Abstract

The gastrointestinal tract harbors a large number and diverse array of commensal bacteria and is an important entry site for pathogens. For these reasons, the intestinal immune system is uniquely dedicated to protect against infections, while avoiding the development of destructive inflammatory responses to the microbiota. Several models have been proposed to explain how the immune system discriminates between, and appropriately responds to, commensal and pathogenic microorganisms. Dendritic cells (DCs) and regulatory T cells (Treg) are instrumental in maintaining immune homeostasis and tolerance in the gut. DCs are virtually omnipresent and are remarkably plastic, having the ability to adapt to the influences of the microenvironment. Different DC populations with partially overlapping phenotypic and functional properties have been described in different anatomical locations. DCs in the draining mesenteric lymph nodes, in the intestinal lamina propria and in Peyer's patches partake both in

the control of intestinal inflammation and in the maintenance of gut tolerance. In this respect, gut-resident DCs and macrophages exert tolerogenic functions as they regularly encounter and sense commensal bacteria. In contrast, migrating DC subsets that are recruited to the gut as a result of pathogenic insults initiate immune responses. Importantly, tolerogenic DCs act by promoting the differentiation and expansion of Treg cells that efficiently modulate gut inflammation, as shown both in pre-clinical models of colitis and in patients with inflammatory bowel disease (IBD). This article reviews the phenotypic and functional features of gut DC subsets and discusses the current evidence underpinning the DC contribution to the pathogenesis of the major clinical subtypes of human IBD. It also addresses the potential clinical benefit derived from DC targeting either *in vivo* or *in vitro*.

INTRODUCTION

The digestive tract has a surface area nearly 200 times greater than that of the skin. Being an important port of entry for microorganisms, the gut must be protected by effective immune responses. However, immune reactivity must be prevented from damaging gut tissues in response

to benign foreign material to which the gut is continuously exposed. T cell immunity relies on the recognition of antigenic peptides processed and presented to T cells by dendritic cells (DCs), which act as initiators, stimulators and regulators of antigen-specific T cell responses, but also play a pivotal role in the maintenance of tolerance towards the commensal microflora^[1,2].

DCs are specialized accessory cells distinguishable from other mononuclear phagocytes (MPs) such as monocytes and macrophages by their unique morphology and ability to capture and process antigens for presentation to effector T cells. Upon encounter with pathogens and activation, DCs undergo rapid maturation characterized by the upregulation of major histocompatibility complex (MHC) and costimulatory molecules and migrate to the draining lymph nodes. The remarkable flexibility of DC functions likely results from their ability to sense the local environment and to shape the ensuing immune response^[3,4]. Intestinal MPs are distributed in organized lymphoid organs, such as Peyer's patches (PP) and mesenteric lymph nodes (MLN), and are highly abundant in the loose connective tissue underlying the epithelium, the lamina propria (LP)^[5].

It is now established that DCs play a crucial role in both immunity and tolerance^[1,6]. In a tolerogenic setting, DC can induce anergy in antigen-specific T cells or generate protective FoxP3⁺ regulatory T cells (Treg) in the lymph nodes. Under steady-state conditions, DCs continuously migrate from peripheral organs *via* the lymph to secondary lymphoid organs, where they present self-antigens or innocuous environmental antigens to maintain peripheral tolerance. The chemokine receptor, CCR7, is a key regulator of the homeostatic and inflammation-induced trafficking of DCs from skin, lung and gut to their respective draining lymph nodes^[7].

Human inflammatory bowel disease (IBD) consists of 2 dominant disease subtypes, Crohn's disease (CD), largely arising from a Th1 response, and ulcerative colitis (UC), largely mediated by interleukin (IL)-5- and IL-13-producing T cells or natural killer T cells^[8]. The immunopathology of human IBD relates to an inappropriate and exaggerated immune response to constituents of the gut flora in a genetically predisposed individual. Amongst other cell types^[9], DCs play a role in IBD pathogenesis, as suggested by mouse models of colitis and by observations in humans. The local microenvironment regulates the function of mucosal DCs through the presence of immune cells, non-immune cells and luminal bacteria^[10]. In principle, DC dysfunction may promote the development of gut inflammation by priming T-cell responses against bacteria, by sustaining T cell reactivity within the inflamed mucosa and by functioning as effector cells releasing pro-inflammatory cytokines^[11].

DC LINEAGE AND SUBSETS IN MICE AND HUMANS

DC origin and precursor-progeny relationships have remained a matter of controversy and debate for decades^[12].

Recent landmark studies have led to a better definition of DC ontogeny in mice (Figure 1), unraveling that a macrophage and DC precursor (MDP) serves as a common bone marrow progenitor for classical or conventional DCs (cDCs), plasmacytoid DCs (pDCs) and monocytes (Table 1). Specifically, Fogg *et al.*^[13] have identified a clonogenic MDP with a CD117⁺CX₃CR1⁺CD11b⁻ lineage⁻ phenotype, representing ~0.5% of total bone marrow cells and giving rise to monocytes, to several macrophage subsets and, ultimately, to steady-state CD11c⁺CD8 α ⁺ and CD11c⁺CD8 α ⁻ DC. Lymphoid organ DCs in the steady state originate from a bone marrow precursor with a Lin⁻CD115⁺Flt3⁺CD117^{lo} phenotype, termed common DC progenitor (CDP)^[14]. Migratory DC precursors (pre-DCs) also exist in the peripheral blood and are in equilibrium with DCs in lymphoid organs and in non-lymphoid tissues, such as skin, lung, kidney and intestine. DCs actively divide *in vivo* and their lifespan varies from 5 to 7 d in the spleen, lymph node, liver and kidney and can be as long as 25 d in the lung^[15].

DCs lack a unique surface marker, but rather express a distinct set of cell surface antigens. The number of DC subsets that have been phenotypically characterized and functionally designated is increasing steadily. In addition to the classical integrin marker CD11c distinguishing DCs, the integrin α E (CD103) recently gained attention and has been used to sub-classify DC subsets based on specific functional activities and anatomic location (see below for a thorough discussion)^[16]. CD103 mediates T cell adhesion to epithelial cells through its binding to E-cadherin, which is expressed on the basolateral side of epithelial cells but not on endothelial cells. Mice with a targeted disruption of *cd103* show a mild reduction in T cell numbers in the intraepithelial and LP compartments, coupled with the inability to reject islet allografts^[17].

MECHANISMS UNDERLYING DC-MEDIATED TOLERANCE IN THE GUT

One of the major functions of tolerogenic DCs may be the differentiation of Treg cells from naïve T cells. Two major subtypes of Treg cells have been described to date, namely, naturally occurring CD4⁺CD25⁺FoxP3⁺ Treg cells (nTreg) and inducible type 1 Treg cells (Tr1).

DCs as inducers of nTreg cells

Naturally occurring Treg cells, a functionally specialized subset of CD4⁺ T cells, have been involved in preventing T cell-mediated and innate immune pathology in a number of disease models^[18]. The transcription factor FoxP3 is expressed by CD4⁺CD25⁺ Treg cells and is fundamental for Treg development and function. nTreg cells mainly suppress effector T cells through a cell contact-dependent and largely contact-independent mechanism. Membrane-bound transforming growth factor (TGF)- β has been implicated in nTreg-mediated inhibition of T cell responses. Moreover, TGF- β 1 acts as a co-stimulatory factor for FoxP3 expression, leading to Treg differen-

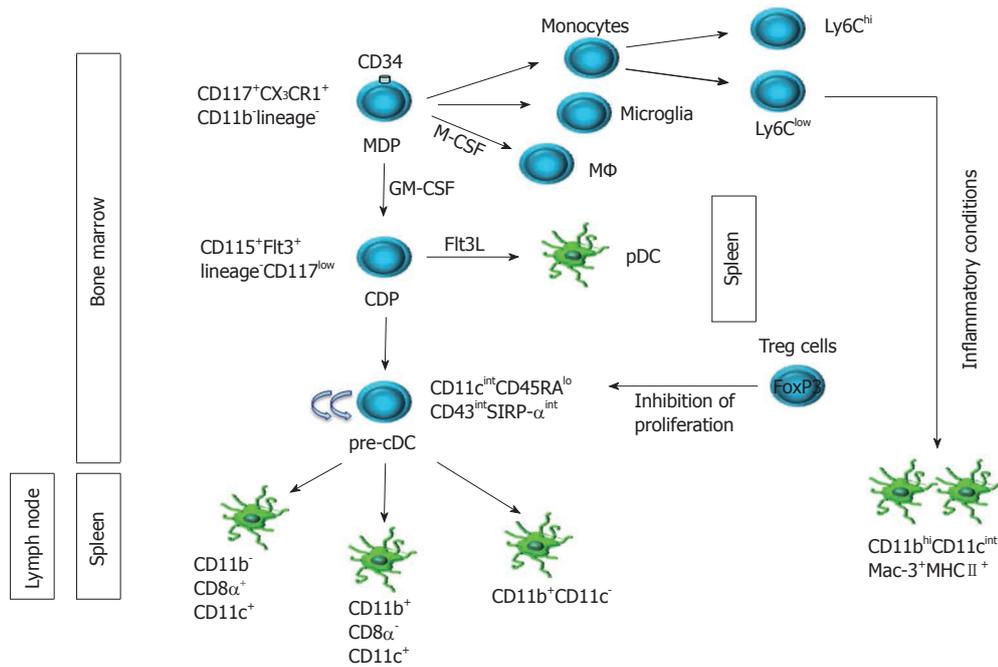

Figure 1 Ontogeny of dendritic cell subsets in mice. The most recent evidence elucidating dendritic cell (DC) ontogeny and unraveling the complexity of the DC compartment in mice is summarized. The curved arrows in cyan denote proliferation potential. Regulatory T (Treg) cells may contribute to DC development and homeostasis in mice, as suggested by studies where Treg depletion has been associated with a 2- and 12-fold increase in precursor conventional DC (pre-cDC) and cDC in spleen and lymph node, respectively^[14]. MDP: Macrophage and dendritic cell progenitor; CDP: Common dendritic cell progenitor; pDC: Plasmacytoid DC.

tiation from CD4⁺CD25⁻ T cells. Interestingly, TGF-β1 production by Treg cells is not required for inhibition of colitis, suggesting that Treg cells may induce TGF-β release by other hematopoietic or stromal cells^[19]. Support for this hypothesis is provided by the observation that suppression of colitis by TGF-β1^{-/-} Treg cells was inhibited by anti-TGF-β antibodies, indicating that TGF-β is central to the function of Treg cells even when they do not synthesize it themselves^[19]. In this respect, DCs remain a key and intriguing candidate for TGF-β production *in vivo*. It is conceivable that Treg cells be required to express TGF-β1 on the cell surface and to present it to pathogenic T cells, as previously shown^[19].

Treg cells are believed to play a crucial role in inhibiting intestinal inflammation and IBD. Notably, Treg cells may contribute differentially to the modulation of experimental autoimmune gastritis and colitis. Protection from colitis, but not from gastric inflammation, has been reported to depend on IL-10 expression by CD4⁺CD25⁺nTreg cells^[20]. The T cell transfer model of colitis allows an understanding of Treg-mediated mechanisms controlling intestinal inflammation. During cure of experimental colitis, Treg cells proliferate and accumulate in MLN and colonic LP, in contact with CD11c⁺ DCs and effector T cells^[21]. Interestingly, IL-10-producing Treg cells selectively enrich within the colonic LP, whereas FoxP3-expressing Treg cells are present in similar frequencies in both the secondary lymphoid organs and LP of colitic animals^[22]. Transfer of CD4⁺CD45RB⁺ T cells into RAG^{-/-} mice causes colitis. Disease development requires β7-integrin-dependent intestinal localization. Importantly, β7-deficient Treg cells prevent colitis, suggesting that Treg

accumulation in the intestine is dispensable for disease suppression^[23]. The presence of Treg cells impacts on CD4⁺CD45RB⁺ T cell accumulation in the intestine, indicating that one major function of Treg cells may involve the inhibition of tissue localization of Th1 effector cells.

Peripheral blood CD4⁺CD25^{high} T cells may be decreased in active human IBD compared with inactive disease^[24]. Notably, Treg cells are increased in mucosal IBD lesions, coincident with an increase in transcripts for IL-8, a hallmark of inflammation in the gut, and for FoxP3^[24]. The higher degree of Treg infiltration in the gut LP of patients with diverticulitis compared with IBD suggests that an insufficient increase of Treg cells in IBD accounts for inflammation and intestinal pathology^[24]. In the LP of human colon, Treg accumulation has been detected in a variety of inflammatory conditions, such as diverticulitis, pseudo-membranous colitis and cytomegalovirus-induced colitis, and may not be a specific feature of CD or UC^[22]. The presence of FoxP3⁺ T cells in the LP of patients with IBD suggests that defects in Treg numbers may not account for the pathology, and that ineffective Treg activity may rather contribute to sustained gut inflammation.

DCs as inducers of Tr1 cells

Tr1 have been described as a CD4⁺ T-cell subset releasing high levels of IL-10, in the absence of measurable IL-2 and IL-4 production, and exerting suppressive functions in an IL-10/TGF-β-dependent but cell contact-independent manner^[25]. The production and release of interferon (IFN)-γ and TGF-β by Tr1 cells are comparable with those of Th0 and Th1 clones, respectively^[25].

Table 1 Intestinal dendritic cell subsets and other mononuclear phagocytes described to date

Subset	Anatomic location	Function, if known	Ref.	
CD11c ^{hi} CD11b ⁺ CD8 α ⁻	Peyer's patches	Localized in the subepithelial dome	[57]	
CD11c ^{hi} CD11b ⁺ CD8 α ⁺		Localized in the interfollicular regions	[57]	
CD11c ⁺ CD11b ⁻ CD8 α ⁻		Localized in both subepithelial dome and interfollicular regions; secretion of IL-10 in response to CD40 cross-linking; induction of T-cell release of IL-4/IL-10; promotion of T-cell proliferation	[58]	
CD11c ^{mid} plasmacytoid DC	Small-intestinal and colonic lamina propria	Low T-cell responses <i>in vitro</i> ; IL-12p40 ^{low} IL-10 ⁺ ; tolerance to OVA (m); secretion of IFN- α ; differentiation of Tr1-like cells that secrete IL-10, IL-4 and IFN- γ	[30,55]	
CD11c ⁺ CD11b ⁺ CD8 α ⁺ DC		Pro-inflammatory activity dependent upon TNF- α production	[101]	
CX ₃ CR1 ⁺ DC	Mesenteric lymph node	Generation of CCR9 ⁺ α ₄ β ₇ ⁺ T cells with gut tropism	[51]	
CD11c ^{hi} class II ^{hi} CD103 ⁺ DC		Conversion of Foxp3 ⁺ T cells to Foxp3 ⁺ T cells; retinoic acid and TGF- β required	[54]	
CD11b ⁺ CD8 α ⁻ CD103 ^{-/-} DC		Promotion of CD4 ⁺ CD25 ⁺ Treg function; differentiation of Tr1-like cells (IL-10 ⁺ IL-4 ⁺ IFN- γ ⁺) from naïve T cells after repeated stimulations	See above	
CD11c ^{lo} B220 ⁺ CD8 α ⁺			See above	
CD11c ^{hi} CD11b ⁺ CD8 α ⁺		~50% of CD11c ⁺ DC in the MLN; conversion of naïve T cells into Treg cells; retinoic acid and TGF- β required; induction of CCR9 on gut-tropic T cells	[16]	
CD11c ^{hi} CD11b ⁻ CD8 α ⁻		Expression of pro-inflammatory cytokines (TNF- α , IL-6, IL-23p19) and genes such as <i>Tbet</i> , <i>tlr2</i> and <i>tbx21</i>		
CD103 ⁺ DC				[16]
CD103 ⁻ DC		Induction of CCR9 gut-homing receptor on CD4 ⁺ T cells	[53]	
CD11c ^{hi} class II ^{hi} CD103 ⁺ DC	Small and large intestine	Induction of Treg cells, secretion of IL-10 but not IL-12p40 or IL-12p70	[105,106]	
CD11b ⁺ CD11c ⁻ macrophages				

DC: Dendritic cell; OVA: Ovalbumin; IFN: Interferon; MLN: Mesenteric lymph node; Tr1: Type 1 Treg cells; TGF: Transforming growth factor; IL: Interleukin; M: Mouse studies.

Colitis in the severe combined immunodeficient (SCID) mouse model involves the development of Th1 cells responding primarily to the intestinal flora. The transfer of ovalbumin (OVA)-specific Tr1 cells in SCID mice with CD4⁺CD45RB^{hi} T cell-induced colitis prevents disease manifestations, an effect that is dependent upon the *in vivo* activation of Tr1 cells by feeding mice with OVA^[25]. This observation indicates that Tr1 cells can inhibit immune responses to unknown antigens by a bystander suppression mechanism. Another report has shown that IL-10^{-/-} mice lack CD4⁺CD45RB^{lo} Treg cells capable of controlling intestinal inflammatory responses, pointing to IL-10 as a crucial mediator of tolerance in the gut^[26]. Similarly, TGF- β is required to suppress Th1-mediated colitis induced by CD4⁺CD45RB^{hi} T cells^[27], indicating that IL-10 and TGF- β play non-redundant roles in the functioning of intestinal Treg cells.

