-adjusted hazard ratio of lymphoproliferative disorder between patients receiving thiopurines and those who had never received the drugs was 5.28 (95% CI: 2.01-13.9, $P = 0.0007$). Most cases associated with thiopurine exposure matched the pathological range of post-transplant disease. Importantly, there was a significant imbalance amongst the forms of disease, since 76% of patients on thiopurine therapy were CD patients *versus* only 48% of patients who never received immunosuppression. Moreover, anti-TNF therapy was also not included in the multivariate analysis, which introduced a significant bias, since there was a 7795 patient-year exposure to anti-TNF therapy and the SIR was significantly increased in patients who had received but discontinued anti-TNF therapy (SIR: 6.92) and exponentially increased in patients on combination therapy (SIR: 10.2).

Whether combined AZA/6-MP and anti-TNF therapy increases toxicity in the long-term, is still debated, but recent studies of 17 hepatosplenic T-cell lymphomas in young male patients with combined therapy have raised considerable concerns^[62]. Unfortunately, most cases were fatal. More data are needed but, in selected patients, particularly those previously exposed to purine analogues or AZA, and scheduled, long-term, maintenance monotherapy with anti-TNF antibodies is certainly a valid option. In contrast, the risk of infections was not higher during combined AZA/6-MP and anti-TNF therapy (OR: 1.6; 95% CI: 0.1-19)^[63]. In a case-control study from the Mayo Clinic, the use of steroids, AZA/6-MP was associated with a 2.2-3.4-fold elevated risk, but the risk was infinite if all three drugs were used.

CONCLUSION

In patients with Crohn's disease, treatment paradigms have been evolving in the last decades, with biological therapy becoming available. In Crohn's disease, the efficacy of immunosuppressive therapy with purine analogues is well established in controlled trials, both as induction agents and as steroid-sparing agents, showing efficacy also in the postoperative setting. In the past several years, numerous studies focusing on the optimal use of both, traditional immunosuppressants and biological therapy, investigating the conventional, accelerated step-up, and top-down approaches, have been published. Emerging new data indicate that earlier use of immunosuppressants is more effective in maintaining remission, reducing further corticosteroid exposure, and decreasing the risk of hospitalization and surgery. However, adverse events are frequent and lead to cessation of therapy in 9% to 25% of patients. Consequently, the benefit of azathioprine, while clearly established, must be balanced against its side-effect profile resulting in a high rate of discontinuation (Table 1).

Additionally, combination therapy with infliximab-azathioprine may have an added benefit in inducing steroid-free remission and mucosal healing compared to either infliximab or azathioprine alone, in azathioprine-naïve patients with early onset of disease. The added benefit of a biological-thiopurine combination is less well-established in non-azathioprine-naïve patients. Long-term combination, however, may potentially be associated with an increased risk for infection and malignancy. In recent years, several important studies on the safety of immunosuppressants, including anti-tumor necrosis factor agents, have been published and the cumulative body of evidence suggests that combined immunosuppressive therapy in patients with inflammatory bowel disease increases toxicity. At present, the risks and benefits of combination therapy should be assessed on a per-case basis and should be discussed with the patient in the everyday clinical practice. Moreover, much emphasis should be placed on defining the important predic-

tive factors in order to enable early patient stratification, thus leading to a tailored management strategy. Certainly, more research is needed in the area, since the impact of changing treatment paradigms with the increasing use of immunosuppressants and biological agents on the natural history is poorly understood. In the future, choosing among treatment paradigms, whether traditional immunosuppressants, biological or a combination in inflammatory bowel diseases may become highly dependent on the individual patient risk profile, the drugs already tried, and disease severity.

Abstract

Although in the past two decades, laparoscopic surgery, considered as a great revolution in the minimally invasive surgery field, has undergone major development worldwide, another dramatic surgical revolution has quietly appeared in recent years. Ever since Kalloo's first report on transgastric peritoneoscopy in a porcine model in 2004, interest in a new surgical procedure named natural orifice transluminal endoscopic surgery (NOTES) has blossomed worldwide. Considering that a NOTES procedure could theoretically avoid any abdominal incision, operation-related pain and scarring, many surgeons and endoscopists have been enthusiastic in their study of this new technique. In recent years, several NOTES studies have been carried out on porcine models and even on humans, including transvaginal cholecystectomy, transgastric appendectomy, transvaginal appendectomy, and transvesical peritoneoscopy. So what is the current situation of NOTES and how many challenges do we still face? This review discusses the current research progress in NOTES.

INTRODUCTION

Since the first laparoscopic cholecystectomy was conducted by Mouret in 1987^[1], conventional surgery using laparotomy has been largely replaced in the two ensuing decades by laparoscopic surgery, due to its lower level of trauma and faster recovery. Currently, laparoscopic cholecystectomy has become a classical approach and laparoscopic surgery has become the standard treatment for many gastrointestinal conditions. Based on the minimally invasive surgery, a novel approach to the endoluminal endoscopic surgery named the natural orifice transluminal endoscopic surgery (NOTES) is currently emerging because it has the advantage of avoiding surface incision. This advantage could help reduce surgical pain, decrease anesthesia and analgesia, shorten recovery time, avoid hernia formation and adhesions, and eliminate any surgical site infection and visible scarring. Ever since Kalloo's first report on transgastric peritoneoscopy in a porcine model in 2004^[2], this dramatic surgical revolution has triggered many surgeons and endoscopists to study this new technique. This complex technique involves breaching the wall of the stomach, colon, vagina or bladder by endoscopic means to gain access into the peritoneum to perform the novel endoscopic therapy. In recent

years, several NOTES experiments have been carried out on porcine models and even on humans, including transvaginal cholecystectomy, transgastric appendectomy, transvaginal appendectomy and transvesical peritoneoscopy. In response to the clinical potential of NOTES, in 2005, a working group, named the Natural Orifice Surgery Consortium for Assessment and Research, composed of Society of American Gastrointestinal and Endoscopic Surgeons and American Society for Gastrointestinal Endoscopy was established. This working group generated a white paper that encouraged future NOTES research and outlined key research areas that needed to be addressed^[3].

NOTES PROCEDURES

NOTES procedures are frequently performed with existing endoscopic techniques and a number of accessories, such as snares, endoscopic biopsy forceps, endoscopic grasping forceps, endoloops and endoscopic clips^[4]. An endoscope may be introduced through a natural external orifice such as the mouth, anus, vagina or urethra to visualize various cavities, or through incisions and sutures to create internal orifices for entry into the free peritoneal cavity and access different viscera^[5].

Transesophageal route

This is probably used for transesophageal intracardiac and mediastinal procedures, including biopsies. Considering the high difficulty for thoracic NOTES technique nowadays, few surgeons and endoscopists have such experiences, with the notable exceptions of Fritscher-Ravens *et al*^[6], who accessed the heart under endoscopic ultrasound (EUS) guidance through the transesophageal route, and von Delius *et al*^[7], who reported transesophageal NOTES mediastinoscopy in eight porcine models.

Transgastric route

To date, most of the published clinical cases report experience with the transgastric approach. The anterior wall of the stomach is usually the ideal incision site for access to the peritoneal cavity^[8], while the posterior wall may be selected to explore the retroperitoneum. After sterilization, a double-channel endoscope enters the stomach through a sterile overtube, and then an endoscopic needle knife is used to create a 2-4 mm incision with electrocautery. A dilation balloon is advanced over a catheter, and the incision is radially dilated to ensure free access of the endoscope to the peritoneal cavity^[4]. Previously, a wide range of NOTES procedures of various complexity were carried out on experimental porcine models, such as peritoneoscopy^[9,10], lymphadenectomy^[11], tubal ligation^[12], oophorectomy^[13], cholecystectomy^[14], cholecystogastrostomy^[15], gastrojejunostomy^[16], distal pancreatectomy^[17], and splenectomy^[18]. Lee *et al*^[19] have successfully performed transgastric endoscopic cecectomy with laparoscopic assistance on three canine models. The first transgastric appendectomies in humans were performed

by Rao and Reddy in India in 2004 (unpublished results). In 2008, Marescaux *et al*^[20] reported the first human case of NOTES cholecystectomy. Also in 2008, Rao *et al*^[21] reported transgastric appendectomy, tubal ligation and liver biopsy in patients. Besides, Horgan *et al*^[22] have successfully carried out transgastric appendectomy in a 42-year-old man and Wang *et al*^[23] have reported transgastric liver cyst fenestration.

Transgastric bariatric NOTES is another promising application for the treatment of obesity. To date, several successful experimental endoscopic interventions for obesity have been reported, such as endoscopically delivering duodenal-jejunal bypass sleeves^[24,25], using the TOGA System, a set of transoral endoscopically guided staplers that are being used to create a stapled restrictive pouch along the lesser curve of the stomach^[26,27], and endoscopically injecting botulinum toxin-A^[28]. However, rigorous testing of the standard transgastric bariatric NOTES techniques is still lacking.

Transcolonic route

Although transcolonic NOTES has been a rarely explored approach to the peritoneal cavity because of concerns related to fecal contamination and intra-abdominal infectious complications^[29], a few surgeons and endoscopists still perform transcolonic cholecystectomy and transcolonic appendectomy^[30,31]. Bazzi *et al*^[32] have successfully performed hybrid transrectal NOTES nephrectomy in three porcine models.

Transvaginal route

Currently, transvaginal access is the preferred approach in humans because this route obviates the risk of intestinal content leakage *via* an imperfectly closed access site^[29]. The first transvaginal cholecystectomy in humans was carried out by Marescaux *et al*^[20] in 2007. In 2009, Horgan *et al*^[22] reported a series of successful transvaginal cholecystectomies in nine patients and one transvaginal appendectomy in a 24-year-old woman. Tarantino *et al*^[33] have reported a study which aimed to evaluate the feasibility and safety of transvaginal rigid-hybrid NOTES anterior resection in 40 patients with symptomatic diverticular disease, and the results were satisfactory. Suzuki *et al*^[34] have found that transvaginal cholecystectomy resulted in cardiopulmonary stability and well-preserved immune function similar to those in laparoscopic cholecystectomy in an experiment that involved 10 porcine models. Haber *et al*^[35] have reported that hybrid robotic transvaginal NOTES pyeloplasty, partial nephrectomy and radical nephrectomy were feasible and safe in a porcine model.

Transvesical route

Considered as another novel surgical route, transvesical peritoneoscopy was performed by Lima *et al*^[36] on a porcine model in 2006. In 2007, Gettman *et al*^[37] have reported transvesical peritoneoscopy in a 56-year-old man.

All of these routes have their own advantages in NOTES procedures. However, no one is perfect to date. Although

the transgastric route is regarded as the easiest way to get into the abdominal cavity, and initially, many NOTES experiments were done *via* the transgastric route, a drawback limiting the use of the transgastric route is the lack of a secure and reliable way to close the gastrotomy, which is an essential step in the procedure. The transcolonic route is similar to the transgastric route except that the former has an increased risk of contamination due to the fecal bacterial load^[38]. The benefits of transcolonic access include in-line endoscopic visualization and the ability to create and close the colotomy with existing transanal endoscopic microsurgery equipment^[29]. The transvesical route allows straight access to the upper abdominal organs such as the gallbladder, which is mechanically more advantageous than the transgastric approach. By far, the most clinical experience has been obtained with transvaginal access used as an accessory entry point to the peritoneal cavity during cholecystectomy. Data from several NOTES registries show that this access is associated with a low complication rate (3%-8%) and has a low technical threshold^[39,40]. Closure of the colpotomy can also be performed under direct vision using standard surgical techniques. However, this route is only suitable for female patients^[29,38]. The urinary tract is normally sterile, therefore, using the transvesical route can reduce infection risk. Anatomical relationships of the lower urinary tract to the peritoneum and retroperitoneum appear to be in the direct line of sight. Thus, all abdominal structures can theoretically be accessed. Closure of bladder access is simplified because catheterization alone promotes healing with considerably less risk of fistula formation and no risk of bowel leak^[37]. However, as the urethra is quite narrow and short, it is controversial to date whether it is possible to experience NOTES through the transvesical route, other than peritoneoscopy, and how surgical specimens can be taken out of the body through the narrow urethra.

CURRENT CHALLENGES OF NOTES

Although the potential benefits of NOTES such as no scarring, no pain and shorter hospitalization represent a new frontier of surgery, many technological challenges still exist. NOTES will not receive widespread adoption for clinical application until these problems are solved.

Surgical platform

The endoscopes that we use nowadays only offer small instrument and suction channels, which makes retraction and dissection of tissues difficult. Therefore, to develop a new platform that is larger, stronger and eventually articulated, instruments that can pass through large working channels are necessary. There are various operative platforms under investigation currently. Basically, all systems for performing NOTES-related procedures that are currently available can be classified into three different types^[41]: (1) mechanical platforms such as EndoSamurai (Olympus, Tokyo, Japan); Anubis (Karl Storz, Tuttlingen,

Germany); Direct Drive System (Boston Scientific, Natick, MA, United States) and Endosurgical Operating System (EOS, USGI Medical, San Clemente, CA, United States), which allows passage of additional larger-caliber endoscopic instruments, without possibility of triangulation^[42]; (2) computer-assisted platforms such as the master and slave transluminal endoscopic robot (University of Singapore) or da Vinci system (Intuitive Surgical, Sunnyvale, CA, United States); and (3) non-tethered systems such as mechanical or magnetic capsules. Cho *et al.*^[43] have successfully performed transgastric NOTES sigmoidectomy on a survival canine model with a custom-paired magnetic intraluminal device. Scott *et al.*^[44] have carried out complete transvaginal cholecystectomy using Magnetic Anchoring and Guidance System (MAGS) instruments on porcine models.

Pneumoperitoneum

Endoscopic insufflation may be used to maintain pneumoperitoneum, but this approach is more difficult to manage and measure than a standard laparoscopic port approach, which is specifically designed for intra-abdominal insufflation. A wider variation in pressure is observed than with laparoscopic insufflation^[45]. On the other hand, a laparoscopic port and insufflation system ensures that any excess insufflation is noted and quickly addressed. The port also allows passage of a single laparoscopic instrument into the abdomen. Horgan *et al.*^[22] have suggested that, until better instruments are developed, having one port available for use with well-developed minimally invasive instruments is important for safe natural orifice surgery at this stage. However, in 2010, von Delius *et al.*^[46] performed pressure-controlled endoscopic insufflation and found that CO₂ insufflation for NOTES showed minor advantages compared with insufflation with room air, regarding intra-abdominal visualization, but resulted in an increase in cardiac afterload.

Spatial orientation

Orientation can be a challenge for NOTES in the peritoneum, because the triangulation used by surgeons during laparoscopy is impossible. Some organs appear relatively easy to find, such as the uterus and ovaries, while others are somewhat surprisingly difficult to localize (gallbladder and spleen)^[3]. Some workers consider that the aid of EUS and miniprobes (MPs) can resolve this problem. Fritscher-Ravens *et al.*^[6] successfully accessed the heart under the guidance of EUS through transesophageal route in 2007. Varas Lorenzo *et al.*^[47] consider that EUS-guided pancreatic pseudocyst or abscess drainage represents a notable advance for NOTES, and in the future, distal pancreatectomy will probably require EUS support along the greater curvature of stomach to locate an entry point for distal pancreatic resection. MPs may also help in selecting an entry point. Fowler *et al.*^[48] have reported that their Queen's NOTES group has devised a novel method of orientation by using a magnetic device that passes within an endoscope channel allowing for 3D imaging of

the shape and orientation of the endoscope. Best *et al*^[49] have found that MAGS instrumentation for NOTES procedures did not cause tissue damage or adverse clinical outcomes in porcine abdominal walls. Fernández-Esparrach *et al*^[50] considered that it was helpful to use a CT-based image-registered navigation system to identify safe gastrointestinal access sites for NOTES and intra-peritoneal structures.

Triangulation of instruments

To date, in NOTES experience, when the target tissue is reached, retraction and dissection are virtually impossible due to the lack of the triangulation of endoscopic instruments, which can provide efficient grabbing and dissection capabilities. Dallemagne *et al*^[29] have reported some novel instruments that are currently under investigation. One prototype of operating endoscope is known as Anubis (Karl Storz). This unique four-way articulating flexible endoscope, with a built-in light and video source, has a 16-mm diameter insertion shaft with an 18-mm diameter distal articulating vertebrae section and distal head. The distal head incorporates two opposing, movable arms with 4.2-mm working channels. Another instrument named as Direct Drive System (Boston Scientific) is an ergonomic, table-mounted, operative platform providing five degrees of freedom to the tip of the instruments^[51]. MAGS, which provides a longer access port (50 cm) that provides easier deployment of instruments and suitable reach, more robust cauterizer with a longer, more rigid, pneumatically deployed tip with better reach and sufficient torque to allow blunt dissection, and a more versatile tissue retractor with bidirectional dual flexible graspers, which provides excellent cephalad fundus retraction and inferolateral infundibulum retraction^[44]. EndoSamurai (Olympus) also aims at providing triangulation of the instruments, using a different operating mode^[29]. NOTES instruments are still developing and few researchers have compared these various instruments.

Closure technique

Among the challenges of the NOTES technique, closure and suture techniques are thought to be critical in view of perforation and infection risks, especially for the transgastric and transcolonic routes. To date, several animal cases of microabscesses, peritonitis and death have been related to unsatisfactory closure of the transluminal access sites^[52]. Currently, clips are frequently used to close the defects, but these have proven to be inadequate. Ryou *et al*^[53] have compared several gastric closure methods including endoclips, surgical suturing and a suction-based suturing device. The investigators were disappointed that mucosal closure with endoclips resulted in significant air and fluid leakage *via* the line of the endoclips. Shabbir *et al*^[54] have compared gastrotomy closure with either hand-sewn, endoloop or endoclip techniques in 24 *ex vivo* porcine stomachs, and found that endoclips seem to be better for gastrotomy closure than endoloops because of their potential to endure relatively

higher pressure without any prolongation of application time. However, two leaks were still noted at the clip bite site. Meanwhile, other scholars have reported some positive experimental outcomes. McGee *et al*^[55] have demonstrated that the NDO Plicator, which is an endoscopic device designed to treat gastroesophageal reflux disease by reducing the inner diameter of the gastroesophageal junction, resulted in leak-proof gastric closure in a porcine model. Meireles *et al*^[56] have used an automated stapler (Surg ASSIST) for reliable closure of the gastrotomy incision in a live porcine model. Schoenberg *et al*^[57] have reported transgastric uterine horn ligations of porcine models with the specific absorbable NOTES loops, which are recommended for use during NOTES appendectomy. However, to date, a commercially available, simple, safe and effective endoscopic instrument for closing these puncture sites has not been created.

Perioperative complications

To date, the perioperative outcomes have been favorable in most reported studies. However, as closure technique is not mature enough, intraperitoneal infection remains a primary concern for NOTES. Yang *et al*^[58] have reported that 45 porcine models underwent transgastric or transvaginal NOTES peritoneoscopy and transumbilical laparoscopic cholecystectomy under NOTES view and found that, after antiseptic preparation such as gastric or vaginal lavage and antibiotic peritoneal irrigation, the bacterial load significantly decreased in the transgastric group, which seems as safe as the sterile transvaginal approach. von Delius *et al*^[7] consider that transesophageal NOTES mediastinoscopy carries a substantial risk of inadvertent development of pneumothorax after animal experiments. Biliary leaks have been reported in a NOTES study involving transvaginal cholecystectomy from Pugliese *et al*^[59], which were treated successfully by endoscopic drainage and stenting. The risk of infertility after transvaginal NOTES procedures is unknown, but Horgan *et al*^[22] have suggested that avoidance of bleeding and inflammation of the pelvis should minimize this potential risk.

NOTES AND LAPARO-ENDOSCOPIC SINGLE-SITE SURGERY

Closely related to NOTES, laparo-endoscopic single-site surgery (LESS) describes minimally access surgical procedures that are performed through a single incision/location^[60]. Rane *et al*^[61] published the first true LESS experience in abstract form in 2007, performing a transumbilical laparoscopic nephrectomy. As a result of the lack of ideal novel endoscopic instruments, NOTES experiences have been much more limited than LESS, and clinical experience with LESS has been more extensively reported^[62]. However, Raman *et al*^[63] have reported a retrospective case-controlled study comparing the outcomes of 11 LESS nephrectomies to 22 matched, conventional laparoscopic nephrectomies, which failed to demonstrate any significant improvement in analgesic use or conva-

lescence. To date, although few studies have focused on the comparison between NOTES and LESS, we still believe that NOTES, considered as the developing terminal minimally invasive surgery, must have a promising future.

CONCLUSION

After the familiar laparoscopic surgical techniques, NOTES has become the next worldwide focus of minimally invasive therapy. The novel surgical procedures, with fast recovery and without general anesthesia, visible scarring, postoperative hernia formation and adhesions, are attractive for most surgeons and endoscopists. Although the novel procedure is far away from being mature and many technical problems have to be overcome before its widespread application in clinical cases, NOTES is undoubtedly a promising procedure for the future. More clinical studies and creation of new NOTES-specific instruments will make NOTES a reality.

Abstract

AIM: To investigate the anti-tumor effects of *Paris chinensis* dioscin (PCD) and mechanisms regarding cell cycle regulation and apoptosis in human gastric cancer SGC-7901 cells.

METHODS: Cell viability was analyzed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide assay. Cell apoptosis was evaluated by flow cytometry and laser scanning confocal microscope (LSCM) using Annexin-V/propidium iodide (PI) staining, and the cell cycle was evaluated using PI staining with flow cytometry.

Intracellular calcium ions were detected under fluorescence microscope. The expression of cell cycle and apoptosis-related proteins cyclin B1, CDK1, cytochrome C and caspase-3 was measured by immunohistochemical staining.

RESULTS: PCD had an anti-proliferation effect on human gastric cancer SGC-7901 cells in a dose- and time-dependent manner. After treatment of SGC-7901 cells with PCD, apoptosis appeared in SGC-7901 cells. Morphological changes typical of apoptosis were also observed with LSCM by Annexin V/PI staining, and the cell number of the G0/G1 phase was decreased, while the number of cells in the G2/M phase was increased. Cell cycle-related proteins, such as cyclin B1 and CDK1, were all down-regulated, but caspase-3 and cytochrome C were up-regulated. Moreover, intracellular calcium accumulation occurred in PCD-treated cells.

CONCLUSION: G2/M phase arrest and apoptosis induced by PCD are associated with the inhibition of CDK-activating kinase activity and the activation of Ca²⁺-related mitochondrion pathway in SGC-7901 cells.

INTRODUCTION

Gastric cancer is the most common cause of death from cancer in China^[1,2]. Recent evidence suggests that cell apoptosis is closely related to the occurrence, progress and metastasis of tumors^[3-5]. The mechanisms of apoptosis in tumor cells is an important field of study for tumor treatment and molecular cancer biology^[6].

The progression of cells through the cell cycle is tightly controlled by the sequential activation and inactivation of a family of serine-threonine kinases known as the cyclin-dependent kinases (CDKs). In particular, CDK1 controls progression from the S phase through G2 and into the M phase. Similarly, progression from the G1 to S phase is controlled sequentially by CDK4/6 and CDK2. CDK activity is regulated by binding to cyclin partners and the action of endogenous inhibitory peptides^[7,8].

Loss of cell cycle control, leading to uncontrolled proliferation, is common in cancer. Therefore, the identification of potent and selective cyclin dependent kinase inhibitors is a priority for anti-cancer drug discovery.

Paris chinensis (Liliaceae) is distributed in many regions of the world, such as India, China, Vietnam, and Germany. As a traditional Chinese medicine, it grows wildly throughout South China and has been used mainly as a folk remedy for treatment of abscesses, throat swelling and pain, thanatophidia bites, contused wounds and convulsions^[9] for centuries. It is also the major component of the famous Chinese patent medicine *Yunnan Baiyao Powder* and snake-bite therapeutics. It also has been used to treat liver cancer in China for many decades^[10-12]. The active components of *Paris chinensis* are the saponin steroids polyphyllin D, dioscin, and balanitin 7. Among its three chemical constituents, polyphyllin D has been previously reported^[13-15] to circumvent drug resistance and elicit apoptosis in HepG2 and R-HepG2 cells *via* mitochondrial damage. However, as there has been no documentation of the use of the other important steroid saponin dioscin in the treatment of cancer, its mechanisms in human gastric cancer cells remain unknown.

Therefore, the aim of the present study was to evaluate the effects of *Paris chinensis* dioscin (PCD) on human gastric cancer SGC-7901 cells and the signaling pathways involved in PCD-induced apoptosis.

MATERIALS AND METHODS

Chemicals and reagents

PCD with a purity of 99% was purchased from Yuancheng Science and Technology Corporation (Wuhan, China). RPMI-1640 medium, 4-hydroxyethyl piperazine ethanesulfonic acid (HEPES), fetal calf serum and trypsin were purchased from Gibco BRL Life Technologies Inc. (Grand Island, New York, United States). 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), penicillin, streptomycin and trypsin were purchased from Amresco Chemical Co. Ltd. (United States). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) reagents were purchased from Sigma (St. Louis, United States). The fluorescent probe Fluo-3/AM is a prod-

uct of Molecular Probes Incorporated (United States). The Annexin V-fluorescein isothiocyanate (FITC) apoptosis detection kit was purchased from BD Biosciences (United States). The primary antibodies for cyclinB1, CDK1, caspase-3, cytochrome C and β -actin and the secondary antibody were acquired from Santa Cruz Biotechnology. Fetal bovine serum (FBS) was purchased from Hyclone (United States), and all chemicals were of analytical grade and were obtained from Tianjin Chemical Reagents Co. Ltd. (Tianjin, China).

Cell culture

SGC-7901 cells were obtained from the Chinese Type Culture Collection (Shanghai Institute of Cell Biology, Chinese Academy of Science, Shanghai, China). SGC-7901 cells were cultured in RPMI-1640 medium supplemented with 10% heat-inactivated FBS, penicillin (100 U/mL) and streptomycin (100 μ g/mL) at 37°C in a humidified atmosphere of 95% air and 5% CO₂; the medium was changed every other day. When the cultures were 80%-90% confluent, the SGC-7901 cells were washed with phosphate-buffered saline (PBS), detached with 0.25% trypsin, centrifuged and re-plated onto 96- or 24-well plates at an appropriate density according to each experimental scale.

Cell viability and cytotoxicity

The cultured cells at the exponential growth phase were harvested from the culture flasks by trypsin and then resuspended in fresh medium. The cell suspensions were dispensed into a 96-well microplate at 100 μ L/well and incubated in an incubator with 5% CO₂ at 37°C. After 24 h, 200 μ L of various concentrations (0-500 μ g/mL) of PCD were added and incubated for 12, 24, 36, 48, 60 and 72 h to evaluate their anti-proliferation effects on SGC-7901. The cell proliferation in the microplate was determined using the MTT assay^[16] after incubation. Twenty microliters of PBS solution containing 5 mg/mL MTT was added to each well. After incubation for 4 h, the cells from each well were solubilized with 100 μ L DMSO for optical density determination at 570 nm. Cell proliferation activity was expressed as the percentage of MTT counts of treated cells relative to those of the control (% of control). The IC₅₀ was taken as the concentration that caused 50% inhibition of cell viabilities and was calculated by the Logit method.

Observation of morphological changes

The SGC-7901 cells were seeded into six-well plates (2.0 \times 10⁵ cells/well) and incubated in RPMI-1640 at 37°C in an atmosphere of 5% CO₂ for 24 h. The cells were treated with several concentrations of PCD. After incubation for 24 h, cellular morphology was observed under a phase contrast microscope (Nikon, Japan). The photographs were taken at a magnification \times 40.

Cell cycle analysis

SGC-7901 cells (2 \times 10⁶ cells/mL) in 100-mm culture dishes were incubated with PCD for 24 h, then harvested by trypsinization and fixed with 90% ice-cold ethanol.

The fixed cells were incubated with a staining solution containing 0.2% NP-40, RNase A (30 µg/mL), and propidium iodide (PI) (50 µg/mL) in a phosphate-citrate buffer (pH 7.2). Cellular DNA content was analyzed by flow cytometry (BD FACS Calibur, United States). At least 10 000 cells were used for each analysis, and the results were displayed as histograms.

Flow cytometry and LSCM analysis of cell apoptosis

SGC-7901 cells were cultured in RPMI-1640 with 10% fetal bovine serum. Before the cell density was modulated to 1×10^5 cells, cell synchronization was conducted to force the cells to the G0 phase *via* a serum-free culture for 12 h, and the cells were washed twice with PBS before being suspended in a binding buffer (10 mmol/L HEPES pH 7.4, 140 mmol/L NaOH, and 2.5 mmol/L CaCl₂). Five microliters of fluorescein isothiocyanate (FITC)-labeled Annexin V was mixed with 100 µL cell suspensions containing 1×10^5 cells, and the cells were incubated at room temperature for 5 min. Thereafter, 50 µL PI solution (10 µg/mL) was added to the cells, followed by an additional 5-min incubation. The scatter parameters of the cells (20 000 cells per experiment) were analyzed using a FACS flow cytometer and Cell Quest analysis software (Becton-Dickinson, CA). Four cell populations were identified according to the following interpretations: viable population in the lower-left quadrant (low-PI and FITC signals), early apoptotic population in the lower-right quadrant (low-PI and high-FITC signals), necrotic population in the upper-left quadrant (high-PI and low-FITC signals), and late apoptotic or necrotic population in the upper-right quadrant (high-PI and high-FITC signals).

At this point, cells treated in the manner described above were examined on a glass slide using a laser-scanning confocal microscope (LSCM) (Bio-Rad Radiance2100, United States) with 488-nm excitation and 525-nm emission wavelengths. Bright green fluorescence was manifested in membranes of the cells undergoing prophase apoptosis because of Annexin V-FITC staining, while nuclear cardinal red fluorescence was associated with advanced stage apoptosis because of PI staining.

Measurement of intracellular calcium

The intracellular calcium ion ($[Ca^{2+}]_i$) was measured as previously described^[17]. After confluence, SGC-7901 cells on a coverslip were loaded by the $[Ca^{2+}]_i$ indicator Fluo-3/AM in HEPES solution at 37°C in the dark for 30 min. HEPES solution contains (concentration in mmol/L): NaCl 118, KCl 4.8, CaCl₂ 2.5, KH₂PO₄ 1.2, HEPES 5, and glucose 10. The pH was brought to 7.4 with NaOH. The final concentration of Fluo-3/AM was 5 µmol/L. After loading with Fluo-3/AM, a fluorescence image of $[Ca^{2+}]_i$ was taken using a laser-scanning confocal microscope (Bio-Rad Radiance2100, United States) at 600×, and qualitative changes of $[Ca^{2+}]_i$ were inferred from the fluorescence intensity using SimplePCI imaging systems (Simple PCI, Compix Inc., United States).

Western blotting analysis

Twenty µg of protein in each 20-µL sample was electrophoresed through 10% SDS-PAGE gels as previously described^[18]. Separated proteins were incubated with primary antibodies overnight at 4 °C, transferred to nitrocellulose membranes, and blocked with a 5% skim milk solution. They were incubated with secondary antibodies for 1 h at 37 °C. Each antigen-antibody complex was visualized by enhanced chemiluminescence Western blotting detection kits (Amersham Pharmacia Biotech, Piscataway, NJ), and band densities were determined using Chemi Doc Software (BioRad); β-Actin was used as a loading for normalization.

Statistical analysis

All experiments were repeated three times. The results of multiple experiments are given as the mean ± SE. Statistical analysis was performed using the statistical software package SPSS 13.0 (SPSS). A *P* value of 0.05 (two-sided) was considered statistically significant.

RESULTS

Cytotoxic activity of PCD on SGC-7901 cells

As shown in Figure 1A, vehicle-treated SGC-7901 cells (control) grew well with clear skeletons, whereas cells treated with PCD exhibited cytoplasmic shrinkage and either detached from each other, floated in the medium, or became distorted and blurry under a phase contrast microscope. The number of sloughed cells increased with increasing drug concentrations. The MTT assay showed that PCD significantly inhibited the viability of SGC-7901 cells (Figure 1B). The cells were incubated in the absence or presence of various concentrations of PCD for specified time periods, and the IC₅₀ values were 13.77 ± 0.18 , 8.73 ± 0.41 , and 3.62 ± 0.29 mg/mL for 24, 48 and 72 h, respectively. The MTT assay showed that PCD decreased the viability of SGC-7901 cells in a concentration- and time-dependent manner (*P* < 0.05 and *P* < 0.01, respectively).

Effect of PCD on cell cycle phase distribution of SGC-7901 cells

To investigate whether PCD affects the cell cycle of SGC-7901 cells, the cell cycle distribution of synchronized cells treated with or without PCD were analyzed by measuring the DNA content with PI after exposure to PCD for 24 h. As shown in Figure 2B, compared to vehicle treatment ($59.26\% \pm 5.12\%$), PCD treatment reduced the percentage of the cells in the G1 phase to $43.58\% \pm 1.79\%$, $49.58\% \pm 1.79\%$ and $45.58\% \pm 1.79\%$, respectively (*P* < 0.05). The percentage of G2/M cells was $12.48\% \pm 1.71\%$ in control cells and increased to $24.48\% \pm 1.62\%$, $33.00\% \pm 3.16\%$ and $38.32\% \pm 3.90\%$ in the cells treated with 10, 50 and 250 µg/mL of PCD for 24 h, respectively. These results showed that PCD exerted its effect of G2/M phase cell cycle arrest rather than S phase arrest induction in SGC-7901 cells, which contributed to the effects of PCD on decreasing viability

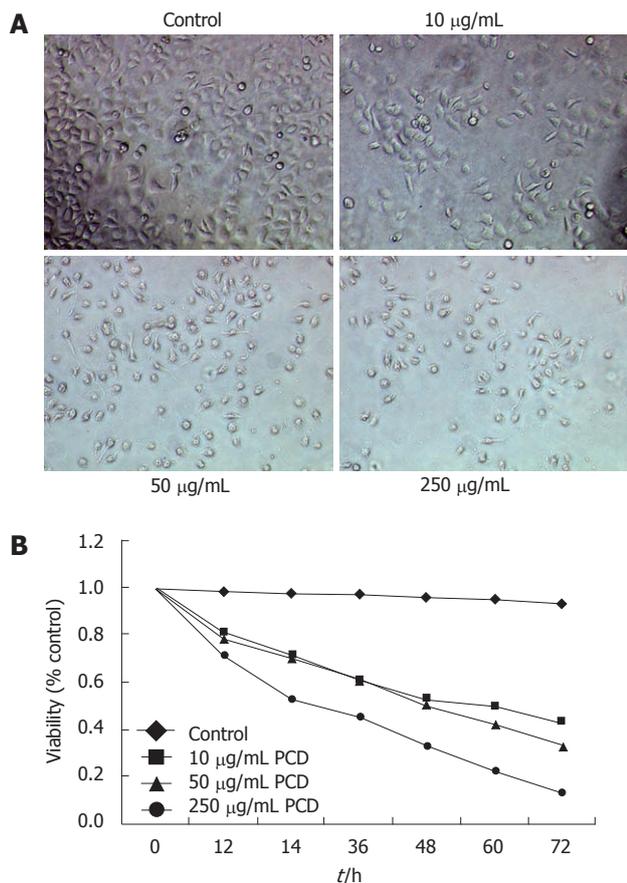

Figure 1 *Paris chinensis* dioscin inhibits the viability of SGC-7901 cells. A: Morphological changes of SGC-7901 cells exposed to *Paris chinensis* dioscin (PCD) for 24 h imaged under a phase contrast microscope at 40 ×; B: Effect of PCD on SGC-7901 viability. SGC-7901 cells were treated with PCD at the indicated concentrations for 0-72 h. Cell viability was then determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide assay and expressed as the mean ± SD, n = 3. The optical density value at 570 nm is proportional to the number of cells with PCD.

against SGC-7901 cells.

To gain insight into the mechanism of G2/M phase cell cycle arrest induced by PCD, we examined the expression of cyclins B and CDK1, which are closely related to G2/M cell cycle progression, using the Western blot assay. As shown in Figure 2C, the expression of cyclin B1 and CDK1 was decreased after PCD treatment for 24 h.

Effect of the PCD on apoptosis in SGC-7901 cells

To identify whether PCD induces apoptosis, the treated cells were also stained with Annexin V-FITC/PI, and the population of apoptotic cells was analyzed by flow cytometry. As seen in Figure 3A, the drug treatment significantly increased the proportion of apoptotic cells. In the vehicle treated cells, 12.04% ± 1.62% were positive for Annexin V-FITC staining, while PCD treatment resulted in increases of 17.18% ± 2.58%, 24.75% ± 2.72% and 54.91% ± 3.35% in apoptosis when cells were treated with PCD (P < 0.05 and P < 0.01, respectively). These results demonstrate the ability of PCD to induce apoptosis in SGC-7901 cells. The morphologic changes of cells treated in the manner described above were also observed under LSCM by Annexin V/PI staining. As shown in Figure 3B, typical

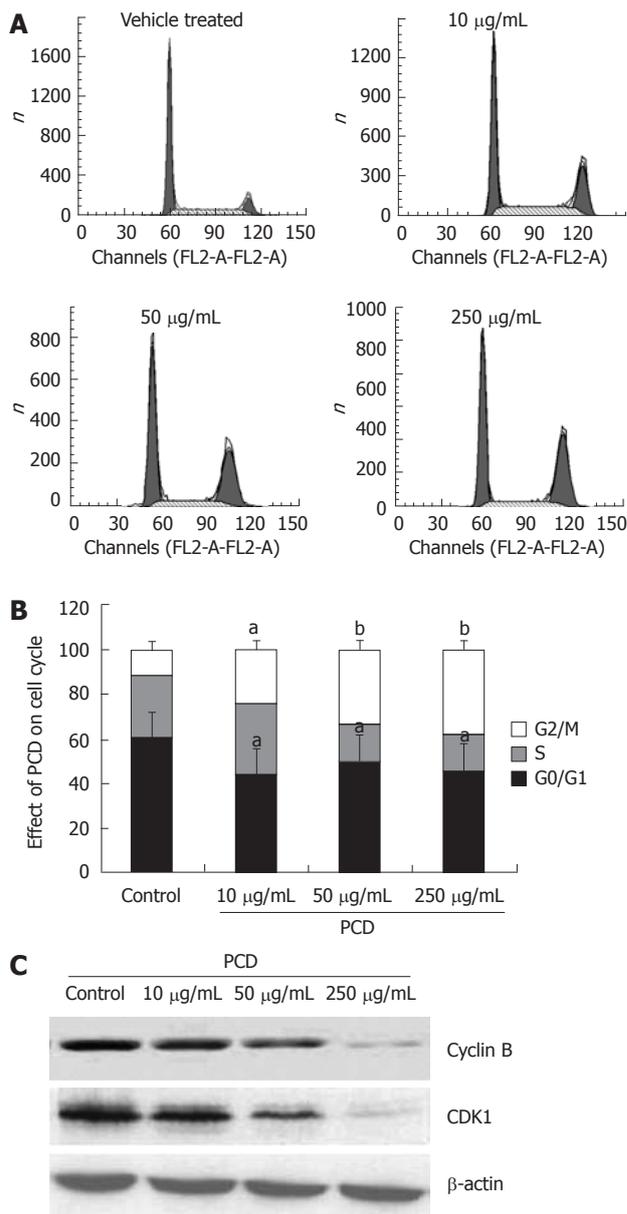

Figure 2 *Paris chinensis* dioscin induces G2/M cell cycle arrest in SGC-7901 cells. A: Cell cycle distribution was monitored by flow cytometry using a propidium iodide staining assay; B: Histogram of cell cycle distribution after treatment with *Paris chinensis* dioscin (PCD) for 24 h. Cell cycle distribution was monitored by flow cytometry using a propidium iodide staining assay. Each histogram represents three parallel experiments, and each bar represents the mean ± SE (One-way ANOVA). ^aP < 0.05, ^bP < 0.01 vs vehicle treated (control); C: Western blotting analysis of the expression of cyclin B and CDK1 with or without PCD treatment of SGC-7901 cells.

morphological changes, such as the formation of apoptotic bodies, appeared after the cells were treated for 24 h with 250 µg/mL PCD, whereas the vehicle-treated cells did not show evident apoptotic morphological changes.

To determine whether apoptosis induced by PCD was due to a mitochondrial-dependent caspase pathway, we further tested whether cytochrome C could be released from the mitochondria into the cytoplasm. We next investigated the levels of cytochrome C and caspase-3, which was the core protein in the caspase cascade in the soluble cytosolic fractions of SGC-7901 cells, after PCD treatment for 24 h. Figure 3C shows that PCD increased the

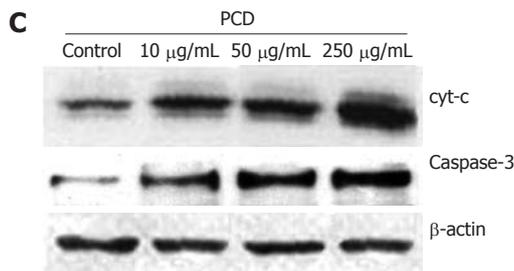

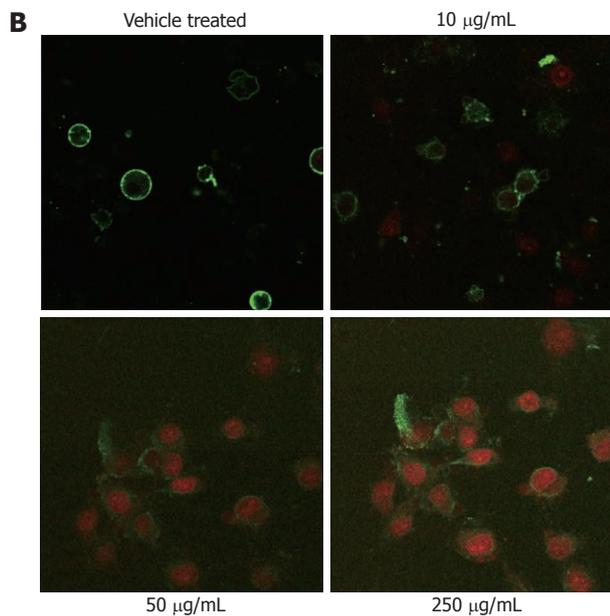

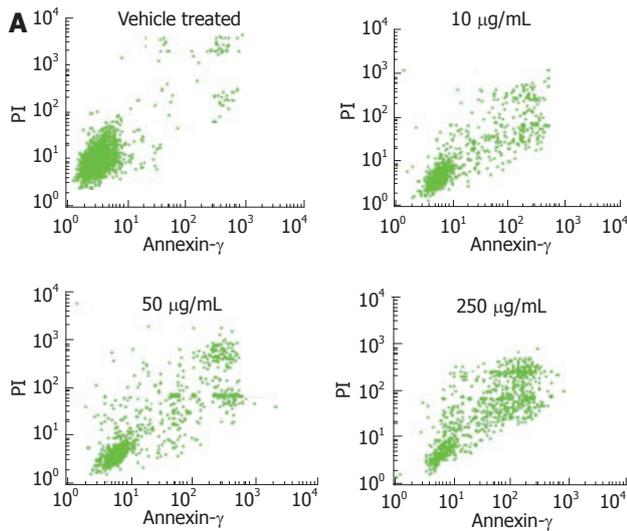

Figure 3 *Paris chinensis* dioscin induces apoptosis in SGC-7901 cells. PCD: *Paris chinensis* dioscin. PI: Propidium iodide.

level of cytochrome C released into the cytosol, and the expression of caspase-3 was increased after PCD treatment for 24 h compared with the vehicle-treated cells ($P < 0.05$), which indicated that PCD increased the caspase-3 level in SGC-7901 cells. Moreover, cells treated with PCD

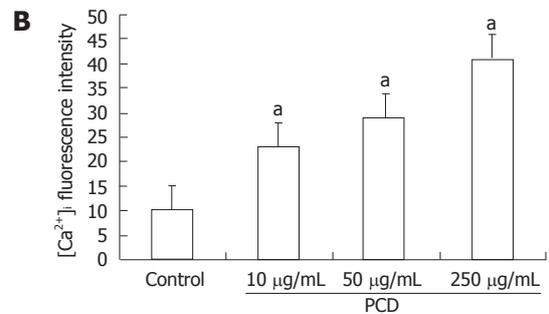

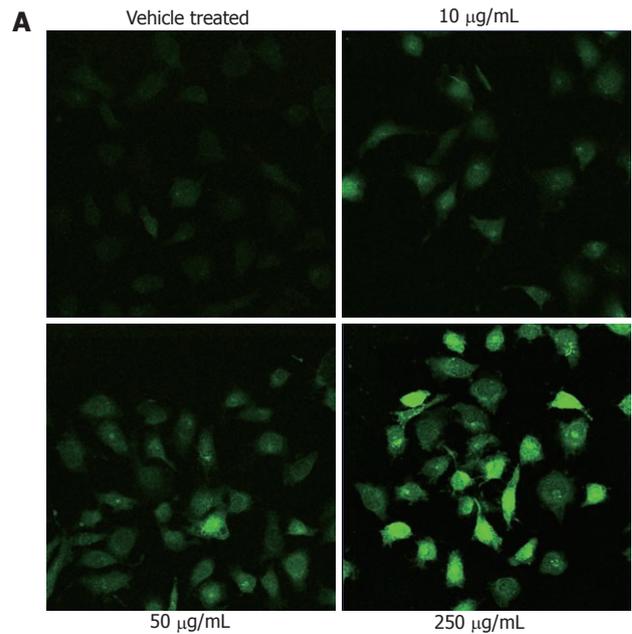

Figure 4 Effects of *Paris chinensis* dioscin on intracellular $[Ca^{2+}]_i$ expression in human gastric cancer SGC-7901 cells. A: Fluorescence image of $[Ca^{2+}]_i$ under laser scanning confocal microscope at 600 ×; B: Qualitative changes of $[Ca^{2+}]_i$ were inferred from the fluorescence intensity after *Paris chinensis* dioscin (PCD) treatment for 24 h, using SimplePCI imaging systems. Data are presented as mean ± SD (error bar). * $P < 0.01$ vs control.

exhibited a dose-dependent increase at this level ($P < 0.05$).

Effect of PCD on $[Ca^{2+}]_i$ in SGC-7901 cells

To explore whether PCD-induced apoptosis involved $[Ca^{2+}]_i$, we used the $[Ca^{2+}]_i$ indicator Fluo-3/AM to detect $[Ca^{2+}]_i$ changes after PCD treatment with various densities. As shown in Figure 4, $[Ca^{2+}]_i$ fluorescence intensity in the group treated with 250 μg/mL PCD was higher than in the vehicle-treated and lower concentration groups ($P < 0.01$), and PCD treatment with 10, 50 and 250 μg/mL induced an increase by 41% ± 4.72%, 66% ± 5.61%, and 86% ± 7.25% *vs* the vehicle-treated cells (25.33% ± 2.17%) ($P < 0.01$, $n = 6$) in Fluo-3/AM fluorescence intensity after 24 h treatment, respectively. These results suggest that the PCD can induce a dose-dependent $[Ca^{2+}]_i$ influx and might induce apoptosis or necrosis that follows *via* calcium ion overload.

DISCUSSION

Natural products with anticancer properties could be

valuable substances in cancer treatment, and this study examined the effect of PCD and its underlying mechanisms on the inhibition of tumor cell proliferation. In this study, we assessed the inhibitory effects and molecular mechanisms of PCD using human gastric cancer SGC-7901 cells. MTT showed that PCD inhibited the growth of SGC-7901 cells in both time-dependent and concentration-dependent manners (Figure 1B). To determine whether the cytotoxic activity of PCD was due to apoptosis, SGC-7901 human stomach carcinoma cells were treated for 24 h with various concentrations of PCD. Not only were morphological changes such as cytoplasmic shrinkage, detachment from each other, floating in the medium, distortion and some blurring under a fluorescence microscope observed (Figure 1A), but marked chromatin condensation and apoptotic body formation in PCD-treated cells were also observed in cells stained with Annexin V-FITC/PI using an LSCM (Figure 3B). Flow cytometry with Annexin V-FITC/PI staining showed that the drug treatment significantly increased the proportion of apoptotic cells, confirming that PCD induced apoptosis in SGC-7901 cells. Dysregulation of the cell cycle mechanism has also been shown to play an important role in the growth of various types of cancer cells, and the induction of cancer cell apoptosis is recognized as an important target in cancer therapy. In this study, PCD-inhibited SGC-7901 cell proliferation resulted partly from an accumulation of cells in the G2/M phase of the cell cycle. The G2/M phase is associated with DNA synthesis and the mitotic preparation period, which plays a crucial role in cell cycle progression. The complex formation of cyclins with CDKs results in an active agent that phosphorylates substrates involved in cell cycle progression^[19]. The mitosis-promoting factor, which comprises a complex of CDK1 and cyclin B, is thought to be the key controller of the progression from G2 to mitosis^[20-22]. In this study, PCD induced G2/M phase cell cycle arrest (Figure 2A and B), the cells of G2/M phase were present at 3.2 folds of the typical concentration after 24 h treatment, and Cyclins B1 and CDK1 were downregulated (Figure 2C), indicating that cell cycle-related proteins were involved in the PCD-induced cell cycle arrest in SGC-7901 cells.

The accumulated data suggest that the mitochondria-initiated death pathway plays an important role in triggering apoptosis in response to those stimuli. In the mitochondria-initiated death pathway, mitochondria undergoing permeability transition release apoptogenic proteins such as cytochrome C or apoptosis-inducing factor from the mitochondrial inter-membrane space into the cytosol. Released cytochrome C can activate caspase-9, and activated caspase-9 in turn cleaves and activates executioner caspase-3.

The apoptotic process is preceded by the collapse of the mitochondrial potential, the opening of a multi-protein structure named the permeability transition pore, which could be triggered by multiple stimuli such as changes in Ca^{2+} , oxygen radicals, pH, swelling of the matrix and rupture of the outer membrane with ensuing changes in the permeability of the outer mitochondrial membrane, and release of apoptogenic factors including cytochrome C from mitochondria^[23-26]. Changes in cell cycle arrest and apoptosis are listed below.

In this study, Western blot showed that cytochrome C increased in cytoplasm accompanying caspase-3 upregulation after PCD treatment (Figure 3C), indicating that the mitochondrial apoptotic pathway played a pivotal role in PCD-induced apoptosis of SGC-7901 cells.

Aside from the mechanisms described above, Ca^{2+} plays a critical role in this process, and intracellular Ca^{2+} overload appears to mediate the lethal effects of receptor overactivation^[27].

Ca^{2+} overload has even been suggested to be the final common pathway for all types of cell death. Over the last few years, several studies have shown that increases of cytosolic Ca^{2+} concentration ($[Ca^{2+}]_e$) occur, both at early and late stages of the apoptotic pathway^[28-33].

More specifically, it has been suggested that both Ca^{2+} release from the endoplasmic reticulum (ER) and capacitive Ca^{2+} influx through Ca^{2+} release-activated Ca^{2+} channels are apoptogenic^[34-36]. There are also data suggesting that very high intracellular Ca^{2+} levels can promote cell death through necrosis, whereas lower intracellular Ca^{2+} increases induced by milder insults promote cell death through apoptosis^[37,38]. In this study, the $[Ca^{2+}]_e$ fluorescence intensity of cells loaded with Fluo-3/AM under a fluorescence microscope in the group treated with 250 $\mu\text{g}/\text{mL}$ PCD was obviously higher than in the control and lower concentration groups (Figure 4).

Corbiere *et al.*^[39] reported that diosgenin-induced apoptosis in different human cancer cells is caspase-3-dependent and is concomitant with a fall in the mitochondrial membrane potential. We characterized the mechanisms by which PCD exerts its inhibitory effects on SGC-7901 cells by inducing G2/M cell cycle arrest and Ca^{2+} - cytochrome C- apoptosis.

Therefore, our results suggest that PCD may be a potential candidate as a novel therapeutic agent originating from a natural source, and the induction of apoptosis by PCD in other cancer cell lines is the subject of on-going investigations.

COMMENTS

Background

Gastric cancer is the most leading cause of death from cancer in China and majority in the world. Currently, no effective treatment is available. Therefore, there is a critical need to develop effective chemotherapeutic strategies for gastric cancer.

Research frontiers

There has been no documentation of the use of the other important steroid saponin dioscin in the treatment of cancer, its mechanisms in human gastric cancer cells remain unknown.

Innovations and breakthroughs

This is the first report on the anti-proliferation, induction of apoptosis by *Paris chinensis* dioscin (PCD) on human gastric cancer SGC-7901 cells. The authors characterized the mechanisms by which PCD exerts its inhibitory effects on SGC-7901 cells by inducing G2/M cell cycle arrest and Ca^{2+} - cytochrome C- apoptosis.

Applications

PCD might be useful as an adjuvant drug in human gastric cancer treatment.

Terminology

Paris chinensis (Liliaceae) is a Traditional Chinese Medicine and has been used mainly as a folk remedy for treatment of thanatophidia bites and convulsions for centuries. The active components of *Paris chinensis* are the saponin steroids polyphyllin D, dioscin, and balanitin 7.

Peer review

This is an interesting and good paper mainly due to its potential clinical application.

Abstract

AIM: To assess nutrition, physical activity and healthful knowledge in obese children with biopsy-proven non-alcoholic steatohepatitis (NASH or NA) compared to children without liver disease.

METHODS: Children with biopsy-proven NASH comprised the NASH group. Age, sex and ethnicity matched control groups consisted of obese (OB) and lean (CO) children with no liver disease. Subjects were administered the School Physical Activity and Nutrition Survey and one blood draw was obtained.

RESULTS: Fifty-seven patients were enrolled with a mean age of 12.1 ± 2.1 years, and all were Hispanic. Even though the OB and NA had a similar increased body mass index (%), 35% of the NA group always read nutrition labels compared to none in the OB (P

< 0.05), and more NA children felt their diet is "less healthy". NA consumed the least amount of fruits with only 25% having ≥ 1 fruit/d *vs* 45% in OB and 64.7% in CO ($P < 0.05$ NA *vs* CO). Only 15% of NA subjects performed light exercise *vs* 35% and 59% of OB and CO groups, respectively ($P = 0.02$). The mean physical activity score was lowest in the NA group ($P < 0.05$). Amongst the subjects with NASH, we found that 100% of patients with grade 2 or 3 fibrosis had a sedentary score > 2 compared to only 63.6% of those with grade 1 or no fibrosis ($P < 0.05$).

CONCLUSION: Children with NASH had increased sedentary behavior, decreased activity, and fruit intake. Larger studies may determine the benefit of changing these behaviors as treatment for NASH.

Physical activity and nutrition attitudes in obese Hispanic children with non-alcoholic steatohepatitis. *World J Gastroenterol* 2011; 17(39): 4396-4403 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i39/4396.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i39.4396>

INTRODUCTION

The prevalence of obesity is increasing in epidemic proportions in both adults and children. This has tripled from 1980 for the age group 6 to 19 years, with national health and nutrition examination survey (NHANES) reporting

17.4%-18.8% of children being obese^[1]. The evidence is clear; obese children become obese adults. In fact, obese 10 to 14 years old adolescents are more than 20 times more likely to become obese adults^[2]. This is unfortunate, since obesity is associated with metabolic syndrome, which has been reported in up to 50% of severely obese children^[3], and other obesity-associated diseases, such as fatty liver disease.

As the epidemic of childhood obesity progresses, it is predicted that the prevalence of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steato-hepatitis (NASH or NA) will also increase^[4]. NAFLD is an umbrella term that includes simple steatosis and simple steatosis with the presence of lobular inflammation. These two forms of NAFLD are generally considered to be non-progressive. Once a patient has portal inflammation, ballooning degeneration of hepatocytes or fibrosis the patient has the type of NAFLD that has been shown to be progressive, or NASH. A diagnosis of NAFLD may be made when the patient has elevated liver enzymes in combination with radiography demonstrating fatty infiltration in the liver. NAFLD is now considered to be the most common cause of chronic liver disease in the pediatric population^[5]. Studies using non-invasive techniques have been performed worldwide and have shown that NAFLD may be present in up to 77% of obese children^[6]. Schwimmer *et al.*^[7] recently reported a population-based study where 13% of all children had biopsy-proven NAFLD and 3% had NASH.

The pathogenesis of the development of NAFLD is not completely understood. In 1999, Day and James^[8] published the current theory “the two hit hypothesis”. The first “hit” is believed to be the development of steatosis, while the second “hit” leads to the progression to inflammation, necrosis and fibrosis. Oxidized by-products are harmful adducts that can cause liver injury, resulting in subsequent fibrosis^[9]. Day^[10] has subsequently pointed out that genetic factors influence the host response to endotoxin, oxidative stress, and severity of steatosis and that environmental factors, such as a diet high in saturated fat or low in antioxidant vitamins, influence the host’s susceptibility to fatty liver disease.

There are still no approved pharmacological therapies for NAFLD/NASH. Therefore, current management is based upon the presence of associated risk factors and aims to improve an individual’s quality of life, thus reducing NAFLD-associated morbidity and mortality. Today, lifestyle intervention (diet and exercise) is the treatment of choice for NAFLD/NASH. Significantly high levels of serum triglycerides, glucose, insulin, alanine aminotransferase (ALT), increased body mass index (BMI) and waist circumference (central adiposity) are all possible clinical features of pediatric NAFLD, which suggests that interventions on these variables can help to treat fatty liver, as well as to prevent progression to NASH^[11]. On the other hand, resolution of histological abnormalities revealed by liver biopsy is, at this time, the main target of NASH treatment^[12]. Studies on pediatric subjects have

shown that moderate weight loss can improve BMI and serum levels of ALT, and reduce fatty liver infiltration and necro-inflammation, although no change has been demonstrated in degree of fibrosis^[13].

One way to assess a child’s diet and physical activity is the School Physical Activity and Nutrition (SPAN) questionnaire^[14], which was developed as a surveillance instrument to measure physical activity, nutrition attitudes, and dietary and physical activity behaviors in children and adolescents. This tool can assess many dietary and physical behaviors over the 24 h prior to questionnaire administration. The food behaviors measured by this instrument include recall of certain foods from the previous day. This type of short-term recall is better for children because their cognitive skill has not developed sufficiently to estimate averaging and frequency as found in a traditional food frequency questionnaire^[15]. It has been validated and found to be reproducible^[16,17].

We hypothesize that there are differences in the dietary behaviors, physical activity and healthful knowledge between obese children who develop NASH and obese and lean children with no evidence of liver disease. These differences would be of greater clinical relevance when examined in subjects who share a similar genetic background and who are affected most frequently by NASH, i.e., being of Hispanic origin. Therefore, identifying those potential environmental differences may have important implications which may guide us towards treatment and possibly even prevention of this condition in the future.

MATERIALS AND METHODS

To test the hypothesis that there are differences in the dietary and physical activity habits between obese children with NASH and obese and lean children with no evidence of liver disease, we enrolled 57 children between the ages of 8 and 16 years into this pilot study. We categorized them into three different groups: the “NA” or NASH group which included 20 obese children with biopsy-proven NASH, the or obese control group (OB) which included 20 obese children with no evidence of liver disease, and the or lean control group (CO) which included 17 lean children with no evidence of liver disease.

Inclusion and exclusion criteria

Each subject in the NA group had a history of chronic serum ALT elevation defined by an ALT > 40 U/L on two separate occasions separated by at least 3 mo (90 d apart). Subjects also underwent a work-up for other causes of chronic hepatitis of unknown etiology including serologic evaluation for alpha-1-antitrypsin with phenotype, hepatitis B surface antigen, hepatitis C antibody, copper, ceruloplasmin, anti-nuclear antibody, anti-smooth muscle antibody (F-actin), anti-liver kidney microsomal antibody, and total immunoglobulin G. Subsequently, the NA subjects had a standard of care liver biopsy to identify the etiology and severity of chronic transaminitis. To be included in the study, the biopsy demonstrated a minimum of 5% of

hepatocytes with macrovesicular fat, without other etiologies for the presence of fat being identified and a pattern of injury consistent with NASH, as determined by an anatomic pathologist. All biopsies were also scored according to the NAFLD Activity Score (NAS), which is the sum of grades for steatosis (0-3), ballooning degeneration (0-2) and lobular inflammation (0-3)^[18]. Each biopsy also received a fibrosis score. All NA subjects had their liver biopsy confirming the diagnosis of NASH within 60 d of study enrollment.

In the OB group, each subject had a BMI percentile > 95% for age/sex as determined on growth chart by the Center for Disease Control (CDC), and no history of abnormal liver enzymes or chronic liver disease. If serum ALT levels were not drawn within the last 6 mo, subjects underwent screening ALT as a requirement for eligibility. If the subject had an ALT > 40 U/L on the day of the study visit, the subject was excluded ($n = 2$).

For inclusion in the CO group, each subject had a normal weight as defined by having a BMI percentile > 5% but less than 85% for age/sex as determined on a growth chart by the CDC. This was followed by Dual X-ray Absorptiometry (DXA) demonstrating less than 30% fat mass for females and less than 25% for males. Two male subjects were excluded for DXA % fat mass > 30% on the day of the study visit. CO subjects also had no history of abnormal liver enzymes or chronic liver disease.

We excluded any subject who had a disease considered by the study physician to be significant, including history of cancer or immunosuppressed state. We also excluded anyone with history of significant alcohol intake, use of medication known to cause NAFLD, or history of total parenteral nutrition. This protocol was reviewed and approved by the institutional review board of Baylor College of Medicine.

SPAN

All 57 subjects underwent the same evaluation; one study visit which included obtaining one blood draw and the administration of the SPAN^[14] questionnaire. This questionnaire was developed as a surveillance instrument to measure physical activity, nutrition attitudes, and food behaviors in children and adolescents. It has two versions, one for elementary students and the other for middle/high school students. We used the elementary school version, which is 10 pages long, with 54 questions. This version was found to have a reading level appropriate for a 9-year-old child and contains pictures to help the child understand the questions. Also, this questionnaire has been validated and has shown good to excellent reproducibility^[16,17].

Each question is generally directed towards one of three parameters of interest: food intake, physical activity and healthful knowledge. Most of the questions that address the child's food intake or physical activity are formatted to ask the child how much he/she has eaten of that food item on the day prior to the administration

of the questionnaire (i.e., "Yesterday, did you eat fruit?"). This is intended to minimize any recall bias. However, the questions that assess their healthful knowledge are formatted in a more general way (i.e., "Do you ever read the nutrition labels on food packages?").

For the purpose of better comparisons between the three groups, we created a scoring system for some of the questions of interest. For example, we created the physical activity score based on the sum of the answers of four different questions in the SPAN questionnaire that addressed physical activity. The higher the score, the more physical activity the child reported. We also added up the answers of two other questions and created the sedentary score (i.e., Sedentary score = the answer to question 35 "Yesterday, how many hours did you watch TV or video movies?" + the answer to question 40 "How many hours per day do you usually spend on the computer or playing video games, like Nintendo®, Sega®, or arcade games?"). Again the higher the score the more sedentary behavior the subject reported.

For other questions, we divided the children's answers into "No" or "Yes". "No" if they had no intake of that food item or "Yes" if they had at least one portion of that food item on the prior day but could be two, three or more portions. For example the answers to "Fruit intake \geq once per day" are either "No", which meant they had no fruit intake the day prior to the administration of the questionnaire or "Yes" which meant that they had at least one fruit the day before but could have had more.

Serological analysis

One blood draw was performed at the time of the visit after an overnight fast of at least 8 h. Serological analysis was performed for insulin, glucose, lipid profile, and hepatic profile in Texas Children's Hospital's clinical laboratory. Heights and weights were measured for all children and BMI, BMI percentile for age/sex, and BMI Z-score were calculated. To assess insulin sensitivity, we determined the Quantitative Insulin Sensitivity Check Index (QUICKI) using the calculation: $1/[\log(\text{fasting insulin in } \mu\text{U/mL}) + \log(\text{fasting glucose in mg/dL})]$ ^[19]. As a measure of insulin resistance, the Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) was calculated using the equation: $(\text{fasting insulin in } \mu\text{U/mL} \times \text{fasting glucose in mmol/L})/22.5$ ^[19]. A QUICKI value of < 0.339 represents impaired insulin sensitivity in children, while a HOMA-IR value of > 2 represents insulin resistance.

Statistical analysis

The data collected (serological levels and questionnaire answers) were analyzed using the Statistical Package for the Social Sciences (SPSS, Version 18.0). Descriptive statistics (means, standard deviations, and percentages) were calculated to describe sample characteristics. Analysis of Variance with Tukey's multiple comparison analysis (Post Hoc Test) was used to compare the three experimental groups. Significance was defined as $P < 0.05$.

Table 1 Patients' demographics

	CO	OB	NA	P value ^c
Male: Female (male %)	12:5 (71)	15:5 (75)	15:5 (75)	1
Age, yr (mean ± SD)	12.4 ± 2.1	11.9 ± 2	12.2 ± 2	0.9
BMI (%)	48.95 ± 21.85 (12.2-83.3)	98.31 ± 1.42 ^a (95.3-99.9)	98.05 ± 1.73 ^a (93.4-99.5)	1
Z-Score	-0.04	2.27 ^a	2.17 ^a	0.8
BMI % males	49.9	98.4 ^a	97.8 ^a	1
BMI % females	50.4	97.9 ^a	98.7 ^a	1
Fasting insulin (μU/mL)	2.7 ± 2.5 (1-11)	12.1 ± 8.6 ^a (1-31)	19.4 ± 10.4 ^{a,c} (5-41)	0.02
Fasting glucose (mg/dL)	78.7 ± 7.6 (62-91)	84.1 ± 5.9 (75-95)	85.9 ± 8.5 ^a (68-111)	0.7
HOMA-IR	0.5 ± 0.5 (0.1-2.0)	2.5 ± 1.9 ^a (0.2-7.0)	4.1 ± 2.3 ^{a,c} (1-9.1)	0.02
QUICKI	0.467 ± 0.069 (0.344-0.558)	0.364 ± 0.073 ^a (0.289-0.527)	0.319 ± 0.027 ^a (0.280-0.383)	0.05
Cholesterol (mg/dL)	158.9 ± 25.2 (130-223)	165.2 ± 30.4 (116-243)	179.4 ± 37.8 (95-245)	0.3
TG (mg/dL)	62.5 ± 28 (25-123)	114.8 ± 38 ^a (63-208)	140.3 ± 81.4 ^a (38-424)	0.3
HDL (mg/dL)	56.7 ± 12.2 (37-87)	43.4 ± 7.9 ^a (32-62)	43.9 ± 9.7 ^a (22-68)	1

^a*P* < 0.05, *vs* lean controls (CO) group; ^b*P* < 0.05, *vs* obese controls (OB) group. Values represent the mean ± SD (range). BMI: Body mass index; HOMA-IR: Homeostatic model assessment for insulin resistance; QUICKI: Quantitative insulin sensitivity check index; TG: Triglyceride; HDL: High-density lipoprotein; NA: Non-alcoholic steatohepatitis subjects.

RESULTS

Patients' demographics

The study population (Table 1) included a total of 57 children; 20 in the NA group, 20 in the OB group and 17 in the CO group. All three groups were age, sex and ethnicity matched. The mean age was 12.1 ± 2.1 years. All subjects were Hispanic, and 74 % of the cohort was males (42 males and 15 females). The mean BMI % was 98.1% for the NA group (Z-score 2.2), 98.3% for the OB group (Z-score 2.3), and 48.9% for the CO group (Z-score -0.04). The mean fasting insulin levels were 19.4, 12.1 and 2.7 for the NA, OB and CO groups respectively (*P* < 0.05 NA *vs* OB). Increased insulin resistance and decreased insulin sensitivity were reflected in the HOMA-IR and the QUICKI (Table 1).

Body image and dieting behavior

While BMI % and BMI Z-score did not differ between NA and OB, differences in body image and dieting behavior between all 3 groups were elucidated (Table 2). We found that 55% of the NA group felt that they weighed too much compared to other students in their grade who were as tall as they were, while only 45% of the OB group and 5.9% of the CO group felt that way (*P* < 0.01, NA *vs* CO; *P* < 0.01, OB *vs* CO). Upon questioning the subjects if they have ever tried to lose weight, 85% of the NA group and 85% of the OB group answered yes compared to only 11.8% of the CO group. (*P* < 0.001, NA *vs* CO; *P*

Table 2 Body image and dieting behavior (%)

Question	CO	OB	NA
Compared to other students in your grade, who are as tall as you, do you think you weigh:			
The right amount	52.9	50	35
Too much	5.9	45 ^a	55 ^a
Too little (or not enough)	41.2	5 ^a	10 ^a
Are you trying to lose weight?			
No	94.1	20 ^a	5 ^a
Yes	5.1	80 ^a	95 ^a
Have you ever tried to lose weight?			
No	88.2	15 ^a	15 ^a
Yes	11.8	85 ^a	85 ^a
Do you ever read the nutrition labels on food packages?			
Almost never or never	41.2	20	10 ^a
Sometimes	52.9	80	55
Almost always or always	5.9	0	35 ^{a,c}
The foods that I eat and drink now are healthy:			
No	0	0	10
Yes, sometimes	94.4	65	80
Yes, all the time	5.9	35 ^a	10

Values represent percentage of children with each answer, ^a*P* < 0.05, *vs* lean controls group; ^c*P* < 0.05, *vs* obese controls (OB) group. CO: Lean controls; NA: Non-alcoholic steatohepatitis subjects.

< 0.001, OB *vs* CO). In response to the question "Are you trying to lose weight now?" 95% of the NA group, 80% of the OB group and 5.9% in the CO group stated "Yes" (*P* < 0.001, NA *vs* CO; *P* < 0.001, OB *vs* CO).

Looking into their healthful dietary knowledge, we found that 35% of the NA group answered that they always or almost always read the nutrition labels on food packages compared to only 5.9% of the CO group and none in the OB group (*P* < 0.05, NA *vs* OB; *P* < 0.05, NA *vs* CO). Interestingly, only 10% of the NA group and 5.9% of the CO group felt that they always eat and drink healthy foods, compared to 35% of the OB subjects (*P* < 0.05, OB *vs* CO).

Food consumption

Children reported food intake of milk, fruits, and fries (Figure 1). The NA group consumed the least amount of fruits when compared to the other groups, with only 25% of NA subjects reporting that they consumed ≥1 fruit per day compared to 45% and 64.7% of the OB and CO groups respectively (*P* = 0.05, between the 3 groups). This difference was even more significant between the NA and CO groups (*P* < 0.05).

The NA group reported the least amount of dairy consumption, with only 55% having ≥ 1 cup of milk per day, compared to 60% of the OB group and 64.7% of the CO group; however this was not statistically significant. There were no statistically significant differences between the 3 groups regarding reported consumption of cereal, grains, vegetables, or sugar sweetened beverages. Also, there were no differences between the NA and OB groups in regards to having breakfast the day prior to the questionnaire or taking a vitamin pill.