The source of IL-10 which regulates colitis remains to be unequivocally identified. Treg-derived IL-10 was recently shown to be dispensable for suppression of colitis in *Rag1*^{-/-} mice, but host IL-10 was required to inhibit disease development^[28]. Specifically, IL-10 production by myeloid CD11b⁺F4/80⁺ cells, mostly macrophages, was important for the maintenance of Foxp3 expression by Treg cells^[28]. IL-10 acted directly on Treg cells, because Treg cells lacking IL-10R β chain failed to suppress colitis when transferred together with CD4⁺CD45RB^{hi} T cells. In addition, this study demonstrates that IL-10 is not required to maintain Foxp3 expression in non-inflammatory conditions, because Treg development and function are unaffected in *Il10rb*^{-/-} mice^[28]. It is conceivable that the differential requirement for IL-10 for Foxp3 expression and maintenance in inflammatory vs non-inflammatory conditions may reflect the need for an additional signal to

counter inflammatory mediators such as IL-6 or tumor necrosis factor (TNF)- α ^[29]. It remains to be determined whether IL-10-mediated mechanisms are unique to the gut microenvironment or whether IL-10 may be required to maintain Foxp3 expression in other organs.

Other studies pointed to Treg-derived IL-10 as a major contributor to Treg-mediated suppression^[25]. These discrepancies may be attributed to differences in the endogenous flora and/or in the model systems studied. Mucosal CD8 α ⁺ DCs with a CD11c^{lo}B220⁺ phenotype can be isolated from mouse MLN and have been reported to promote the suppressive function of CD4⁺CD25⁺ Treg cells and to promote the conversion of naïve T cells into Tr1-like cells^[30]. At variance with classical Tr1 cells, the Tr1-like cells described in this study released IL-10, IL-4 and IFN- γ and suppressed T helper proliferation^[30]. The CD8 α ⁺ DC were capable of supporting Tr1-like cell differentiation also in the presence of a maturational stimulus, such as CpG, as reported for other tolerogenic, semi-mature DC preparations^[6,31].

DC expression of indoleamine 2,3-dioxygenase 1 and gut tolerance

Indoleamine 2,3-dioxygenase 1 (IDO1) is a tryptophan-catabolizing enzyme implicated in maternal allograft acceptance and in immune tolerance to tumors^[32-36]. IDO1 converts tryptophan into immune suppressive kynurenines that profoundly affect T-cell functions, promoting T-cell unresponsiveness, T-cell apoptosis and differentiation of Treg cells. IDO expression has been associated with CD103⁺ DCs in the gut LP and MLN of mice^[37]. Similarly, human intestinal CD11c⁺CD103⁺ DCs express higher levels of IDO mRNA compared with CD11c⁺CD103⁻ DCs. IDO inhibition of mouse CD103⁺ DCs with the D

isomer of 1-methyl-tryptophan (1MT) reduced the ability of IDO⁺ DCs to convert Treg cells and augmented the generation of IL-17-producing T cells. Mice treated with 1MT concomitant with adoptive transfer of OVA transgenic T cells and oral immunization with OVA led to a reduction in the frequency of Treg cells in the LP, PP and MLN. *Ido1*^{-/-} mice displayed a decreased percentage of Foxp3⁺ Treg cells in the LP and an almost double the proportion of IL-17⁺CD4⁺ and IFN- γ ⁺CD4⁺ T cells in the intestine compared with wild-type animals. Finally, *Rag1*^{-/-} mice injected with colitogenic T cells from C57BL/6 mice experienced more extensive gut inflammation and aggressive disease if treated with 1MT. Similar effects were demonstrated in mice with dextran sodium sulfate (DSS)-colitis, where 1MT administration worsened the mortality rate and colon shortening. Collectively, these experiments indicate that IDO may play a previously unappreciated and fundamental role in regulating gut inflammation through the control of Th1/Th17/Treg balance.

The expression of IDO in the murine gut may increase with age via an IFN- γ -dependent mechanism that involves commensal microorganisms^[38]. IDO-deficient mice have abnormally high levels of both IgG and IgA, a phenomenon driven by the commensal flora. IDO may then physiologically restrict B-cell responses to intestinal commensal bacteria. The elevated levels of IgG and IgA in IDO-deficient mice might in principle confer resistance to enteric pathogens such as *Citrobacter rodentium*, a gram-negative bacillus similar to human enteropathogenic *Escherichia coli*. When infected orally with *Citrobacter*, IDO-deficient mice appeared well throughout the course of the experiment, at variance with wild-type animals that had decreased activity, ruffled fur and hunched posture, and had attenuated gut colonization by the pathogen^[39]. IDO-deficient mice had reduced edema, inflammatory cell infiltration and epithelial damage in colonic tissue sections, associated with lower levels of TNF- α compared with wild-type mice. These observations point to IDO as a novel target to manipulate intestinal inflammation and to control diseases caused by enteric pathogens.

Crosstalk between DCs and intestinal epithelial cells

Intestinal epithelial cells (IECs) are a central component of the immune system of the gut. They express receptors for microbial-associated molecular patterns that activate signaling cascades leading to the production of antimicrobial products and chemokines^[40]. IECs can also recruit leukocytes to complement their barrier function or to participate in the activation of gut adaptive immune responses, including the production of IgA and the differentiation of effector Th1, Th2 and Th17 cells.

IECs are in close contact with LP DCs and have been shown to release molecules that influence DC functions. Thymic stromal lymphopoietin (TSLP) is a cytokine secreted by IECs under steady-state conditions and imparts a Th2-polarizing phenotype to DCs^[41]. IEC-derived factors also stimulate the expression of both chains of TSLP receptor on DCs, namely the common

IL-7 receptor α chain and the TSLP receptor, thus conferring the ability to respond to TSLP and to drive Th2 responses. Importantly, TSLP expression by primary IECs may be deregulated in a proportion of patients with IBD. The same study also showed that mRNA signals for TSLP are readily detected in IECs from healthy controls, although the protein is consistently below the detection limit by immunoprecipitation, unless IECs are challenged with bacteria such as *S. typhimurium*. TSLP has been detected in epithelial cells of the Hassall's corpuscles and activates myeloid CD11c⁺ DCs in the thymic medulla^[42]. These apparently mature DCs promote the development of Treg cells through a mechanism that requires peptide-MHC class II interactions, and the presence of CD80, CD86 and IL-2. Plasmacytoid DCs can be also activated by TSLP and become efficient generators of Treg cells from thymocytes through an IL-10-dependent mechanism^[43]. CD4⁺ T cells triggered through the T cell receptor, but not resting CD4⁺ T cells, respond to TSLP with robust proliferation and acquire sensitivity to low doses of IL-2^[44].

INTESTINAL DCs UNDER STEADY-STATE CONDITIONS AND IN EXPERIMENTAL COLITIS

DCs in the non-inflamed gut

Cells with antigen-presenting function within the intestine and associated lymphoid tissue include macrophages, conventional CD11c-expressing DCs and plasmacytoid DCs. Macrophages belong to a family of tissue cells that includes Kupffer cells in the liver and glial cells in the brain and have predominantly innate immune functions, such as capturing and killing of microbes, scavenging of apoptotic and dead cells, and production of regulatory cytokines^[45]. Macrophages are the most abundant population of phagocytic cells in the intestine. Distinctive characteristics have also been assigned to intestinal macrophages as compared with splenic macrophages or blood monocyte-derived macrophages. Early studies identified macrophages in the small and large intestine in the mouse, based on the expression of the F4/80 glycoprotein in association with CD11b^[46]. LP macrophages are detected in juxtaposition to CD4⁺ T cells and in close contact with the epithelium^[23,47]. CD11b⁺CD11c⁻ macrophages are scattered throughout the villus-tip axis of small and large intestine, express immune regulatory molecules such as programmed death ligand 1 (PD-L1) and PD-L2, and secrete IL-10 but not IL-12p40 or IL-12p70. They are hyporesponsive to Toll-like receptor (TLR) stimulation, suppress the differentiation of Th1 and Th17 cells, and promote the differentiation of Treg cells^[23]. Local macrophages may contribute to colitis development in IL-10^{-/-} mice^[48]. The pharmacological depletion of macrophages in this model of colonic inflammation ameliorated colitis, suggesting that IL-10 deficiency impedes the conditioning of macrophages, leading to macrophage-mediated destructive inflammatory responses.

Under steady-state conditions, the functional properties of the DC subpopulations vary according to their anatomical location. For instance, functional differences among DCs from PP, from MLN and from small intestinal and colonic LP have been reported. Within a single anatomical site, DCs can be distinguished and further subdivided according to their surface membrane phenotype. Under inflammatory conditions, DC recruitment to the intestine occurs, although it is presently unclear whether these DC populations are separate from DCs present in the steady-state or whether DCs arriving in the inflamed intestinal microenvironment acquire the ability to foster pro-inflammatory responses as a result of their exposure to pathogens and local inflammatory mediators.

LP DCs can be isolated in the absence of overt inflammatory stimuli and perform a tolerogenic function by constitutively migrating to the draining MLN, where they present antigen to T cells. The carriage of antigens from commensal bacterial strains to the MLN might be triggered by low-level production of pro-inflammatory cytokines. In this respect, the chemokine receptor CCR9 is crucial for the positioning of plasma cells^[49] and plasmacytoid DCs^[50] to the small intestine, suggesting that the chemokine CCL25/TECK may regulate DC homing during inflammatory processes. After their migration to the MLN, DCs interact with T and B cells and initiate immune responses aimed at maintaining a non-inflammatory state in the intestine. Intestinal DCs have been reported to promote the peripheral induction of FoxP3-expressing Treg cells from naïve T cells. Such Treg cells with specificity for commensal bacteria and dietary antigens may prevent naïve T cells from inducing pathological responses, thus complementing the pool of thymus-derived Treg cells. In this respect, gut-associated lymphoid tissue DCs may synthesize the vitamin A metabolite retinoic acid, that selectively induces CCR9 and $\alpha_4\beta_7$ integrin on CD8⁺ T cells with gut tropism^[51]. This phenomenon occurs more efficiently after oral as compared with intraperitoneal antigen administration, indicating differential DC targeting by the 2 immunization routes^[51].

CD103 is the α chain of the $\alpha E\beta 7$ integrin expressed by most mouse and human intestinal lymphocytes and mediating lymphocyte adhesion to E-cadherin-expressing intestinal epithelial cells. CD103-expressing DCs may also be required to induce gut-tropic effector T cells in the MLN^[51]. Interestingly, TGF- β plays a dominant role in CD103 induction on gut-tropic CD8⁺ T cells, as shown in a mouse model of post-transplantation graft-*versus*-host disease (GVHD) with T-cell infiltration of the intestinal epithelium^[52]. T cells from 2C T cell receptor-Tg mice that express a dominant negative TGF- β type II receptor were incapable of upregulating CD103 upon migration into the intestinal epithelium^[52]. In addition, CD103 expression on host-reactive CD8⁺ T cells was causally related to the development of GVHD pathology and mortality. Although TGF- β activity is present locally within the intestinal milieu, this study did not exclude the possibility that CD8 effectors encounter TGF- β and upregulate CD103 expression before their entry into the intestinal epithelium.

CD103^{-/-} T cells migrate into the host intestine but are retained much less efficiently than wild-type T cells, indicating that CD103 expression may also contribute to T-cell accumulation in the gut^[52]. In a T-cell transfer model of colitis, disease-inducing CD4⁺CD45RB^{high} T cells were shown to promote colitis development irrespective of their expression of CD103^[53]. However, anti-CD103 antibodies abrogated the suppression of colitis mediated by Treg cells. Further experiments suggested that CD103 expression by Treg cells was not essential for their function, indicating the requirement for CD103 on non-T host cells for protection from colitis^[53]. Of interest, ~50% of CD11c⁺ DCs in the MLN co-expressed CD103 at high density, at variance with ~30% of splenic DCs. Sorted CD103⁺ DCs activated the proliferation of allogeneic CD4⁺ T cells to a similar extent compared with the CD103⁻ counterpart but were potent inducers of CCR9 co-expression by day 4 of culture, suggesting their ability to impart gut tropism on T cells. In addition, CD103⁺ DCs were inefficient at inducing IL-10 and IFN- γ production by T cells. Collectively, this study suggested that DC subsets that are primed in the immunosuppressive environment of the gut may be unable to drive the release of pro-inflammatory cytokines such as IFN- γ , thus preventing the development of unwanted effector responses to ingested antigens. Another report by the same investigators has shown that CD103⁺ DCs isolated from the MLN may both induce *de novo* expression of Foxp3 in naïve T cells and maintain pre-existing Foxp3⁺ cells^[16]. The conversion of naïve T cells into Treg cells by CD103-expressing DCs was completely inhibited by anti-TGF- β antibodies, but further enhanced by exogenous TGF- β , so that provision of 1 ng/mL TGF- β to the T-cell/DC co-cultures translated into the expression of Foxp3 by ~50% of T cells^[16]. Even the provision of high concentrations of TGF- β to CD103⁻ DCs did not allow the generation of similar percentages of Treg cells to CD103⁺ DCs, suggesting that CD103⁻ DCs may lack an essential cofactor. Further experiments led the authors to identify retinoic acid as the cofactor for the TGF- β -driven conversion of Treg cells from naïve T cells. Compared with the CD103⁺ DCs, CD103⁻ DCs released higher amounts of pro-inflammatory cytokines (TNF- α , IL-6), and expressed higher levels of IL-23p19 and Tbet^[16]. Collectively, this study showed the existence of functionally distinct DC populations in the MLN of normal mice, with apparent diverging functions. A companion paper by Sun *et al.*^[54] has shown, both in a lymphopenic mouse transfer model and in an immunologically complete setting, that retinoic acid released by LP DCs promotes Treg conversion in the presence of TGF- β . The LP DCs expressed a CD8 α CD11c⁺ phenotype and displayed the morphologic features of conventional DCs, consisting of a stellar shape comparable to freshly isolated splenic DCs^[54].

LP DCs

The extensive phenotypic and functional characterization of mouse LP DCs so far pursued has revealed a greater complexity than previously appreciated. The majority of

LP DCs express a CD11b⁺CD8 α ⁻ phenotype, although CD11b⁻CD8 α ⁺ and CD11b⁻CD8 α ⁻ DCs have also been identified^[55]. Treatment of mice with Flt3 ligand increases the proportion of LP DCs without significantly altering the relative proportion of DC subsets, thus allowing the purification of a higher DC number for detailed functional analyses. Using this approach, some authors have shown that LP DCs are not fully mature *in situ* but they can be induced to differentiate in response to appropriate stimuli^[55]. LP DCs were also less efficient at stimulating OVA-specific T-cell proliferation *in vitro* when compared with splenic DCs, and mediated the development of tolerance when transferred to mice fed with OVA^[55]. LP DCs exhibited a unique cytokine profile, consisting of low levels of IL-12p40 mRNA associated with constitutive IL-10 and type I IFN production^[55]. A specialized subset of LP DCs with a CD8 α ⁺ phenotype has been identified in mice^[30]. Gut-derived CD8 α ⁺ DCs secrete IFN- α and support antigen-specific suppression mediated by CD4⁺CD25⁺ Treg cells. Furthermore, CD8 α ⁺ DCs favor the differentiation of Tr1-like cells that release high quantities of IL-10, IL-4 and IFN- γ upon activation with plate-bound anti-CD3 antibodies^[30]. The ability of CD8 α ⁺ DCs to induce Tr1-like cells was not affected by their exposure to maturation stimuli, as reported for other populations of maturation-resistant, tolerogenic DCs^[31].

Other LP DC subsets identified in mice include CD11b⁻CD103^{hi} and CD11b⁻CD103^{low} DCs. LP DCs can be further subdivided into CD11b⁻CD103^{hi}CX₃CR1⁻ DCs and CD11b⁻ DCs with different CX₃CR1 (fractalkine receptor) expression levels^[56]. The CD103^{hi}CX₃CR1⁻CD11b⁻ LP DCs originate through a DC-committed non-monocytic intermediate from MDP, a differentiation pathway that is driven by Flt3L. Conversely, CD103^{hi}CX₃CR1⁺CD11b⁺ LP DCs derive from Ly6C^{hi} monocytes and their derivation involves an extensive, granulocyte-macrophage colony-stimulating factor (GM-CSF)-driven local expansion in the mucosa. Importantly, mice that were persistently or transiently depleted of LP DCs neither developed spontaneous intestinal inflammation nor were susceptible to colitis development. In contrast, mice that harbored predominantly CD103^{hi}CX₃CR1⁺CD11b⁺ LP DCs developed severe colitis in response to a DSS challenge, as evaluated by colonoscopy and histological examination. This pro-inflammatory activity was dependent on TNF- α secretion with ensuing epithelial damage, and might also be regulated through IL-10/TGF- β production by the CD103^{hi}CX₃CR1⁻CD11b⁻ LP DC subset^[23]. This study highlighted the importance of a critical balance between LP DC subsets for tissue repair and gut homeostasis.

PP DCs

PP are the primary sites for the induction of immune responses in the intestinal mucosa and are representative of lymphoid follicles present in diffuse mucosal tissues. DCs from PP possess a unique capacity to induce T-cell responses that regulate systemic immunity through the release of IL-4 and IL-10 and that provide help for IgA B-cell differentiation. It has been shown that PP DCs

reside in different anatomical sites, with CD11b⁺CD8 α ⁻ DCs being localized in the subepithelial dome, CD11b⁻CD8 α ⁺ in the interfollicular regions and CD11b⁻CD8 α ⁻ [double-negative (DN) DCs] in both compartments^[57]. The DN DCs constitute approximately 30% of PP DCs, are interspersed within the follicle-associated epithelium, with processes extending to the luminal surface, and occasionally associated with M cells within the M-cell pocket^[58]. DN DCs express intracellular MHC molecules, indicating their immaturity, and secrete IL-12p70, suggesting functional similarity to the lymphoid DC subset^[58]. Collectively, these studies indicate that DN DCs should be able to induce Th1 differentiation, at variance with myeloid DC subsets that have been implicated in IL-10 release and in skewing the immune response towards a Th2 profile. It has been proposed that orally delivered antigens may initially encounter the myeloid and DN DCs located underneath or within the follicle-associated epithelium. As a result of feeding with low-dose antigen, antigen uptake by the DCs would not result in DC activation and migration but rather in the differentiation of Th2 or Th3 cells with regulatory properties. The T cells interacting with antigen would then secrete IFN- γ in the absence of activation signals by the DN DCs, thus becoming anergized. If soluble protein antigen is given at high dose, T-cell activation would occur in the PP and LP as a result of DC stimulation and migration to the interfollicular regions or the MLN. In this scenario, IL-10 produced by the myeloid DCs may serve to control detrimental inflammation induced by microbial antigens, whereas DN DCs and lymphoid DCs may be acting as the primary source of IL-12 for the induction of Th1 responses^[58].

DCs in experimental colitis

The availability of mice expressing the diphtheria toxin receptor under the control of the *Cd11c* promoter has allowed the selective depletion of DCs and the study of DC role in the development of intestinal inflammation. DC ablation has been correlated with the amelioration of DSS-induced colitis^[59]. DSS-stimulated bone marrow-derived DCs release high quantities of proinflammatory cytokines and chemoattractants *in vitro*. Furthermore, DC adoptive transfer exacerbated disease manifestations, whereas DC ablation attenuated disease severity as shown by histological examination of tissue sections. However, DC activation with TLR9 ligands before colitis induction with DSS exacerbated disease manifestations. Since DSS injures the colonic epithelium, it is conceivable that, at least in this model, DCs exerted protective effects through stimulating repair of colonic epithelial cell layers rather than modulating the immune response.

There is evidence that DCs may play both protective and detrimental roles in intestinal pathology. In DSS colitis, an experimental model resembling acute colitis, DC ablation during DSS administration ameliorated disease manifestations^[60]. Conversely, colitis was exacerbated if DCs were ablated before DSS treatment, suggesting that DCs are protective in initial phases of colitis but play a pathogenic role during the disease course^[60].

In a T-cell transfer model of colitis induced by CD45R-B^{hi}CD4⁺ T cells, transplanted T cells formed aggregates with sub-epithelial CD11c⁺ DCs in the MLN^[61]. Blocking OX40-OX40L interactions prevented the development of colitis. DC activation *via* CD40 has been reported to cause colitis in the absence of T and B cells and through a cytokine-dependent mechanism^[62].

Intestinal inflammation is correlated with significant changes in the cellular composition of the colonic LP. Gut inflammation in mice is accompanied by a marked infiltration of CD11c⁺ DCs within the LP^[63]. From a phenotypic standpoint, these DCs express high levels of CD80 and resemble mature activated DCs, while secreting low levels of IL-10 and IFN- α . Of interest, CD103⁺ DCs were dramatically reduced in the LP of colitic mice but were detectable in the spleen, suggesting that intestinal CD103⁺ DCs may migrate to lymphoid organs during inflammation.

The observation that IL-10-deficient and TGF- β -deficient mice develop spontaneous colitis point to IL-10 and TGF- β as important determinants of DC function in the gut. In a T-cell transfer model of colitis, Treg production of IL-10 was dispensable for disease suppression but IL-10 secreted by LP CD11b⁺ macrophages was crucial to maintain FoxP3 expression in Treg cells^[28]. It is conceivable that intestinal bacteria are a fundamental trigger of IL-10 production by LP macrophages through the activation of TLR signaling. It is presently unknown whether IL-10 signals are also required to maintain FoxP3 expression in Treg cells from other organs during inflammation^[29]. Serum IL-10 is reportedly normal in patients with IBD^[64]. However, LP mononuclear cells are impaired in the ability to release and respond to IL-10^[64], suggesting that IL-10 provision might be beneficial in human IBD through effects on the DC compartment^[65].

DCs IN HUMAN IBD

DCs accumulate at sites of inflammation in patients with IBD, whereas both myeloid DC and pDC populations are depleted in the peripheral blood of patients with active disease. DC recruitment to the gut may be the result of an increased expression of chemokines such as CCL20 or of addressins, such as mucosal vascular addressin cell adhesion molecule-1 (MAdCAM-1). CCL20 is a nuclear factor- κ B-regulated molecule that mediates the CCR6-dependent recruitment of DCs and T cells to mucosal surfaces. CCL20 has been detected at increased levels in the mucosal epithelium covering lymphoid follicles in patients with both types of IBD, in proximity to CCR6-expressing cell types, such as langerin⁺ DC, B cells and memory T cells^[66]. Phenotypically heterogeneous populations of DCs have been identified in colonic tissues and MLN from patients with IBD^[67]. One population consists of immature DCs expressing DC-specific intercellular adhesion molecule-grabbing non-integrin (SIGN) and mainly located at antigen-capturing sites in the mucosa and medullary cords. A second population expresses CD141 and has a similar localization as that of DC-SIGN⁺ DCs. The third DC subset consists of mature DCs expressing S-100 and

CD83 and is located in the T-cell areas in both the colonic lymphoid follicles and the MLN. In contrast, pDCs were hardly detected in the colon and MLN. The fraction of circulating DC precursors has been found to correlate with established IBD activity indices^[68]. Specifically, higher percentages of pDC and myeloid DCs were measured during disease remission compared with acute flares, suggesting DC migration to secondary lymphoid organs. In line with this hypothesis, DC precursors from patients with IBD expressed α 4 β 7, a gut-homing integrin marker and receptor for MAdCAM-1 also detected on LP T cells^[69]. Importantly, immature DCs are significantly reduced in active IBD, indicating that potentially tolerogenic DC subsets may be defective during disease reactivation.

M-DC8⁺ DCs have been detected in the subepithelial dome of ileal PP from 3 patients with untreated CD^[70]. In one of these patients, an ileal biopsy performed 6 mo after glucocorticoid-induced clinical remission documented the complete disappearance of M-DC8⁺ DCs from the ileal mucosa. The observation that M-DC8⁺ DCs secrete large amounts of TNF- α but not IL-10 upon stimulation with lipopolysaccharide (LPS) suggests that these cell types might contribute to the pathogenesis of IBD^[70].

Colonic CD11c⁺ DCs from patients with either CD or UC express higher levels of TLR2 (interacting with peptidoglycan and bacterial lipoproteins), TLR4 (a receptor for LPS) and CD40 compared with non-inflamed CD tissues and tissues from healthy controls^[71]. This may lead to enhanced recognition of bacterial products and an increased response to them. Importantly, treatment with TNF- α blocking antibodies translated into the downregulation of CD40 expression on DCs, irrespective of resolution of inflammation at the tissue level. Also, production of IL-6 and IL-12 at the single-cell level was increased in DCs from patients with CD but not with UC compared with healthy controls.

Although the DC abnormalities documented in UC generally resemble those evidenced in CD, differences may exist when comparing these 2 major forms of IBD. Epstein-Barr virus-induced gene 3 (EBI3) encodes a secreted protein that shares 27% amino acid sequence identity with IL-12p40. EBI3 can substitute for p40 to form a heterodimer with IL-12p35, and is an IL-27 subunit^[72]. EBI3 expression is upregulated by macrophage/DC-like cells within the LP of patients with active UC but not CD^[73]. These data are consistent with a scenario in which EBI3 opposes the IL-12p40/p35 heterodimer and downregulates the cytotoxicity promoted by IL-12. In addition, this study reinforced the view that macrophages and DCs serve more than one role in the pathogenesis of IBD, being either protective or detrimental.

DCs AS TOOLS AND TARGETS FOR THERAPY IN IBD

Different approaches have been proposed to restore and/or enhance the tolerogenic properties of DCs, including *in vitro* treatment with growth factors and use of drugs that target DC number and/or function (Figure 2)^[74,75].

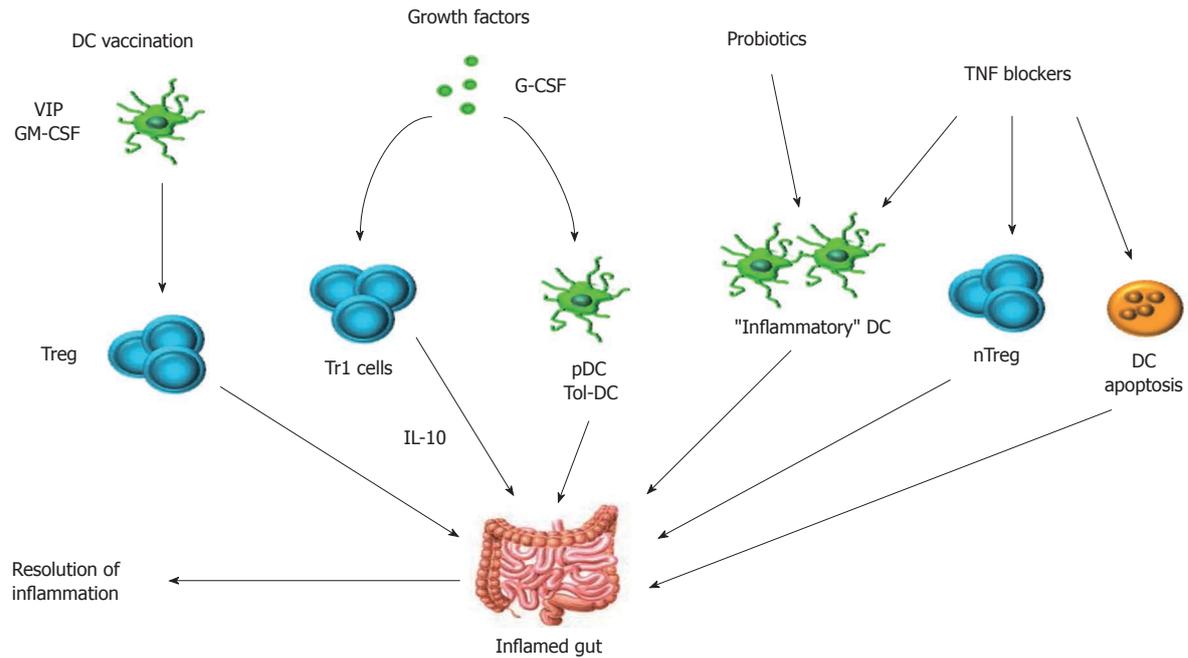

Figure 2 Potential strategies to modulate dendritic cell functionality in human inflammatory bowel disease. *In vitro* differentiated tolerogenic dendritic cell (DC) have been administered to mice with inflammatory/autoimmune disorders. Vasoactive intestinal peptide (VIP) has a unique ability to skew DC function towards a tolerogenic profile and has been used to vaccinate animals with colitis, rheumatoid arthritis and post-transplantation graft-versus-host disease^[76,77]. Selected growth factors have shown to modulate immune reactivity *in vivo*. For instance, granulocyte colony-stimulating factor (G-CSF) has been successfully given to patients with Crohn's disease, leading to accumulation of pDC in the lamina propria and increase in IL-10 production, with favorable repercussions on disease manifestations^[89]. GM-CSF: Granulocyte-macrophage colony-stimulating factor; IL: Interleukin; TNF: Tumor necrosis factor.

Adoptive transfer of cytokine-modulated DCs

DCs have been targeted in animal models of intestinal inflammation. Regulatory DCs differentiated with vasoactive intestinal peptide (VIP) and GM-CSF (DC-VIP) have been transferred to BALB/c mice with colitis induced by trinitrobenzene sulfonic acid (TNBS), a Th1-mediated disease requiring T-cell activation with subsequent macrophage recruitment and activation^[76]. Mice received the DC preparations either 8 h after TNBS instillation or 6 d after colitis induction in order to assess their therapeutic effects both on colitis induction and on established disease. DC infusion ameliorated disease severity and histopathology, being associated with inhibited Th1 responses and with the *in vivo* differentiation of IL-10-producing Treg cells. DC-VIP decreased the production of proinflammatory cytokines both systemically and locally, and deactivated spleen macrophages, blunting the *in vitro* production of TNF- α and IL-12 in response to LPS challenge. Importantly, DC-VIP augmented the number of TGF- β /IL-10-secreting CD4⁺ T cells within LP mononuclear cells cultured in the presence of colonic proteins extracted from colitic mice. Also, CD4⁺ T cells obtained by the MLN of DC-treated mice suppressed proliferation and IL-2 production by autoreactive CD4⁺ T cells in response to colonic proteins. These CD4⁺ T cells were also capable of reversing the body weight loss which is characteristic of TNBS-induced colitis when transferred to colitic mice, suggesting the acquisition of a potent regulatory activity after their *in vivo* encounter with DC-VIP. Finally, the therapeutic effect of CD4⁺ T cells was dependent on TGF- β

and IL-10 production, being reversed by *in vivo* blocking of these cytokines. This elegant study suggests that *in vitro* conditioning of DC preparations with VIP and self-antigens might be pursued as therapeutic strategy in colitis and possibly other inflammatory disorders^[77,78], also to minimize patients' dependence on non-specific immune suppressive drugs currently in use for human IBD.

TGF- β 1 gene-modified immature DCs with enhanced tolerogenicity undergo efficient transport to inflamed colonic tissues and delay the progression of murine IBD induced by DSS^[79]. DC injections in mice with established colitis alleviated weight loss and reduced intestinal bleeding, translating into a lower disease activity index compared with control DC or untreated mice. DC vaccination was associated with increased Treg numbers in the MLN and with increased TGF- β 1 levels in mouse colon tissues^[79].

Probiotic bacteria

Probiotics, mainly belonging to the lactic acid bacteria (LAB) family, exert beneficial effects in human or animal health and are presently considered as peace-keepers in the gut^[40,80]. The regular intake of probiotic bacteria may contribute to immune homeostasis by altering microbial balance or by interacting with intestinal immune cells. Dysbiosis, namely, an imbalance between pro-inflammatory and anti-inflammatory bacteria in favor of the former, may have a causative role in patients with IBD. Probiotics have been tested both in animal models of colitis and in patients with IBD. The potential mechanisms of action of probiotic bacteria include their interaction with

TLR and DCs in the gut. The demonstration of anti-inflammatory effects after systemic administration of probiotics suggests that regulatory cell populations may be induced distant from the site of inflammation^[81].

Importantly, probiotics may present strain-specific *in vitro* immune modulating actions, that are strictly correlated with their *in vivo* anti-inflammatory effects. For instance, *L. salivarius* Ls33 and *L. rhamnosus* Lr32 possess high immunoregulatory capacities and efficiently protect from murine TNBS-induced colitis, at variance with other strains such as *L. acidophilus* NCFM and *L. lactis* MG1363 that exhibit an opposite immunological profile^[82]. The protective effect of probiotic-treated DCs was attributed to a downregulation of proinflammatory mediators such as IL-12 and IL-17, paralleled with an acute overexpression of IFN- γ and IDO^[82]. Of interest, pre-formed naturally occurring Treg cells were required for the protective effect of probiotic-treated DCs, as shown by experiments with an anti-CD25 rat monoclonal antibody.

The probiotic mixture designated IRT5 contains 5 different probiotic strains. IRT5 has been shown to induce T-cell and B-cell hyporesponsiveness when administered for 20 d to mice by the oral route^[83]. Even more intriguingly, IRT5 increased FoxP3 expression in MLN as a result of the enhanced conversion of naïve T cells into Treg cells and the augmentation of the suppression function of pre-existing natural Treg cells. These effects were mediated through the promotion of DC tolerogenic activity, with high expression of IL-10, TGF- β , IDO and COX-2 mRNA. IRT5 retarded the progression of TNBS-induced colitis and was also efficacious in other immune-mediated disorders, such as atopic dermatitis and collagen-induced arthritis. Both the atopic ear and the inflamed colon of IRT5-treated mice were enriched with FoxP3-expressing Treg cells, likely as a result of increased tissue levels of CCL1 and CCL22, chemokines involved in Treg attraction.