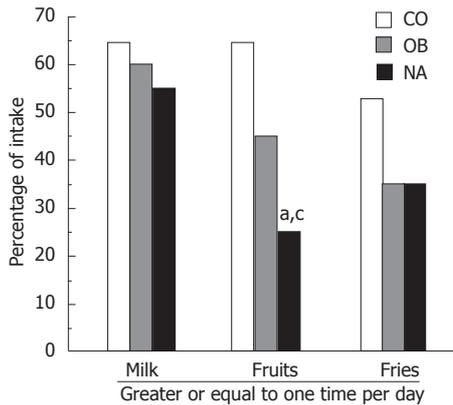

Figure 1 Intake of milk, fruits and fries. This figure plots the percentage of subjects responding to school physical activity and nutrition questions regarding food consumption. Non-alcoholic steatohepatitis subjects reported consuming significantly less fruits than obese and lean control subjects. CO: Lean controls; OB: Obese controls; NA: Non-alcoholic steatohepatitis subjects. ^a*P* < 0.05, vs CO group; ^c*P* < 0.05, vs OB group.

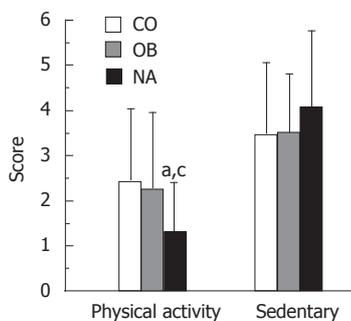

Figure 2 Physical activity and sedentary behavior. This figure demonstrates the physical activity scores and sedentary scores of obese children with non-alcoholic steatohepatitis (NASH) compared with obese controls and lean controls. NASH subjects reported significantly less physical activity than obese and lean controls. CO: Lean controls; OB: Obese controls; NA: Non-alcoholic steatohepatitis subjects. ^a*P* < 0.05, vs CO group; ^c*P* < 0.05, vs OB group.

Physical activity and sedentary behaviors

Differences in reported light to vigorous exercise and sedentary behaviors were evaluated in this cohort. We found that 45% of the NA group performed vigorous exercise (e.g., basketball, running or jogging, fast dancing, swimming laps, tennis, fast bicycling or similar aerobic exercises) for at least 20 min the day prior to the administration of the questionnaire, compared to 64.7% in the CO group and 25% in the OB (*P* = 0.05, between the 3 groups; *P* < 0.05, OB *vs* CO). However, only 15% of the NA subjects had performed light exercise (defined as fast walking, slow bicycling, skating, pushing a lawn mower, or mopping the floors) for at least 30 min the day before, compared to 35% and 59% of the OB and CO groups, respectively (*P* < 0.01, NA *vs* CO, *P* < 0.05 OB *vs* CO). The mean physical activity score was lowest in the NA group (NA = 1.3 *vs* OB = 2.3 *vs* CO = 2.4; *P* < 0.05), but the mean sedentary score was not significantly different between the groups (NA = 4.1 *vs* OB = 3.5 *vs* CO = 3.5; *P* = NS) (Figure 2).

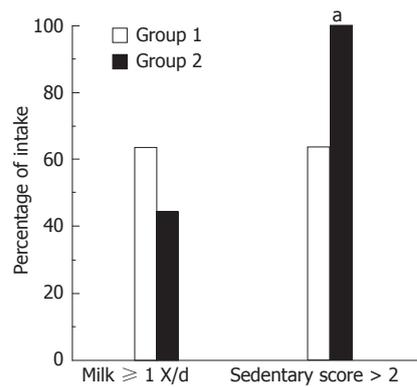

Figure 3 Milk intake and sedentary score by severity of fibrosis in non-alcoholic steatohepatitis subjects. This figure demonstrates milk consumption and sedentary scores amongst subjects with non-alcoholic steatohepatitis. All subjects with advanced fibrosis (grades 2 or 3), had a sedentary score > 2 compared to only 63.6% of those with grade 1 or no fibrosis (^a*P* < 0.05, vs group 1).

Behaviors in subjects with NASH

In an attempt to clarify possible differences in diet and activity amongst obese children with differing degrees of liver injury, a sub-group analysis of the NA group was performed (Figure 3). Amongst the subjects with NASH, we found that 100% of patients with grade 2 or 3 fibrosis had a sedentary score > 2 compared to only 63.6% of those with grade 1 or no fibrosis (*P* < 0.05). We also noted that 44.4% of patients with grade 2 or 3 fibrosis had ≥ 1 cup of milk per day, compared to 63.6% of patients with no fibrosis or with grade 1 fibrosis; however, this difference was not statistically significant. Also, 16.7% of patients with grade 3 steatosis reported having pasta on at least 2 occasions the day prior to the questionnaire while none of the subjects with grade 1 or 2 steatosis had that amount (*P* < 0.05). Comparing the patients’ NAFLD Activity Score (NAS), we found that there were no differences between subjects with NAS score ≥ 4 and those with NAS score < 4 in regards to their dietary habits, physical activity and healthful knowledge.

Subjects with NASH vs non-NASH

Upon comparing subjects with NASH to those with no evidence of liver disease (“non-NASH” = CO + OB groups), we found that 75% of the NA group reported no fruit intake at all compared to only 45.9% in the non-NASH group (*P* < 0.05). Additionally, 35% of the NA group “always” or “almost always” read nutrition labels, compared to only 2.7% of the non-NASH group (*P* < 0.01). In evaluating light exercise, we found that 85% of the NA group reported not performing any light exercise on the prior day, compared to 54.1% in the non-NASH group (*P* < 0.05). And finally, 95% of the NA group stated that they were currently trying to lose weight compared to only 45.9% of the non-NASH group (*P* < 0.001).

DISCUSSION

Our pilot study demonstrates clear differences in dietary

behaviors, physical activity and healthful knowledge between lean healthy children, obese children with no evidence of liver disease and obese children with NASH. One potential caveat to our study is that we didn't obtain a liver biopsy to confirm the absence of NAFLD in the CO and OB groups. However, given the invasive nature of liver biopsy and normal transaminases in these subjects, it would be unethical to perform this procedure on children with no other clinical indication. Hence, in order to minimize this possibility, we excluded any child with a history of liver disease of any sort, history of elevated ALT or ALT > 40 U/L on the day of the study visit.

We performed this study in a cohort of Hispanic children; this must be taken into account when considering generalizing this to the population as a whole. Ogden *et al.*^[19] recently reported that the highest rate of obesity in children of all age groups was among teenage African American girls followed by Hispanic boys and girls of all ages with Hispanic males having the highest percentage of obesity compared to white and African American males^[20]. Additionally, the role of gender, race and ethnicity has been described in a population based study on NAFLD by Schwimmer *et al.*^[21], where they noted that obese adolescent boys were six times more likely to have fatty liver compared to obese adolescent girls. This study also supported the observation that NAFLD is more common in Hispanic adolescents compared to other ethnicities, with Hispanic ethnicity making a child five times more likely to have NAFLD than an African American child^[7]. Given the prevalence and severity of obesity and NAFLD in Hispanic children, our study population provides a unique insight into this population.

In our cohort, all subjects were Hispanic, and 74% of them were males. This male:female ratio is similar to Schwimmer's report of 82% of children with NASH being male^[7]. There were no differences between the 3 groups in regards to age and sex; however, there were clear differences between the groups in regards to their fasting glucose and insulin levels - findings that are consistent with previous studies (e.g., Louthan *et al.*^[22] and Vos *et al.*^[23] studies). Evidence supports the concept that a trio of obesity, dyslipidemia, and insulin resistance play an important role in the pathogenesis and severity of NASH in children, and we found that children with NASH had an increase in HOMA-IR and a decrease in QUICKI when compared to the obese and lean control groups^[19,22,23]. The NA and OB groups had a significantly higher level of triglyceride (TG) and lower level of high-density lipoprotein (HDL) when compared to the lean control subjects. Those values were comparable to the values from other studies such as Viva La Familia study by Butte *et al.*^[24] and Quirós-Tejeira *et al.*^[25], as the mean HDL in our NA subjects was 43.85 ± 9.7 (in Viva La Familia; HDL: 46.6 ± 0.5 mg/dL) and mean TG was 140.3 ± 81.4 (in Quirós-Tejeira *et al.*^[25]; TG for boys: 157.2 ± 86.9 mg/dL and for girls: 145.0 ± 71.7 mg/dL).

Recent studies have shown that the majority of Hispanic mothers of overweight children may not perceive

their children as being overweight^[26-28]. In another study by Mikhail *et al.*^[29] both children and parents underestimated the child's body fat with parents' estimates being slightly, but not significantly, better (unpublished data). Similarly, we found that only half of the NA children found themselves heavier than their classmates; however, the majority of them had tried and/or are currently trying to lose weight.

Interestingly, even though the NA and the OB groups had the same mean BMI % (98%), similar proportions reported feeling heavier than their classmates, and a similar percentage had tried or are currently trying to lose weight, the NA and OB groups had notable differences in their healthful knowledge. For example about one third of the NA children read food labels on a regular basis compared to none in the OB group, and more NA than OB children recognized that their diets are "less healthy". This finding may be attributed to the fact that the NA children had multiple physician's visits including seeing a specialist (i.e., a hepatologist), and had undergone multiple blood draws and a liver biopsy for obesity-related health issues, while the OB group were recruited generally during their well-child visit, through Baylor Pediatric Residents Primary Care clinics at Texas Children's Hospital. Therefore, the NA subjects may have a heightened sense that their diet is not as healthy as it should be and may truly be reading food labels on a more regular basis.

A growing body of evidence supports that oxidative stress may play a vital role in the development of NASH^[30,31]. Intake of antioxidants may help prevent the occurrence of this disease and antioxidant vitamin supplementation studies have been performed^[13,32,33]. In our study, there were no differences between the three groups in regards to their daily intake of a vitamin pill to explain a difference in their antioxidant intake; however, we noted that the NA group had the lowest intake of fruits per day while the CO group had the highest intake. Fruits are rich in antioxidants^[34-36], and this difference in fruit intake between the groups may give insight into why some obese Hispanic children develop NASH while others do not.

In an analysis of NHANES looking at whole grain consumption and weight status, it was found that women consuming at least one serving of whole grain had a significantly lower mean BMI and waist circumference than women with no whole grain consumption^[37]. In another study done in the United Kingdom, it was found that a higher intake of whole grains (about three servings per day) was associated with lower BMI and central adiposity^[38]. Nicklas *et al.*^[39] have found that consuming ready-to-eat cereal at breakfast was associated with improved weight and nutrient adequacy in African American children. Surprisingly, in our study there were no differences between the 3 groups in regards to having breakfast or cereal intake. This, however, may be due to the small sample size in our pilot study.

While differences between the 3 groups were noted in respect to vigorous activity, it was even more notable in regards to light exercise, with only 15% of the NA sub-

jects performing light exercise for at least 30 min on the prior day, compared to one third and almost two thirds of the OB and CO groups, respectively. While we have not evaluated for patatin-like phospholipase domain-containing protein 3 (PNPLA 3) variants in our study subjects, it has been recognized that PNPLA 3 variants have been associated with NASH, especially in Hispanics. Johansson, *et al*^[40] reported that PNPLA 3 mutations were associated with decreased light physical activity. This highlights the need for studies to evaluate PNPLA 3 mutations in children with NASH.

Amongst the subjects with NASH, we found that all patients with advanced fibrosis had a sedentary score > 2 compared to less than two thirds of those with grade 1 or no fibrosis. Realizing that this was a one-time study visit, we can not be certain as to where our subjects are in regards to the natural history of disease progression. However, in a study out of Italy by Nobili *et al*^[41], children with NASH who improved their BMI, partially by increased exercise, decreased the degree of liver injury. This could explain the above finding in our study.

In conclusion, both genetic and environmental factors play major roles in the development of NASH and determine why only a minority of obese, insulin resistant individuals progress from simple steatosis to inflammation and fibrosis^[10]. This pilot study aimed to use a validated tool, the SPAN questionnaire, to assess the role of specific environmental factors such as diet and physical activity in pediatric NAFLD. Our results suggest that pediatric hepatologists should consider counseling children with NASH regarding the potential benefits of decreasing sedentary behavior, increasing light activity level, and increasing fruit intake. We conclude that future studies identifying environmental factors involved in pediatric NASH may help target therapeutic measures and preventative measures.

COMMENTS

Background

As the epidemic of obesity in childhood is increasing, it is predicted that non-alcoholic fatty liver disease and non-alcoholic steato-hepatitis (NASH or NA) prevalence will increase as well. Currently, there is no approved therapy for this condition, so life style changes, e.g., diet and exercise have become the mainstays of therapy.

Research frontiers

The authors hypothesize that there are differences in the dietary behaviors, physical activity and healthful knowledge between obese children who develop NASH and obese and lean children with no evidence of liver disease. Therefore, identifying those potential environmental differences may have important implications in regards to treatment and possibly even prevention of this condition in the future.

Innovations and breakthroughs

The authors demonstrated clear differences between obese children with NASH and obese and lean children with no evidence of liver disease. Children with NASH had increased sedentary behavior, decreased activity level, and decreased fruit intake.

Applications

This pilot study highlights the potential benefits of decreasing sedentary behavior, increasing light activity level, and increasing fruit intake in obese children as this may help prevent the development of NASH in this population.

Peer review

In this manuscript the authors evaluated nutrition, physical activity and healthful knowledge in obese children with NASH compared to children without liver disease and concluded that children with NASH had increased sedentary behavior and decreased activity. **This study is interesting.**

Abstract

AIM: To determine the prevalence of restless legs syndrome (RLS) in patients with irritable bowel syndrome (IBS).

METHODS: Patients with diarrhea-predominant IBS ($n = 30$), constipation-predominant IBS ($n = 30$), or mixed-symptom IBS ($n = 30$) were recruited from the community between March 2008 and February 2009. Rifaximin 200 mg three times daily was administered empirically to alleviate small intestinal bowel overgrowth in all patients. The presence of RLS was assessed *via* an RLS questionnaire and polysomnography.

RESULTS: Twenty-six patients with IBS (29%) were diagnosed with RLS using the RLS questionnaire. Twenty-four of the 26 patients (92%) underwent polysomnography,

and all had confirmation of RLS. A greater percentage of patients with RLS had diarrhea-predominant IBS (62%) compared with patients with constipation-predominant IBS (4%) or mixed-symptom IBS (33%).

CONCLUSION: Restless legs syndrome is prevalent in patients with IBS, especially those with diarrheal symptoms. Assessment of concomitant disorders may improve diagnosis and expand relevant treatment options for patients.

INTRODUCTION

Irritable bowel syndrome (IBS) is a common gastrointestinal (GI) disorder that affects between 3% and 25% of the population in Western countries^[1]. It is characterized by chronically recurring symptoms associated with alterations in bowel habits, which may be classified as constipation predominant (IBS-C), diarrhea predominant (IBS-D), or mixed symptom (IBS-M)^[2,3]. Other symptoms include abdominal pain or discomfort, bloating, flatulence, straining, sensations of urgency, and incom-

plete evacuation^[3]. Symptoms may fluctuate in severity and frequency, with some periods of remission^[1]. The etiology of IBS is unknown, but multiple, possibly inter-related, pathophysiologic mechanisms may be involved, including psychological disturbances^[1,2,4], genetic predisposition^[1], alterations in inflammatory responses^[2,4], visceral hypersensitivity^[4], abnormal intestinal motility^[3], alterations in neurotransmitter levels^[2-4], and small intestinal bacterial overgrowth (SIBO)^[2]. Small intestinal bacterial overgrowth in particular may be an important factor because of its impact on mucosal inflammation. Inflammation may lead to increased cytokine activity, increased motility, and the release of neurotransmitters such as 5-hydroxytryptamine (5-HT), thereby disrupting central and enteric nervous system crosstalk^[4]. This may explain why IBS, which is associated with SIBO^[5-8], is often comorbid with other sensitivity disorders, including fibromyalgia and interstitial cystitis^[9-11].

Restless legs syndrome (RLS) is a common sensorimotor disorder^[12] affecting 1% to 10% of the population^[13]. It is clinically characterized as a compelling urge to move the legs that is often associated with discomfort, is worse during rest or inactivity, is relieved by movement, and is worse or only occurs in the evening or at night^[12]. The etiology of RLS remains incompletely characterized^[13,14]; however, dopaminergic dysfunction and altered control of iron homeostasis may contribute to the pathophysiology of RLS^[13,14]. Studies have also linked RLS with GI disorders, including Crohn's disease^[15], celiac disease^[16], and SIBO^[17,18]. Further, a small observational study of patients with IBS and RLS ($n = 13$) demonstrated that RLS symptoms improved following antibiotic therapy for SIBO^[18]. This study expounds on these observations by determining the prevalence of RLS in a large number of patients ($n = 90$) with IBS.

MATERIALS AND METHODS

This observational clinical study was conducted in patients ≥ 18 years of age diagnosed with IBS according to Rome III criteria. Participants were recruited between March 2008 and February 2009 from a community-based gastroenterology center and administered rifaximin 200 mg three times daily for 14 d as empiric therapy for SIBO before diagnosis of RLS. Patients with scleroderma, diabetes mellitus, Parkinson's disease, chronic kidney disease, hepatic encephalopathy, peripheral neuropathy, dysmotility disorder, high ferritin levels, or iron deficiency were excluded. Patients who were pregnant; who were taking dopamine antagonists, antidepressants, caffeine, alcohol, cocaine, or amphetamines; or who had used antibiotics 6 wk before enrollment were also excluded from the study. The study protocol, all protocol amendments, and the informed consent form were approved by the Central Institutional Review Board. All individuals provided written informed consent, and the study was conducted in accordance with ethical standards of the responsible committee on human experimentation and with the Helsinki Declaration of 1975.

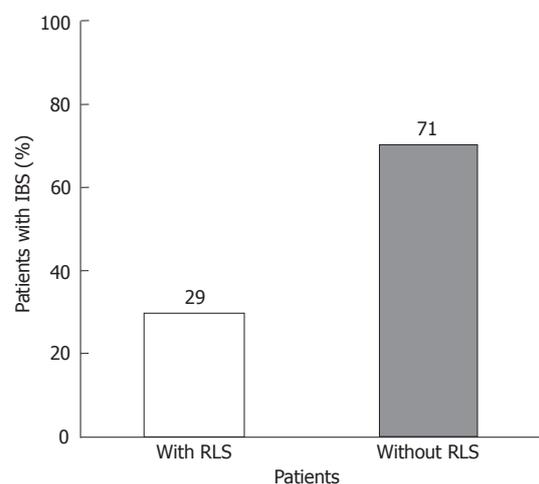

Figure 1 Prevalence of restless legs syndrome in patients with irritable bowel syndrome. Twenty-nine percent of patients with irritable bowel syndrome (IBS) were diagnosed with restless legs syndrome (RLS).

Initial diagnosis of RLS was made *via* the use of a standard RLS questionnaire formulated by the International Restless Legs Syndrome Study Group^[12]. The questionnaire was administered by medical students who were unaware of the study objective, and responses were interpreted by a gastroenterologist (*i.e.*, Basu). Diagnosis of RLS was confirmed *via* polysomnography conducted by a sleep specialist at a single center using criteria established by the Association of Sleep Disorders Centers^[19].

RESULTS

Ninety patients with IBS who met inclusion criteria and did not meet exclusion criteria were included in the study (Table 1). Of these patients, 30 (33%) displayed IBS-D, 30 (33%) exhibited IBS-C, and 30 (33%) presented with IBS-M. Initial diagnosis of RLS was established in 26 patients (29%) using the RLS questionnaire (Figure 1). Of

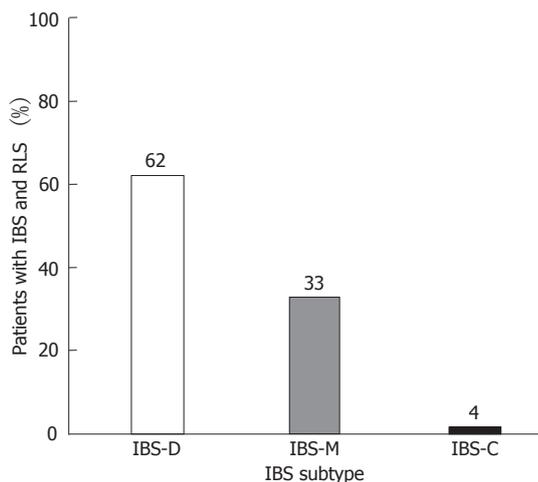

Figure 2 Distribution of irritable bowel syndrome subtypes in patients with restless legs syndrome, which was assessed in each patient using a questionnaire and sleep study analysis. IBS: Irritable bowel syndrome; IBS-C: Constipation-predominant irritable bowel syndrome; IBS-D: Diarrhea-predominant irritable bowel syndrome; IBS-M: Mixed-symptom irritable bowel syndrome; RLS: Restless legs syndrome.

these 26 patients, 24 (92%) underwent sleep study analysis to confirm RLS; two patients chose not to participate in this analysis and were excluded from the study.

Polysomnography confirmed RLS during REM and non-REM phases in all patients tested (100%). Salient sleep disturbances other than RLS included wakefulness > 30% of sleep time (63%), sleep maintenance < 30% of sleep time (100%), and disruption of sleep onset (100%). Moderate (myoclonus time > 30-40 s) and mild (myoclonus time > 10-30 s) involuntary jerks of limbs not related to RLS were also noted in 50% and 25% of patients, respectively. Patients with RLS were more likely to have IBS-D than IBS-C or IBS-M (Figure 2).

DISCUSSION

Irritable bowel syndrome is a common GI disorder with a sex-adjusted incidence rate of 196 cases per 100 000 people^[1], which is associated with approximately 8 billion dollars per year in medical costs^[4]. Individuals diagnosed with IBS take more time off work^[20], spend more days in bed^[20], and have an overall reduction in health-related quality of life compared with those without IBS^[21]. Although the etiology of IBS is unknown, it has been associated with psychological factors such as anxiety^[22] and verbal or emotional abuse^[23], as well as with sleep disturbances^[24]. Furthermore, alterations in GI motility (e.g., the migrating motor complex)^[25,26] and GI flora (e.g., SIBO)^[5,6,8] have been described in patients with IBS. Taken together, these data suggest disruption of communication between the central and enteric nervous system in IBS, which may explain the comorbidity of IBS with other sensory disorders^[9-11,18].

This study demonstrated that RLS was a comorbid condition with IBS in 26 of 90 patients (29%). This finding adds support to previous studies examining the prev-

alence of RLS in patients with intestinal disorders. In a study of 161 patients with an abnormal lactulose breath test indicative of SIBO, 19 patients (12%) perceived themselves to have RLS^[18]. Of these, 11 patients (58%) were confirmed to have RLS by the Johns Hopkins validated interview process. The prevalence of RLS in patients with celiac disease or Crohn's disease has also been examined, with 35% (30 of 85) and 43% (93 of 218) of patients reporting comorbid RLS, respectively^[15,16].

The mechanism underlying these comorbidities remains unknown, but the disruption of enteric and central nervous system communication because of alterations in inflammatory mediators and neurotransmitters triggered by SIBO has been implicated^[4]. It has been suggested that an excess of sulfate-reducing bacteria may lead to increases in hydrogen sulfide, which may act as a gaseous neurotransmitter^[11]. In addition, inflammation may lead to increased cytokine activity and altered release of 5-HT^[4]. This may explain why both the 5-HT antagonist alosetron and the minimally absorbed antibiotic rifaximin are effective in relieving IBS symptoms. Interestingly, rifaximin in combination with tegaserod (a prokinetic agent) and zinc reduced symptoms of RLS in patients with SIBO^[18], and treatment of 2 patients with RLS with tandospirone (a 5-HT_{1A}-receptor agonist) relieved RLS symptoms^[27]. The results presented herein suggest that factors in addition to SIBO may play a role in RLS because SIBO was eliminated in patients by prophylactic treatment with rifaximin before RLS diagnosis. Together, these studies suggest involvement of SIBO, altered neurotransmission, and other factors in the pathophysiology of RLS.

In conclusion, this study contributes to the available literature supporting an association between IBS and RLS. Screening of patients with IBS for RLS, or vice versa, may permit more accurate diagnosis based on revelation of potentially undisclosed symptoms. Concomitant diagnosis of these disorders may enhance treatment options for patients, given that some medications may provide relief for both conditions. Further investigations to determine the underlying mechanisms common in both disorders are needed to address the causality of this connection.

COMMENTS

Background

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder characterized by abdominal pain or discomfort, bloating, flatulence, straining, urgency and incomplete evacuation. The pathophysiologic mechanisms underlying this disease are incompletely understood, but alterations in gastrointestinal and systemic inflammatory responses have been implicated. Disruption of inflammatory processes has also been associated with restless legs syndrome (RLS), a sensorimotor disorder associated with a compelling urge to move the legs that is relieved with movement and may result in sleep disruption. This prevalent

disease has been associated with a variety of inflammation-related gastrointestinal disorders including Crohn's disease, celiac disease, and small intestinal bacterial overgrowth, which have also been linked with IBS.

Research frontiers

Although common, RLS may be underdiagnosed because primary care physicians may be unaware of the manifestations of RLS and the impact these symptoms may have on patient quality of life. Identification of certain patient populations at risk for RLS may aid primary care physicians in recognizing and treating patients with RLS symptoms. In this study, the prevalence of RLS was evaluated in patients with IBS.

Innovations and breakthroughs

The results suggest that RLS is a common comorbid condition in patients with IBS, particularly in patients with diarrhea-predominant IBS. In addition, patients with RLS and IBS had sleep disturbances unrelated to RLS, suggesting that IBS may be a contributing factor in sleep disorders in general.

Applications

Based on these results, primary care physicians treating patients with IBS should be cognizant of patient reports of trouble sleeping and conditions that may be associated with poor sleep, such as difficulty concentrating. Furthermore, given the association of RLS with inflammatory gastrointestinal disorders including IBS, treatment and resolution of such disorders may be beneficial for patients with RLS.

Peer review

This is a straight-forward and well-written paper describing the association of RLS with IBS, in particular diarrhea-predominant IBS.

Abstract

AIM: To compare narrow-band imaging (NBI) without image magnification, and chromoendoscopy with Lugol's solution for detecting high-grade dysplasia and intramucosal esophageal squamous cell carcinoma (SCC) in patients with head and neck cancer.

METHODS: This was a prospective observational study of 129 patients with primary head and neck tumors consecutively referred to the Gastrointestinal Endoscopy Unit of Hospital das Clínicas, São Paulo University Medical School, Brazil, between August 2006 and February 2007. Conventional examinations with NBI and Lugol chromoendoscopy were consecutively performed, and the discovered lesions were mapped, recorded and sent for biopsy. The results of the three methods were compared regarding sensitivity, specificity, accuracy, positive predictive value, negative predictive value, positive likelihood value and negative likelihood value.

RESULTS: Of the 129 patients, nine (7%) were diagnosed with SCC, 5 of which were *in situ* and 4 which were intramucosal. All carcinomas were detected through NBI and Lugol chromoendoscopy. Only 4 le-

sions were diagnosed through conventional examination, all of which were larger than 10 mm.

CONCLUSION: NBI technology with optical filters has high sensitivity and high negative predictive value for detecting superficial esophageal SCC, and produces results comparable to those obtained with 2.5% Lugol chromoendoscopy.

INTRODUCTION

In recent studies, narrow-band imaging (NBI) technology was found to be useful for detecting squamous cell carcinomas (SCC) of the pharynx and esophagus. Morphologic patterns in the changes of intrapapillary capillary loops were found by Muto *et al*^[1], Arima *et al*^[2] and Yoshida *et al*^[3], and can be useful for diagnosing SCC and even predicting the extent of this type of lesion. Accordingly, various reports on early-stage pharyngeal and esophageal SCC diagnosed through the use of NBI technology can be found in the literature. A small, su-

perforated SCC of the pharynx with a small, well-defined brown area was diagnosed by Muto *et al.*⁴¹, without the use of magnification. Using NBI technology without image magnification, Watanabe *et al.*⁴¹, in a prospective study, found six pharyngeal squamous cell carcinomas and Goda *et al.*⁵¹ found an esophageal SCC not identified by conventional endoscopy (obscure lesion).

Despite encouraging results with this new technology, esophageal Lugol staining remains the gold standard for detecting mucosal superficial neoplasias formed by glycogen-poor cells, including epidermoid carcinoma of the esophagus^{6,7}. Although Lugol staining is a simple and low-cost method, instillation of its solution may lead to complications, namely hypersensitivity to iodine, laryngitis, pneumonitis, as well as frequent painful sensations and nausea⁸⁻¹¹. A significant reduction in retrosternal discomfort was demonstrated by Kondo *et al.*¹¹ with the use of sodium thiosulphate costing \$0.15. However, Lugol's solution is not used in the pharynx or larynx. Therefore, the evaluation of alternative methods for "optical staining" such as NBI is desirable because these methods are potentially simpler, with no complications. The groups most likely to benefit from these methods are those at high risk of developing esophageal SCC, namely patients with malignant squamous cell neoplasias of the head and neck^{17,12-14}, because these patients routinely undergo endoscopic surveillance for this type of cancer.

The aim of this study was to compare NBI technology with Lugol staining during endoscopic examination of the esophagus for the detection of high-grade intraepithelial neoplasia and superficial SCC in this organ in patients with head and neck cancer.

MATERIALS AND METHODS

Patients and design

From August 2006 to February 2007, 136 consecutive patients with head and neck tumors were referred to the Gastrointestinal Endoscopy Unit of Hospital das Clínicas, São Paulo University Medical School, Brazil, for detection of esophageal SCC. Patients with head and neck SCC undergo annual upper gastrointestinal (GI) endoscopy and associated chromoendoscopy of the esophageal mucosa with Lugol's solution.

The inclusion criteria were indication of upper GI endoscopy examination for patients with head and neck SCC under surveillance for the detection of synchronous or metachronous lesions.

Exclusion criteria for patients were as follows: (1) clinical conditions precluding upper GI endoscopy examination and 2.0% Lugol staining; (2) **history of allergic reaction to iodine**; and (3) **diagnosis of esophageal neoplasia of advanced endoscopic appearance** defined as an ulcerated, infiltrative or stenotic lesion easily detected on conventional examination

All participants provided written informed consent. This study was approved by the Ethics Committee of the Gastroenterology Department of São Paulo University

Medical School, under research protocol No. 1083/06.

Endoscopy system

An Exera II Evis 180 GIF180 (Olympus, Tokyo, Japan) videoendoscope with high resolution (1080 dpi), 1.5-fold magnification and NBI technology was used. Examinations were performed conventionally under conscious sedation with midazolam and fentanyl chlorhydrate. A 2.0% Lugol's solution was used for staining. NBI and Lugol staining procedures were followed up by a single physician, and both methods were performed in one single procedure. First the organ was conventionally assessed with white light, and adhered residues or exudates were removed through potable water instillation. Assessment with NBI and 2.0% Lugol staining was subsequently performed. Upon mucosal analysis and biopsy, 0.5% sodium thiosulfate solution was instilled to remove the Lugol's solution from the mucosa to reduce spasm and pain. Therefore, the examination was divided into three phases. The first phase was the white light analysis, the second phase was the analysis of the mucosa with NBI, and the final phase was the assessment following Lugol staining. At the end of each phase, changes were documented in dynamic and static images and mapped using the anterior, posterior, and right and left lateral walls of the organ and the distance of the lesion from the anterior incisors as references. A biopsy was always performed after staining was completed.

For patients with malignant or actinic stenosis of the pharyngeal-esophageal tract, a smaller-diameter endoscope, GIF 180N model (Olympus, Tokyo, Japan), with a 4.9-mm caliber and 2.1-mm biopsy channel was used. Some of the possible complications resulting from Lugol's solution, such as laryngitis, chemical pneumonitis, hypersensitivity, and anaphylactic shock were registered.

When NBI was used, brown-stained areas of the mucosa were considered lesions suspected to be neoplasia (compared to "normal" mucosa, which is green independently of changes in surface or vascular texture). As for the Lugol dye solution, areas clearly not stained were suspected to be neoplasia, which is characterized by a white color in contrast with brown or brownish "normal" areas. The size and macroscopic shape were evaluated according to the Paris Classification¹⁵ for superficial esophageal lesions and their topography (cervical up to 5 cm of cricopharyngeal, thoracic and abdominal esophagus).

Histology

Histopathology was performed by a senior pathologist from the Department of Pathology of Hospital das Clínicas, São Paulo. The pathologist was aware of the endoscopic suspicion of esophageal SCC. Biopsy specimens were immersed in formaldehyde for fixation and stained using hematoxylin and eosin. The lesions were classified according to the Revised Vienna Classification. In the absence of lamina propria invasion, noninvasive neoplastic lesions were divided into two groups based on the degree of intraepithelial neoplasia: low grade and high grade.

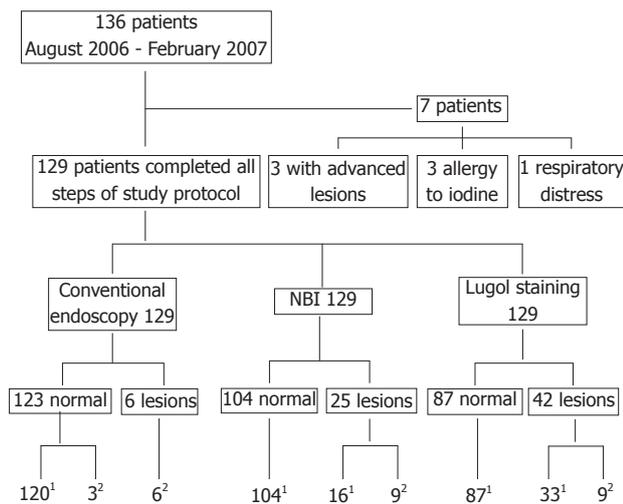

Figure 1 Flow chart of the study protocol. ¹Total patients without squamous cell carcinoma (SCC) ($n = 120$), ²Total of patients with SCC ($n = 9$). NBI: Narrow band imaging.

High-grade dysplasia, intraepithelial carcinoma and carcinoma *in situ* were considered equivalent entities^[15]. Whenever the lamina propria of the mucosa was invaded, the lesion was referred to as a microinvasive or intramucosal carcinoma.

In this study, only the findings of high-grade intraepithelial neoplasia (carcinoma *in situ*) and intramucosal carcinoma of squamous cells were considered true-positives for esophageal epidermoid carcinoma^[15].

Statistical analysis

Values were calculated for sensitivity, specificity, positive predictive value, negative predictive value, accuracy, positive and negative likelihood ratio, and their respective 95% confidence intervals (CIs).

RESULTS

Of the 136 patients, three were excluded as they had malignant esophageal lesions that were easily detected by conventional endoscopy, three as they had a prior history of allergy to iodine, and one had respiratory distress that prevented Lugol staining. Of the remaining 129 patients, there were 103 males and 26 females, aged 33 to 89 years (mean, 59 years).

One hundred and twenty-nine patients underwent all stages of the protocol of investigation for this study (Figure 1). For 42 patients in whom lesions were detected by NBI or Lugol dye, 9 (24.5%) proved to have esophageal neoplasias (four intramucosal neoplasias and five carcinomas *in situ*), and the remaining 33 patients exhibiting unstained lesions with Lugol’s solution had inflammatory disease only (Table 1).

Macroscopic classification, size, location, and histopathologic findings of the samples of the endoscopic or surgical resection are presented in Table 2. All carcinomas were found in the thoracic esophagus. The incidence was

4% for females and 8% for males.

Conventional endoscopy was able to identify most of the 10 mm lesions, and the sensitivity was 85.7% (95% CI, 59.8%-100%). However, this method failed in the diagnosis of smaller lesions (< 10 mm), where the sensitivity was 0%.

The performance of NBI was similar to that obtained by Lugol staining. Sensitivity and negative predictive value were 100% for both methods, and the specificity was 86.7% for NBI (95% CI, 80.6%-92.7%) and 72.5% (95% CI, 64.5%-80.5%) for Lugol’s solution.

Diagnostic performances for conventional endoscopic examinations, NBI and Lugol staining are presented in Table 3, and the performance results by lesion size are presented in Table 4.

Table 4 Comparison of diagnostic performance of the three procedures for lesions < 10 mm and > 10 mm (%)

Figure 2 Sequential endoscopic images of the esophagus. A: Lesion type 0 IIc; B: Narrow-band imaging image; C: After Lugol staining.

In the Lugol's solution group, there were 3 cases of chemical laryngitis and one of hypersensitivity to iodine (3% complication rate). No complications were reported with the conventional or NBI procedures.

DISCUSSION

Upper GI endoscopy with Lugol's solution staining is still considered the best method for tracking, diagnosing and delimiting superficial neoplasias of the esophagus^[16-18]. From 1965 to 1984, no intraepithelial and/or intramucosal lesion was diagnosed in the University Hospital of Kyushu, Japan^[19]. These lesions have only been observed since 1985, when Lugol's solution was initially used routinely for endoscopic evaluation of the mucosal surface. From 1985 to 1988, Sugimachi *et al*^[19] reported an increase in the number of patients with early stages of the disease receiving surgical treatment, ranging from 7% to 23% of patients undergoing surgical treatment. The results for the surgical treatment of esophageal-thoracic SCC in two major referral centers in Japan and China were compared by Fang *et al*^[20], and demonstrated a 2-year survival rate of 70.9% in Japan *vs* 56.2% in China. According to these authors, the use of Lugol chromoendoscopy to detect early lesions could explain the better results obtained at the Japanese center.

Lugol chromoendoscopy also proved useful for the detection of early esophageal SCC in patients with head

and neck cancer, a recognized high-risk group for the disease. In more than half of the head and neck cancer patients exhibiting the minimal mucosal changes associated with a lack of iodine impregnation (negative Lugol staining area), biopsies confirmed the presence of malignant neoplasia (sensitivity of 81.96% *vs* 59.1% when only the negative Lugol staining area was evaluated separately). Furthermore, no cases of neoplasia in normally-stained areas were found by Hashimoto *et al*^[7].

However, Lugol's solution irritates the mucosa and may lead to retrosternal chest pain and discomfort because of its alcoholic nature. Its use is limited by other factors, namely hypersensitivity to iodine and the risks of chemical esophagitis, laryngitis and bronchopneumonia. Several authors have reported necrosis and injury to esophageal and gastric mucosa caused by hypersensitivity to Lugol's solution^[8-10,12]. Furthermore, Lugol chromoendoscopy significantly increases the examination period^[11].

Slightly over 50% of early lesions are detected on conventional endoscopy, and the use of Lugol staining is still restricted to patients considered at high risk of developing this neoplasia. Furthermore, because of the previously mentioned risks and difficulties, a large portion of the population does not have access to efficient and safe examinations for the detection of early lesions, including those that are locally resectable. NBI does not have the limitations of Lugol chromoendoscopy and should therefore be considered as a replacement if it is equally

efficient in detecting esophageal SCC.

A few studies have evaluated the capacity of NBI without the use of image magnification for detecting esophageal SCC. A 2-fold capacity for detecting pharyngeal SCC compared with conventional white-light evaluation was found by Watanabe *et al*^[4]. In a multicenter study comparing the evaluation by narrow-band technology *vs* conventional white-light evaluation, the accuracies were 90.2% and 55.3%, respectively, ($P < 0.0001$)^[22]. Comparing Lugol chromoendoscopy to NBI technology with image magnification, equal results were found in the sensitivity of the two methods (92.3% *vs* 92.3%), but NBI had a better specificity (91.7% *vs* 72.2%)^[24].

The present study compared use of NBI technology with Lugol chromoendoscopy (a method considered the gold standard) for the detection of esophageal epidermoid carcinoma. This study was conducted in patients with head and neck cancer and without the use of image magnification. Many medical services do not have the resources for magnification; therefore, the aim of this study was to analyze whether NBI alone would suffice to detect small, superficial neoplasias of the esophagus. Of nine esophageal neoplasias, conventional white light could not detect three neoplasias, whereas both NBI and Lugol chromoendoscopy detected all neoplasias. The elevated likelihood ratio certifies the equivalence and high sensitivity of both methods. On the other hand, NBI esophagoscopy without image magnification, similar to Lugol chromoendoscopy, has a lower specificity for detecting early squamous cell neoplasias in the esophagus. Although Ponchon *et al*^[25] reported a 75% specificity for NBI, this may have been related to false detection of nonspecific inflammation. In two recent studies by Takenaka *et al*^[26] and Lee *et al*^[27], similar results were found: the sensitivity of NBI endoscopy for detecting esophageal SCC and high-grade intraepithelial neoplasia was 90.9% (95% CI, 58.7%-99.8%), specificity was 95.4% (95% CI, 90.3%-98.3%), and accuracy was 95.1% (95% CI, 90.1%-98.0%). Recently, transnasal endoscopy with NBI and Lugol staining were employed to screen patients with head and neck cancer whose condition prevented oral intubation with a standard endoscope and, as in our study, NBI and Lugol staining had the same sensitivity (88.9%) for the detection of high-grade mucosal lesions and performed far better than standard endoscopy (27.3% sensitivity)^[26,27]. The equivalent performance of NBI esophagoscopy and Lugol chromoendoscopy indicate that NBI esophagoscopy, without image magnification, is a potential surveillance method for patients at risk of esophageal squamous cell neoplasia. Therefore, this technology should be tested in other groups that are at risk of SCC (e.g., chronic corrosive esophagitis patients, tobacco smokers and alcohol users), and should be compared to Lugol chromoendoscopy.

The current study has some limitations. First, a sequential approach was adopted in which, in order, standard endoscopy, NBI and Lugol staining were employed by the same operator. This approach has the potential

bias of the same operator entering an examination phase having already detected any lesion in the prior phase. However, the sequential approach seems to be the best strategy for daily practice. Furthermore, the same methodology was used in similar studies^[22-25].

In conclusion, narrow-band technology with optical filters has a high sensitivity and high negative predictive value for detecting superficial squamous cell carcinomas of the esophagus (intramucosal carcinoma and carcinoma *in situ*). These results are comparable to those obtained with 2.5% Lugol chromoendoscopy but without the risks and technical difficulties related to this method. NBI could replace Lugol chromoendoscopy as a screening tool for detecting esophageal squamous cell carcinoma in patients with head and neck cancer.

COMMENTS

Background

Squamous cell carcinoma (SCC) of the esophagus is aggressive with high mortality. Early diagnosis has a major impact on survival and treatment costs. Narrow-band imaging (NBI) technology without magnification is simple to use and increases the rate of diagnosis of early lesions.

Research frontiers

In this study, the authors showed that NBI without magnification can replace Lugol staining in early diagnosis of lesions of the esophagus SCC.

Innovations and breakthroughs

The device used in Japanese studies are different from those used in Western countries (Lucera system), and led to the first use of NBI technology without magnification in detection of SCC of the esophagus.

Applications

NBI technology is easy to learn and use, increasing the diagnosis rate of early lesions in patients considered at risk of SCC.

Peer review

This is an interesting study comparing NBI to Lugo's staining and white light endoscopy for detection of early esophageal cancer in a Brazil medical center over 6 mo involving 129 patients. This study evaluated the usefulness of NBI in daily practice for screening of esophageal cancer. The study shows NBI is as effective as Lugol's chromoendoscopy for detecting early esophageal cancer.

Abstract

AIM: To evaluate the efficacy of L-carnitine on alleviating anemia, thrombocytopenia and leukopenia, and minimizing dose reductions in patients with chronic hepatitis C virus (HCV) in treatment with Interferon α (IFN- α) plus ribavirin.

METHODS: Sixty-nine patients with chronic hepatitis C were enrolled in the study and divided into two groups. group A ($n = 35$) received Peg-IFN- α 2b plus ribavirin plus L-carnitine, and group B ($n = 34$) received Peg-IFN- α and ribavirin for 12 mo. All patients underwent laboratory investigations including: red cell count, hemoglobin, white cell count, platelets, bilirubin, alanine

aminotransferase (ALT), aspartate aminotransferase (AST), and viremia.

RESULTS: After 12 mo in group A compared to group B we observed significant differences in AST 108.8 vs 76.8 (IU/L; $P < 0.001$), ALT 137.9 vs 112.3 (IU/L; $P < 0.001$), viremia 4.04 vs 2.36 ($\times 10^6$ copies/mL; $P < 0.001$), Hb 1 vs 3.5 (g/dL; $P < 0.05$), red blood cells 0.3 vs 1.1 ($\times 10^{12}$ /L; $P < 0.001$), white blood cells 1.5 vs 3 ($\times 10^9$ /L; $P < 0.001$) and platelets 86 vs 85 ($\times 10^9$ /L; $P < 0.001$). The end treatment responders were 18 vs 12 (60% vs 44%) and the non responders were 12 vs 15 (40% vs 50%) [odds ratio (OR) 1.65, 95% CI = 0.65-5.37, $P < 0.05$]. In group A compared to group B there was a significant improvement of sustained virological response in 15 vs 7 patients (50% vs 25%), while the relapsers were 3 vs 5 (10% vs 18%) (OR 3.57, 95% CI = 0.65-19.3, $P < 0.001$).

CONCLUSION: L-carnitine supplementations modulate erythropoiesis, leucopoiesis and thrombocytopoiesis, and may be useful in patients treated for HCV. L-carnitine treatment offers the possibility of achieving a sustained virological response while preventing overtreatment.

L-carnitine supplementation improves hematological pattern in patients affected by HCV treated with Peg interferon- α 2b plus ribavirin. *World J Gastroenterol* 2011; 17(39): 4414-4420 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i39/4414.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i39.4414>

INTRODUCTION

Interferon α (IFN- α), in combination with ribavirin (RBV) treatment, represents the most efficacious therapeutic tool in the management of chronic hepatitis C^[1,2]. The current standard of care results in successful outcomes in 70% of patients with hepatitis C virus (HCV) genotype 2 or 3 and in 48% of patients with HCV genotype 1. Systemic side effects such as fatigue, fever, chills, myalgia and nausea occur in most patients and normally disappear after a few weeks of treatment. Other side effects include hematologic, autoimmune, neurological and psychiatric disorders^[3-7]. The frequency of hematologic adverse events including thrombocytopenia, anemia and neutropenia is higher. A recent study^[5] reported anemia in 16%, thrombocytopenia in 20%, and leukopenia in 10% of Peg-IFN- α 2b plus RBV treated patients with HCV. These adverse events most frequently lead to drug discontinuation or to dose modifications. In our previous reports we have observed that L-carnitine improves responses and quality of life and reduces steatosis in patients with HCV treated with interferon^[8-10]. L-carnitine (4-N-trimethyl ammonium 3-hydroxybutyric acid) is a conditionally synthesized nutrient from the amino acids lysine and methionine in the human liver, brain and kidney, but is largely obtained from meat and dairy products. Administration of L-carnitine is an accepted treatment for mitochondrial myopathy and encephalomyopathy, as well as other states of primary and secondary L-carnitine deficiency^[11]. Recently, L-carnitine has been proposed as a potential adjuvant treatment to improve anemia, thrombocytopenia, leukopenia and immunological function^[12-17]. The aim of our study was to evaluate the efficacy of L-carnitine in alleviating anemia, thrombocytopenia and leukopenia, and minimizing dose reductions in patients with chronic hepatitis C virus in treatment with IFN- α plus RBV.

MATERIALS AND METHODS

Patients

Between January 2004 and December 2007, a total of 69 patients with chronic hepatitis (27 women and 42 men, mean age 48 years) aged 32-63 years (median 46 years), were consecutively enrolled in the study (Figure 1).

The patients had to fulfill the following inclusion criteria: alanine aminotransferase (ALT) levels greater than 1.5-fold higher than the upper limit of normal, the presence of anti-HCV antibodies in the serum, HCV-RNA > 1000 copies/mL, and histological modifications in the

liver biopsy. Exclusion criteria were: positive test for serum hepatitis B surface antigen, positive test for serum HIV antibodies, negative for HCV antibodies, alcoholic liver disease (daily alcohol consumptions < 20 g/d), and diabetes. The presence of other causes of hepatopathy, decompensated cirrhosis, pregnancy, and known contraindications for Peg-IFN- α or RBV therapy such as hemoglobinopathies, cardiopathy, hemochromatosis, diabetes mellitus, autoimmune diseases, major depression or other severe psychiatric pathological conditions were considered causes for ruling out.

Study design

The study was a prospective, randomized, open-label trial. Eligible patients were randomly assigned to one of the two study treatments in equal proportions by means of a computer-generated table of random numbers. They were divided into two groups (A and B) and they were stratified by HCV genotype (1 *vs* others) and the viremia. Group A received Peg-IFN- α 2b at a dose of 1.5 μ g/kg per week for 12 mo intramuscularly, plus daily oral RBV, plus L-carnitine 2 g twice a day. The dose of ribavirin was adjusted to body weight: 800 mg for body weight below 60 kg, 1000 mg when it was between 65 kg and 75 kg, and 1200 mg when it was above 75 kg. Group B received Peg-IFN- α and RBV at the same dosage, way and duration. Patients were evaluated before treatment, 6 mo and 12 mo after the initiation of the therapy. A follow up evaluation was performed 6-mo after the end of the planned treatment. A medical interview and a physical examination were realized for all patients included in the study before starting therapy. Guidelines for discontinuing, interrupting or decreasing the dose of study medication because of adverse events and hematologic or biochemical abnormalities were prespecified in the protocol. Study drug was reduced and discontinued when: hemoglobin values of < 10 g/dL and 8.5 g/dL, absolute neutrophil counts of $0.75 \times 10^9/L$ and $0.50 \times 10^9/L$, and platelet counts of < $50 \times 10^9/L$ and < $25 \times 10^9/L$ respectively. The study protocol was approved by the research ethics committee of Cannizzaro Hospital, Catania, Italy and was performed in accordance with the Declaration of Helsinki principles and the Good Clinical Practice Guidelines^[18].

Clinical laboratory tests

A complete routine chemistry (including red cell count, hemoglobin, white cell count, platelets prothrombin time, fasting plasma glucose, blood urea nitrogen, serum creatinine, bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, γ -glutamyl transpeptidase and creatine phosphokinase levels) was performed at every medical visit. Anti-HCV antibodies were evaluated by using second generation enzyme-linked immunosorbent assay ELISA (Ortho-Diagnostic Systems, Raritan NJ, United States) and positive samples were confirmed by immunoblotting (RIBA; Chiron Corporation, Emeryville, CA, United States). Serum HCV

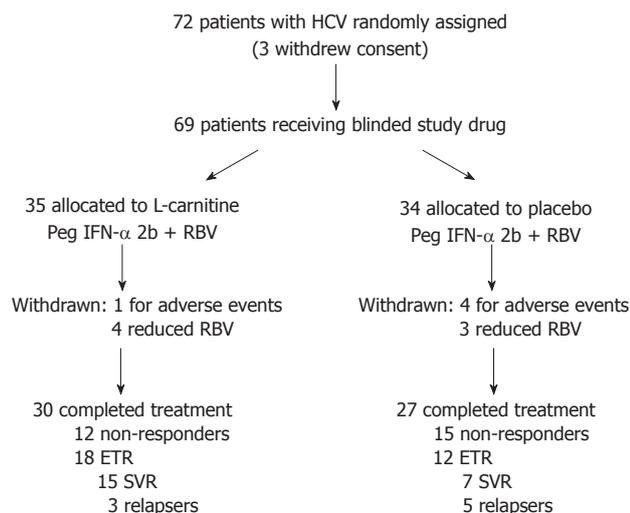

Figure 1 Trial profile of L-carnitine treatment. IFN- α : Interferon α ; HCV: Hepatitis C virus; RBV: Ribavirin; SVR: Sustained virological responders; ETR: End-of-treatment responders.

RNA levels were detected first time by standardized quantitative polymerase chain reaction (PCR) assay, with a lower limit of detection of 50 IU/mL. Then serum HCV RNA levels were measured by standardized quantitative PCR assay with a lower limit of detection of less than 1000 copies/mL, using the amplicor quantitative PCR system (Roche Diagnostic System Inc.-Branchburg, NJ, United States). HCV genotypes and subtypes were identified through a modification of the specific line probe assay (Inno-LiPA system; Innogenetics NV, Zwijnaarde, Belgium) as described by Stuyver *et al*^[19]. The HCV genotypes were designated according to the nomenclature proposed by Simmonds *et al*^[20].

Histology

Liver biopsy was realized in the 6 mo before the initiation of therapy and 6 mo after the end of treatment. It was obtained using a modified Menghini technique. The specimen was fixed in neutral formaldehyde 4% solution for routine histological processing and evaluation. The Knodell and Ishiak Histological activity index (HAI) score was used to assess the histological grading of the disease^[21].

Efficacy and safety assessment

All enrolled patients were included in the intention-to-treat efficacy analysis and patients who received at least one dose of IFN- α plus ribavirin were included in the safety analysis. Data were analyzed by an “intention-to-treat” principle. We considered patients as “sustained virological responders” (SVR) when they showed an undetectable HCV RNA (< 50 IU/mL) in serum at the end of the follow up period. Relapse was defined as undetectable HCV-RNA levels at the end of treatment, but detectable levels during the follow up period. Adverse events were assessed by interviews, laboratory examinations and clinical examinations during treatment. They were graded as mild, moderate and severe on the basis of the WHO score. The treatment was definitively stopped

Table 1 Characteristics of the subjects included in the study (mean \pm SD)

	¹ Group A (n = 35)	² Group B (n = 34)

There were not significant differences between groups. IFN- α : Interferon α ; HCV: Hepatitis C virus; BMI: Body mass index. ¹Group A: Peg IFN- α + RBV + L-carnitine; ²Group B: Peg IFN- α + RBV.

in the case of severe events, such as hematological toxicity, hepatic failure or no compliance. In moderate and mild cases of adverse effects, a dose reduction of 50% was performed, until the resolution of the event, when a full dose was restarted.

Statistical analysis

Means and standard deviations have been used to describe the distribution of continuous variables. Differences in response rates in the two study groups and histological findings between the initial and follow-up liver biopsy specimens were evaluated by paired *t* test. A *P* value < 0.05 was considered statistically significant.

RESULTS

Baseline characteristics

A total of 69 patients were included in the study (35 in the Peg-IFN- α plus RBV plus L-carnitine group and 34 in the Peg-IFN- α plus RBV group). Baseline demographic characteristics and histological findings in liver biopsy were similar between the two treatment groups.

The mean time since their chronic hepatitis C infection was comparable. The most frequent viral genotype in patients was 1b. Baseline viremia was parallel in the two groups (Table 1). No significant differences were assessed between the two groups for ALT, aspartate aminotransferase (AST) or fasting plasma glucose.

Effects of Peg-IFN- α plus RBV plus L-carnitine

Effects on biochemical pattern: After 6 and 12 mo and at follow up, we observed a significant decrease in AST (*P* < 0.001) and ALT (*P* < 0.001) levels.

Effects on viremia and histological grading of the disease: After 6 and 12 mo and at follow up viremia was significantly reduced (*P* < 0.001). HAI score was significantly reduced after 12 mo (*P* < 0.05).

Table 2 Laboratory parameters of subjects included in the study (mean \pm SD)

	¹ Group A (n = 35)		² Group B (n = 34)	
	Before treatment	After 12 mo	Before treatment	After 12 mo

Albumin (g/dL)	4.2 \pm 0.8	4.2 \pm 0.8	4.4 \pm 0.8	4.0 \pm 0.8 ^a
Viremia ($\times 10^6$ copies/mL)	5.44 \pm 3.12	1.4 \pm 1.1 ^{b,d}	5.32 \pm 3.21	2.96 \pm 1.9 ^{b,d}
HAI score	10.7 \pm 3.1	8.4 \pm 2.9 ^a	10.5 \pm 2.9	9.0 \pm 3.0 ^a
Hemoglobin (g/dL)	13.1 \pm 1.8	12.1 \pm 2.7 ^d	13.4 \pm 1.9	9.9 \pm 2.7 ^{b,d}
RBC ($\times 10^{12}$ /L)	4.7 \pm 0.4	4.4 \pm 0.7 ^{a,d}	4.9 \pm 0.6	3.8 \pm 0.7 ^{b,d}
WBC ($\times 10^9$ /L)	7.9 \pm 1.8	6.4 \pm 0.8 ^{b,d}	7.8 \pm 1.8	4.8 \pm 0.8 ^{b,d}
Platelets ($\times 10^9$ /L)	384 \pm 22	298 \pm 36 ^{b,d}	412 \pm 21	327 \pm 24 ^{b,d}

^a $P < 0.05$, ^b $P < 0.001$, comparison within group A and within group B according to the values before the treatment; ^d $P < 0.001$, groups A vs B after treatment. RBV: Ribavirin; HAI: Histological activity index; RBC: Red blood cells; WBC: White blood cells; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; IFN- α : Interferon α . ¹Group A: Peg IFN- α + RBV + L-carnitine; ²Group B: Peg IFN- α + RBV.

Effects on hematological pattern: After 6 mo red blood cells (RBCs), white blood cells (WBCs) and platelets were significantly reduced ($P < 0.001$); a significant decrease was also observed after 12 mo in RBCs ($P < 0.05$), WBCs ($P < 0.001$) and platelets ($P < 0.001$). At follow up, the decrease was observed only in platelets ($P < 0.001$).

Effects of Peg-IFN- α plus RBV

Effects on biochemical pattern: After 6 mo there was a significant decrease in albumin ($P < 0.05$). After 6 and 12 mo and at follow up we observed a significant decrease in AST ($P < 0.001$) and ALT ($P < 0.001$) levels.

Effects on viremia and histological grading of the disease: Viremia was significantly reduced after 6 mo ($P < 0.05$), after 12 mo ($P < 0.001$) and at the follow up ($P < 0.001$). The HAI score was significantly reduced after 12 mo ($P < 0.05$).

Effects on hematological pattern: After 6 and 12 mo and at follow up RBCs, WBCs and platelets were significantly reduced ($P < 0.001$).

Comparison between treatments

The comparison between the Peg-IFN- α plus RBV plus L-carnitine group and the Peg-IFN- α plus RBV group showed a significantly greater decrease after 6 mo in Hb 0.7 vs 2.8 (g/dL; $P < 0.05$), RBCs 0.5 vs 1 ($\times 10^{12}$ /L; $P < 0.001$), WBCs 0.9 vs 3.7 ($\times 10^9$ /L; $P < 0.001$) and platelets 82 vs 100 ($\times 10^9$ /L; $P < 0.001$). After 12 mo there were significant improvements in AST 108.8 vs 76.8 (IU/L; $P < 0.001$), ALT 137.9 vs 112.3 (IU/L; $P < 0.001$), viremia 4.04 vs 2.36 ($\times 10^6$ copies/mL; $P < 0.001$), Hb 1 vs 3.5 (g/dL; $P < 0.05$), RBCs 0.3 vs 1.1 ($\times 10^{12}$ /L; $P < 0.001$), WBCs 1.5 vs 3 ($\times 10^9$ /L; $P < 0.001$) and platelets 86 vs 85 ($\times 10^9$ /L; $P < 0.001$). At the end of the follow up, the results confirmed the improvements in AST 90.9 vs 69.6 (IU/L; $P < 0.001$), ALT 125.3 vs 101.9 (IU/L; $P < 0.001$), viremia 3.64 vs 2.34 ($\times 10^6$ copies/mL; $P < 0.001$), Hb 0.3 vs 2 (g/dL; $P < 0.05$), RBCs 0.1 vs 0.8 ($\times 10^{12}$ /L; $P < 0.001$), WBCs 0.3 vs 2.3 ($\times 10^9$ /L; $P < 0.001$)

and platelets 68 vs 56 ($\times 10^9$ /L; $P < 0.001$) (Table 2). The end treatment responders were 18 vs 12 (60% vs 44%) and the non responders were 12 vs 15 (40% vs 50%) (OR 1.65; 95% CI = 0.65-5.37; $P < 0.05$). When comparing the Peg-IFN- α plus RBV plus L-carnitine group and the Peg-IFN- α plus RBV group we observed a significant improvement of SVR in 15 vs 7 patients (50% vs 25%), while the relapsers were 3 vs 5 (10% vs 18%) (OR 3.57; 95% CI = 0.65-19.3; $P < 0.001$).

Adverse events

No serious adverse events (WHO grade 3 or 4) have been reported in the two groups. Five patients of the Peg-IFN- α 2b plus RBV treated group and 2 of the other group showed mild psychological disorders such as anxiety, irritability and depression. Furthermore, other side effects registered in both groups were anorexia (12% in Peg-IFN- α 2b plus RBV patients vs 18% in Peg-IFN- α 2b plus RBV plus L-carnitine), nausea (20% vs 21% respectively), weight loss (14% vs 5%), headaches (44% vs 40%), fatigue (44% vs 25%), myalgia (30% vs 20%), musculoskeletal pain (30% vs 22%), irritability (18% vs 16%), hypertriglyceridemia (34% vs 18%), hypercholesterolemia (24% vs 8%), and hyperglycemia (12% vs 4%). Median Hb concentration significantly falls during the first 3 mo of treatment in the Peg-IFN- α 2b plus RBV group, but remained stable in the Peg-IFN- α 2b plus RBV plus L-carnitine group. The patients treated with Peg-IFN- α 2b plus RBV plus L-carnitine experienced a fall in median hemoglobin concentration from 13.1 g/dL (range 11.8-14.0 g/dL) to 12.1 (range 11.2-14.0 g/dL) at the end of therapy. The patients treated with Peg-IFN- α 2b plus RBV experienced a fall in median hemoglobin concentration from 13.4 g/dL (range 11.4-15.1) to 9.9 g/dL (range 9.1-12.4 g/dL) at the end of therapy. In the Peg-IFN- α 2b plus RBV plus L-carnitine group, 30 patients showed good adherence to their medication and duration of therapy, 2 reduced RBV dose to 1000 mg; 2 reduced RBV dose to 800 mg; and 1 dropped out from the treatment due to headaches. In the Peg-IFN- α 2b plus RBV group, 23 patients showed good adherence to their medication

and duration of therapy; 3 reduced RBV dose to 800 mg; 4 dropped out from the treatment for anemia; 2 reduced RBV dose to 1000 mg; and 2 dropped out from the treatment due to leukopenia.

DISCUSSION

The primary goal of treatment for chronic HCV infection is a sustained virological response. However, a substantial proportion of patients do not have an optimum response to current treatment regimens^[22]. In our study, when comparing the Peg-IFN- α plus RBV plus L-carnitine group versus the Peg-IFN- α plus RBV group we observed a significant improvement of sustained virological response in 50% *vs* 25% of patients. L-carnitine is a necessary nutrient factor in energy production and its deficiency is known to decrease energy availability in vital organs. The carnitine content decreases when endogenous synthesis becomes insufficient, and under such conditions carnitine has been beneficial in restoring the level to normalcy^[23]. L-carnitine is a natural constituent of higher organisms, in particular cells of animal origin, and its deficiency is usually associated with a failure to thrive or due to recurrent infections^[24]. L-carnitine is also reported to inhibit apoptosis and improve the function of the bone marrow progenitors by increasing the number of colony forming units^[25]. In patients treated with a placebo, we observed a significant decrease in Hb, in RBCs, in WBCs and in platelets after 6 and 12 mo and at the end of follow up. Decreased Hb levels represent a common side effect of the IFN- α and RBV combination, or the pegylated IFN- α (Peg IFN- α) and RBV combination used to treat HCV infection, with 29% to 36% of treated patients developing anemia. In a recent study, 54% of patients on this regimen experienced Hb decreases of 3g/dL or more from pre-treatment levels^[26,27]. In a large clinical trial^[28] anemia (defined as Hb < 12 g/dL) resulted in a RBV dose reduction in 22% of patients and, in a community-based setting, anemia resulted in the discontinuation of therapy in 36% of patients. In 3070 patients with HCV genotype 1 treated with RBV plus IFN 2a or 2b the RBV dose was reduced owing to an adverse event in 30.2%^[29]. Between 2.1% and 3.8% of patients met the discontinuation criterion^[29]. Anemia might become evident in the first several weeks of RBV therapy and might continue for the duration of combination therapy^[30,31]. Anemia is a common complication associated with RBV, by both a decrease in erythrocyte precursor production and reduced survival of red blood cells^[32]. In our study we observed a significantly greater decrease in hemoglobin and red blood cells in the Peg-IFN- α plus RBV group than the Peg-IFN- α plus RBV plus L-carnitine group^[33]. In thalassemic patients, El-Beshlawy *et al*^[34] observed a significant increase in blood transfusion interval after L-carnitine therapy. This was previously reported and can be explained by the protective effect of L-carnitine on the red blood cells from oxidative stress and the stabilization to their membranes where latent peroxidative damage has occurred^[35,36]. The

autoxidation of globin chains and iron overload were the suggested mechanisms for the increased oxidative stress. The counteracting effect of antioxidants on lipid peroxidation and their protective effect against oxidative damage of erythrocytes in β -thalassemia were demonstrated^[37]. It has been suggested that L-carnitine may act via stabilization of the red blood cell membrane, thereby increasing the erythrocyte^[38]. Relationships between L-carnitine and erythrocyte osmotic fragility, deformability and membrane fluidity have been demonstrated^[39,40]. Alternatively, the beneficial effects on anemia may be a result of a reduction in lipid peroxidation^[41]. The results of our study showed a greater decrease in white blood cells in the Peg-IFN- α plus RBV group compared to the Peg-IFN- α plus RBV plus L-carnitine group. In 3070 patients with HCV genotype 1, the proportion of patients with neutropenia who met the criterion for Peg IFN dose reduction were: 21.1% receiving Peg IFN- α 2a, 19.4% receiving standard dose Peg IFN- α 2b, and 12.5% receiving low dose Peg IFN- α 2b. Between 2.1 and 5.9% of patients met the discontinuation criterion based on neutropenia^[29]. L-carnitine is known to improve neutrophil and macrophage functions, such as chemotaxis and phagocytosis in aged rats, at lower concentrations^[16]. Sener *et al*^[42] suggested that this compound inhibited leukocyte apoptosis possibly through its free radical scavenging and antioxidant properties. The increase in neutrophil functions, observed after L-carnitine treatment may be attributed to the ability of L-carnitine to increase the activities of glucose-6-phosphate dehydrogenase and myeloperoxidase by L-carnitine^[23]. Moreover, preservation of membrane integrity is a vital phenomenon for efficient phagocytosis as well as chemotaxis. The increase in neutrophil functions and organ cell counts observed in aged animals after L-carnitine treatment may also be related to the property of L-carnitine to preserve membrane integrity. L-carnitine is well known to exhibit membrane modulatory effects and thereby preserve cellular membrane integrity^[43]. In a recent study, Poynard *et al*^[6] reported thrombocytopenia in 20% of HCV patients treated with Peg-IFN- α plus RBV. The results of our study showed a significantly greater decrease in platelet count in the Peg-IFN- α plus RBV group compared to the Peg-IFN- α plus RBV plus L-carnitine group. Some studies indicate that L-carnitine modulates platelet functions and production^[44,46]. L-carnitine acts by reacting with fatty acids and this mechanism may affect the biological function of cells. Pignatelli *et al*^[47] showed that carnitine affects arachidonic acid metabolism and, in turn, blood platelet functions. *In vitro* studies by Saluk-Juszczak *et al*^[17] demonstrated that L-carnitine may modulate platelet activation through antioxidant mechanisms and the inhibition of the arachidonic acid cascade. Arachidonic acid has a key role in the activation of blood platelets and in the formation of free radicals via the stimulation of NADPH oxidase in these cells. L-carnitine interfering with arachidonic acid metabolism has a direct effect on platelet activation and oxidative stress. L-carnitine inhibits platelet superoxide anion formation elicited

by arachidonic acid and collagen, but it has no effect on thrombin-induced platelet aggregation^[47,48]. The well established beneficial effects of L-carnitine (including modulation of cell energy production, fat metabolism, erythropoiesis, leucopoiesis and thrombocytopoiesis) strongly suggests that supplementation of these nutrients may be useful in patients treated for HCV even if our study was conducted on a relatively small sample size. L-carnitine treatment offers the possibility of tailoring treatment to patients and selecting the treatment duration that ensures the best chance of achieving a SVR while preventing overtreatment.

COMMENTS

Background

Interferon α (IFN- α), in combination with ribavirin (RBV), represents the most efficacious therapeutic tool in the management of chronic hepatitis C, but the frequency of hematologic adverse events including thrombocytopenia, anemia and neutropenia during treatment is high. These adverse events most frequently lead to drug discontinuation or to dose modifications.

Research frontiers

Recently L-carnitine has been proposed as a potential adjuvant treatment to improve anemia, thrombocytopenia, leukopenia and immunological function. L-carnitine is also reported to inhibit apoptosis and improve the function of the bone marrow progenitors by increasing the number of colony forming units.

Innovations and breakthroughs

The study showed a significantly greater decrease in platelets, and red and white cells in the Peg-IFN- α plus RBV group compared to the Peg-IFN- α plus RBV plus L-carnitine group. L-carnitine treatment may offer the possibility of tailoring treatment to patients and selecting the treatment duration that ensures the best chance of achieving a sustained virological response while preventing overtreatment.

Applications

The well established beneficial effects of L-carnitine, including modulation of cell energy production, fat metabolism, erythropoiesis, leucopoiesis and thrombocytopoiesis strongly suggested that supplementation of these nutrients may be useful in patients treated for HCV.

Peer review

Although being small in sample number, this is a sound clinical trial with promising results. This is a straight and well conducted investigation. The manuscript is well written.

Abstract

AIM: To clarify the similarities and differences in gastric cancer epidemiology between Japan and China.

METHODS: A comprehensive literature search of the PubMed database was performed. The relevant literature published in China was also been cited. Data on incidence and mortality rates in 2008 were obtained from the Cancer Mondial database, published by International Agency for Research on Cancer at <http://www-dep.iarc.fr/>.

RESULTS: Gastric cancer remains a significant public

health burden in both Japan and China. The prevalence of *Helicobacter pylori* (*H. pylori*) colonization is high in the adult populations of both countries. Accumulating evidence from intervention studies in both countries has shown the effectiveness of *H. pylori* eradication in reducing gastric cancer incidence. There are differences, however, in many aspects of gastric cancer, including patterns of incidence and mortality, trends in the prevalence of *H. pylori* infection, *H. pylori* strains, the magnitude of risk of gastric cancer related to *H. pylori* infection, and associations with dietary habits. Compared with China, Japan has seen a more rapid decline in *H. pylori* infection among adolescents. While Japanese cohort studies have dominated the literature concerning the associations between gastric cancer and dietary habits, numerous case-control studies in China suggest a positive association between a high intake of preserved fish and vegetables and gastric cancer risk. There is a need for a multidisciplinary research approach to understand the interactions between various strains of *H. pylori*, host factors, and other lifestyle and environmental factors in gastric carcinogenesis in both countries.

CONCLUSION: The shared high incidence of gastric cancer and high prevalence of *H. pylori*, as well as differences in many aspects of gastric cancer, provide an excellent opportunity to establish Sino-Japanese collaborations.

INTRODUCTION

Gastric cancer is a heterogeneous, multifactorial disease. The incidence and mortality vary geographically, with the highest rates in East Asia (Japan, China and Korea)^[1]. Although a trend of declining incidence has been observed in Japan and China, gastric cancer still represents a tremendous burden in each country. According to the vital statistics released by the Ministry of Health, Welfare and Labor in Japan, approximately 50 000 Japanese men and women die from gastric cancer annually, representing approximately 15% of annual cancer-related deaths over the past four decades^[2]. No systematic national vital statistics exist in China, but a retrospective sampling survey on malignant tumors from 2004 to 2005 found that the mortality rate from gastric cancer ranked third in overall cancer mortality^[3]. Notably, China alone accounts for 42% of all gastric cancer cases worldwide, at least in part because of its large population^[1].