The probiotic mixture VSL#3, which contains 8 different bacterial strains and is clinically beneficial in human IBD and pouchitis, has been reported to downregulate IL-12 and upregulate IL-10 production by human blood and colonic LP DCs in a dose-dependent fashion^[84]. This change in DC functional polarization translated into the inhibition of *in vitro* generation of Th1 cells from allogeneic CD4⁺ T cells.

A comprehensive analysis of previously published studies detailing the activity of different probiotics in animal models of colitis suggests that the colitis model used may affect the results^[85]. An interesting study has evaluated the ability of 3 *Lactobacilli* strains (*plantarum*, *LGG* and *paracasei* B21060) to activate DCs either directly or indirectly through epithelial cells. While inducing similar degrees of DC phenotypic maturation, the different strains elicited differential cytokine release, with *L. paracasei* inducing lower levels of IL-12p70, TNF- α and IL-10. The lactobacilli also affected epithelial cell function, and supernatants of *L. paracasei*-treated epithelial cells drastically reduced the ability of DCs to activate T cells and drive their polarization towards a Th1 pheno-

type. Finally, the *in vitro* activity of probiotics was predictive of their *in vivo* efficacy in an acute model of colitis. Taken together, these studies indicate that probiotics interact both with immune cells and with non-immune cells and that the clinical use of individual bacterial strains should be proposed and recommended only after taking into account *in vitro* immunostimulatory or immunoregulatory activity.

Immune modulating drugs

Granulocyte-CSF (G-CSF) has remarkable immune modulating activities^[86]. Indeed, G-CSF mobilizes DC2, differentiates tolerogenic DCs *in vitro* through IL-10 and IFN- α , and polarizes naïve T cells to a Tr1-like functional profile^[31,87,88]. G-CSF has been administered to patients with CD in order to modulate immune reactivity and induce potential clinical benefit^[89]. Nine patients with active CD received subcutaneous G-CSF for 28 d at 5 $\mu\text{g}/\text{kg}$ of body weight. Six patients reported improvement in the CD activity index (CAI) and achieved either a clinical response (4 patients) or remission (2 patients). The 3 non-responding patients had a longer duration of disease, had had bowel resections and one was the only CD patient with active fistulae. In responder patients, IL-10 production by isolated memory CD4⁺ T cells was significantly higher at the end of G-CSF treatment compared with non-responders. Conversely, IFN- γ production in post-G-CSF peripheral blood samples was significantly higher in non-responders. G-CSF also affected the relative proportion of circulating myeloid DCs and pDCs, inducing a decrease in the myeloid DC-to-pDC ratio in responding patients. Notably, 4 patients in the responder group showed an increase in LP CD123⁺ DCs^[89]. In sharp contrast, accumulation of CD123⁺ pDCs could not be evidenced in the LP of non-responders. Finally, the percentage of FoxP3-expressing cells within LP CD25⁺ cells decreased significantly in non-responders at the end of treatment. In line with this, the fraction of CD25^{hi}FoxP3⁺ cells increased in the LP of responding patients at the end of treatment, although these differences failed to achieve statistical significance. Collectively, this study provided proof-of-principle in favor of IL-10-mediated immune regulation by G-CSF in patients with IBD and suggested that treatment with this cytokine may translate into disease control. G-CSF at 3 $\mu\text{g}/\text{kg}$ of body weight was also highly effective at controlling an UC-like syndrome in a 23-year-old patient with glycogen storage disease Ib^[90]. G-CSF therapy was maintained for 16 years, with good control of gastrointestinal symptoms and dramatic improvement of colon histology.

There is evidence that TNF- α antagonism translates into changes in DC function. Although this has been primarily shown in patients with rheumatoid arthritis, it is likely that modifications of DC functions by TNF blockers may also impact on the clinical manifestations of IBD. Both etanercept and adalimumab were shown to downregulate CD83, CD80 and CD86 expression on monocyte-derived DCs and to reduce their T-cell stimula-

tory capacity^[91]. Anti-TNF-treated DCs polarize T-cell responses *in vitro* and favor T-cell release of IL-10, IL-4 and IL-17. Although no correlation was found between the clinical response to TNF blockade and the functional modulation of DCs *in vitro*, DCs derived from patients with rheumatoid arthritis given TNF blocking agents enhanced T-cell production of IL-10, while decreasing the release of IL-4, IL-17 and IFN- γ . Infliximab may also suppress the antigen-presenting capacity of DCs derived from patients with psoriasis by reducing the expression of CD1a and costimulatory molecules, an effect that is not reversed by LPS^[92].

Mesenchymal stromal cells

Mesenchymal stromal cells (MSC) are cells endowed with multi-lineage differentiation capacity and have been isolated from bone marrow, adipose tissue, amniotic fluid, placenta and umbilical cord blood. MSC affect both innate and adaptive immune responses and have reduced immunogenicity, thus being a promising therapeutic tool for inflammatory, autoimmune and degenerative diseases^[93]. Adipose tissue-derived MSC have been shown to ameliorate experimental colitis through the promotion of IL-10 release with subsequent inhibition of activated macrophages and differentiation of Treg cells^[94]. Importantly, the intrafistular injection of *in vitro*-expanded MSC (median number: 64×10^6 for each patient) has resulted into sustained complete closure of fistula tracks, reduction of perianal disease activity index, and with rectal mucosal healing in 10 patients with CD^[95]. Intriguingly, the percentage of mucosal and circulating Treg cells significantly increased during treatment and remained stable until completion of the 12-mo follow-up period. T cells isolated from the inflamed mucosal areas released higher amounts of IL-10 when co-cultured with MSC *in vitro*. Based on previously published data on the ability of IL-10 to skew DC differentiation towards a tolerogenic profile^[96,97], it is tempting to speculate that MSC therapy may target pro-inflammatory DCs *in vivo*, through the promotion of IL-10 release by colitogenic T cells.

Based on the experience reported in patients with GVHD^[98], MSC have also been infused intravenously, at a dose of $1-2 \times 10^6$ cells/kg of body weight, in 10 patients with chronic active CD, refractory to all currently available medical therapeutic options^[99]. Although MSC-based therapy did not induce clinical remissions as defined by a CDAI < 150, reductions of 70 points in CDAI were recorded in 3 patients. The biological effects of MSC intravenous infusion included a trend towards higher percentages of CD4⁺CD127⁺ *bona fide* Treg cells. *In vitro*, patient-derived MSC inhibited the proliferation of autologous peripheral blood mononuclear cells and decreased their production of TNF- α . Collectively, the studies published so far demonstrate that MSC from patients with CD can be expanded *in vitro* and may induce favorable therapeutic effects *in vivo*, including differentiation of Treg cells, and possibly functional inhibition of DCs within the inflamed gut.

CONCLUSION

It is now clear that DC activation is a contributing factor in generation of IBD, as indicated both by mouse models of gut inflammation and by human disease. The recent advances in the phenotypic and functional characterization of DC populations in humans have unveiled a remarkable and previously unappreciated heterogeneity within the DC compartment but have also led to the identification of potential targets for therapeutic manipulation. A thorough understanding and knowledge of DC subsets and functionality in humans is a prerequisite for delivering interventions aimed at correcting DC malfunctioning. Several other cell types with APC function cooperate to ensure appropriate immune responses in the gut. They include IEC, basophils, MSC and other non-immune cells^[10,41]. Theoretical strategies to interfere with DC activity include vaccination with gene-modified DCs or cytokine-treated DCs to restore tolerance, growth factor administration, therapy with DC-modulating drugs, and use of probiotics. The impact of TNF blocking antibodies on DC functions needs to be further investigated. Some of these approaches have been successfully applied to animal models of gut inflammation and other autoimmune/inflammatory disorders such as multiple sclerosis and arthritis. In this respect, “tolerogenic vaccination” with cytokine-modulated DCs may hold promise for the treatment of intestinal inflammation. However, there is a theoretical concern that tolerogenic DCs suppress beneficial anti-infective and anti-tumor responses, in addition to unwanted immune reactivity. These issues must be carefully addressed before this approach is translated into the clinic. Studies in murine GVHD are somehow reassuring, having clearly indicated that the injection of cytokine-treated DCs preserves CD8⁺-mediated cytotoxic responses against leukemia while blunting GVH reactivity^[100,101]. Finally, the patient categories that may benefit from DC-based therapeutic approaches need to be identified. It should be emphasized that other cell-based interventions such as the intravenous infusion of MSC have not induced any clinical remission in severe refractory CD^[99]. Conceivably, patients with IBD should be offered DC-centered treatments earlier in the disease course, following patient profiling and stratification on the basis of molecular predictors for complicated disease (genetic markers such as NOD2 homozygous or compound heterozygous, and anti-microbial antibodies) as well as clinical features at diagnosis^[102]. There is evidence from both pediatric and adult IBD that treatment of short-duration CD with TNF antagonists is associated with better response and remission rates^[103,104]. Whether DC-based approaches have the potential to slow disease progression and alter the natural history of IBD will hopefully be determined in the near future.

Abstract

The spleen could be considered a neglected organ. To date, it has been deemed an ancillary organ in portal hypertension or an organ localization in lymphoproliferative diseases, even though it has had significant attention in infectious diseases for some time. Now, it is thought to be central in regulating the immune system, a metabolic asset and involved in endocrine function with regard to nonalcoholic fatty liver disease. The main mechanisms involved in this complex network will be critically discussed in this article.

SCENARIO

Due to the view that the “spleen is useless”, research on this organ has lagged behind that of other organs. Since 1952, when King and Schumacker reported overwhelming post-splenectomy infection^[1], there has been a growing recognition of the importance of the spleen in the human body. On the other hand, physicians often encounter spleen enlargement, i.e., splenomegaly which is almost always a consequence of other disorders. Hypersplenism is a secondary process that can arise from splenomegaly of almost any cause. In recent years, following in-depth studies of spleen organization and structure, cell function, secretion and innervations, a better understanding of the function of the spleen has been gained. It was initially accepted that the spleen not only filters blood but is an important regulation center of the body’s immune-metabolic-endocrine network. However, a number of questions have arisen: Is the spleen a player or a bystander, and what are the roles of some cytokines, adipokines/growth factors and neurotransmitters in this complex mechanism? In other words, what is the contribution of the spleen to non-alcoholic fatty liver disease, is it a further expression of Metabolic Syndrome^[2]?

ANATOMY

The spleen, in healthy adult humans, is approximately 11 cm (4.3 in) in length. It usually weighs 150 g (5.3 oz)

Anatomy	Composition
Red pulp	“Sinusoids” which are filled with blood “Splenic cords” of reticular fibers “Marginal zone” bordering on white pulp
White pulp	Nodules, called Malpighian corpuscles, containing “lymphoid follicles” rich in B-lymphocytes “periarteriolar lymphoid sheaths”, plenty of T-lymphocytes

and lies beneath the 9th to the 12th thoracic ribs. The spleen is an intraperitoneal organ with a smooth serosal surface and is attached to the retro-peritoneum by fatty ligaments that also contain its vascular supply. The splenic surfaces are described relative to their locations and are termed the diaphragmatic (phrenic) and visceral surfaces. The visceral surface is divided into an anterior or gastric ridge and a posterior or renal portion. The splenic hilum is directed antero-medially. The splenic artery and vein emerge from the splenic hilum in the form of six or more branches; the splenic artery is remarkable for its large size and tortuosity. The splenic artery is slightly superior to the vein. The spleen is part of the lymphatic system. The germinal centers are supplied by arterioles called penicilliary radicles. The spleen is derived from mesenchymal tissue (Table 1).

SPLEEN FUNCTION

Immune function (through phagocytosis, but also through T cell-mediated immunity and B cell-mediated humoral immunity) is the most important function of the spleen (Table 2). A current paradigm states that monocytes circulate freely and patrol blood vessels but differentiate irreversibly into dendritic cells (DCs) or macrophages upon tissue entry. Recently, it was shown that bona fide undifferentiated monocytes reside in the spleen and outnumber their equivalents in the circulation. The reservoir monocytes assemble in clusters in the cords of the subcapsular red pulp and are distinct from macrophages and DCs. In response to ischemic myocardial injury, splenic monocytes increase their motility, exit the spleen en masse, accumulate in injured tissue, and participate in wound healing. These observations uncover a role for the spleen as a site for storage and rapid deployment of monocytes and identify splenic monocytes as a resource that the body exploits to regulate inflammation^[3]. The spleen plays a complex role in tumor immunity, which changes in the different periods of cancer^[4]. The initiation of T-cell immune responses requires professional antigen-presenting cells. Emerging data point towards an important role for macrophages (Mphi) in the priming of naïve T cells. In this study we analyzed the efficiency and the mechanisms by which Mphi derived from spleen (Sp-Mphi) or bone marrow (BM-Mphi) present lymphocytic choriomeningitis virus antigens to epitope-specific T cells. It was demonstrated that because of phagosomal

Red pulp	Extramedullary hematopoiesis if required Facilitating an environment wherein erythrocytes rid themselves of solid waste material Blood filter for foreign material and damaged and senescent blood cells Storage site for iron, erythrocytes, platelets, plasmablasts and plasma cells Rapid release of antigen-specific antibodies into the circulation produced by red pulp plasma cells Defense against bacteria using iron metabolism by its macrophages
White pulp	T cell zone (periarterial lymphatic sheath) and B cell zone (follicles) Storage site for B and T lymphocytes Development of B and T lymphocytes upon antigenic challenge Release of immunoglobulins upon antigenic challenge by B lymphocytes Production of immune mediators involved in clearance of bacteria such as complement, opsonins, properdin and tuftsin
Marginal zone	Phagocytosis of circulating microorganisms and immune complexes by MZ macrophages Development of marginal zone B lymphocytes upon TI-2 antigenic challenge Blood trafficking of B and T lymphocytes Release of immunoglobulins upon antigenic challenge by splenic B lymphocytes

maturation, Sp-Mphi downregulate their ability to cross-present cell-associated, but not soluble, antigens, as they are further differentiated in culture without altering their capacity to directly present virus antigens after infection. Authors proposed that Sp-Mphi are extremely efficient at direct and cross-presentation. However, if these cells undergo further M-CSF-dependent maturation, they will adapt to be more scavenger and phagocytic and concurrently reduce their cross-presenting capacity. Accordingly, Sp-Mphi can have an important role in regulating T-cell responses through cross-presentation depending on their differentiation state^[5]. The spleen is one of the centers of activity of the reticulo-endothelial system and can be considered analogous to a large lymph node, as its absence leads to a predisposition toward certain infections. Other functions of the spleen are the production of opsonins^[6], properdin^[7], and tuftsin^[8], as well as the creation of red blood cells. While the bone marrow is the primary site of hematopoiesis in the adult, the spleen has important hematopoietic functions up until the fifth month of gestation. After birth, erythropoietic functions cease, except in some hematologic disorders. As a major lymphoid organ and a central player in the reticuloendothelial system, the spleen retains the ability to produce lymphocytes and, as such, remains a hematopoietic organ. In horses, roughly 30% of red blood cells are stored in the spleen. These red blood cells can be released when needed^[9]. In humans, the spleen does not act as a reservoir for red blood cells but it can store platelets in case of an emergency. Platelets are major carriers of serotonin (5-HT) in the blood^[10]. 5-HT has been reported to modulate T cell and natural killer (NK) cell proliferation. This aspect

was clearly elucidated by studies on cultures of mouse and rat spleen cells. Results showed that serotonin up-regulates mitogen-stimulated B lymphocyte proliferation through 5-HT_{1A} receptors, thus providing an important link between this neurotransmitter and the immune system^[11]. Another study using RT-PCR methods to examine the mRNA expression of 5-HT receptors in the cells of lymphoid tissues of the rat (*ex vivo* isolated spleen, thymus, and peripheral blood lymphocytes) confirmed 5-HT receptors (5-HT_{1B}, 5-HT_{1F}, 5-HT_{2A}, 5-HT_{2B}, 5-HT₆, and 5-HT₇) in mitogen-stimulated spleen cells. In contrast, 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2C}, 5-HT₄, 5-HT_{5A}, and 5-HT_{5B} mRNAs were not detected in any of the examined cell populations^[12]. The role of platelets and serotonin was recently highlighted as novel contributors in the mechanisms of liver regeneration after partial hepatectomy^[13]. Furthermore, platelets are attracted to the liver following systemic inflammatory stimuli^[14].