Numerous epidemiologic studies have been conducted in Japan and China to identify environmental and lifestyle factors that contribute to the development of gastric cancer; these studies have identified *Helicobacter pylori* (*H. pylori*) infection as an important risk factor for gastric cancer^[4]. Additionally, high salt intake and exposure to *N*-nitroso compounds significantly increase the risk among *H. pylori* infected individuals^[5]. It is noteworthy that Japan has a strong tradition of gastric cancer research, not only in basic science but also in epidemiology and clinical trials. Seminal papers published during the last three decades have greatly contributed to our understanding of gastric cancer etiology and prevention^[6-9]. However, an increasing number of case-control studies in different regions of China have examined risk factors for gastric cancer, and cohort studies are ongoing to investigate the role of lifestyle in urban and rural areas^[10-12].

In this article, we first summarize the current understanding of gastric cancer etiology on the basis of existing literature. We then compare the burden of gastric cancer between Japan and China in terms of trends in incidence and mortality. Next, we address three of the principal risk factors, based on epidemiologic studies conducted in each country: *H. pylori* infection, cigarette smoking and diet. Finally, we propose three potential avenues for Sino-Japanese collaboration.

MATERIALS AND METHODS

We performed a comprehensive literature search of the

PubMed database using the search terms “risk factors”, “*H. pylori*”, “smoking”, “diet”, “gastric cancer”, “China”, and “Japan”. In addition, relevant literature published in China was also cited. Data on incidence and mortality in 2008 were obtained from the Cancer Mondial database, published by International Agency for Research on Cancer (IARC) at <http://www-dep.iarc.fr/>.

RESULTS

Current knowledge about gastric carcinogenesis

Gastric cancer is a multifactorial disease with a complex interplay between genetics and both lifestyle and environmental factors. Gastric cancer can be classified as intestinal or diffuse. While the triggering factor and the histopathologic changes in the progression of diffuse gastric cancer remain incompletely understood, the progression of intestinal gastric cancer is well characterized^[13]. An individual develops intestinal cancer through a series of histological changes beginning with the transition from normal mucosa to chronic superficial gastritis, which then leads to atrophic gastritis, intestinal metaplasia, and finally dysplasia and adenocarcinoma^[13]. Before the discovery of *H. pylori* in 1983, epidemiologic studies had already suggested an important role for lifestyle in the etiology of gastric cancer. In particular, a high-salt diet and foods rich in *N*-nitroso compounds appeared to be major inducers of gastric cancer. Since the discovery of *H. pylori*, its close association with peptic ulcers and gastric cancer has been supported by numerous studies. Asia-Pacific consensus guidelines on gastric cancer prevention define *H. pylori* infection as necessary but not sufficient for the development of non-cardia gastric adenocarcinoma^[4]. From an epidemiologic perspective, the synergistic interaction between *H. pylori* and diet plays an overriding role in gastric carcinogenesis^[14].

However, current studies have not provided a clear answer as to why only a minority of individuals with *H. pylori* infection develop gastric cancer. One reason is that the interactions of *H. pylori* strains, host factors, and other lifestyle and environmental factors in gastric carcinogenesis are not well defined. Another reason is that few causally linked genes have been found, and the role of genetic and epigenetic changes in gastric carcinogenesis is poorly understood. These two issues need to be addressed in future studies.

Descriptive epidemiology of gastric cancer in Japan and China

Patterns of gastric cancer incidence, mortality and trends: According to Globocan 2008, gastric cancer is the third most frequently diagnosed cancer and the second leading cause of cancer deaths in Japan, with an estimated 102 040 new cases and 50 156 cancer deaths in 2008. The overall estimated age-adjusted incidence rate (standardized for world population) in 2008 was 31.1 per 100 000 people. However, gastric cancer is the second most frequently diagnosed cancer and the third lead-

Table 1 Comparisons of crude and age-standardized incidence rates of gastric cancer between Japan and China (1993-1997)

	Men		Women	
	Crude	ASR	Crude	ASR
Japan				
Hiroshima	113.1	85.5	55.1	33.9
Miyagi	109.2	69	52.2	27.1
Nagasaki	119.9	65.4	56.5	25.6
Osaka	87.7	59.9	42.9	23.8

Wuhan	29.3	29.8	17.1	14.5

Source: Cancer incidence in five continents Vol. VIII, IARC scientific publications No. 155. ASR: Age standardized rate, per 100 000 population.

ing cause of cancer death in China, with an estimated 464 439 new cases and 352 315 cancer deaths in 2008. The overall estimated age-adjusted incidence rate in 2008 was 29.9 per 100 000 people in China.

Although China's overall incidence rate is comparable to that of Japan, a wider variation in both crude and age-standardized rates is apparent when cancer registry data (1993-1997) from the 2 countries are compared (Table 1). For example, the incidence in Changle was 145 per 100 000 people, approximately 7 times higher than in Beijing. The highest rates were often found in economically undeveloped rural areas in China, including Gansu, Henan, Hebei, Shanxi, and Shaanxi Provinces^[15]. Although gastric cancer incidence is declining in both rural and urban areas in China^[16-18], the rate of decline may be slower than in developed countries^[19]. The number of new gastric cancer cases has been projected to increase continuously over the next 40 years because of population growth and aging^[19].

Risk factors for gastric cancer in Japan and China

From the large body of literature on gastric cancer etiology in Japan and China, we cite selected epidemiologic studies conducted in each country. Three major risk factors, namely *H. pylori* infection, cigarette smoking and high intake of salt/salty food, are addressed in detail.

H. pylori colonization: Prevalence of *H. pylori* colonization in the general population

Japan: Gastric *H. pylori* infection is common among middle-aged and elderly Japanese people. A seroepidemiological study of *H. pylori* infection among apparently healthy residents of Sapporo found a prevalence of 70%-80% for individuals born before 1950^[20]. For those residents born after 1950, the frequency of *H. pylori* in-

fection increased at approximately 1% per birth year^[20]. The prevalence of *H. pylori* infection, however, has been decreasing over the past several decades. The overall *H. pylori* seropositivity was 72.7% in 1974, 54.6% in 1984, and 39.3% in 1994, based on an assay of serum samples from 1015 healthy people living in several prefectures in central Japan^[21]. As in other developed countries, a clear birth cohort effect has been observed for *H. pylori* infection in Japan, with younger generations experiencing a more rapid decline than older generations^[22,23]. In a 2007 study involving 777 university students with a mean age of 19.6 years, *H. pylori* prevalence was only 14.7%^[24].

China: The Chinese population has a high prevalence of *H. pylori* infection. A 2003 meta-analysis, based on studies published between 1990 and 2002, concluded that the prevalence of *H. pylori* infection for the entire Chinese population was approximately 58%^[25]. Since 2003, numerous studies have also been conducted to examine the prevalence of *H. pylori* in healthy people in different regions of China, with reported prevalence ranging from 40% to 81%^[26-29]. Generally, studies in rural areas found a higher prevalence of *H. pylori* than studies in urban areas. Furthermore, areas with high gastric cancer incidence generally have a higher prevalence of *H. pylori* infection than low-incidence areas.

Because *H. pylori* is acquired during childhood, some surveys of *H. pylori* prevalence in China have focused on children. One recent study reported a prevalence of 37.7% in children aged 10-19 years in Beijing and 25.5% in the same age group in Shandong^[30]. Some studies suggest a downward trend in *H. pylori* seroprevalence in some regions; for example, a significant decrease was observed across age groups in Guangzhou^[31]. Evidence on this subject, however, is fragmentary and inconclusive. In particular, it remains unclear whether the rate of decline is accelerating, especially in the younger segments of the population.

H. pylori colonization: Findings from observational epidemiologic studies addressing the association between *H. pylori* and gastric cancer risk

Japan: Both case-control and cohort studies have been conducted to estimate the degree of gastric cancer risk associated with *H. pylori* infection in the Japanese population. To date, all four prospective studies have shown a positive association, with relative risks (RRs) ranging from 1.0 to 5.1^[32-35] (Table 2). In the prospective study that used the largest dataset (511 cases and 511 control subjects), Sasazuki *et al.*^[35] showed that the adjusted odds ratio (OR) of gastric cancer associated with *H. pylori* infection was 5.1, which is quite similar to the estimate of 5.9 for non-cardia gastric cancer in a combined analysis of 12 case-control studies nested within prospective cohorts^[36]. Based on the substantial evidence from both case-control and cohort studies, it is clear that *H. pylori* infection is causally linked to gastric cancer in the Japanese population.

Table 2 Summary of findings on the associations between *H. pylori* carriage and risk of gastric cancer in prospective studies from Japan and China

Author ^[Ref.] , yr	Country	Study design	Case patients /control subjects	Seroprevalence of <i>H. pylori</i> in cases vs controls (%)	ELISA kit used for measuring seroprevalence of <i>H. pylori</i>	OR (95% CI)
Watanabe <i>et al.</i> ^[32] , 1997	Japan	Nested case-control study	45/225	91.1 vs 75.6	Pirikaplate G <i>Helicobacter</i> enzyme immunoassay (Fujirebio Inc., Tokyo)	3.4 (1.2-9.9)
Sasazuki <i>et al.</i> ^[35] , 2006	Japan	Nested case-control study	511/511	93.5 vs 74.5	E Plate, produced by Eiken Kagaku Co.Ltd., Tokyo	5.1 (3.2-8.0)
Yamagata <i>et al.</i> ^[33] , 2000	Japan	Cohort study	1070 men and 1532 women at baseline	71.5 among men vs 62.4 among women	HM-CAP, Enteric Products Inc, Westbury, NY	Men: RR = 2.9 (1.1-7.4) Women: RR = 1.0 (0.3-3.0)
Yatsuya <i>et al.</i> ^[34] , 2004	Japan	Nested case-control study	202/394	88.6 vs 79.2	HM-CAP, Enteric Products Inc, Westbury, NY	Men: 1.7 (0.5-5.1) Women: 5.1 (1.6-16.5)

Kamangar <i>et al.</i> ^[12] , 2007	China	Case-cohort study	Cardia 582/992 Noncardia 343/992	Cardia 81.0 vs 73.0 Noncardia 80.0 vs 73.0	IgG antibodies to whole-cell antigen	Cardia 1.6 (1.3-2.1) Noncardia 1.6 (1.2-2.1)

OR: Odds ratio; RR: Relative risk; CI: Confidence interval.

China: The majority of epidemiologic studies that examined the association between *H. pylori* infection and gastric cancer in China are retrospective case-control studies. Of 11 case-control studies included in a 2001 meta-analysis, all studies showed a positive association. The ORs ranged from 2.1 to 5.6, with a combined OR of 3.0^[37].

This positive association was also observed in two prospective cohort studies. Yuan *et al.*^[38] reported that the OR was 3.7 for individuals seropositive for *H. pylori* who were followed for 5 or more years, on the basis of a nested case-control study within a cohort of Shanghai residents. A prospective, nested case-control study in Linxian, one of the highest-incidence regions in China, found that *H. pylori* seropositivity results in an approximately 2-fold increased risk of gastric cancer^[39]. This result was confirmed by a 2007 case-cohort study, in which *H. pylori* was associated with a 1.6-fold increased risk of both cardia and non-cardia gastric adenocarcinomas^[12].

***H. pylori* colonization: Findings from clinical studies, including both non-intervention and intervention studies**

Japan: Several recent clinical studies have greatly improved our understanding of the role of *H. pylori* in the development of gastric cancer. Umemura *et al.*^[7] (2001) found that gastric cancer developed in 36 of 1246 *H. pylori*-infected patients but none of the 280 uninfected patients in a prospective study involving 1526 Japanese patients with peptic ulcers, gastric hyperplasia or non-ulcer dyspepsia. The results are convincing because *H. pylori* colonization was confirmed by a combination of tests, including endoscopy, biopsy, histology, a rapid urease test, and serologic testing. This seminal study thus offers compelling evidence that *H. pylori* infection is associated with the development of both intestinal and diffuse gastric cancers. Another important study, a multi-center, open-label randomized controlled trial followed

544 patients who underwent endoscopic resection of early gastric cancer, half of whom underwent eradication of colonizing *H. pylori*^[8]. Eradication decreased the risk of developing metachronous gastric cancer by approximately 65%, even though these patients had already been diagnosed with early gastric cancer.

China: To determine whether *H. pylori* eradication reduces the incidence of gastric cancer at the population level in high-risk areas in China, Wong *et al.*^[40] (2004) conducted a randomized, placebo-controlled trial, using subjects without precancerous lesions. Unfortunately, however, this study was restricted by a short follow-up period and did not address whether those subjects with precancerous lesions experience a similar reduction in gastric cancer risk.

Cigarette smoking

Japan: Numerous epidemiologic studies over the past several decades have examined the association between cigarette smoking and gastric cancer risk in Japan, with the majority showing a significantly increased risk in current smokers when compared with those subjects who have never smoked. According to a systematic review and meta-analysis conducted by the Research Group for the Development and Evaluation of Cancer Prevention Strategies in Japan in 2006, the summary RR for current smokers were estimated to be 1.8 (95% CI: 1.5-2.1) in men and 1.2 (1.1-1.4) in women^[41]. Based on these results, the research group concluded that there is convincing evidence that tobacco smoking moderately increases the risk of gastric cancer in the Japanese population. Approximately 28.4% of gastric cancers are related to cigarette smoking, according to data from the Hisayama Study, a population-based prospective study of the combined influence of cigarette smoking and *H. pylori* infection^[42]. That study found that cigarette smoking is sig-

nificantly associated with increased risk of gastric cancer independent of *H. pylori* infection.

Although cigarette smoking is associated with an increased risk of gastric cancer, it remains unclear whether the observed positive association is homogeneous in terms of histologic type or anatomic location; such information has not been included in most previous studies. A cohort study was designed to address this question, incorporating complete histologic data. The results suggest that smoking significantly increases the risk of differentiated, but not undifferentiated, distal gastric cancer^[43].

China: The association between cigarette smoking and gastric cancer has been investigated in a number of epidemiologic studies, including both case-control and cohort studies, but the results are inconsistent^[44]. No association was found in a cohort study involving 9351 middle-aged adults in urban Shanghai^[45]. Another cohort study showed a non-significant increase in risk, with an RR of 1.4 for current smokers^[46]. In contrast, a recent prospective study of men in Shanghai showed that among nondrinkers, smokers have an 80% greater risk of gastric cancer, suggesting that cigarette smoking and alcohol consumption exert independent effects on gastric cancer risk^[47].

High intake of salt/salty food and food sources of nitrosamines

Japan: Collective evidence from epidemiologic and experimental studies over the past several decades strongly suggests that high intake of salt/salty food is associated with an increased risk of gastric cancer in Japanese populations^[9]. Japanese cohort studies dominate the published literature on gastric cancer epidemiology; of the 11 cohort studies included in a recent meta-analysis of salt consumption and gastric cancer risk, six of these studies came from Japan^[10]. In four of these Japanese studies, a statistically significant association was observed, with the RR ranging from 2.2 to 5.4 at the highest intake level.

The positive association observed between salt/salty food intake and gastric cancer risk in epidemiologic studies is also supported by experimental evidence. Using chemical carcinogens such as *N*-methyl-*N*'-nitro-*N*-nitrosoguanidine (MNNG), Tatematsu *et al*^[6] reported the first experimental model of gastric carcinogenesis in *H. pylori*-infected Mongolian gerbils. Experiments with this model demonstrated that sodium chloride (NaCl) enhances the carcinogenic effects of MNNG and 4-nitroquinoline-1-oxide. Another notable finding is that salt and *H. pylori* act synergistically to promote the development of gastric cancer in Mongolian gerbils^[48].

No cohort or case-control studies in Japan have published results on nitrite or nitrosamine intake in relation to gastric cancer risk; however, the association between gastric cancer and dietary intake of exogenous and/or endogenous nitrosamine, including meat, processed meat, preserved fish, and preserved vegetables, was ex-

amined in 11 cohort studies published between 1985 and 2005^[49]. The results are inconsistent, but most studies show no statistically significant association.

China: Of the 45 case-control studies and 11 cohort studies that were included in a 2009 meta-analysis of salt consumption and gastric cancer risk, 13 case-control studies, but no cohort studies, focus on Chinese populations^[10]. The associations of gastric cancer with intake of salt, salty fish, salty vegetables, pickled vegetables, salted and fermented soya paste, and other salted foods have been examined, with ORs for individuals at the highest intake level ranging from 1.1 to 2.6. Overall, these findings indicate that high intake of salt and salty food increase the risk of gastric cancer.

Neither cohort nor case-control studies have been conducted to examine the risk of gastric cancer in relation to nitrite or nitrosamine intake in China. One cohort study, however, found no significant association between processed meat consumption and gastric cancer risk^[49]. Additionally, a number of case-control studies have found that high intake of preserved fish and preserved vegetables is significantly associated with increased risk of gastric cancer^[49].

DISCUSSION

We aimed to clarify the similarities and differences in gastric cancer epidemiology in Japan and China by closely examining patterns of incidence, mortality rates and risk profiles. It can be difficult to compare data from two different countries because of differences in genetic susceptibility; environmental exposure; lifestyle; and the way each country defines, reports and interprets data. Commonalities emerge, however, when the data are carefully compared. First, gastric cancer still poses a tremendous health burden in both countries. Second, the prevalence of *H. pylori* remains high in adults, and *H. pylori* infection significantly increases the risk for gastric cancer. The magnitude of positive association may have been underestimated in studies from both countries if only conventional IgG enzyme-linked immunosorbent assay (ELISA) serology was used to detect past *H. pylori* exposure. Because atrophy of the gastric mucosa progresses with time, seroreversion may result from loss of infection. In an analysis restricted to early diffuse cancer, a very strong association with *H. pylori* infection was observed among all age groups^[50]. In a 2001 Swedish study that combined IgG ELISA with CagA immunoblot to detect *H. pylori* exposure, the adjusted OR for noncardia gastric cancer was 21.0 (8.3-53.4) among *H. pylori*-positive subjects^[51]. Third, almost all *H. pylori* strains are CagA-positive, and CagA plays a central role in *H. pylori*-induced gastric carcinogenesis^[52]. Fourth, in addition to *H. pylori* infection, cigarette smoking and high intake of salt/salty food are two important risk factors for gastric cancer. Fifth, clinical studies have provided important insights into the effects of *H. pylori* eradication on the

development of gastric cancer.

Despite these similarities, there are significant differences in many aspects of gastric cancer epidemiology between Japan and China, including patterns in mortality and the prevalence of *H. pylori* infection, *H. pylori* strains, the magnitude of gastric cancer risk related to *H. pylori* infection, and associations with diet. Studies in China have found a wider variation in patterns of incidence and mortality than have studies in Japan. Because the highest rates of gastric cancer are often seen in economically undeveloped rural areas in China, reduction of the mortality rate in these high-risk areas should be given top priority. Because of the pivotal role of *H. pylori* infection in gastric carcinogenesis, trends in infection prevalence likely affect the incidence of gastric cancer. The decline in *H. pylori* prevalence may have occurred faster in Japan than in China. Furthermore, in Japan, the observed decrease in gastric cancer was more marked than in China, especially among 20-39 years old subjects, suggesting a clear cohort effect. Further research is required to determine whether such an effect has been or will be occurring in China. Although it is unclear why only a small percentage of individuals infected with *H. pylori* develop gastric cancer, differences in *H. pylori* strains (i.e., virulence factors), inflammatory responses, and environmental exposure may be important factors in determining individual susceptibility to gastric cancer. In an analysis of 419 *H. pylori* strains from Japanese subjects and 65 *H. pylori* strains from Chinese subjects, East Asian CagA type accounted for 94% and 93%, respectively, of the detected strains^[51]. This result suggests that almost all Japanese and Chinese *H. pylori* strains are CagA-positive; however, differences in other virulence factors, such as VacA and OipA, also warrant further study.

Diet is commonly believed to play an important role in the development of gastric cancer^[53]. Because of the complexity of diet and the limitations of questionnaire-based surveys, clarifying its precise role remains a major challenge in epidemiologic studies. Compared to China, Japanese cohort studies dominate the literature on the associations of gastric cancer with diet; in particular, salt/salty food and dietary *N*-nitroso compounds are associated with gastric cancer incidence. There is substantial evidence suggesting that high intake of salt/salty food significantly increases the risk of gastric cancer in the Japanese population. Similarly, numerous case-control studies in China strongly suggest a positive association between high intake of preserved fish and vegetables and gastric cancer risk. The role of *N*-nitroso compounds is also crucial in gastric carcinogenesis, but epidemiologic studies from both Japan and China do not provide a clear picture of this role, at least in part because the intake of *N*-nitroso compounds is notoriously difficult to measure.

There is a need to accelerate the reduction of gastric cancer incidence and mortality in both countries and to determine the most effective strategy for the prevention of gastric cancer. Cost-effective prevention strategies have been extensively discussed in Japan^[54]; one dif-

ficult issue is whether to adopt a test-and-treat policy for asymptomatic individuals. The available data do not provide a clear picture of the optimal timing for *H. pylori* eradication to achieve the maximum benefit while doing the least harm. In China, tobacco control could confer substantial public health benefits. With 20% of the world's population, China produces and consumes about 30% of the world's cigarettes and suffers about a million deaths a year from tobacco^[55]. Efforts to promote tobacco control and decrease salt consumption should effectively reduce incidence and mortality from gastric cancers.

We propose the following three avenues for potential collaborative work based on the comparison of gastric cancer epidemiology between Japan and China. First, data comparisons on *H. pylori* genotyping are useful for identifying those people at increased risk of neoplastic transformation. Second, because the prevalence of premalignant disease states in the general population is currently undefined, it is important to estimate the prevalence of precancerous lesions, such as chronic atrophic gastritis and gastric intestinal metaplasia, and their associations with *H. pylori* infection, on the basis of endoscopic findings and serologic tests. Third, a multidisciplinary study is needed to address the role of *N*-nitroso compounds in the development of gastric cancer because epidemiologic studies are limited by difficulties in the precise measurement of *N*-nitroso compound intake. It is a challenge to find common ground for international collaboration. However, the similarities between these two countries, namely a high incidence of gastric cancer and a high prevalence of *H. pylori* infection, along with differences in many aspects of gastric cancer epidemiology, provide an excellent opportunity for Sino-Japanese collaboration. Such collaborations will facilitate a more complete understanding of gastric cancer etiology and the development of more effective interventions to reduce the mortality and incidence of gastric cancers. Given the pivotal role of *H. pylori* in gastric carcinogenesis, screening strategies in both countries based on *H. pylori* infection status would be very powerful for developing appropriate and cost-effective screening programs.

COMMENTS

Background

Japan and China have the highest incidences of gastric cancer in the world. Although a trend of declining incidence has been observed over the past several decades, gastric cancer still poses a tremendous burden to populations in each country. Although numerous gastric cancer studies have been conducted in each country, this article is the first to clarify the similarities and differences in gastric cancer between Japan and China by closely examining both epidemiologic features, such as patterns of incidence and mortality rates, and risk profiles on the basis of extensive published literature.

Research frontiers

To address why only a minority of individuals with *Helicobacter pylori* (*H. pylori*) colonization develop gastric cancer, the authors need to elucidate the interacting roles of various strains of *H. pylori*, host factors, and other lifestyle/environmental factors in gastric cancer. The authors also need more evidence on the optimal timing for *H. pylori* eradication in the interest of preventing gastric cancer.

Innovations and breakthroughs

The authors found differences in many aspects of gastric cancer between Japan and China, including patterns of mortality, trends in prevalence of *H. pylori* infection, *H. pylori* strains, and risk profiles. Due to the pivotal role of *H. pylori* infection in gastric carcinogenesis, trends in its population prevalence are likely to affect gastric cancer incidence. The decline in *H. pylori* prevalence may have occurred faster in Japan than in China. In Japan, a more marked decrease in gastric cancer was observed, especially among those people aged 20-39 years old; this evidence suggests a clear cohort effect. It will therefore be intriguing to see whether such a cohort effect has occurred in China or will do in the future.

Applications

This article has implications for future collaborative studies between Japan and China. First, comparing data on *H. pylori* genotyping is useful for identifying those patients at increased risk of neoplastic transformation. Second, it is important to estimate the prevalence of precancerous lesions, such as chronic atrophic gastritis and gastric intestinal metaplasia, and to evaluate the distribution of *H. pylori* in high-risk populations, on the basis of endoscopic findings and serologic tests. Third, a multidisciplinary study is needed to address the role of *N*-nitroso compounds in the development of gastric cancer. Specifically, screening strategies based on *H. pylori* negativity or positivity in both countries would be very powerful in terms of developing appropriate and cost-effective screening programs.

Terminology

H. pylori colonizes the human stomach, and individuals with *H. pylori* infection have an increased risk of developing gastric cancer.

Peer review

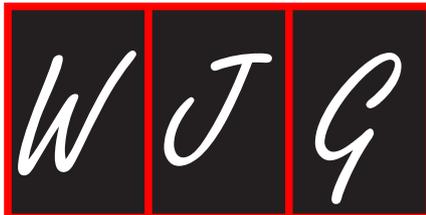

This article compares factors associated with the risk for developing gastric cancer in *H. pylori*-infected individuals from China or Japan. It summarizes a large body of literature on the rates of *H. pylori* infection along with the links between smoking, high salt and nitrate diets and gastric cancer rates. This article should be well received, especially in Asian countries, where the prevalence of *H. pylori* infection and gastric cancer remains unacceptably high.

Abstract

AIM: To evaluate the efficacy of Stretta procedure with gastroesophageal reflux disease (GERD) based on symptom control, medication changes and oesophagitis grade.

METHODS: Ninety patients with a history of GERD underwent Stretta procedure from June 2007 to March 2010. All patients with GERD diagnosed by the presence of endoscopically evidenced oesophagitis or abnormal esophageal pH testing. We evaluated GERD-health-related quality of life, satisfaction, medication use and endoscopy at baseline, 6, 12 mo after treatment. Complications of the procedure were analyzed.

RESULTS: We found that patients experienced significant changes in symptoms of GERD after Stretta procedure. The onset of GERD symptom relief was less than 2 mo (70.0%) or 2 to 6 mo (16.7%). The mean GERD-HRQL score was 25.6 (baseline), 7.3 (6 mo, $P < 0.01$), and 8.1 (12 mo, $P < 0.01$). The mean heartburn score

was 3.3 (baseline), and 1.2 (12 mo, $P < 0.05$). The percentage of patients with satisfactory GERD control improved from 31.1% at baseline to 86.7% after treatment, and patient satisfaction improved from 1.4 at baseline to 4.0 at 12 mo ($P < 0.01$). Medication usage decreased significantly from 100% of patients on proton pump inhibitors therapy at baseline to 76.7% of patients showing elimination of medications or only as needed use of antacids/H₂-RA at 12 mo. An improvement in endoscopic grade of oesophagitis was seen in 33 of the 41 patients. All patients had either no erosions or only mild erosive disease (grade A) at 6 mo.

CONCLUSION: The experience with Stretta procedure confirms that it is well tolerated, safe, effective and durable in the treatment of GERD. The Stretta procedure provides the drug-refractory patients with a new minimally invasive method.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is one of the most common illnesses of the gastrointestinal tract, with a large proportion of the population affected. Patients report adverse effects on their quality of life because of symptoms such as heartburn, regurgitation, or dysphagia. GERD is associated with severe health-related quality-of-life impairment, which is comparable to patients afflicted with diabetes mellitus, congestive heart failure or arthritis^[1]. Although GERD is known as a chronic disease requiring life-long treatment, many patients have inadequate symptom control with medication, usually proton pump inhibitors (PPIs). About 20% of patients will have breakthrough heartburn and regurgitation causing detrimental effects on the quality of life. GERD treatment using a minimally invasive endoluminal method to deliver low-level radiofrequency energy to the gastroesophageal junction (Stretta procedure) is a new method^[2-4]. Several clinical trials showed that the Stretta procedure improves GERD symptoms, quality of life, esophageal acid exposure, and eliminates the need for antisecretory drugs in most patients^[5-8]. This study reports our experience using the Stretta procedure in patients with persistent GERD symptoms in China.

MATERIALS AND METHODS

Patients

Fifty-seven men and 33 women (ages 31-72 years, 22.2% hiatal hernia, Table 1) were treated using the Stretta procedure. These patients had a history of GERD symptoms ranging from 1 to 26 years. They were either self-referred or recruited from the outpatient endoscopy unit from June 2007 to March 2010. All patients had significant GERD with persistent symptoms of heartburn and regurgitation in spite of the use of PPI drugs taken everyday. All patients had the diagnosis of GERD confirmed by finding erosive esophagitis at upper endoscopy (Los Angeles grade A or higher) or abnormal acid contact time detected at ambulatory esophageal pH testing. They were excluded if they were under 18 or over 80 years of age, pregnant, achalasia, or if they had a sliding hiatal hernia > 2 cm, collagen vascular disease, or severe uncontrolled medical illness.

Stretta procedure

Radiofrequency energy was delivered using the Stretta system (Curon Medical Inc., Sunnyvale, Calif., United States) in an outpatient endoscopy unit. The Stretta procedure catheter uses a balloon basket assembly to deploy 4 nitinol needle electrodes into the muscular layer of the esophageal wall. Radiofrequency energy delivered by the needle electrodes causes a thermal reaction in the LES with controlled temperature elevation to 85 °C, while continuous mucosal irrigation with chilled water prevents the development of stricture or ulceration. Deploying the needle electrodes at 5 mm levels above and below the squamocolumnar junction (SCJ) produces 56 thermal lesions. After informed consent, the patient is prepared

GERD: Gastroesophageal reflux disease.

for upper endoscopy with conscious sedation by using midazolam or fentanyl in the usual manner^[9]. Diagnostic upper endoscopy is used to carefully inspect the esophagus and the cardia, and to determine the SCJ location. The Stretta catheter is passed over the guidewire, and introduced into the esophagus, where it is positioned 1 cm above the SCJ. After appropriate balloon inflation, the treatment elements are deployed 1 to 2 mm into the lower esophageal sphincter muscle, where energy is delivered in a series of thermal treatments at 4 levels in 2 positions (distal esophagus) and at 2 levels in 3 positions (gastric cardia). Constant monitoring and feedback of temperature and impedance ensures that each treatment element is maintained safely within target tissues. The mucosa was cooled during this procedure to prevent ulceration or stricture. After completion of the procedure and catheter removal, the diagnostic endoscopy procedure is repeated to verify that there have been no complications such as bleeding or perforation and to document the appropriate site of treatment. All pre-Stretta medication is maintained for 6 to 8 wk after the procedure to maintain baseline and allow time for complete healing.

Procedure at baseline and after treatment

GERD symptom assessment has been described as the most appropriate measure for the definition of treatment success, because it directly pertains to patients and the clinicians who provide their care. Before undergoing the Stretta procedure, patients underwent symptom assessment with the GERD health-related quality-of-life questionnaire (rated 0-50, with scores less than 10 considered normal)^[10]. This is a validated questionnaire assessing specific GERD symptoms, followed by questions about heartburn severity on a scale of 0 to 5, with higher scores

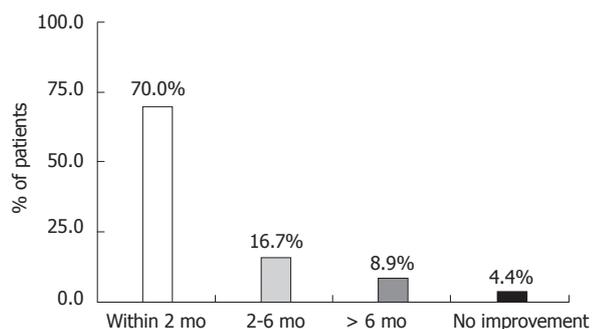

Figure 1 Time interval for onset of gastroesophageal reflux disease. Symptom relief after Stretta procedure, demonstrating significant improvement of gastroesophageal reflux disease-related symptoms within 6 mo.

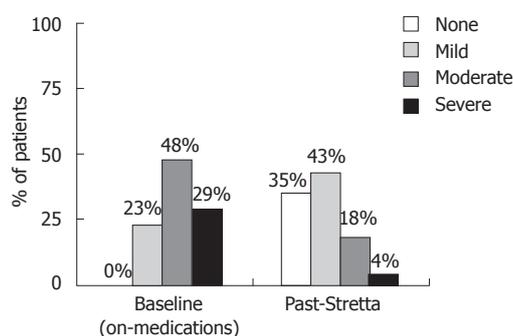

Figure 2 Improvement in gastroesophageal reflux disease symptom severity after Stretta procedure. The percentage of patients with gastroesophageal reflux disease symptom severity is shown at baseline on medications and 12 mo after Stretta procedure.

indicating more severe symptoms, and with questions about patient satisfaction on a scale of 0 to 5, with higher scores indicating better satisfaction/quality of life^[11]. This testing was repeated 6 and 12 mo after the Stretta procedure. Assessment of medication usage was performed at baseline and 6 mo with the assistance of patient diaries and detailed questions addressing the use of all GERD medications such as PPIs, histamine-2 blockers, antacids, and prokinetic agents.

Statistical analysis

The date of the experiment was represented in the form of mean \pm SD. Variance analysis and *t* test for non-match data were performed by a professional SPSS statistical program.

RESULTS

Complications

Minor complications occurred after the procedure, including 5 cases of dyspepsia (5.6%), 9 transient chest pain (10%), 2 superficial mucosal injury (2.2%), 3 mucosal bleeding (3.3%), 2 low-grade fever after procedure (2.2%). These complications resolved within 1 wk, without sequelae. No serious complications were noted after the procedure.

Table 2 Comparison of clinical parameters at baseline and after Stretta procedure

Parameters	Baseline	6 mo	12mo	<i>P</i> value
GERD health-related quality-of-life questionnaire	25.6 \pm 9.0	7.3 \pm 4.1	8.1 \pm 3.9	< 0.01
Heartburn	3.3 \pm 1.3	1.0 \pm 0.9	1.2 \pm 1.1	< 0.01
Satisfaction	1.4 \pm 1.1	4.3 \pm 1.3	4.0 \pm 0.9	< 0.01
Percent without PPI	0	78.9	76.7	< 0.05

GERD: Gastroesophageal reflux disease; PPI: Proton pump inhibitors.

Improvement of GERD symptoms

The onset of GERD symptom relief was reported as within 2 mo by the majority (70%) of patients, 2 to 6 mo by 16.7%, after 6 mo by 8.9%, and no improvement by 4.4% (Figure 1). At baseline, 77% of patients had moderate or severe symptoms despite PPI therapy. After Stretta, however, this number fell to 22%, indicating that 78% of patients had good control after treatment (Figure 2). The mean GERD-HRQL scores improved from 25.6 \pm 9.0 at baseline to 7.3 \pm 4.1 at 6 mo, and 8.1 \pm 3.9 at 12 mo (*P* < 0.01). The mean heartburn scores improved from 3.3 \pm 1.3 at baseline to 1.0 \pm 0.9 at 6 mo, and 1.2 \pm 1.1 at 12 mo (*P* < 0.05) (Table 2).

Improvement of quality of life

At baseline, only 31.1% of patients reported that they were satisfied with GERD symptom control on twice-daily PPI, whereas after Stretta treatment, 86.7% reported satisfactory GERD symptom control. This is also reflected in the satisfaction score, which improved from 1.4 \pm 1.1 at baseline to 4.3 \pm 1.3 at 6 mo, and 4.0 \pm 0.9 at 12 mo (*P* < 0.01) (Table 2).

Improvement in medication use

Medication usage decreased significantly (*P* < 0.05) (Table 2). At baseline, 100% of patients were receiving twice-daily PPI therapy. After Stretta treatment, 76.7% of patients showed elimination of medications or only as needed use of antacids/H2-RA at 12 mo.

Improvement in endoscopic grade of oesophagitis

Six months after Stretta treatment, an improvement in endoscopic grade of oesophagitis was seen in 33 of the 41 patients, 80.5% patients had no erosions, and only 19.5% patients had mild erosive disease (grade A).

DISCUSSION

GERD is a common disease that significantly impairs the quality of life of patients, and it is associated with pathophysiologic alterations such as transient lower esophageal sphincter relaxations and the presence of a hiatal hernia. Although antisecretory medications such as PPIs are considered as the mainstay of GERD treatment, they do not address any of the underlying pathophysiologic derangements. It is not surprising, therefore, that up to 20% of

patients do not have adequate symptom control despite these drugs effectively control GERD in most patients by reducing acid reflux. Moreover, long-term use of these medications may provide a significant and lifelong economic expense. These patients may seek antireflux surgery, which has high success rates but may wane over time, with 50% of patients requiring medications to control recurrent reflux symptoms^[12]. The invasiveness, high costs, and risks associated with surgery, and the dependence and long-term costs of medical management have caused patients and physicians alike to pursue a minimally invasive, effective, and durable treatment alternative that actually addresses the underlying pathophysiologic problems of GERD^[7,13].

The Stretta endoscopic antireflux procedure was introduced in 2000 for the treatment of patients with GERD who had suboptimal symptom control with GERD therapy. The Stretta procedure has been found to have multiple mechanisms of action, including mechanical alteration of the gastroesophageal junction, with increased gastric yield pressure^[14]; neural modulation of transient lower esophageal sphincter relaxation^[15]; and normalization of delayed gastric emptying^[14]. The Stretta procedure uses temperature-controlled delivery of radio-frequency energy to the lower esophageal sphincter to address the underlying pathophysiology. Production and healing of these lesions causes inflammation, subsequent collagen deposition^[16,17], and muscular thickening^[18], whereas efferent/afferent vagal nerve ablation causes a decrease in total lower esophageal sphincter relaxations and thus a decrease in esophageal acid exposure^[19,20].

The Stretta procedure is an endoluminal radiofrequency energy delivery system to the gastroesophageal junction. Several clinical trials showed that the Stretta procedure improved GERD-related symptoms, decreased symptom scores and heartburn scores, increased the satisfaction. Meier *et al*^[21] reported the results of an European multicenter, open-label, prospective study. At 12 mo after treatment, 75% of the patients were more satisfied with their symptom control and had statistically significantly fewer GERD symptoms. GERD-HRQL score decreased from 19.2 to 6.6 ($P < 0.0001$) and overall physical and mental health also improved significantly. This is also reflected in the satisfaction score, which improved significantly from 2 to 4 ($P < 0.0001$). Wolfsen *et al*^[22] reported the multicenter Stretta registry study of 558 patients. The percentage of patients with satisfactory GERD control improved from 26.3% at baseline (on drugs) to 77.0% after treatment ($P < 0.0001$). Median baseline symptom control on drugs was 50%, compared with 90% at follow-up ($P < 0.0001$). Baseline patient satisfaction on drugs was 23.2%, compared with 86.5% at follow-up ($P < 0.0001$). Subgroup analysis showed a superior effect on symptom control in these patients beyond 1 year of follow-up, supporting procedure durability. Noar *et al*^[9] reported on a series of 109 consecutive patients treated with the Stretta procedure who have reached 4-year follow-up. Heartburn scores decreased from 3.6 to 1.2 ($P < 0.001$), GERD-HRQL score decreased from 27.8 to

7.1 ($P < 0.001$), and patient satisfaction improved from 1.4 to 3.8 ($P < 0.001$). In our study, we found significant changes in symptoms of GERD. After treatment, onset of GERD symptom relief was less than 2 mo (70.0%) or 2 to 6 mo (16.7%). The GERD-HRQL score decreased from 25.6 to 8.1 ($P < 0.01$). The mean heartburn score decreased from 3.3 to 1.2 ($P < 0.05$). The percentage of patients with satisfactory GERD control improved from 31.1% at baseline to 86.7% after treatment, and patient satisfaction improved from 1.4 to 4.0 ($P < 0.01$).

The need for medication for GERD symptoms improved significantly one year after Stretta treatment compared to baseline. In our study, about 76.7% of the patients studied needed no medication or less medication after Stretta treatment. This is in line with results from Tam *et al*^[15]. They report that at 12 mo after treatment, 75% of the patients are off all medication. Noar *et al*^[9] presented 4-year of follow-up in 109 patients treated with the Stretta procedure. In their follow-up, medication usage decreased significantly from 100% of patients on twice-daily PPI therapy at baseline to 75% of patients showing elimination of medications or only as-needed use of antacids/over-the-counter PPIs. In a European study, Meier *et al*^[21] report that at 6 mo after treatment, 45% and at 12 mo 38% of the patients are off all medication. Perhaps the lower percentage of patients that were off medication in Meier's study was caused by the patient population having slightly different characteristics. 8.5% of their population had hiatal hernia > 2 cm, while other studies only included patients with hiatal hernia < 2 cm.

The Stretta procedure produced significant improvements in oesophagitis grade. Despite most patients being off therapy at 6 mo, only mild erosive reflux oesophagitis (grade A) was noted in 19.5% of the patients while remainder had no visible mucosal breaks. This is in line with results from Tam *et al*^[23]. They report that at 6 mo after treatment, half of the patients had no macroscopic mucosal breaks and half of the patients had mild erosive reflux oesophagitis (Los Angeles grade A).

Taken together, the patients in this study had statistically significant improvement and a sustained effect in all parameters. In these patients, the observed improvement was superior to that achieved with escalated PPI therapy above baseline dosing. The Stretta procedure is a viable, well tolerated, minimally invasive endoluminal procedure^[24,25]. This procedure should be considered for patients who are not satisfied with pharmacologic therapy and who are considering anti-reflux surgery.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is one of the most common illnesses of the gastrointestinal tract, with a large proportion of the population affected. GERD is associated with severe health-related quality-of-life impairment, which is comparable to patients afflicted with diabetes mellitus, congestive heart failure, or arthritis. Although antisecretory medications such as PPIs are considered as the mainstay of GERD treatment, up to 20% of patients do not have adequate symptom control despite these drugs effectively control GERD in most patients by reducing acid reflux. These patients may seek antireflux surgery,

which has high success rates but may wane over time, with 50% of patients requiring medications to control recurrent reflux symptoms. The invasiveness, high costs, and risks associated with surgery, and the dependence and long-term costs of medical management have caused patients and physicians alike to pursue the minimally invasive, effective, and durable treatment methods.

Research frontiers

The devices of endoluminal minimally invasive treatment of gastro-oesophageal reflux disease, which included endoluminal fundoplication (EndoCinch, NDO Plicator), biopolymer injection (Enteryx), and Stretta procedure, have gained popularity over the last several years. Endoluminal minimally invasive treatment of gastroesophageal reflux disease has been shown to be safe and effective in recent studies.

Innovations and breakthroughs

The experience with Stretta procedure confirms that it is well tolerated, safe, effective, and durable in the treatment of GERD. It has produced significant improvements in symptom control and oesophagitis grade and decreased medication usage. Stretta procedure is a new minimally invasive endoluminal therapeutic technique.

Applications

The Stretta procedure provides the drug-refractory patients with a new minimally invasive method. The Stretta procedure improves GERD symptoms, quality of life, esophageal acid exposure, and eliminates the need for antisecretory drugs in most patients.

Terminology

Refractory GERD: Refractory GERD is a patient-driven phenomenon. What constitutes refractory GERD remains an area of controversy. Many investigators suggest that only patients who exhibit incomplete or lack of response to PPI, twice daily, should be considered as PPI failures. Others believe that a lack of symptomatic response to PPI once a day is sufficient to consider patients as PPI failures.

Peer review

This is an interesting work. The study is useful in order to take advantages from a new therapeutic technique, above all for such a widespread disease like the gastroesophageal reflux. Moreover the possibility to avoid the more invasive surgery would be a desirable outcome for patients with severe GERD.

Abstract

AIM: To investigate the effects of the somatostatin analogue, octreotide, on maltase and sucrase activities and expression of glucose transporter type 2 (GLUT2) in obese rat intestinal mucosa.

METHODS: We divided 49 Sprague-Dawley rats into a group of 31 high fat diet-induced obese rats and a group of 18 normal controls. The obese rats were separated into an octreotide treated group of 16 rats and an obese group of 15. The intervention group was injected with octreotide at 40 µg/kg body weight every 12 h for 8 d. Rat body weight was measured weekly to calculate Lee's index. After euthanization, maltase and sucrase activities in the small intestine were measured

by activity assays, and the fasting plasma glucose level was measured. The expression of GLUT2 in small intestinal mucosa was analyzed by immunohistochemistry, reverse transcriptase polymerase chain reaction and Western blotting assays.

RESULTS: Body weight, Lee's index, fasting plasma glucose level, maltase activity in small intestinal mucosa, mucosa and apical GLUT2, GLUT2 mRNA and protein expression levels were all significantly higher in the obese group than in the normal control group (605.61 ± 141.00 vs 378.54 ± 111.75 , 337.61 ± 10.82 vs 318.73 ± 20.10 , 8.60 ± 1.38 vs 7.33 ± 0.70 , 156.01 ± 58.81 vs 50.43 ± 30.49 , $390\ 744.2 \pm 62\ 469.21$ vs $170\ 546.50 \pm 50\ 646.14$, $26\ 740.18 \pm 3809.60$ vs 354.98 ± 57.19 , 0.26 ± 0.11 vs 0.07 ± 0.02 , and 2.08 ± 0.59 vs 1.27 ± 0.38 , respectively, all $P < 0.01$). Sucrase activity did not differ between the two groups. Octreotide intervention significantly decreased the body weight and fasting plasma glucose level of obese rats (508.27 ± 94.39 vs 605.61 ± 141.00 , 7.58 ± 1.51 vs 8.60 ± 1.38 , respectively, all $P < 0.05$). The intestinal mucosa and apical GLUT2, expression of GLUT2 mRNA and protein were also significantly lower in the octreotide intervention group than in the obese group ($269\ 975.2 \pm 53\ 730.94$ vs $390\ 744.2 \pm 62\ 469.21$, 3758.06 ± 364.51 vs $26\ 740.18 \pm 3809.60$, 0.08 ± 0.02 vs 0.26 ± 0.11 , and 1.31 ± 0.27 vs 2.08 ± 0.59 , respectively, all $P < 0.01$).

CONCLUSION: High fat diet-induced obesity is associated with elevated intestinal maltase activity, GLUT2 expression, and permanent apical GLUT2 in the small intestinal mucosa of rats. Octreotide can inhibit these effects.

INTRODUCTION

Recently, obesity has become a worldwide health issue, as it increases the risk of a variety of human medical consequences^[1] such as type 2 diabetes, cardiovascular and cerebrovascular disease. Nutritional obesity is a metabolic disorder involving chronic imbalance of energy. Feeding a high fat diet to rodents normally results in disorders of glucose metabolism, and leads to impaired glucose tolerance or diabetes^[2].

Carbohydrates are the main source of energy in rats. With the exception of monosaccharides, which can be absorbed directly into the intestinal mucosa, carbohydrates and their intermediate metabolites must be hydrolyzed to disaccharides in the gastrointestinal tract. The disaccharides then broken down to glucose through maltose and sucrose on the surface of intestinal villi. There are two mechanisms of intestinal glucose absorption^[3]. When the luminal glucose level is lower than the blood glucose level, absorption occurs *via* the sodium-dependent glucose transporter 1 (SGLT-1) through classical active transport. Once the glucose concentration in the intestine is beyond the transport saturation of SGLT-1, the diffusion is mediated primarily through the transient insertion of glucose transporter type 2 (GLUT2) into the apical membrane^[3].

Somatostatin (SST), a multifunctional gut peptide synthesized and released by intestinal endocrine cells (D cells), regulates the physiological function of intestinal epithelial cells and immune cells, as well as gastric motor activity^[4,5]. Somatostatin's effects are mediated by the SST receptor (SSTR) which is located in the cell membrane. Somatostatin secreted from the intestine can thus suppress replication of gastrointestinal epithelial cells. The clinical utility of somatostatin is limited by its short half-life of about two minutes^[6]. Octreotide is an artificial synthetic analogue of SST that is more convenient to use and has a longer half-life, duration of activity and fewer side effects.

The expression of SGLT-1 in intestinal mucosa is significantly elevated in high-fat-diet-induced obese rats, and octreotide can dramatically inhibit the expression of SGLT-1 (unpublished results). However, it is unknown whether obesity induced by a high fat diet is associated with maltase and sucrase activities and expression of GLUT2. It is also unknown whether octreotide can influence maltase and sucrase activities and GLUT2 expression. Thus, the authors conducted an experiment to investigate these questions.

MATERIALS AND METHODS

Experimental animals and study design

All experiments were approved by the Institutional Animal Care and Use Committee of Sichuan University (Chengdu, China).

We used 66 healthy male 21-d-old Sprague-Dawley (SD) rats which had been weaned for 3 d. All animals were obtained from the Animal Center of Sichuan University. After adaptive feeding for 3 d, rats were placed into two groups, one group of 18 (the normal control group) fed with standard chow (290 kcal/100 g, in line with the People's Republic of China National Standard GB 14924-2001), and another group of 48 fed with high-fat chow (430 kcal/100 g).

Food and water were supplied *ad libitum*, and the animals were housed in independently ventilated cages on a 12:12-h light: dark schedule and kept at 20 °C-25 °C. They were weighed and measured for body and tail length each week for 24 wk. After 24 wk, rats from the high-fat chow group with body weight at least 1.4 times the mean body weight of the normal control group were selected as obese rats. Obese rats were then placed into two groups, an obese group of 16 rats, and an octreotide-treated group of 15 rats. The octreotide-treated group was injected subcutaneously with octreotide (40 g/kg body weight) every 12 h for 8 d. Rat body weight was measured weekly to calculate Lee's index [body weight (g)^{1/3} × 1000/body length (cm)].

Sample preparation

At the end of the experiment, after fasting for 12 h, rats were euthanized intraperitoneally with 2% sodium pentobarbital. The small intestine was removed from each rat. The mucosa from 15 cm of the small intestine was collected by scraping with a glass slide and kept at -80 °C for measurement of sucrase and maltase activities and Western blot analysis. Another 1-cm section of small intestine was kept at -140 °C until total RNA extraction. Plasma and serum were collected for blood glucose measurement. Blood glucose levels were measured by the enzymatic method. Each specimen was measured in duplicate.

Sucrase and maltase activities measurement

Sucrase and maltase activities were measured using a sucrase and maltase activity assay kit (Jiancheng Bio-Engineering Institute, Nanjing, China) according to the manufacturer's instructions. The sucrase and maltase activity unit was defined as the nanomoles of disaccharide hydrolyzed per milligram of protein in 1 min (U/mg protein, 37 °C, pH = 6.0), and activity was calculated as follows:

$$\text{activity (U/mg protein)} = \frac{\frac{A_{\text{sample}} - A_{\text{control}}}{A_{\text{standard}} - A_{\text{blank}}} \times \text{standard concentration (5.55 mmol/L)}}{\text{reaction time (20 min)} \times \text{protein concentration (mg protein/mL)}} \times 1000$$

The small intestine mucosa was homogenized in phosphate buffered saline (PBS, pH = 7.4) with a homogenizer. After centrifugation at 1050 × *g*, 4 °C for 5 min, the supernatant was used to measure sucrase and maltase activi-

ties. The protein concentrations in the homogenate were determined by a BCA Protein Assay Kit (Pierce Biotechnology, Inc., Rockford, IL, United States) according to the manufacturer's instructions.

Immunohistochemistry of small intestine mucosa

For the immunohistochemical detection of GLUT2, a paraffin-embedded tissue section was deparaffinized and antigen retrieval was performed at high pressure. For nonspecific blocking, 10% goat sera was added, each section was incubated for 20 min at 37 °C, then GLUT2 goat anti-rat polyclonal antibody was added (1:400; Santa Cruz Biotechnologies, Santa Cruz, CA, United States). After incubating overnight at 4 °C and rewarming to 37 °C, each section was stained with a ready-to-use streptavidin-catalase immunohistochemical reagent system for detection. The color reaction was developed with diaminobenzidine (DAB; Zhongshan Bioagent Company, Beijing, China). A semiquantitative immunohistochemical analysis of raw data with Image-Pro Plus 4.0 software (Media Cybernetics, Silver Spring, MD, United States) was used to score integrated optical density (IOD) for positive reaction area.

Reverse transcriptase polymerase chain reaction analysis

Total RNA was extracted from the frozen small intestine using Trizol reagent (Takara Bio-Engineering Co., Ltd., Kyoto, Japan). First-strand cDNA was synthesized from 2 mg of total RNA for each sample using reverse transcription kits (MBI, Fermentas Life Sciences Inc., Vilnius, Lithuania). The GLUT2 sense and antisense PCR primers were 5'-TGCTGGAAGAAGCGTAT CAG-3' and 5'-GGCCAAGTAGGATGTGCCAG-3', respectively; the GAPDH sense and antisense primers were 5'-CATGAC-CACAGTCCATGCCA-3' and 5'-CACCCCTGTTGCT CTAGCCATATTC-3', respectively^[7]. The PCR reaction was catalyzed using Taq DNA polymerase (MBI, Fermentas Life Sciences Inc., Vilnius, Lithuania). The thermal cycling parameters consisted of an initial denaturation step of 5 min at 94 °C, followed by 23 cycles of 1 min at 94 °C, 1 min at 63 °C, and 1 min at 72 °C. The final extension step lasted 7 min at 72 °C. PCR products were resolved by 2% agarose gel electrophoresis, and visualized by ethidium bromide staining. Densitometry was carried out using a Bio-Rad GelDoc image acquisition system and Quantity One (v4.3) quantitation software (Bio-Rad, Hercules, CA, United States).

Western blotting analysis

Small intestinal mucosa homogenate was prepared in lysis buffer containing protease inhibitor and phosphatase inhibitor (KeyGEN Biological Company, Nanjing, China). The protein concentrations were determined by a BCA Protein Assay Kit (Pierce Biotechnology, Inc., Rockford, IL, United States). The extracted protein (60 µg) was incubated in loading buffer and heated at 100 °C for 5 min. Samples were loaded onto a 10% sodium dodecyl sulfate-polyacrylamide gel, then transferred electronically to poly-

vinylidene difluoride membranes (Millipore, Bedford, MA, United States). The membranes were incubated with a 1:2000 dilution of rabbit polyclonal GLUT2 antibody (Millipore, Bedford, MA, United States) at 4 °C overnight. The membranes were then washed three times in blocking solution and incubated with a secondary antibody (Santa Cruz Biotechnologies, Santa Cruz, CA, United States, 1:50000). The signals were developed using Super-Signal West Pico chemiluminescent substrate (Pierce, Rockford, IL, United States). Band densities were quantified using Quantity One software 4.3.1 (Bio-Rad, Hercules, CA, United States). Each value was expressed as the ratio of the IOD of the GLUT2 band to that of β-actin.

Statistical analysis

Data are presented as means and standard deviations. Groups were compared using analysis of variance or the *t* test. All tests were two-tailed and $P \leq 0.05$ was considered statistically significant. All data met the assumptions of the tests used to analyze them. All data were analyzed by statistical software SPSS 13.0 (SPSS Inc., United States).

RESULTS

Octreotide treatment and parameters associated with obesity and activities of disaccharidases

The rats with high-fat-diet-induced obesity showed typical features of obesity, such as higher body weight, Lee's index and blood glucose levels than those in the normal control group ($P < 0.01$) (Table 1). The octreotide-treated group had significantly lower body weight and blood glucose levels than those in the obese comparison group ($P < 0.05$) (Table 1). Maltase activity in the small intestinal mucosa of the obese group was significantly higher than that in the normal control group ($P < 0.01$) (Table 1).

Octreotide treatment and GLUT2 expression

GLUT2 distribution and expression in the intestinal mucosa were measured by immunohistochemistry. GLUT2 resided mainly in the basolateral membrane (BLM) in the small intestinal mucosa (Figure 1). GLUT2 expression in the obese group was significantly higher than that in the normal control group ($P < 0.01$). In the octreotide-treated group, GLUT2 expression was significantly lower than that in the obese group ($P < 0.01$) (Figure 1 and Table 1).

Apical GLUT2 expression in the obese group was significantly higher than that in the normal control group ($P < 0.01$). After octreotide intervention, the level of apical GLUT2 was significantly lower than that in the obese group ($P < 0.01$) (Figure 1 and Table 1).

Reverse transcriptase polymerase chain reaction and Western blotting showed that GLUT2 mRNA and protein expression levels in the intestinal mucosa of the obese group were significantly higher than those in the normal control group ($P < 0.01$). GLUT2 mRNA and protein expression levels were significantly lower in the octreotide-treated group than in the obese rats ($P < 0.01$) (Figures 2 and 3, Table 1).

Table 1 Obesity and metabolic indicators in normal control and obese rats, and in obese rats treated with octreotide

	Control (<i>n</i> = 18)	Obese (<i>n</i> = 16)	Octreotide treated (<i>n</i> = 15)

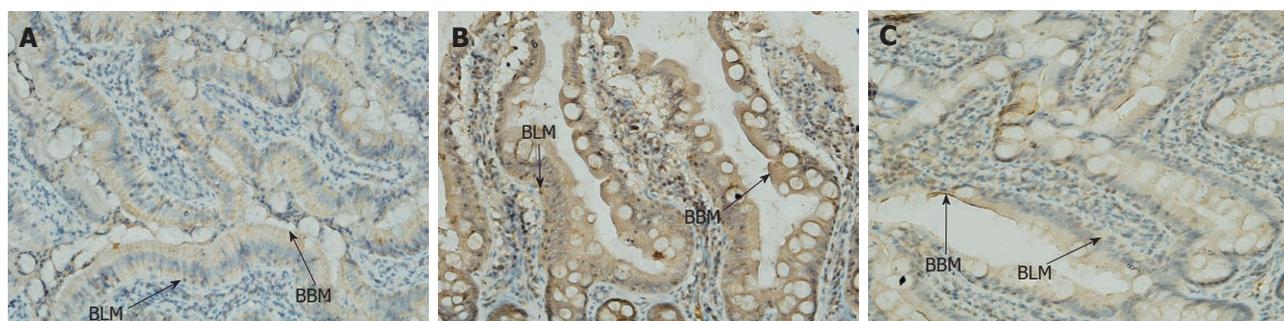

Figure 1 Expression of glucose transporter type 2 and apical glucose transporter type 2 in the small intestinal mucosa. A: In normal control rats, glucose transporter type 2 (GLUT2) mainly resides at the BLM (arrows); B: In obese rats, the GLUT2 and apical GLUT2 expression was increased (arrows) compared to the controls; C: In octreotide-treated rats, GLUT2 and apical GLUT2 expression was significantly decreased (arrows) compared to non-treated obese rats. Magnification: × 400.

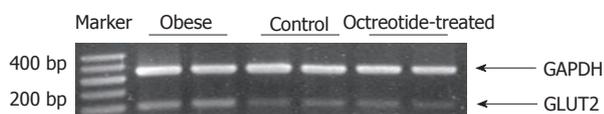

Figure 2 Expression of glucose transporter type 2 mRNA in the small intestinal mucosa. Obese rats showed increased mRNA levels of glucose transporter type 2 (GLUT2) when compared with the controls, whereas octreotide-treated rats showed decreased levels of GLUT2 mRNA, when compared with obese rats. Total RNA was analyzed by reverse transcriptase polymerase chain reaction. House-keeping gene *GAPDH* was used as an internal control.

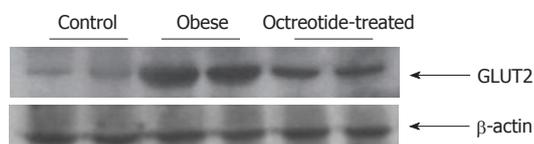

Figure 3 Expression of glucose transporter type 2 protein by Western blotting. Obese rats showed increased protein levels of glucose transporter type 2 (GLUT2) when compared with the controls, whereas the octreotide-treated rats showed decreased levels of GLUT2 protein, when compared with obese rats. β-actin was used as an internal loading control.

DISCUSSION

Starch is the major source of food glucose, and its digestion to maltose requires amylases in the gastrointestinal tract. Disaccharides, such as maltose, must be hydrolyzed to glucose by disaccharidase before being absorbed direct-

ly. As the most essential disaccharides, maltose and sucrose are broken down in the top of the intestinal brush border membrane (BBM)^[8], which hydrolyzes sugar to glucose and fructose and plays a vital role in the utilization of carbohydrate.

Maltase and sucrase activities are regulated by diet, and are enhanced by increasing substrate concentration^[9]. Our finding that maltose activity was markedly higher in the obese group suggests there is more robust intestinal digestion of starch in obese rats. Ferraris^[10] reported that sucrase activity increased 68% when sucrose was added to the diets of mice. We fed rats a high fat diet with some sucrose to establish an obese model. In contrast with Ferraris's results, we found no significant difference in sucrase activity between the obese and normal control groups. A possible explanation for this is that a high fat diet can stimulate secretion of trypsin, which reduces sucrase activity by degrading sucrose^[11]. Thus, the obese rats' high fat diet may account for the lack of variability in sucrase activity between the two groups.

According to Kellett's review^[3], there are two mechanisms of intestinal glucose absorption. When the luminal glucose level is lower than the blood glucose level, absorption occurs *via* SGLT-1 through classical active transport. Once the glucose concentration in the intestine is beyond the transport saturation of SGLT-1, the diffusion is mediated primarily by transient insertion of GLUT2 into the apical membrane (the apical membrane is op-

posed to the BLM). Lostao *et al.*^[12] reported that the diffusive component was three to five times greater than the active component at high luminal glucose concentrations. Therefore, GLUT2 is a key transport protein for glucose in the intestine.

We found that SGLT-1 and GLUT2 expression in the intestinal mucosa, as well as fasting plasma glucose levels, were all higher in obese rats than in non-obese rats. These findings are consistent with those of others^[2,13]. A prolonged high-fat diet may downregulate muscle insulin receptors, inducing insulin resistance or hyperinsulinemia^[3,13], and eventually leading to higher fasting plasma glucose levels. Sterol response element-binding protein (SREBP)-1c may exert beneficial effects in transporting glucose out of hepatocytes into blood, contributing to hyperglycemia^[14]. SREBP-1c may mediate glucose-stimulated GLUT2 gene expression upregulation by binding to the -84/-76 region to activate the GLUT2 promoter^[14]. In diabetic rats, GLUT2 expression increased hyperglycemia in the liver^[15,16], intestine, and pancreatic β -cells^[16]. Our results suggest that along with the increase in fasting plasma glucose levels, GLUT2 mRNA and protein expression are enhanced in the intestinal mucosa of obese rats, which results in greater glucose digestive ability and eventually obesity.

We observed that obese rats fed a high fat diet showed greater insertion of apical GLUT2 than did non-obese controls. It has been proposed that GLUT2 normally resides at the BLM but it can insert within min into the apical membrane of the intestine in response to high glucose concentrations; this facilitated component of absorption is called the apical GLUT2 pathway^[3]. GLUT2 translocates to the apical membrane by at least two signaling pathways: one related to calcium absorption *via* the nonclassical neuroendocrine L-type voltage-dependent calcium channel (Cav1.3), and the other activated by sweet taste receptors stimulated by natural sugars and artificial sweeteners^[17].

After the activation of protein kinase C (PKC) β II, a large number of GLUT2 proteins are inserted into the apical membrane to transport glucose^[3]. As glucose is absorbed and its concentration in the intestine decreases, the signaling system is reversed, and GLUT2 leaves the apical membrane to restore the condition of low luminal glucose concentrations^[18]. However, permanent apical GLUT2 insertion in a pathological state may result in increased sugar absorption and eventually lead to obesity, insulin resistance and diabetes^[3,17]. All rats in our experiment were denied food for 12 h before being euthanized to avoid high glucose concentrations in the intestine. Thus, we speculate that the apical GLUT2 in obese rats was a kind of pathological permanent insertion^[3]. Insulin binding to its enterocyte receptor (IR) inhibits the insertion of apical GLUT2, resulting in rapid trafficking of GLUT2 away from both the apical membrane and the BLM into the cell^[19]. This function of insulin could be impaired by a prolonged high fat diet, leading to the permanent insertion of apical GLUT2.

Octreotide, a type of octopeptide, is an artificial syn-

thetic analogue of SST. It has a longer half-life than natural SST. It binds to SSTR2 with high affinity, and has intermediate affinity for SSTR3 and SSTR5^[4]. According to the work of Aydede *et al.*^[20], octreotide was safe and effective when administered subcutaneously (at 100 μ g/kg 12 h apart) for 2 wk in rats with portal hypertensive colopathy. Thus, octreotide at 40 μ g/kg 12 h apart for 8 d in our experiment seems reasonable. Some studies reported that children with hypothalamic obesity and hyperinsulinaemic obese adults received octreotide at a dosage of 5-15 μ g/kg per day or long-acting release octreotide 40 mg/28 d for 6 mo, respectively, could decrease body weight by inhibiting β -cell insulin secretion^[21,22]. In the present study, we also observed decreased body weight in obese rats after octreotide treatment. Lustig *et al.*^[21] found that almost half of children with hypothalamic obesity developed gallstone or sludge formation after treatment with octreotide for about 6 mo. However, ursodeoxycholic acid could reverse these problems^[23].

Our experiments show that in comparison to the untreated obese rats, the octreotide-treated obese rats had much lower fasting plasma glucose levels. It may be that octreotide has a high affinity for SSTR2, which inhibits the release of glucagon by pancreatic α -cells^[24] and results in a decrease in fasting plasma glucose levels. Moreover, decreased GLUT2 mRNA and protein levels were found in the octreotide-treated obese rats, which is consistent with the idea that glycemia is a systemic factor that can affect GLUT2 expression^[25].

We found that the octreotide-treated group had significantly lower apical GLUT2 levels than the obese group. A possible explanation for this is that octreotide tightly binds to SSTR2, and SSTR2 binds with $G_{\alpha 02}$ to inhibit the L-type calcium channel and reduce Ca^{2+} transportation^[4,26], which in turn suppresses the translocation of GLUT2 by depressing the activation of PKC β II^[3].

In conclusion, our results indicate that high fat diet-induced obesity in rats is associated with increased fasting plasma glucose levels, intestinal maltase activity, GLUT2 expression, and permanent apical GLUT2 in small intestinal mucosa. After treatment with octreotide, an analogue of somatostatin, fasting plasma glucose levels, expression of GLUT2, and insertion of apical GLUT2 were inhibited, and eventually the obese rats lost weight. Therefore, the use of an analogue of somatostatin, such as octreotide, to suppress glucose absorption in intestinal mucosa may provide a novel approach in the pharmacological treatment of obesity.

COMMENTS

Background

Obesity induced by a high fat diet can result in disorders of glucose metabolism, and lead to impaired glucose tolerance or diabetes. Maltase and sucrase are the most important disaccharidases in sugar absorption. In addition, Glucose transporter type 2 (GLUT2) is a key transport protein for glucose in the small intestine. It is unknown whether obesity induced by a high fat diet is associated with glucose absorption. The relationship between the somatostatin analogue, octreotide, and glucose absorption in obesity has not yet been reported.

Research frontiers

Although diet is an important way of treating nutritional obesity, many patients

fail to lose weight with diet control. It is not known whether octreotide, a somatostatin analogue, which has an important role in the regulation of physiological functions in the small intestine, is able to inhibit glucose absorption. In the present study, the authors demonstrated that octreotide can inhibit glucose absorption and the potential mechanisms involved in obese rats.

Innovations and breakthroughs

Recently, several studies have shown the change in GLUT2 expression in diabetes or insulin resistance. Other researchers focused on the role of somatostatin analogues by suppressing β -cell insulin secretion in obesity in humans. This is the first study to provide evidence that the somatostatin analogue, octreotide, can inhibit glucose absorption in obese rats.

Applications

Since this study suggested that octreotide may be effective in inhibiting glucose absorption, octreotide might have potential applications as an alternative medicine in the treatment of obesity.

Terminology

GLUT2 is normally thought to reside at the basolateral membrane in the small intestine, and it can be inserted within minutes into the apical membrane *in vivo* in response to high glucose concentrations. Somatostatin is a 14- or 28-amino-acid peptide, which mainly inhibits exocrine and endocrine secretion, motility and absorption via different somatostatin receptors in the gastrointestinal tract. Octreotide, a type of octapeptide, is an artificial synthetic analogue of somatostatin which is more convenient to use and has a longer half-life and duration of activity and fewer side effects.

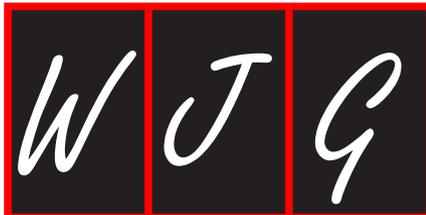

Peer review

The authors well demonstrated that high fat feeding produces permanent apical GLUT2 expression in addition to increased maltase activity, and octreotide improves all of them leading to decreased body weight and blood glucose levels compared to controls. The authors indicated the clinical significance of their findings. The authors need to discuss on the dosage of octreotide used in this and human studies. The potential side effects of octreotide such as gallstone should also be considered.

metastases are a risk factor for intracranial hemorrhage during anti-vascular endothelial growth factor (VEGF) therapy. We report a 64-year-old man and a 65-year-old man with recurrent colorectal cancer without brain metastases; these patients developed multifocal and solitary intracranial hemorrhage, respectively, after the administration of bevacizumab. Our findings suggest that intracranial hemorrhage can occur even if the patient does not have brain metastases prior to bevacizumab treatment and also suggest that brain metastases are not a risk factor for intracranial hemorrhage with bevacizumab treatment. These findings also question the necessity of excluding patients with brain metastases from clinical trials on anti-VEGF therapy.

Abstract

Treatment with bevacizumab, an antiangiogenic agent, in patients with metastatic or unresectable colorectal cancer was approved less than 4 years ago in Japan. Bevacizumab improves the survival of patients with metastatic colorectal cancer; however, it may lead to complications such as bleeding, which are sometimes fatal. Bevacizumab should be administered only after careful consideration because the potential risks of therapy outweigh its benefits. Therefore, pharmaceutical companies do not recommend bevacizumab therapy for patients with brain metastases. While some reports support the cautious use of bevacizumab, others report that it is not always necessary to prohibit its use in patients with metastases to the central nervous system (CNS), including the brain. Thus, bevacizumab therapy in colorectal cancer patients with brain metastases is controversial, and it is unclear whether brain

INTRODUCTION

Bevacizumab (Avastin[®], Chugai, Tokyo, Japan) is a recombinant humanized monoclonal antibody that selectively binds to and neutralizes the biological activity of vascular endothelial growth factor (VEGF) receptor^[1-4].

It reduces tumor vascularization and inhibits tumor growth, and has been shown to be efficacious in metastatic breast, colorectal, non-small cell lung, and renal cell carcinoma in combination with other agents^[1,5-9]. Thus, therapeutically bevacizumab can greatly enhance overall survival and progression-free survival in cases where patients are undergoing treatment for cancer metastasis or recurrence of colorectal cancer.