ASSESSMENT OF SPLEEN FUNCTION

Patients with impaired splenic function are difficult to identify^[15]. IgM memory B cells are a potential parameter for assessing splenic function^[16]; however, more studies are necessary for its validation. The detection of Howell-Jolly bodies does not reflect splenic function accurately^[17], whereas determining the percentage of pitted erythrocytes is a well-evaluated method and seems a good first-line investigation for assessing splenic function^[18]. When assessing spleen function, (99m)Tc-labeled, heat-altered, autologous erythrocyte scintigraphy with multimodality single photon emission computed tomography (CT)-technology is the best approach, as all facets of splenic function are evaluated^[19].

THE BLOOD-SPLEEN-BARRIER

The blood-spleen-barrier (BSB) is a barrier composed of macrophages and endothelial cells of the marginal sinus. Their basement membrane is composed of reticular tissue (reticular cells and reticular fibers) and collagen fibers. It can regulate splenic filtration and its intrasplenic consequences including blood flow, cell homing and migration, hematopoietic and immune responses, and clearance of infectious organisms. Here, the cells of the barrier can trap circulating infectious organisms and monocytes on their cell surfaces, clearing them from the blood and providing a selective environment for monocyte differentiation into macrophages and subsequent phagocytosis of the microorganisms. The interactions between the circulating lymphocytes and the macrophages may regulate the entry of lymphocytes into the white pulp. Thus, the functions of the BSB are to filter antigens, to keep the microenvironment of the white pulp stable, and to present antigen information to white pulp through the effects of the mechanical barrier, which depends on the connection between cells and the phagocytosis of macrophages. Compared to other biological barriers in the human body, such as the blood-brain barrier and the blood-thymus barrier, the structure of the BSB is relatively

loose without the tight junction between cells; however, the BSB has more constituents and ability to stop and phagocytize more xenobiotic materials than other barriers^[20,21]. As compared to the normal spleen, the density of macrophages in the portal hypertension (PH) spleen was decreased, but the macrophages were mainly located in the marginal zone and distributed around the splenic corpuscle, with many villi and pseudopodium-like protrusions on the cell surface. The accretion of collagen fibers was obvious around the splenic corpuscle and central artery. The increased reticulate fibers encircled the splenic corpuscle with more connection between the fibers. The vascular endothelial cells were in diffused distribution, without any regionality in PH spleen, but the vessel with enlarged lumina increased in red pulp^[22].

THE OLD PLAYER

Except for malaria and genetic metabolic diseases (e.g., Gaucher disease), splenic enlargement can be caused by diseases such as PH, lymphoma and leukemia. PH is considered the most common cause of splenomegaly in Western countries. Previous findings showed that splenomegaly is secondary to PH with associated liver cirrhosis. In fact, the increase in the width of the celiac axis in cirrhotic patients with PH was closely related to the increased width of the splenic artery which in turn was related to enlargement of the spleen, and increased blood flow through the spleen. The increased size of the spleen is due partly to venous engorgement and partly to reticulo-endothelial cell hyperplasia, and is accompanied by an increased total blood supply, although flow per 100 g tissue is often reduced. An increase in blood flow can not occur without dilatation of the entire splenic arterial tree (Pousselle's law) and in keeping with this are the studies of^[23], using injected spleen casts, which showed an increased number of peripheral arterioles of 100 mm diameter. In addition to local factors, circulating vasodilator substances may sometimes have an additional effect. The cardiac output is often raised, the blood flow through skin and muscle is also increased, and there is evidence of an increased number of small peripheral arterioles in the lungs. All these findings show that a generalized vasodilatation may occur in some patients with cirrhosis. Increasing tortuosity of peripheral vessels is a well-known accompaniment of aging, but in cirrhotic patients there was no relationship between tortuosity and either age or length of history. The increased length and tortuosity of the splenic artery is probably a secondary effect of arterial dilatation, although there was no direct relationship either to total splenic blood flow or size of the spleen. This was particularly striking in patients with tropical splenomegaly who had enormously enlarged spleens, increased blood flows, but splenic arteries of normal length^[24]. Currently, there is controversy on the immune function of enlarged spleen in patients with PH and hypersplenism. As compared to the normal spleen, the density of macrophages in the PH spleen was decreased, but the macrophages were mainly located in the marginal zone and distrib-

uted around the splenic corpuscle, with many villi and pseudopodium-like protrusions on the cell surface. The “accrementation”, i.e., growth by addition of similar collagen fibers, was obvious around the splenic corpuscle and central artery. The increased reticulate fibers encircled the splenic corpuscle with more connection between the fibers. The vascular endothelial cells were in diffused distribution, without any regionality in PH spleen, but the vessel with enlarged lumina increased in red pulp. Those morphological changes of the BSB may be one of the pathological fundamentals for the abnormality of immune function and the increased destruction of blood cells located in the spleens of patients with PH^[22].

Lymphoma is the commonest malignant tumor of the spleen. Although a number of lymphomas and leukemias can involve the spleen and may present clinically with splenomegaly, only the B cell disorders SMZL and hepato-splenic γ/δ T cell lymphoma can be considered true primary splenic lymphomas^[25]. It is important to detect splenic involvement because it can alter the management and for this reason Gadolinium-enhanced sequences are sensitive.

LIVER CIRRHOSIS, SPONTANEOUS SPLENORENAL SHUNT AND HYPERSPLENISM

Although significant advances are expected to be made in the assessment of PH-related complications, the prognostic role of spleno-renal shunts (SRS) has not been fully explored so far. Clarifying this aspect could help tackle the life-threatening events occurring in patients suffering from liver cirrhosis. A recent study on SRS^[26] focused on the role of the spleen and showed a strict link between spleen size and the presence of SRS and the development of hepatocarcinoma.

An up-to-date study evaluated the effect of liver transplantation on spleen size, spontaneous SRS function, and platelet counts in patients with hypersplenism in 462 adult patients who underwent orthotopic liver transplantations (OLT). Of these patients, CT or magnetic resonance imaging information was reviewed retrospectively in 55 patients. Volume measurements of the spleen and liver, spleen/liver volume ratio (S/L ratio), presence and size of SRS, and platelet counts were evaluated before and after OLT. Spleen size and SRS size were significantly smaller after OLT. However, patients with postoperative S/L ratio > 0.35 tended to have lower platelet counts after OLT^[27].

THE NOVEL PLAYER

Nonalcoholic fatty liver disease (NAFLD), the most common cause of steatosis, is associated with obesity, mainly visceral and insulin resistance. In the presence of more severe risk factors (major obesity, diabetes mellitus, metabolic syndrome, MS), simple hepatic steatosis or fatty liver (FL) may be complicated by liver inflammation

(nonalcoholic steatohepatitis or NASH). NASH can lead to perisinusoidal fibrosis and cirrhosis. Fat-laden hepatocytes are swollen, and in steatohepatitis, further swelling occurs due to hydropic change (ballooning) of hepatocytes to cause sinusoidal distortion, as visualized by *in vivo* microscopy, reducing intrasinusoidal volume and microvascular blood flow. Involvement of other cell types (sinusoidal endothelial cells, Kupffer cells, stellate cells) and recruitment of inflammatory cells and platelets lead to dysregulation of microvascular blood flow. In animal models, the net effect of such changes is a marked reduction of sinusoidal space (approximately 50% of control), and a decrease in the number of normally perfused sinusoids. Such microvascular damage could accentuate further liver injury and disease progression in NASH. Hepatic steatosis is also exquisitely sensitive to ischemia-reperfusion injury, at least partly due to the propensity of unsaturated fatty acids to undergo lipid peroxidation in the face of reactive oxygen species. This has important clinical consequences, particularly limiting the use of fatty donor livers for transplantation^[28]. NASH is a progressive liver disease characterized by Kupffer cell dysfunction which contributes to its pathogenesis. It is noteworthy that the reticular-endothelial system also plays a key role in the spleen. Colloid scintigraphy is a good method of reflecting Kupffer cell activity. A study on 22 patients with biopsy-proven NASH who underwent colloid liver scintigraphy, after intravenous injection of 185 MBq Tc tin colloid, showed that liver right/left lobe ratio was altered in all of these patients. Colloid shift to the spleen was observed in 55% of patients as well as prolonged blood pool clearance time^[29].

The first group of researchers^[30] who aimed to determine if there was an association between NAFLD and spleen enlargement, measured spleen volume using CT. The values were compared with the patient's demographic data, the liver-to-spleen (L/S) ratio of CT Hounsfield unit measurements, and the results of liver function tests. Diagnosis of fatty liver was made if the L/S ratio was less than 1.0. The mean spleen volume was $73.0 \pm 24.4 \text{ cm}^3$ (range, 21.1-106.1) in normal subjects and $141.2 \pm 54.1 \text{ cm}^3$ (range, 44.1-267.3) in patients with fatty liver ($P < 0.0001$). Multivariate linear regression analysis identified that only the L/S ratio ($P < 0.0001$) and age ($P < 0.01$) were significantly correlated to spleen volume. Using forward selection stepwise regression, the L/S ratio entered first ($\beta = -0.634$) and age second ($\beta = -0.293$).

Obesity and insulin resistance are strongly associated with systemic markers of inflammation. Focusing on this aspect, authors have attempted to find a noninvasive method that could likely assess the presence of NASH and help to decide liver biopsy performance. Using histology as a gold standard to diagnose NAFLD, 43 patients with NASH and 40 with fatty liver were consecutively studied, their data were compared with those of 48 healthy control participants. The outcomes evaluated were ultrasonographic spleen longitudinal diameter coupled with the splenic artery resistive index, serum interleukin (IL)-6 and vascular endothelial growth factor

concentrations. The NASH group had higher spleen longitudinal diameter values ($P = 0.0001$) as well as significantly higher IL-6 and vascular endothelial growth factor concentrations than the other groups ($P = 0.0001$). The optimal cut-off value for spleen longitudinal diameter that best discriminated NASH from fatty liver patients was 116 mm (specificity 95% and sensitivity 88%); the sensitivity and specificity of this parameter was better than both IL-6 and vascular endothelial growth factor in the same setting (area under the receiver operating characteristic curve 0.920 *vs* 0.817 and 0.678, respectively). Splenic artery resistive index was similar between patients with NASH and those with fatty liver, but differed when compared with controls ($P = 0.0001$). IL-6 was highly specific in confirming the absence of NASH at normal values. In that series of patients, normal values of spleen longitudinal diameter and IL-6 were strongly associated with fatty liver^[31]. Further confirmation of these findings comes from another study which highlighted that spleen enlargement may be a distinct feature of NASH, especially early-stage NASH^[32].

A subsequent study^[33] showed that spleen enlargement was found at significant levels (38%) in obese patients as determined by Cavalieri stereologic volume calculation, an unbiased stereological method. Finally, recent results clearly indicated that high fat diet caused splenomegaly *via* sinusoidal dilatation and intracellular or intercellular deposits in obese female rats^[34]. Although in patients with NAFLD, liver biopsy remains the only reliable method to differentiate simple steatosis from NASH, the objective of the study was to evaluate the efficacy of non-invasive (^{99m}Tc-phytate scintigraphy in the diagnosis of NASH. Thirty-seven patients with suspected NAFLD at the time of liver biopsy also underwent (^{99m}Tc-phytate scintigraphy. Signal intensities of regions of interest in the liver and spleen were measured. The same authors also examined scintigraphic features in a nutritional model of NASH in rats fed a methionine- and choline-deficient (MCD) diet. The liver/spleen uptake ratio determined by scintigraphy was significantly decreased in patients with NASH in comparison with patients with simple steatosis. The liver/spleen ratio was an independent predictor distinguishing NASH from simple steatosis. The decrease was observed for all stages of NASH, including the early stage (stages 1 and 0). In animal studies, the liver/spleen uptake ratio was significantly decreased in rats after 8 wk of a MCD diet in comparison with control diet-fed rats. These authors concluded that non-invasive (^{99m}Tc-phytate scintigraphy is a reliable tool to differentiate NASH from simple steatosis^[35]. The frequency of ischemic heart disease observed after splenectomy for trauma and the low cholesterol levels found in patients with hypersplenism are observations that suggest a possible role for the spleen in lipid metabolism and in the etiology of atherosclerosis^[36,37]. Previous studies showed that obese subjects are more susceptible to cardiovascular disease, hypertension, cerebrovascular disease, and diabetes mellitus than are non-obese subjects. They have a higher incidence of infection and some types of cancer, suggesting impaired

immune function. In humans, only a few studies have directly compared specific immune responses in obese and non-obese subjects. It is known that obesity induces decreases in both T lymphocyte response to concanavalin A and B lymphocyte response to pokeweed mitogen^[38]. In addition, a negative correlation between percentage body fat and natural killer cell activity was found in both elderly women^[39], and adult men^[40]. Elderly people (> 60 years of age) are also at risk of an increased incidence of infection. Their peripheral blood lymphocytes show an impaired proliferative capacity and a decreased reactivity to mitogens^[41]. Researchers found and reported that obesity suppresses lymphocyte functions, natural killer cell activity, and lymphocyte mitogenesis in men and women > 60 years of age^[42]. This suggests that obesity is a risk factor for deteriorating cellular immune functions. However, the mechanism by which obesity decreases cellular immune functions remains to be elucidated. Expression of glucose transporter 1 (GLUT-1), analyzed by Western blot analysis, was lower in the splenic lymphocytes of obese compared with lean Zucker rats. In obese subjects it is associated with the decreased uptake of glucose into immune cells, which in turn is associated with the decreased expression of GLUT-1. This suggests that decreased proliferation of splenic lymphocytes in obese Zucker rats is associated with the impairment of glucose uptake, which is due to the decreased expression of GLUT-1^[43]. An up-to-date study assessed the magnitude of antigen-specific immunity in a murine model of NAFLD. Because antigen-specific immunity was diminished in NAFLD mice, the underlying mechanisms were evaluated through analysis of the functions of antigen-presenting DC and other immunocytes. For 12 wk, NAFLD mice received a high-fat and high-calorie diet. NAFLD mice and control mice were immunized with hepatitis B vaccine containing hepatitis B surface antigen (HBsAg) and hepatitis B core antigen (HBcAg). Antibody to HBsAg (anti-HBs), HBsAg and HBcAg-specific cellular immune response and functions of whole spleen cells, T lymphocytes, B lymphocytes and spleen DCs of NAFLD and control mice were assessed *in vitro*. Levels of anti-HBs and the magnitude of proliferation of HBsAg and HBcAg-specific lymphocytes were significantly lower in NAFLD mice than control mice. The spleen cells of NAFLD mice produced significantly higher levels of inflammatory cytokines and exhibited significantly increased T cell proliferation compared with control mice. However, the antigen processing and presenting capacities of spleen DCs were significantly decreased in NAFLD mice compared with control mice. Palmitic acid, a saturated fatty acid, caused diminished antigen processing and presenting capacity of murine DCs^[44]. Liver fat represents a balance between input, secretion, and oxidation of fatty acids. As humans spend the majority of a 24-h period in a postprandial state, dietary fatty acids make an important contribution to liver fat metabolism. Oxidation of dietary fatty acids, hepatic desaturation and elongation of palmitic acid occurs to a greater extent in abdominally obese men.