In spite of its efficacy, bevacizumab sometimes causes complications such as hypertension, gastrointestinal perforation, wound healing complications, arterial thromboembolic events, and bleeding, which are associated with mechanism-based adverse events. In 1977, it was reported that treatment with bevacizumab in a patient with undiagnosed brain metastasis from hepatocellular carcinoma caused fatal cerebral hemorrhage; this led to the suggestion that patients with brain metastases should not be treated with bevacizumab^[9]. Conversely, several investigators have reported that there is no evidence that anti-VEGF therapy, including bevacizumab, results in an increased risk of intracranial hemorrhage (ICH), regardless of the presence of central nervous system (CNS) metastases^[1,10]. Bhaskara *et al.*^[11] suggested that bevacizumab therapy is promising in the case of primary brain malignancies as well as metastatic disease. Therefore, whether cases with metastases to the CNS should be treated with combination chemotherapy including bevacizumab has provoked an ongoing discussion in this field^[1,10]. Only a limited number of cases of CNS bleeding associated with bevacizumab treatment have been reported, offering little, if any, strong argument for limiting the use of bevacizumab as a combination therapy in cancer.

In this study, we report 2 patients with recurrent colorectal cancer in the absence of brain metastases who underwent bevacizumab treatment; severe multifocal or solitary ICH was observed after this treatment.

CASE REPORT

Case 1

A 64-year-old man with lower rectal carcinoma underwent abdominoperineal excision with lymph node dissection in January 2004. According to tumor-node-metastasis (TNM) classification, the pathological stage of the carcinoma was T2N0M0 (stage II). He underwent adjuvant chemotherapy with oral 5-fluorouracil (5-FU) for 6 mo. Approximately 2 years after surgery, the serum carcinoembryonic antigen (CEA) level started to increase; however, radiological examination failed to show whether the cancer had recurred. The patient was afraid of recurrence and wished to receive an oral anticancer agent; therefore, S-1 treatment was provided. At the 3-year follow-up visit, computed tomography (CT) of the pelvis and the lateral segment of the liver revealed the first recurrence sites. He was subsequently prescribed FOLFOX-4 [oxaliplatin/5-FU/leucovorin (LV)] every 2 wk over 5 courses. Partial hepatectomy was

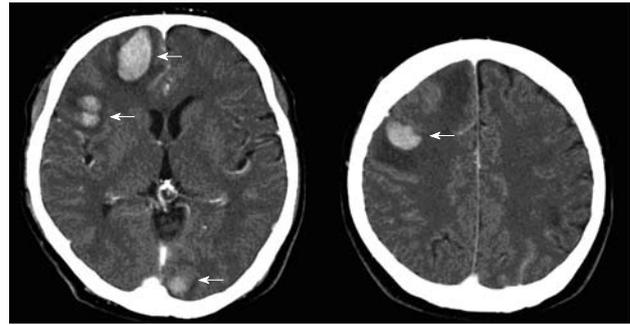

Figure 1 Contrast-enhanced computed tomography scan shows multifocal hemorrhage in the right frontal lobe, right temporal lobe, left occipital lobe, and right parietal lobe (white arrows).

performed for the solitary liver metastasis. Subsequently, FOLFOX-4 was repeated for approximately 12 mo; however, because of augmentation of the intrapelvic recurrence, bevacizumab was added in February 2010. After 4 courses of FOLFOX-4 in combination with bevacizumab (5 mg/kg), the patient suddenly developed dysarthria on day 2 of the 5th course, although he had tolerated the regimen fairly well until then. Brain CT revealed massive multifocal intracranial hemorrhage in the right frontal lobe, right temporal lobe, left occipital lobe, and right parietal lobe, although brain CT performed before bevacizumab administration revealed that there was no disorder in the brain, including metastasis (Figure 1). He had no history of head injury, but had hypertension before and after administration of bevacizumab, which was well controlled with medication. Hematological testing revealed slight thrombopenia (platelet count, $8.5 \times 10^4/\mu\text{L}$). These data together with other laboratory data for this patient met the criteria for the administration of FOLFOX-4 with bevacizumab. A neurosurgeon was immediately consulted, and an urgent craniotomy was performed to judge whether the multiple hemorrhages were accompanied by brain metastases. A hematoma was removed from the right frontal lobe of the brain. The removed hematoma did not show any histological signs of tumor components microscopically, which suggested that the multiple ICHs might be caused by bevacizumab. The patient soon recovered, and follow-up brain CT revealed the complete disappearance of multiple ICHs 6 wk after craniotomy. We discontinued chemotherapy, which included FOLFOX-4 with bevacizumab, and the patient was placed under another regimen; FOLFIRI (irinotecan/5-FU/LV), which the patient had not previously undergone, and was restarted within 8 wk after craniotomy. The serum CEA level gradually leveled off; intrapelvic recurrence has been uncontrollable since we discontinued the combination therapy of FOLFOX-4 with bevacizumab.

Case 2

A 65-year-old man with ascending colon carcinoma and liver metastases underwent right hemicolectomy with lymph node dissection, and partial hepatectomy in

February 2008. According to TNM classification, the pathological stage of the carcinoma was T2 N0 M1 (stage IV). He was treated with an intra-arterial infusion of 5-FU/intravenous infusion of LV for 5 mo. Subsequently, pulmonary metastasis became obvious in the 6-mo follow-up CT scan. Chemotherapy with oral 5-FU/LV was then prescribed for 6 mo, but the metastatic lesion progressed. He subsequently received FOLFOX-4 which was repeated for 15 courses over 12 mo. However, the lesion developed further. For the solitary pulmonary metastasis, partial lung resection was performed in March 2010. After that, a course of FOLFIRI with bevacizumab 5 mg/kg was started in July 2010. After 2 courses of FOLFIRI in combination with bevacizumab every 3 wk, which was tolerated fairly well, the patient suddenly developed left hemiplegia on day 11 of the 3rd course. Brain CT revealed right thalamus hemorrhage, although brain CT performed before starting chemotherapy showed no brain disorder, including metastasis, similar to case 1 (Figure 2). He had no history of head injury, but had hypertension that was well controlled with antihypertensive agents before and after administration of bevacizumab. His hematological results met the criteria for the administration of FOLFIRI with bevacizumab. Because of the right thalamic hemorrhage, combination chemotherapy of FOLFIRI with bevacizumab was discontinued.

DISCUSSION

Although minor bleeding, for example, grade 1 or 2 epistaxis, is a well-known complication of bevacizumab, serious bleeding such as hematemesis or hemoptysis (grade 3 and 4) occurs only in 3% of the patients treated with bevacizumab^[10,12]. As there is a possibility that bevacizumab administration can increase the risk of bleeding, it is advised that patients with CNS metastases should be excluded from treatment with bevacizumab. If bleeding into brain metastases occurs even once, it can have devastating complications that could develop into serious morbidity and mortality. To our knowledge, 8 cases of bevacizumab-associated CNS bleeding have been reported^[13-16]. Table 1 shows the characteristics of these cases. There have been 2 case reports that raise caution regarding ICH in patients without brain metastases under bevacizumab administration due to the use of anticoagulant agents^[13,14]. The first reports 2 cases where bevacizumab was accompanied by low-molecular-weight heparin. It draws attention to the fact that a full dose of anticoagulation agent with bevacizumab may increase the risk of ICH, regardless of whether a patient has any underlying parenchymal or intracranial vascular lesions^[13]. The second study reports a case of arteriovenous malformation (AVM)^[14]. These 3 patients did not have brain metastases, but presented with factors related to bleeding such as anticoagulation therapy and AVM. In addition to these 3 cases and the 2 cases presented here, 3 other cases of CNS bleeding have been reported by Chen *et al*^[15] and Giantonio *et al*^[16]. However, these 2 reports did not mention whether the patients had brain metastases^[16].

In contrast, more information on the safety of bevacizumab therapy in patients with CNS metastases is being reported. There has been several reports affirming the use of bevacizumab in treating patients with CNS metastases or primary brain tumors^[1,17-20]. Bhaskara *et al*^[11] presented a challenging case of a treatment-naïve patient with colorectal cancer and brain metastases. They emphasized the importance of weighing the risks and benefits of a treatment course when selecting treat-

ment options, and demonstrated the feasibility of bevacizumab in the treatment of metastatic brain tumors from colorectal cancer. Labidi *et al*^[21] showed no tumor-associated cerebral hemorrhage in patients with metastases from breast carcinoma treated with bevacizumab and paclitaxel. Moreover, Besse *et al*^[11] explored whether the general exclusion of patients with CNS metastases from bevacizumab treatment is justified, and concluded that patients with CNS metastases from advanced or metastatic breast cancer, non-small cell carcinoma, renal cell carcinoma, and colorectal cancer should not generally be excluded from bevacizumab therapy because such patients are at a similar risk of developing cerebral hemorrhage, independent of bevacizumab therapy.

The mechanism of bevacizumab is mainly thought to inhibit angiogenesis through VEGF. VEGF is an important mediator in new blood vessel formation in both physiological and pathological settings^[2]. Among the multitude of factors driving tumor angiogenesis, VEGF is the most potent, exerting myriad effects on vascular pruning and sprouting, permeability, network formation, proliferation, and cell death. Despite the initial unimpressive clinical performance of anti-VEGF antibodies, such as bevacizumab, as a cancer monotherapy, clear improvements in clinical outcomes following combination therapy of bevacizumab with chemotherapy regimens, and multi-targeted VEGF receptor tyrosine kinase inhibitors, such as sorafenib and sunitinib, in selected tumor types have established VEGF-targeted agents as an effective means of controlling cancer growth^[22]. Anti-VEGF therapeutic agents have been shown to have clinical benefits, although induction of bleeding is a recognized side effect that can sometimes occur and become troublesome during therapy.

The recent safety information on anti-VEGF therapy has been encouraging. Carden *et al*^[10] reviewed the current literature to determine whether there is a high incidence of significant bleeding due to anti-VEGF therapy. They identified 57 trials examining the safety of anti-VEGF therapy including bevacizumab in a total of 10 598 patients. In their studies, phase I and II clinical trials of anti-VEGF agents that excluded or included brain metastases did not show any significant differences (2 out of 1711; < 1% *vs* 1 out of 524; < 1%). Trials of anti-VEGF therapy, such as sunitinib and sorafenib, which included patients treated for active brain metastases revealed no episodes of ICH. Thus, the authors concluded there was no evidence of anti-VEGF therapy conferring an increased risk of cerebral hemorrhage, regardless of CNS metastases.

As well as metastatic lesions, data are available from bevacizumab trials in primary malignant brain tumors. For instance, Vrendenburgh *et al*^[23] reported the results of a phase II trial of bevacizumab and irinotecan treatment every 2 wk in recurrent malignant glioma, and showed that anti-VEGF therapy was not associated with an increased risk of ICH. Studies of anti-VEGF agents in patients with high-grade gliomas have been collective-

ly presented by Carden *et al*^[10]. They collated 5 studies of anti-VEGF agents including bevacizumab, vatalanib, and cediranib used in the treatment of high-grade gliomas^[10]. The limited data currently available on these studies showed no evidence that anti-VEGF therapy for high-grade gliomas increased the risk of ICH^[23,24].

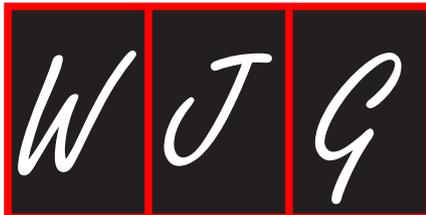

Collectively, the existing clinical literature and the cases presented here, suggest that patients with metastatic or primary brain tumors need not necessarily be excluded from treatment with anti-VEGF agents, rather that anti-VEGF therapy needs to be prescribed only after careful examination of the patient's history. This is because at least 6 out of 8 cases had CNS bleeding without CNS metastasis^[13-15]. Although, we cannot deny that ICH in the 2 cases presented here could have occurred by chance, they both have commonalities in their clinical presentation. Both had high-blood pressure, even though it was well controlled with medication. Although only 2 such cases are presented here, we think that rather than examining whether primary or metastatic brain tumors are present or absent when considering risk factors for ICH during anti-VEGF treatment (including bevacizumab), precautions should be taken when treating patients who have thrombocytopenia or are undergoing therapy with anticoagulation or antihypertensive agents. The 2 cases presented here and recent available reports do not confirm that anti-VEGF therapy for patients with metastatic brain tumors from colorectal cancer is a safe treatment, but suggest that anti-VEGF agents, including bevacizumab, are an alternative for patients with metastatic colorectal cancers, even in the presence of brain metastases. Epidemiological prospective studies should be carried out in order to identify the risk factors for ICH in patients treated with anti-VEGF agents.

Abstract

I read with great interest the article of Fu *et al* who investigated whether non-alcoholic fatty liver disease (NAFLD) is an early mediator for prediction of metabolic syndrome, and whether liver B-ultrasound could be used for its diagnosis, in a study involving 861 obese children (6-16 years old). In this study, it was reported that NAFLD is not only a liver disease, but also an early mediator that reflects metabolic disorder, and that liver B-ultrasound can be a useful tool for metabolic syndrome (MS) screening. The authors reported that NAFLD and MS were present in 68.18% and 25.67% of obese children, respectively. Moreover, they observed that the prevalence of MS in NAFLD children was 37.64%, which was much higher than that in the non-NAFLD group. Criteria analogous to those of the Adult Treatment Panel III definition for MS were used for children in this study. The reported prevalence data on MS in the young has varied markedly, in large part because of disagreement among the variously proposed definitions of MS. Therefore, in my opinion, a study aiming to assess the association between MS components and NAFLD in obese children has to take into account a simple, easy-to-apply clinical definition proposed by the international diabetes federation for MS. Interpretation of the results of the Fu *et al* study are limited by

another major caveat: that the diagnosis or exclusion of NAFLD was based on liver enzymes and ultrasound imaging, but was not confirmed by liver biopsy. Indeed, it is known that liver enzymes may be within the reference interval in up to 70% of patients with diagnosed NAFLD and that the full histopathological spectrum of NAFLD may be present in patients with normal liver enzymes, which therefore cannot be reliably used to exclude the presence of NAFLD.

TO THE EDITOR

I read with great interest the article of Fu *et al*^[1], who investigated whether non-alcoholic fatty liver disease (NAFLD) is an early mediator for prediction of metabolic syndrome, and whether liver B-ultrasound can be used for its diagnosis, in a study of 861 obese children (6-16 years old). In this study, it was reported that NAFLD is not only a liver disease, but also an early mediator that reflects metabolic disorder, and that

liver B-ultrasound can be a useful tool for metabolic syndrome (MS) screening. The authors reported that NAFLD and MS were present in 68.18% and 25.67% of obese children, respectively. Moreover, they observed that the prevalence of MS in NAFLD children was 37.64%, which was much higher than that in the non-NAFLD group. Criteria analogous to those of the adult treatment panel (ATP) III definition for MS were used for children in this study.

Since De Ferranti *et al*^[2] demonstrated different prevalence rates of MS by using slightly different modifications of the ATP III criteria in the same population using the same dataset, there has been a need for standardization of MS in children. For example, De Ferranti *et al*^[2] analyzed the same population which consisted of 2430 adolescents aged 12-19 years who had been previously evaluated by Cook *et al*^[3] using slightly different criteria. Changing the criteria for the diagnosis increased the prevalence of the MS from 4.2% to 9.3% in the total population and from 28.7% to 31.2% among the obese population in the total cohort.

In our previous study^[4], we have reported that MS defined according to modified WHO criteria adapted for children was found in 27.2% of young people, with a significantly higher rate among obese adolescents aged 12-18 years (37.6%) than among obese children aged 7-11 years (20%) ($P < 0.001$). Several studies have revealed race/ethnic differences in the prevalence of MS in children as well as in adults.

In 2007, recognizing how difficult it is to have multiple working definitions of the MS, the international diabetes federation (IDF) published its definition for children^[5]. The new IDF definition is ranked according to age groups 6 to < 10 years, 10 to < 16 years, and ≥ 16 years. This was believed to be necessary because of the developmental challenges presented by age-related differences in children and adolescents. Children < 6 years were excluded as a result of insufficient data in this age group. The IDF suggests that below 10 year of age, the MS should not be diagnosed, and a strong message for weight reduction should be delivered to parents and caregivers of those with abdominal obesity.

As described, the reported prevalence data on MS in the young has varied markedly, in large part because of disagreement among the variously proposed definitions of MS. Therefore, in my opinion, a study aiming to assess the association between MS components and NAFLD in obese children has to take into account the simple, easy-to-apply clinical definition proposed by the IDF for MS. Moreover, the statement: "There were significantly higher incidences concerning every component of MS in obese children with NAFLD compared with

the non-NAFLD group" is unclear and probably wrong since data for MS were derived from a prepubertal age group most of whom were below 10 years of age. The major concern originates from the assumption that in order to validate such a result it is mandatory to consider a wide population of adolescents. The authors have not referenced other studies evaluating MS in children in this paper, but they offer a new observation.

Interpretation of the results of the Fu *et al*^[1] study are limited by another major caveat that the diagnosis or exclusion of NAFLD was based on liver enzymes and ultrasound imaging, but was not confirmed by liver biopsy. Indeed, it is known that liver enzymes may be within the reference interval in up to 70% of patients with diagnosed NAFLD and that the full histopathological spectrum of NAFLD may be present in patients with normal liver enzymes, which therefore cannot be reliably used to exclude the presence of NAFLD^[6]. Moreover, although liver ultrasonography is widely used for diagnosing NAFLD, this imaging method has good sensitivity and specificity only for detection of moderate and severe hepatic steatosis, but its sensitivity is reduced when hepatic fat infiltration on liver biopsy is < 33%^[7]. Only liver biopsy can be used for diagnosing NAFLD and accurately determining the histological severity and prognosis of liver damage^[6].

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

This systematic review addresses the pathophysiology, diagnostic evaluation, and treatment of several chronic pain syndromes affecting the pelvic organs: chronic proctalgia, coccygodynia, pudendal neuralgia, and chronic pelvic pain. Chronic or recurrent pain in the anal canal, rectum, or other pelvic organs occurs in 7% to 24% of the population and is associated with impaired quality of life and high health care costs. However, these pain syndromes are poorly understood, with little research evidence available to guide their diagnosis and treatment. This situation appears to be changing: A recently published large randomized,

controlled trial by our group comparing biofeedback, electrogalvanic stimulation, and massage for the treatment of chronic proctalgia has shown success rates of 85% for biofeedback when patients are selected based on physical examination evidence of tenderness in response to traction on the levator ani muscle—a physical sign suggestive of striated muscle tension. Excessive tension (spasm) in the striated muscles of the pelvic floor appears to be common to most of the pelvic pain syndromes. This suggests the possibility that similar approaches to diagnostic assessment and treatment may improve outcomes in other pelvic pain disorders.

INTRODUCTION

Chronic or frequently recurring pain in the anal canal, rectum, or pelvis is a prevalent symptom that affects an estimated 6.6% of the population^[1]. Although only 1/3 of people with such pains consult physicians, they nev-

ertheless report significant impairment in quality of life, work absenteeism, and psychological distress. However, despite its prevalence and impact, relatively little research has been published which addresses its epidemiology, pathophysiology, and treatment; and pelvic and rectal pain is widely considered frustrating to diagnose and treat. This may soon change: Our group recently reported a randomized controlled trial^[2] in which we compared different approaches to treating chronic proctalgia and showed that the results were excellent 85% success rate if the patients were appropriately screened. This study also provided new insights into the pathophysiology of chronic proctalgia and stimulated renewed interest in anorectal pain syndromes. The aims of this review are to critically assess what is known about the diagnosis and treatment of the most common forms of anorectal and pelvic pain, namely chronic proctalgia, chronic pelvic pain, coccygodynia, and pudendal neuralgia. This review is meant to help Gastroenterologists and Colorectal Surgeons when dealing with complex consultation on pelvic pain syndromes. It is mostly focused on chronic proctalgia and issues of differential diagnosis with other pelvic pain syndromes.

One of the challenges in caring for patients with anorectal and pelvic pain is that a number of inflammatory and structural etiologies must be considered. The organic diseases that are most commonly involved in chronic anorectal and pelvic pain are cryptitis, fissure, abscess, hemorrhoids, solitary rectal ulcer, inflammatory bowel disease, and rectal ischemia^[3]. One should also consider chronic prostatitis and pelvic endometriosis as potential contributors to chronic pelvic pain^[3]. Although the differential diagnosis is large and unfortunately poorly standardized, our experience^[2] suggests that no organic disease explanation will be found in approximately 85% of patients presenting to gastroenterologists with chronic anorectal or pelvic pain. We screened 227 patients referred for unremitting, chronic rectal pain with a diagnostic evaluation that included digital rectal examination, colonoscopy, pelvic ultrasound and surgical consultation in all patients, plus gynecology and urology referrals in selected cases^[2]. This extensive work-up identified only 33 patients (15%) with a probable organic disease accounting for their symptoms. Thus, for most patients with chronic anorectal or pelvic pain, the origin of the pain is uncertain and the relevant pathophysiological mechanisms are unclear. These are commonly defined as “functional” chronic anorectal and pelvic pain syndromes since no structural and anatomical disease was found. These functional pain syndromes constitute the main subject of this review.

CHRONIC PROCTALGIA

Chronic proctalgia is a general term for chronic or recurring pain in the anal canal or rectum^[3]. Other names considered synonymous with chronic proctalgia are levator ani syndrome, puborectalis syndrome, chronic

idiopathic perineal pain, piriformis syndrome, and pelvic tension myalgia. Thiele, one of the first researchers to investigate this pain syndrome, called it coccygodynia, although he acknowledged that the pain was not in the coccyx^[4]. To provide greater consistency in the diagnosis and labeling of anorectal pain syndromes, the Rome III criteria^[3] define chronic proctalgia as chronic or recurrent rectal pain or aching lasting at least 20 min, in the absence of structural or systemic disease explanations for these symptoms^[3]. Pain duration of at least 20 min is a key feature since shorter episodes of pain are suggestive of proctalgia fugax, which is defined as a sudden, severe pain in the anorectal region lasting less than 20 min and then disappearing completely^[3]. Proctalgia fugax may recur, but episodes are rare. Proctalgia fugax is believed to have a different etiology to chronic proctalgia, although there is no consensus on what causes it. Its consideration is beyond the scope of this review, which is intended to deal with chronic unremitting diseases.

Chronic proctalgia is further divided by the Rome III criteria into two subtypes—levator ani syndrome (LAS) and unspecified functional anorectal pain—based on the presence or absence of a sensation of tenderness when the levator muscle is palpated during digital rectal examination. This classification updates the previous Rome II classification in which LAS was designated as “highly likely” if traction on the pelvic floor produced a report of tenderness and only “possible LAS” if no tenderness was elicited^[5]. Subgrouping patients with chronic proctalgia is consistent with clinical experience of different response to treatment, but distinct epidemiology and pathophysiology data are lacking^[5]. Therefore, data provided mostly refer to chronic proctalgia patients as a whole.

Pathophysiology

Chronic tension or spasm of the striated muscles of the pelvic floor is commonly assumed to be the pathophysiological basis for chronic proctalgia^[3,5-7], although there is no definitive evidence for this hypothesis. Inflammation of the levator or arcus tendon of the levator ani muscle has also been suggested as a cause of chronic proctalgia, since tenderness on palpation is most commonly found on the left side where the muscle inserts into the pubic ramus of the pelvis. However, contrary to this tendinitis hypothesis, local steroid injection has not been shown to be an effective treatment for chronic proctalgia^[8]. In retrospective studies, many patients reported prior pelvic surgery, anal surgery and even spinal surgery as significant in the development of their pain syndrome^[6,9]. Childbirth can be another precipitating factor^[9]. In addition, high rates of anxiety disorders, depression, and stress are frequently reported in chronic proctalgia, and may act as significant precipitating factors in some patients^[6,10].

Except for the exclusion of organic diseases, tests of anorectal physiology and imaging studies were traditionally considered to be of little diagnostic or prognostic

value^[11,12]. Increased anal canal resting pressures tested by anorectal manometry were sometimes reported, but results were inconsistent. Grimaud and coworkers reported that LAS was associated with anal sphincter hypertonia and disordered defecation on dynamic proctography in a study of 12 patients, but this was not confirmed in a larger prospective study of 60 patients by Ger and coworkers^[11,13]. Ger *et al.*^[11] reported that LAS was associated with paradoxical contraction of the pelvic floor muscles on straining as evidenced by anal electromyography or defecography. However, all these studies were potentially biased by small size, mixed patient population, and poor patient selection^[3,5]. In addition, a number of structural disorders (descending perineum, rectocele, mucosal prolapse and pelvic floor dyssynergia) have been reported in small studies^[6,11-13].

In a recent study, Hompes *et al.*^[14] reported on 59 patients referred to a Pelvic Floor Clinic for chronic functional anorectal pain who were tested by means of defecating proctography, anorectal manometry, anal ultrasound, and in selected cases, rectal examination under anesthesia. The same diagnostic protocol was applied to 543 rectal prolapse patients complaining of obstructed defecation and to a control group of patients with fecal incontinence. In the control group with fecal incontinence, pain was reported in 50% of patients but was a non-dominant symptom. Anorectal manometry failed to show any difference among groups. Rectal morphology examinations demonstrated high grade internal rectal prolapse in 59% of pain patients, which was often associated with symptoms of obstructed defecation. The authors concluded that rectal prolapse commonly underlies chronic proctalgia, particularly when obstructed defecation is present. However, the severity of prolapse did not correlate with pain intensity, leaving pain pathophysiology unclear^[14]. In addition, chronic idiopathic rectal pain is sometimes reported as a complication of corrective surgery for rectal prolapse^[14].

An innovative pathophysiology explanation for chronic proctalgia was recently reported by our group in a large, prospective, randomized controlled trial comparing biofeedback, electrogalvanic stimulation (EGS), and digital massage of the levator muscles for the treatment of chronic proctalgia. In this study, 157 patients with chronic proctalgia (confirmed by Rome II criteria) were studied by anorectal manometry and a balloon evacuation test at baseline and again after 3 mo of treatment^[2]. Based on a priori exclusion criteria, patients reporting symptoms consistent with either irritable bowel syndrome or functional constipation were not enrolled in the study. In patients reporting tenderness on palpation of the levator muscles (Rome II: highly likely LAS, Rome III: LAS), physiologic features of dyssynergic defecation (i.e., paradoxical contraction or failure to relax the pelvic floor on straining) were seen in approximately 85% of subjects in the absence of symptoms of constipation. Conversely, in patients who denied tenderness when the levators were palpated during digital rectal

examination, inability to relax pelvic floor muscles when straining was an uncommon finding (19%). Dyssynergic defecation was a strong predictor of successful treatment outcome. These observations led us to conclude that the physiologic mechanisms responsible for LAS and dyssynergic defecation are similar^[2].

This study also showed that the inability to relax pelvic floor muscles when straining to defecate may occur without symptoms of constipation, even though it is commonly assumed that dyssynergic defecation invariably results in obstructed defecation. Factors that interact with pelvic floor physiology to determine which symptoms develop—either pain or constipation—are left unanswered by our study and deserve further investigations. Also, we were not able to provide a physiological explanation for unspecified functional anorectal pain (i.e., anorectal pain without tenderness on digital palpation), which may represent a heterogeneous group of patients. Our study suggests, however, that adding a simple balloon evacuation test with a disposable Foley catheter to the diagnostic work up of chronic proctalgia patients enables one to select subjects that are more likely to benefit from pelvic floor rehabilitation.

Clinical presentation

Chronic proctalgia is often described by patients as a dull ache or pressure sensation in the rectum that is exacerbated by prolonged sitting and relieved by standing or lying down^[3,5]. This pain rarely occurs at night; rather, it usually begins in the morning and increases in severity throughout the day. The pain may be precipitated by long-distance car travelling, stress, sexual intercourse and defecation^[6,7]. During digital rectal examination, the examining finger is moved from the coccyx posteriorly to the symphysis pubis anteriorly^[5,7]. For unexplained reasons, tenderness is often non-symmetric, being greater on the left side than on the right^[5]. When performing digital rectal examination, the examiner should pause after inserting their finger into the rectum before applying traction on the levator muscles to avoid false positive results. In our experience, repeating the posterior traction on the levator muscle on the same exam is also useful to check for reproducibility and to avoid false positive results.

Diagnostic assessment

Although our recent study provides new insights into the pathophysiology of chronic proctalgia, these observations require validation by other laboratories before they can be incorporated as diagnostic criteria. The diagnosis of chronic proctalgia still relies on (1) clinical symptoms of recurring or chronic pain or aching in the anal canal or rectum with episodes lasting 20 min or longer^[3], and (2) exclusion of alternative disease explanations for these symptoms by multiple diagnostic tests and consultations by other specialists. In addition, digital rectal examination should be performed to ascertain whether the patient reports tenderness when traction is applied to the levator ani muscles because this diagnostic sign

is a strong predictor of whether the patient is likely to benefit from treatments directed at relaxing pelvic floor muscles.

Treatment

No single treatment has been reported to be consistently effective in chronic proctalgia^[3,7], and management can be a frustrating endeavor for both patients and physicians^[11]. The first-line treatment most commonly provided is reassurance that the pain is of benign origin and is not suggestive of malignancy^[7,9]. No data are available on the impact of reassurance, but education and counseling are often incorporated as a component of treatment.

Digital massage of the puborectalis sling, intended to relax tense muscles, was one of the first treatments proposed for chronic proctalgia^[9]. Massage of the puborectalis muscle should be performed in a firm manner with the affected side massaged up to 50 times, depending on the patient's tolerance. Some claim that if the massage is not uncomfortable to the patient while being performed, it may not be effective^[9]. Massage of the levator ani muscle is rarely performed as the sole therapy, with the most common adjunctive treatments being hot sitz baths or a short-term course of oral Diazepam, both of which are assumed to have myorelaxant properties. Earlier open-label studies suggested that digital massage combined with hot sitz baths and/or Diazepam were effective for relieving pain in 68% of 316 chronic proctalgia patients^[15]. However, benefits seemed to fade away during long-term follow-up, and the addictive potential of Diazepam discourages long-term treatment^[7].

Electrogalvanic stimulation, traditionally used by physiatrists to treat muscle spasticity^[9], has also been advocated for the treatment of LAS when conservative therapy is ineffective. A low frequency oscillating current applied to the pelvic floor muscles through an anal probe, induces fasciculation and prolonged fatigue, which breaks the spastic cycle and may produce sustained symptom relief. Low frequency current has no thermal effect. No side effects have ever been reported other than mild worsening of pain on the first days of treatment. Sohn and coworkers were the first to test EGS in an open study of 80 chronic proctalgia patients^[16]. They recommended a pulse frequency of 80 cycles per second with the voltage being gradually increased from zero to the point of discomfort (250-300 Volts according to patient's tolerance). Recommended treatment duration is one hour per day for 3 sessions in a ten-day period. In the Sohn study^[16], 91% of patients reported good to excellent pain relief from EGS in the short-term, but no long-term follow-up was reported. This high percentage of success was never replicated by subsequent open label studies, although approximately two-thirds of patients did report short-term pain relief. Treatment protocols varied widely in terms of number and duration of sessions. Authors claimed that non-responders showed features of psychology disturbances,

but no evidence was provided on the issue. However, three additional studies that investigated the long-term benefits of EGS treatment in chronic proctalgia found that only 25%-38% of patients reported persistent pain improvement^[17-19].

Biofeedback treatment of LAS was first described in 1991 by Grimaud and coworkers^[13]. They treated 12 patients with biofeedback techniques focused on voluntary relaxation of external anal sphincter tone. Pain disappeared in all patients after a mean of eight sessions. Subsequent studies using biofeedback were not able to replicate these results, with success rates varying from 35% to 87.5%^[6,11,19]. All studies were small, none was controlled, and treatment modalities varied.

Botulinum Toxin A (BoTox A) was tested in a randomized controlled trial run in 12 patients, and no differences in rectal pain were observed between patients injected with active BoTox *versus* those injected with saline^[20]. The average amount of time required to defecate a rectal balloon was actually increased after BoTox injection. The tendinitis (inflammation) hypothesis for chronic proctalgia was tested by steroid caudal block and by pelvic tender point injection of a mixture of Triamcinolone Acetonide and Lidocaine with negative results^[8,11]. Sacral nerve stimulation was also reported to be beneficial in an open study involving 27 chronic proctalgia patients. However, when benefits were assessed by intent to treat analysis, pain relief was reported in less than 50% of subjects^[21].

A major drawback in assessing the literature on chronic proctalgia treatment is the huge variation in inclusion criteria, outcome criteria, and follow-up intervals. Additional limitations are small sample sizes and lack of an appropriate control group. The few quasi-randomized studies had control groups that included subjects who received more than one treatment and patients not responding to a former therapy^[7]. To overcome these limitations, Chiarioni and coworkers recently reported a prospective, randomized controlled trial of 157 chronic proctalgia patients to investigate the comparative effectiveness of the 3 most commonly prescribed treatments: biofeedback to teach pelvic floor muscle relaxation, EGS, and digital massage of the levator muscles^[2]. A physiological assessment including manometry and balloon defecation was carried-out at baseline and at 1-3 mo follow-up. In addition, self-reported stool frequency was assessed at baseline and at 6-mo follow-up. The primary outcome was subjective reporting of adequate pain relief by the patient. Secondary outcomes included subjective pain improvement on an ordinal scale, number of days per month with rectal pain, and visual analog scale ratings of pain. According to Rome II criteria, proctalgia patients were subgrouped into highly likely LAS and possible LAS based on the presence or absence of levator tenderness at digital rectal exam, and randomization to treatment groups was stratified so that each treatment group contained a similar number of patients with a highly likely diagnosis of LAS.

At one-month follow-up, biofeedback was significantly more effective than EGS and massage by intent-to-treat analysis, with adequate relief of pain reported by 59.6% *vs* 32.7% *vs* 28.3% for biofeedback, EGS, and massage, respectively. Benefits were maintained throughout follow-up (12 mo) and no side effects were reported with any treatment. When results were further investigated in subgroups of patients, no treatment was effective in possible LAS patients (Rome III unspecified functional anorectal pain). However, among patients with highly likely LAS (Rome III levator ani syndrome) adequate relief was reported by 87% for biofeedback, 45% for EGS and 22% for massage at 1 mo follow-up. Improvements were maintained for the whole follow-up. The superiority of biofeedback was supported by all the secondary outcome measures including number of days per month with pain, which decreased from 14.7 per month to 3.3 per month for biofeedback, 8.9 for EGS, and 13.3 for massage^[2].

Physiological measurements revealed that the mechanism for achieving adequate pain relief was an improvement in pelvic floor function from being unable to relax anal canal pressures on straining to being able to do so and/or an improvement on the balloon evacuation test from being unable to pass a 50 mL balloon to being able to do so^[2]. This interpretation of the mechanism of action was confirmed by a post-hoc analysis showing that 94.2% of those who improved pelvic floor dysfunction on one or both of these measures reported adequate pain relief, while only 13.6% of those who did not improve pelvic floor function reported positive therapy outcome regardless of the treatment provided. In addition, stool frequency increased from baseline to post-treatment in responders, even in the absence of a former complaint of constipation. This study led us to conclude that biofeedback is an effective treatment for LAS, and EGS is somewhat effective. However, the minority of proctalgia patients affected by unspecified functional anorectal pain are still left without a satisfactory treatment option. In this regard, depression and anxiety are both frequently reported in non-responsive proctalgia patients^[6,10]. Brain processing of pain may be altered in functional gastrointestinal disorders, but data in proctalgia patients are lacking^[22]. In addition, no trial has actually evaluated the effect of either psychotherapy intervention or psychotropic drugs in proctalgia patients. Finally, there is no evidence that surgery can help these severely disabled patients. Invasive interventions should be avoided in the absence of a clearer etiologic understanding of non-responsive proctalgia patients^[3].

COCCYGDYNIA

Coccygodynia is defined as pain arising in or around the coccyx, usually triggered by prolonged sitting on hard surfaces^[23]. The pain is considered chronic when it lasts more than two months and it is commonly reported after repetitive trauma or childbirth^[23,24]. Coccygodynia may also be of idiopathic origin or secondary to lumbar

disc degeneration^[23-25]. It is also rarely reported as a complication of epidural injection of anesthetic or of various rectal and spine surgery^[25].

Pathophysiology

It is up to five times more common in women than in men, and obesity seems to be a predisposing factor due to the associated pelvic rotation^[23-25]. The female pelvic anatomy may also predispose to coccygodynia by leaving the coccyx more exposed to traumatic injury. The exact etiologic mechanism/s associated with coccygodynia are still obscure. Chronic spasm of the pelvic floor exerting a painful tension on a stiff coccyx has been traditionally considered a relevant etiologic factor, with accidental trauma acting as a trigger^[23-25]. However, instability of the coccyx potentially correlated with symptom severity was then discovered in a high percentage of patients by dedicated X-Ray examination^[26]. In addition, it is unclear whether pre-existing spine alterations play a role by predisposing patients to develop post-traumatic coccygodynia^[26,27]. Inflammation of structures (i.e., bursitis) in close proximity to the spine has also been described as a causative factor in a minority of patients complaining of coccygodynia^[27]. Depression and anxiety disorder have been reported to amplify coccygeal pain symptoms^[23]. Some authors do not diagnose coccygodynia when there is an ongoing medicolegal litigation, even if it occurs following a traumatic injury^[24,25].

Clinical presentation

Pain in the coccyx and in close anatomical regions (sacrum, perineum, anorectum) is the main reported symptom^[23]. Epidemiologic data on coccygodynia in the general population are lacking, but coccygodynia is considered to be a rare disorder. Retrospective data suggest that coccygodynia accounts for less than 1% of all reported cases of lower back pain^[24,25]. Diagnosis of coccygodynia relies heavily on history and clinical exam. Questioning the patient about previous trauma to the coccyx or childbirth trauma is a must, since according to Salvati the absence of a previous trauma makes the diagnosis unlikely^[9]. In addition, patients should report worsening of pain by prolonged sitting, bending, lifting or having a restricted poor posture for long intervals^[23-25]. Some patients may report that standing from a sitting position triggers the pain^[23].

Diagnostic assessment

Reproducing the usual pain by pressure or manipulation of the coccyx is key to diagnosis^[23]. Patients may also report mild tenderness on puborectalis posterior traction on digital rectal examination and a differential diagnosis of chronic proctalgia needs to be entertained^[9,28]. However, this maneuver should never be able to provoke the usual pain. Abnormal movement of the coccyx on palpation is an additional sign to confirm the clinical suspicion of coccygodynia^[25]. Dynamic X-Ray investigation may support the clinical diagnosis. The standard lateral

X-Ray investigation of the coccyx in the standing position should be supplemented with a second film taken while the patient is sitting on a hard surface possibly in a posture worsening the pain^[26]. More than 50% of patients would show features of coccyx instability (either exaggerated flexion or luxation) that seem to correlate with pain severity and previous traumatic events. An additional 15% of coccygodynia patients would show features of an abnormal bone spur at the end of the tailbone (so called spicule)^[26]. Spine magnetic resonance imaging (MRI) could be performed to exclude tumors or disc disease, but do not seem to add significantly to the diagnosis in coccygodynia^[25].

Treatment

The initial treatment of coccygodynia is focused on avoiding potentially offending factors and includes sitting on a donut-shaped pillow or a gel cushion to reduce pressure, posture ameliorating interventions, sitz bath and on demand nonsteroidal anti-inflammatory drugs^[23,24]. This treatment is commonly applied for 6-8 wk. No controlled study has investigated the therapeutic outcome of these simple measures. When initial treatment fails most authors recommend adding digital manipulation of the coccygeal ligaments as well as intrarectal manipulation of the pelvic floor muscles. Various massage and manipulation techniques have been described in open studies to decrease coccygeal pain in up to 85% of patients, particularly when combined with local steroid injection or physiotherapy^[29]. A recent prospective, randomized, controlled study aimed to compare intrarectal pelvic floor muscles manipulation (3 sessions) *vs* placebo physiotherapy (sacral short wave magnetic field applied at marginal power) in 102 chronic coccygodynia patients^[30]. Primary outcome was subjective decrement of more than 50% in pain intensity on a visual analog scale score at follow-up intervals of 1-6 mo. At 1 mo follow-up, 22% of patients in the manipulation group reported a significant pain decrement compared to only 12% of patients in the placebo group. Benefits persisted throughout follow-up in both groups. Manipulation was more effective in recent onset coccygodynia of post-traumatic origin not associated with instability of the coccyx. Psychosocial factors seemed to predict a poorer treatment outcome. The authors concluded that intrarectal manipulation is at least mildly effective in chronic coccygodynia and suggested either to increase the number of therapeutic sessions or to add local steroid injection to improve outcome. However, no randomized study has actually evaluated both treatment options for coccygodynia. In selected patients with severe and unresponsive coccygodynia, surgery may be considered^[31].

A recent review on surgical treatment of coccygodynia reported on 24 studies, but 22 of them were retrospective case series^[32]. Surgery was a treatment option in a minority of patients (approximately 19%), but mean satisfaction rate for pain relief was high (over 80% of treated patients). Some series reported a satisfactory out-

come of just 54% which was attributed to patient selection bias. Mean overall complication rate was 10.9% with wound infection being the most commonly reported complication. Surgeon expertise seemed to play a role since the smallest series reported the highest procedure-related complication rates (up to 50%). The type of surgery chosen was either total or partial removal of the coccyx and this did not seem to influence outcome. However, the worst outcomes were reported in patients with a history of rectal or spinal diseases and ongoing compensation issues^[32].

PUDENDAL NEURALGIA

Pathophysiology

Pudendal neuralgia is a chronic pain in the perineal area secondary to entrapment and injury to the pudendal nerve in its musculo-osteo-aponeurotic tunnel between the sacrotuberal and sacrospinal ligaments, in the absence of organic diseases that may explain this symptom^[23]. Pudendal neuralgia has been rarely described as secondary to herpetic neuropathy, stretch neuropathy, and post-radiotherapy neuropathy, but pudendal nerve entrapment is by far the most common etiology^[33,34]. Pudendal neuralgia is also called Alcock's canal syndrome, or pudendal canal syndrome^[23].

Clinical presentation

It is commonly described as a superficial pain, burning sensation, numbness, or paresthesia in the gluteal, perineal, and/or genital areas^[23]. It may be homolateral or bilateral, radiate to the pelvis and the thighs, and be associated with deep pelvic discomfort^[33,34]. Pain may be worsened by sexual intercourse and initially reported as sciatic pain^[53,34]. The epidemiology of pudendal neuralgia in the general population is unknown. The diagnosis is rarely considered except in highly focused Pelvic Floor Units or in specialized Urogynecologist practices. It is usually considered to be a rare entity, but it may be overdiagnosed due to the functional comorbidities associated with pudendal nerve dysfunction^[33,34]. Recently, a multidisciplinary Committee reported that pudendal neuralgia may be simply diagnosed by default in the presence of pelvic, perineal, and buttock pain without evidence of organic disease at diagnostic workup^[35]. Particularly controversial is its association with rectal pain, the presence of which requires differential diagnosis with chronic proctalgia^[23].

Diagnostic evaluation

Clinical neurophysiology has improved our knowledge of this disorder, but a definitive diagnostic test is still not available. As in many neuropathic pain syndromes, the diagnosis of pudendal neuralgia remains primarily clinical and should be reviewed in the light of the course of the disease. In 2006, a multidisciplinary working party on pudendal neuralgia held in Nantes, France, concluded that only the operative finding of nerve entrapment

and post-operative pain relief can formally confirm the diagnosis, provided the placebo effect of surgery is excluded^[35]. However, this panel of experts identified four domains of diagnostic criteria for pudendal neuralgia: (A) essential criteria, (B) complementary diagnostic criteria, (C) exclusion criteria, (D) associated signs not excluding the diagnosis. Essential criteria are particularly relevant and will be discussed in detail. (1) Pain should be limited to the innervation territory of the pudendal nerve. This excludes any pain that is limited to the coccygeal, pelvic or gluteal areas; (2) Pain is predominantly experienced while sitting, in accordance with the nerve compression etiology hypothesis. In long-standing pudendal neuralgia, pain may become continuous, but it is still worsened by the sitting position; (3) The pain rarely awakens the patient at night; (4) On clinical examination, no objective sensory impairment can be found even in the presence of paresthesia. The presence of a sensory defect should prompt investigations to exclude diseases of the sacral nerve roots and the cauda equina; and (5) Pain should be relieved by anesthetic infiltration of the pudendal nerve. This is an essential criterion, but it lacks specificity as pain related to any perineal disease may be relieved by pudendal nerve block. Moreover, a negative block does not exclude the diagnosis of pudendal neuralgia because it may have been performed inadequately (e.g., too distally). The complementary diagnostic criteria include the sensation of a rectal foreign body and the worsening of pain during defecation, both of which should prompt the physician to entertain the differential diagnosis of chronic proctalgia. Exclusion criteria for pudendal neuralgia are pain in a territory unrelated to the pudendal nerve, symptomatic pruritus instead of paresthesia, exclusively paroxysmal pain, and imaging abnormalities that could explain the symptom^[35].

Treatment

Pudendal neuralgia is treated by pudendal nerve block, which is both diagnostic and therapeutic. However, data on the long-term benefits of pudendal nerve block are lacking^[35]. In addition, only the operative demonstration of nerve entrapment and post-operative pain relief can formally confirm the diagnosis of pudendal neuralgia secondary to it, except for a potential placebo effect of surgery^[35].

CHRONIC PELVIC PAIN IN WOMEN

Chronic pelvic pain (CPP), which is diagnosed only in women, is commonly defined as noncyclic, nonmalignant pain in any organs related to the pelvis, in the absence of pregnancy and inflammatory bowel disease, that has lasted for at least six months^[36]. Pain occurring exclusively in association with menstruation (dysmenorrhea) and sexual intercourse (dyspareunia) are generally not considered to be CPP, but general agreement is lacking. Other definitions include a pain severity sufficient to cause functional disability or to require medical care^[36]. Since

the definition of CPP varies, it is difficult to ascertain its exact prevalence. However, the prevalence of CPP in the general population assessed by mail questionnaires among women aged 18-50 has been reported to be as high as 15% in the United States and 24% in the United Kingdom^[37,38]. CPP has been estimated to account for 10% of all outpatient referrals to gynecologists and 40% of diagnostic laparoscopies, so it constitutes a significant economic burden^[39,40]. No organic disease is found on laparoscopy in at least a third of women with CPP^[40]. In the community, 32% of patients who consult for this symptom report high rates of anxiety and quality of life impairment as measured by the SF-36^[37,38]. Consulting behavior is directly influenced by the severity of pain^[39].

Pathophysiology

The etiology of CPP is considered to be complex and multifactorial^[36,40]. Some gynecological diseases such as endometriosis, pelvic inflammatory disease, and interstitial cystitis may cause CPP, but gastrointestinal comorbidities are also reported in up to 1/3 of CPP patients in primary care^[38,40]. A psychosomatic component of pain has also been hypothesized^[36,40]. The common association of CPP with irritable bowel syndrome has led some to question whether these two diseases are actually a single clinical entity that is diagnosed differently according to the specialist consulted^[41]. The etiology of CPP is poorly understood.

Diagnostic assessment

Initial evaluation should include a history and physical examination to narrow the differential diagnosis^[40]. When this examination does not identify another explanation for the pain, limited laboratory testing and transvaginal ultrasound scanning is often employed to rule out organic disease and reassure the patient^[40]. The laboratory workup should include: complete blood count, beta human chorionic gonadotropin level, erythrocyte sedimentation rate, vaginal swabs for Chlamydia and Gonorrhea, and urinalysis with urine and culture^[40]. Additional magnetic resonance imaging should be considered when in doubt for organic disease and diagnostic laparoscopy may be eventually performed in selected cases^[40]. A tense pelvic floor is often reported during vaginal examination in CPP and spasm of the pelvic floor muscles is considered a relevant etiologic factor^[36]. In addition, up to 60% of patients may report symptoms of either voiding dysfunction or dyschezia^[42].

Treatment

Physiotherapy to relax the pelvic floor is often prescribed as first-line treatment for CPP, but randomized, controlled trials to confirm its effectiveness are lacking. Vaginal electrical stimulation was retrospectively reported to decrease pain in 52% of 66 chronic pelvic pain patients when coexistent levator ani spasm was also diagnosed by clinical exam^[43]. Benefits were generally sustained during a 30-wk follow-up. Nonetheless, few studies have evalu-

ated pelvic floor function in women with CPP. Abbott and coworkers reported pelvic floor myalgia in 68 out of 118 patients referred for long-standing, unresponsive CPP^[44]. They diagnosed pelvic floor myalgia based on objective evidence of contracted, painful pelvic muscles on palpation and elevated resting intraluminal pressures as measured by vaginal manometry. This study was a double blind, placebo controlled trial to test the efficacy of BoTox A in patients who had CPP with pelvic floor spasm. BoTox injection was associated with a significant reduction in vaginal resting pressure compared to placebo, but pain was only partially relieved and was not significantly different between BoTox and placebo. The authors concluded that pelvic floor spasm can cause CPP and that improvement in some symptoms occurs following reductions in muscle spasm^[44]. In open studies, a number of treatment modalities have been reported to be effective for decreasing symptoms in CPP. These options include either oral or intramuscular hormone therapy, levator ani trigger point steroid injections, and sacral neuromodulation^[36,40,42,45]. Most studies are open, retrospective, single center experiences with poor generalizability of treatment outcome.

Tricyclic antidepressants and Sertraline seem to work no better than placebo in CPP^[40]. Surgery should be limited to patients with an organic cause for pelvic pain^[36,40]. In non-responsive, severely disabled patients a multidisciplinary approach is advocated to fit with a biopsychosocial model of pain^[40].

CONCLUSION

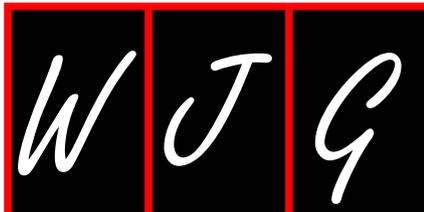

Chronic anorectal and pelvic pain syndromes receive little research attention despite the fact that they are prevalent, often disabling pain syndromes which are associated with significant health care costs and quality of life impact. Their frequency in the general population may be as high as 24% for chronic pelvic pain in women and 6.6% for chronic proctalgia. It is common for these patients to be referred to multiple specialists. Etiology is poorly defined, but chronic tension (spasm) in the striated muscles of the pelvic floor is often considered to be the pathophysiological mechanism for most of them. A recent randomized, controlled trial provided evidence that dyssynergic defecation (i.e., paradoxical contraction or failure to relax the pelvic floor muscles when straining to defecate) is the primary cause of pain for the majority of patients with chronic proctalgia, even for patients who do not complain of constipation. Biofeedback to treat dyssynergic defecation was an effective treatment for the subset of patients with chronic proctalgia who reported tenderness when traction was applied to the levator ani muscles during digital rectal exam (a sign of excessive tension in these muscles). This finding should prompt researchers to look for features of dyssynergic defecation in other pelvic pain syndromes and to try a similar treatment. A multidisciplinary and tailored approach to treat anorectal and pelvic pain patients without pelvic floor dysfunction is strongly suggested.

Abstract

Multiphoton microscopy, relying on the simultaneous absorption of two or more photons by a fluorophore, has come to occupy a prominent place in modern biomedical research with its ability to allow real-time observation of a single cell and molecules in intact tissues. Multiphoton microscopy exhibits nonlinear optical contrast properties, which can make it possible to provide an exceptionally large depth penetration with less phototoxicity. This system becomes more and more an inspiring tool for a non-invasive imaging system to realize "optical biopsy" and to examine the functions of living cells. In this review, we briefly present the physical principles and properties of multiphoton microscopy as well as the current applications in biological fields. In addition, we address what we see as the future potential of multiphoton microscopy for gastroenterologic research.

INTRODUCTION

A remarkable evolution of biological science has induced the need to visualize cells in an intact whole organism. To date, most applications using microscopy are limited to fixed cells or excised tissues. However, characterization of morphological features and establishment of cell function of native tissues is important for the diagnosis of disease in the early stage and has improved understanding of the associated pathophysiological processes. Therefore, the need for real-time observation of cells and their subcellular components in intact tissues is of great interest and imaging techniques have been developed to pursue this goal.

One of these techniques is fluorescence imaging. Although the combination of microscopy with fluorescent labeling has improved sensitivity, this approach provides only a two-dimensional view of samples. The use of confocal microscopy allows for the observation of subcellular material with three-dimensional resolution. However, confocal microscopy is limited by the effective imaging depth of typically less than 100 μm and phototoxicity, which is caused by using a short wavelength laser^[1].

Recent advances in nonlinear optical processes of multiphoton microscopy compensate single photon-linear microscopy technologies such as confocal microscopy by the capacity for deeper tissue penetration with

clear images and the reduction of direct ultraviolet damage^[2]. Thus, multiphoton microscopy has been applied to various parts of the imaging task and has now become the technique of choice for subcellular observations of thick tissues and in living animals^[3].

In addition, endoscopists often want to know the relationship between the gross endoscopic findings and the microscopic diagnosis during routine endoscopy. Although a mucosal biopsy is the standard method for histopathological diagnosis of an abnormal mucosal lesion, this approach is limited by sampling error, bleeding risk and the time lag for results. Therefore, endoscopists would like to have the ability to directly observe and promptly identify pathology of cellular and/or subcellular structures without biopsy. Multiphoton microscopy has the full potential to achieve this goal because it can provide thin optical sections from thick specimens.

In this article, the principles of multiphoton microscopy and its applications in bioscience are reviewed, as well as the prospects for clinical use.

MULTIPHOTON MICROSCOPY

Early in the development of quantum mechanics, the theoretical concept was first proposed by Göppert-Mayer in 1931. Multiphoton excitation is based on the probability that fluorophore molecules are excited by multiple low energy photons that can arrive “simultaneously” at the fluorophore and interact with it. The fluorophore molecule absorbs the sum of the energy from each photon, and an electron in the fluorophore is transferred to the excited state, which can induce an electronic transition similar to a single high-energy photon^[4]. Soon after, the molecule in the excited state falls back to the ground state with emission of fluorescence, which has most, but not all, of the initial energy, owing to non-radiative relaxation (Figure 1).

Because the energy of a photon is inversely proportional to its wavelength (λ), the emitted fluorescence is a longer wavelength than the exciting light. However, in the case of multiphoton excitation, the fluorophore molecule almost simultaneously absorbs the energy from multiple photons, each of which contributes a part of the total energy required to induce the fluorescent emission. Thus, the emitted fluorescent photon has a shorter wavelength than each of the photons involved in excitation. For this reason, multiphoton microscopy can induce fluorescence equal to the energy of single photon excitation microscopy by low energy photons.

However, multiphoton excitation requires enormously high light intensities that, if continuous, would almost instantly vaporize the specimen. Therefore, to generate enough fluorescence practical for multi-photon microscopy, a pulsed laser source is needed. In other words, using a laser that produces extremely brief pulses (femtosecond laser, about 10^{-5}) at a high repetition rate, thus generating high instantaneous energy but low average energy^[5].

Multiphoton microscopy exhibits nonlinear optical contrast properties that are predicated upon second

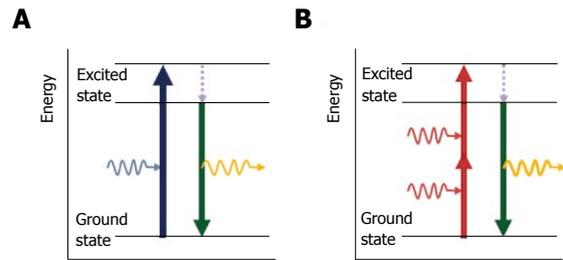

Figure 1 Multiphoton excitation. A: Single-photon excitation. Individual photons of high-energy blue light (wavelength, $\lambda = 480$ nm) excite fluorophores in the sample. After an electron in the fluorophore is transferred to the excited state (blue arrow), it loses energy rapidly owing to non-radiative relaxation (dashed arrow). Subsequently, fluorescence emission (yellow curved arrow) occurs at a longer wavelength than the excitation light as the electron falls back to the ground state (green arrow); B: Two-photon excitation. Two infrared photons ($\lambda = 780$ nm) are absorbed simultaneously (red arrows) to excite the fluorophore and light is emitted in the same manner as for single-photon excitation (green arrow) with emission of fluorescein.

and third-order nonlinear interactions between light and particles^[6]. The nonlinear optical effects are proportional to the square or cube of the fundamental light intensity; this gives multiphoton microscopy the intrinsic characteristics of 3-dimensional images. This is because the photon density is high at the focal point, and it falls off steeply from the focal point^[7]. This eliminates out-of-focus contributions and allows multiphoton microscopy to obtain high resolution images from the scattered photons of the fluorophore emission used to produce the image. In addition, photobleaching is restricted to a narrow region around the plane of focus.

To date, the most widely used imaging modalities associated with multiphoton microscopy are multiphoton excitation with fluorescence, second harmonic generation, multiphoton fluorescence lifetime imaging microscopy, and spectral lifetime imaging microscopy^[1]. For example, with two-photon microscopy, a fluorophore molecule is excited by the nearly simultaneous absorption of two photons, each twice the wavelength required for a single photon excitation^[8]. A molecule of fluorescein can be excited by two photons of near-infrared light ($\lambda \approx 780$ nm), each of which has approximately half the energy of a single blue photon ($\lambda \approx 480$ nm), and then emit a photon of green light, in the same manner as for standard (one-photon) excitation with blue light^[7]. According to nonlinear excitation, fluorescent emission from fluorophore molecules is proportional to the square of the excitation intensity. This intensity-squared dependence of two-photon microscopy provides “optical sectioning” capability, without using an adjustable pinhole aperture in front of the detector to reject out-of-focus fluorescence like confocal microscopy^[9].

Multiphoton microscopy has several advantages over confocal microscopy. Most of all, the use of long excitation wavelengths has major advantages. Since light scattering declines rapidly with an increasing wavelength, deeper penetration can be achieved by using a longer wavelength of light than with single-photon confocal microscopy. In addition to an increase in the penetration

Table 1 Comparison of two-photon microscopy with confocal microscopy

	Confocal microscopy	Two-photon microscopy
Excitation wavelength	Short (ultraviolet light)	Long (infra-red light)
Tissue imaging depth	About 50-100 μm	About 400-1000 μm
Spatial resolution	nm (3D-resolution with pinhole aperture)	nm (3D-resolution with inherent optical sectioning)
Photodamage and photobleaching	High	Low

depth, a longer wavelength of light, such as infrared light (700-1000 nm) used for multiphoton microscopy, has much less energy than confocal microscopy, and therefore causes negligible photodamage and phototoxicity to cells and tissues. Cells and molecules deep inside living tissues can be observed for long periods of time. Moreover, because excitation and emission take place only at the focal plane, multiphoton microscopy reduces the photobleaching outside of the focal plane, unlike confocal microscopy. Therefore, it results in high fluorescence collection efficiency and thus greater signal intensity at any given tissue depth.

Table 1 details comparative differences in excitation wavelength, tissue imaging depth, resolution and photo damage/bleaching between two-photon microscopy and confocal microscopy.

BIOLOGICAL APPLICATIONS

Multiphoton microscopy is a powerful tool for visualizing cellular and subcellular events within living tissue with its inherent “optical sectioning” capability, deeper penetration and minimal phototoxicity and photobleaching. Multiphoton microscopy can capture whole organisms or embryos on a large scale. Though transparent organisms such as the zebra fish and drosophila are ideal candidates for such studies, the development of the hamster embryo model has allowed for observations over long periods of time, for several days^[10].

In addition to morphological studies, multiphoton microscopy can be used for dynamic and functional cellular imaging with the development of various fluorescent probes. For example, two-photon microscopy of the calcium sensitive fluorophore allows for the collection of subcellular spatial and temporal information on (Ca^{2+}) ion entry through voltage-gated channels or release from intracellular stores within a single myocyte at depths of up to 200 μm below the epicardial surface. Therefore, two-photon microscopy is well suited to determine the functional state of donor cells following intracardiac transplantation^[11].

Neuroscientists use multiphoton microscopy for the observation of neuronal plastic changes within brain slices, measuring ionized-calcium dynamics deep in brain tissues^[12]. The dendritic spines, which are a major functional component of the nervous system associated with learning and memory activated by chemical and electrical

transmission mechanisms, are very tiny structures. Since neurons are very sensitive to phototoxicity and brain tissue is highly scattered, it has been difficult to visualize these dynamic processes in live tissues^[13,14]. However, multiphoton microscopy overcomes these obstacles by using long wavelength light and providing high resolution deep imaging without causing injury to the living material^[15]. It allows visualization of fine structures of the brain in the head and neck area, including unique signaling and dynamic motility of the dendritic spines 300-400 μm into the brain tissue^[16,17].

Multiphoton microscopy enables imaging of dynamic and heterogeneous immune processes at the cellular and molecular levels deep within intact organs of living animals. Due to the depth of penetration and minimal photodamage, multiphoton microscopy permits six-dimensional (x, y, z, time, intensity, wavelength) imaging of intact lymphoid organs and can be used to observe naïve lymphocytes for hours without loss of viability or motility^[18]. Dynamic movements and cellular interactions of viable T- and B-cells can be revealed, as well as the antigen presenting cells in the *in vivo* setting^[7,19].

Multiphoton microscopy is also a preferred imaging technique for cancer research, for example in studies on angiogenesis and metastasis *in vivo*^[20,21]. Tumor micro-invasion and metastasis involves complex interactions between cells and extracellular matrix proteins, most notably collagen^[22]. Due to the ability of imaging more deeply in tissues with less toxicity, multiphoton microscopy facilitates imaging of tumor-stroma interactions and thus facilitates improved understanding of the processes of cell migration, metastasis, and tumor progression with direct observation *in vivo*^[23].

Gastrointestinal endoscopists have to rely on visual inspection for the diagnosis of disease. Therefore, multiphoton excitation imaging may be helpful in the diagnosis and offer additional diagnostic benefit. Indeed, a pilot study of multiphoton microscopy to diagnose gastric cancer has been reported recently^[24]. The results of the study showed that multiphoton microscopy can be used to diagnose gastric cancer by optical biopsy. Multiphoton microscopy has proved to be a promising tool for real-time histological diagnosis. Recent developments in imaging technology now make this possible.

Multiphoton microscopy also has the ability to penetrate deeper inside the tissue and excite endogenous autofluorescence molecules such as intracellular nicotinamide adenine dinucleotide phosphate (reduced form), flavin, melanin and lipofuscin, instead of using fluorescent dyes which must be used for *in vivo* confocal laser microscopy^[25]. It provides the ability to detect cellular and subcellular details of the gastrointestinal mucosa without fixation or staining. Multiphoton imaging of intact human gastrointestinal mucosa *ex vivo* provides improved cellular detail compared to confocal imaging, without the need for fluorescent dyes^[2].

Suitable indicators for two-photon microscopy are required in order to get a clearer image. Recently, our col-

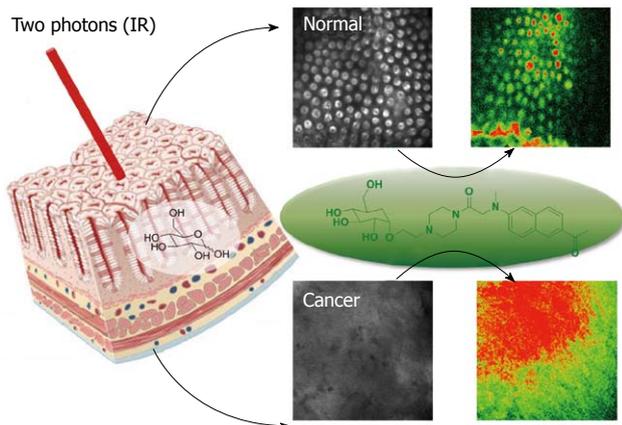

Figure 2 Images of normal tissue (above) and cancer tissue (below) treated with AG2. Normal tissues were incubated in artificial cerebrospinal fluid (ACSF) for 4 h, and cancer tissues were incubated in ACSF for 4 h, after which AG2 uptake was monitored. Right-side images are bright-field images, left-side images are pseudocolored two-photon microscopy (TPM) images obtained after incubation with AG2 for 4 h. The TPM images were obtained at a depth of 100 μm by collecting the two-photon excited fluorescence spectra in the range of 520-620 nm on excitation with fs pulses at 780 nm. IR: Infrared.

laborators have developed many new two-photon tracers. One tracer, a hydrogen probe, AH2, which emits fluorescence at $\text{pH} < 4$ can be used to obtain images of live esophageal tissue from the mucosal surface to 100 μm in depth. Emitted fluorescence of the hydrogen probe in reflux esophagitis tissue was stronger than that in control tissue. Multiphoton-emitted fluorescence of low esophageal tissue of the reflux model was similar to that of stomach^[26]. Visible images of pH changes in reflux esophageal tissue can be obtained by use of the multiphoton hydrogen probe.

Another new probe, AG2, that can be easily taken up by cancer cells and tissues through glucose-specific translocation has been developed. AG2 shows negligible cytotoxicity and high photostability. It can monitor glucose uptake in colon cancer tissues and visualize at depth of 75-150 μm by two-photon microscopy (Figure 2). This compound may be useful in diagnosing the early stages of cancer and make it possible to develop customized cancer therapy according to the uptake rates of AG2 in normal and cancerous tissues (Figure 3). In addition, this laboratory has used multiphoton laser scanning microscopy to study gastric and colon cancer with other probes. Multiphoton images of normal and cancer cell lines, as well as normal mucosa and dysplastic tissues, (adenoma, adenocarcinoma) labeled with the multiphoton microscopy probes AZn1 and ACu1, have been studied. The findings showed that the Cu1 content was higher, Zn1 content was lower, and the ratio of Cu1 to Zn1 was much higher in adenomas and adenocarcinoma than in the normal mucosa. These results suggest the possibility that multiphoton endomicroscopy might be developed further to use as a technique for performing virtual biopsies during the course of routine endoscopy.

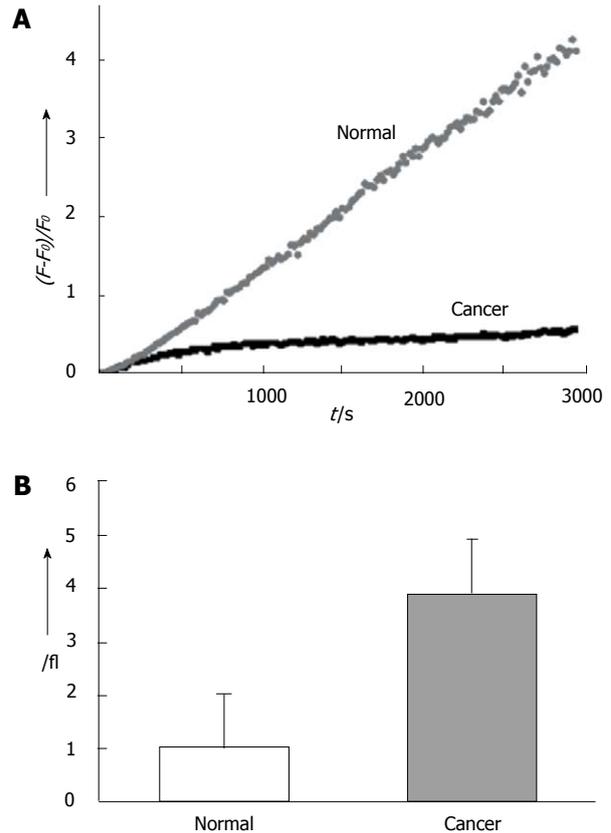

Figure 3 AG2 uptake in normal and cancerous tissues. A: Time course of AG2 uptake by normal tissue and cancer tissue at 100 μm depth as a function of time; B: Relative AG2 uptake by normal tissue and cancer tissue for 4000 s. The columns indicate the sum of the two-photon excited fluorescence intensities measured by photomultiplier tube at depths of 75, 100, 125 and 150 μm from the tissue surface, relative to that of normal tissue. The data are the average of three independent experiments.

CONCLUSION

Multiphoton microscopy has rapidly evolved and become a standard device for cell-based biological research in the fields of genomics, proteomics and tissue engineering. A major advantage of multiphoton microscopy is the ability to observe deep within intact organs and cells. Its applications are being extended beyond basic research to the clinical setting, such as detection of skin cancers, mucosal dysplasia of the intestinal tract, Alzheimer's disease, and metabolic disorders just by visualizing patient's tissue at the cellular level of resolution^[27].

Although multiphoton microscopy has already been used by many biologists for research and some clinicians, as mentioned briefly above, its advantages are partly limited by the bulkiness of the system including lasers, objective lenses, and scanning devices. Therefore, several groups currently are trying to develop smaller fluorescence microscopes, either by using a gradient index lens as a thin, rodlike probe to extend the working distance of a conventional objective^[15] or by using fiber optics to construct multiphoton endoscopes^[28]. Imaging of goblet cells as a marker for intestinal metaplasia of the stomach

by two-photon endomicroscopy has been reported^[29]. Its techniques can three-dimensionally observe goblet cells in mouse large intestine, and it provides the possibility that two photon endomicroscopy is advantageous in diagnoses.

The development of miniature laser scanning multiphoton endoscopes will provide advantages over currently available endomicroscopy technologies and be of great utility to gastroenterologists. Moreover, miniature multiphoton endoscopy may be used for minimally invasive endoscopic procedures and has enormous potential for histological evaluation of organs outside the gastrointestinal tract, namely, the liver, pancreas, and ovaries by transluminal endoscopic approaches^[30].

With the development of novel laser sources, new fluorophores and more specific probes, multiphoton microscopy and its applications will open up a wide range of possibilities. In addition, it can be combined with other imaging modalities such as ultrasound or magnetic resonance imaging, which provide complementary information.

The development of multiphoton microscopy marks a significant step in the advancement of imaging modalities and will likely aid in our understanding of the basis of disease as well as the management of the clinical manifestations of disease.

Abstract

Colorectal anastomotic leakage is a serious complication of colorectal surgery, leading to high morbidity and mortality rates. In recent decades, many strategies aimed at lowering the incidence of anastomotic leakage have been examined. The focus of this review will be on mechanical aids protecting the colonic anastomosis against leakage. A literature search was performed using MEDLINE, EMBASE, and The Cochrane Collaborative library for all papers related to prevention of anastomotic leakage by placement of a device in the colon. Devices were categorised as decompression devices, intracolonic devices, and biodegradable devices. A decompression device functions by keeping the anal sphincter open, thereby lowering the intraluminal pressure and lowering the pressure on the anastomosis. Intracolonic devices do not prevent the formation of dehiscence. However, they prevent the faecal load from contacting the anastomotic site, thereby preventing leakage of faeces into the peritoneal cavity. Many attempts have been made to find a device that decreases the incidence of AL; however, to date, none of the devices have been widely accepted.

INTRODUCTION

Colorectal anastomotic leakage (AL) is a serious complication after colorectal surgery and may lead to high morbidity and mortality rates. The incidence of AL varies between 2.5% and 20% and the aetiology is multifactorial^[1-5].

In recent decades, many strategies aimed at lowering the incidence of anastomotic leakage have been examined. A protective stoma reduces the consequence of anastomotic failure, thereby preventing the number of clinical leaks^[6,7]. The Dutch TME trial demonstrated a lower rate of surgical re-intervention in patients with a diverting stoma ($P < 0.001$)^[2]. However, a protective stoma can also result in stoma-related complications, and the obligatory operation to take down the stoma is associated with additional mortality, morbidity, and cost^[8]. In addition, so-called temporary protective stomas tend to be left *in situ* for much longer than initially anticipated, sometimes even lifelong^[9].

Many definitions are used to describe anastomotic leakage. The Surgical Infection Study Group (1991) categorised AL into clinical and subclinical leakage^[10]. In 2001, Bruce *et al*^[11] recommended the subdivision of anastomotic leakage into three groups: radiological (no

clinical signs), clinical minor (no intervention needed), and clinical major (intervention required) leakage. This grading of AL resembles the grading of AL proposed by the International Study Group of Rectal Cancer (IS-REC)^[12]. The ISREC defines AL as a communication between the intra- and extraluminal compartments due to a defect of the integrity of the intestinal wall at the anastomosis between the colon and rectum or the colon and anus. The extent or severity of AL should be graded according to the impact on clinical management. Grade A does not require active therapeutic intervention; grade B requires active therapeutic intervention, but is manageable without relaparotomy; and grade C requires relaparotomy.

In this review, we focus on the use and potential success of mechanical intraluminal devices that may protect a colonic anastomosis against leakage. Different strategies have been adopted to lower the incidence of AL. In this respect we will differentiate between transanal decompression, intracolonic, and biodegradable devices. In addition, devices encircling the bowel have been tested. The use of some of these devices showed promising results in lowering the incidence of AL (Table 1).

Considering the persisting associated morbidity and mortality of AL, and availability of intraluminal colonic devices today, a revival of the discussion of their effectiveness in lowering the incidence of AL is worthwhile.

LITERATURE SEARCH

This is a retrospective review describing the literature on devices protecting colonic anastomoses. In March 2010, an extensive literature search was performed using MEDLINE, EMBASE, and The Cochrane Collaborative Library for all papers related to prevention of anastomotic leakage by placement of an intraluminal device in the colon. Our search comprised the following: (tube OR tubes OR bypass* OR by-pass OR stent* OR device* OR coloshield) AND (anastomosis OR anastomo*) AND (leak* OR dehiscen*) AND (colon OR rectum OR colonic OR intracolonic OR colorectal) AND (prevent* OR protect*). Articles were marked as relevant if an intraluminal device was studied that protected a colonic anastomosis from leakage. Articles describing glues or fluids that protect the anastomosis are not included in this review, neither are studies on techniques of anastomosing the bowel. The reference list of each relevant article was checked for further relevant papers. All first authors of relevant papers were checked for other relevant publications. All articles were selected by one reviewer and in case of doubt, a second reviewer was consulted. The Internet was also searched using www.scholar.google.com. The search yielded 337 articles of which 44 were related to an intraluminal device intended to protect a colonic anastomosis. These 44 articles include experimental animal studies, as well as retrospective and prospective clinical studies.

TRANSANAL DECOMPRESSION DEVICES

A decompression device functions by keeping the anal sphincter open, thereby decreasing the intraluminal pressure, as well as the pressure on the anastomosis. In this way, the device serves as a protective vent. In addition, a number of authors have hypothesized that some tubes permit reinforcement and prevent angulation of the bowel and anastomosis. As early as in the 13th century, Lanfrank reported the placement of a reed pipe as an intraluminal stent in the colon^[13]. More recently, Gurjar^[14] assessed the current practice of rectal tubes in the United Kingdom and Ireland. A questionnaire was sent to all members of the Association of Coloproctology (ACP-GBI). The response rate was 58%, and 35% of those reported to use a rectal tube, in the majority of cases after ileo-anal or colonic pouch surgery. Sixteen percent used the tube after low anterior resection (LAR). Predominantly, a Foley catheter was positioned above the anastomosis (80%). The catheter was left *in situ* for a median of five days. Most respondents used the tube with the intention to decompress the rectum and/or pouch.

Animal studies

In 1988, Goldman *et al*^[15] tested an intrarectal, conically shaped flexible silastic tube in a dog model of LAR. The tube was fixed to the submucosa 5 cm proximal to the anastomosis. Twenty-five dogs underwent an LAR; 15 with a tube and 10 controls. In some animals, the anastomosis was deliberately made incomplete, leaving gaps. Mortality occurred only in the control group. Morbidity in the control group was six times higher (three colocolic fistulae and three anastomotic abscesses). Only one dog with a tube and an incomplete anastomosis was diagnosed with a pelvic abscess. The tubal fixation sites showed oedema and minor inflammatory reaction on microscopic examination. The authors concluded that their procedure presented effective practical implications, such as omitting the need for a proximal protective colostomy.

Human studies

Indwelling rectal tubes: Stewart^[16] used an indwelling rectal tube in 153 patients who underwent a left hemicolectomy or sigmoid resection. After completion of the anastomosis, a No. 32-34 French latex tube was introduced through the anal canal and directed through the anastomosis to a distance of approximately 15 centimeters above the anastomosis. The rectal tube was sutured to the perianal skin for fixation. Twice daily, the tube was irrigated with neomycin solution and after five or six days, the tube was removed. Suture-line complications occurred in seven patients (4.6%), with three patients being graded as C according to the ISREC classification. In the other four patients, the anastomotic complications were grade A/B (haematoma, stricture, and abscess noted only on sigmoidoscopy). Adverse effects of the tube (e.g., ulceration of the colon) were not observed.

Table 1 Studies on intracolonic devices aimed at preventing anastomotic leakage

¹Randomized trial; ²Randomized trial, with/without stent and with/without ostomy; ³Patient could choose between VIB and LI. AL: Anastomotic leakage, according to the ISREC classification^[12]; LAR: Low anterior resection; VIB: Valtrac-secured intracolonic bypass; LI: Loop ileostomy; ISREC: International Study Group of Rectal Cancer.

Figure 1 Transanal stent.

In 1978, Balz *et al*^[18] reviewed a series of 392 patients undergoing anterior resection with placement of an indwelling rectal tube. Anastomotic complications occurred in 3.8%. In addition to decompression, the rectal tube facilitated intraluminal antibiotic irrigation of the anastomosis.

Transanal rubber drain: In 2001, Sterk *et al*^[19] used a transanal rubber drain to protect the anastomosis after low anterior resection in 50 patients. The maximal distance between the anastomosis and the anal skin was 7 cm. The transanal rubber drain had openings on the side, a length of 40 cm, and a diameter of 12-15 mm. The tip of the drain was positioned about 10 cm proximal to the anastomosis; the other end was fixed to the

perineal skin. Two patients (4%) developed a grade C AL and three patients (6%) a grade A AL. The authors concluded that the transanal drain was at least equivalent to a conventional colostomy to reduce symptomatic AL.

Human trials

Transanal stent: The transanal stent (TAS) is a radio-opaque soft silicone tube, 4 cm in length with funnel-shaped flanges. It is inserted into the anal canal at the end of the procedure, and is left *in situ* for 5-7 d (Figure 1). Amin *et al*^[20] performed a randomised trial with the TAS in LAR for rectal cancer. Forty-two of 118 patients were not randomised because of high dose pre-operative radiotherapy, concern about the anastomosis, or obstructing tumours. Seventy-six patients were randomised to TAS or a proximal defunctioning loop stoma (LS). No significant difference in AL rate was demonstrated between the two groups (TAS: three AL's, all grade C; LS: two AL's grade A and C). Patients with a TAS had fewer general infectious complications (17% *vs* 35%) and a shorter hospital stay (13 *vs* 23 d; $P < 0.001$). This study is one of the few trials that actually tested an intracolonic device. Unfortunately, the randomisation strategy is not very clear and no control group with patients without an LS or TAS were described.

In 2006, Bülow *et al*^[21] performed a prospective randomised trial to evaluate TAS in patients undergoing anterior resection for a mobile rectal tumour. The use of a protective ileostomy was left to the discretion of the operating surgeon. After completion of the opera-

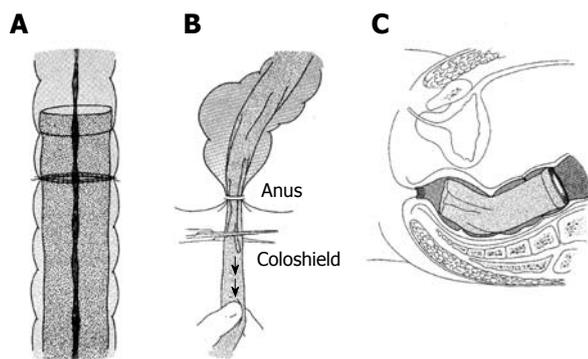

Figure 2 The Coloshield. A: The coloshield is sutured to the submucosa of the bowel proximal of the anastomosis; B and C: Slight traction is placed on the coloshield and it is cut so that it lies in the rectal ampulla.

tion, patients were randomised to the TAS group or the control group. After inclusion of 194 patients (of the planned 448 patients) an interim analysis was performed because of the occurrence of several leaks over a short time. Clinically significant leakage was diagnosed in 25 patients (13%), of whom seven were treated with drainage only and 18 with relaparotomy. AL occurred more frequently in the TAS groups (17%) than in the control group (8%). Although the difference in leak rate appears to be clinically relevant, the difference was not statistically significant because of the small sample size ($P = 0.09$). The study was stopped prematurely for ethical reasons because of this trend. Although this study was unable to demonstrate a statistical difference in AL between the groups, it seems unlikely that inserting the TAS reduces the incidence of AL (Figure 1).

INTRALUMINAL DEVICES

Intracolonic devices do not aim at preventing anastomotic dehiscence. However, they may prevent the faecal load from contacting the anastomotic site, thereby preventing leakage of faeces into the peritoneal cavity when the walls of the anastomosis have become dehiscent. When the faecal stream is bypassed from contacting the bowel mucosa, a gap in the anastomosis will not lead to extravasation of intraluminal content. Shielding the anastomosis from contact with faeces might also reduce the incidence of AL^[22].

Animal studies

Coloshield: In the 1980's, Ravo and Ger developed an intraluminal colonic tube to prevent anastomotic leakage. The application procedure is illustrated in Figure 2. After the bowel resection, the proximal loop is inverted for 4–6 centimetres. The proximal end of the tube, reinforced with a cloth strip, is fixed to the proximal bowel loop using polyglycolic acid sutures. The inverted intestinal portion is overturned to its normal anatomic position and the posterior half of the anastomosis is performed. Then, a rectal probe is introduced through the anus and

is connected to the tube by a built-in connector. The probe is drawn outside the intestinal lumen through the distal bowel and the anastomosis is completed by suturing the anterior part. The tube is then cut at the level of the anal orifice after a light traction, spontaneously returning inside. In cases where the mid- or lower rectum is resected, the tube is left protruding from the anus and an incontinence bag is attached to the perineum^[23]. Studies on dogs were performed using different tubes varying in width and length, material (latex, silicone, rubber), and suture technique. The colon tube placement was found to be a safe, uncomplicated procedure and none of the dogs (three studies, 14 dogs per study) developed AL (evaluated by laparotomy and barium studies). All tubes were expelled naturally together with the faecal stream^[24–26]. Even when an intentionally incomplete anastomosis was made after inserting the tube, no AL occurred. In 1985, the bypass tube was successfully tested on five dogs using a (circular) stapler^[27].

Silicone prosthesis: In 1992, Serra *et al.*^[28] studied the efficacy of intracolonic silicone prosthesis in 42 dogs. The use of the prosthesis is similar to the technique described by Ravo and Ger^[23,26,29]. The primary objective of the study was to evaluate the efficacy of the intracolonic silicone prosthesis in protecting the anastomosis. Three groups of 14 dogs each (colonic occlusion, diverticulitis, and control) were randomized to undergo resection and anastomosis with or without the silicone prosthesis. A significant difference in mortality was found: six dogs without prosthesis developed anastomotic failure, of which three died. No deaths or AL occurred in the prosthesis groups.

Soft latex tube: Intraluminal colonic tubes were studied by Ross^[30] in a rat model. The rats were divided in four groups; all underwent colon diversion with creation of an incomplete anastomosis. The first group consisted of rats treated with an intracolonic tube made from rat duodenum. In the second group, an intracolonic soft latex tube was introduced. The third group had a tube placed outside the colon lumen, and the last group was a control group with an incomplete anastomosis. The tubes were attached 1.5 cm above the incomplete anastomosis. The tubes remained inside the rectum, barely reaching the dentate line and were removed after five or six days. Rats treated with latex and rat duodenum tubes showed a better survival compared to controls (52% and 71%, respectively *vs* 25% in controls). Rats treated with rat duodenum showed a significant better survival compared to the control group ($P < 0.02$). A mortality rate of 100% was found in rats with a tube placed outside the lumen of the colon. The results suggest that only intraluminal tubes have a survival advantage compared to controls. This finding may be explained by the fact that tubes will prevent faecal contamination of the anastomotic site and allow time for secondary healing of the anastomosis.

Figure 3 Polyflex stents with a proximal flare.

Polyflex self-expandable covered plastic stent: As a result of achievements in biomedical technology, in 2008 Tsereteli *et al*^[31] performed a randomized controlled trial in 16 pigs comparing the incidence of AL after open rectosigmoid resection with or without a 21 mm Polyflex self-expandable covered plastic stent (Figure 3). The stent was placed over a guidewire with use of a flexible colonoscope and deployed under fluorescence control. A 2-cm anastomotic gap was created. After 6-9 d, stents were spontaneous expelled. At autopsy, none of the animals in the study group ($n = 8$) showed leak-related complications, although two pigs developed an unrelated postoperative complication (evisceration and bladder necrosis) and died. Five out of eight control animals (63%) showed intra-abdominal infection around the anastomosis at autopsy, with four abscesses and one fistula. This demonstrated a significant beneficial effect of the stent group *vs* controls ($P = 0.002$). The authors stated that the stent could be a breakthrough solution for the complicated colorectal anastomosis, avoiding the necessity of a stoma during the healing process. A potential new indication for this stent was also to seal an acute anastomotic leak, which is supported by one case report describing the successful use of a coated stent in healing a 1-cm fistula from a rectosigmoid anastomosis two weeks after surgery^[32]

Human studies

Coloshield: The development of the intraluminal tube led to the final version of the Coloshield: a soft, pliable tube like a surgical glove. This intraluminal protective device, developed by Ravo, was first used in humans in 1984^[25,33]. Indications for use include perforated diverticulitis, colonic obstruction, volvulus, carcinoma, and fistula. Several non-randomized studies were performed in patients (ranging from $n = 6$ to $n = 98$) undergoing colon surgery with the Coloshield. The reported anastomosis-related complication rates varied between 0% and 8.7%^[23,25,34-37]. The Coloshield related complications included two anastomotic dehiscences (from a group of 98 patients) following low anterior resection, both attributed to technical errors^[23]. Egozi *et al*^[38] described a case with a complicated course after insertion of a rigid

intracolonic bypass. On the 8th postoperative day, the Coloshield was found to have eroded through the colon. Castrini *et al*^[33] tested an intracolonic latex bypass in 19 patients undergoing left colon or rectal resection. None of these patients developed anastomotic complications. Regrettably, no detailed information concerning procedures, patients, and complications was reported.

The last article concerning the Coloshield was published by Ravo in 1991. Ravo described a method of inserting the Coloshield in the proximal colon after completion of the anastomosis by performing a longitudinal colostomy on the antimesenteric border of the afferent loop, proximal to the anastomosis^[39]. Ravo and Ger pioneered the use of intracolonic stents, testing different materials (silicone, rubber, and latex) before developing and, finally, filing the patent of the latex Coloshield^[40]. They concluded that the one-stage intracolonic bypass procedure is a viable alternative to the two- or three-stage procedure because it reduces the length of hospital stay and the length of disability. Despite its promise, the Coloshield has not been widely accepted. Ravo still uses the Coloshield (personal communication).

Condom: In 1994, Yoon *et al*^[41] used a condom instead of a Coloshield to protect the colo-anal anastomosis. Ten patients with rectal carcinoma undergoing LAR received this condom. The ring of the sterilised condom was sutured to the mucosal and submucosal layer of the proximal colon before completing the anastomosis. The condom was brought to the exterior and transected with scissors. The device is expelled naturally from the anus between the 10th and 14th postoperative day. No anastomotic dehiscence, leakage, or colonic necrosis occurred. In 1995, Ruiz *et al*^[42] described the same method using a condom (termed a skinless skin) as a protective device in a colonic anastomosis. When using a stapler, the distal end of the condom is attached to the anvil of the EEA stapler with two stay sutures, permitting it to be pulled through the anastomosis. Ruiz *et al* hypothesized that a latex condom is a cheap and safe device that decreases the risk of dehiscence and permits the performance of a large number of primary anastomoses. Unfortunately, for both studies, no detailed information on the procedures and patients are available.

BIODEGRADABLE DEVICES

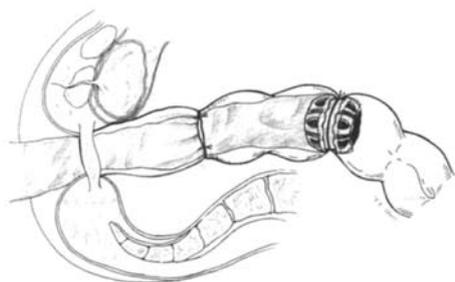

Animal studies

In 1993, Winkeltau tested the protective effect of biodegradable bipolymer intraluminal stents in 90 rats under the adverse condition of induced general peritonitis (verified by inspection, microbiology, and histology)^[43]. Peritonitis was induced using the cecal ligation and puncture model^[44]. Stents of various shapes and biodegradable materials were compared to controls with no stents, in rats undergoing jejunostomy. The survival rate in the control group was 25% and rats receiving a tube had a significantly better survival, varying between

Figure 4 Murphy's button. John Benjamin Murphy developed his device in 1892 as a quick and safe method of intestinal anastomosis. The steel Murphy button had two rounded heads mounted on hollow shafts. After the intestinal ends were tied on the shafts, the heads were screwed together to compress the tissue.

A

B

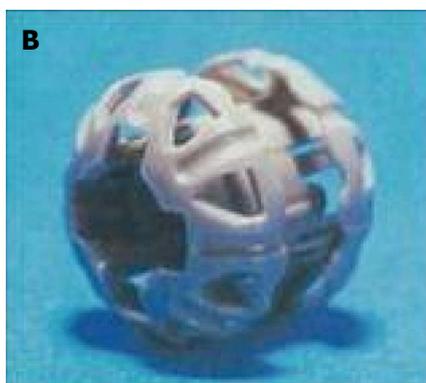

Figure 5 Valtrac-secured intracolonic bypass device. A: Rough colorectal anastomosis with large gaps between sutures protected by the intracolonic bypass; B: Biofragmentable anastomosis ring.

65% and 90%. The best results were obtained in rats with a funnel shaped BCL-004 tube, mainly composed of polyhydroxybutyric acid (PHB). The use of degradable materials is not restricted to the distal parts of the gastrointestinal tract, since it does not carry the risk of causing an obstruction.

Valtrac secured intracolonic bypass (VIB): Chen^[45] introduced the VIB, which consists of a soft vinyl tube attached to a biofragmentable anastomosis ring (BAR). The

BAR was introduced by Hardy *et al*^[46] in 1985 (inspired by Murphy's button). The BAR realises a sutureless intestinal anastomosis composed of two identical segments. The two components interdigitate and can be approximated to a semi-closed position with a 6 mm gap between the two edges of the ring (Figures 4 and 5).

Chen attached the BAR to the lumen of a pig's colon, 5-10 cm proximal from the anastomotic site, by putting a simple suture encircling the colon at the site of the BAR gap. The tube attached to the BAR passed through the anastomosis to the anus, thereby preventing contact between the anastomotic site and the faecal stream. Eighteen pigs underwent colonic resection with the deliberate creation of an incomplete anastomosis. Six pigs received the bypass, six received the bypass under the condition of a colonic outlet obstruction (created by tying a purse string suture at the level of the anus) and six pigs were controls. All pigs with the bypass had no anastomotic leakage (checked by a barium enema) and survived. Temporary anorexia and abdominal distension were noted in pigs with a colonic outlet obstruction. Four of six controls developed anastomotic leakage, of which three died.

Human studies

Valtrac secured intracolonic bypass: In 2002, the VIB was tested on 83 patients undergoing LAR for rectal cancer^[47]. After inclusion, the patient decided whether he/she wanted to be treated with the VIB or with a loop ileostomy (LI) to protect the anastomosis. The VIB was attached to the colon 5-7 cm proximal of the anastomosis by the same method Chen *et al* used in their experimental study. The fragmentation and excretion of the BAR occurred 12-22 d postoperatively. Fifty-three percent of patients chose the VIB and 47% chose the LI as treatment. Four subclinical anastomotic dehiscences were diagnosed, two in each group. Total hospital stay and costs were significant lower in the VIB group ($P = 0.001$); no readmission for a take down of the stoma was indicated. In two patients, the BAR detached en-bloc, which led to a difficult expulsion. In these cases the BAR was manually crushed and excreted through the anus. The authors concluded that the VIB is a safe and effective diverting technique to protect an elective low colorectal anastomosis; it avoids stoma-related complications and lowers the cost. This study can be criticized because the lack of randomization and high probability of introduction of bias.

C-seal: A recent development from the Groningen group is the C-seal: a thin walled tube like a soft sheet or condom, with a diameter of 4 cm, a length of 25 cm and a wall thickness of 70 μm (Figure 6). The C-seal is a tubular device composed of a biodegradable synthetic material. Two flaps with adhesive tape are located at one end of the tube. These flaps are used to attach the C-seal to the stapler cap, to facilitate an easy pull-through of the C-seal after the anastomosis is made (<http://www.jove.com/index/details.stp?ID=2223>). The C-seal remains

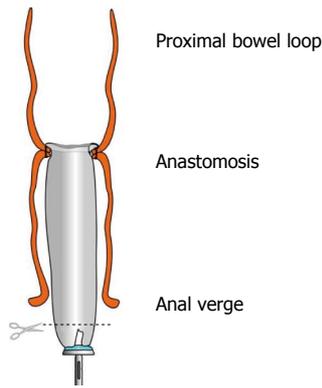

Figure 6 C-seal: A biodegradable drain protecting the anastomosis.

in place for about 10 d, according to the engineered composition of the biodegradable material. Thereafter, it loses strength, degrades, and is secreted from the body together with the gastrointestinal natural contents. In 2007, a pilot study was performed testing the C-seal in 15 patients diagnosed with colorectal carcinoma undergoing LAR with stapled anastomoses^[48]. No (sub) clinical AL was diagnosed in these 15 patients. Currently, the C-seal is being tested in a second phase study of 35 patients undergoing (colo-)rectal resection with stapled colorectal anastomosis.

CONCLUSION

The relative high incidence of anastomotic leakage after colorectal surgery, with its major consequences for morbidity and mortality, remain of great concern. Some authors concentrate on early detection of anastomotic dehiscence to reduce the consequences of AL^[49-52]. The ideal situation, however, would be prevention of anastomotic leakage. Many devices have been developed to prevent AL by protecting the anastomotic site. We categorised these devices as transanal decompression, intraluminal, and biodegradable protective devices. A number of studies concerning intraluminal tubes demonstrate low leakage rates^[18,33-35,48]. Despite these positive results, the use of protective devices has not been widely implemented. Clinicians are probably reluctant to use these devices in clinical practice for a number of reasons.

First, the use of intraluminal devices has only a small basis of evidence in the literature. Most papers are either animal studies or small, non-randomized human studies, often without a control group. Furthermore, most studies are heterogeneous and use different devices^[33,37,41,53]. Only two randomized, controlled studies are published, both on decompression devices. Amin *et al.*^[20] compared a defunctioning stoma with the transanal stent. This study does not show a benefit of the transanal stent. The study suffers from unclear eligibility criteria and a non-transparent randomisation process: one-third of the registered patients were not randomised. With 76 evaluable patients, the study is not sufficiently powered to detect significant differences in leakage rate between

the groups. A similar study by Bülow^[21] was prematurely stopped due to a high overall leakage rate, with a trend for a higher leakage rate in the TAS group.

Contrary to the transanal stent, a number of papers suggest that the Coloshield may help to reduce AL, though this beneficial effect has only been demonstrated in small studies with no control group^[33-35,39,41,53]. Unfortunately, no proper, randomised trial comparing the Coloshield to the standard of care has been performed until now.

Another aspect of the Coloshield is that it is considered time-consuming and tedious to apply, making it less attractive than the standard procedure. Tsereteli hypothesized that the Coloshield never found wide acceptance because of its technical difficulties and the requirement of a laparotomy for placement^[31]. Finally, medical devices are often only successfully introduced by companies who can organize an optimal marketing campaign and a widespread network of representatives. According to Ravo, the Coloshield was never widely accepted because it lacked these factors. Nevertheless, Ravo still uses the Coloshield in daily practice (personal communication).

We conclude that there is currently no high-level evidence demonstrating a benefit of intraluminal devices to reduce AL. Based on the literature, we think that the intraluminal device holds clinical promise to reduce or prevent early leakage of colo-rectal anastomoses and concomitant sequelae (Table 1). Although a number of very innovative approaches have been reported, not all devices have been appropriately studied in a randomized, controlled fashion with sufficient power to rule out chance or bias.

Abstract

AIM: To explore the role of actin-bundling protein, fascin during the progression of pancreatic cancer.

METHODS: The plasmid expressing human fascin-1 was stably transfected into the pancreatic cancer cell line MIA PaCa-2. The proliferation, cell cycle, motility, scattering, invasiveness and organization of the actin filament system in fascin-transfected MIA PaCa-2 cells and control non-transfected cells were determined.

RESULTS: Heterogeneous overexpression of fascin markedly enhanced the motility, scattering, and inva-

siveness of MIA PaCa-2 cells. However, overexpression of fascin had minimal effect on MIA PaCa-2 cell proliferation and cell cycle. In addition, cell morphology and organization of the actin filament system were distinctly altered in fascin overexpressed cells. When transplanted into BALB/c-nu mice, fascin-transfected pancreatic cancer cells developed solid tumors at a slightly slower rate, but these tumors displayed more aggressive behavior in comparison with control tumors.

CONCLUSION: Fascin promotes pancreatic cancer cell migration, invasion and scattering, thus contributes to the aggressive behavior of pancreatic cancer cells.

INTRODUCTION

Pancreatic cancer is characterized by aggressiveness and early metastasis, and the survival rate for this cancer is among the lowest of all cancer types. In an effort to elucidate additional targets for the detection and therapy for this type of cancer, our lab completed a proteomic analysis of primary pancreatic cancer and normal pancreas samples^[1]. We identified 70 proteins that were expressed at least 2-fold higher in pancreatic cancers when compared with normal pancreas samples. Of these proteins,

18 were involved in cytoskeleton regulation, and fascin was one of the identified proteins that had the greatest change between pancreatic cancer and normal pancreas samples. Because cell motility is based on rearrangement of the actin cytoskeleton and this process of rearrangement is governed by multiple actin-binding proteins, we postulated that these proteins may play some role in the invasion and metastasis of pancreatic cancer. Several other studies have previously shown that the actin-bundling protein, fascin, which is specifically expressed in pancreatic cancer when compared with normal pancreas, is closely associated with the status of pancreatic cancer cell differentiation and plays an important role in pancreatic cancer progression^[2-5].

Fascin was identified in the 1970s to be a 55-kD globular protein that cross-links F-actin into well-ordered and tightly packed parallel bundles that are concentrated in cell protrusions during cell migration. Fascin is highly expressed in specialized cells that are rich in filopodia, such as neurons, glial cells, mature dendritic cells and actively migrating cells, such as the endothelial cells of microvessels^[6,7]. Fascin expression is often absent in normal epithelial cells, such as the epithelia of the bile duct^[8], urinary bladder^[9], breast^[10], colon^[11], ovary^[12], pancreas^[1] and stomach^[13]. Fascin expression is upregulated in several human neoplasms, such as breast^[10], lung^[14], kidney^[15], ovary^[12], prostate and pancreatic cancers^[3,5,16]. Fascin overexpression is often correlated with an invasive tumor phenotype, poor prognosis and decreased disease-free survival.

The role of fascin in the malignant behavior of pancreatic cancer remains unknown. To determine the functional consequences of fascin overexpression in pancreatic cancer cells, we stably transfected a human pancreatic cancer cell line, MIA PaCa-2, with a plasmid containing full-length human fascin cDNA. The proliferation, cell cycle, motility, scattering, invasiveness and organization of the actin filament system were evaluated in fascin-transfected MIA PaCa-2 cells and in non-transfected control cells.

MATERIALS AND METHODS

Cell culture

The human pancreatic cancer cell lines, BxPC-3, MIA PaCa-2 and AsPC-1 were obtained from American Type Culture Collection (Rockville, MD, United States), and the PC-1, PC-4 and PC-7 cell lines were established and maintained in our laboratory. The BxPC-3, AsPC-1, PC-1, PC-4 and PC-7 cell lines were cultured in RPMI 1640 (GIBCO, Paisley, United Kingdom) with 10% fetal bovine serum (FBS) (HyClone Laboratories, United States) and penicillin-streptomycin (100 IU/mL-0.1 mg/mL). The MIA PaCa-2 cell line was cultured in Dulbecco's modified Eagle's medium (DMEM) (GIBCO, Paisley, United Kingdom) supplemented with 10% FBS and penicillin-streptomycin (100 IU/mL-0.1 mg/mL). All cells were maintained in a humidified 5% CO₂ atmosphere at 37 °C.

Antibodies

The fascin antibody (M3567) was purchased from DAKO (Glostrup, Denmark); the β -actin antibody was purchased from Sigma (MO, United States); the EnVasion™ Detection Kit was purchased from DAKO (Glostrup, Denmark); and the FITC-conjugated secondary antibody was purchased from Boster (WuHan, China).

Transfection

A pcDNA3 vector containing the full-length human fascin cDNA (pcDNA3-Fascin) was kindly provided by Dr. Josephine C. Adams (Lerner Research Institute, Cleveland, Ohio, United States). The insert was cut out with the EcoR I restriction enzyme to acquire the pcDNA3 control vector (pcDNA3-Vector). The sequence was verified by DNA sequencing. MIA PaCa-2 cells were transfected with either pcDNA3-Fascin or pcDNA3-Vector. Approximately 5×10^4 MIA PaCa-2 cells per well were seeded in a 6-well culture plate and were subsequently transfected with 5 μ g of plasmid using 10 μ L of Lipofectamine 2000 (GIBCO, United States) in 250 μ L of Opti-MEM (GIBCO, United States). After 48 h, G418 (GIBCO, United States) was added to the cells for selection at a concentration of 800 μ g/mL. After 10 to 14 d, antibiotic-resistant colonies were picked, pooled and maintained in DMEM containing 10% FBS and 400 μ g/mL G418.

Western blotting analysis

Cells were rinsed twice with D-Hanks and solubilized with lysis buffer [50 mmol/L Tris (pH 8.0), 1% Nonidet p-40, 150 mmol/L NaCl, 0.1% sodium dodecyl sulfate, 0.5% deoxysodium cholate, 1 \times cocktail (Roche, Mannheim, Germany)] for 30 min on ice. The total extract was cleaned by centrifugation at 12 000 r/min for 30 min at 4 °C, and the supernatant was collected. The protein concentration was determined with the Bradford assay (BioRad, CA, United States). A total of 40 μ g of total cell extract was separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis. The separated proteins were transferred onto an Immobilon-PVDF membrane (Millipore, Bedford, MA, United States) and were blocked and incubated with the primary antibody overnight at 4 °C. The EnVasion™ Detection Kit with DAB liquid substrate (DAKO, Glostrup, Denmark) was used for protein detection.

Immunocytochemistry and Immunofluorescence

Cells were cultured on sterile coverslips and were incubated for 24 h in a humidified 5% CO₂ atmosphere at 37 °C. The coverslips containing the cells were then fixed with 4% paraformaldehyde in phosphate buffered solution (PBS) for 10 min, washed with PBS, permeabilized in 0.2% Triton X-100 in PBS for 5 min, washed and then blocked with normal goat-serum for 30 min at room temperature. Cells were then incubated with an appropriate primary antibody for 1 h at 37 °C, and were rinsed 3 times with PBS. For protein detection by immunocytochemistry, an EnVasion™ Chem™ Detection Kit

(DAKO, Glostrup, Denmark) was used. The reaction color was developed by incubating sections with DAB liquid substrate. The slides were then washed with water and counterstained with hematoxylin. The slides were then dehydrated and mounted with mounting media. For immunofluorescence, a FITC-conjugated goat anti-mouse IgG secondary antibody was used. After washing, the slides were mounted with glycerol and imaged with an immunofluorescence microscope (Olympus BX51).

Proliferation assay

For the proliferation assay, 1×10^4 MIA PaCa-2 cells per well were seeded in a 24-well culture plate in DMEM supplemented with 10% FBS. Every 24 h, cells from 3 independent wells were collected by trypsinization and counted using a hemocytometer.

Wound healing/cell migration assay

Cell migration was evaluated by the wound healing assay^[17]. Fascin-transfected MIA PaCa-2 cells and non-transfected control cells were plated separately into 6-well culture plates and cultured to 70%-80% confluence in DMEM containing 10% FBS. After a 24-h serum starvation period, the monolayer of cells was wounded by manual scratching with a sterile plastic 200 μ L micropipette tip, washed with PBS 5 times to remove cell debris, photographed with an inverted tissue culture microscope (Leica LEITZDM IL) and then placed in complete medium in a humidified 5% CO₂ atmosphere at 37 °C. After 20 h of incubation, the wells were re-evaluated under the microscope, and the wounded area was re-imaged for comparison.

Aggregation assay

The ability of the cells to aggregate was tested by hanging drop suspension cultures^[18]. Cells were trypsinized with 0.25% trypsin in the presence of 0.01% ethylene diamine tetraacetic acid, washed twice in PBS, and resuspended at 2.5×10^5 cells/mL in DMEM containing 10% FBS. Drops of medium (20 μ L in each drop, containing 5000 cells) were pipetted onto the inner surface of a Petri dish lid. The lid was then placed on the Petri dish, and the drops with the cells suspended were left hanging from the lid. To compensate for evaporation, 8 mL of serum-free culture medium was added to the bottom of the Petri dish. After incubation at 37 °C for 12 h, the lid of the Petri dish was inverted and photographed under an inverted tissue culture microscope.

Invasion assay

For the invasion assay, the BioCoat Matrigel Invasion Chamber (Becton Dickinson Bioscience, United States) was used according to the manufacturer's instructions. Briefly, 2.5×10^4 MIA PaCa-2 cells suspended in 500 μ L serum-free medium were seeded onto Matrigel-coated filters, and 750 μ L of DMEM containing 10% FBS was added as a chemoattractant in the lower portion of the wells. After incubation at 37 °C with 5% CO₂ for 24 h, the inserts were removed, and the non-invading cells that

remained on the upper surface of the filter were scraped off with cotton swabs. Cells on the bottom surface of the membranes were fixed with ethanol and stained with 0.05% crystal violet. The number of cells invading through the Matrigel membrane was counted. Data are presented as the average of triplicate determinants.

Cell cycle analysis

For the cell cycle analysis, a minimum of 1×10^6 cells were harvested and fixed in 70% ethanol at 4 °C. After 12 h, cells were centrifuged (1000 g, 7 min, 4 °C), resuspended in PBS containing 0.05 mg/mL RNase A (Sigma, United States) and then incubated at room temperature for 30 min. After the cells were washed, they were stained with 10 μ g/mL propidium iodide, filtered through a 60 μ m mesh, and analyzed by flow cytometry (Elite Epics ESP, Coulter, United States). A total of 10 000 cells were analyzed with MODFIT software.

Xenograft tumor model

All procedures involving mice were approved by the College Committee on Use and Care of Animals at the Peking Union Medical College and conformed to the relevant regulatory standards. Four-week-old male athymic nude (BALB/c-nu) mice (Vitalriver, Beijing) were housed in specific pathogen-free conditions. To generate tumor xenografts, 5×10^6 tumor cells suspended in 0.1 mL of medium were inoculated subcutaneously in the right flank of the mice. Animals were inspected every 3 d. When the tumors from fascin-overexpressing MIA PaCa-2 cells (named MIA PaCa-2 Fascin) or vector control MIA PaCa-2 cells (named MIA PaCa-2-Vector) developed to a visible size, the mice were euthanized, the tumors were collected, cut into 1 mm³ pieces and then implanted subcutaneously in the right flank of BALB/c-nu mice. A total of 6 mice were used in each group. Animals were inspected and the tumors were measured every 3 d. Mice were humanely euthanized when they were overwhelmed by tumor burden. All tumors and major organs were fixed in formalin and embedded in paraffin. Histopathological analysis was performed following routine hematoxylin and eosin (HE) staining on tissue sections. The tumor volume was calculated on the basis of the following formula: volume = ($\pi/6$) LWH (L = length, W = width, H = height).

Statistical analysis

The Student *t*-test and the Fisher exact probability test were used for statistical analysis; a *P* value of less than 0.05 was considered significant.

RESULTS

Fascin expression in pancreatic cancer cell lines and the generation of fascin-overexpressing pancreatic cancer cells

Western blotting analysis was performed to investigate the expression of fascin in different human pancreatic cancer cell lines. Fascin protein was present at different

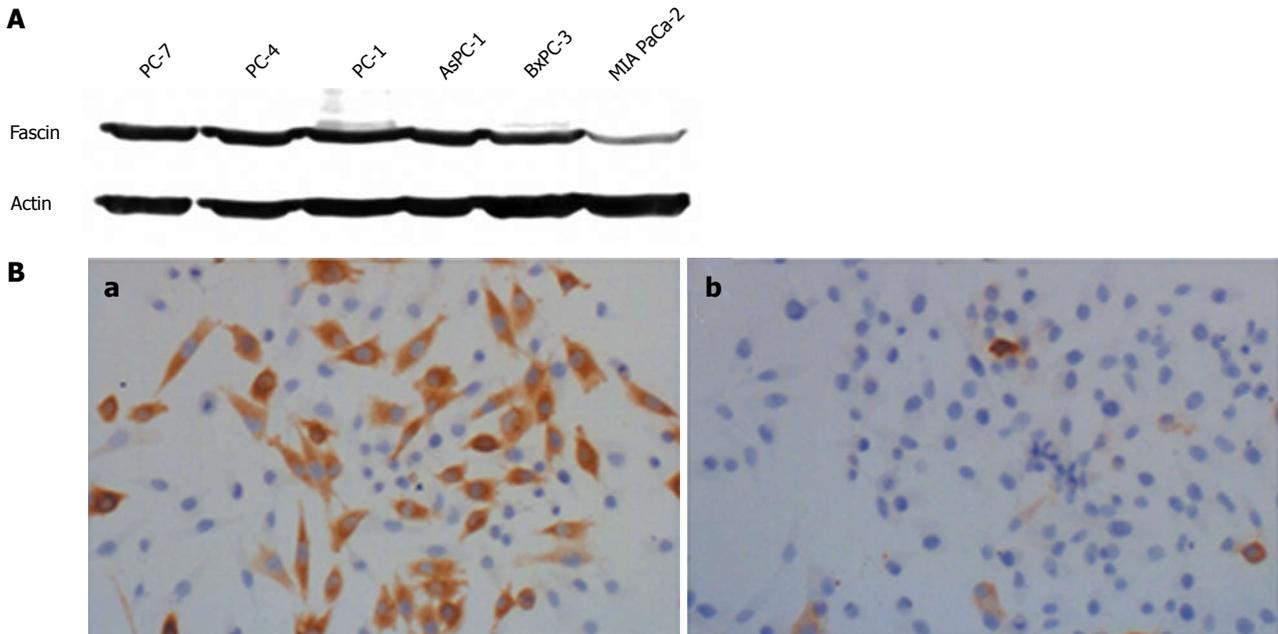

Figure 1 The selection and generation of fascin-overexpressing pancreatic cancer cells. A: Western blotting analysis of fascin expression in pancreatic cancer cell lines. Fascin protein was present in all pancreatic cancer cell lines at different expression levels. BxPC-3, AsPC-1, PC-1, PC-4 and PC-7 express fascin at a high level, whereas MIA PaCa-2 expresses fascin at a very low level. Actin served as a loading control; B: Immunohistochemical analysis of fascin expression in MIA PaCa-2 cells transfected with either pcDNA3-Fascin or pcDNA3-Vector. (a) MIA PaCa-2 Fascin represents the stable transfected fascin-expressing cell line; (b) MIA PaCa-2 Vector is the control cell line. Magnification is $\times 200$.

expression levels in all of the tested pancreatic cancer cell lines. BxPC-3, AsPC-1, PC-1, PC-4 and PC-7 expressed fascin at a high level, whereas MIA PaCa-2 expressed fascin at a very low level (Figure 1A). Because MIA PaCa-2 cells endogenously express fascin at low levels, we chose this cell line to examine the effect of heterogeneous fascin expression on the biological properties of pancreatic cancer cells.

MIA PaCa-2 cells were transfected with either pcDNA3-Fascin or the pcDNA3-Vector and stable clones were selected by G418 treatment. MIA PaCa-2 Fascin cells and MIA PaCa-2 Vector cells were used for further analysis (Figure 1B).

Fascin overexpression induces alteration of cell morphology and cytoskeleton

There was an increase in membrane protrusions in the MIA PaCa-2 Fascin cells when compared with the control MIA PaCa-2 Vector cells. Morphologically, the MIA PaCa-2 Vector cells were more rounded and had fewer projections, whereas MIA PaCa-2 Fascin cells were polarized with elongated membrane projections. In MIA PaCa-2 Fascin cells, actin filaments were distributed as bundles in the cytoplasm that protruded into membrane projections, whereas the actin filaments in MIA PaCa-2 Vector cells were distributed in a diffuse manner (Figure 2A). This result was also visualized *via* immunofluorescence as an accumulation of actin filaments in MIA PaCa-2 Fascin cells and as a diffuse distribution in MIA PaCa-2 Vector cells (Figure 2B).

Table 1 Cell cycle analysis of fascin-transfected MIA PaCa-2 cells (MIA PaCa-2 Fascin) and vector-transfected control MIA PaCa-2 cells (MIA PaCa-2-Vector) (mean \pm SD)

	G1 (%) ^a	S (%)	G2 (%)
MiaPaCa-2-Fascin	74.67 \pm 3.89	17.1 \pm 4.16	8.23 \pm 0.81
MiaPaCa-2-Vector	66 \pm 3.01	22.83 \pm 4.55	11.17 \pm 1.66

Percentages of the total cell population in different phases of the cell cycle were determined. The mean values of three experiments are shown. (^a*P* < 0.05).

Heterogeneous expression of fascin does not promote pancreatic cancer cell growth in vitro and in vivo

The growth curves of MIA PaCa-2 Fascin and MIA PaCa-2 Vector cells showed no significant difference between the two groups (Figure 3). Therefore, the heterogeneous expression of fascin does not seem to affect pancreatic cancer cell growth rate *in vitro*.

As shown in Table 1, fascin transfection induced an increase in G1 phase without a significant decrease in G2/M and S phases.

When transplanted into nude mice, both the MIA PaCa-2 Fascin and MIA PaCa-2 Vector cells developed solid tumor masses. The mean tumor volume from MIA PaCa-2 Fascin and MIA PaCa-2 Vector cells was $2.86 \pm 2.24 \text{ cm}^3$ and $3.08 \pm 1.16 \text{ cm}^3$, respectively. Tumors from fascin-transfected cells grew at a slightly slower rate in comparison with control tumors, but this difference was not significant (*P* = 0.8439). These results are in agreement with our *in vitro* experiments.

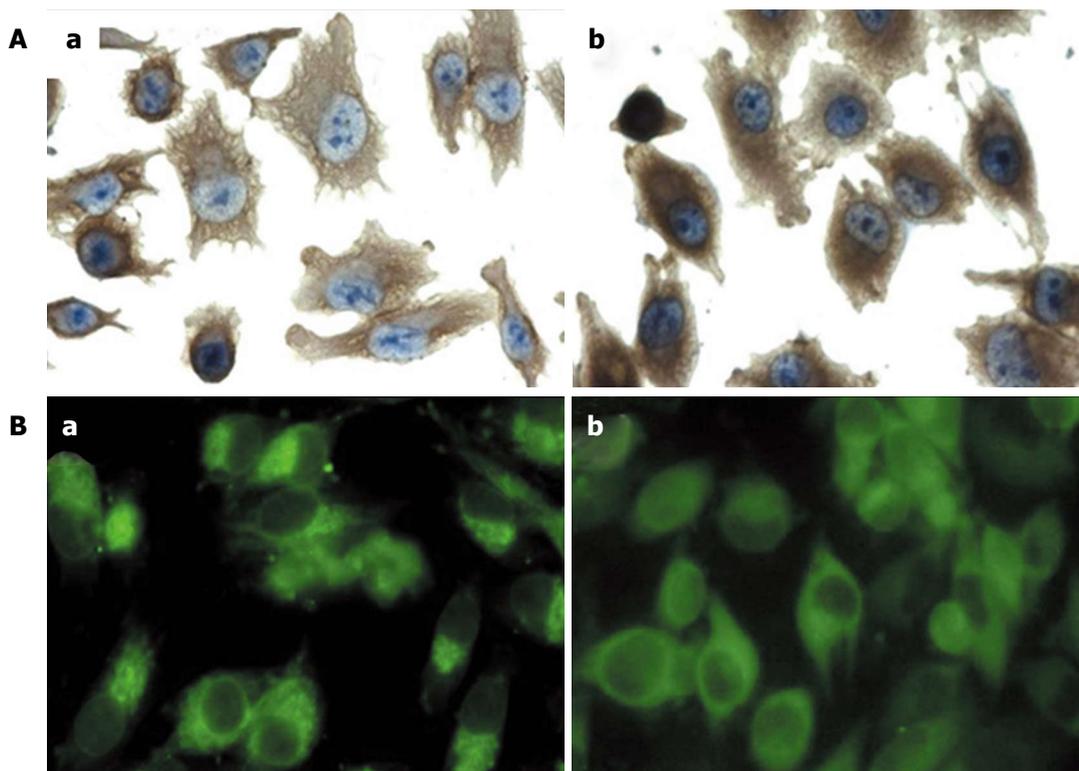

Figure 2 Fascin overexpression induces alteration of cell morphology and cytoskeleton. A: Immunohistochemical analysis of actin distribution in fascin-overexpressing cells and vector control cells ($\times 400$). (a) MIA PaCa-2 Fascin cells were more polarized with elongated membrane projections. Actin filaments were distributed as bundles in the cytoplasm which protruded into membrane projections in MIA PaCa-2 Fascin cells. (b) MIA PaCa-2 Vector cells showed a diffuse actin distribution; B: Immunofluorescence analysis of actin distribution in fascin-overexpressing cells and vector control cells ($\times 400$). (a) Actin accumulated in a polarized manner in MIA PaCa-2 Fascin cells, whereas (b) MIA PaCa-2 Vector cells demonstrated a diffuse actin distribution.

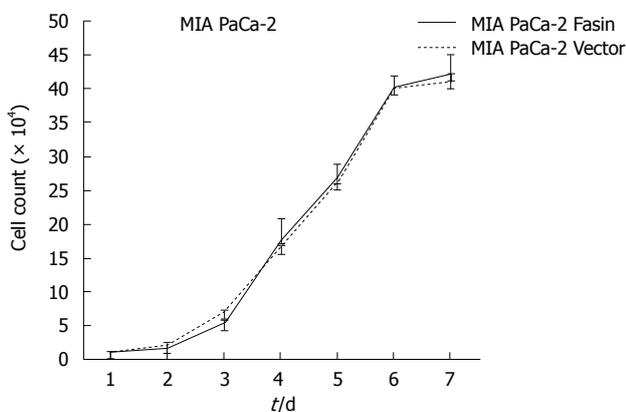

Figure 3 The growth curves of MIA PaCa-2 Fascin and MIA PaCa-2 Vector cells. There were no significant differences between the two groups.

Fascin promotes cell migration and inhibits cell aggregation

To investigate the effects of fascin on cell migration, *in vitro* wound healing assays were performed. After wounds were made for 20 h, the MIA PaCa-2 Fascin and MIA PaCa-2 Vector cells exhibited a cell reorientation response along the wounded edge margin and migrated into the wound area. MIA PaCa-2 Fascin cells repopulated the open space more efficiently than did MIA PaCa-2 Vector cells (Figure 4A).

Cell aggregation is an important factor that may critically affect tumor cell metastasis. We tested this using a hanging drop cell aggregation assay. Our results showed that the heterogeneous expression of fascin resulted in a reduction in aggregation when compared with vector control cells (Figure 4B).

Fascin promotes pancreatic cancer cell invasiveness in vitro and in vivo

To determine whether fascin promotes pancreatic cancer cell invasion, an *in vitro* invasion assay was performed using a Matrigel Invasion Chamber. Overexpression of fascin dramatically increased the cell invasive properties of the MIA PaCa-2 cells when compared with control MIA PaCa-2 cells (Figure 5A).

When transplanted into nude mice, the tumors developed from fascin-overexpressing MIA PaCa-2 Fascin cells grew in a more aggressive pattern, as 4 out of 6 of these tumors showed skin invasion, whereas only 1 of the control tumors exhibited skin invasion (Figure 5B and 5C).

DISCUSSION

We detected fascin expression in 6 pancreatic cancer cell lines (BxPC-3, AsPC-1, MIA PaCa-2 and 3 cell lines established by our laboratory: PC-1, PC-4 and PC-7). All of the cell lines expressed fascin at a relatively high

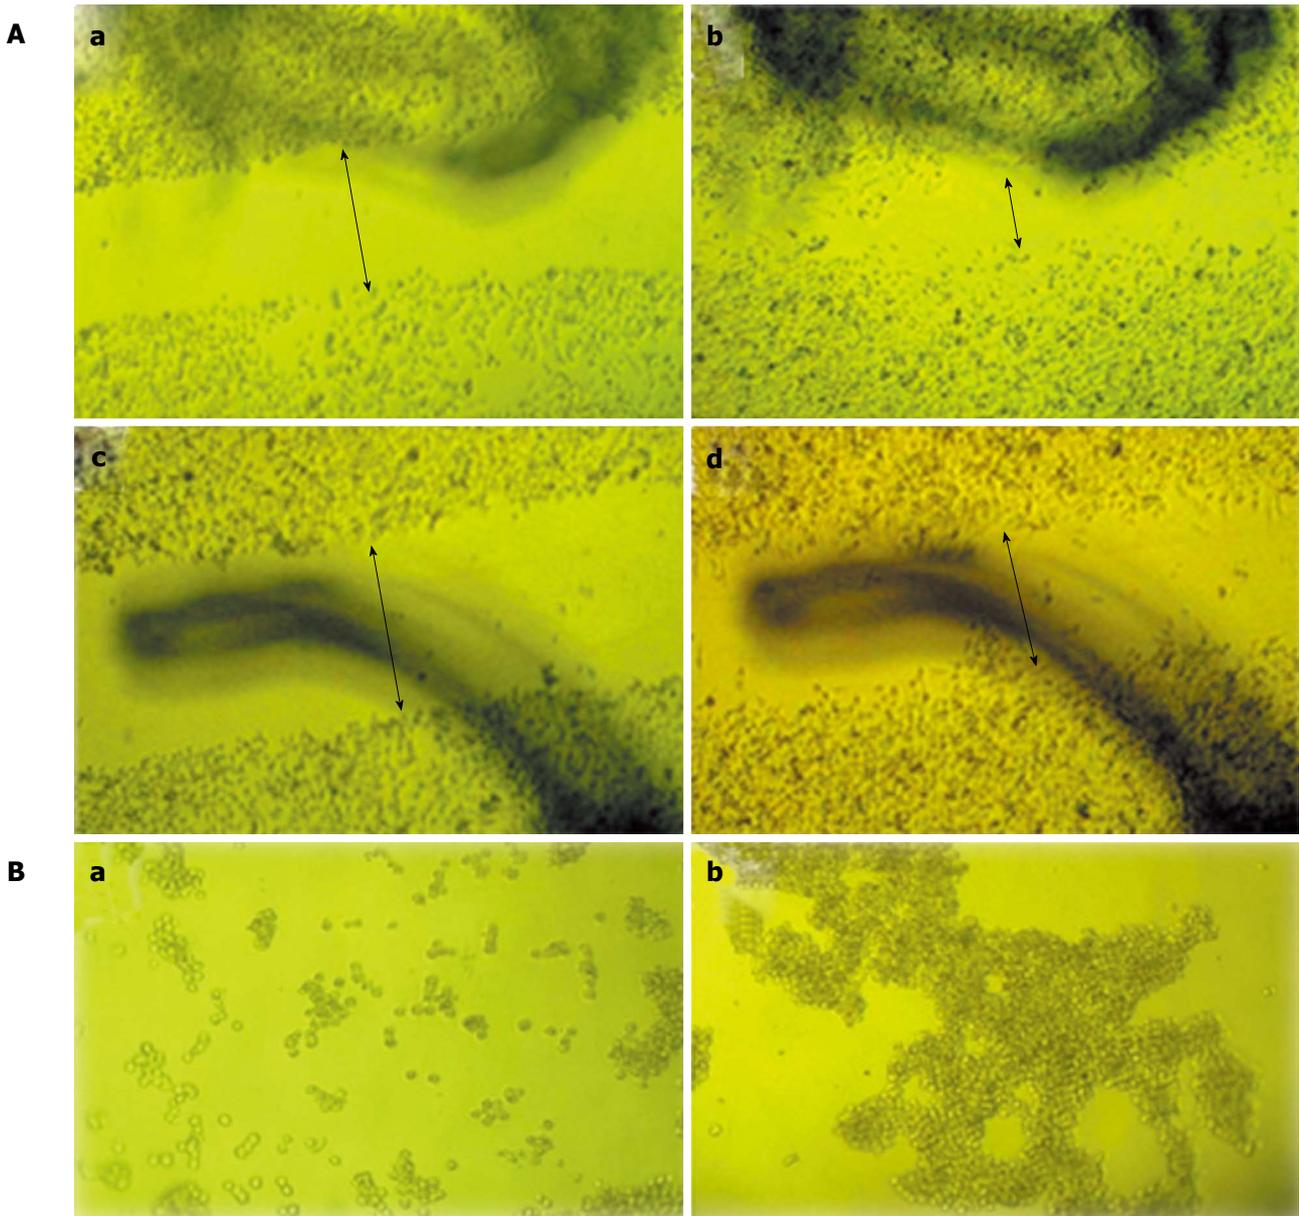

Figure 4 Fascin promotes cell migration and inhibits cell aggregation. A: The effect of fascin overexpression on the cell migration of MIA PaCa-2 cells. Images were taken at 0 h (a, c) and 20 h (b, d) ($\times 60$). MIA PaCa-2 Fascin cells (a, b) repopulated the open space more efficiently than did MIA PaCa-2 Vector cells (c, d). The arrows in figure 4a (MIA PaCa-2-Fascin cells group) and figure 4c (MIA PaCa-2-Vector cells group) showed initial distances between two side of cells (0 h), and the arrow in figure 4b (MIA PaCa-2-Fascin cells group) was short than the one in figure 4d (MIA PaCa-2-Vector cells group) in 20 h, which showed the ability of cell migration increased in the state of fascin overexpression; B: The effect of fascin overexpression on the aggregation of MIA PaCa-2 cells. Images were taken at 12 h ($\times 60$). The heterogeneous expression of fascin resulted in a reduction in aggregation compared with control cells. a: MIA PaCa-2 Fascin cells; b: MIA PaCa-2 Vector cells.

level, except MIA PaCa-2. This finding may indicate that fascin overexpression is a common event in pancreatic cancer, but the pathogenic effects of fascin are different among these cell lines. To elucidate the function of fascin in pancreatic cancer cells, we introduced a fascin-expression vector into MIA PaCa-2 cells and found that heterogeneous expression of fascin resulted in an increase in cell invasiveness and motility with a decrease in cell aggregation. The proliferation and cell cycle distribution of pancreatic cancer cells was not obviously affected by fascin overexpression. To our knowledge, this is the first study to ascertain the function of fascin by means of heterogeneous overexpression in pancreatic

cancer cells.

Pancreatic cancer progresses rapidly and demonstrates strong invasion and early metastatic properties with poor prognosis. The characteristics of tumor progression, cell motility and invasiveness, result from a rearrangement of the cytoskeletal microfilaments that is modulated by several types of actin cross-linking proteins^[19]. Among these molecules, fascin is implicated in the organization and persistence of filopodia, which plays an important role in cell-matrix adhesion, cell interactions and cell migration^[20,21]. Additional evidence has shown fascin-overexpressing tumors to have increased invasive properties. In breast cancer cells, overexpression

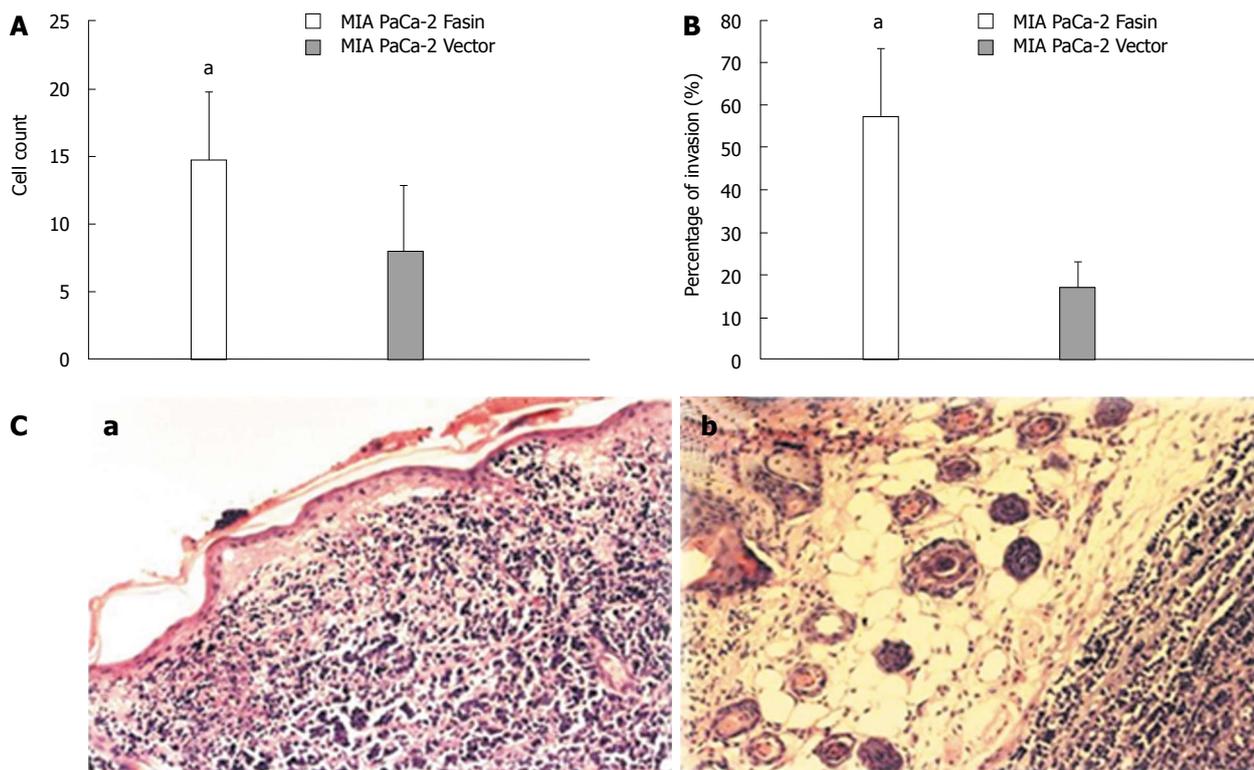

Figure 5 The effect of fascin overexpression on invasiveness of MIA PaCa-2 cells. A: Matrigel invasion assay showed that the overexpression of fascin dramatically increased cell invasive properties compared with control cells. ($^*P < 0.05$); B: *In vivo* invasion assay. Tumors from fascin-overexpressing MIA PaCa-2 Fascin cells showed an increase in skin invasion when compared with control MIA PaCa-2 Vector cells; C: Histological examination of skin invasion of tumors from MIA PaCa-2 Fascin cells and control MIA PaCa-2 cells. (a) Tumor from MIA PaCa-2 Fascin cells had skin invasion and (b) tumor from MIA PaCa-2 Vector cells showed no skin invasion (HE, $\times 150$). HE: Hematoxylin and eosin.

of c-erbB2 resulted in an increase in fascin expression and tumor cell motility^[22]. Also in gastric carcinoma, the outer edges of the tumors tended to have the most intense fascin staining in an immunohistochemical assay^[13]. Jawhari *et al*^[23] found that de novo expression of fascin in well-differentiated colon cancer cells increased cell migration through collagen type I- or IV-coated filters, and the cells showed a significant increase in dynamic membrane activity. In addition, in esophageal squamous cell carcinoma the down-regulation of endogenous fascin by RNA interference resulted in a dramatic decrease in cell invasiveness^[24]. In this study, we found that heterogeneous overexpression of fascin in pancreatic cancer cells resulted in an increase in cell motility and invasiveness. In fascin-overexpressing cells, there were more membrane protrusions, and the actin filaments were arranged as bundles in the cytoplasm which protruded into the membrane projections. In contrast, the control cells were rounded with diffusely distributed actin filaments and fewer projections. Thus, it seems likely that the rearrangement of the actin cytoskeleton induced by fascin overexpression in pancreatic cancer cells promoted their motility and invasion, which resulted in a more aggressive phenotype.

Cancer cell adhesion and migration are distinct but related events in the process of cancer progression, and cell dissociation is one of the limiting steps during the course of cancer cell migration. Heterogeneous

overexpression of fascin in pancreatic cancer cells resulted in an obvious decrease in cell-cell adhesion, as shown in the aggregation assay. To date, there are few reports on the role of fascin in cell-cell adhesion. Ectopic expression of fascin in rat Con8 cells disrupted the dexamethasone-induced formation of tight junctions and adherent junctions by preventing the recruitment of occludin and β -catenin to the site of cell-cell contact, which suggested that fascin was a negative regulator of cell-cell interactions^[25]. Another study demonstrated that fascin competed with E-cadherin for an association with β -catenin *in vitro*^[26], and it is conceivable that fascin plays a role in modulating cell adhesion. In contrast, a study in colon cancer cells did not find an effect of fascin on the E-cadherin- β -catenin association and distribution^[27]. Thus, the molecular mechanism of fascin involved in cell-cell adhesion still needs to be further explored.

In this study, the overexpression of fascin had no obvious effect on pancreatic cancer cell proliferation, which is in contrast to Jawhari *et al*^[23], who reported that fascin promoted the proliferation of colon cancer cells. In lung carcinomas, highly fascin-positive tumors had a high Ki-67 index^[14]. However, in colorectal adenoma, fascin and ki-67 were inversely correlated^[11]. The reasons for these divergent findings are currently unknown and may be related to the differences in growth-regulating signaling pathways. As a poorly differentiated pancreatic cancer cell line with the shortest doubling time compared

to the other 11 pancreatic cancer cell lines^[28], the MIA PaCa-2 cell line may have growth-regulating signaling pathways which are less dependent on fascin expression.

In summary, our study showed that overexpression of fascin promoted pancreatic cancer cell dissociation, migration and invasion, indicating its usefulness as a pancreatic cancer gene therapy target.

ACKNOWLEDGMENTS

We thank Dr. Josephine C Adams for kindly providing the fascin expression plasmid and thank Institute of Laboratory Animal Science, Chinese Academy of Medical Sciences for its support.

COMMENTS

Background

Pancreatic cancer is one of the most devastating human malignancies, with an overall 5 year survival rate of 5% and a median survival time of 6 mo, and the major biological hallmarks of this disease are its early and aggressive local invasion and metastasis. Fascin is associated with cell movement and was identified to show the greatest change between pancreatic cancer and normal pancreas samples.

Research frontiers

Fascin expression is often absent in normal epithelial cells, and its expression is upregulated in several human neoplasms. Fascin overexpression is often correlated with an invasive tumor phenotype, poor prognosis and decreased disease-free survival. The role of fascin in the malignant behavior of pancreatic cancer remains unknown. In this study, the authors demonstrate that the overexpression of fascin could be a potential mechanism for migration and invasion in pancreatic cancer.

Innovations and breakthroughs

Recent reports have highlighted the importance of fascin in many types of cancer. This is the first study to verify that fascin is over-expressed in pancreatic cancer cells and that it promotes tumor migration and invasion. Furthermore, our *in vitro* and *in vivo* studies would suggest that this protein may be a positive factor of invasion and metastasis in this cancer.

Applications

By understanding fascin's overexpression and whether it induces migration and invasion, the findings of this study may represent a future strategy for therapeutic intervention in the treatment of patients with pancreatic cancer.

Terminology

The cytoskeletal protein, fascin, is an actin-bundling protein that plays a role in cell matrix adhesion, cell interaction and migration. Its overexpression has been reported in many types of tumors, but its function in pancreatic cancer is still unknown.

Peer review

The authors explored the role of Fascin during the progression of pancreatic cancer in pancreatic cancer cell lines and a mouse model. The key findings were that fascin promotes cancer cell migration, invasion and scattering leading to a more aggressive phenotype. Fascin overexpression did not result in increased cell cycle and proliferation which is in contrast to other tumor types, i.e., colon cancer. In general, the experiments are well explained and executed.

Abstract

AIM: To investigate the expression and localization of paxillin in rat pancreas during development.

METHODS: Pancreata from Sprague Dawley rat fetuses, embryos, young animals, and adult animals were used in this study. Expression levels of paxillin in pancreata of different development stages were detected by reverse transcription polymerase chain reaction and Western blotting. To identify the cell location of paxillin in the developing rat pancreas, immunohistochemistry and double-immunofluorescent staining were performed using antibodies for specific cell markers and paxillin, respectively.

RESULTS: The highest paxillin mRNA level was detected at E15.5 (embryo day 15.5) following a decrease in the later developmental periods ($P < 0.05$ vs E18.5, P0

and adult, respectively), and a progressively increased paxillin protein expression through the transition from E15.5 to adult was detected. The paxillin positive staining was mainly localized in rat islets of Langerhans at each stage tested during pancreas development.

CONCLUSION: The dynamic expression of paxillin in rat pancreas from different stages indicates that paxillin might be involved in some aspects of pancreatic development.

INTRODUCTION

Development of the endocrine and exocrine pancreas involves a complex process of cell differentiation that ultimately gives rise to four distinct hormone producing cell types (α , β , δ , PP) and two kinds of enzyme secreting cells (acinar and ductal cells)^[1]. Organogenesis of the pancreas is a highly coordinated process. Morphologic development of the mouse pancreas first appears at E9.5. At approximately E16 the islet progenitor cells leave the

contiguous epithelium, migrate through the adjacent extracellular matrix (ECM) into the surrounding mesenchyme, and aggregate to form the islets of Langerhans^[2,3]. The islets are not fully formed until shortly before birth in E18-E19, and undergo further remodeling and maturation for 2-3 wk after birth^[4]. Thus, the developing pancreas presents a challenge for developmental biologists because of the complex morphogenetic processes underlying the development of this organ.

The factors that control pancreatic organogenesis and tissue maintenance remain unclear. Of particular interest are the ECM and their receptors, integrins, which exert a profound role during development controlling morphogenetic decisions and maintaining homeostasis during adulthood. Progression in islet cell development is accompanied by, and dependent upon, cell adhesion *via* β 1 integrin and its respective α -subunits. The β 1 family of integrins play critical roles in islet cell architecture, development, integrity and function^[5].

Paxillin interacts directly with several focal adhesion proteins including vinculin, talin, and integrin β 1^[6,7]. A principal function for paxillin is in the integration and dissemination of signals from integrins and growth factor receptors to provide efficient cellular migration^[8]. Paxillin is an important mediator of signal cross-talk in the complex multistep process of net cellular movement through its phosphorylation and multipotent associations^[9-12], and functions as an adaptor protein coordinating the activities of many focal adhesion proteins. Thus, paxillin is in a position to play a role in the integration and regulation of adhesion and signaling, yet little is known regarding its function during embryogenesis^[13]. Given that it mediates integrin signal transduction, it might be expected that paxillin may be involved in numerous aspects of cell behavior and development in the pancreas. To the best of our knowledge, no study has investigated the relationship between paxillin expression and pancreas development, and the expression of paxillin during pancreatic development in rats is poorly understood. Knowledge of the regional and temporal expression of paxillin will be useful in understanding its potential role in pancreatic development. Therefore, we examined the expression of paxillin in rat pancreas during development.

MATERIALS AND METHODS

Animals and preparation of rat pancreatic tissue

Sprague-Dawley (SD) rats were purchased from the Animal Center of Nanjing Medical University (Nanjing, China). SD rats (2:1, male:female) were mated overnight. At noon the next day, if a vaginal plug was discovered, it was considered as Day 0.5 of gestation (E0.5). Embryos were removed at E12.5, E15.5 and E18.5 from the uterus of pregnant rats, which were sacrificed by cervical dislocation. Pancreata from E15.5 and E18.5 rat embryos were isolated according to their specific vacuolated morphology, as previously described^[14], under a stereomicroscope. Rat pancreata at postnatal (P) days 0, 7, 14, 21 and from adults, were directly isolated by the unaided eye.

All experiments were conducted in accordance with the Chinese Law for Animal Protection and were approved by the local animal care committee. Five rats were used at each age stage. Dissected tissues were immediately rinsed 3 times with phosphate buffered saline (PBS) to remove serum proteins, and fixed with 4% paraformaldehyde in PBS overnight for histology, or frozen in liquid nitrogen for RNA and protein isolation.

Immunohistochemistry

Pancreata from E15.5, E18.5, P0, P14, P21, and nonpregnant adult rats were fixed with 4% paraformaldehyde in PBS overnight and embedded in paraffin. Pancreata were cut into 5- μ m sections and mounted on gelatin/chrome alum-coated glass slides. Following deparaffinization, the presence of paxillin and insulin was determined immunohistochemically. To expose antigenic sites for paxillin/insulin, dewaxed sections were heated four times to 95 °C in a 600 W microwave oven maintained for 5 min and allowed to cool for 20 min. Endogenous peroxidase activity was then eliminated by incubation with 0.5% (v/v) hydrogen peroxide solution in absolute methanol for 15 min at 20 °C. Non-specific protein binding was eliminated by incubation with 10% non-fat dry milk in PBS for 1 h at 20 °C. Sections were then incubated with a polyclonal antibody (sc-7336; Santa Cruz Biotechnology) against paxillin or insulin (sc-9168; Santa Cruz Biotechnology) at a dilution of 1:200 and 1:500, respectively, for 18 h at 4 °C. Incubation for 1 h with horseradish peroxidase conjugated secondary antibody (1:500 dilutions) at room temperature followed. The antigen-antibody complex was then visualized by incubating the sections with 3, 3'-diaminobenzidine solution in the dark for 3 min. Sections counterstained with hematoxylin were dehydrated, and coverslipped. Images were taken at a magnification of \times 400. Controls were processed by omitting the primary antibody in the immunolabeling procedure.