NEUROTRANSMITTER, HORMONES, VITAMIN D AND THE SPLEEN

Increasing evidence has placed hormones and neurotransmitters among potent immunomodulators, in both health and disease. 5-HT functions as a neurotransmitter in the nervous systems of simple as well as complex animals. 5-HT diffuses to serotonin-sensitive neurons, which control the animal's perception of nutrient availability. This system has been partially conserved during the 700 million years of evolution which separates *C. elegans*, a transparent nematode, from humans. When humans smell food, dopamine is released to increase the appetite. However, unlike that in worms, serotonin does not increase anticipatory behaviour in humans; instead the serotonin released while consuming activates 5-HT_{2C} receptors on dopamine-producing cells. This halts their dopamine release, and thereby serotonin decreases appetite. Drugs which block 5-HT_{2C} receptors make the body unable to shut off appetite, and are associated with increased weight gain^[45], especially in people who have a low number of receptors^[46]. The expression of 5-HT_{2C} receptors in the hippocampus follows a diurnal rhythm, just as the 5-HT release in the ventromedial nucleus, which is characterized by a peak in the morning when the motivation to eat is strongest^[47]. In humans, serotonin levels are affected by diet. An increase in the ratio of tryptophan to phenylalanine and leucine will increase serotonin levels. Fruits with a good ratio include dates, papaya and banana. Foods with a lower ratio inhibit the production of serotonin. Research also suggests that eating a diet rich in carbohydrates and low in protein will increase serotonin by secreting insulin, which helps in amino acid competition^[48]. However, increasing insulin for a long period may trigger the onset of insulin resistance, obesity, type 2 diabetes, and lower 5-HT levels. Researchers showed that expression of 5-HT(2A) receptors was up-regulated in hypertrophic 3T3-L1 adipocytes, which exhibited decreased expression of adiponectin and increased expression of PAI-1. 5-HT(2A) receptor antagonists and suppression of 5-HT(2A) receptor gene expression enhanced adiponectin expression. Activation of Gq (the G protein-coupled receptor is activated by an external signal in the form of a ligand or other signal mediator) negatively regulated adiponectin expression, and inhibition of mitogen-activated protein kinase reversed the Gq-induced effect. Moreover, the 5-HT(2A) receptor blockade reduced PAI-1 expression^[49]. As food intake and energy balance are among the functions regulated by 5-HT in the brain, it would be interesting to discover its link with some adipokines. Recent studies have shown an interaction between the serotonergic system and leptin, a protein released from adipose tissue that inhibits feeding behavior and increases fuel expenditure. An up-to-date study found low brain serotonin immunoreactivity in all animals with high neuronal leptin accumulation in the raphe nucleus, independently of their age. In contrast, high brain serotonin immunoreactivity was accompanied by a low neuronal accumulation of leptin. These findings indi-

cate that serotonin regulates leptin uptake by neuronal cell bodies of the dorsal raphe and hypothalamus, suggesting that at least part of the effects of serotonin may be mediated by the regulation of neuronal trafficking in the brain^[50]. 5-HT promotes the release of growth hormone (GH) by a hypothalamic site of action^[51]. Exogenous GH enhances thymic microenvironmental cell-derived secretory products such as cytokines and thymic hormones. Moreover, GH increases thymic epithelial cell (TEC) proliferation *in vitro*, and exhibits a synergistic effect with anti-CD3 in stimulating thymocyte proliferation, which is in keeping with data showing that transgenic mice overexpressing GH or GH-releasing hormone exhibit overgrowth of the thymus. GH also influences thymocyte traffic: it increases human T-cell progenitor engraftment into the thymus; augments TEC/thymocyte adhesion and the traffic of thymocytes in the lymphoepithelial complexes, the thymic nurse cells; modulate *in vivo* the homing of recent thymic emigrants, enhancing the number of fluorescein isothiocyanate positive cells in the lymph nodes and diminishing them in the spleen. In keeping with the effects of GH on thymic cells, is the detection of GH receptors in both TEC and thymocytes. Insulin-like growth factor (IGF)-1 is a potent hormone that stimulates growth and differentiation and inhibits apoptosis in numerous tissues. Preliminary evidence suggests that IGF-1 exerts differentiating, mitogenic and restoring activities in the immune system, however, the sites of synthesis of local IGF-1 are unknown. Identification of these sites would allow the functional role of local IGF-1 to be clarified. The presence of IGF-1 in non-immune cells suggests that it acts as a trophic factor, while its occurrence in subtypes of lymphocytes or antigen-presenting cells indicates paracrine/autocrine direct regulatory involvement of IGF-1 in the human immune response. Additionally, data indicate that IGF-1 is involved in several effects of GH in the thymus, including the modulation of thymulin secretion, TEC proliferation as well as thymocyte/TEC adhesion. This is in accordance with the demonstration of IGF-1 production and expression of IGF-1 by TEC and thymocytes. Also, it should be seen as an intrathymic circuitry, involving not only IGF-1, but also GH itself, as intrathymic GH expression is seen both in TEC and in thymocytes, and that thymocyte-derived GH could enhance thymocyte proliferation^[52]. With regard to the implication of the IGF family in immune physiology and development, a recent study has focused on type 1 IGF receptor, a transmembrane tyrosine kinase homologous to the insulin receptor that mediates most of the biological effects of IGF-1 and IGF-2. Normal development and *ex vivo* activation of T and B cells are observed in chimeric *Rag2*-deficient C57BL/6 mice reconstituted with fetal liver cells from *Igf1r*^{-/-} mice. However, this model revealed an unexpected decrease in the T-independent B cell response which is important in bacterial defense mechanisms^[53]. The major role of IGF-2 is as a growth promoting hormone during gestation. To date, very few studies have investigated the function of IGF-2 in immune development and physiology.

This growth factor is the dominant peptide of the insulin family expressed in the thymus epithelium of different species. Thymic IGF-2 influences thymic development and T cell differentiation as evidenced by the analysis of IGF-2 transgenic dwarf mice, which develop thymic hyperplasia with an increased number of thymocytes (and CD4⁺ T lymphocytes in particular). This increase in T cells is also observed in the spleen compartment of IGF-2 transgenic mice, but there is no significant effect on B cell development^[54]. There is further evidence that IGF-2 may intervene in the control of T cell differentiation^[55]. A recent study investigated the location of IGF-1 messenger RNA and protein on archival human lymph node samples by *in situ* hybridization, immunohistochemistry and double immunofluorescence staining using an IGF-1 probe and antisera specific for human IGF-1 and CD3 (T lymphocytes), CD20 (B lymphocytes), CD68 (macrophages), CD21 (follicular DCs), S100 (interdigitating DCs) and podoplanin (fibroblastic reticular cells). Numerous cells within the B- and T-cell compartments expressed the IGF-1 gene, and the majority of these cells were identified as macrophages. Solitary follicular DCs exhibited IGF-1. A few T lymphocytes, and no B lymphocytes, contained IGF-1 immunoreactive material. Furthermore, IGF-1 immunoreactive cells outside the follicles that did not react with CD3, CD20, S100 or podoplanin markers were identified as high-endothelial venule cells^[56]. GH was used to counteract the catabolic metabolism in critically ill patients until it was demonstrated that administration of GH was associated with increased morbidity due to uncontrolled infections and sepsis^[57]. The immunomodulatory effect of GH and its main mediator IGF-1 during systemic inflammation remain to be established. Authors investigated the effect of GH and IGF-1 on cellular immune functions in a murine model of sepsis and found that GH did not affect cellular immune functions or the survival rate in that model. In contrast, IGF-1 improved splenocyte proliferation and cytokine release independently of GH but did not affect the determined clinical parameters of septic mice^[57]. Aging is under the control of a small number of regulatory genes. Mice genetically selected for high immune responses, in most cases, exhibit a longer life span and lower lymphoma incidence than do mice selected for low responses. The link between immunity and aging is further evidenced by the age-related alterations in the immune system, mostly of the T-cell population, in terms of replacement of virgin by memory cells, accumulation of cells with signal transduction defects, and changes in the profile of Th1 and Th2 type cytokines^[58]. Also, B cells exhibit intrinsic defects, and NK cell activity is profoundly depressed by aging. *In vitro* experiments indicate that the production of IL-2, interferon (IFN)- γ , and IL-4 by mouse spleen cells changes with aging and may be up-regulated by recombinant cytokines. These findings suggest possible cytokine interventions to prevent or treat age-related immune disorders, as they may affect the duration and the biological quality of life^[59]. Excessive alcohol consumption continues to be a major public health

problem, particularly in the adolescent and young adult populations. Generally, such behavior tends to be confined to the weekends, resulting in frequent binge drinking. Various authorities have emphasized the strict link between mechanisms inducing alcoholic and nonalcoholic liver diseases, thus it could be of interest to ask questions about alcohol toxicity, such as: is there a link between alcohol abuse and impaired immune system and what is the link? A study in peri-pubertal male rats compared the effect of the discontinuous feeding of a liquid diet containing a moderate amount of ethanol (6.2% wt/vol) to that of continuous ethanol administration or a control diet, taking as end points the 24-h variations in plasma prolactin levels and mitogenic responses and lymphocyte subset populations in the spleen. Animals received the ethanol liquid diet starting on day 35 of life, the diet being similar to that given to controls except that maltose was iso-calorically replaced by ethanol. Ethanol provided 36% of the total caloric content. Each week, the discontinuous ethanol group received the ethanol diet for 3 d and the control liquid diet for the remaining 4 d. After 4 wk the rats were killed. A significant decrease in splenic cell response to concanavalin A, and of splenic cell response to lipopolysaccharide was found in rats under the discontinuous ethanol regime, when compared with control- or ethanol-chronic rats. Under discontinuous ethanol feeding, mean values of splenic CD8(+) and CD4(+)-CD8(+) cells decreased, whereas splenic T cells, and splenic B cells were augmented. In rats chronically fed with ethanol, splenic mean levels of CD8(+) and CD4(+)-CD8(+) cells were augmented. Both modalities of ethanol administration disrupted the 24 h variation in immune function seen in controls. Mean plasma prolactin levels increased by 3.6-fold and 8.5-fold in rats chronically or discontinuously fed with alcohol, respectively. These results supported the view that the discontinuous drinking of a moderate amount of ethanol can be more harmful for the immune system than continuous ethanol intake, presumably by inducing greater stress as indicated by the augmented plasma prolactin levels observed^[60]. Numerous studies have focused their attention on the role played by vitamin D in obesity, MS and NAFLD. The hormonal form of vitamin D, 1,25-dihydroxyvitamin D3, is well known for its immunosuppressive, anti-proliferative and pro-apoptotic activities. In a recent work, authors studied the effect of 1,25-dihydroxyvitamin D3 on *Toxoplasma gondii*-infected mice. They observed that 1,25-dihydroxyvitamin D3 reduces the survival rate of infected mice by up to 37% at day 10 post-infection compared to untreated infected mice ($P < 0.0001$). IFN- γ and IL-12p40 levels were significantly reduced by 1,25-dihydroxyvitamin D3 in infected mice sera indicating an inhibition of Th-1-type cytokines. CD4⁺ T lymphocyte and splenocyte counts were also reduced following 1,25-dihydroxyvitamin D3 treatment and a marked induction of apoptosis, accompanied by down-regulation of the anti-apoptotic proteins Bcl-2 and Bcl-X(L), was observed. The above results indicate that 1,25-dihydroxyvitamin D3 induces splenocyte apoptosis and enhances host suscepti-

bility to toxoplasmosis^[61]. Bone components participate in the regulation of hematopoietic stem cells (HSC) in the adult mammal. Vitamin D regulates bone mineralization and is associated with pleiotropic effects in many cell types including putative roles in hematopoietic differentiation. Researchers reported that deletion of the vitamin D receptor (VDR) in hematopoietic cells did not result in cell autonomous perturbation of HSC or progenitor function. However, deletion of VDR in the microenvironment resulted in a marked accumulation of HSC in the spleen that could be reversed by dietary calcium supplementation. These data suggest that VDR participates in restricting splenic hematopoiesis through maintenance of bone calcium homeostasis and are consistent with the concept that calcium regulation through VDR is a central participant in localizing adult hematopoiesis preferentially to bone marrow^[62].

CONCLUSION

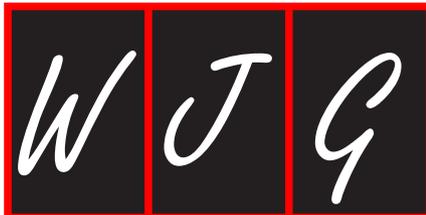

This special organ should be taken into account when interpreting the mechanisms of NAFLD and in its diagnosis, mainly when dealing with the more severe form, i.e., NASH, although recent research has challenged the benignity of FL^[63].

Abstract

The incidence of obesity has dramatically increased in recent years. Consequently, obesity and associated disorders such as nonalcoholic fatty liver disease constitute a serious problem. Therefore, the contribution of adipose tissue to metabolic homeostasis has become a focus of interest. In this review, we discuss the latest discoveries that support the role of lipids in nonalcoholic fatty liver disease. We describe the common mechanisms (c-Jun amino-terminal kinases, endoplasmic reticulum stress, unfolded protein response, ceramide, low-grade chronic inflammation) by which lipids and their derivatives impair insulin responsiveness and contribute to inflammatory liver and promote plaque instability in the arterial wall. Presenting the molecular mechanism of lipid activation of pro-inflammatory pathways, we attempt to find a link between nonalcoholic fatty liver disease, metabolic syndrome and cardiovascular diseases. Describing the common mechanisms by which lipid derivatives, through modulation of macrophage function, promote plaque instability in the arterial wall, impair

insulin responsiveness and contribute to inflammatory liver and discussing the molecular mechanism of lipid activation of pro-inflammatory pathways, the key roles played by the proliferator-activated receptor and liver X receptor α , nuclear receptors-lipid sensors that link lipid metabolism and inflammation, should be emphasized. Further studies are warranted of anti-inflammatory drugs such as aspirin, anti-interleukin-6 receptors, immune-modulators (calcineurin inhibitors), substances enhancing the expression of heat shock proteins (which protect cells from endoplasmic reticulum stress-induced apoptosis), and anti-c-Jun amino-terminal kinases in well-designed trials to try to minimize the high impact of these illnesses, and the different expressions of the diseases, on the whole population.

INTRODUCTION

The rapid increase in the prevalence of obesity is a major global health problem. Its associated complications are burdened by an increased risk of death by 20%-40% in overweight individuals and by 2-3-fold in obese individuals compared to normal controls, even though the

strength of the association between body mass index and heart failure events declines with age^[1]. Obesity is a known risk factor for non-alcoholic fatty liver disease (NAFLD)^[2], hypertension, stroke, gallbladder disease, osteoarthritis, obstructive sleep apnea, and other breathing problems as well and some forms of cancer (breast, colorectal, endometrial and kidney). Type 2 diabetes (T2D) and obesity, now collectively referred to as “diabesity”, are interrelated, in that obesity is known to exacerbate the pathology of T2D and greater than 60% of diabetics are obese. Low grade chronic inflammation, strictly linked to overweight/obesity, causes insulin resistance (IR) that interacts with other complex mechanisms such as hypercholesterolemia, smoking, hypertension, hyperglycemia, type A behavioral patterns, hemostatic factors, hereditary differences in such diverse aspects as lipoprotein structure and that of their associated receptors, homocysteine processing/metabolism, and high levels of lipoprotein(a) to increase the risk of coronary heart disease (CHD). CHD is present not only in nondiabetic and normotensive obese adult subjects^[3], but also in obese children^[4]. IR is a condition in which normal amounts of insulin are inadequate to produce a normal insulin response from fat, muscle and liver cells. Indeed, lipolysis, which is normally inhibited by insulin, is overstimulated in insulin-resistant states leading to an increase in free fatty acid (FFA) flux^[5]. IR in muscle reduces glucose uptake whereas IR in liver reduces glucose storage, both effects serving to elevate blood glucose. High plasma levels of insulin and glucose due to IR often leads to metabolic syndrome (MS) and T2D. Plasma FFAs from white adipose tissue lipolysis have been shown to be the major contributor to triglyceride accumulation^[6] observed in NAFLD, further expression of MS, which ranges from simple fatty liver (FL) through the more severe form, non alcoholic steatohepatitis (NASH) to cryptogenic cirrhosis. Sharing the same mechanisms of NASH, FL is no longer considered completely benign, accordingly to recent data^[7]. Activation of the endoplasmic reticulum (ER) by stress has been reported in most models of hepatic steatosis in rodents and its contribution to hepatic fat deposition has been recently documented, with lipogenesis being the main metabolic pathway affected. ER stress-related activation, observed in adipose tissue of obese humans^[8], could have metabolic consequences and participate in fat deposition in the liver. Activation of ER could directly induce an insulin-resistant state in adipocytes. Indeed, it has been shown that activation of the ER stress sensor kinase/endonuclease inositol-requiring protein 1 (IRE1), a component of the unfolded protein response (UPR) could stimulate c-Jun amino-terminal kinase [JNKs or stress-activated protein kinases (SAPKs)]^[9], which, by phosphorylating serine residues of insulin substrate receptor 1, is a key player in the development of IR^[10]. The IRE1/box binding protein 1, a branch of the ER stress signaling pathway, has been recently shown to regulate and be regulated by innate immune signaling pathways in both the presence and absence of ER stress^[11]. Disruption of ER homeostasis has been observed in liver and

adipose tissue of humans with NAFLD and/or obesity. Importantly, the signaling pathways activated by disruption of ER homeostasis, the UPR, has been linked to inflammation and apoptosis, lipid biosynthesis, insulin effects, all of which are involved in the initiation/evolution of NAFLD. The ER is a crucial organelle for cellular homeostasis, in which the synthesis and the post-translational modifications of membrane and secreted proteins take place, as well as the synthesis of lipids and cholesterol for membranes formation. However, the ER quality control system can be compromised under a variety of conditions such as accumulation of unfolded protein, alteration of calcium homeostasis or disruption of the redox state. The UPR activates JNKs^[9,12]. Up-to-date results provide evidence that heat shock proteins protect cells from ER stress-induced apoptosis. Obesity and associated disorders constitute a serious problem, for example NAFLD can lead to hepatocarcinoma, and the contribution of adipose tissue to metabolic homeostasis has become a focus of interest. Adipose tissue secretes FFAs and hormones, known as adipokines, and thus seems to play a major role in the development of NAFLD. Apoptotic cell death is a prominent feature in NASH. Indeed, toxic FFAs can activate the intrinsic apoptosis pathway in hepatocytes *via* c-JNK. JNK activates the proapoptotic protein Bim, resulting in Bax activation^[13] and enhanced apoptosis, termed “lipoapoptosis”.