Double fluorescence immunohistochemistry

The paraffin sections were deparaffinized in xylene and rehydrated in graded ethanol and distilled water. The non-specific binding sites were blocked in 1% bovine serum albumin for 30 min. For paxillin and amylase or glucagon double immunofluorescence, the goat anti-paxillin primary polyclonal antibody was applied and revealed using fluorescein isothiocyanate-labeled rabbit anti-goat IgG (1:400, sc-2777, Santa Cruz Biotechnology). Mouse anti-amylase primary polyclonal antibody (1:500, sc-45667; Santa Cruz Biotechnology) or mouse anti-glucagon primary polyclonal antibody (1:1000, G2654; Sigma Aldrich) was then applied and revealed by cy3-labeled anti-mouse IgG (1:400, AP192C; Chemicon International, Inc. Temecula, CA, United States). Sections were placed in gel mounted aqueous mounting medium (G0918; Sigma, St. Louis, United States) with a cover glass, and examined under an Olympus BX51 Research Microscope (Olympus Optical, Tokyo, Japan). To rule out cross-reactivity in this staining system, the controls used were: first, single stain-

ing with the alternative secondary antibody and second, staining in the absence of primary antibody. In neither case was staining detectable. Images were taken at a magnification of $\times 400$.

Preparation of protein samples

The pancreata was homogenized in a detergent lysis buffer containing 8 mol/L urea, 2% CHAPS, 40 mmol/L Tris, 65 mmol/L DTT and 2% IPG buffer. The lysate was then centrifuged at 15000 *g* for 1 h at 4 °C. The total protein concentration of each sample was analyzed using a modified Bradford assay. All samples were stored at -80 °C prior to the electrophoresis.

Western blotting analysis

An equal amount of protein sample (40 μ g) from each time point was resolved by 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis and blotted onto a nitrocellulose membrane (Bio-Rad, Hercules, CA). After transfer, the membrane was blocked with 5% fat-free milk in Tris-buffered saline and 0.05% Tween 20 overnight at 4 °C. Primary antibodies were incubated with the membrane as described above and detected by peroxidase-linked rabbit anti-goat conjugates (Santa Cruz Biotechnology). Densitometric quantification of bands at subsaturating levels was performed using the Syngene-tool gel analysis software (Syngene, Cambridge, United Kingdom). Loading controls of presumably constantly expressed proteins such as β -tubulin were used; however, their variability and increase in development precluded their use^[5]. For negative controls, the primary antibody was omitted.

RNA extraction, reverse transcription-polymerase chain reaction

Total RNA was extracted from the pancreata at each time point with TRIZOL reagent (Invitrogen Life Technologies, Burlington, Ontario, Canada), according to the manufacturer's instructions. The quality of the RNA was verified by agarose gel electrophoresis using ethidium bromide staining. For each polymerase chain reaction (PCR), 2 μ g DNA-free total RNA with oligo (deoxythymidine) primers and reverse transcriptase were used. PCR was performed in 25- μ L reactions

containing 25 ng of cDNA, 0.2 nmol of each primer pair, and 0.3 μ L of *Taq* DNA polymerase. PCR was carried out in a T-gradient Biometra PCR thermal cycler (Montreal Biotech Inc., Kirkland, Quebec, Canada) to determine the annealing temperature for paxillin primers. The primer pairs used were as follows: paxillin, forward: 5'-GGAGCAGAACGACAAGCC-3', reverse: 5'-GCACAGAGCCCAGGAGA-3' (256 bp); 18S rRNA, forward: 5'-ACGAACCAGAGCGAAAGC-3', reverse: 5'-GGACATCTAAGGGCATCACAG-3' (514 bp). PCR conditions were as follows: 2 min at 94 °C for hot start, followed by up to 35 cycles of 94 °C for 30 s, 53.4 °C for 30 s, and 72 °C for 45 s, with a final extension of 5 min at 72 °C. To estimate the linear range of the nested reactions, we analyzed the PCR products at 10, 15, 20, 25, 30, and 35 cycles. The amplified products were analyzed on 1% agarose gels and visualized by ethidium bromide staining. The data were normalized by 18S rRNA.

cRNA probe generation and hybridization to Affymetrix microarray chips

Total RNA samples were used to generate cRNA probes by two rounds of transcription. A poly (dT) primer (with its 5' end carrying T7 promoter sequence) was used to synthesize cDNA from total RNA. The cDNA were used to amplify cRNA using T7 polymerase. The cRNA product from this first round amplification was then used to generate more cDNA by random priming, with the 3' end carrying a T7 promoter sequence. This cDNA was used to transcribe biotinylated cRNA, which was used to hybridize to the RAE 230A microarrays produced by Affymetrix.

Statistical analysis

Analysis of the experimental data was performed using PD Quest 7.0 software and the paired Student *t*-test. *P* < 0.05 was considered statistically significant. Data are presented as the mean \pm SD.

RESULTS

Paxillin mRNA expression in the process of pancreatic development

The mRNA expression levels of paxillin in the whole

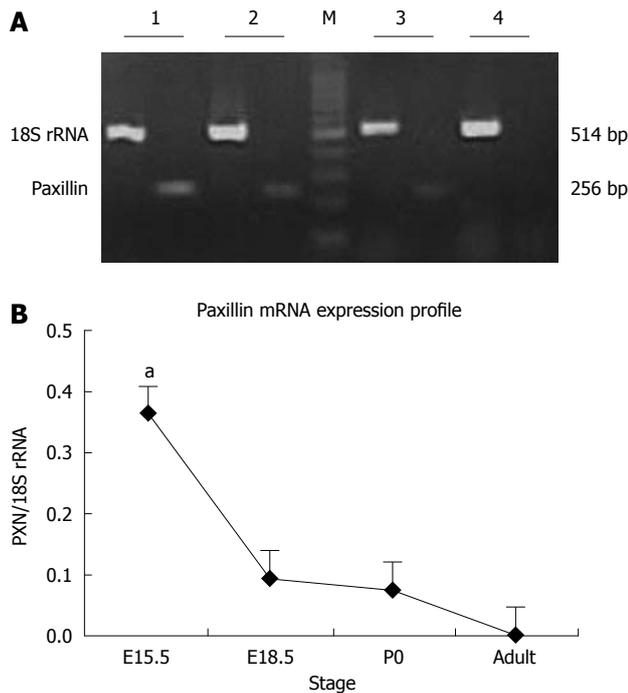

Figure 1 Paxillin mRNA expression level in the developing rat pancreas measured by reverse transcriptional polymerase chain reaction. A: From embryonic day (E) 15.5 to adulthood, paxillin mRNA expression in pancreas was highest at E15.5, following a dramatic decrease. Paxillin mRNA was almost undetectable in the adult pancreas. 1: E15.5; 2: E18.5; 3: P0; 4: Adult; M: Marker; B: Paxillin mRNA expression was analyzed and normalized to 18S rRNA. Results are indicated in percentages above the 18S rRNA value and are representative of three independent experiments. Compared to E15.5, the level of paxillin mRNA was lower at E18.5, P0 and adult ($^*P < 0.05$ vs E18.5, P0 and adult, respectively).

pancreas of the developing rat were examined through Affymetrix oligonucleotide microarray (RAE230A) (Table 1) and reverse transcription-PCR (Figure 1). As shown in Figure 1, the highest paxillin mRNA expression level was observed at E15.5, followed by decreased mRNA level of paxillin from E18.5 to adult. At the same time, mRNA expression of genes related to paxillin was also detected by Affymetrix oligonucleotide microarray (RAE230A), such as actopaxin, ILK, clathrin, vinculin, and Integrin β 1, as shown in Table 1. Absolute signal values of a selection of genes expressed in E12.5, E15.5, E18.5, P0 and adult rat pancreata were given. The highest expression level of these genes was almost detected at E15.5 (paxillin and actopaxin) or E18.5 (Integrin β 1, Integrin β 4, Integrin β 5, vinculin, ILK and clathrin). Expression profile of these mRNAs was similar to paxillin.

Regional localization of paxillin protein in rat pancreas at different developmental stages

To investigate the spatiotemporal expression of paxillin within the rat pancreas through fetal to postnatal life, we examined paxillin expression through immunohistochemistry (Figure 2). We found that paxillin maintained expression in the pancreas from E18.5 to adult, and at P14 and P21 paxillin was mainly localized in rat islets of Langerhans. Furthermore, double immunofluorescence

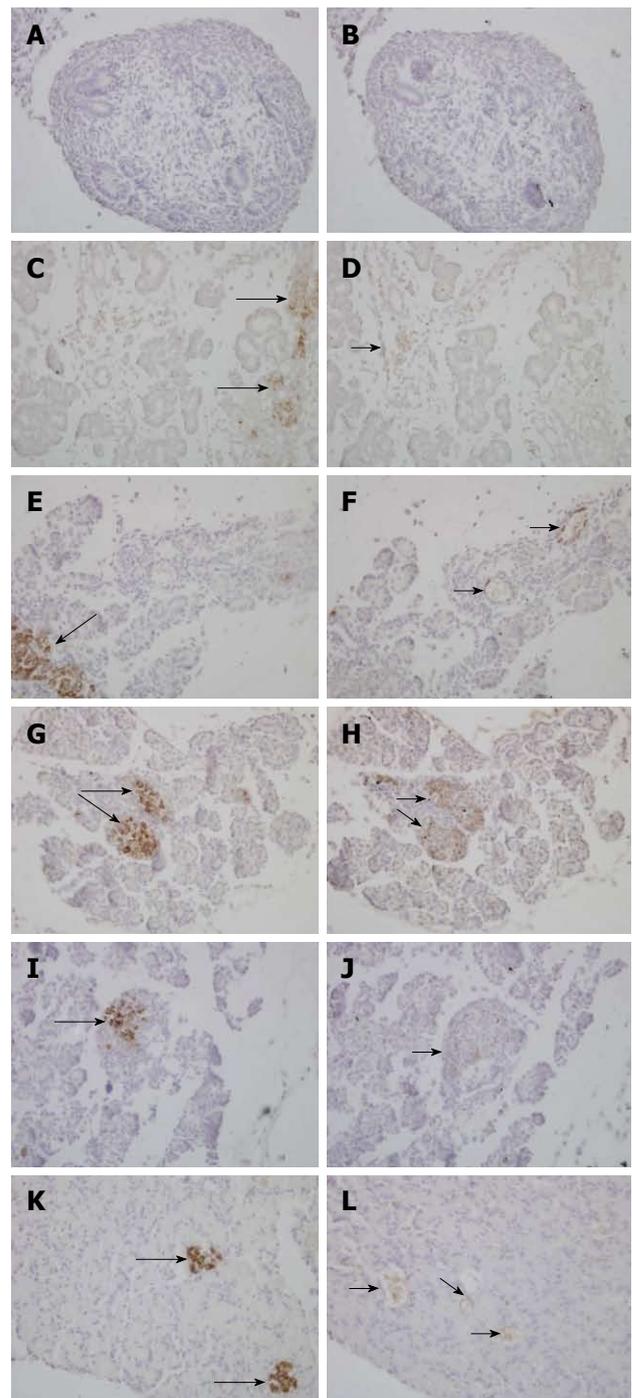

Figure 2 Immunohistochemical analysis of insulin and paxillin in the serial sections of the rat pancreas at E15.5 (A, B), E18.5 (C, D), P0 (E, F), P14 (G, H), P21 (I, J) and adult (K, L). Adjacent pancreatic sections from six developmental stages were stained with antibodies against insulin (left lane) and paxillin (right lane), respectively. We acquired images using an OLYMPUS DP70 digital camera. Strong cytoplasmic staining was observed for insulin (long arrows) for five stages except E15.5. Immunolocalization for the paxillin revealed a sporadic positive staining (short arrows) in the pancreas. In E18.5 and P0 rats, some cells in the pancreas, but not in islets, were stained. As shown in G-J, at P14 and P21 paxillin was mainly localized in islets. All magnifications are $\times 400$.

was used to detect expression of paxillin and amylase (Figure 3) or glucagon (Figure 4). As shown in Figure 3, although little co-expression of paxillin and amylase was

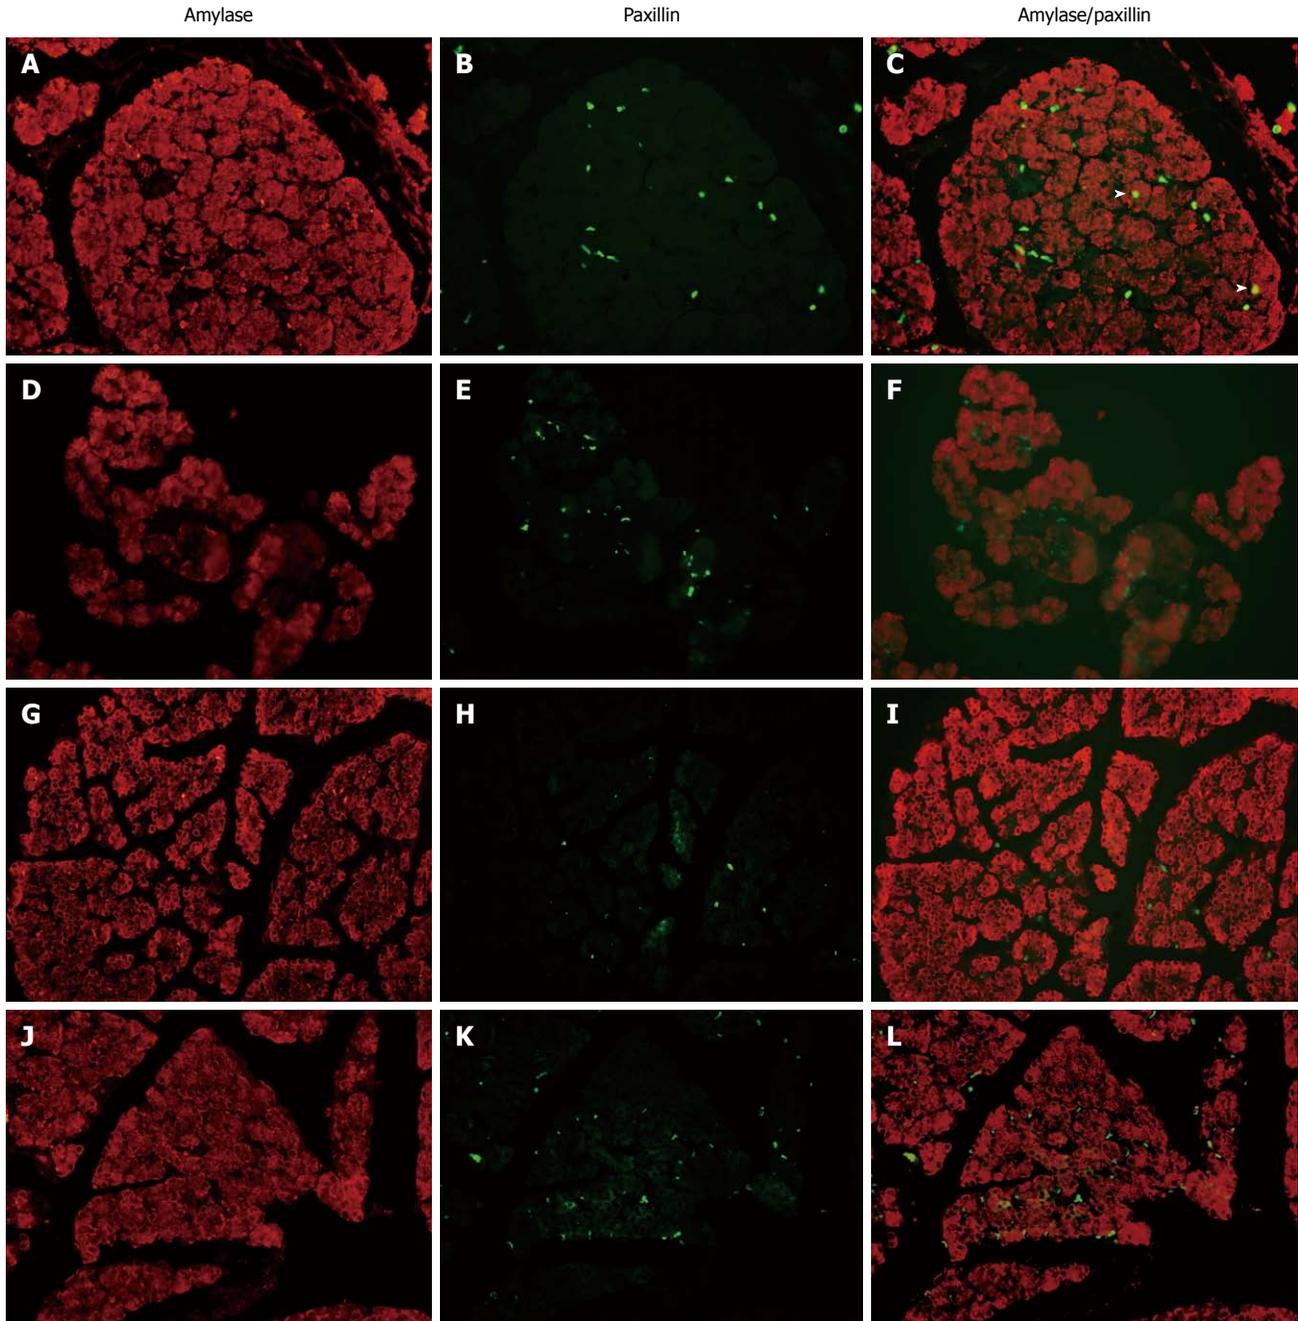

Figure 3 Immunofluorescent localization of paxillin and amylase in the pancreas of P0, P7, P21 and adult rats. The paxillin antibody was detected with an fluorescein isothiocyanate (green)-labeled secondary antibody and the amylase antibody was detected with a Cy3 (red)-labeled secondary antibody. Overlap between paxillin (green) and amylase (red) labeling is indicated by arrowheads. Original magnification 400 ×. A-C: P0; D-F: P7; G-I: P21; J-L: Adult.

detected, paxillin could be detected in the exocrine portion during development as has been reported previously^[15]. As shown in Figure 4, although little co-expression of paxillin and glucagon was detected, paxillin positive cells could be found in the center of islets of Langerhans from E18.5. To the best of our knowledge, there have been no reports concerning the expression of paxillin in rat islets of Langerhans.

Paxillin protein expression in the process of pancreatic development

Examining the abundance of paxillin at the protein level

during rat pancreatic development, from embryonic to postnatal life in whole pancreata by Western blotting analysis (Figure 5), revealed that there exist two isoforms of paxillin protein at 68 KD in pancreas during the developmental process, which was in agreement with previous reports^[13]. During embryonic and neonatal development phases, only the smaller isoform was detected, while the larger isoform was detected only after birth. Interestingly, in the adult pancreas, the two isoforms could both be identified. Paxillin began to be expressed at E15.5, and significantly increased after birth, with a 10 fold increase at birth. The differential expression pattern of two iso-

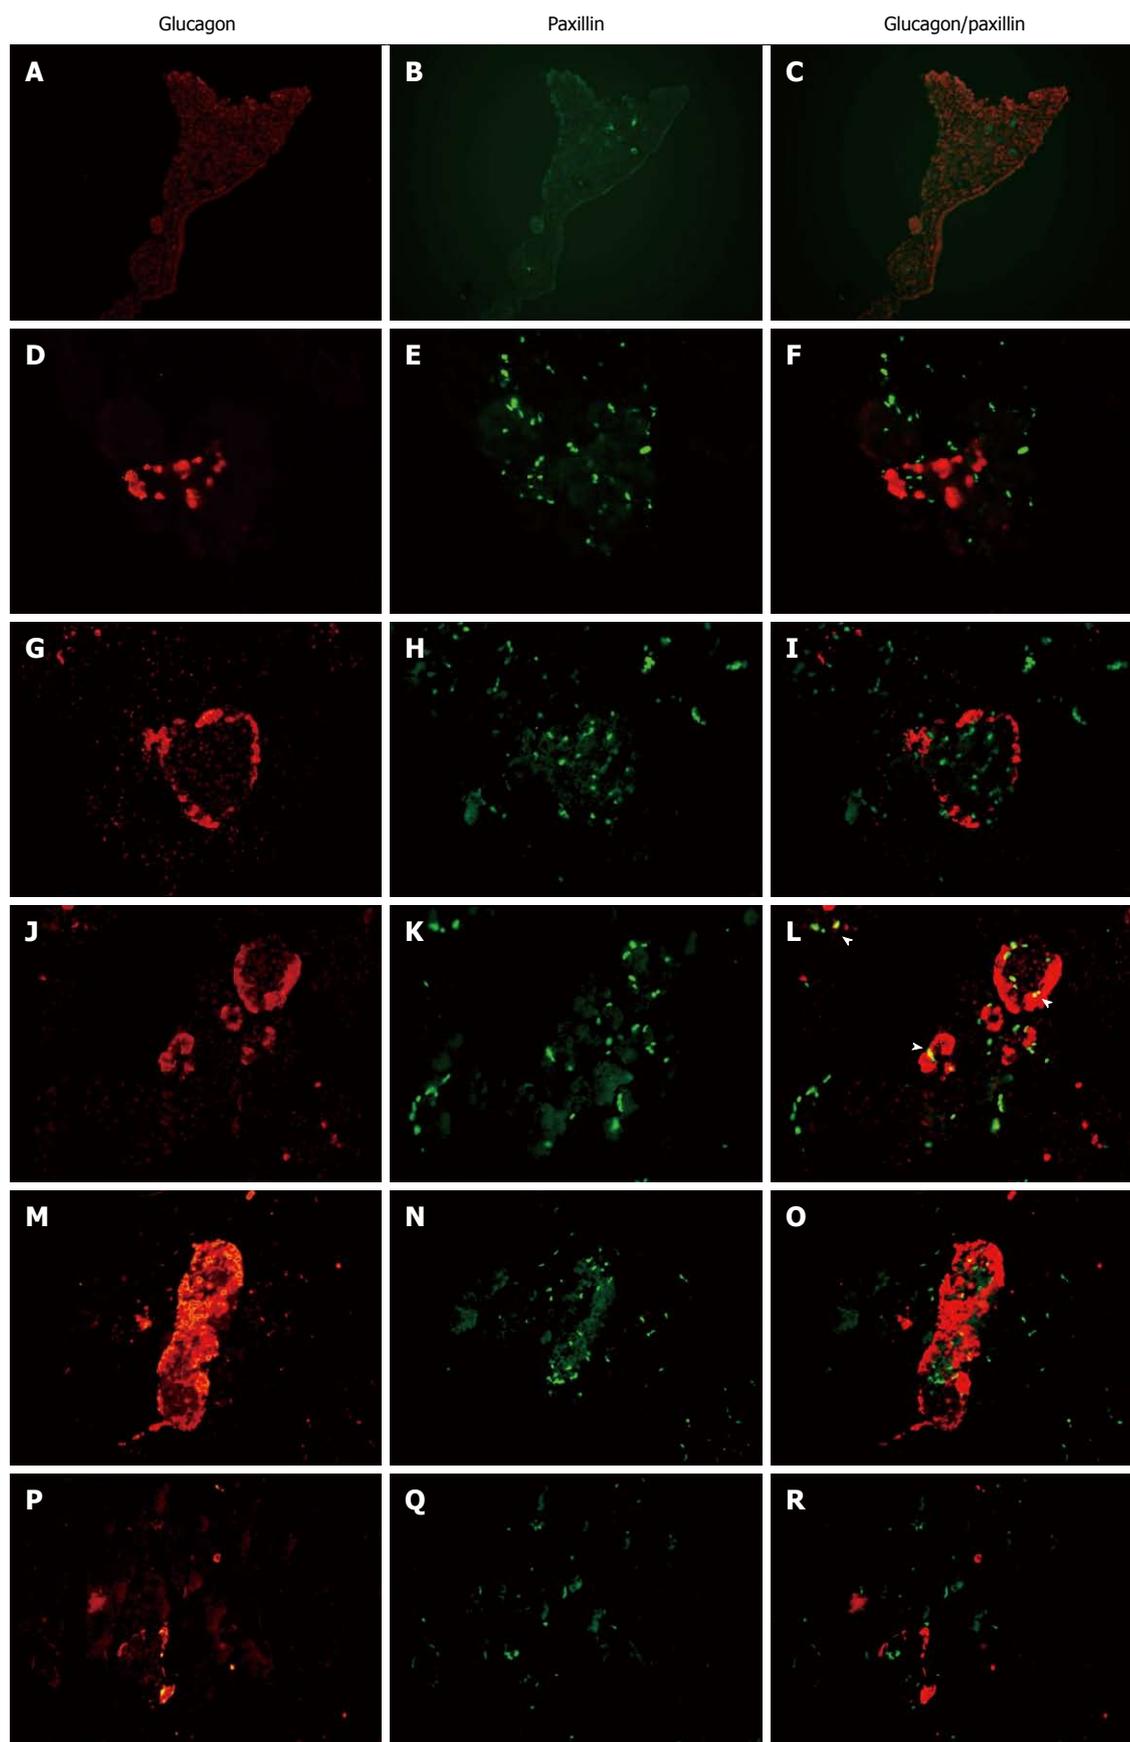

Figure 4 Immunofluorescent localization of paxillin and glucagon in the pancreas of E15.5, E18.5, P0, P7, P21 and adult rats. The paxillin antibody was detected with an fluorescein isothiocyanate (green)-labeled secondary antibody and the glucagon antibody was detected with a Cy3 (red)-labeled secondary antibody. Overlap between paxillin (green) and glucagon (red) labeling is indicated by arrowheads. Original magnification 400 ×. A-C: E15.5; D-F: E18.5; G-I: P0; J-L: P7; M-O: P21; P-R: Adult.

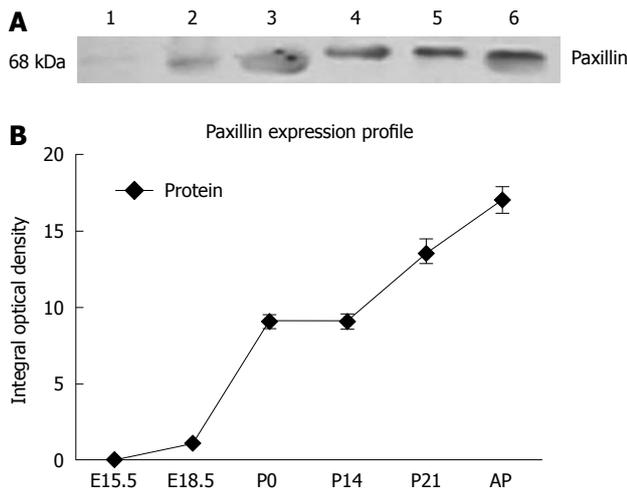

Figure 5 Paxillin protein expression level in the developing rat pancreas measured by Western blotting. A: From E15.5 to adulthood, paxillin protein (68 KD) expression in pancreas was highest at adult. 1: E15.5; 2: E18.5; 3: P0; 4: P14; 5: P21; 6: Adult; B: Progressively increased level of paxillin protein through the transition from E15.5 to adult is observed. Results are representative of three independent experiments.

forms of paxillin in the developmental process suggested their distinct physiological function^[7].

DISCUSSION

During organogenesis, specialized cell types are generated from progenitor cell populations and are precisely organized into the elaborate structure of the adult organ^[16,17]. Biochemical and ultrastructural studies delineated three distinct phases of pancreatic development in rats and mice. The first is during early organogenesis and is known as the “primary transitional phase” in which cytodifferentiation into exocrine or endocrine cells is minimal (approximately from E10 to E12/12.5 in rat). This is followed by the “proto-differentiated state” (from E12.5 to E15.5), in which epithelial cell proliferation is high, leading to rapid growth and lobulation, while cytodifferentiation is poor. During late organogenesis, a third phase or “secondary transitional phase” (from E15.5 to E18.5) is detected in which a dramatic increase in the number of endocrine and exocrine cells with high levels of insulin and exocrine enzymes is observed. During the secondary transition, endocrine cell migration and adhesion, and primary islet formation are key events. At approximately E16 the islet progenitor cells leave the contiguous epithelium, migrate through the adjacent ECM into the surrounding mesenchyme, and aggregate to form the islets of Langerhans. The islets are not fully formed until shortly before birth in E18-E19 and undergo further remodeling and maturation for 2-3 wk after birth^[4]. Although some studies have addressed the function of single gene, such as integrins in islet formation, much less is known about the multifactor network that guides islet formation during embryogenesis^[18-20]. The present study demonstrates that pancreatic development is accompanied by a specific spatiotemporal pattern of protein and

mRNA expression of paxillin, which is a mediator in integrin signaling, suggesting a role for paxillin during pancreatic development.

The protein and mRNA expression of paxillin in the whole pancreas determines a specific temporal pattern of expression from embryonic development to postnatal development. High mRNA expression, along with low protein level of paxillin, was observed in the embryonic pancreas (Figures 1 and 5). Subsequently, into postnatal life, decreased paxillin mRNA expression was paralleled to increased protein levels in postnatal life. What is more, genes related to paxillin, such as ILK, clathrin, vinculin and integrin β 1, shared the same expression pattern with paxillin. The highest expression level of these genes was almost detected at E15.5 or E18.5. In the present study, a dramatic increase of paxillin protein expression in the neonatal pancreas, compared with embryonic period, was detected. From the 18th day of gestation until birth, active cellular reorganization takes place to form the classic cellular features of the islet. After birth, apoptosis of a great amount of islet cells take place. From P14 to P21, islet cell proliferation increased dramatically and islet structure is remodeled. Cell adhesion and migration are necessary to islet structure remodeling. Immunohistochemical staining of paxillin demonstrated its expression within rat islets at P14 and P21. To the best of our knowledge, there have been no reports concerning the expression of paxillin in islets of Langerhans. Given the pivotal role of paxillin in cell adhesion and migration, the specific high expression of paxillin protein after birth indicates a potential role in islet structure remodeling.

The expression of paxillin at both the mRNA and protein level indicates that paxillin may be critical in mediating the biological functions of the developing pancreas, especially in maintaining islet structure and function. Regardless, these studies demonstrate that paxillin is expressed at the protein and mRNA level throughout development, indicating potential molecular signals mediated by paxillin that may control various aspects of pancreatic function and development.

In higher eukaryotes, paxillin exists as multiple isoforms (α , β , γ and δ)^[6]. Paxillin α is the principal, ubiquitously expressed isoform, whereas the β - and γ -isoforms exhibit restricted expression. The β - and γ -isoforms contain a 34- and 48-amino acid insertion, respectively, between amino acids 277/278. However, there have been reports suggesting the lack of a murine γ -isoform^[21,22]. Our study revealed that there exist two isoforms at 68 KD of paxillin protein in the pancreas during development, with different expression profiles. During the embryonic and neonatal development phases, only the smaller isoform was detected, while the larger isoform was detected only after birth. Interestingly, in the adult pancreas, the two isoforms could both be identified. It has been documented in a previous study that different paxillin isoforms show a distinct expression profile in whole embryos during development in mice, which suggested distinct physiological roles for each isoform^[7]. Thus, the differential expression of paxillin isoforms in the pancreas during development may indicate their distinct roles in pancreas

development. Of course, further studies are needed to verify our hypothesis.

The morphogenesis of embryos depends both on interactions between cells and their surrounding ECM *via* integrin complexes, and direct cell-cell borders perceived as discrete adhesion systems that may interact with each other during morphogenesis^[5,23-26]. The integrin family of transmembrane receptors physically connects the actin cytoskeleton of the cells to the ECM at focal adhesions, and thus, mediates migration and adhesion in many cells. The importance of focal adhesion in early development is well illustrated by mouse embryos deficient in fibronectin or focal adhesion components, including focal adhesion kinase (FAK), paxillin, or integrins. These embryos die early in development (days 5-10) with mesodermal defects. Data from previous studies support roles for paxillin and FAK in the organization of actin around tight junctions or adherens junctions; functions that would help stabilize or remodel cell-cell borders during the migration of this epithelial sheet^[9,12].

In summary, our present study has, for the first time, demonstrated that paxillin is localized to the islets of Langerhans in developing rat pancreata *via* immunohistochemistry and immunofluorescence. Given the important roles of paxillin in intercellular adhesion and cell migration, it may play important roles in pancreas islet formation, which is a process of cell-cell adhesion and cell migration, especially in islet structure and functional maintenance. Further investigations are needed to verify our hypothesis.

ACKNOWLEDGMENTS

Special thanks to Dr. Ying-Bing Ge for his technical skills. Our gratitude also goes to Dr. Zheng-Xian Tao for his comments and criticisms.

COMMENTS

Background

Knowledge of the regional and temporal expression of paxillin will be useful in understanding its potential role in pancreatic development. However, no study has investigated the relationship between paxillin expression and pancreas development, and the expression of paxillin during pancreatic development in rats is poorly understood.

Research frontiers

The authors examined the expression of paxillin in rat pancreas during development.

Innovations and breakthroughs

The study, for the first time, demonstrated that paxillin is localized to the islets of Langerhans in developing rat pancreata *via* immunohistochemistry and immunofluorescence. Given the important roles of paxillin in intercellular adhesion and cell migration, it may play important roles in pancreas islet formation, which is a process of cell-cell adhesion and cell migration, especially in islet structure and functional maintenance.

Peer review

This is an interesting and fairly well performed study.

Abstract

AIM: To analyse α_v integrin expression induced by gastrin in pancreatic cancer models.

METHODS: α_v integrin mRNA expression in human pancreatic cancer cells was analysed using a "cancer genes" array and confirmed by real-time reverse transcription-polymerase chain reaction (PCR). Western blotting and semi-quantitative immunohistochemistry were used to examine protein levels in human pancreatic cancer cell lines and pancreatic tissues, respectively. The role of α_v integrin on gastrin-induced cell adhesion was examined using blocking anti- α_v integrin monoclonal antibodies. Adherent cells were quantified by staining with crystal violet.

RESULTS: Using a "cancer genes" array we identified α_v integrin as a new gastrin target gene in human pancreatic cancer cells. A quantitative real-time PCR approach was used to confirm α_v integrin gene expression. We also demonstrate that Src family kinases and the PI 3-kinase, two signalling pathways specifically activated by the CCK-2 receptor (CCK2R), are involved in gastrin-mediated α_v integrin expression. In contrast, inhibition of the ERK pathway was without any effect on α_v integrin expression induced by gastrin. Our results also show that gastrin modulates cell adhesion *via* α_v integrins. Indeed, *in vitro* adhesion assays performed on fibronectin show that gastrin significantly increases adhesion of pancreatic cancer cells. The use of blocking anti- α_v integrin monoclonal antibodies completely reversed the increase in cell-substrate adhesion induced by gastrin. In addition, we showed *in vivo* that the targeted CCK2R expression in the pancreas of Elas-CCK2 mice, leads to the overexpression of α_v integrin. This process may contribute to pancreatic tumour development observed in these transgenic animals.

CONCLUSION: α_v integrin is a new gastrin target in pancreatic cancer models and contributes to gastrin effects on cell adhesion.

INTRODUCTION

Pancreatic cancer has a poor prognosis with a 5-year survival rate < 5%. Despite intensive efforts to improve therapy, treatment remains unsatisfactory and most patients die within months as a result of rapid local spread of tumour or metastatic dissemination^[1]. This poor prognosis is mainly due to the propensity of this tumour to invade the adjacent structures and metastasize to distant organs early in the course of this disease; however, the molecular basis for these characteristics of pancreatic cancer is incompletely understood. A better understanding of the genes involved in tumour growth and migration may allow development of novel treatment strategies to rapidly tackle this disease.

Several lines of evidence support the role of gastrin, a digestive peptide hormone and its G protein-coupled receptor (CCK2R) in pancreatic cancer development. Gastrin and its receptor are up-regulated in human pancreatic adenocarcinoma as well as in preneoplastic lesions^[2,3]. A splice variant of the CCK2R has recently been identified, which has constitutive activity and is exclusively expressed in certain human colon and pancreatic cancers^[4-6]. In addition, we have reported in *Elas-CCK2* transgenic mice, expressing functional human CCK2R in pancreatic exocrine cells, an increased pancreatic growth, an acinar to ductal trans-differentiation, postulated to be a preneoplastic step in pancreatic carcinogenesis and the development of tumours^[7,8].

Besides proliferation, gastrin has been shown to modulate cell adhesion and migration. We and others have recently demonstrated *in vitro* that prolonged activation of the CCK2R by gastrin induces stress fibre formation, alters cell morphology, increases loss of cell-cell adhesion, as well as motility of epithelial cells^[9-12]. We have also shown the loss of intercellular adhesion in acini of *Elas-CCK2* mice before tumour formation^[13].

Several signalling pathways activated by the CCK2R have been implicated in the proliferative effects or cell migration induced by gastrin. They include: MAP-kinases^[14,15], the phosphatidylinositol 3-kinase and the JAK2/STAT3 pathway^[16,17]. In addition, Src family tyrosine kinases and p125FAK have also been shown to play a crucial role in these biological effects of gastrin^[18].

In gastric epithelial cells, several target genes of the CCK2R have already been identified. They include genes involved in gastric acid secretion^[19], early response genes, c-Fos^[20], c-Jun and c-Myc^[21,22] and other growth-related genes such as cyclin D1^[23], Reg-1^[24], or the HB-EGF^[25]. In addition, in the same cellular model, gastrin also regulates the expression of genes associated with cell migration

and invasion such as the *MMP9* gene, a matrix metalloproteinase^[26]. In several cellular models such as gastric and colonic cancer cells, intestinal epithelial cells or fibroblasts transfected with the CCK2R, gastrin has also been shown to enhance *cyclooxygenase-2* gene expression, known to play an important role in inflammation processes and carcinogenesis^[27-29].

In contrast, to our knowledge, very few gastrin-regulated genes have been identified in pancreatic models expressing the CCK2R. Recently, we showed that Reg proteins are targets of CCK2R activation and are induced during the early steps of carcinogenesis in *Elas-CCK2* mouse pancreas^[30]. In addition, we also identified β_1 integrin as a gastrin-regulated gene in human pancreatic cancer cells and demonstrated its involvement in modulation of cell adhesion by the CCK2R^[31].

In this study, we identified αv integrin, another member of the large integrin family, as a new gastrin target in the human pancreatic cancer cell line, Panc-1. Integrins which mediate cell adhesion play an important role in cell migration, survival and differentiation. Here we show *in vitro* that αv integrin is involved in the modulation of cell adhesion by the CCK2R. In addition, we demonstrate *in vivo* that the targeted CCK2R expression in the pancreas of *Elas-CCK2* mice, which present preneoplastic lesions and develop pancreatic tumours, leads to αv integrin expression.

MATERIALS AND METHODS

Cell culture

The human pancreatic cancer cell line, Panc-1 was obtained from the American Type Culture Collection (ATCC, Manassas, VA, United States). The cells were grown in Dulbecco's modified Eagle's medium supplemented with 10% FCS at 37 °C in a humidified atmosphere containing 5% CO₂. In all experiments, cells were serum-starved for 18 h prior to gastrin stimulation. Human gastrin 2-17_{ds} (Bachem, Switzerland) was used in all experiments.

RNA extraction and reverse transcription

Total RNA was isolated from Panc-1 cells treated with or without gastrin as indicated using the RNeasy RNA Isolation Kit (Qiagen, Valencia, CA, United States). After pretreating RNA with 10 units DNase (Invitrogen, Carlsbad, CA, United States), cDNA was produced from 1 μ g of total RNA using the Superscript First-Strand Synthesis System for reverse transcription-polymerase chain reaction (PCR) (Invitrogen, Carlsbad, CA, United States).

"Cancer super array"

A specific "Cancer array" (96 genes) from SuperArray (Bioscience Corporation, Beverly, MA, United States) was used in this study. Total RNA was isolated from Panc-1 cells as described above. Reverse transcription of cellular RNA was carried out with the RT-Labeling kit (SuperArray, Bioscience Corporation, Beverly, MA,

United States) according to the manufacturer's instructions. The biotinylated probes from gastrin-stimulated cells and unstimulated cells were hybridized overnight to separate membranes at 60 °C, washed with SSC/SDS solutions, incubated with the avidin-alkaline phosphatase conjugate and exposed to a chemiluminescent substrate. Analysis of the images and quantitation of the spots in both membranes were performed by the ScanAlyze 2.5 software, and normalization of the values and comparison of the intensities was achieved by the GE ArrayAnalyzer 1.3 (SuperArray, Bioscience Corporation, Beverly, MA, United States) software.

Real-time PCR

α_v integrin expression was determined *via* real-time PCR, using fluorescent SYBR green dye (Applied Biosystems, Framingham, MA, United States) to allow semi quantitative analysis of gene expression levels. Amplification was conducted using ABI-Stepone + Detection System (Applied Biosystems, Framingham, MA, United States). Relative fold changes were determined using the $2^{-\Delta\Delta CT}$ method, in which *18S* gene was used for normalization.

Primers used (18S: forward-CGCAGCTAGGAATA-ATGGAATAGG, reverse-CATGGCCTCAGTTCC-GAAA; α_v integrin: forward-TGCCAGCGCTCTTC, reverse-TGGGTGGTGTGTTGCTTTGG).

Western blotting

Western blotting analyses were performed on lysates from Panc-1 cells stimulated or not with gastrin. Fractions, containing identical levels of proteins, were separated by SDS-PAGE and analyzed by Western blotting with the indicated antibodies. The immunoreactivity was visualized with an enhanced chemiluminescence system (Pierce, IL, United States). Anti- α_v integrin antibodies were from Chemicon (Temecula, CA, United States).

Cell adhesion assay

Cell adhesion assays were carried out in 96-well plates using 10^5 cells/cm² in a final volume of 100 μ L/well of serum-free medium. Wells were coated overnight at 4 °C with fibronectin diluted at 5 μ g/mL in phosphate buffered solution (PBS) then washed twice with 100 μ L of PBS and blocked with 1% bovine serum albumin (BSA)-PBS for 30 min at room temperature before addition of the cell suspension. The cells were incubated for 2 h at 37 °C with or without gastrin. Adherent cells were fixed with 50 μ L of 96% ethanol for 10 min, stained with 50 μ L of 0.1% crystal violet, rinsed extensively with water and dried at room temperature. Stained cells were solubilised with 50 μ L of 0.2% Triton X-100 and quantified by measuring the absorbance at 570 nm. For adhesion inhibition experiments, cells were pretreated for 30 min at 37 °C with or without 5 μ g/mL function-blocking antibodies directed against α_v integrin and treated or not with gastrin for 2 h.

Animals

Homozygous *Elas-CCK2* mice used in this study have

been described previously^[8]. Homozygous *Elas-CCK2* mice in a B6SJLF1 background 3 at least 6-mo old and 3 corresponding control littermates were used. Mice were reared in a routine animal facility of the I2MR and maintained on a 12:12 h light-dark cycle. All the experiments were performed during the daytime. All procedures were approved by the I2MR Animal Facility Care Committee.

Immunohistochemistry

Mice were killed by decapitation, the pancreas was excised, fixed and embedded in paraffin using standard techniques. Immunohistochemistry was performed as previously described^[16] using anti- α_v integrin antibodies (Chemicon, Temecula, United States). Sections were incubated with the appropriate secondary and tertiary peroxidase-labelled antisera (DAKO, Glostrup, Denmark) at room temperature, exposed to a solution of diaminobenzidine. All dilutions and washes were performed with phosphate-buffered saline, pH 7.4, containing 0.1% bovine serum albumin.

Statistical analysis

All results are presented as mean \pm SE. Statistical significance was calculated using unpaired Student's *t* test. Values of $P < 0.05$ were considered statistically significant. All analyses were performed using "GraphPad Prism" software.

RESULTS

Gastrin increases α_v integrin expression in Panc-1 cells

In order to identify new gastrin-regulated genes, a human cancer array of 96 genes was probed with samples from either control Panc-1 cells or cells treated with gastrin for 24 h.

Among the genes positively modulated by the CCK2R in these experiments, we observed a significant increase in the expression of α_v integrin (Figure 1A). A quantitative real-time PCR approach was used to confirm and quantify the α_v integrin gene expression. In response to gastrin, the increase in α_v integrin gene expression was time-dependent. A significant effect due to gastrin was detectable 3 h after treatment. At 24 h, we observed a 5-fold increase in the expression of α_v integrin in response to gastrin (Figure 1B).

In addition, we also confirmed the increase in protein levels of α_v integrin in gastrin-stimulated cells using Western blotting analysis (Figure 1C and D).

Signalling pathways involved in α_v integrin expression stimulated by gastrin

As mentioned in the Introduction, gastrin exerts its trophic effects and modulates cell adhesion through a variety of intracellular pathways depending on the cellular model. We previously identified the signalling pathways specifically activated by the CCK2R in Panc-1 cells^[51]. They include the ERK pathway, the PI3K/AKT pathway

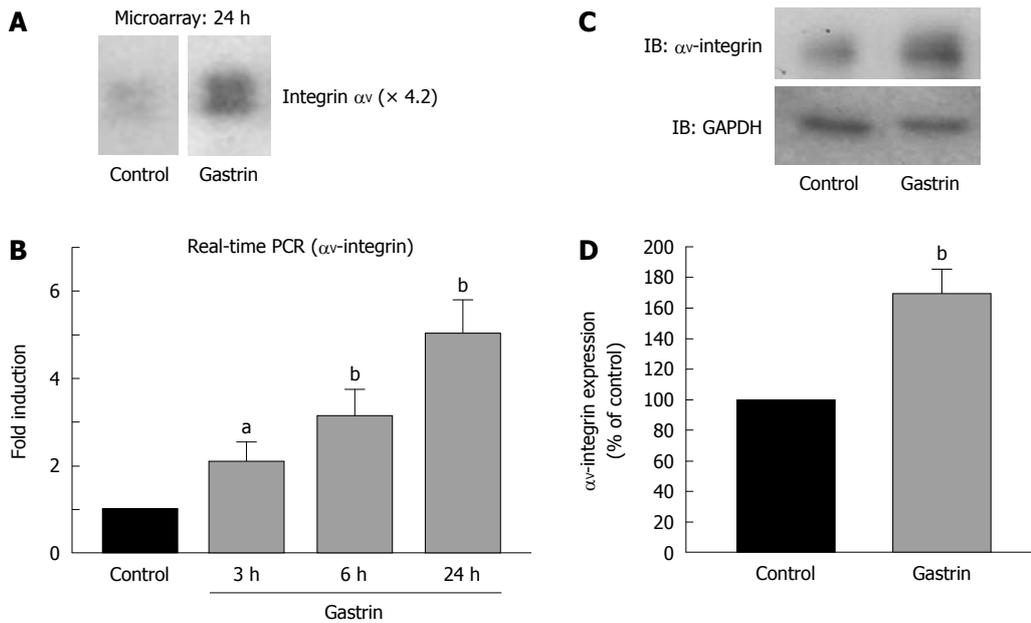

Figure 1 Increased expression of α_V integrin in response to gastrin in Panc-1 cells. A: Results of probing a 96 genes array with samples from unstimulated Panc-1 cells (control) or cells stimulated with 100 nmol/L of gastrin for 48 h; B: Real time polymerase chain reaction (PCR) analysis of α_V integrin mRNA expression in Panc-1 cells. Cells were treated or not with gastrin for the time indicated. Total RNA was isolated and α_V integrin mRNA expression was determined by real time PCR as described Materials and Methods; C, D: Expression of α_V integrin protein was examined by Western analysis following treatment of the cells with gastrin for 24 h. Blots were also probed with an antibody against GAPDH to ensure equal loading of proteins. Representative data from 3 experiments are shown. Quantifications of three experiments are presented as mean \pm SE. Significance was accepted at $P \leq 0.05$, ^a $P < 0.05$, ^b $P < 0.01$.

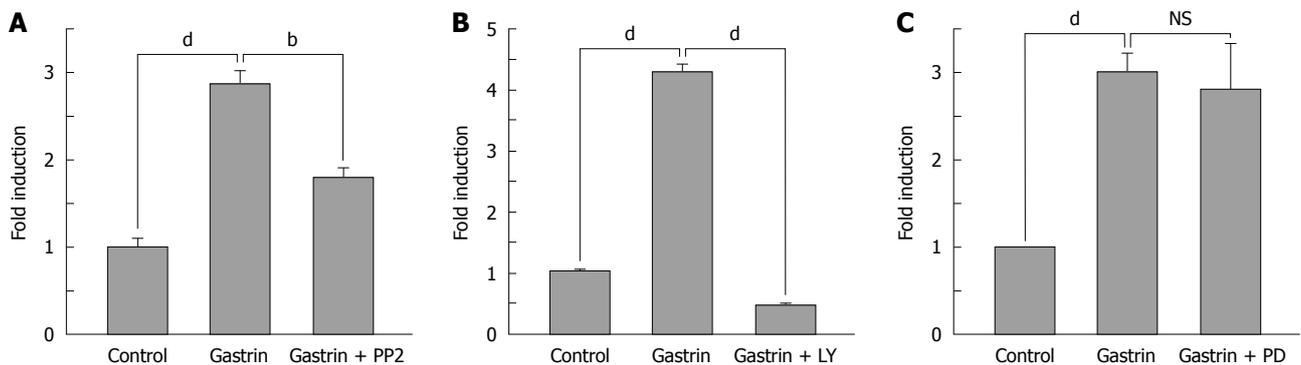

Figure 2 Signalling pathways involved in α_V integrin expression stimulated by gastrin. Cells were pretreated for 30 min with (B) a specific PI3K inhibitor (LY294002, 20 μ mol/L), (A) a Src-kinase inhibitor (PP2, 30 μ mol/L) or (C) a MEK inhibitor (PD PD098059, 20 μ mol/L) prior to gastrin stimulation. After 24 h, total RNA was isolated. Quantitative real-time polymerase chain reaction was performed as described in Materials and Methods. Quantifications of three experiments are presented as mean \pm SE. Significance was accepted at $P \leq 0.05$, ^b $P < 0.01$, ^d $P < 0.001$. NS: Not significant.

and the activation of Src-kinases.

To determine the cellular mechanism by which gastrin increased α_V integrin gene expression, we examined gastrin-regulated α_V integrin gene expression in Panc-1 by quantitative real-time PCR in the absence or presence of different specific inhibitors, LY294002, PP2, or PD098059 which block the PI 3-kinase pathway, Src family kinases and the ERK pathway, respectively. When cells were pre-incubated with PP2, the response to gastrin was decreased by 60% and totally blocked in cells pre-treated with LY294002 (Figure 2A and B), whereas the inhibitors alone did not significantly affect basal α_V integrin expression (PP2: 1.09 \pm 0.2 fold induction, LY204002: 0.93 \pm 0.35 fold induction). These results indicate that Src fam-

ily kinases and the PI 3-kinase pathway mediate gastrin-increased α_V integrin gene expression in Panc-1 cells. In contrast, the inhibitor of the ERK pathway was without any effect (Figure 2C).

Effect of gastrin on Panc-1 cell adhesion to fibronectin

In this study, we have identified α_V integrin as a new gastrin target in Panc-1 cells. Integrins act as adhesion receptors linking the extracellular matrix (ECM) to the cytoskeleton. For many cell types, integrin-mediated adhesion is required for cell growth and cell survival. In the second part of this study, we investigated whether gastrin had an effect on Panc-1 cell adhesion. In a cell adhesion assay using fibronectin-coated wells, we showed

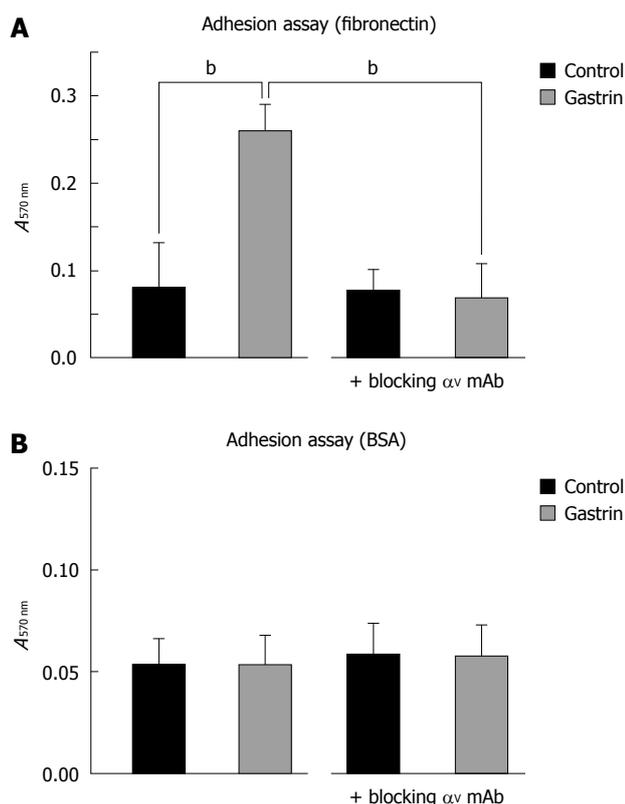

Figure 3 Effect of gastrin on Panc-1 cell adhesion. Cells were added to fibronectin-coated (A) or non-coated (BSA alone) (B) 96-wells for 2 h in the presence or absence of gastrin. Adherent cells were fixed and stained with crystal violet as described in Materials and Methods. After solubilisation, absorbance was measured at 570 nm. When indicated, Panc-1 cells were pre-incubated, with a blocking α_v mAb for 30 min prior to gastrin treatment for 2 h. Quantifications of three experiments are presented as mean \pm SE. Significance was accepted at $P \leq 0.05$. ^b $P < 0.01$. BSA: Bovine serum albumin.

that gastrin induced a significant increase in Panc-1 cell adhesion (Figure 3A). As expected in BSA only controls, we did not observe any effect of gastrin on cell adhesion (Figure 3B).

To determine the role of α_v integrin in gastrin-enhanced Panc-1 cell adhesion, we used blocking anti- α_v integrin monoclonal antibodies. When added 30 min prior to gastrin stimulation, the antibodies significantly decreased gastrin-stimulated Panc-1 cell adhesion (Figure 3A). This confirmed that α_v integrin plays an important role in Panc-1 cell adhesion stimulated by gastrin.

Immunohistochemical staining of α_v integrin in the pancreas of Elas-CCK2 mice

We recently described that Elas-CCK2 mice express human CCK2R in acini. These mice exhibited an increased pancreatic growth, an acinar to ductal trans-differentiation, postulated to be a preneoplastic step in pancreatic carcinogenesis, and developed tumors^[8].

Thus, to analyse *in vivo* the relevance of α_v integrin expression in correlation to CCK2R expression, we analysed α_v integrin overexpression in pancreatic tissue sections from Elas-CCK2 mice and control littermates using

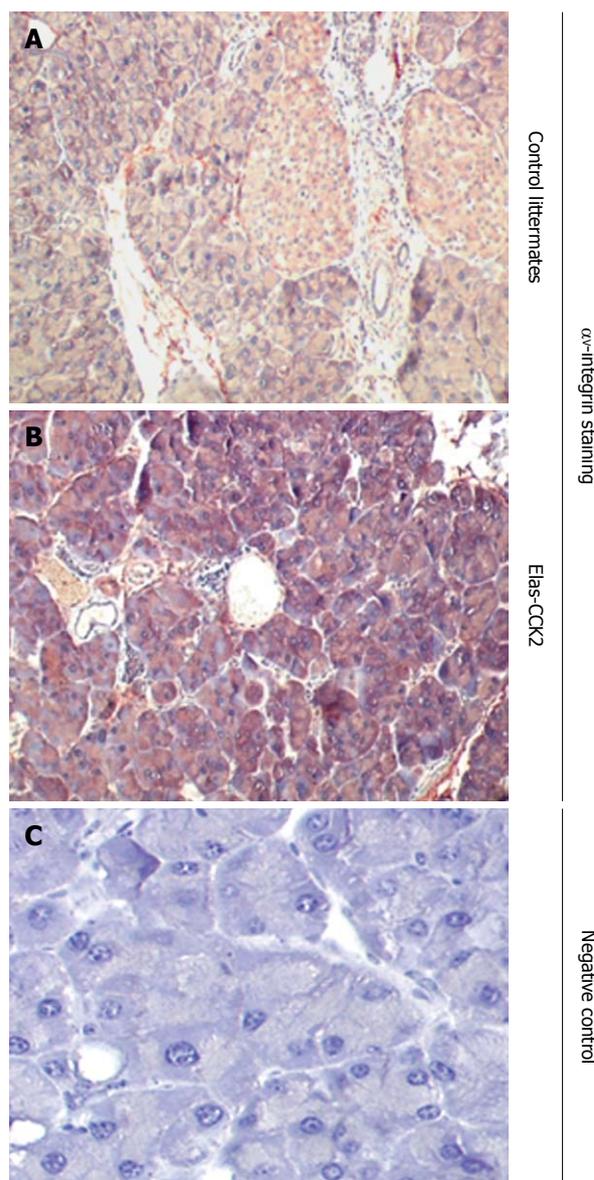

Figure 4 Overexpression of α_v integrin in the pancreas of Elas-CCK2 mice. Immunohistochemistry analysis of paraffin-embedded pancreatic tissues from Elas-CCK2 mice and control littermates were performed using antibodies specific for α_v integrin (A, B). Representative data from 3 experiments (3 different animals in each group) are shown. A negative control without secondary antibody was also included (C).

immunohistochemistry methods. As shown in Figure 4, tissues derived from Elas-CCK2 mice showed an upregulation of α_v integrin (Figure 4B) as compared to control mice (Figure 4A).

DISCUSSION

Several lines of evidence suggest that gastrin and CCK2R could contribute to pancreatic carcinogenesis by modulating processes such as proliferation, cell adhesion or migration. In the current study, we identified α_v integrin as a new gastrin-regulated gene in human pancreatic cancer cells and demonstrated its involvement in modulation of

cell adhesion by gastrin.

Integrins, a large family of cell-surface receptors, act as the bridge between ECM proteins and cytoskeletal proteins^[32]. They are crucial for cell migration but also modulate signal transduction cascades implicated in cell survival or proliferation. Several studies have demonstrated that integrins played a key role in the malignant behaviour of neoplastic cells and were important mediators of tumour invasion and metastasis formation through interactions with ECM proteins^[33-35]. Alterations in integrin expression have been correlated with aggressive growth and metastatic capacity of several tumours^[36-40]. In addition, several integrin subunits are upregulated in pancreatic carcinoma, in particular the fibronectin receptor β_1 and β_3 integrins, two subunits known to interact with α_v integrin^[41-43]. We previously identified β_1 integrin as a gastrin target in pancreatic cancer^[31]. Here, we show that gastrin increases the expression of another member of the integrin family, α_v integrin, at the mRNA and protein level in a human pancreatic tumour cell line. In addition, the use of blocking anti- α_v integrin monoclonal antibodies completely reversed the increase in cell-substrate adhesion induced by gastrin. Previously we showed an inhibitory effect of anti- β_1 integrin antibodies on gastrin-induced cell adhesion, suggesting that the heterodimer $\alpha_v\beta_1$ might be important in gastrin signalling. However, since the β_3 subunit is also overexpressed in pancreatic adenocarcinomas and can interact with α_v subunit, it might be important to analyse, using anti- β_3 integrin, whether it also contributes to gastrin-induced cell adhesion.

In gastric cells, the regulation by gastrin of numerous genes, including genes involved in gastric acid secretion^[19], early response genes^[20] or genes associated with cell migration^[26], involves the activation of the ERK1/2 pathway. In other cellular models such as colon cancer cells, the PI-3-kinase pathway is also involved in the regulation of gastrin target genes. To our knowledge, very little is known about gene regulation by gastrin in pancreatic tumour models. In this study, we demonstrated in pancreatic cancer cells that Src family kinases and the PI-3-kinase pathway play a crucial role in the expression of α_v integrin modulated by gastrin.

The present study and previously published studies by our group demonstrate that gastrin affects cell adhesion and migration by different complementary mechanisms. First, gastrin modulates cell-cell adhesion by inducing a dissociation of the E-cadherin-catenin-complex leading to cytoskeleton reorganization and cell invasion. Here, we show that gastrin also modulates cell-substrate adhesion *via* the α_v integrin.

Another important finding of this study is that the expression of a G protein-coupled receptor, namely the CCK2R, targeted in mouse pancreatic acinar tissue, leads to the over-expression of α_v integrin. These transgenic mice display an increased growth of the pancreas and develop preneoplastic lesions then pancreatic tumours presenting a ductal phenotype similar to that observed in

human pancreatic tumours.

ACKNOWLEDGMENTS

We thank Dr. André F (Marseille, France) for blocking anti- α_v integrin antibodies. We thank Dr. Dufresne M (Toulouse, France) for providing us with pancreatic tissue sections from Elas-CCK2 mice and control mice.

COMMENTS

Background

Pancreatic cancer has a poor prognosis with a 5-year survival rate < 5%. Despite intensive efforts to improve therapy, treatment remains unsatisfactory and most patients die within months as a result of rapid local spread of tumour or metastatic dissemination. A better understanding of the genes involved in tumour growth and migration may allow the development of novel treatment strategies to rapidly tackle this disease.

Research frontiers

Integrins play a key role in the malignant behaviour of neoplastic cells and are important mediators of tumour growth invasion and metastasis. Several publications support the role of gastrin, a peptide hormone, in pancreatic cancer development. However, the mechanism by which gastrin regulates integrin signalling in pancreatic cancer has not been addressed. In this study, the authors show that regulation of α_v integrin by gastrin may contribute to pancreatic tumour development.

Innovations and breakthroughs

This is the first study to report that α_v integrin is a gastrin target in human pancreatic cancer cells. Furthermore, we identified the signalling pathways involved in gastrin-mediated α_v integrin expression. Another important finding of this study is that the expression of a G protein-coupled receptor, namely the CCK2R, targeted in mouse pancreatic acinar tissue, leads to the over-expression of α_v integrin. These transgenic mice display an increased growth of the pancreas and develop preneoplastic lesions then pancreatic tumours presenting a ductal phenotype similar to that observed in human pancreatic tumours.

Applications

A better understanding of the genes involved in tumour growth and migration may allow the development of novel treatment strategies for patients with pancreatic cancer.

Terminology

Integrins, a large family of cell-surface receptors, act as the bridge between extracellular matrix proteins and cytoskeletal proteins. They are crucial for cell migration but also modulate signal transduction cascades implicated in cell survival or proliferation.

Peer review

This is a very well written and clearly laid out manuscript. The authors appear to have carried out the experiments to a high standard and the data are convincing. There are one or two experimental controls that are not included however if the authors can include these or comment on the fact that their inclusion would strengthen their observations.

Abstract

AIM: To elucidate cell proliferation in erosive reflux disease (ERD) and non-erosive reflux disease (NERD), we evaluated markers in squamous epithelial cells.

METHODS: Thirty-four consecutive patients with gastroesophageal-reflux-disease-related symptoms (21 NERD and 13 ERD) were evaluated for the enrolment into the study. All patients underwent 24-h pH monitoring, standard endoscopy, and biopsy for histological evaluation. The expression of cyclins D and A was evaluated by real-time reverse transcription polymerase chain reaction (RT-PCR) from isolated epithelial cells. In all samples, analysis of the isolated cell population revealed the presence of epithelial cells only.

RESULTS: Real-time RT-PCR showed that, in patients

with ERD, the relative expression of cyclin D1 mRNA in esophageal epithelium was strongly decreased in comparison with NERD patients. The mean value of relative expression of cyclin D1 mRNA in NERD patients was 3.44 ± 1.9 , whereas in ERD patients, it was 1.32 ± 0.87 ($P = 0.011$). Real-time RT-PCR showed that, in patients with ERD, relative expression of cyclin A mRNA in esophageal epithelium was decreased in comparison with that in NERD patients (2.31 ± 2.87 vs 0.66 ± 1.11). The mean bromodeoxyuridine labeling index in the NERD patients was $5.42\% \pm 1.68\%$, whereas in ERD patients, it was $4.3\% \pm 1.59\%$.

CONCLUSION: We confirmed reduced epithelial proliferation in ERD compared with NERD patients, and that individuals who develop ERD are characterized by weaker epithelial cell proliferation.

INTRODUCTION

Most of the patients with gastroesophageal reflux disease

(GERD) fall into one of two categories: non-erosive reflux disease (NERD) or erosive reflux disease (ERD). The two main phenotypes of GERD appear to have different pathophysiological and clinical characteristics. NERD is the most common phenotypic presentation of GERD. Although separation of ERD and NERD on a clinical level is difficult, there are clearly physiological, pathophysiological, anatomical, and even histological characteristics that are unique to NERD. Natural course studies have demonstrated that most NERD patients do not progress over time to ERD or even Barrett's esophagus. NERD patients compared to those with ERD demonstrate a highly variable and unpredictable symptomatic response rate to antireflux treatment^[1].

Cell replication of basal layers is hypothesized to be one of the causes implicated in the resistance of the mucosa and structural epithelial defense. In previous investigations, we have demonstrated that, in patients with GERD, the number of proliferating cells, evaluated by Ki-67 immunostaining, was reduced in esophageal mucosa exposed to chronic acid-peptic insult^[2,3]. Two reasonable hypotheses can be suggested to explain the reduced epithelial proliferation activity observed in GERD: (1) chronic cell damage induced by GER determines a reduction in the proliferation rate of esophageal epithelium; or (2) a constitutive lower capacity for cell proliferation brings a major susceptibility to damage induced by GER.

Our findings are in contrast to the results of a recent study^[4] on the cell proliferation of squamous epithelium in GERD. This study has shown a significantly higher number of proliferating cells in GERD patients compared with that in controls, as evaluated by Ki-67 immunostaining.

To elucidate the different proliferation in NERD and ERD patients, the present study evaluated squamous epithelial cell proliferation in patients with GERD, in comparison with NERD, by measuring the S-phase fraction using the bromodeoxyuridine labeling index (BrdU-LI), and by quantifying the expression of cyclins A and D, which are associated with cell cycle progression.

MATERIALS AND METHODS

Study design

Fifty consecutive patients with GERD-related symptoms were evaluated for enrolment into the study. Inclusion criteria were the presence of typical symptoms (heartburn and/or regurgitation) for at least 1 year (frequency was > 2 times/wk) and abnormal 24-h pH parameters and symptom-association probability (SAP). Exclusion criteria were patients with esophageal or gastric malignancy or histologically proven Barrett's esophagus, gastric or duodenal ulcer, previous esophageal or gastric surgery, extra-esophageal symptoms, patients taking antisecretory or prokinetic drugs at least 30 and 15 d before the procedure, respectively. Forty-six patients (mean age 45.2 ± 13.4 years, range 22-78 years; 20 men) fulfilled the inclusion/exclusion criteria and were evaluated. All these

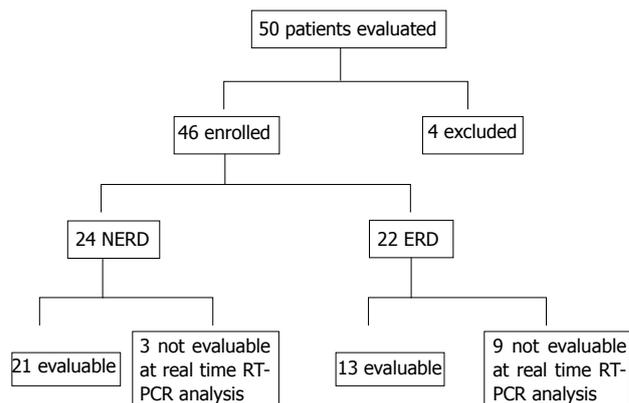

Figure 1 Study profile. RT-PCR: Reverse transcription polymerase chain reaction; NERD: Non-erosive reflux disease; ERD: Erosive reflux disease.

M: Male; F: Female; NERD: Non-erosive reflux disease; ERD: Erosive reflux disease.

patients underwent standard endoscopy and biopsy for histological evaluation. Twenty-four had an apparently normal esophageal mucosa at endoscopy (NERD), whereas 22 had ERD. None of the patients had received cyclical therapy with proton pump inhibitors (PPIs) (not more than 8 wk in the past year). This study was single-blinded for the pH, histological, immunostaining and real-time reverse transcription polymerase chain reaction (RT-PCR) evaluations.

The frequency and intensity of symptoms and their impact on quality of life were registered using a structured and validated questionnaire for the diagnosis of GERD^[5], and patients with a score > 3.1 were considered positive. For real-time RT-PCR, only 34 patients (mean age 47.08 ± 16.04 years, range 22-73 years; 16 men) were evaluable (Figure 1). Twenty-one had an apparently normal esophageal mucosa at endoscopy (NERD), whereas 13 had ERD (Table 1).

Patients gave written informed consent to participate in the study, which was approved by the local research ethical committee.

Twenty-four-hour ambulatory pH monitoring

Every patient underwent 24-h esophageal pH monitoring according to standard methodology. To define better the localization of the lower esophageal sphincter (LES) and upper esophageal sphincter (UES), esophageal manometry was performed before pH monitoring, with a water-perfused catheter that incorporated three distal openings, radially oriented for LES pressure recording, and three side-hole recording sites at 5, 10 and 15 cm above the distal openings. Multichannel 24-h pH monitoring was performed using two probes, with one and two antimony sensors, respectively, with a separate skin reference (Zinetics Medical Inc., Salt Lake City, UT, United States). In accordance with manometric findings, the three pH sensors were placed at the gastric level, at 5 cm above the LES and 10 cm below the UES, respectively. Data were stored on a single portable digital recorder (Digitrapper pH 200; Medtronic, Minneapolis, MN, United States). Before each study, the pH probe was calibrated in buffer solutions of pH 7 and pH 1.

During the test day, meal time and composition were standardized. The reflux parameters were assessed according to Johnson and DeMeester^[6]. Of these, only the percentage of time spent at pH < 4.0 over 24 h was evaluated. The pH testing was considered abnormal if pH < 4.0 was present for > 5% of the total 24 h. The SAP was calculated according to Weusten *et al.*^[7] and was considered positive if it exceeded 95%.

Endoscopic evaluation

Patients underwent upper gastrointestinal (GI) endoscopy (videogastroscope Olympus GIF 160) after sedation by intravenous midazolam (2.5 mg), to assess the presence or absence of erosions.

The Los Angeles classification was used to grade esophagitis^[8]. In each subject, eight specimens were taken with standardized biopsy forceps (Olympus FB 24K), from each of the four quadrants, two bites from each quadrant, 5 cm above the squamous-columnar junction (SCJ), from macroscopically intact (non-eroded) esophageal mucosa. The SCJ (or Z-line) was defined as the border between gastric glandular and esophageal squamous epithelium, and it roughly corresponded to the proximal edge of the gastric folds.

Of the eight biopsies taken during endoscopy from each patient, two were used for total RNA extraction, and two for BrdU labeling. Four were oriented to appropriate cellulose acetate supports (Endofilters Bioptica, Milan, Italy), fixed in 4% buffered formalin, and embedded in paraffin, for processing by hematoxylin-eosin for histological and immunohistochemical analysis.

Histological evaluation

Four-micrometer-thick serial sections were cut from each paraffin block and stained with hematoxylin-eosin. For each case, whole longitudinally sectioned samples were examined. Esophagitis was identified and graded according to the classification of Ismail-Beigi *et al.*^[9]: (1) the de-

gree of basal cell hyperplasia, expressed as a percentage of epithelial thickness: none (0%-15%), mild (16%-33%), moderate (34%-67%), severe (> 67%); (2) presence or absence of papillary zone elongation, determined by calculating papillary length as a percentage of epithelial thickness: absent (0%-67%) and present (> 67%); and (3) density of neutrophil and eosinophil infiltration: none (0/high power field), mild (1-2/high power field), moderate 3-10/high power field) and severe (> 10/high power field). The area of one high power field was 0.229 mm.

In vitro BrdU incorporation and immunohistochemical evaluation of S-phase cells

Each biopsy was immersed in 5 mL RPMI 1640 containing non-essential amino acids, 100 U/mL penicillin, 100 µg/mL streptomycin and 10% fetal bovine serum (FBS) supplemented with 160 µmol/L BrdU (Sigma-Aldrich, St Louis, MO, United States) and incubated for 4 h at 37 °C in a 5% CO₂/air incubator. Tissues were rapidly rinsed with three washes of cold phosphate buffered saline (PBS), fixed in 10% buffered formalin, and embedded in paraffin. Sections were cut from each paraffin block and picked up on poly-L-lysine-coated slides. Sections were dewaxed, hydrated through decreasing concentrations of ethanol, rinsed in distilled water, and autoclaved in 10 mmol/L sodium citrate buffer (pH 6.0) at 120 °C for 21 min for antigen retrieval. After cooling and washing, the endogenous peroxidase activity was quenched using 3% hydrogen peroxide in absolute methanol for 10 min at room temperature. Sections were incubated with primary mouse anti-BrdU antibody (Bu20a; Abcam, Cambridge, United Kingdom) diluted in 1% bovine serum albumin in PBS overnight at 4 °C, using appropriate dilutions.

Sections were processed according to a non-biotin amplified method (NovoLink™ Polymer Detection System; Novocastra Laboratories, Newcastle Upon Tyne, United Kingdom) and counterstained with hematoxylin.

Quantitative analysis of BrdU immunostaining was performed on contiguous field visualized on the color monitor of a personal computer equipped with a 3 CCD (charge-couple device) color video camera (KY F55B; JVC, Pinebrook, NJ, United States) connected to a light microscope (Leitz DIAPLAN, Wetzlar, Germany). For each case, whole longitudinally sectioned samples were examined. Samples that did not contain at least 1000 cells were excluded. Quantitative evaluation was only carried out on portions of epithelium in between vertically sectioned stromal papillae, and corresponding to 100 µm from the basal layer. BrdU-LI was defined as the ratio of BrdU-positive nuclei to the total number of epithelial cells, and was expressed as a percentage.

Esophageal epithelial cell isolation, RNA extraction, reverse transcription and real-time PCR

Total RNA was extracted from esophageal epithelial cells that were isolated as follows. Esophageal biopsy samples were washed in PBS and incubated in 0.5% collagenase type II (C6885; Sigma-Aldrich) in 4-(2-hydroxyethyl)-1-

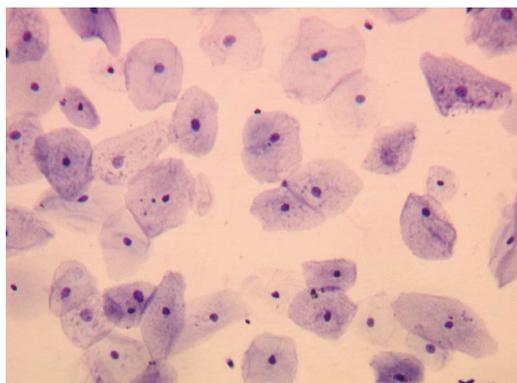

Figure 2 Cytological preparation from esophageal biopsy after epithelial cell isolation. Only epithelial cells were present. Toluidine blue staining (300 ×).

piperazineethanesulfonic acid (HEPES) buffer for 30 min at 37 °C in a shaking bath.

Collagenase activity was blocked by adding the same volume of 20% FBS in HEPES buffer. The digested material was re-suspended and passed through a 40- μ m pore size cell strainer (BD Falcon™, Franklin Lakes, NJ United States) and centrifuged for 5 min at 800 *g*. Cells were washed in PBS and counted in a hemocytometer. From each biopsy sample, an average of 50 000 cells were recovered. Cell morphology was evaluated by seeding cells on poly-L-lysine-coated slides for 2 h at 37 °C. Cells were fixed with 2% paraformaldehyde in PBS for 5 min and stained with 1% toluidine blue in distilled water for 1 min (Figure 2).

Total RNA was extracted from isolated esophageal epithelial cells using TRI Reagent (Ambion, Austin, TX, United States) according to the manufacturer's instructions. Whole cell RNA was quantified spectrophotometrically and 2 μ g RNA for each sample was reverse-transcribed using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, United States), following the manufacturer's protocol.

The relative expression of cyclin A (CCNA1), cyclin D1 (CCND1) and the housekeeping gene β -glucuronidase were evaluated by real-time polymerase chain reaction (PCR) performed on an ABI Prism 7000 Sequence Detection System (Applied Biosystems) using TaqMan Gene Expression Assay primers and probe kits (Assays catalog number Hs00927505 for CCNA1 and Hs00277039 for CCND1; Applied Biosystems). Cycling conditions were as follows: 50 °C for 2 min, 95 °C for 10 min, 40 cycles at 95 °C for 15 s, and 60 °C for 1 min. For each sample, three replicates were analyzed. The relative amounts of the transcripts were calculated with the $2^{-\Delta\Delta CT}$ method against aliquots from a single preparation of calibrator cDNA from the U2OS cell line.

Statistical analysis

Differences between groups were assessed by Student's *t* test. $P < 0.05$ was considered statistically significant. Data were analyzed with SPSS software (SPSS, Chicago, IL, United States).

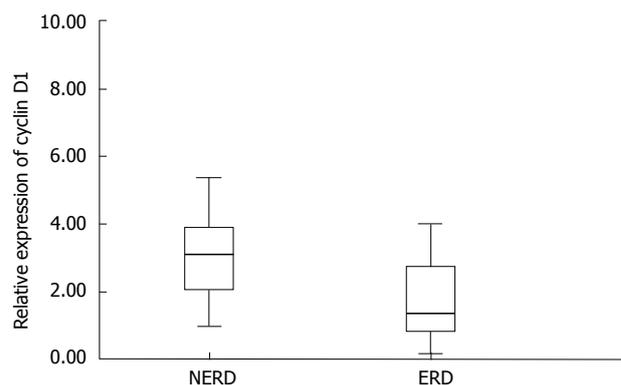

Figure 3 Box plots of relative expression of cyclin D1 mRNA by real-time RT-PCR analysis; median (bold line in box), and interquartile range (upper and lower lines of the box) in human esophageal mucosa of NERD and ERD patients ($P < 0.01$). RT-PCR: Reverse transcription polymerase chain reaction; NERD: Non-erosive reflux disease; ERD: Erosive reflux disease.

RESULTS

At pH monitoring, the percentage time with esophageal pH < 4 in the two groups of patients (NERD and ERD) was $10.4\% \pm 1.3\%$ and $10.7\% \pm 1.4\%$, respectively. No significant differences were found in the mean percentage time between the two groups.

Histological analysis showed that, among 13 patients affected by erosive esophagitis in endoscopic normal mucosa, 12 had a normal pattern, and 1 had mild esophagitis. None of the patients with NERD showed signs of esophagitis (Table 1).

Expression of cyclins A and D was evaluated by real-time RT-PCR from isolated epithelial cells. To check for purity of isolated cells, morphology was assessed after toluidine blue staining (Figure 2). In all samples evaluated, analysis of the isolated cell population revealed the presence of epithelial cells only.

Real-time RT-PCR analysis shows that, in patients with ERD, the relative expression of cyclin D1 mRNA, in esophageal epithelium, was strongly decreased in comparison with that of NERD patients (Figure 3). In particular, the relative expression of cyclin D1 mRNA in NERD epithelium was twofold higher, and showed elevated variability between patients, with respect to ERD epithelium. The relative expression of cyclin D1 mRNA ranged from 0.17 to 8.36 among all patients, with a mean (\pm SD) value of 2.41 ± 1.8 . The mean (\pm SD) cyclin D1 value in 21 NERD patients was 3.44 ± 1.9 , whereas in 13 ERD patients, it was 1.32 ± 0.87 ($P = 0.011$).

Only 25 of the 34 patients enrolled were evaluable for real-time RT-PCR analysis of cyclin A mRNA (18 NERD and 7 ERD). The relative expression of cyclin A mRNA ranged from 0 to 8.13 among all patients with a mean (\pm SD) value of 1.84 ± 2.59 . Real-time RT-PCR analysis showed that, in patients with ERD, the relative expression of cyclin A mRNA in esophageal epithelium was decreased in comparison with that in NERD patients (Figure 4). In particular, the mean (\pm SD) cyclin A value of NERD patients was 2.31 ± 2.87 , whereas in ERD patients, it was 0.66 ± 1.11 . Despite the fact that

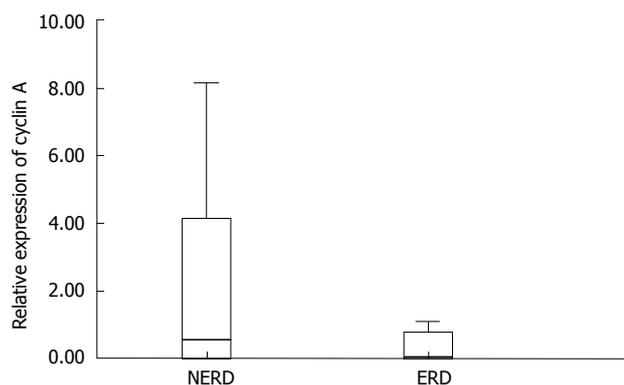

Figure 4 Box plots of relative expression of cyclin A mRNA by real-time RT-PCR analysis values; median (bold line in box), and interquartile range (upper and lower lines of the box) in human esophageal mucosa of NERD and ERD patients. RT-PCR: Reverse transcription polymerase chain reaction; NERD: Non-erosive reflux disease; ERD: Erosive reflux disease.

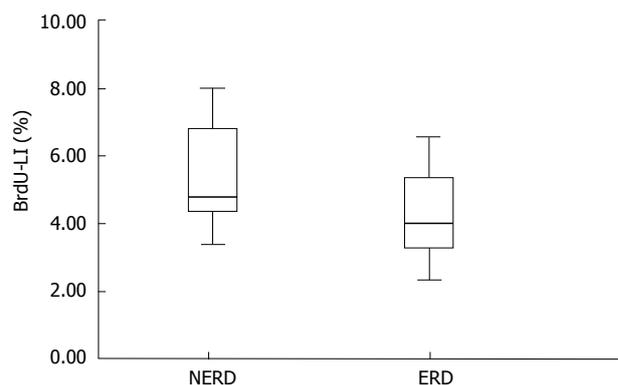

Figure 5 Box plots of BrdU-LI analysis values, median (bold line in the box), and interquartile range (upper and lower lines of the box) in human esophageal mucosa of NERD and ERD patients. NERD: Non-erosive reflux disease; ERD: Erosive reflux disease.

the relative expression of cyclin A mRNA in NERD epithelium was fourfold higher than in ERD epithelium, the difference between the two groups was not statistically significant ($P = 0.158$); both for the low number of cases evaluated, in particular in the ERD group, and for the high variability of the values relative to NERD patients.

Twelve patients were evaluable for BrdU analysis. BrdU-LI ranged from 2.33% to 8%, with a mean (\pm SD) value of $4.95\% \pm 1.67\%$. The mean BrdU-LI of the NERD patients ($n = 7$) was $5.42\% \pm 1.68\%$, whereas in ERD patients ($n = 5$), it was $4.3\% \pm 1.59\%$ (Figure 5). Once again, NERD epithelium showed a greater number of BrdU-positive cells than ERD epithelium did, but the difference between the two groups was not statistically significant ($P = 0.272$).

DISCUSSION

In the present study, we evaluated a series of esophageal biopsies to define the proliferation activity of the epithelium in patients with erosive or non-erosive GERD. In previous investigations, we have demonstrated that, in patients with GERD, cell proliferation evaluated by MIB1 immunostaining was reduced in esophageal mucosa exposed to chronic acid-peptic insult^[2,3]. In particular, patients with NERD and ERD showed a decrease in cell proliferation to 50% and 75%, respectively, compared to normal subjects^[2].

In contrast to our results, Mastracci *et al*^[4] have found that MIB1 immunostaining of GERD patients is significantly greater than in controls. These different data might reflect different sampling conditions that could influence the proliferating activity of the epithelial cells. In particular, Mastracci and co-workers have evaluated specimens that were taken from 2-4 cm to the Z line, and observed a progressive decrease in the Ki-67 LI by increasing the distance from the Z line.

Feagins *et al*^[10] have shown that multiple acid exposures decrease cell proliferation in non-neoplastic,

telomerase-immortalized Barrett's cell lines. This decrease in cell proliferation is the result of a delay in cell cycle progression that is mediated by p53. In agreement with these results, we have recently demonstrated that, in patients with ERD and NERD, long-term PPI therapy increases esophageal cell proliferation^[3]. These data confirm that acid-peptic insults have an antiproliferative effect on esophageal epithelial cells.

In the present study, only patients with at least a 1-year history of GERD were included. Upper endoscopy was performed and biopsies were taken only in apparently normal mucosa at 5 cm above the Z-line. In this way, we studied the behavior of the mucosa exposed to chronic acid insult, but far from erosions, and especially, from reparative changes secondary to the lack of the superficial mucosa, where basal cell hyperplasia has been reported^[11], which can be characterized by increased proliferative activity.

Regardless of these considerations, in the present study, we evaluated proliferative activity of the epithelium in patients with erosive and non-erosive GERD. For this purpose, three proliferation markers were assessed: cyclins A and D relative expression, evaluated by real-time RT-PCR, and *in vitro* BrdU incorporation for immunohistochemical detection of S-phase cells in histological samples.

Cyclins are a family of proteins involved in cell cycle regulation. Cyclin expression rises and falls at various stages of the cell cycle, thus activating specific cyclin dependent kinases (CDKs), which, by phosphorylation of multiple substrates, control a number of critical steps in cell cycle progression^[12]. Cyclin D1 is encoded by the *CCND1* gene located on chromosome 11q13, and in association with CDK4 or CDK6, regulates the transition from G1 to S phase^[13,14]. It is synthesized in response to extracellular mitogenic signals and is maximally expressed in mid-to-late G1-phase^[15]. Cyclin A, in association with CDK1 or CDK2, promotes the transition from G2 to M phase^[16], and is expressed later in the cell cycle, during DNA replication, achieving its maximal levels during late S-phase^[17,18]. Cyclins D1 and A are regarded

as specific markers of the G1 and S phases of the cell cycle, respectively. Therefore, in the present study, we evaluated their mRNA expression to assess the proliferative activity of esophageal epithelial cells. In previous investigations, we have in fact demonstrated that the relative expression of cyclin mRNA is directly related to the cell proliferation rate in breast cancer specimens^[19]. Moreover, to identify S-phase cells specifically, in the present study, DNA-synthesizing cells were detected *in situ* after BrdU incorporation by immunohistochemical analysis with anti-BrdU antibodies.

Our results demonstrated that cyclin D, as a marker of G1 phase, was significantly higher in NERD compared to ERD. Also the S-phase markers evaluated in our study (cyclin A and BrdU) were higher in NERD compared to ERD, although in this case, because of the small number of evaluable samples, the difference was not statistically significant. The reduction in the number of samples analyzed for cyclin A compared to those analyzed for cyclin D was due to the fact that the thickness of the epithelium in ERD was significantly reduced, and therefore, in these samples, it was not always possible to isolate a sufficient number of epithelial cells for molecular analysis.

The limitation of this study was the small number of patients, but this is believed to be the first study to evaluate, at the molecular level, esophageal epithelial cells. This method is clean but it creates considerable tissue loss.

In conclusion, the present study confirmed our previous results regarding the reduction of epithelial proliferative activity in ERD compared with NERD patients. Besides, this study supports the previous data on an antiproliferative effect of acid-peptic injury in esophageal cell epithelium, and reinforces the idea that individuals who develop ERD might be genetically characterized by weaker epithelial cell proliferation. On the other hand, patients with more efficient epithelial proliferation capability could have a lower probability of developing macroscopic mucosal lesions when stressed by acid and pepsin. Further studies are required to understand better the mucosal defense mechanisms, and in particular, those controlling the cellular proliferative activity of esophageal mucosa.

COMMENTS

Background

Cell replication in basal layers has been suggested as one of the causes of mucosal resistance and structural epithelial defense. To elucidate better the different proliferative activity between non-erosive reflux disease (NERD) and erosive reflux disease (ERD), the authors evaluated a series of molecular and immunohistochemical markers of cell proliferation in squamous epithelial cells of patients with gastroesophageal reflux disease (GERD).

Research frontiers

In previous investigations, the authors have demonstrated that, in patients with GERD, cell proliferation evaluated by MIB1 immunostaining is reduced in esophageal mucosa exposed to chronic acid-peptic insult, in contrast with other studies. These different data might reflect different sampling conditions that could influence the proliferating activity of the epithelial cells.

Innovations and breakthroughs

The present study confirmed the previous results with regard to reduction of epithelial cell proliferative activity in ERD compared with NERD patients. It supports previous data on an antiproliferative effect of acid-peptic injury in esophageal cell epithelium, and reinforces the idea that individuals who develop ERD might be genetically characterized by a weaker proliferating epithelial cell capability.

Applications

This paper shows that patients with more efficient epithelial proliferative capability could have a lower probability of developing macroscopic mucosal lesions when stressed by acid and pepsin.

Peer review

The paper by Dr. Calabrese and colleagues discusses activity of cells in esophageal squamous epithelium in patients with NERD and ERD. This is a very well written manuscript that contributes to the knowledge of the molecular mechanisms in patients with GERD.

Abstract

AIM: To investigate whether systemic lupus erythematosus (SLE) is associated with benign focal liver lesions and vascular liver diseases, since these have been occasionally reported in SLE patients.

METHODS: Thirty-five consecutive adult patients with SLE and 35 age- and sex-matched healthy controls were evaluated. Hepatic and portal vein patency and presence of focal liver lesions were studied by colour-Doppler ultrasound, computerized tomography and magnetic resonance were used to refine the diagnosis, clinical data of SLE patients were reviewed.

RESULTS: Benign hepatic lesions were common in SLE patients (54% vs 14% controls, $P < 0.0001$), with

hemangioma being the most commonly observed lesion in the two groups. SLE was associated with the presence of single hemangioma [odds ratios (OR) 5.05; 95% confidence interval (CI) 1.91-13.38] and multiple hemangiomas (OR 4.13; 95% CI 1.03-16.55). Multiple hemangiomas were associated with a longer duration of SLE (9.9 ± 6.5 vs 5.5 ± 6.4 years; $P = 0.04$). Imaging prior to SLE onset was available in 9 patients with SLE and hemangioma, showing absence of lesions in 7/9. The clinical data of our patients suggest that SLE possibly plays a role in the development of hemangioma. In addition, a Budd-Chiari syndrome associated with nodular regenerative hyperplasia (NRH), and a NRH associated with hepatic hemangioma were observed, both in patients hospitalized for abdominal symptoms, suggesting that vascular liver diseases should be specifically investigated in this population.

CONCLUSION: SLE is associated with 5-fold increased odds of liver hemangiomas, suggesting that these might be considered among the hepatic manifestations of SLE.

Liver hemangioma and vascular liver diseases in patients with systemic lupus erythematosus. *World J Gastroenterol* 2011; 17(40): 4503-4508 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i40/4503.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i40.4503>

INTRODUCTION

The spectrum of liver disease in systemic lupus erythematosus (SLE) patients is wide, ranging from benign conditions (such as benign liver lesions and mild chronic hepatitis), to aggressive and potentially lethal disorders (such as vascular liver diseases, including portal and hepatic veins thrombosis, nodular regenerative hyperplasia and idiopathic portal hypertension)^[1,2]. Benign focal liver lesions, such as cavernous hemangioma, have been reported in SLE^[3,4], and vascular liver diseases in SLE have been frequently observed in autopsic series^[5], suggesting an association between these disorders, but data in living SLE patients are scarce and rely on isolated case reports.

Color-Doppler ultrasonography (CDUS) is the initial imaging technique used to screen patients with suspected liver disease, since it allows a non-invasive, real-time evaluation of abdominal organs and vessels, which is repeatable, easy to perform and inexpensive compared with other techniques. Ultrasound allows an accurate identification and characterization of focal hepatic lesions^[6], and of portal vein and hepatic veins patency; in cases of portal or hepatic vein thrombosis, CDUS accuracy is similar to that of computerized tomography (CT)^[7-13].

This case-control study was aimed at investigating, *via* CDUS, whether SLE is associated with focal lesions and vascular liver diseases.

MATERIALS AND METHODS

Patients and controls

We prospectively included in the present study all consecutive patients with an established diagnosis of SLE, namely at least 4 criteria among those published in the guidelines by the American College of Rheumatology^[14]. Exclusion criteria were the presence of previously recognized liver disease from alcohol, hepatitis B virus (HBV) or hepatitis C virus (HCV) virus or autoimmune causes, and personal history of malignancy.

Thirty subjects with SLE, normal aspartate transaminase (AST)/alanine transaminase (ALT) and no recognized liver disease observed at our outpatient Unit, and 5 patients with SLE requiring hospitalization for any cause at our Unit over 24 mo were consecutively enrolled.

Thirty-five age and sex-matched healthy controls without SLE were included. Controls were consecutively recruited among subjects referred for an abdominal ultrasound examination to the Ultrasound Laboratory of our Unit for the following reasons: routine screening ($n = 12$), follow-up of renal or hepatic cyst ($n = 11$), evaluation of gallbladder lithiasis ($n = 6$), and abdominal discomfort ($n = 6$). Healthy state was ensured by specific questions on liver, heart, lung or renal diseases, history of malignancy, and chronic medication intake. Subjects with history of any of these conditions were excluded.

This study was approved by the Senior Staff Committee of University Hospital, a board which regulates non-interventional studies and is comparable to an Institutional Review Board. The nature of the study was

explained to the patients and controls, and a written informed consent was obtained in each case, according to the principles of the Declaration of Helsinki (revision of Edinburgh 2000).

Ultrasound-Doppler examination

After an overnight fast, patients and controls were entered in the ultrasound examination room and invited to remain in the supine position for 10 min. Thereafter, an abdominal color-Doppler ultrasonography (CDUS) examination was performed by an experienced operator by using last-generation duplex equipment (Esaote Ansaldo AU Technos, Genoa, Italy) with a 4.5-7 MHz convex probe provided by a color, power and pulsed Doppler device.

Liver parenchyma and portal and hepatic veins patency were systematically evaluated. Location, number and size of the focal liver lesions were recorded. If present, they were diagnosed as^[6]: (1) typical liver hemangioma: round-shaped, hyperechoic lesion with sharp margins, up to 4 cm in size. No Doppler signal inside the lesion; (2) atypical liver hemangioma: size > 4 cm; hypoechoic lesion or heterogeneous echopattern. No Doppler signal inside the lesion; and (3) focal nodular hyperplasia (FNH): hypo- or slightly hyperechoic lesion < 3 cm with sharp margins and typical color-Doppler findings: central feeding artery and spoke wheel centrifugal vascular pattern.

When ultrasound (US) suggested atypical hemangioma, FNH or lesions of uncertain nature, a definite diagnosis was achieved by magnetic resonance imaging or by multislice CT scan.

Clinical and laboratory data of SLE patients

Routine clinical and laboratory data were collected, and data on the duration of the disease and its treatment were recorded. Systemic lupus erythematosus disease activity index (SLEDAD)^[15] and Systemic lupus international collaborating clinics/American college of rheumatology damage index for systemic lupus erythematosus (SLICC/ACR)^[16] were calculated.

Statistical analysis

Statistical analysis was performed by SPSS 12.0 statistical package (SPSS Inc., Chicago, IL, United States). All results are expressed as mean \pm SD. Comparisons between cases and controls were done by Student's *t* test for unpaired data for continuous normally distributed variables, and by χ^2 test for frequencies; Mann-Whitney test was used for non-normally distributed continuous variables. The strength of the association between SLE and the conditions in study were estimated by odds ratios (OR) and their 95% confidence interval (CI). A *P* value of < 0.05 was considered statistically significant.

RESULTS

Focal hepatic lesions in SLE patients and controls

ied patients with SLE.

As shown, 19 patients (54.2%) showed one or more benign focal liver lesion. Hemangioma was the most frequent diagnosis, being observed in 19 cases (54.2%). FNH was observed in 2 cases (5.7%), and in both cases was associated with hemangioma.

Hemangiomas were observed both in outpatients and in hospitalized patients. Among hospitalized patients, a single hemangioma was seen in association with nodular regenerative hyperplasia (NRH); in two additional patients with no abdominal symptoms, admitted for fever in one case and for polyarthralgia in one case, a single hepatic hemangioma of large size in the right lobe (4.5 cm and 6 cm) was diagnosed.

Among outpatients, 16 (53.3%) had focal liver lesions; 9 had a single hepatic hemangioma (in two cases with atypical hypoechoic US aspect requiring CT scan; size 10–22 mm), and 7 (20% of patients of the whole series and 23.3% of outpatients) had multiple typical hepatic hemangiomas (number 2–9; size 10–22 mm) (Figure 1).

Hemangiomas did not demonstrate a preferential location inside the liver, being equally distributed in all segments.

Two patients with multiple hepatic hemangiomas had a FNH associated (confirmed by magnetic resonance imaging). Furthermore, one patient showed previously un-

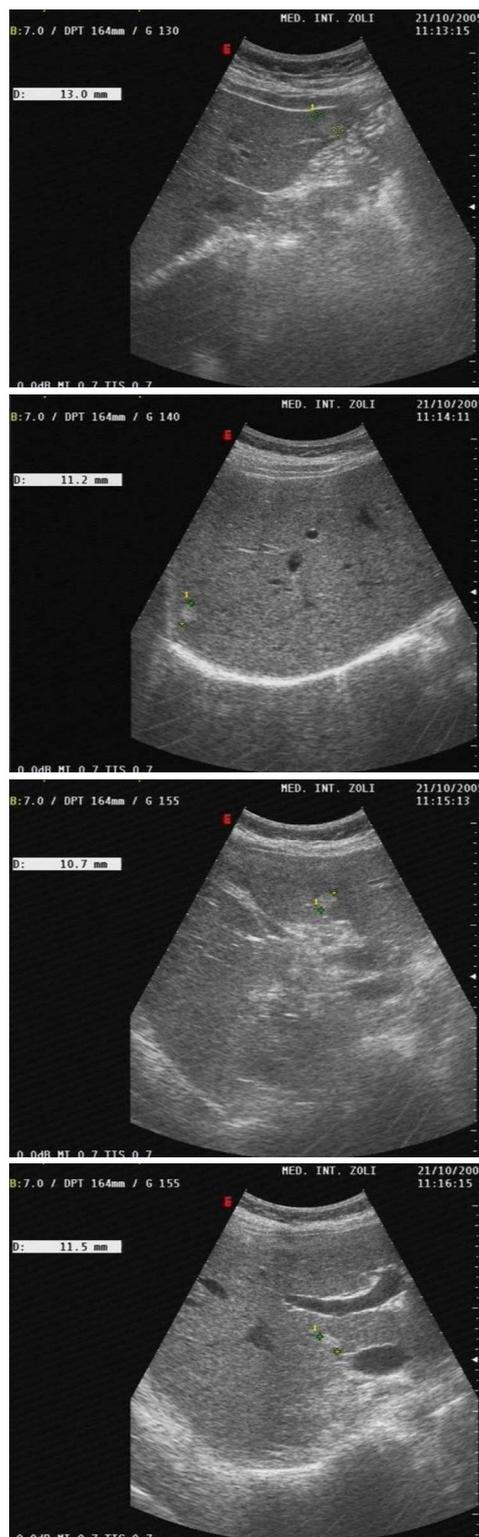

Figure 1 Ultrasonographic appearance of multiple hemangiomas in one of the studied patients. In this 47-year-old woman, 4 hepatic lesions were detected in 4 different segments of the liver.

diagnosed Caroli disease of left liver lobe associated with a single atypical hemangioma of the right lobe. These findings were confirmed by abdominal MR.

Five control subjects (14%) were diagnosed of hemangioma. Two of them had multiple lesions (2 lesions in

¹Data available in n = 33. ^aP < 0.05 vs patients with single hepatic hemangioma and ^bP = 0.02 vs patients with hepatic hemangioma. M: Male; F: Female; SLE: Systemic lupus erythematosus; SLEDAI: Systemic lupus erythematosus disease activity index; SLICC: Systemic lupus international collaborating clinics; ACR: American college of rheumatology damage index for systemic lupus erythematosus; LAC: Lupus anticoagulant; AST: Aspartate transaminase; ALT: Alanine transaminase; GGT: Gamma-glutamyl transpeptidase; ALP: Alkaline phosphatase; HH: Hepatic hemangioma.

both cases).

SLE was associated with the presence of single hemangioma (OR 5.05; 95% CI 1.91-13.38) and multiple hemangiomas (OR 4.13; 95% CI 1.03-16.55).

Time-course of hemangioma in SLE

In order to ascertain whether hemangiomas formation was associated with SLE onset, we evaluated the clinical files of patients with liver hemangioma to identify imaging prior to SLE development. These data were found in 9/19 cases and consisted of US examination in 7 and CT scan in 2. In 7/9 cases imaging studies documented a normal liver, while in two cases a hemangioma was already present. In the two cases of pre-existent liver hemangioma, the lesion's size at the time of the present study was stable in one, and increased from 15 to 21 mm in one.

Association between clinical variables and liver hemangioma in SLE

We did not find any significant difference between patients with and without hemangiomas for laboratory parameters, age and prevalence of the main clinical manifestation of SLE (glomerulonephritis, neurological symptoms, pulmonary hypertension, and polyserositis) (Table 2).

We observed a significantly higher prevalence of acrocyanosis in patients with hemangioma compared with patients without focal liver lesions: 94% vs 47% (P = 0.02).

We evaluated whether the presence of liver hemangi-

oma was associated with duration of SLE disease, activity of the disease at onset (SLEDAI), damage index at the time of US examination (SLICC) and number of clinical flares of SLE.

Multiple hepatic hemangiomas were associated with a longer duration of SLE disease (9.9 ± 6.5 vs 5.5 ± 6.4, P = 0.049). Patients with hepatic hemangiomas also showed a higher number of clinical flares, but the difference did not reach statistical significance.

As for treatment, the rate and duration of corticosteroid therapy for SLE were similar in patients with and without hemangioma.

Prevalence of vascular liver disease in SLE patients

We observed 2 cases of vascular liver diseases (5.7%). Both were identified in hospitalized patients with abdominal symptoms. The first patient (female, 39 year) was admitted for ascites and showed chronic Budd-Chiari syndrome with clinical and US signs of portal hypertension (namely small esophageal varices at endoscopy and enlargement of portal vein and spleen, and porto-collateral circulation at US), and NRH. A percutaneous biopsy was obtained and confirmed the radiological diagnosis. The second patient (female, 47 year) was admitted for a biliary colic, and CDUS identified a diffuse and severe alteration of liver echopattern associated with a 4 cm hyperechoic nodule. On CT scan she was diagnosed of probable NRH associated with a 4 cm hemangioma; portal and hepatic veins were patent. The patient refused liver biopsy.

DISCUSSION

The main result of the present study is the demonstration of an association between SLE and liver hemangioma. The prevalence of liver hemangioma was 54.2% in our SLE patients; this figure is more than twice the maximum expected in the general adult population (0.4%-20%)^[17], and was significantly higher than the 14% observed in healthy control subjects. Accordingly, in this study SLE was associated with increased odds (5 fold increase) of hemangioma occurrence.

This data suggests that SLE may be directly implicated in the formation of benign vascular neoplasia. Some additional findings from our study support this hypothesis: hemangioma seemed to appear after SLE onset in 7 patients; it increased in size in one; hemangiomas were multiple in 40% of patients, and patients with multiple hemangiomas had a long-lasting disease.

Hepatic hemangioma is a benign vascular neoplasia of endothelial origin. Even if the pathogenetic mechanisms leading to its formation have not been fully elucidated yet, it has been proposed that hemangiomas are caused by unregulated angiogenesis due to an imbalance between angiogenic and angiostatic factors^[18]. This hypothesis is supported by the observation that hemangiomas may increase in dimension over time during pregnancy and estrogen therapy^[19], as a consequence of estrogens-enhanced neo-

angiogenesis^[20].

It has been shown that SLE patients have increased circulating levels of estrogens^[21] and other angiogenic factors such as vascular endothelial growth factor (VEGF) and IL-18, which are associated with activity of disease^[22,23]. It could be speculated that an activation of angiogenesis might lead to liver hemangiomas formation in the course of the disease. Regrettably we lack evidence to support this hypothesis, since VEGF and other pro-angiogenic cytokines were not dosed in our patients.

In two patients of our series, hemangiomas were associated with FNH. FNH is a benign hepatocellular lesion which has been reported in 0.6%-3.0% of the general population^[17]. It has been showed that FNH represents an abnormal adaptive responsive of liver parenchyma to local hemodynamic disturbances^[24]. The association of hemangioma and FNH is frequent^[25,26], and several authors have speculated that both lesions may have causative factors in common, including focal disturbance of the hepatic blood supply that somehow facilitates the hyperplastic development of these benign lesions^[27].

In the present series of SLE patients, we found 2 cases of vascular diseases of the liver, which were diagnosed in patients hospitalized for abdominal symptoms (ascites and increase of hepatic enzymes, and suspect of biliary colic). Vascular diseases of the liver, such as hepatic and portal vein thrombosis, are life-threatening events occurring more often in patients with congenital or acquired prothrombotic condition^[28]. SLE is a well recognized prothrombotic condition and vascular liver diseases have been reported in this setting^[1,2]; our experience is in line with these previous reports, and suggests that US examination should be performed in cases of abdominal symptoms in SLE patients to specifically rule out vascular liver diseases.

The present study suffers from some limitations. We lack histological confirmation for the imaging findings since most lesions were found in asymptomatic patients, in whom biopsy was not performed. Still, in patients without chronic hepatic diseases, imaging techniques are considered sufficient to diagnose benign liver lesions^[29].

The clinical observations from our series suggest an association between SLE and liver hemangioma formation. Future studies are needed to assess the mechanisms leading to this association.

In conclusion, this study shows that the liver is a frequent site of abnormal findings in SLE patients. SLE is associated with an increased likelihood of liver hemangiomas and multiple hepatic hemangiomas, which can be associated with FNH and vascular liver diseases. Vascular disorders can be found in patients with SLE, and should be actively looked for in SLE patients with abdominal symptoms.

COMMENTS

Background

Benign focal liver lesions, such as cavernous hemangioma, and vascular liver diseases have been reported in systemic lupus erythematosus (SLE), suggest-

ing an association between these disorders.

Research frontiers

Only a few case reports and autoptic series have been published hitherto regarding the prevalence of benign liver lesions and vascular liver diseases in patients with SLE.

Innovations and breakthroughs

In this study, the authors found that the prevalence of hepatic hemangioma is very high in patients with SLE. Moreover, liver hemangiomas in this population were often multiple, and associated in some instance with focal nodular hyperplasia and vascular liver diseases.

Applications

The clinical observations from this study suggest an association between SLE and liver hemangioma formation. Vascular hepatic disorders can be found in patients with SLE, and should be actively looked for in SLE patients with abdominal symptoms.

Peer review

Although this study on liver findings in SLE patients does not lead to direct therapeutic consequences, it evaluates an interesting aspect of this disease. Histological proof would of course be desirable, but in general, biopsy cannot be justified in this context.

Abstract

AIM: To establish the prevalence of *Helicobacter pylori* (*H. pylori*) infection in patients with a bleeding peptic ulcer after consumption of non-steroidal antiinflammatory drugs (NSAIDs).

METHODS: A very early upper endoscopy was performed to find the source of upper gastrointestinal bleeding and to take biopsy specimens for analysis of

H. pylori infection by the rapid urease (CLO) test, histological examination, and bacterial culture. IgG anti-CagA were also sought. The gold standard for identifying *H. pylori* infection was positive culture of biopsy specimens or contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections.

RESULTS: Eighty patients, 61 males (76.3%), mean age 61.2 ± 15.9 years, were consecutively enrolled. Forty-seven (58.8%) patients occasionally consumed NSAIDs, while 33 (41.3%) were on chronic treatment with low-dose aspirin (LD ASA). Forty-four (55.0%) patients were considered infected by *H. pylori*. The infection rate was not different between patients who occasionally or chronically consumed NSAIDs. The culture of biopsy specimens had a sensitivity of 86.4% and a specificity of 100%; corresponding figures for histological analysis were 65.9% and 77.8%, for the CLO test were 68.2% and 75%, for the combined use of histology and the CLO test were 56.8% and 100%, and for IgG anti-CagA were 90% and 98%. The highest accuracy (92.5%) was obtained with the culture of biopsy specimens.

CONCLUSION: Patients with a bleeding peptic ulcer after NSAID/LD ASA consumption frequently have *H. pylori* infection. Biopsy specimen culture after an early upper gastrointestinal tract endoscopy seems the most efficient test to detect this infection.

INTRODUCTION

Acute upper gastrointestinal (GI) bleeding is a life-threatening emergency frequently observed in patients admitted to tertiary care hospitals, with peptic ulcer bleeding accounting for approximately 50% of cases^[1]. A high number of these emergency admissions for upper GI bleeding are attributable to non-steroidal anti-inflammatory drug (NSAID) use, especially in older patients^[2,3].

The fact that peptic ulcers can be effectively treated by acid suppression strongly suggests that it is largely a disease of acid hypersecretion^[3-5], although there is much evidence for a role of *Helicobacter pylori* (*H. pylori*) infection^[6], and NSAID-induced injury^[3]. Published data about the combined role of *H. pylori* infection and NSAID use in patients with peptic ulcer bleeding are conflicting. *H. pylori* infection has been demonstrated in a variety of studies, with a considerable degree of consistency, to increase the risk of NSAID-related GI injury^[7]. Moreover, a recent meta-analysis indicated that prophylactic *H. pylori* eradication may help to reduce the risk of both gastric and duodenal ulcers and their complications, including bleeding, in chronic users of non-steroidal antiinflammatory drugs (NSAIDs)^[8]. Other studies on the interaction between *H. pylori* infection and low-dose aspirin (LD ASA) use in patients with a history of upper GI bleeding demonstrated the protective role of *H. pylori* eradication on rebleeding. In these patients, *H. pylori* eradication may allow the use of LD ASA instead of other antithrombotic drugs^[9]. On the other hand, some studies evidenced a lower rate of *H. pylori* infection in patients with bleeding peptic ulcers than in patients with uncomplicated peptic disease. In particular, a negative interaction between *H. pylori* infection and NSAID use was postulated, indicating a lower risk of bleeding in ulcer patients taking NSAIDs^[10].

H. pylori infection can be diagnosed by invasive techniques requiring endoscopy and biopsy (histological examination, culture, and rapid urease test) and by non-invasive tests (serology, urea breath test, detection of *H. pylori* antigen in stool specimen). With the exception of the culture test, a single test has not reached acceptable accuracy for the diagnosis of *H. pylori* infection^[11]. The rapid urease test and histological examination may indicate the presence of any urease-producing or helix-shaped bac-

teria, respectively. Moreover, serological tests are markers of exposure to *H. pylori* but do not indicate whether active infection is ongoing^[11,12]. The results of the urea breath test are influenced by factors related to the patient, the bacteria, and the test itself^[13]. Rapid gastric emptying, contamination with oral commensals, achlorhydria, and gastric atrophy may cause false positive results, while false negative results can occur through suppression of urease activity if the breath test is performed too soon after antibiotic or acid suppression therapy. The detection of *H. pylori* antigen in stools has some limitations related to bowel movements: a short transit time could favor elimination of unaltered antigens, while constipation could lead to degradation of the antigens^[13]. Finally, in patients with recent upper GI bleeding the diagnosis of *H. pylori* infection can be challenging^[14,15]. In fact, the hemorrhage itself (given the pH buffering effect of blood in the GI tract), the use of proton pump inhibitors and antibiotics may influence the results of invasive and non-invasive tests for *H. pylori*^[15-17].

Our study was planned to give further information about the prevalence of *H. pylori* infection in occasional and chronic NSAID/LD ASA users admitted for peptic ulcer bleeding and submitted to very early upper endoscopy with a concomitant search for *H. pylori*.

MATERIALS AND METHODS

Ethics

The study was approved by the Institutional Review Board of the A. Cardarelli Hospital of Naples, Italy, and was conducted in compliance with the Declaration of Helsinki (1964 and following amendments), current Good Clinical Practices and the applicable European and local regulatory requirements.

Study design

This was a single-center, observational, prospective, registered study (EMOFANS Study: ACTRN12607000521426) carried out in the A. Cardarelli Hospital, a high volume hospital dedicated to emergencies. This study was planned to obtain information about the prevalence of *H. pylori* infection in patients regularly or occasionally consuming NSAIDs/LD ASA who were admitted for peptic ulcer disease complicated by hemorrhage. Taking into account our previous data, we calculated that it would be possible to recruit a total of 80 consecutive patients with the characteristics required by the protocol within a period of 12 mo. The primary objective of the study was to establish the prevalence of *H. pylori* infection in patients consecutively admitted to the emergency unit with upper GI bleeding from complicated peptic ulcer, who had been on chronic treatment or occasionally consumed NSAIDs/LD ASA. A secondary objective was to compare the efficiency of invasive (culture of biopsy specimens, *H. pylori* on tissue sections, rapid urease test) and non-invasive (IgG anti-CagA) techniques for the detection of *H. pylori* infection.

Table 1 Forrest classification

1 Actively bleeding ulcer
1a: Spurting
1b: Oozing
2 Non-actively bleeding ulcer
2a: Non-bleeding visible vessel
2b: Ulcer with surface clot
2c: Ulcer with red or dark blue spots
3 Ulcer with clean base

Inclusion and exclusion criteria

We recruited patients who fulfilled the following criteria: (1) male or female patients, of any ethnic origin, 18 years or more of age, who provided written informed consent prior to any study-related procedures and who were, in the opinion of the investigator, able to understand and to follow the protocol and likely to comply with all the requirements of the study; (2) patients with peptic ulcer disease complicated by hemorrhage (hematemesis, melena, hematochezia, or with other clinical signs of blood loss, i.e., hemodynamic instability with hypotension and tachycardia) in the 72 h before admission; (3) patients on chronic treatment with NSAIDs/LD ASA or who had received occasional treatment with NSAIDs in the 30 d before admission. Treatment with LD ASA was defined as the continuous use of up to 300 mg of aspirin per day for prophylaxis against vascular occlusive diseases^[18]; and (4) patients with an ulcer, defined as a lesion with loss of mucosal integrity and continuity of ≥ 5 mm with an apparent depth of ≥ 1 mm, as measured using gastric biopsy forceps as standard. The exclusion criteria were: (1) patients who had received treatment with antibiotics or proton pump inhibitors within the 4 wk prior to potential enrolment in order to avoid false negative *H. pylori* results; (2) a history of previous major upper GI surgery; (3) patients with upper GI neoplastic ulcer; and (4) patients already hospitalized for other reasons.

Data collection

The patients' details were collected in a database and included: (1) demographic data; (2) comorbidities according to the Charlson Comorbidity Index^[19]; (3) clinical and biochemical parameters; (4) occasional or regular use of NSAIDs/LD ASA; (5) other treatments taken; (6) endoscopy findings; (7) histology findings; (8) serological findings; and (9) microbiology results. The American Society of Anesthesiology classification of physical status^[20] was calculated for each patient at admission prior to the endoscopy. Lesions were localized and classified according to the Forrest classification (Table 1)^[21], and the Rockall risk score was also calculated after endoscopy^[22].

Helicobacter pylori detection

The study plan included very early upper endoscopy, defined as within 6 h of arrival at the hospital^[23], or as soon as possible after hemodynamic stabilization, to evaluate the source of upper GI bleeding and to take biopsies in

eligible subjects. Gastric biopsies were obtained during endoscopy after successful hemostasis if needed. Biopsy specimens were taken from the antrum and gastric body to search for *H. pylori*, according to guidelines^[24], and from all suspicious lesions. In particular, two specimens from the antrum as well as two specimens from the gastric body were used to perform the rapid urea (CLO) test (GASTREX, Warsaw, Poland) with separate kits. Moreover, two biopsy specimens from the antrum as well as two specimens each from the anterior and posterior parts of the gastric body were cultured for *H. pylori*. Finally, two biopsy specimens from the antrum and two specimens from the body were taken to detect *H. pylori* infection on tissue sections after modified Giemsa staining^[25]. At the same time a blood sample was collected and IgG antibodies against CagA protein (DIA.PRO, Diagnostic Bioprobes Srl, Milan, Italy) were analyzed by enzyme immunoassays. CagA antibody titers (> 5 U/mL) were classified as positive according to the manufacturer's instructions.

The CLO test was carried out at room temperature, with the sample examined at 24 h, and considered positive when the appropriate color change (yellow to red) occurred. With regards to culture of biopsy specimens, primary isolation was performed on commercial selective Pylori agar (BioMérieux, 43263, Marcy-L'Étoile, France). Following primary selective isolation, *H. pylori* strains were identified by usual phenotypic tests (Gram stain and by oxidase, catalase and urease tests). To overcome the instability of *H. pylori* in biopsy material during its transport from the collection site to the laboratory, which is a limiting factor for culture and susceptibility testing, the biopsy specimens for the bacterial culture were immediately placed in an appropriate transport medium (Portagerm-Pylori, BioMérieux, 42041, Marcy-L'Étoile, France). The biopsy histology was interpreted by a GI pathologist blind to the patient's information and the results of the other *H. pylori* tests.

The gold standard for identifying *H. pylori* infection was a positive culture of biopsy specimens or contemporary positivity for the CLO test and the presence of *H. pylori* on tissue sections, in accordance with current guidelines^[26].

Statistical analysis

Continuous data are expressed as means and standard deviations and compared by an independent samples *t* test. Categorical variables were analyzed by Pearson's chi-square test or Fisher's exact test. All tests of significance were two-sided. A *P*-value less than 0.05 was considered statistically significant. The PASW (Predictive Analytics Software) Statistics for Windows (Release 18.0.0-Jul 30, 2009; SPSS Inc., Chicago, Ill., United States) was used for the statistical analyses. Sensitivity, specificity, positive and negative predictive values, and false positive and false negative rates were determined using StatsDirect statistical software (release 2.7.8, March 15, 2010). The diagnostic accuracy was calculated as follow: Overall Ac-

NSAID: Nonsteroidal anti-inflammatory drug; LD ASA; Low dose aspirin. ¹According to the Charlson Comorbidity Index. Because of rounding, not all percentages total 100.

curacy = (True Positive + True Negative)/(True Positive + False Positive + False Negative + True Negative).

RESULTS

Study population

Eighty consecutive patients (61 male, 19 female; mean age 61.2 ± 15.9 years (range, 21-85)) with upper GI bleeding from complicated peptic ulcer disease and on treatment with NSAIDs/LD ASA before admission, were enrolled. All patients were admitted to the emergency unit of the A. Cardarelli Hospital of Naples between January and December 2008. The characteristics of the study population are summarized in Table 2. No patients had a history of *H. pylori* eradication. In 67 (83.8%) patients endoscopic examinations took place within 6 h of arrival at the hospital, while in the remaining subjects endoscopies were delayed because of the patients' condition and were performed within 24 h. The site of the ulcers was duodenal in 41 patients (51.3%),

gastric in 29 (36.3%), and in both segments in the remaining 10 patients (12.5%). In 14 cases (17.5%) the ulcers were classified as F1, in 23 (28.8%) as F2, and in 43 (53.8%) as F3 (Table 2). Six (7.5%) patients suffered rebleeding. None required surgery for bleeding or died during hospitalization. All patients were given proton-pump inhibitors intravenously in the emergency area and orally thereafter.

Consumption of non-steroidal antiinflammatory drugs

Most of the patients had occasionally consumed NSAIDs, particularly for a fever or moderate pain. In detail, 36 patients (45.0%) had occasionally consumed only one NSAID before their bleeding event, with one of these on concomitant chronic treatment with an antiaggregant (ticlopidine). Nine (11.3%) and two (2.5%) patients had consumed two and three NSAIDs in sequence, respectively. Thirty three patients (41.3%) were on chronic treatment with LD ASA for primary or secondary prevention of cardiovascular diseases., 18

Table 3 Patients' distribution on the basis of occasional or chronic consumption of nonsteroidal anti-inflammatory drugs

Occasional NSAID use	
One NSAID	35 (43.8)
Two NSAIDs (in sequence)	9 (11.3)
Three NSAIDs (in sequence)	2 (2.5)
NSAID + ticlopidine	1 (1.3)
Chronic NSAID use	
LD ASA alone	18 (22.5)
LD ASA + another NSAID ¹	8 (10.0)
LD ASA + two other NSAIDs (in sequence) ¹	1 (1.3)
LD ASA + ticlopidine	3 (3.8)
LD ASA + clopidogrel + NSAID ¹	1 (1.3)
LD ASA + LMWH	1 (1.3)
LD ASA + LMWH + 2 NSAIDs (in sequence) ¹	1 (1.3)

Data are expressed as number (percentage). NSAID: Non-steroidal anti-inflammatory drug; LD ASA: Low dose aspirin; LMWH: Low-molecular-weight heparin. ¹NSAIDs consumed occasionally. Because of rounding, not all percentages total 100.

Table 4 Frequency of positive diagnostic tests for *Helicobacter pylori* in culture-positive or culture-negative patients

	Culture-positive (n = 38)	Culture-negative (n = 42)
CLO test + tissue section-positive	19 (23.8)	6 (7.5)
CLO test positive	5 (6.3)	9 (11.3)
Tissue section-positive	4 (5.0)	8 (10.0)

Data are expressed as number (percentage).

(22.5%) on treatment with LD ASA alone, eight (10.0%) had occasionally consumed another NSAID, and one (1.3%) had taken two other NSAIDs in sequence. Four (5.0%) patients were on treatment with ticlopidine or clopidogrel (one of whom had occasionally consumed a NSAID), and two (2.5%) were receiving low-molecular-weight heparin (one of whom had consumed two NSAIDs in sequence) (Table 3). Thirty-nine (48.8%) patients were on treatment with other drugs considered not harmful to the intestinal mucosa. Twenty-eight out of 47 (59.6%) patients who occasionally consumed NSAIDs and 16/33 (48.5%) on chronic treatment with LD ASA were considered infected by *H. pylori*, with no statistically significant difference between the two groups ($P = 0.326$).

Diagnostic tests for *Helicobacter pylori*

Among the 80 bleeding patients, 38 (47.5%) had positive cultures of biopsy specimens, 37 (46.3%) had positive histopathological findings, 39 (48.8%) had a positive CLO test, and 36 (45.0%) were positive for IgG anti-CagA. The frequency of positive diagnostic tests for *H. pylori* in culture-positive or culture-negative patients is summarized in Table 4. Contemporaneous positivity of the CLO test and the presence of *H. pylori* on tissue sections were found in 25 (31.3%) patients. In particular, among 42 patients who had a negative culture of biopsy specimens, 6 (14.3%) had contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections. On the other hand, among 55 patients who did

not have contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections, 19 (34.5%) had a positive culture of biopsy specimens. In accordance with the pre-established gold standard, 44 (55.0%) patients were considered infected by *H. pylori*. Among 44 infected, 25 (56.8%) had contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections, and 38 (86.4%) had a positive culture of biopsy specimens. With regards to IgG anti-CagA, among the infected and non-infected patients 26 (59.1%) and 10 (27.8%), respectively, had antibody titers > 5 U/mL.

Sensitivity, specificity, positive and negative predictive values, false positive rate, false negative rate and accuracy for all techniques are shown in Table 5. Culture of biopsy specimens had a sensitivity of 86.4% and a specificity of 100%. In this analysis, the sensitivities and specificities of the remaining tests were 65.9% and 77.8%, respectively, for histological analysis; 68.2% and 75.0%, respectively, for the CLO test; 56.8% and 100%, respectively, for the combined use of histology and the CLO test; and 90.0% and 98.0%, respectively, for the anti-CagA test. The highest accuracy (92.5%) was obtained with the culture of biopsy specimens.

The 80 patients with bleeding ulcers were divided into two groups for further analysis on the basis of presence or absence of *H. pylori* infection. These two groups were identical with regards demographic, clinical and endoscopic parameters (Table 2).

DISCUSSION

The reported prevalence of *H. pylori* infection in healthy persons (without GI illness) among many studies ranges from a minimum of 11% to a maximum of 69%, with some of the variability depending on the socioeconomic status of the country of the patients investigated^[27,28]. The prevalence of *H. pylori* infection in patients with peptic ulcer disease is not well established as yet, especially because the prevalence of non-NSAID non-*H. pylori* ulcer is rising in the West, with current good evidence that 20%-40% of peptic ulcers are not associated with *H. pylori* infection or the use of NSAIDs^[29]. In one study it was found that, after excluding NSAID users, only 61% of patients with peptic ulcers had *H. pylori* infection^[30]. Data about *H. pylori* infection in patients with peptic ulcer disease complicated by hemorrhage, chronically or occasionally treated with NSAIDs/LD ASA are scarce. Such data might be difficult to collect, especially because of the choice of appropriate tests to detect *H. pylori* infection, and the timing of their performance in patients who bleed.

In our study *H. pylori* infection was found in 55% of patients with peptic ulcer disease complicated by hemorrhage after consumption of NSAIDs/LD ASA, who were not on treatment with antibiotics or proton-pump inhibitors. The Italian National Project for Gastrointestinal Bleeding (PNED) study reported a prevalence of *H. pylori* infection of 44.3% among patients who had bleeding from a non-variceal upper GI source, when the

CI: Confidence interval; NPV: Negative predictive value; PPV: Positive predictive value.

presence of the infection was determined by histological evaluation performed during the patients' stay in hospital; 36% of the patients were on treatment with NSAIDs^[31]. In our study, 46.3% of patients had positive histopathological findings, confirming the results of the PNED study^[31]. Another study performed in patients who bled from peptic ulcers (57.4% users of NSAID and/or antiplatelet drugs) found, by histological examination and the CLO test, an overall prevalence of *H. pylori* infection of 53.7%. In detail, the prevalences according to the histological examination and the CLO test were 42.3% and 44.8%, respectively^[32]. In a study by Schilling *et al* the CLO test was positive in 50% of patients, while *H. pylori* infection was detected by the ¹³C-urea breath test and histological examination (gold standard) in 62% of the cases^[33]. Our study showed positive CLO test results in 48.8% of cases.

Data about the use of culture of biopsy specimens for the detection of *H. pylori* in bleeding patients are scarce. Three studies performed between 1998 and 2000 involving a total of 314 patients showed percentages of *H. pylori*-positive patients from 24.7% to 69.1%^[34-36]. In another study involving children with upper GI bleeding, *H. pylori* infection was considered to be present when histology and/or culture were positive; unfortunately, data about the culture test alone were not presented, but *H. pylori* infection was detected in 48.8% of patients, with 29.8% of the children on treatment with NSAIDs^[37]. In our study 47.5% of patients had a positive culture of biopsy specimens.

We used a restrictive gold standard to consider a patient infected by *H. pylori*. In view of its absolute specificity, if culture alone was positive the patient was considered *H. pylori*-positive^[26]. Moreover, because a patient with at least two positive tests should be considered as *H. pylori*-positive^[26], we used as adjunctive gold standard, the contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections. In fact, the concomitant positivity of the rapid urease test and of the histological examination indicates, with the highest probability, the presence of helical urease-producing bacteria. Six patients whose cultures were negative showed contemporary positivity for the CLO test and the presence

of *H. pylori* on tissue sections. This finding demonstrates that culture tests are responsible for a number, albeit low, of false negative results. On the other hand, by using the second gold standard, only 25 (31.3%) patients would have been considered infected by *H. pylori*, even though 37 (46.3%) had positive histopathological findings and 39 (48.8%) had a positive CLO test. Moreover, among 55 patients who did not have contemporary positivity of the CLO test and the presence of *H. pylori* on tissue sections, 19 had a positive culture of biopsy specimens. These results indicate that by using the criterion of at least two positive tests to consider patients as infected by *H. pylori*, many false negative results can be expected. In our study the combined use of three invasive tests performed during a very early upper endoscopy was adequate for the diagnosis of *H. pylori* infection. With regards to the non-invasive test, 36 (45%) patients were positive for IgG anti-CagA. This test showed a low sensitivity and specificity confirming that it is a rather inaccurate diagnostic method which cannot be recommended as the first diagnostic test for *H. pylori* infection.

Patients with complicated peptic ulcer disease are candidates for testing for *H. pylori* infection. Indeed, accurate and early diagnosis of *H. pylori* infection is a critical clinical problem in these patients. The discovery of the link between the *H. pylori* bacterium and peptic ulcer is one of the greatest breakthroughs in medical history, but it is surprising that so far a large bulk of data has led to discordant results in patients with hemorrhagic complicated disease, treated or not with NSAIDs. It has been suggested that the rate of *H. pylori* infection is lower in patients with bleeding peptic ulcer than in patients with uncomplicated peptic disease, and that there is a negative interaction between *H. pylori* infection and NSAID use^[38,10]. Our study demonstrated that many patients with peptic ulcer disease complicated by hemorrhage and consuming NSAIDs/LD ASA are actually infected (55%), and that the infection may be detected with appropriate tests performed during a very early endoscopy. Culture of biopsy specimens appears to be more efficient than other techniques at detecting *H. pylori* infection (accuracy 92.5%). We believe that the discordant data in the literature are due to the different cohorts of

patients studied, the kinds of invasive/non-invasive test used, the timing at which the tests were performed, the contemporary use of proton-pump inhibitors or antibiotics, and resources available in the context in which the patient is admitted. We had two ideal conditions for eliminating some of these sources of variability: (1) the presence of a rota of gastroenterologists skilled in diagnostic and therapeutic measures available 24 h a day, 7 d a week (not as a 24-h “on call” service), and able to enroll all consecutive patients; and (2) close local collaboration between specialist gastroenterologists and microbiologists, with the possibility of methodologically sound performance of the culture tests, which is a tedious, time-consuming procedure that can be influenced by the transport conditions from the endoscopy room to the laboratory and the speed of processing, because the viability of the organism is reduced by exposure to atmospheric oxygen. Finally, we did not find a statistically significant difference in the percentage of *H. pylori* infections between patients who occasionally consumed NSAIDs and those on chronic treatment with LD ASA, indicating that chronic consumption does not modify the infection rate.

In conclusion, faced with a person with a bleeding peptic ulcer we suggest that invasive methods should be used to identify *H. pylori* infection. The accuracy of results of biopsy specimen culture in patients with peptic ulcer bleeding remains very high, and the sensitivity and specificity of this method do not seem to be affected by blood in the stomach or by the use of NSAIDs or LD ASA, when performed after a very early upper endoscopy.

ACKNOWLEDGMENTS

We acknowledge the great deal of work performed by the medical, biology, pharmacology, and nursing staff of the A. Cardarelli hospital.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) has been considered as a major cause of the development of peptic ulcer disease. Several studies have reported that the prevalence of *H. pylori* infection may be underestimated in patients with bleeding peptic ulcers. Moreover, knowledge regarding the detection of *H. pylori* infection in patients with peptic ulcer disease complicated by hemorrhage, chronically or occasionally treated with non-steroidal anti-inflammatory drugs (NSAIDs) is limited. Numerous invasive and non-invasive diagnostic methods are available for the detection of *H. pylori*. Effectiveness values of these tests may vary depending on the brand of test used, age of the population tested, treatment used and, probably, the bleeding situation.

Research frontiers

In this article, the authors assess the prevalence of *H. pylori* infection in patients with peptic ulcer disease complicated by hemorrhage after consumption of NSAIDs.

Innovations and breakthroughs

More than 50% of patients with peptic ulcer disease complicated by hemorrhage after consumption of NSAIDs are infected by *H. pylori*.

Applications

In these patients the authors recommend searching for *H. pylori* infection by using the culture of biopsy specimens after an early upper gastrointestinal tract

endoscopy.

Peer review

This is an interesting and well presented study, in which the authors using an approach that overcomes the previous conditions negatively influencing results presented in the literature, clearly showed that invasive methods should be used to identify *H. pylori* infection in a patient with a bleeding peptic ulcer.

Abstract

AIM: To evaluate the impact of liver steatosis upon response to given therapy in chronic hepatitis B (CHB) patients.

METHODS: 84 consecutive CHB patients treated with 48-wk PEGylated interferon (PEG-IFN) therapy were enrolled. Baseline characteristics and sustained viral response (SVR) to PEG-IFN therapy were evaluated.

RESULTS: Mean body mass index (BMI) was 27.36 ± 4.4 kg/m². Six (7.1%) had hypertension and three (3.5%) had diabetes mellitus. Steatosis was present in 22.6% (19/84) of liver biopsy samples. Age, BMI, and triglyceride levels of the patients with hepatic steatosis were significantly higher than those without hepatic steatosis ($P < 0.05$). SVR to PEG-IFN therapy was 21.4% (18/84). Sixteen of these 18 CHB patients with SVR (88.9%) did not have any histopathologically determined steatosis. On the other hand, only two of the 19 CHB patients with hepatic steatosis had SVR (10.5%). Although the SVR rate observed in patients without steatosis (16/65, 24.6%) was higher compared

to those with steatosis (2/19, 10.5%), the difference was not statistically significant ($P > 0.05$).

CONCLUSION: Occurrence of hepatic steatosis is significantly high in CHB patients and this association leads to a trend of decreased, but statistically insignificant, SVR rates to PEG-IFN treatment.

Ateş F, Yalnız M, Alan S. Impact of liver steatosis on response to pegylated interferon therapy in patients with chronic hepatitis B. *World J Gastroenterol* 2011; 17(40): 4517-4522 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i40/4517.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i40.4517>

INTRODUCTION

Fatty livers, defined by the accumulation of lipid droplets, mainly triglycerides, in hepatocytes, are vulnerable to factors associated with further hepatic injury by their increased sensitivity to oxidative stress and to cytokine-mediated hepatic damage. This alone may not only lead to chronic liver disease, but can also influence the progression of chronic liver diseases with different etiologies and the response to given therapy. Steatosis, together with obesity and type 2 diabetes mellitus (DM), is also a proposed risk factor for the development of hepatocellular carcinoma^[1].

Steatosis has been observed in the majority of chronic alcoholics and is also a common histopathological feature of chronic hepatitis C (CHC) infection. In patients with CHC, steatosis of the liver, accompanied by metabolic

and viral factors, increases the severity of fibrosis and unfavorably influences the response to given therapy^[2-4]. Steatosis, however, may co-exist with other chronic liver diseases, in addition to alcoholic liver diseases and hepatitis C, because of the increasing prevalence of obesity and metabolic syndrome.

The number of studies reporting co-existence of steatosis and chronic hepatitis B (CHB), a major cause of chronic liver disease worldwide, is increasing. The impact of superimposed non-alcoholic fatty liver disease in patients with CHB, however, is less clear. There are only a few studies on this topic^[5,6]. The components of metabolic syndrome [obesity, hypertension (HTA), and dyslipidemia] are associated with the presence of nonalcoholic steatohepatitis in patients with CHB, and the presence of hepatic fibrosis seems to be associated with known host and viral factors, as well as the presence of abdominal obesity^[7].

We aimed to determine the frequency and risk factors of liver steatosis in patients with CHB, and to investigate its correlation with the response to given PEGylated interferon (PEG-IFN) therapy.

MATERIALS AND METHODS

Patients

Twenty-one hepatitis B e antigen (HBeAg) (+) and 63 HBeAg (-) ($n = 84$) consecutive patients with CHB, who were diagnosed by liver biopsy, and received 48-wk PEG-IFN therapy were enrolled in the study between December 2006 and July 2009. Patients were given either PEG-IFN α -2a or 2b. Forty patients received PEG-IFN α -2a 180 μ g sc and 44 patients received Peg-IFN α -2b 1.5 μ g/kg sc once a week. Sixty of the patients were male (71.4%) and 24 were (28.6%) female, their mean age was 38.6 ± 10.9 years and their age range was 18-61 years.

Before inclusion, the patients were informed and their written consents were obtained. The study protocol was approved by the local Ethics Committee, and the study was performed in accordance with the ethical standards laid down in an appropriate version of the 1975 Declaration of Helsinki.

Inclusion criteria

In the serum samples of the patients enrolled to the study, the hepatitis B surface antigen (HBsAg) had to have been present for more than 6 mo and, within the last 6 mo, at least two different measurements must have shown an elevation of alanine aminotransferase (ALT) $> \text{ULN} \times 2$. Using polymerase chain reaction (PCR), it was found that HBV DNA levels were > 10000 copies/mL in cases with HBeAg (-) and > 100000 copies/mL in cases with HBeAg (+). The liver biopsies of all patients were consistent with the diagnosis of CHB.

Exclusion criteria

Patients who met at least one of the following were excluded from the study: patients co-infected with other viruses, such as hepatitis A, C, D, E, Cytomegalovirus, Epstein-Barr virus and HIV; patients with toxic hepatitis;

patients with another liver disease; alcohol consumers (more than 20 g per day); patients who were taking antiviral drugs or interferon before the biopsy.

Body mass index (BMI) was calculated by dividing the body weight (kg) by the square of height (m). Based on the BMI values, $< 25 \text{ kg/m}^2$ was considered as normal, $25\text{-}30 \text{ kg/m}^2$ as overweighted, and $> 30 \text{ kg/m}^2$ as obese.

Serum analyses

Fasting blood samples were obtained 1 d before the liver biopsy, and ALT, aspartate aminotransferase, γ glutamyltransferase, glucose (GLU), cholesterol, and triglyceride levels were measured.

Virological analyses

For the analyses, HbsAg, HBeAg, Anti-HBe, Anti-HBc ARCHITECT chemiluminescent microparticle immunoassay kits (Abbott Park, Wiesbaden-Delkenheim, Germany) and ARCHITECT i2000 system were used. HBV DNA levels were studied quantitatively using an HBV RG PCR Kit (sensitivity: 100 copies/mL) and Rotor-Gene 3000 (Corbett Research) device. Sustained viral response (SVR) was defined as the fall in HBV DNA to undetectable levels (< 100 copies/mL) 6 mo after (week 72) the end of 1-year PEG-IFN α therapy and disappearance of HBeAg in cases with HBeAg (+).

Histological evaluation

All percutaneous liver biopsies were performed by two experienced gastroenterologists using a 16-gauge needle. All histological analyses were performed by one experienced pathologist who was blinded to the study. Necroinflammation was determined by scoring according to Knodell's histological activity index (HAI): portal inflammation (0-4), lobular degeneration and focal necrosis (0-4), periportal \pm bridging necrosis (0-10)^[8]. The stage of fibrosis was classified from "no fibrosis" (Stage 0) to cirrhosis (Stage 4). Grading of hepatosteatosis was semi-quantitatively performed according to hepatocyte involvement: None:0, Mild: 0%-10%, Moderate:10%-30%, Marked: 30%-60%, and Severe: $> 60\%$ ^[9].

Statistical analysis

While the numerical data of the patients were presented as mean \pm SD, categorical variables were presented together with frequency and percentages. The intergroup differences of numerical variables were investigated using Student's t test, while the differences of categorical values were investigated using the χ^2 test. Variables that were found to be significant in univariate analysis ($P < 0.05$) were subjected to a multivariate logistic regression model to be investigated. All analyses were performed using a statistical software program (SPSS version 15.0).

RESULTS

Patient characteristics

Among 84 patients enrolled to the study, six (7.1%) had HTA and three (3.5%) had DM. The mean BMI value was

27.36 \pm 4.4 kg/m². When the patients were evaluated according to their BMI, 28 (33.3%) were grouped as normal (< 25 kg/m²), 34 (40.5%) as overweighted (25-30 kg/m²), and 22 (26.2%) as obese (> 30 kg/m²). The demographic, clinical, and laboratory data of the patients are presented in Tables 1 and 2.

Incidence of liver steatosis and related factors

Hepatosteatois was histologically present in 19 of 84 patients with CHB (22.6%). For patients with hepatosteatois, 36.8% (7/19) showed mild, 36.8% (7/19) moderate, 21.1% (4/19) marked, and 5.3% (1/19) severe hepatosteatois. The factors that were statistically cor-

BMI: Body mass index; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: γ glutamyl transferase; ALP: Alkaline phosphatase; HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; HAI: Histological activity index; SVR: Sustained viral response. NS: Non significant.

related with hepatosteatois were patient's age, BMI, and triglyceride (TG) levels. In the hepatosteatois group, the age (50.5 \pm 8.7 years *vs* 35.2 \pm 8.9 years, $P < 0.01$), BMI (32.9 \pm 3.1 kg/m² *vs* 25.7 \pm 3.3 kg/m², $P < 0.01$), and TG levels (188.3 \pm 52.0 mg/dL *vs* 114.2 \pm 44.2 mg/dL, $P < 0.01$) were higher compared to the group without hepatosteatois. No significant correlation was found between hepatosteatois and other parameters, such as HBeAg status, stage of fibrosis, HAI score, or HBV DNA level ($P > 0.05$). In multivariate analysis, it was found that advanced age, increased BMI, and elevated TG are independent predictors of the presence of hepatosteatois (Table 3).

Factors associated with SVR

Among 84 patients with CHB who received PEG-IFN therapy, 21.4% (18/84) showed SVR. The rate of SVR was 23.8% (5/21) in cases with HBeAg (+) and 20.6% (13/63) in cases with HBeAg (-). 88.8% (16/18) of CHB patients with SVR did not have any histopathologically determined steatosis. On the other hand, only two of the 19 CHB patients with liver steatosis - one with mild steatosis and the other one with moderate steatosis - had an SVR (10.5%). Although the SVR rate observed in patients without hepatosteatois (16/65, 24.6%) was higher compared to those with hepatosteatois (2/19, 10.5%), the difference was not statistically significant ($P > 0.05$). Using multivariate analysis, it was found that only ALT elevation was an independent predictor of SVR. No significant difference was found between SVR (+) and SVR (-) groups in terms of other parameters (Table 4). There

was no difference in patients with or without steatosis regarding treatment response between the types of PEG-interferon (data not shown).

Subgroup analysis according to the HBeAg status

In HBeAg (-) patients, SVR was seen 7.7% (1/13) patients with hepatosteatois, while it was 92.3% (12/13) without hepatosteatois. Although the SVR rate was higher in the patients without hepatosteatois, the difference was not statistically significant (Table 5).

In HBeAg (+) patients, SVR was seen in 20% (1/5) patients with hepatosteatois while it was 80% (4/5) patients without hepatosteatois. This difference was also not statistically significant (Table 6).

HBeAg seroconversion was seen in only four (19%) patients; all four patients had undetectable HBV DNA levels. None of our patients had HBsAg seroconversion.

DISCUSSION

This study investigated the incidence and clinical importance of liver steatosis in patients with CHB. The factors associated with liver steatosis were determined. In patients who were given 48 wk PEG-IFN α therapy, the effects of liver steatosis and other factors upon persistent viral response were also investigated. In previous studies, the incidence of hepatosteatois in patients with CHB was reported to range between 4.5% and 76%^[9-14]. Especially in the studies where the alcohol consumers are not excluded, patients with CHB showed higher rates of hepatosteatois^[15,16]. In the present study, hepatosteatois was histopathologically determined in 22.6% of CHB patients, and this prevalence is similar to that of the general population. Cases with other accompanying liver diseases, such as hepatitis C or alcohol consumers, were excluded and, thereby, misleading results were avoided.