JUN AMINO-TERMINAL KINASES

Jun N-terminal kinases (JNKs), also named SAPKs, are one of 3 members of the mitogen-activated protein kinase (MAPK) superfamily, which also includes the extracellular signal-regulated kinases (ERKs) or classical MAPKs and the p38 MAPK. JNKs bind and phosphorylate c-Jun on Ser63 and Ser73 within its transcriptional activation domain. MAPK kinases (MKK) are responsive to stress stimuli, mainly inflammatory signals, but also to a lesser extent, to ultraviolet irradiation, heat and osmotic shock, and are involved in apoptosis and T cell differentiation. This latter immunological aspect should not be overlooked.

JNKs consist of 10 isoforms derived from 3 genes: JNK1 (4 isoforms), JNK2 (4 isoforms), and JNK3 (2 isoforms). JNK1 and JNK2 are found in all cells of every tissue. JNK3 is found mainly in the brain, but is also found in the heart and the testes. JNK1 is involved in apoptosis, neurodegeneration, cell differentiation and proliferation, inflammatory conditions and cytokine production mediated by activation protein-1 (AP-1) such as regulated upon activation, normal T-cell expressed, and secreted cytokine, interleukin-8 and granulocyte-macrophage colony-stimulating factor. Recently, JNK1 has been found to regulate Jun protein turnover by phosphorylation and activation of the ubiquitin ligase Itch (polyubiquitination marks proteins for degradation by the proteasome). JNKs can associate with scaffold proteins, JNK-interacting proteins as well as their upstream Jun N-terminal kinase kinase 1 and Jun N-terminal kinase

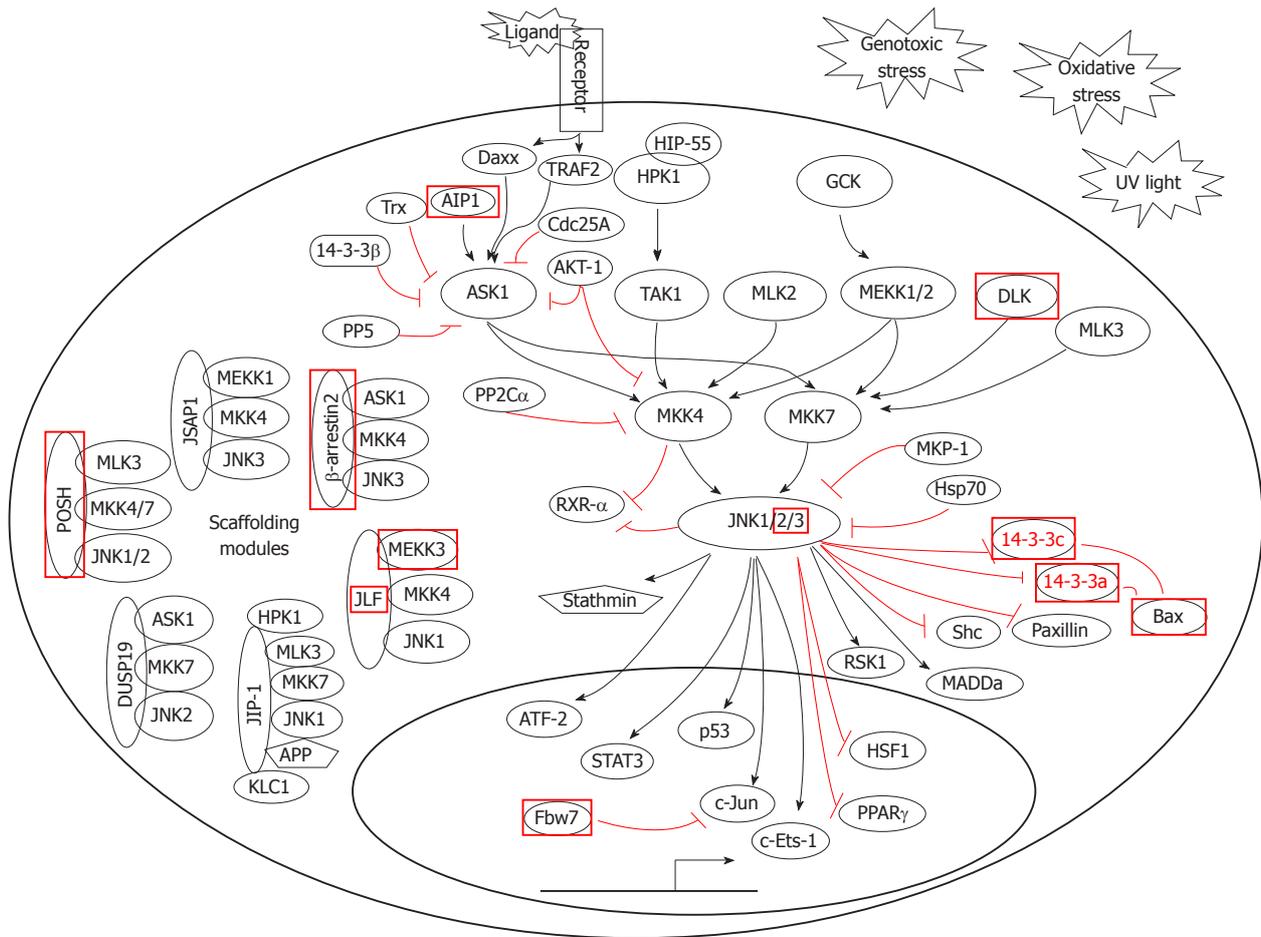

Figure 1 Jun N-terminal kinase signaling pathway. ERK: Extracellular signal-regulated kinase; MAPK: Mitogen-activated protein kinase; MKK: MAPK kinase; MEKK: MAPK/ERK kinase kinase; MLK: Mixed lineage kinase; JNK: Jun N-terminal kinase; ASK: Apoptosis signal-regulating kinase; HSP: Heat shock protein; RSK: p90 ribosomal S6 kinase; HPK: Hematopoietic progenitor kinase; PPAR: Peroxisome proliferator-activated receptor; DLK: Dual leucine zipper-bearing kinase; RXR: Retinoid X receptor; ATF: Activating transcription factor; STAT: Signal transducers and activators of transcription; MADD: Mitogen-activated kinase activating death domain protein; TRAF: Tumor necrosis factor receptor-associated factor; MKP: MAPK phosphatase; TAK: Transforming growth factor-activated kinase; KLC: Kinesin light chain; DAXX: Death domain-associated protein.

kinase 2 following their activation. JNK, by phosphorylation, modifies the activity of numerous proteins that reside at the mitochondria or act in the nucleus. Thus, JNK activity regulates several important cellular functions. One way this activation may occur is through disruption of the conformation of sensitive protein phosphatase enzymes; specific phosphatases normally inhibit the activity of JNK itself and the activity of proteins linked to JNK activation. The JNK proteins lead to varied and seemingly contradictory cellular responses. In particular, JNKs have been reported to have a role in the induction of apoptosis, but have also been implicated in enhancing cell survival and proliferation. The opposing roles of JNKs have been attributed to the observation that JNKs activate different substrates based on a specific stimulus, cell type or temporal aspects^[14].

JNK signaling pathway

JNKs are activated by MAPK kinases such as MKK-4, MKK-6 and MKK-7 (Figure 1). These kinases are in turn activated by the MAP3 kinases, such as apoptosis signal-

regulating kinase 1 (ASK1) also known as mitogen-activated protein kinase kinase 5 (MAP3K5), mixed lineage kinases (MLKs) (MLK1, MLK2 and MLK3), MAP/ERK (extracellular signal-regulated kinase) kinase kinase 1 (MEKK1), MEKK4 and transforming growth factor (TGF)-β-activated kinase 1 (TAK1). JNK MAP3 kinase pathways are activated by MAP4 kinases that link to a variety of cell receptors which sense stress and inflammation, including death receptors (Fas), inflammatory cytokine receptors of tumor necrosis factor alpha (TNF-α) and TGF-β, G-protein-coupled receptors (GPCRs) and antigen receptors. Signals are communicated to JNK pathway MAP4 kinases by tyrosine kinase receptor associated adapter and effector molecules and/or by G-protein mediated signaling. GPCRs signal the JNK pathway through trimeric G-proteins to monomeric p21RhoGTPases, Ras-related C3 botulinum toxin substrate 1 (Rac1) and cell division control protein 42 homolog (CDC42). ASK1 links to stress receptors such as TNF receptor (TNFR) and Fas, and is activated by reactive oxygen species (ROS)-mediated dissociation

of thioredoxin, binding to TNFR associated factor 2 (TRAF2) or death domain-associated protein (DAXX) and oligomerization. ASK1 activates the JNK MAP2Ks, MKK4 (SEK1) and MKK6 (MKK3/MAPKK6). The JNK MAP3 kinases: TAK1, MEKK1 and MLK3 are activated by the tyrosine kinase (TK) receptor-activated MAP4 kinase, hematopoietic progenitor kinase 1 (HPK-1). HPK-1 associates with TK receptors through adaptor proteins, such as CT10-regulated kinase (Crk), Crk-like (CrkL) and growth factor receptor-bound 2 (Grb2). Activation of HPK1 requires multiple phosphorylation events including autophosphorylation and protein kinase phosphorylation by protein kinase D1 (PKD1). The JNK MAP3 kinases, MEKK1, MEKK4 and MLK3 are also activated by the p21Rho-GTPases, Ras-related C3 botulinum toxin substrate 1 also known as Rac1 and Cdc42 through the MAP4K, P21-activated kinase-1 (PAK-1). This links the JNK pathways to a wide variety of GPCR, integrin and receptor pathways. In addition to participating in the stress response, the MAPKs c-Jun N-terminal Kinases JNK1 and JNK2 regulate the proliferation of normal and neoplastic cells. JNKs contribute to these processes largely by phosphorylating c-Jun and thus contributing to the activation of the AP-1 complex. Furthermore, JNKs control entry into mitosis. It has been observed that JNK activity and phosphorylation of c-Jun become elevated during the G/M transition of the cell cycle in immortalized fibroblasts and ovarian granulosa cells. Pharmacological inhibition of JNK causes a profound cell cycle arrest at the G/M transition in both cell types. This effect is specific as it occurs with 2 distinct small molecular compounds. Inactivation of JNK prior to mitosis prevents expression of aurora B and phosphorylation of histone-H3 at Ser 10. Silencing of JNK1 and 2 causes a similar effect, whereas overexpression of JNK1 and 2 causes the opposite effect. Inhibition of JNK delays activation of Cdc2 and prevents downregulation of cyclin B1, whereas Ras controls the activation of MAPKs. Authors have recently observed that in certain cells, the small guanosine triphosphate (GTP)-binding proteins Rac1 and Cdc42 but not Rho regulate the activity of JNKs^[15]. Furthermore, because Rac1 and Cdc42 but not Rho, bind and activate a P21-activated kinase 1 (Pak1), it has been suggested that Pak1 is the most upstream component of the pathway linking these GTPases to JNK. However, in mammalian cells, Rho1p, a Rho homologue, and RhoA directly interact with a number of proteins, including kinases related to protein kinase C. Exploring the ability of Ras and Rho-related GTP-binding proteins to activate MAPK or JNK in a variety of cell lines, it was found that in the human kidney epithelial cell line, 293T, Cdc42 and all Rho proteins, RhoA, RhoB, and RhoC, but not Rac or Ras can induce activation of JNK. Furthermore, other researchers provided evidence that signaling from Rho proteins to JNK in 293T cells does not involve Pak1^[16]. c-JNK activity is abnormally elevated in obesity. Furthermore, an absence of JNK1 results in decreased adiposity, significantly improved insulin sensi-

tivity and enhanced insulin receptor signaling capacity^[17]. As previously mentioned, elevated FFAs and hepatocyte lipoapoptosis are the main features of NAFLD. However, the mechanism by which FFAs mediate lipoapoptosis is unclear. Recently, data have indicated that saturated FFAs induce JNK-dependent hepatocyte lipoapoptosis by activating the pro-apoptotic Bcl-2 family Bim and Bax-mediated apoptosis, which triggers the mitochondrial apoptotic pathway^[18]. Additional support for involvement of JNK1 overactivation in conditions associated with IR and MS has been provided^[19]. A positive correlation was found between the expression intensity of JNK1 and IR^[20], and JNK1 contributes to the development of liver fibrosis by inducing chronic inflammation as ascertained in a mouse NASH model^[21]. Methionine-choline-deficient feeding causes NASH coincident with the activation of c-JNK and caspase-12 in a murine model^[22].

Further data indicated that the increased oxidative stress and its associated JNK activation, as well as an imbalance in pro- and anti-apoptotic proteins in the Bcl-2 family all contribute to marked hepatocyte apoptosis in a rat NASH model^[23]. Examining fat biopsy samples from obese insulin-resistant nondiabetic individuals, UPR activation in subcutaneous adipose tissue was demonstrated, with JNK being a link between obesity, IR, and inflammation^[8]. ER stress activates the proteolytic cleavage of the lipogenic transcription factor sterol regulatory element binding protein-1c leading to the induction of lipogenic enzyme expression. A role for X box-binding protein 1, an ER stress-activated transcription factor, has also recently emerged. ER stress, by inhibiting apoB100 secretion, has associated with impaired very low density lipoprotein (VLDL) secretion. In rodents, treatment with molecular or chemical chaperones that reduce ER stress markers have demonstrated effectiveness in the treatment of hepatic steatosis^[24].

INSULIN RESISTANCE

SAPK/JNKs are activated by inflammatory cytokines, and JNK signaling is involved in IR and β -cell secretory function and survival. An up-to-date study suggested that FFAs stimulate functional autophagy of β cells, possibly through the RNA-dependent protein kinase (PKR)-JNK1 pathway independent of the ER or oxidative stress^[25].

Post-transcriptional modifications altering activity of insulin signaling molecules are the most proposed mechanism for inhibition of the insulin pathway. Various kinases including stress activated protein kinase, c-JNK, and protein kinase C (PKC) can phosphorylate insulin receptor substrate (IRS) 1-2 at specific serine and threonine residues, leading to inhibition of insulin signaling^[26]. A high fat diet is an established cause of systemic and adipose tissue IR. Activated JNK is a major contributor to FFA-induced cellular IR, and TNF- α is an autocrine/paracrine downstream effector of activated JNK that can also mediate IR^[27]. TNF- α is over-expressed in adipose tissue of obese rodents and humans, and its concentra-

tion is reduced after weight loss. TNF- α inhibits insulin signaling in the liver by mechanisms which include the activation of serine kinases such as JNK-1 and induction of suppressor of cytokine signaling proteins^[28]. An important consequence of IR in adipose tissue is to reduce the anti-lipolytic effect of insulin that in turn leads to elevated plasma FFA in obese and diabetic patients. Released FFAs from adipose tissue is taken up by liver and muscle cells. In the liver, FFAs induce gluconeogenesis and VLDL overproduction. Increased FFAs, especially metabolites such as acyl-CoAs, ceramides, and diacylglycerol, have been shown to inhibit insulin signaling by activating protein kinases such as PKC, JNK, and the inhibitor of nuclear factor- κ B (IKK- β)^[29].

Chronic high glucose concentrations and leptin induce IL-1 β secretion from pancreatic islets, an event that is possibly promotes β -cell dysfunction and death. A recent study provided evidence that chronically elevated concentrations of leptin and glucose induced β -cell apoptosis through activation of the JNK pathway in human islets and in insulinoma (INS 832/13) cells. JNK inhibition by the dominant inhibitor JNK-binding domain of IB1/JIP-1 (JNKi) reduced JNK activity and apoptosis induced by leptin and glucose. Exposure of human islets to leptin and high glucose concentrations led to a decrease of glucose-induced insulin secretion, which was partly restored by JNKi. An interplay between the JNK cascade and the caspase 1/IL-1 β -converting enzyme in human islets has been found. The *caspase 1* gene, which contains a potential activating protein-1 binding site, is upregulated in pancreatic sections and in isolated islets from T2D patients. Similarly, cultured human islets exposed to high glucose- and leptin-induced caspase 1 and JNK inhibition prevents this upregulation. Therefore, JNK inhibition may protect β -cells from the deleterious effects of high glucose and leptin in diabetes^[30].

Obesity is closely associated with IR and is established as a leading risk factor for T2D, yet the molecular mechanisms of this association are poorly understood. JNKs can interfere with insulin action in cultured cells and are activated by inflammatory cytokines and FFAs, molecules that have been implicated in the development of T2D. As previously highlighted, it has been shown that JNK activity is abnormally elevated in obesity. Furthermore, an absence of JNK1 results in decreased adiposity, significantly improved insulin sensitivity and enhanced insulin receptor signaling capacity in 2 different models of mouse obesity. Thus, JNK is a crucial mediator of obesity and IR and a potential therapeutic target^[31]. Chronic oxidative stress results in decreased responsiveness to insulin, eventually leading to T2D and CHD. Activation of the JNK signaling pathway can mediate many of the effects of stress on IR through inhibitory phosphorylation of IRS-1. In contrast, exercise, which acutely increases oxidative stress in muscle, improves insulin sensitivity and glucose tolerance in patients with T2D. Authors used a cellular model of insulin-resistant muscle to induce either chronic or acute oxidative stress and investigate their contrasting effects on insulin and JNK signaling. Chronic oxidative stress

resulted in increased levels of phosphorylated (activated) JNK in the cytoplasm, whereas acute oxidative stress led to redistribution of JNK-specific phosphatase MKP7 from the nucleus into the cytoplasm, a reduction in cytoplasmic phospho-JNK, and concurrent accumulation of phospho-JNK in the nucleus. Acute oxidative stress restored normal insulin sensitivity and glucose uptake in insulin-resistant muscle cells, and this effect was dependent on MKP7^[32].