In the development of non-alcoholic hepatosteatois, insulin resistance constitutes the main mechanism^[17]. Insulin resistance leads to hyperinsulinemia and an increase in free fatty acid concentrations, resulting with TG accumulation in hepatocytes^[18]. Insulin might also play an important role in the development of fibrosis accompanied by hepatosteatois by activating the profibrogenic pathways^[19]. The cause and clinical importance of hepatosteatois accompanying CHB are not well defined. In previous studies, non-alcoholic hepatosteatois seen in patients with CHB was related to advanced age, large waist circumference, high fasting GLU and C-peptide levels, HTA, or dyslipidemia^[10,20]. In the present study, we found that advanced age, higher BMI, and elevated TG levels were independent risk factors of hepatosteatois in patients with CHB. Hepatosteatois and fibrosis scores, however, were not correlated.

The virus by itself might be the cause of the hepatosteatois as seen in some CHC patients with hepatic steatosis^[21]. However, we did not find any correlation between hepatosteatois and viral factors, such as HBeAg status, HBV DNA level, and HAI. Taken together, the presence of steatosis correlates with some host factors (advanced age, high BMI, and TG levels), but not with viral genotype or viral load. Accordingly, the results of the present study support the finding that metabolic factors, rather than viral factors, are more determinant for hepatosteatois encountered in cases with CHB^[22] and that, whereas the association between steatosis and HCV is specific, this not the case in HBV-infected patients.

Hepatosteatois is related to metabolic factors, and hepatitis C virus infection *per se* leads to hepatosteatois

directly in different genotypes (in genotype 2 and 3)^[21]. The presence of liver steatosis in chronic viral hepatitis B might vary according to different genotypes, as reported in CHC^[3,4,20]. In the present study, HBV genotyping could not be performed due to lack of laboratory resources. Nevertheless, hepatitis B infection in Turkey is accepted to be virtually all genotype D (almost 100%); hence, a genotype effect is not expected, and analyzing the genotype is not recommended as cost-effective in such studies.

Treatment of CHB is a big challenge. The response rates are still low despite novel therapy strategies. Besides the viral factors, other accompanying conditions might hamper the success of a therapy. Hepatosteatois encountered in other chronic liver diseases not only has the potential to influence the progression of diseases, but is also suggested to diminish the response to the given therapy^[23]. In the literature, there is only one study that retrospectively investigated the effect of co-existent steatosis upon the response to treatment in CHB patients^[24]. That study reported that the presence of steatosis does not have any effect on the outcome of the treatment. In the present study, persistent viral response to 48 wk of PEG-IFN was 21.4%, which was consistent with previous studies^[25,26]. As a support for the study of Moucari *et al.*^[25], only ALT elevation was an independent predictor of SVR. Strikingly, 88.9% (16/18) of CHB patients with SVR did not have any histopathologically determined steatosis. On the other hand, only two of the 19 (10.5%) CHB patients with liver steatosis had SVR. The high SVR rates obtained in patients without hepatosteatois compared to those with hepatosteatois, however, were not significant statistically. The fact that hepatosteatois has no statistically significant effect on SVR may be due to our small number of patients.

It would be better if the homeostasis model assessment (HOMA) could also be determined. However, HOMA was designed to determine the relationship between chronic viral hepatitis and the presence of steatosis with respect to the effect upon treatment of viral hepatitis. The role of risk factors of steatosis, including the GLU HOMA index upon the course of chronic viral hepatitis B patients with steatosis, was beyond the scope of this study. This will be the subject of future studies.

In conclusion, hepatosteatois is encountered frequently in patients with CHB. This association leads to a trend of decreased, but statistically insignificant, SVR rate to PEG-IFN treatment, both in HBeAg (+) and HBeAg (-) patients. Hepatic steatosis, a risk-free, benign condition in healthy subjects, might become a dangerous co-factor of disease progression when it is present in patients affected by another liver disease. It might affect the response to antiviral treatment and the significant negative effect of hepatosteatois on response to therapy in CHB patients should be demonstrated using larger prospective studies. Advanced age, BMI, and high levels of TG are independent risk factors of hepatic steatosis development. Treatment strategies against obesity and TG elevations would have positive effects on CHB progression and the response to the given therapy. Hence,

combating steatosis and its associated factors might aid in increasing the response to therapy in CHB patients.

COMMENTS

Background

Fatty livers encountered frequently in clinical practice may co-exist with other chronic liver diseases, and can influence the progression of the chronic liver diseases with different etiologies. The number of studies reporting co-existence of steatosis and chronic hepatitis B (CHB) is increasing. The impact of superimposed non-alcoholic fatty liver disease in patients with CHB, however, is less clear.

Research frontiers

Fatty livers are more vulnerable to factors associated with further hepatic injury because of their increased sensitivity to oxidative stress and cytokine-mediated hepatic damage, which may lead to chronic liver disease. The presence of a fatty liver can influence the progression of the chronic liver diseases with different etiologies and the response to given therapy. Steatosis of the liver in patients with chronic hepatitis C increases the severity of fibrosis and unfavorably influences the response given to therapy. Nevertheless, the association of liver steatosis and CHB, a major cause of chronic liver disease worldwide, is less clear.

Innovations and breakthroughs

Hepatosteatois is not infrequent in patients with CHB. Advanced age, body mass index (BMI), and high levels of triglyceride (TG) are independent risk factors for the development of hepatic steatosis in patients with chronic viral hepatitis B. This coexistence leads to a trend of decreased, but statistically insignificant, sustained viral response rate to PEGylated interferon treatment both in hepatitis B e antigen (HBeAg) (+) and HBeAg (-) patients.

Applications

Hepatic steatosis, a risk-free, benign condition in healthy subjects, might become a dangerous co-factor of disease progression when it is present in patients affected by another liver disease. It might affect the response to antiviral treatment and the significant negative effect of hepatosteatois upon response to therapy in CHB patients should be demonstrated using larger prospective studies. Given the importance of advanced age, BMI, and high levels of TG as being independent risk factors for development of hepatic steatosis, treatment strategies against obesity and TG elevations would have positive effects on CHB progression and the response to given the therapy. Hence, combating steatosis and its associated factors might aid in increasing the response to therapy in CHB patients.

Peer review

This study, even is observational, is fairly interesting.

Abstract

AIM: To study the pharmacological profile and inhibition of smooth muscle contraction by YFa and its analogs in conjunction with their receptor selectivity.

METHODS: The effects of YFa and its analogs (D-Ala₂) YFa, Y (D-Ala₂) GFMKKKFMRF amide and Des-Phe-YGGFMKKKFMRF amide in guinea pig ileum (GPI) and mouse vas deferens (MVD) motility were studied using an isolated tissue organ bath system, and morphine and DynA (1-13) served as controls. Acetylcholine was used for muscle stimulation. The observations were validated by specific antagonist pretreatment experiments using naloxonazine, naltrindole and norbinalorphimine norBNI.

RESULTS: YFa did not demonstrate significant inhibi-

tion of GPI muscle contraction as compared with morphine (15% vs 62%, $P = 0.0002$), but moderate inhibition of MVD muscle contraction, indicating the role of κ opioid receptors in the contraction. A moderate inhibition of GPI muscles by (Des-Phe) YFa revealed the role of anti-opiate receptors in the smooth muscle contraction. (D-Ala-2) YFa showed significant inhibition of smooth muscle contraction, indicating the involvement of mainly δ receptors in MVD contraction. These results were supported by specific antagonist pretreatment assays.

CONCLUSION: YFa revealed its side-effect-free analgesic properties with regard to arrest of gastrointestinal transit. The study provides evidences for the involvement of κ and anti-opioid receptors in smooth muscle contraction.

INTRODUCTION

Centrally acting μ -opioid agonists are still the most widely used analgesics for the relief of severe pain, but their

utility is limited by a number of well-known side effects, including tolerance, physical dependence, respiratory depression, and adverse gastrointestinal effects. To rectify these complications, the effects of opioid drugs on gastrointestinal transit have been extensively studied using rat models. Transit arrest is a common effect of opioids in mammals but the underlying secretomotor changes appear to vary between species^[1]. Studies on gut muscle contractility have demonstrated that the circular muscle contractility plays a dominant role in segmentation and peristaltic propulsion of the gut^[2]. Also, the drug sensitivity of circular muscle contraction differs from that of longitudinal muscle contraction^[3,4].

The efforts to study opioids and opioid-receptor pharmacology have largely relied upon the availability of highly subtype-selective agonists and antagonists. Although immunohistochemical studies have revealed that the opioid receptor subtypes, μ , δ and κ , are present in the neural tissue of the rat enteric nervous system (ENS), but not in smooth muscle cells^[5,6], various other studies have indicated their involvement in intestinal smooth muscle movement. *In vivo* studies using the charcoal meal method have indicated that μ and δ receptor activation causes slow transit in rats, but κ receptor activation has negligible effect^[7-9]. On the contrary, Mitolo-Chieppa *et al.*^[10] have reported the involvement of κ -opioid receptors in inhibiting gut motility. An *in vitro* study has indicated that activation of both μ and δ receptors has an inhibitory influence on the peristaltic reflex of the rat ileum^[11]. Similarly, *in vitro* studies using electrical stimulation have indicated an inhibitory influence of δ receptors (but not of μ receptors) on longitudinal muscle contractions in the rat jejunum^[12,13]. Thus, the ambiguity regarding the role of κ -opioid receptors in gastrointestinal and vas deferens motility still persists. Keeping in mind these findings and current efforts to develop peripherally acting opioid analgesics directed towards different opioid receptor profiles (e.g., δ agonists or mixed μ agonist/ δ antagonists)^[14,15], we designed the methionine-enkephalin-Arg6-Phe7 (MERF)-based chimeric opioid peptide analogs, which have an affinity for multiple opioid receptors, to study tolerance behavior and other side effects of opioids.

MERF peptide has overlapping sequences of Met-enkephalin and FMRF amide, belongs to the opioid family^[16], and is comprehensively distributed in the central nervous system of different mammals^[17]. Conversely, peptides of the NPPF [Neuropeptide FF (FLFQQR-Fa)/FMRFa family antagonize morphine-induced supraspinal analgesia^[18] and may function as endogenous anti-opioid agents^[19]. NPPF has also been perceived to exhibit opioid effects along with a role in tolerance. The intriguing relationship between opioid and anti-opioid activity of the peptide can be attributed to the FMRF amino acid sequence at the C terminus of MERF. Along these lines, a chimeric peptide YFa (YGGFMKKKFMRF

amide) of met-enkephalin and FMRFa was designed to determine the role of endogenous amphipathic sequences like MERF in analgesia, and its modulation^[20]. YFa administered intraperitoneally induces naloxone-reversible antinociception, suggesting the involvement of opioid receptors in mediation of its antinociceptive effects. Moreover, YFa-potentiated morphine induced antinociception and attenuated the development of tolerance to morphine analgesia, suggesting its possible role in pain modulation^[21]. mRNA expression studies have revealed that YFa produces κ receptor specific antinociception without any tolerance^[22], and it further induced cross tolerance to 20 mg/kg morphine analgesia after 4 d pretreatment with 80 mg/kg YFa^[23]. The results of these studies have been substantiated by forskolin-stimulated cAMP inhibition and Eu-GTP- γ S binding studies^[24].

In addition to YFa, its analogs (D-Ala2) YFa, Y (D-Ala2) GFMKKKFMRF amide, and Des-Phe (YGGFMKKKFMRF amide) have also been studied. (D-Ala2) YFa (1 mg/mouse) administered intracerebroventricularly (icv) with 5.86 nmol/L morphine (2 mg/mouse, icv) produced an additive antinociceptive effect, suggesting its modulatory role in opioid (morphine) analgesia^[21]. Furthermore, mRNA studies have indicated that (D-Ala2) YFa acts mainly through δ receptors and partially through κ and μ opioid receptors^[25], suggesting that D-Ala2 substitution in YFa leads to changes in its receptor selectivity from κ to δ subtype. Des-Phe (YGGFMKKKFMRF amide) demonstrates the loss of mRNA expression of μ opioid receptor and shows κ opioid receptor agonist activity at a higher concentration (unpublished observations). Thus, the observed tolerance-free antinociception of YFa and its analogs prompted us to examine their other pharmacological properties so as to understand the role of opioid receptors in inhibition of gut motility and vas deferens contraction.

In our previous study, we observed early onset of antinociceptive effect (5 min) by chimeric peptide, YFa, which could be a result of direct opioid receptor stimulation and/or due to release of endogenous opioid peptides. In the present study, *in vitro* guinea pig ileum (GPI) and mouse vas deferens (MVD) assays were performed. These assays provided a more physiologically favorable environment for the ligand-receptor interaction to understand the peripheral action of the peptides, because these peripheral opioid responses are important for some of their therapeutic properties such as analgesia and side effects like constipation. The effect of opioid receptor activation in these isolated organ preparations is to reduce smooth muscle contraction *via* inhibition of excitatory neurotransmitter release, which is revealed by measuring the inhibitory action on electrically stimulated contraction of the ileal and vas deferens muscles.

MATERIALS AND METHODS

Peptide synthesis

Peptides YFa, (D-Ala2) YFa, (Des-Phe) YFa and Dynor-

phin A (Tyr1-Gly2-Gly3-Phe4-Leu5-Arg6-Arg7-Ile8-Arg9-Pro10-Lys11-Leu12-Lys13) [DynA(1–13)], were synthesized by the solid-phase method on an ACT-90 peptide synthesizer (Advanced ChemTech, Louisville, KY, United States) using the standard chemistry of 9-flourenylmethoxycarbonyl amino acids (Novabiochem, Laufelfigen, Switzerland) and 1-hydroxybenzotriazole/diisopropylcarbodiimide activation method on Rink amide-MBHA and Wang resin. The peptides were purified by RP-C18 column (mBondapak 10 mm, 7.8 mm × 300 mm; Waters, Milford, MA, United States) on semi-preparative reverse-phase HPLC (Waters 600) with a 40-min linear gradient from 10% to 90% acetonitrile (containing 0.05% trifluoroacetic acid) in water. The mass analysis of the peptides was done in linear positive ion mode by MALDI-TOF/TOF (Bruker Daltonics Flex Analysis, Germany) with 2, 5-dihydroxybenzoic acid as the matrix. The peptide sequence was confirmed by automated peptide sequencing (Procise 491; Applied Biosystems, Carlsbad, CA, United States).

Chemicals

All the chemicals including naloxonazine, naltrindole, norBNI and acetylcholine were purchased from Sigma (St. Louis, MO, United States). Morphine was obtained from AIIMS (New Delhi, India). All the peptides were dissolved in Mili-Q water.

Animals

Male guinea pigs, 300-400 g (AIIMS), were housed, two per cage, kept on a 12-h light/dark cycle, and fed standard rat chow and water *ad libitum*. Male albino mice were obtained from Maulana Azad Medical College (Delhi, India). Animals were housed in temperature-controlled room (25 °C ± 1 °C) and exposed to a 12-h light/dark cycle. The animals were handled according to the guidelines of The Committee for the Purpose of Control and Supervision of Experiments on Animals, India, and the Animal Ethical Committee of the Institute of Genomics and Integrative Biology (Delhi, India).

Bioassay

The experimental procedures were essentially those used previously^[26-28]. For GPI and MVD bioassay, tissue strips were obtained from adult male guinea pigs weighing 300-400 g and male Swiss albino mice weighing 25-30 g. All the animals were sacrificed by intraperitoneal administration of overdose thiopentone (200 mg/kg). Tissues were suspended under 1 g tension in a 10-mL organ bath chamber containing Tyrode solution at 37 °C and bubbled with 95% O₂ and 5% CO₂. The tissues were connected to an isotonic force transducer connected to eight channel organ baths (AD Instruments, Sydney, NSW, Australia) and allowed to equilibrate for 30-45 min. All the tissues were stimulated by chemical method using acetylcholine^[29,30]. Only the tissue preparations that responded to 2 × 10⁻⁴ mol/L acetylcholine by producing contractions of more than 1.5 g tension, were used. Preparations were

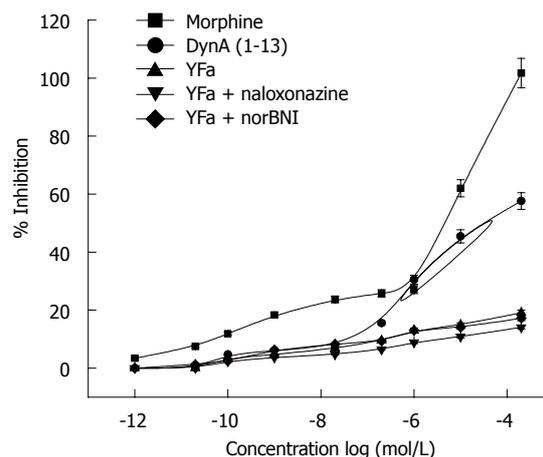

Figure 1 Guinea pig ileum assay of YFa. Morphine and DynA (1-13) were used as controls. Values represent mean ± SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.0002$.

equilibrated for at least 1 h with washes every 10 min before exposure to drugs. At the start of each experiment, a maximum response to acetylcholine (10⁻⁶ mol/L) was obtained in each tissue to check its suitability and the responses to opioid antagonists were expressed as percentages of the maximum acetylcholine. Each experiment was repeated with at least four separate tissue preparations obtained from different animals. Naloxonazine and naltrindole, specific antagonists of μ and δ opioid receptors, were used as negative controls.

Data analysis

GPI and MVD muscle contraction was measured as tension in grams. The inhibition percentage was calculated by taking acetylcholine contraction as 100% in all the tissues. All the assays were performed in triplicate and data were analyzed by Student's *t* test and one-way ANOVA in ORIGIN version 7.1. The data of each ligand were compared with morphine and DynA(1-13) separately, and $P < 0.05$ was considered statistically significant.

RESULTS

Effect of YFa on guinea pig ileum muscle contraction

In THE GPI assay (Figure 1), YFa demonstrated negligible inhibition of ileal muscle contraction, even at the highest concentration. Morphine, which interacts through μ opioid receptors, exhibited a highly significant inhibition rate of 62% ($P = 0.001$) at 10⁻⁵ mol/L and 101% at 2 × 10⁻⁴ mol/L. However, DynA (1-13), a known κ receptor agonist, showed a moderate inhibition of 57% ($P = 0.004$) at the highest dose of 2 × 10⁻⁴ mol/L.

Effect of YFa on mouse vas deferens muscle contraction

In MVD preparations (Figure 2), YFa exhibited a moderate inhibition of 24% ($P = 0.001$) at 2 × 10⁻⁷ mol/L and 45% at 10⁻⁵ mol/L. The maximum inhibitory response rate was 68% ($P = 0.001$), which was significantly lower

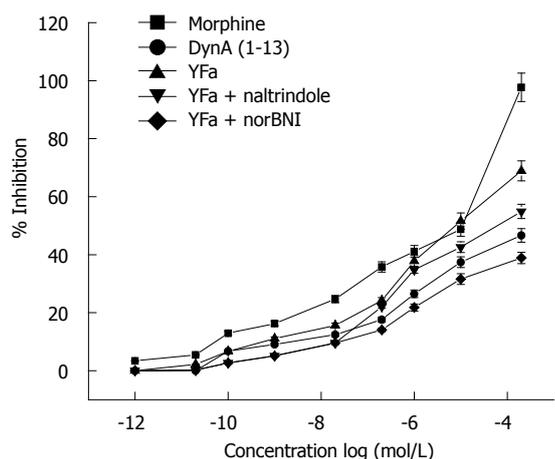

Figure 2 Mouse vas deferens assay of YFa. Morphine and DynA (1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.001$.

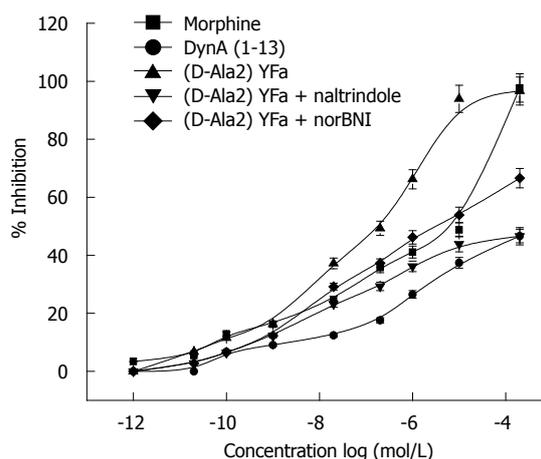

Figure 4 Mouse vas deferens assay of (D-Ala2) YFa. Morphine and DynA (1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.0006$.

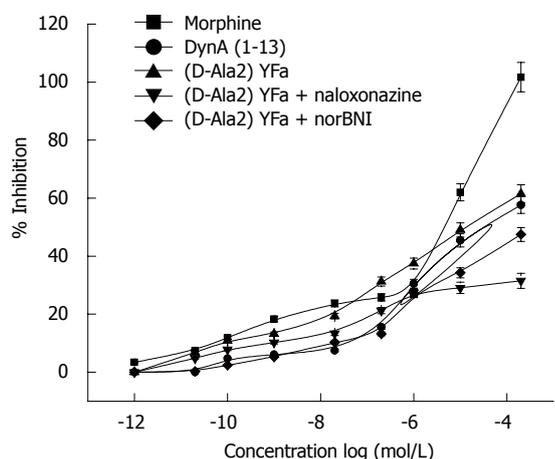

Figure 3 Guinea pig ileum assay of (D-Ala2) YFa. Morphine and DynA (1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.0002$.

than that of morphine (101%) but higher than DynA (1-13) (47%, $P = 0.004$). IC_{50} of YFa (7.10 $\mu\text{mol/L}$, $P = 0.001$) was nearly half that of morphine (13.41 $\mu\text{mol/L}$, $P = 0.001$), (Table 1). Vas deferens preparations pretreated with κ receptor specific antagonist norBNI showed a 44% reversibility of inhibitory activity, whereas, with naltrindole, the δ receptor specific antagonist, the activity was declined by only 20%.

Effect of (D-Ala2) YFa on guinea pig ileum muscle contraction

In contrast to YFa, (D-Ala2) YFa treatment resulted in moderate inhibition of GPI muscle contraction (Figure 3). It showed escalating behavior in inhibition from a value of 31.27% ($P = 0.0006$) at 2×10^{-7} mol/L to 61.51% at 2×10^{-4} mol/L. The IC_{50} of (D-Ala2) YFa was 12 $\mu\text{mol/L}$ ($P = 0.001$) (Table 1) compared with that of morphine (4.44 $\mu\text{mol/L}$, $P = 0.001$) (Table 1), which again indicat-

ed a moderate interaction with GPI muscle. Antagonist pretreatment of ileal tissue with naloxonazine exhibited a 50% decline in inhibition of muscle contraction, whereas only a 20% reversibility was observed with pretreatment with norBNI.

Effect of (D-Ala2) YFa on mouse vas deferens muscle contraction

(D-Ala2) YFa demonstrated a considerable inhibition of MVD muscle contraction (Figure 4), which increased progressively from 11.49% ($P = 0.0006$) at 10^{-10} mol/L to 37.22% at 2×10^{-8} mol/L ($P = 0.0006$). The maximum inhibitory response of 96% ($P = 0.0006$) at 2×10^{-4} mol/L was comparable to that of morphine (97%, $P = 0.0006$), but significantly higher than that of DynA (1-13) (46%). D-(Ala2) YFa showed an IC_{50} of 0.20 $\mu\text{mol/L}$ ($P = 0.0006$) (Table 1), demonstrating the selective interaction of the peptide with δ opioid receptors, which are substantially present in MVD muscles.

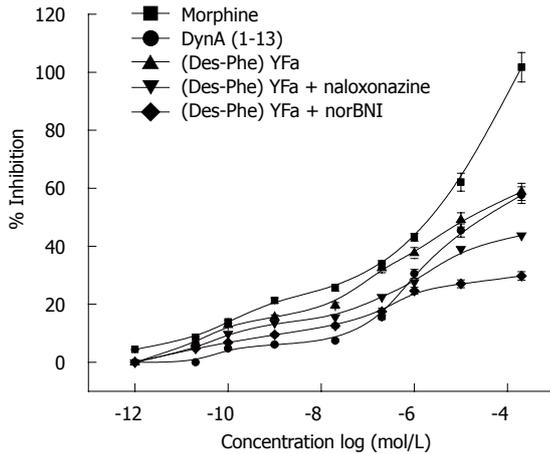

Figure 5 Guinea pig ileum assay of (Des-Phe) YFa. Morphine and DynA (1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.0002$.

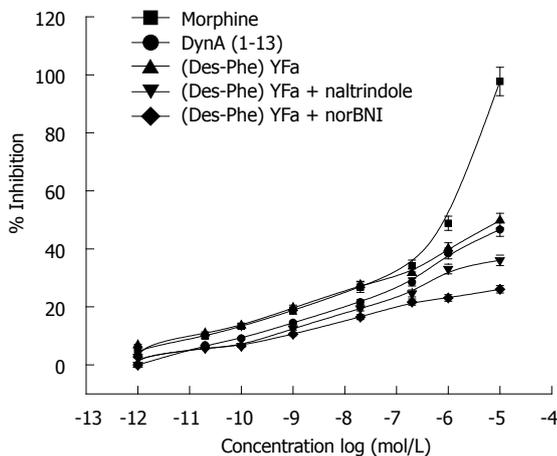

Figure 6 Mouse vas deferens assay of (Des-Phe) YFa. Morphine and DynA(1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.001$.

Pretreatment with naltrindole or norBNI resulted in a 52% ($P = 0.0006$) and 30% ($P = 0.0006$) reversibility of inhibition of MVD muscle contraction. DynA (1-13) also showed a weak inhibition of MVD contraction with a non-significant IC_{50} value.

Effect of (Des-Phe) YFa on guinea pig ileum muscle contraction

Moderately significant inhibition was observed with (Des-Phe) YFa treatment comparable to that of DynA(1-13) (Figure 5). The inhibitory response was stronger than that of YFa but weaker than that of morphine. A two-fold increase in inhibition from 15.54% ($P = 0.0002$) to 32.49% ($P = 0.0002$) was noted as concentration increased from 10^{-9} mol/L to 2×10^{-7} mol/L with IC_{50} at 14.9 μ mol/L ($P = 0.0002$) (Table 1). The specific-antagonist-pretreated GPI preparations demonstrated that the reversibility in inhibitory activity of (Des-Phe) YFa was higher with nor-

BNI (50%, $P = 0.0002$) than with naloxonazine (26%, $P = 0.0002$).

Effect of (Des-Phe) YFa on mouse vas deferens muscle contraction

(Des-Phe) YFa treatment resulted in a weak inhibition of MVD muscle contraction (Figure 6). The inhibitory response was comparable to that of dynorphin with a maximum response of 49.78% ($P = 0.001$) at 2×10^{-4} mol/L. Pretreatment with norBNI resulted in a 48% ($P = 0.001$) reversibility of inhibitory activity, while naltrindole pretreatment led to a 28% reversibility ($P = 0.001$).

Effect of MERF-COOH on guinea pig ileum muscle contraction

MERF-COOH, an endogenous opioid receptor agonist, has been reported to bind to all three subtypes of opioid receptors. GPI assay (Figure 7) showed a dose-dependent response that was comparable to that of morphine at all concentrations. Analogous to morphine and MERF-COOH, exhibited a steady rise in inhibition at a dose of 10^{-5} mol/L (58.57%, $P = 0.005$ and 62.10%, $P = 0.001$, respectively), and further demonstrated a sudden (almost twofold) elevation in inhibition profile by 95.27% ($P = 0.005$) at the highest dose. The IC_{50} value (3.71 μ mol/L, $P = 0.005$) (Table 1) was comparable to that of morphine (4.40 μ mol/L, $P = 0.001$). Moreover, a similar reversibility (50%) in inhibition profile was noted in the GPI preparations pretreated with norBNI and naloxonazine.

Effect of MERF-COOH on mouse vas deferens muscle contraction

In the MVD assay (Figure 8), MERF-COOH demonstrated a significant inhibition of MVD muscle contraction. At 10^{-6} mol/L concentration, it exhibited a comparable inhibition profile to morphine, whereas at higher concentrations, the trend varied. MERF-COOH exhibited an IC_{50} value of 5.51 μ mol/L ($P = 0.001$), which was less than half that of morphine (13.41 μ mol/L, $P = 0.001$) (Table 1). Moreover, the peptide showed a 72.57% ($P = 0.001$) inhibition at the highest dose. The δ - and κ -specific antagonist pretreatment of MVD preparations exhibited a similar degree of reversibility (35%) of inhibitory activity with naltrindole and norBNI, respectively.

Effect of MERF-NH₂ on guinea pig ileum and mouse vas deferens smooth muscle contraction

Contrary to MERF-COOH, MERF-NH₂ treatment resulted in a weak inhibition of GPI (41%, $P = 0.001$) and MVD (31%, $P = 0.0005$) muscle contraction at the highest concentration of 10^{-4} mol/L (Figures 9 and 10). The specific-antagonist-pretreated preparations of GPI (naloxonazine and norBNI) and MVD (naltrindole and norBNI) did not show any significant reversibility in inhibition profile.

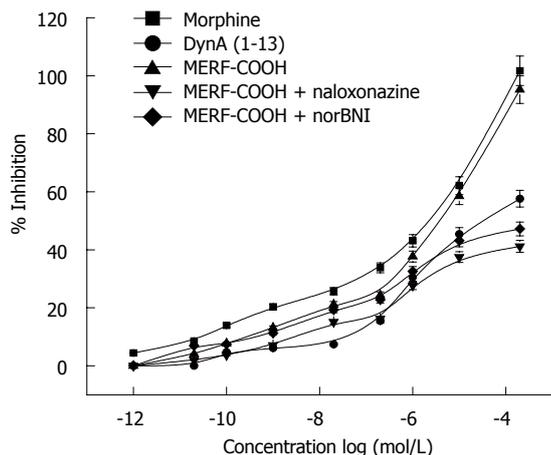

Figure 7 Guinea pig ileum assay of methionine-enkephalin-Arg6-Phe7-COOH. Morphine and DynA (1-13) were used as controls. Values represent mean \pm SE for three experiments performed in triplicate. Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.005$. MERF: Methionine-enkephalin-Arg6-Phe7.

Data were analyzed by one-way ANOVA using ORIGIN 7.1 and $P = 0.0005$. MERF: Methionine-enkephalin-Arg6-Phe7.

DISCUSSION

This study examines the effects of YFa and its analogs on GPI and MVD motility, in conjunction with their receptor selectivity. It is well documented that μ opioid receptors are primarily responsible for constipation, along with inhibition of nitric oxide generation^[31]. In the gastrointestinal tract, activation of μ opioid receptors results in the inhibition of gut motility that leads to constipation, whereas similar receptors in the central nervous system mediate the analgesic actions of opioids^[32]. The μ -receptor-selective drug, morphine, significantly restricted the smooth muscle contractions in lower intestine, indicating the presence of μ opioid receptors in the ileal muscle. Therefore, by inhibiting gastric flow and reducing propulsive peristalsis of the intestine, morphine decreases the rate of intestinal transit. Reduction in gut

secretion and increase in intestinal fluid absorption further contribute to the constipating effect^[33].

In 1993, Smith and Leslie^[34] reported the δ subtype of opioid receptors as the major form in MVD, with a smaller number of μ receptors. Alternatively, in 1999, Pound^[35] reported that morphine induced significant inhibition of MVD muscle contraction, which indicated the presence of separate μ opioid receptors. Furthermore, functional interactions between μ and δ opioid receptors, for several biochemical and pharmacological responses have also been reported by various groups^[36-39]. These functional interactions of μ receptors could be rationalized on the basis of their indirect activation by δ receptors^[40]. Collectively, these findings reveal that δ opioid receptors are prominent in MVD and there exists some cooperation between μ and δ opioid receptors that supports the hypothesis of synergistic interactions

between these two receptors.

Although the presence of μ receptors in the gut and MVD is well supported in the literature, the role of κ receptors is still ambiguous. Here, we used YFa and its analogs as probes to unravel these hidden aspects. Our previous studies on YFa have revealed its κ -receptor-selective nature. However, at higher concentrations, it also interacts with μ receptors^[22-24]. In the present study, YFa showed a negligible inhibition of GPI contraction. This could be due to non-availability of κ opioid receptors or to the counteracting effect of the anti-opioid side (FMRF-amide) of the peptide, through its interaction with the anti-opiate receptors, by increasing sensitivity to cholinergic stimulation upon acetylcholine release^[41-43].

To investigate further the reason behind these observations, an analog of YFa, (Des-Phe) YFa, was designed and studied. Upon modification, (Des-Phe) YFa retained its κ -receptor-selective antinociceptive nature but removal of Phe from the C terminus resulted in loss of RF-amide interaction with anti-opiate receptor, hence nullifying the counteractive effect of anti-opiate moiety (RFa) in YFa. (Des-Phe) YFa exhibited a significant inhibition of GPI muscle contractions, comparable to those of dynorphin. In comparison with YFa, a threefold increase in inhibition was observed as a result of the modification. Therefore, the counteractive effect of the anti-opioid side of YFa could be the reason for the non-significant inhibitory effect of YFa. This observation emphasizes the existence of κ -receptor-mediated contractions, in addition to the known μ receptor involvement in GPI muscle contractions^[10,44-47]. Reversibility of contraction by pretreatment with κ -receptor-specific antagonist nor-BNI confirmed the κ -receptor-mediated interaction in GPI.

To substantiate the role of the anti-opiate moiety in the effect of YFa, analogs of MERF were studied. As mentioned earlier, MERF is a well-documented peptide belonging to the opioid family. Here, we studied the inhibitory profiles of two slight modifications of this peptide, MERF-COOH and MERF-NH₂, the latter of which has a C-terminal RFamide residue that interacts with the anti-opiate receptors. As expected, in the GPI assay, MERF-COOH led to a 100% inhibition and MERF-NH₂ treatment resulted in a negligible response. This complete reversal in properties confirms the role of counteractive effects of anti-opioid moieties in antinociception.

In the MVD assay, YFa demonstrated moderately significant inhibition of vas deferens contractions, in a dose-dependent fashion. This observation firmly suggests the involvement of the κ receptors in the observed effect, which corroborates the earlier reports suggesting the involvement of κ receptors in MVD muscle contraction^[10,44,48]. Moreover, the maximum inhibitory response was found to be stronger than that of dynorphin (κ -receptor-specific agonist), suggesting the involvement of other receptors also, which may be due to the saturation of κ opioid receptors. The role of κ receptors was substantiated by antagonist pretreatment studies

that showed a higher reversibility of contraction by κ -receptor than δ -receptor antagonist. The role of anti-opiate receptor is still not evident in MVD, therefore, that possibility was not considered in this case.

Recently, we have reported that (D-Ala2) YFa mediates its action primarily through δ opioid receptors and partially through μ and κ opioid receptors^[25]. In the present study, (D-Ala2) YFa demonstrated a moderate inhibition of GPI muscle contraction, comparable to that of dynorphin, suggesting the involvement of μ and κ receptors in the observed effect. Specific antagonist pretreatment studies have emphasized the role of μ receptors and naloxonazine (μ -receptor antagonist) pretreatment resulted in a 50% reversibility in inhibition. The IC₅₀ value of (D-Ala2) YFa of 12 μ m, which was much lower than that of DynA (1-13) (33.8 μ m), substantiated the role of μ receptors in (D-Ala2) YFa-mediated GPI contraction.

Furthermore, in the MVD assay, (D-Ala2) YFa demonstrated a significantly greater inhibition than that of morphine at all concentrations up to 10⁻⁵ mol/L. As expected, this suggests the involvement of δ and μ receptors in MVD muscle contraction. Pretreatment with naltrindole resulted in an almost 50% reduction in inhibition that suggested the involvement of δ receptors, which was further demonstrated by the IC₅₀ value of (D-Ala2) YFa of 0.2 μ mol/L ($P = 0.01$). However, significant inhibition of MVD muscle contraction by morphine (μ -receptor specific) and (D-Ala2) YFa (δ -receptor specific) further signifies that some cooperation may exist between μ and δ receptors in vas deferens preparations^[40], or the δ receptors may regulate μ -receptor function *via* heterodimerization^[49]. Further studies on heterodimerization of opioid receptors (μ , δ and κ) are required to elucidate their synergistic behavior and are currently in progress in our laboratory.

In conclusion, YFa and its analogs can be viewed as promising candidates to understand the role of opioid receptors in gastrointestinal transit and MVD motility. Although the precise mechanism by which anti-opiate receptors normalize the effects mediated by opioid receptors in GPI and MVD contraction is currently not clear, we provide convincing evidences that anti-opioid receptors are involved in the phenomenon. We also confirmed the presence of κ receptors in GPI and MVD muscles. Furthermore, the present findings provide a systematic approach to advance the researches on opioids due to the similar nature of opioid receptors in GPI and human intestines.

COMMENTS

Background

To date, centrally acting μ -receptor-specific agonists are the most widely used analgesics but their relieving effect is accompanied by a number of side effects including tolerance and adverse gastrointestinal effects.

Research frontiers

Opioids mediate their effects through various receptors (μ , κ and δ) present in the central nervous system, but the presence of similar receptors in the en-

teric nervous system leads to disturbances in gastrointestinal transit. Previous studies have reported the presence of μ and δ receptors in the gut and vas deferens, whereas the role of κ receptors is still ambiguous. In this study, the authors demonstrated the role of κ receptors and anti-opioid receptors using methionine-enkephalin-Arg6-Phe7 (MERF) peptide analogs.

Innovations and breakthroughs

The study reported YFa, an analgesic peptide molecule, free of gastrointestinal inhibition effect.

Applications

By understanding the roles of various opioid receptors in gastrointestinal transit, this study will provide a systematic approach to advance the researches on opioids.

Terminology

Guinea pig ileum (GPI) and mouse vas deferens (MVD) assays are the well reported methods for screening the drugs/molecules for smooth muscle contractions.

Peer review

Overall, the present work is a useful study which is potentially helpful for establishing the connection between opioid agents and smooth muscle contraction in humans. One goal is to develop pharmacological means to counteract undesirable effects of chronic administration of opioids in patients.

Abstract

AIM: To evaluate the difference between the performance of the (CKD-EPI) and Modification of Diet in Renal Disease (MDRD) equations in cirrhotic patients.

METHODS: From Jan 2004 to Oct 2008, 4127 cirrhotic patients were reviewed. Patients with incomplete data with respect to renal function were excluded; thus, a total of 3791 patients were included in the study. The glomerular filtration rate (GFR) was estimated by the 4-variable MDRD (MDRD-4), 6-variable MDRD (MDRD-6), and CKD-EPI equations.

RESULTS: When serum creatinine was 0.7-6.8 mg/dL and 0.6-5.3 mg/dL in men and women, respectively, a significantly lower GFR was estimated by the MDRD-6 than by the CKD-EPI. Similar GFRs were calculated by both equations when creatinine was > 6.9 mg/dL and > 5.4 mg/dL in men and women, respectively. In predicting in-hospital mortality, estimated GFR obtained by the MDRD-6 showed better accuracy [81.72%; 95% confidence interval (CI), 0.94-0.95] than that obtained by the MDRD-4 (80.22%; 95%CI, 0.96-0.97), CKD-EPI (79.93%; 95%CI, 0.96-0.96), and creatinine (77.50%; 95%CI, 2.27-2.63).

CONCLUSION: GFR calculated by the 6-variable MDRD equation may be closer to the true GFR than that calculated by the CKD-EPI equation.

INTRODUCTION

Routine tests for serum creatinine (Scr) have been found to significantly improve the prognostic accuracy of

Child-Pugh score and to be an independent predictor of survival in patients with end-stage liver disease^[1]. In the early 2000s, the Model for End-stage Liver Disease (MELD) score emerged as a simple and more objective score than Child-Pugh score, with Scr as one of the 3 variables included [the other 2 being international normalized ratio (INR) and serum bilirubin]^[2-4]. Unlike those of the Child-Pugh score, the 3 variables of the MELD score are selected on the basis of statistical analysis and not empirical analysis. Different from INR and serum bilirubin, which are the basic markers of liver function, Scr is essentially a marker of renal function; and highlights the prognostic significance of the interactions between liver and renal functions in patients with cirrhosis^[5].

Kidney injury is an ominous and common event in cirrhotic patients^[6]. Although Scr shows a strong prognostic value in patients with cirrhosis, it is considered an insensitive predictor in such patients because of reduced muscle mass, protein-deficient diet, severe hyperbilirubinemia, and diminished hepatic biosynthesis of serum creatinine, all of which lead to an overestimation of creatinine clearance as compared with inulin clearance^[7]. Therefore, Scr level and creatinine-based equations also tend to overestimate glomerular filtration rate (GFR) in patients with cirrhosis.

Recently, a new creatinine-based equation known as the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation has been proposed as a more accurate formula than the Cockcroft and Modification of Diet in Renal Disease (MDRD) equations^[8]. However, the CKD-EPI equation has not been tested in patients with cirrhosis. The aim of the present study was to evaluate the difference between the performance of the MDRD and CKD-EPI equations when evaluating renal function in a broader population of patients with cirrhosis than liver transplant registries.

MATERIALS AND METHODS

Patient information and data collection

A retrospective, cross-sectional, single-center study design was used, and the study protocol was approved by the local ethics committee. Patients diagnosed with cirrhosis were selected from those admitted to Mackay Memorial Hospital between January 2004 and October 2008.

Of a total of 228 345 admitted patients, the records of 4127 patients with cirrhosis were reviewed. Patients who survived and were followed up in the outpatient department were defined as survivors, and the most recent laboratory data available for them were collected. Patients whose records indicated death any time during the hospital stay were defined as non-survivors (cases of in-hospital mortality), and laboratory data for these patients were those collected during the admission in which death occurred. In the case of patients with multiple admissions, the records before those of the last admission were excluded. Demographic data, Child-Pugh

scores, and information regarding underlying comorbidities were obtained from the most recent laboratory examinations. Patients with incomplete data with respect to Child-Pugh score and renal function or with cirrhosis due to congenital abnormality were excluded; thus, a total of 3791 patients were included in the study. None of the included patients had received liver transplants. The data on renal function in the common populace were based on the results of health examinations conducted among the residents of Taipei city, Taiwan, which were recently published as part of an epidemiologic study conducted at our institution^[9].

Laboratory methods

We calibrated serum creatinine values using the modified Jaffe method (Beckman Coulter, Inc. UniCel[®] Dx_C 800 Synchron[®] Clinical System) which were further standardized using the isotope dilution mass spectrometry (IDMS) reference method at Mackay Memorial Hospital Laboratory

Equations

The GFR was calculated according to the listed formulae: MDRD-4 = $175 \times (\text{Scr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.178 \text{ if black})$ ^[10], MDRD-6 = $170 \times (\text{Scr})^{-0.999} \times (\text{Age})^{-0.176} \times (0.762 \text{ if patient is female}) \times (1.180 \text{ if black}) \times (\text{SUN})^{-0.170} \times (\text{Albumin})^{0.318}$ ^[10], CKD-EPI = $141 \times \min(\text{Scr}/\kappa, 1)^\alpha \times \max(\text{Scr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018$ (if female) $\times 1.159$ (if black)^[8], where MDRD-4 is the 4-variable MDRD, MDRD-6 is the 6-variable MDRD, age is given in years, albumin in g/dL, Scr is serum creatinine (mg/dL), SUN is serum urea nitrogen concentration (mg/dL), κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum of Scr/ κ or 1, and max indicates the maximum of serum creatinine/ κ or 1.

Statistical analysis

Continuous variables are summarized as mean \pm standard deviation unless otherwise stated. We initially compared the demographic data and laboratory variables of survivors, non-survivors, and the common populace using the analysis of variance (ANOVA) test and chi-square test. Student's *t* test was used to assess differences in estimated GFR (eGFR) by CKD-EPI between cirrhotic patients and the common populace, and the difference in eGFR in cirrhotic patients calculated by MDRD6 or CKD-EPI, respectively. Logistic regression analyses were conducted to investigate the accuracy of predicting in-hospital mortality by the different creatinine-based equations. The results of these analyses were used to construct a receiver-operating characteristic (ROC) curve from which we sought the optimum cut-off point for predicting successful sites. The optimum cutoff point was defined as the point on the ROC curve closest to the point (0.1), where the false-positive rate was zero and the sensitivity was 100%. The area under the curve (AUC) and 95% confidence interval (CI) were

Table 1 Demographic and laboratory data of 3791 cirrhotic patients and 4292 common populace *n* (%)

Variables (<i>n</i> , %)	Survived cirrhotic patients (<i>n</i> = 2337)	Expired cirrhotic patients (<i>n</i> = 1454)	Common populace (<i>n</i> = 4292)	<i>P</i> value

Hepatic encephalopathy	431 (18.44)	649 (44.64)		< 0.001
Child-Pugh points	7.12 ± 1.97	10.37 ± 2.09		< 0.001

BUN: Blood urea nitrogen; eGFR: Estimated glomerular filtration rate; MDRD: Modification of Diet in Renal Disease; MDRD4: 4-variable MDRD; MDRD6: 6-variable MDRD; CKD-EPI: The Chronic Kidney Disease Epidemiology Collaboration; INR: International normalized ratio.

calculated. A *P* value of less than 0.05 was considered statistically significant. All statistical analyses were performed using SPSS software (version 17.0, SPSS Inc., Chicago, IL, United States).

RESULTS

Patient characteristics

Table 1 shows the demographic data, clinical characteristics, and laboratory data of patients with cirrhosis and the common populace. Older age, poorer renal function, and worse nutritional status were noted in the patients with cirrhosis than in the common populace. Thus, the average eGFR in patients with cirrhosis was significantly lower than that in the common populace, irrespective of the equation used for calculation (MDRD-4, MDRD-6, or CKD-EPI equation).

Difference between the performance of the MDRD-4, MDRD-6, and CKD-EPI equations in patients with cirrhosis and the common populace

Figure 1 shows the application of the 3 creatinine-based equations for calculating GFR in the common populace. The slope of the CKD-EPI equation was similar to that of the MDRD-4 equation when the Scr level was > 0.8 mg/dL and > 0.6 mg/dL in men and women, respectively, but less steep below the knots, which leads to less overestimation of GFR by the CKD-EPI equation at a lower Scr level^[8]. Figure 2 shows the application of the CKD-EPI equation in calculating GFR in both the patients with cirrhosis and the common populace. At the same Scr level, the CKD-EPI equation tended to estimate a significantly lower value of GFR in patients with cirrhosis when the Scr level was 0.8-1.2 mg/dL and 0.5-1.1 mg/dL in men and women, respectively. Figure 3 shows the eGFR obtained by the 3 creatinine-based equations in patients with cirrhosis. The eGFRs obtained by the 3 equations were similar when the Scr level was > 6.9 mg/dL and > 5.4 mg/dL in men and women, respective-

ly. Interestingly, significantly lower eGFR was obtained by the MDRD-6 equation than by the CKD-EPI equation when the Scr level was 0.7-6.8 mg/dL and 0.6-5.3 mg/dL in men and women, respectively. When the Scr level was < 0.5 mg/dL in men (1.8% of men with cirrhosis) and < 0.4 mg/dL in women (1.4% of women with cirrhosis), a lower eGFR was obtained by the CKD-EPI equation than by the MDRD-6 equation.

Prediction of in-hospital mortality by the different methods of renal function evaluation

The eGFR obtained by the MDRD-6 equation showed better accuracy (81.72%; 95% CI, 0.94-0.95) in predicting in-hospital mortality than that obtained by the MDRD-4 equation (80.22%; 95% CI, 0.96-0.97) and CKD-EPI equation (79.93%; 95% CI, 0.96-0.96). In general, eGFR showed a better prognostic value as a surrogate of renal function than Scr level (accuracy, 77.50%; 95% CI, 2.27-2.63). In the ROC curve (Figure 4), the cutoff point for eGFR obtained by the MDRD-6 equation was 41 (AUC, 0.85; 95% CI, 0.84-0.87). Interestingly, the cutoff point for Scr level was 1.3 mg/dL (AUC, 0.83; 95% CI, 0.81-0.84), which was lower than 1.5 mg/dL, a value suggested to indicate renal failure in patients with cirrhosis and the threshold value for the diagnosis of hepatorenal syndrome.

DISCUSSION

This retrospective, cross-sectional, single-center study involved a broader population of patients with cirrhosis than liver transplant registries to obtain eGFR using different creatinine-based equations. A significantly lower eGFR was obtained by the MDRD-6 equation than by the CKD-EPI equation when the Scr level was 0.7-6.8 mg/dL and 0.6-5.3 mg/dL in men and women, respectively. In view of the overall overestimation of GFR by the creatinine-based equations in patients with cirrhosis, eGFR obtained by the MDRD-6 equation may be closer to the

true GFR than that obtained by the CKD-EPI equation. The use of eGFR obtained by the MDRD-6 equation as a surrogate of renal function offered better accuracy in predicting in-hospital mortality than that of eGFR obtained by the MDRD-4 equation, CKD-EPI equation, or Scr level.

The prognostic significance of renal function in patients with cirrhosis is reflected by the inclusion of Scr in the MELD score, which predicts short-term mortality

(3 mo) and is used for the prioritization of transplant recipients in the United States^[2,5,11]. However, it has recently been suggested that Scr weighs too heavily on the MELD score^[12]: the assumption that mortality is constant at the Scr level of < 1 mg/dL is likely to be false. On the other hand, Scr level and creatinine-based equations tend to overestimate GFR, and creatinine clearance from the time of urine collection also leads to overestimation of GFR. As a result, a modified MELD score

with a lower weighting for Scr than that in the current MELD score has been proposed and has been shown to be slightly superior^[12]. However, even after these adjustments, Scr is still a determinant of prognosis.

The creatinine-based Cockcroft and MDRD equations are widely used to estimate GFR in the general population, and MDRD is considered the gold standard in nephrology^[5,13]. However, both the Cockcroft and MDRD equations tend to overestimate GFR: a series has shown that only 66% of estimates were within 30% of the measured GFR^[14,15]. Unfortunately, most of the cited studies evaluated GFR in patients in liver transplant registries, who tend to have more advanced cirrhosis and decreased GFR, in part, due to the liver disease and malnourishment. The present study included a broader population that may have been better nourished or not as ill as that in previous studies.

The CKD-EPI equation, a newly developed equation for estimating GFR, has been proposed to be more accurate than the MDRD equation, especially when GFR is high. Moreover, it shows less bias, improved precision, and greater accuracy^[8]. Our study results agreed with this fact since the slope of the CKD-EPI equation was less steep when the Scr level was < 0.8 mg/dL and < 0.6 mg/dL in men and women, respectively. When the CKD-EPI equation was applied at the same Scr level in patients with cirrhosis and the common populace, a lower GFR was calculated in the former than in the latter. This result was probably related to the older age of the patients with cirrhosis, with the same Scr level. When the CKD-EPI, MDRD-4, and MDRD-6 equations were applied in the case of patients with cirrhosis, the performance of the CKD-EPI and MDRD-4 equations was similar to that in the common populace. However, a significantly lower GFR was estimated by the MDRD-6 equation than by the CKD-EPI equation when the Scr level was 0.7-6.8 mg/dL and 0.6-5.3 mg/dL in men and women, respectively. This result was probably related to the higher blood urea nitrogen (BUN) and lower albumin level-the additional 2 variables used in the MDRD-6 equation-in patients with cirrhosis. Although the CKD-EPI equation also yielded a lower eGFR than the MDRD-6 equation when the Scr level was < 0.5 mg/dL and < 0.4 mg/dL in men and women, respectively, the value was only found in 1.8% men and 1.4% women in all the study subjects. In view of the overall overestimation of GFR by the creatinine-based equations in patients with cirrhosis, eGFR obtained by the MDRD-6 equation seemed to be closer to the true GFR than that obtained by the CKD-EPI equation.

Creatinine shows a significant prognostic value in patients with cirrhosis^[2,5,11]. Theoretically, the creatinine-based equations show a similar prognostic value. However, the Cockcroft equation is less accurate than the MDRD equation since it incorporates body weight, which is markedly biased in patients with edema and/or ascites^[16]. The MDRD-4 (simplified MDRD) equation is usually and most often used to calculate GFR, since it is considered as accurate as the original MDRD-6 equation^[17]. However, its usefulness has not been proved in

healthy individuals, and its accuracy may be low in specific clinical settings^[15,18]. Therefore, the MDRD-6 equation is considered the best, possibly because it incorporates BUN and albumin level, the 2 variables which are abnormal in patients with cirrhosis^[18]. Our data also showed that eGFR obtained by the MDRD-6 equation was more accurate than that obtained by the MDRD-4 equation, CKD-EPI equation, or even Scr level in predicting in-hospital mortality. It is most likely that the improved predication due to BUN and albumin, in particular serum albumin is an excellent predictor of mortality. Thus, the use of eGFR obtained by the MDRD-6 equation as a surrogate of renal function offers a better prognostic value than that of eGFR obtained by the other equations. However, the accuracy of the MDRD equation has only been estimated on a large scale, in patients with chronic kidney disease. This suggests that a specific formula should be derived for patients with cirrhosis.

The present study has several limitations. First, there was no comparison between the CKD-EPI equation and the gold standard for GFR estimation such as that using ¹²⁵I-iothalamate or inulin. Thus, the true performance of the CKD-EPI equation in patients with cirrhosis could not be evaluated. Second, due to the variation in assay of BUN and albumin across labs which is not standardized, these results may not be useful in other populations. Third, the study was retrospective and cross-sectional in nature, and therefore, a prospective, cohort study is needed to test and verify our conclusions.

In conclusion, in view of the overall overestimation of GFR in patients with cirrhosis by creatinine-based equations, GFR calculated by the MDRD-6 equation may be closer to the true GFR than that calculated by the CKD-EPI equation and, hence, more suitable as a surrogate of renal function. However, a formula specifically derived for calculating GFR in patients with cirrhosis is warranted.

COMMENTS

Background

The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation has been proposed to be more accurate than the Cockcroft and Modification of Diet in Renal Disease (MDRD) equations. However, the CKD-EPI equation has not been tested in patients with cirrhosis.

Research frontiers

This is a retrospective study. Glomerular filtration rate (GFR) calculated by the 6-variable MDRD equation is closer to the true GFR than that calculated by the CKD-EPI equation. The 6-variable MDRD equation is a better way of calculating GFR in cirrhotic patients.

Innovations and breakthroughs

To our knowledge, this is the first study to evaluate the difference between the performance of the CKD-EPI and MDRD equations in cirrhotic patients. Although the CKD-EPI equation been proposed to be more accurate than the MDRD equation in the general population, the 6-variable MDRD equation remains the best way to calculate GFR in cirrhotic patients.

Applications

GFR should be calculated by the 6-variable MDRD equation in cirrhotic patients.

Peer review

It is a good study. However the authors have adequately mentioned the limitation.

Abstract

Retroperitoneal duodenal perforation as a result of endoscopic biliary sphincterotomy is a rare complication, but it is associated with a relatively high mortality risk, if left untreated. Recently, several endoscopic techniques have been described to close a variety of perforations. In this case report, we describe the closure of a persistent sphincterotomy-related duodenal perforation by using a covered self-expandable metallic biliary (CEMB) stent. A 61-year-old Greek woman underwent an endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy for suspected choledocholithiasis, and a retroperitoneal duodenal perforation (sphincterotomy-related) occurred. Despite initial conservative management, the patient underwent a laparotomy and drainage of the retroperitoneal space. After that, a high volume duodenal fistula developed. Six weeks after the initial ERCP, the patient underwent a repeat endoscopy and placement of a CEMB stent with an indwelling nasobiliary drain. The fistula healed

completely and the stent was removed two weeks later. We suggest the transient use of CEMB stents for the closure of sphincterotomy-related duodenal perforations. They can be placed either during the initial ERCP or even later if there is radiographic or clinical evidence that the leakage persists.

Closure of a persistent sphincterotomy-related duodenal perforation by placement of a covered self-expandable metallic biliary stent. *World J Gastroenterol* 2011; 17(40): 4539-4541 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i40/4539.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i40.4539>

INTRODUCTION

Retroperitoneal duodenal perforation as a result of endoscopic biliary sphincterotomy (ES) is a well-recognized complication. Although it is reported to have an incidence of 0.3% to 1.3%, it is associated with a relatively high mortality rate of 7% to 14%^[1-4]. The overriding question is whether or not immediate surgical exploration is required or if a trial of non-operative management is safe. Recently, several endoscopic techniques have been described to close a variety of perforations^[5,6]. This is, to the best of our knowledge, the first report of a delayed closure of a sphincterotomy-related duodenal perforation by placement of a covered self-expandable metallic bili-

ary (CEMB) stent.

CASE REPORT

A 61-year-old lady with a history of previous laparoscopic cholecystectomy underwent endoscopic retrograde cholangiopancreatography (ERCP) for biliary colic, abnormal liver function tests and a grossly dilated common bile duct (20 mm). The suspected diagnosis was either choledocholithiasis or sphincter of Oddi dysfunction type I. ES was performed over a guidewire using an ERBE VIO 200 S diathermy (ERBE Elektromedizin, Germany) at Endocut mode. Due to an unusual direction of the papilla, the ES was carried out laterally towards the 9 o'clock position. After insertion and removal of the balloon catheter, a visible laceration was recognized just posteriorly to the ES. The presence of free air in the retroperitoneum was immediately apparent (Figure 1). The patient was treated initially with broad spectrum antibiotics and nasogastric drainage. The following day an abdominal computed tomography (CT) scan was performed (Figure 2). A large amount of retroperitoneal air was identified, but no leak of contrast was found. Over the following days the patient deteriorated, became pyrexial and unstable, and a laparotomy was carried out on the 15th post-ERCP day. The retroperitoneal space was explored with debridement of necrotic tissue and placement of drains.

The patient's condition was improved postoperatively, but a high volume duodenal fistula (500-1500 mL/24 h) developed, which was refractory to conservative treatment.

Four weeks later an endoscopy was performed. The procedure was technically difficult because of an edematous duodenum, but the laceration was found at the sphincterotomy site (Figures 3 and 4). A CEMB stent (Wallstent, Boston Scientific) and subsequently a nasobiliary drainage catheter were placed (Figures 5 and 6). The proximal 5 mm uncovered portion of the Wallstent had been cut prior to insertion. The fistula had healed completely a week later and the stent was removed at 2 wk. The nasobiliary drain was left in place for five days, although the output was minimal. A cholangiography and contrast study before removal of the nasobiliary drain showed no existence of leak.

The patient was discharged home 2 mo post-ERCP and remains well 8 mo later.

DISCUSSION

Perforation during ES is usually retroperitoneal in location. It results from an extension of the incision beyond the intramural portion of the bile duct. It is widely believed that perforation is more likely to occur if the incision strays beyond the usual recommended sector (11 to 1 o'clock)^[7]. Due to the low incidence of perforation, the risk factors are not well defined. The risk appears to be increased in patients with Billroth II anastomosis and when needle-knife sphincterotomy is performed^[3]. The incision in these situations is not well controlled and therefore the chances of perforation are higher.

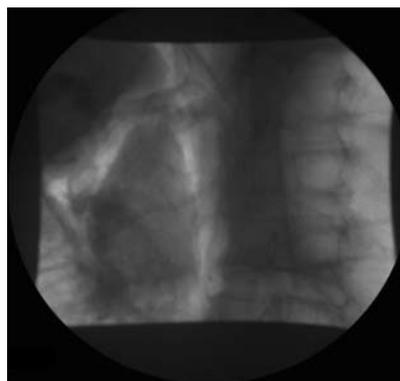

Figure 1 Free gas in the retroperitoneal space.

Figure 2 Computed tomography scan showing the presence of air in the retroperitoneal space and subcutaneous emphysema.

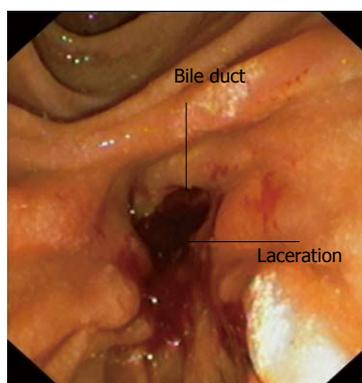

Figure 3 The laceration is evident just below the lower end of the bile duct.

No consensus exists on management guidelines, because ES-related retroperitoneal perforations are rare and the clinical consequences vary enormously. In general, non-operative management of these perforations is possible despite the presence of extensive retroperitoneal air, provided the patient remains well clinically. If the patient develops abdominal pain, fever and appears toxic clinically, surgical exploration should be considered^[8]. Delayed diagnosis can lead to severe morbidity^[9]. Patients with biliary stenting appear to have a lower rate of operative intervention. This is likely related to the higher rate of guidewire-induced injuries in these patients, who are much less likely to require operative intervention^[8].

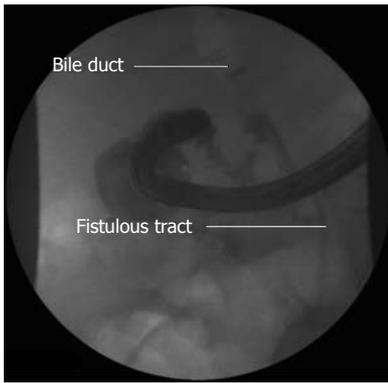

Figure 4 Injection of contrast from the endoscope enables visualization of the fistulous tract. The bile duct is also delineated with the presence of gas.

Figure 5 The covered self-expandable metallic biliary stent covers the laceration.

Figure 6 Covered self-expandable metallic biliary stent and nasobiliary catheter in place.

It is possible that biliary stenting has a protective effect by diverting bile into the duodenum instead of into the retroperitoneum. Endoscopic closure of ERCP-related duodenal perforations by using endoclippping devices^[10], approximation sutures^[5] or duodenal stents^[6] have also been described.

The above described endoscopic techniques are applied after the recognition of the perforation during the initial ERCP. In our case, a repeat ERCP was performed 6 wk

after the initial procedure, in order to repair the perforation and drain the bile duct. A repeat endoscopy after a duodenal perforation is technically demanding, carries the risk of extending the laceration, and excessive skill is required.

CEMB stents have the advantage of covering the laceration and permit free flow of bile into the duodenum instead of into the retroperitoneal space. Additionally, they protect against the leakage of pancreatic and gastric fluid. The additional use of a nasobiliary drainage catheter may reduce bile flow to the duodenum and allows checking of the healing process by performing contrast studies. Fully covered metallic self-expandable biliary stents should be preferred because they can easily be removed after a short period. In our case, a fully covered stent was not available and we modified a partially covered as mentioned previously.

In conclusion, we suggest the transient use of CEMB stents for the closure of sphincterotomy-related duodenal perforations. They can be placed either during the initial ERCP or even later, if there is radiographic or clinical evidence that the leakage persists.

Abstract

Neoadjuvant chemotherapy (NAC) has drawn more attention to the treatment of locally advanced gastric cancer (AGC) in the current multidisciplinary treatment model. EORTC trial 40954 has recently reported that NAC plus surgery without postoperative adjuvant chemotherapy could not benefit the locally AGC patients in their overall survival. We performed a meta-analysis of 10 studies including 1518 gastric cancer patients. Stratified subgroups were NAC plus surgery and NAC plus both surgery and adjuvant chemotherapy (AC), while control was surgery alone. The results showed that NAC plus surgery did not benefit the patients with locally AGC in their overall survival [odds ratio (OR) = 1.20, 95% CI 0.80-1.80, $P = 0.37$] and the number needed to treat (NNT) was 74. However, the NAC plus both surgery and AC had a slight overall survival benefit (OR = 1.33, 95% CI 1.03-1.71, $P = 0.03$) and NNT was 14, which is superior to the NAC plus surgery. Therefore, we recommend that combined NAC and AC should be used to improve the overall survival of the locally AGC patients.

TO THE EDITOR

We have read with great interest the excellent article by Li *et al*^[1]. Gastric cancer is still one of the most common malignancies worldwide and about 80% patients with gastric cancer have advanced diseases^[2]. Surgery is known as the only potentially curative treatment for this disease at resectable stages, while chemotherapy could play an important role in improving the prognosis of the patients^[2,3]. Neoadjuvant chemotherapy (NAC) has drawn more attention to the treatment of locally advanced gastric cancer (AGC) in the current multidisciplinary treatment model. The EORTC trial 40954 observed the effect of the NAC without adjuvant chemotherapy (AC) following surgery for locally AGC (UICC stage III and IV-cM0). The protocol did not benefit the survival of the patients, but the R0 resection rate was significantly increased^[4]. However, the fluorouracil-containing AC for AGC has shown significant survival benefit compared with surgery alone^[5-7]. Therefore, we consider that combined NAC and AC may benefit locally AGC patients in overall survival.

The meta-analysis performed by Li *et al*^[1], including 14

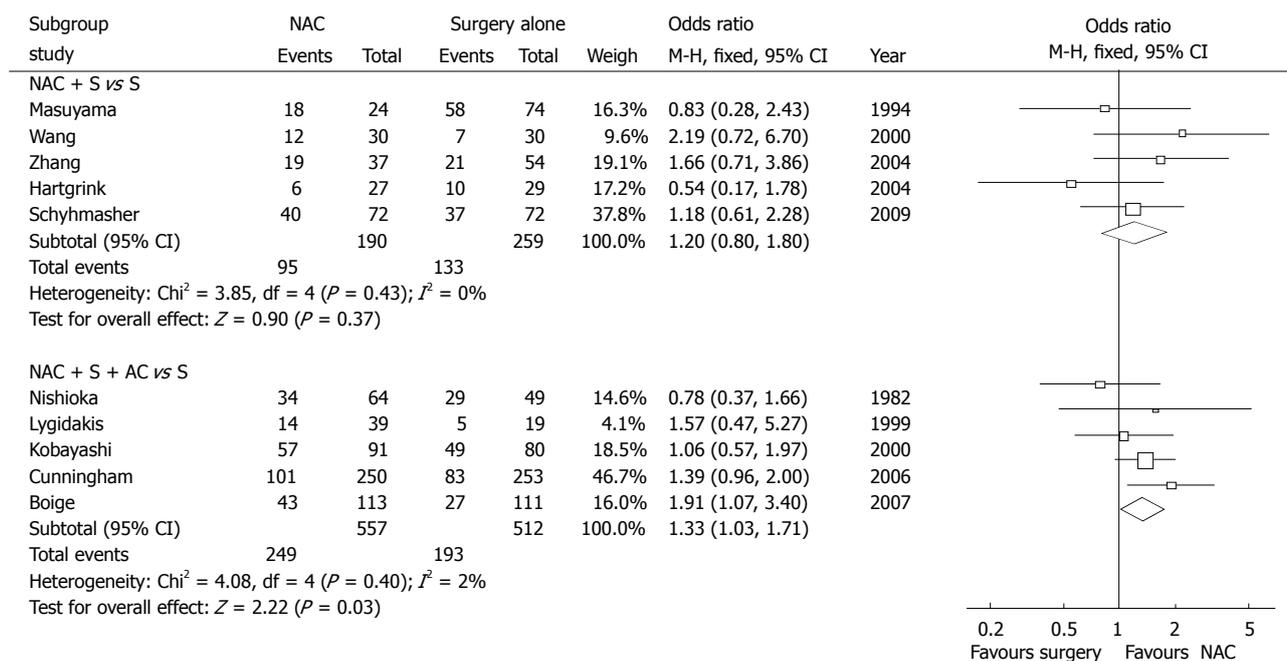

Figure 1 Subgroup comparison of neoadjuvant chemotherapy or neoadjuvant chemotherapy plus adjuvant chemotherapy vs surgery alone for locally advanced gastric cancer (based on the published meta-analysis and excluding the trials contaminated with adjuvant chemotherapy in control arm)^[1]. M-H: Mantel-Haenszel test. NAC: Neoadjuvant chemotherapy; AC: Adjuvant chemotherapy.

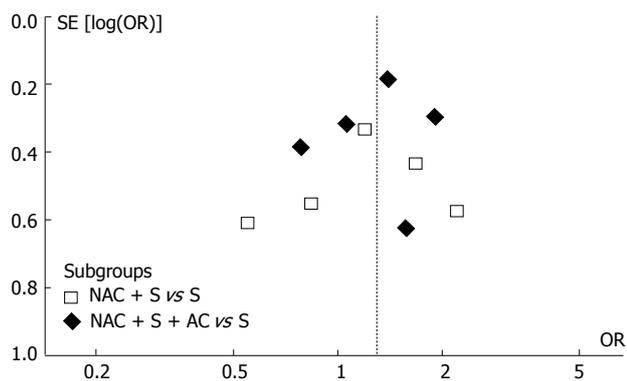

Figure 2 Funnel plot analysis of publication bias. OR: Odds ratio; NAC: Neoadjuvant chemotherapy; AC: Adjuvant chemotherapy.

trials, compared the patients treated with NAC and those without NAC, showed an R0 resection rate of 75.2% *vs* 66.9% [odds ratio (OR) = 1.51, $P = 0.0006$, fixed model]. Therefore, this made us well understand the substantial effectiveness of NAC for locally AGC.

Based on the original meta-analysis, we performed another subgroup analysis by classifying the intervention arms into NAC plus surgery or NAC plus both surgery and AC, while the trials contaminated with AC in the control arm were excluded^[1]. In each subgroup, 5 prospective trials were included for repooled analysis (1518 patients). The meta-analysis showed that the NAC plus surgery did not bring overall survival benefit to the patients with locally AGC (OR = 1.20, 95% CI 0.80-1.80, $P = 0.37$) and the number needed to treat (NNT) was 74 (Figure 1). However, NAC plus both surgery and AC

had a slight overall survival benefit (OR = 1.33, 95% CI 1.03-1.71, $P = 0.03$) and NNT was 14, which was superior to the NAC plus surgery (Figure 1). It implies that one out of 14 locally advanced patients treated by NAC plus both surgery and AC was benefited in survival, while the remainings might be at risk of recurrence or even death.

In addition, funnel plot observation did not indicate obvious publication bias in the two subgroups (Figure 2). The sensitivity analysis showed similar results by excluding the trials with Jadad score less than 3^[1]. The original meta-analysis noted that the effect of NAC is more pronounced in Western countries and in doublet or triplet chemotherapy regimens^[1]. In our subgroup analysis, the subgroups involved both Western and Asian studies as well as both single-agent and multi-agent regimens. These factors might not confound the present analysis.

Interestingly, EORTC trial 40 954 did not show any survival benefit by NAC for the locally advanced diseases (UICC stage III and IV-cM0)^[4], but the meta-analysis by Li *et al*^[1] found that more advanced diseases (pT3-4) were benefited by NAC (OR = 1.91, $P < 0.05$) than pT1-2 diseases ($P > 0.05$). Based on the original data from Li *et al*^[1], it is impossible to perform subgroup analysis of stage III and IV-cM0 diseases, but it would be meaningful to figure out which sub-population might actually benefit from NAC plus both surgery and AC.

In summary, we think NAC is an effective therapy to increase the R0 resection rate for locally AGC, however, combined NAC and AC would improve the overall survival of the patients. Whether the increased R0 resection rate is associated with the improved overall survival and which sub-population might benefit from the combined

treatment requires further studies.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copy-right" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.