Finally, it is likely that JNK activity modulates pancreatic islet function and/or survival in numerous ways. First, there is convincing evidence for the involvement of JNK in islet cell inflammation and death mediated by cytokines^[33]. Second, JNK activation may generate a state of β -cell dysfunction and defective insulin production, thereby contributing to the development of overt diabetes^[34]. Third, administration of SP600125, a synthetic inhibitor of JNK, results in improved glucose-stimulated insulin production in isolated islets in the *db/db* model of obesity and diabetes^[35]. Hence, there is a strong possibility that JNK may integrate defects in insulin secretion with peripheral IR in T2D through its actions in pancreatic β -cells as well as peripheral sites of insulin action. If this is the case, it is also likely that JNK may be important in the pathogenesis of type 1 diabetes, and recent studies have provided evidence to support a role for the JNK-2 isoform in this disease^[36].

LIPOLYTIC MACHINERY, ADIPOCYTES AND NAFLD

Several lines of evidence implicate an inadequate response to lipid storage/catabolism of cellular fat stores as being important in NAFLD. Subcutaneous adipose tissue (AT) is composed mostly of small, differentiated adipocytes that absorb circulating FFAs due to their insulin-sensitivity. They form triglycerides (lipogenesis) and store them in cellular lipid droplets (LD) or lipid bodies (surrounded by a monolayer of lipase-regulating proteins) until FFAs are needed during fasting. They also secrete adiponectin, which by opposing hepatic lipogenesis and stimulating long chain fatty acid β -oxidation, protects the liver from harmful effects of lipid accumulation, such as IR^[37]. In MS, failure of subcutaneous AT to store energy leads to swollen adipocytes that are stressed and de-differentiated. They continually release FFAs from triglycerides (lipolysis). Lipolysis is the biochemical pathway responsible for the catabolism of triacylglycerol (TAG) stored in cellular LD. The hydrolytic cleavage of TAG generates FFAs, which are subsequently used as energy substrates, essential precursors for lipid and membrane synthesis, or mediators in cell signaling processes. Consistent with its central importance in lipid and energy homeostasis, lipolysis mostly occurs in white and brown adipose tissue. Over the last few years, important enzymes and regulatory protein factors involved in lipolysis have been identified. These include an essential TAG hydrolase named adipose triglyceride lipase (ATGL) [a

patatin-like phospholipase domain-containing protein A2 (PNPLA2)], the ATGL activator comparative gene identification-58 (an α/β hydrolase containing protein 5), and the ATGL inhibitor G0/G1 switch gene 2. ATGL catalyzes the first step in adipocyte and muscle triglyceride hydrolysis. Together with the established hormone-sensitive lipase (lipase E) and monoglyceride lipase, these proteins constitute the basic “lipolytic machinery”. Additionally, a large number of hormonal signaling pathways and lipid droplet-associated protein factors regulate substrate access and the activity of the “liposome”^[38]. Activation of β -(AR) in adipocytes triggers acute changes in metabolism that can alter patterns of gene expression. A recent work examined the mechanisms by which activation of hormone sensitive lipase induces expression of inflammatory cytokines in adipocytes *in vivo* and model adipocytes *in vitro*. β 3-adrenergic receptor (AR) activation in mice triggered expression of inflammatory genes CCL2, IL-6, and PAI-1, as well as ER stress markers GRP78 and CHOP^[39]. Recent findings suggest that genetic variants in PNPLA3 predispose towards hepatic steatosis and, in the context of other environmental stressors, progression to irreversible liver failure. PNPLA3 is predominantly expressed in human liver and adipose tissue, possesses both lipolytic and lipogenic activity *in vitro*, and is localized on the surface of lipid droplets in hepatocytes. The 148M mutant protein has reduced lipolytic activity, with attendant increased cellular triglycerides^[40], only recently confirmed^[41]. Studies in animal models of NAFLD demonstrate that inhibition of acyl-coenzyme A:diacylglycerol acyltransferase (DGAT)-1, the enzymes that catalyze the final step in triglyceride synthesis, results in improvement in hepatic steatosis and insulin sensitivity. Researchers recently confirmed that hepatic-specific inhibition of DGAT-1 with antisense oligonucleotides improved hepatic steatosis in obese, diabetic mice but, unexpectedly, exacerbated injury and fibrosis in that model of progressive NAFLD. When hepatocyte triglyceride synthesis was inhibited, FFA accumulated in the liver, leading to induction of fatty acid oxidizing systems that increased hepatic oxidative stress and liver damage. These findings suggest that the ability to synthesize triglycerides may, in fact, be protective in obesity^[42]. This is a key point. MEK1/2 inhibition significantly increased both cellular and microsomal triglycerides mass, and mRNA levels for DGAT-1 and DGAT-2. In contrast to ERK, modulation of the phosphatidylinositol 3-kinases pathway or inhibition of the p38 MAP kinase, had no effect on lipoprotein density profile^[43]. The biogenesis of LD induced by serum depends on group IVA phospholipase A(2) [cPLA(2) α /GIVA PLA(2)], a regulatory enzyme that releases arachidonic acid for production of prostaglandins and leukotrienes. Recent data suggest that cPLA(2) α regulates the transport of tight junction and adherens junction proteins through Golgi cell-cell contacts in confluent endothelial cells. Expression of specific activators of different MAP kinases show that phosphorylation of cPLA(2) α at Ser-505 is due to JNK. This was confirmed by pharmacological inhibition and

expression of a dominant-negative form of the upstream activator MEKK1. LD biogenesis was accompanied by increased synthesis of ceramide 1-phosphate. Overexpression of its synthesizing enzyme ceramide kinase increased phosphorylation of cPLA(2) α at Ser-505 and the formation of LD, and its downregulation blocked the phosphorylation of cPLA(2) α and LD biogenesis. These results demonstrate that LD biogenesis induced by serum is regulated by JNK and ceramide kinase^[44].

The effect of glucose and palmitate on the phosphorylation of proteins is associated with cell growth and survival. Fresh results suggest that short-term changes in MAPK and AKT signaling pathways, and c-fos and c-JNK expressions induced by glucose are abolished by palmitate through phosphatidylinositol 3-kinase inhibition *via* ceramide synthesis^[45].

Activation of β -AR in mouse adipocytes triggered expression of inflammatory genes CCL2, IL-6, and PAI-1, as well as ER stress markers GRP78 and CHOP. Pharmacological inhibition of hormone sensitive lipase (HSL) blocked induction of inflammatory genes, but not ER stress markers. Promoting intracellular accumulation of FFAs in 3T3-L1 adipocytes increased the expression of inflammatory cytokines, whereas inhibiting ceramide synthesis partly blocked PAI-1 expression, but not IL-6. Induction of inflammatory markers *in vivo* and *in vitro* was preceded by phosphorylation of p38 and JNK, and inhibition of HSL prevented activation of these kinases. Together, these results demonstrate that FFAs liberated by HSL activate p38 and JNK, and p38 mediates pro-inflammatory cytokine expression in adipose tissue^[39].

As previously emphasized, accumulation of lipid metabolites within non-adipose tissues can induce chronic inflammation by promoting macrophage infiltration and activation. Oxidized and glycated lipoproteins, FFAs, free cholesterol, triacylglycerols, diacylglycerols and mainly ceramides have long been known to induce cellular dysfunction through their pro-inflammatory and pro-apoptotic properties. Emerging evidence suggests that macrophage activation by lipid metabolites and further modulation by lipid signaling represents a common pathogenic mechanism underlying lipotoxicity in atherosclerosis, obesity-associated IR and inflammatory diseases related to MS such as NAFLD and chronic kidney disease.

The sphingolipid ceramide is an important second signaling molecule that regulates diverse signaling pathways involving apoptosis, cell senescence, the cell cycle and differentiation. For the most part, effects of ceramide are antagonistic to growth and survival. Interestingly, ceramide and the pro-growth agonist, diacylglycerol (DAG) appear to be regulated simultaneously but in opposite directions in the sphingomyelin cycle. While ceramide stimulates signal transduction pathways that are associated with cell death or at least are inhibitory to cell growth (SAPK), DAG activates the classical and novel isoforms of the PKC family. These PKC isoforms are associated with cell growth and cell survival. Furthermore, DAG activation of PKC stimulates other signal transduction

pathways that support cell proliferation, e.g., MAPK pathways. Thus, ceramide and DAG generation may serve to monitor cellular homeostasis by inducing pro-death or pro-growth pathways, respectively. The production of ceramide is emerging as a fixture in programmed cell death. Ceramide levels are elevated in response to diverse stress challenges including treatment with pro-death ligands such as TNF- α , chemotherapeutic drug treatment or irradiation. Consistent with this notion, ceramide itself is a potent apoptogenic agent. Ceramide activates c-JNK and thus affects its transcription pathways. Ceramide activates protein phosphatases such as protein phosphatase 1 and PP2A. Ceramide activation of protein phosphatases has been shown to promote inactivation of a number of pro-growth cellular regulators including the kinases PKC α and Akt, Bcl-2 and the retinoblastoma protein. A new role has recently emerged for ceramide in the regulation of protein synthesis. Ceramide-induced activation of PKR, a protein kinase important in anti-viral host defense mechanisms and recently implicated in cellular stress pathways, results in the inhibition of protein synthesis as a prelude to cell death^[46].

ENDOPLASMIC RETICULUM, CHAPERONES AND LONGEVITY

Heat shock proteins (HSPs) have proven to be effective tools for extending invertebrate lifespan, and in *C. elegans* daf-2 mutants, longevity resulting from loss of insulin/insulin-like signals is at least partly dependent upon elevated HSP expression. In mice, inhibition of the orthologous growth hormone/insulin-like growth factor I (GH/IGF- I) pathway has similar pro-longevity effects. A recent study, however, suggested that loss of GH/IGF- I signaling in long-lived mice did not broadly elevate HSP expression, but in fact decreased HSP expression in many tissue types, such as liver and kidney. The contribution of chaperones to the longevity of long-lived mice with altered GH/IGF- I signals may therefore differ from that described in *C. elegans* daf-2 mutants. This result, in combination with other recent findings, underscores the possibility that systemic overexpression of chaperones will have dissimilar effects on longevity in vertebrate and invertebrate systems^[47].

MS AND CARDIOVASCULAR DISEASE RISK

MS is a constellation of common metabolic disorders that is strictly linked to CHD. It is now commonly accepted that low-grade chronic inflammation associated with obesity induces IR in the liver. Low-grade chronic inflammation is characterized by the production of abnormal cytokines and adipokines such as IL-6, TNF- α , IL-1, leptin and resistin. These factors inhibit insulin signaling in hepatocytes by activating SOCS proteins, several kinases such as JNK, IKK- β and PKC and protein

tyrosine phosphatases such as PTP1B and PTEN that in turn impair insulin signaling at the insulin receptor and IRS level. Hepatic IR in turn causes impaired suppression of glucose production by insulin in hepatocytes leading to hyperglycemia. An important and early complication of hepatic IR is the induction of hepatic VLDL production, *via* changes in the rate of apoB synthesis and degradation and *de novo* lipogenesis, or increased FFA flux from adipose tissue into the liver. IR also stimulates the production of C-reactive protein (CRP) and plasminogen activator inhibitor-1 (PAI-1), both markers of an inflammatory state. All these subsequent metabolic abnormalities related to hepatic IR have been shown to directly or indirectly promote atherosclerosis. Hyperglycemia induces a series of alterations including endothelial dysfunction, cellular proliferation, changes in extracellular matrix conformation and impairment of low density lipoprotein (LDL) receptor-mediated uptake, decreasing the *in vivo* clearance of LDL. Small dense LDLs associated with high circulating VLDL levels have higher affinity for the intimal proteoglycans leading, to the penetration of more LDL particles into the arterial wall. CRP can also accelerate atherosclerosis by increasing the expression of PAI-1 and adhesion molecules in endothelial cells, inhibiting nitric oxide formation and increasing LDL uptake into macrophages.

Recently it has been shown that a small molecule pan-JNK inhibitor, dosed orally and compared to rimonabant and rosiglitazone, significantly impacted parameters such as adiposity, glucose levels, and insulin sensitization without any effect on liver enzymes, thus establishing the role of JNK as a useful target for metabolic syndrome linked to the pre-diabetic state^[48]. A JNK1 specific antisense oligonucleotide was studied in ob/ob and diet-induced obese mouse models. Profound improvement in insulin sensitivity, glucose levels, plasma cholesterol level, and adiposity without a negative impact on liver function was observed. Decreased body weight and lowered adiposity were attributed to increased food combustion/metabolic rate and decreased lipogenesis^[49].

Describing the common mechanisms by which lipid derivatives, through modulation of macrophage function, promote plaque instability in the arterial wall, impair insulin responsiveness and contribute to inflammatory liver and discussing the molecular mechanism of lipid activation of pro-inflammatory pathways [JNK, nuclear factor (NF) κ B], the key roles played by the proliferator-activated receptor and liver X receptor α , nuclear receptors-lipid sensors that link lipid metabolism and inflammation, should be emphasized^[50]. Atherosclerosis begins as local inflammation of artery walls at sites of disturbed blood flow. JNK is thought to be among the major regulators of flow-dependent inflammatory gene expression in endothelial cells in atherosclerosis. Researchers have shown that JNK activation by both onset of laminar flow and long-term oscillatory flow is matrix-specific, with enhanced activation on fibronectin

compared to basement membrane protein or collagen. Flow-induced JNK activation on fibronectin requires new integrin ligation and requires both MKK4 and p21-activated kinase. *In vivo*, JNK activation at sites of early atherogenesis correlates with the deposition of fibronectin. Inhibiting p21-activated kinase reduces JNK activation in atheroprone regions of the vasculature *in vivo*. These results identify JNK as a matrix-specific, flow-activated inflammatory event. These data elucidate a network of matrix-specific pathways that determine inflammatory events in response to fluid shear^[51].

Visceral AT is known to confer a significantly higher risk of T2D and CHD. Epicardial AT has been shown to be related to cardiovascular disease and myocardial function. Epicardial AT expresses an inflammatory profile of proteins. Authors studied key mediators of the NF κ B and c-JNK pathways in paired epicardial and gluteofemoral (thigh) AT from CHD and investigated circulating endotoxin levels in CHD and control subjects. Serums and AT biopsies (epicardial and thigh) were obtained from CHD and non-CHD patients. Inflammation was assessed in tissue and serum samples through western blot, real-time PCR, ELISAs, and activity studies. Western blotting showed epicardial AT had significantly higher NF κ B, inhibitory- κ B kinase (IKK)- γ , IKK- β , and JNK-1 and -2 compared with thigh AT. Epicardial mRNA data showed strong correlations between CD-68 (again the impaired immunity function) and toll-like receptor-2, toll-like receptor-4, and TNF- α . Circulating endotoxin was elevated in patients with CHD compared with matched controls. Epicardial AT from patients with CHD shows increased NF κ B, IKK- β , and JNK expression compared with both CHD thigh AT and non-CHD epicardial AT, suggesting a depot-specific as well as a disease-linked response to inflammation^[52].

METHODS TO DETECT JNK

The detection of protein kinases is possible in biological liquids such as blood serum or cell lysate. Sandwich ELISAs for detecting phosphoproteins have commonly been used to quantify kinase function and can be performed in 2 configurations. In the first configuration, polyclonal antibodies directed against the structural part of the protein and away from the phosphorylation site (panprotein) are coated onto the bottom of a microwell plate. A cell lysate containing the phosphorylated target protein is added to the well, allowed to bind and the excess lysate is removed by washing. A monoclonal antibody of either mouse or rabbit origin, specific for the phosphorylated form of the protein, is added followed by an enzyme-labeled secondary antibody specific for the monoclonal antibody species. A chromagen is added and the color is quantified spectrophotometrically. In the second configuration, the capture antibody is directed against the phosphor-antibody and the detection antibody is an antibody directed against the panprotein. The latter configuration is sometimes preferred as the amount of phosphor-protein present may be small compared to the total amount of

the panprotein.

In this situation, the large amount of non-phosphorylated panprotein can outcompete the phosphorylated protein for binding to the microwells. This decreases the overall sensitivity of the assay for the phosphor-protein. Using a phosphor-specific capture antibody enriches for the desired target and significantly increases the sensitivity of the assay. Phospho-ELISAs can be used to assess kinase activity in cell lysates or, alternatively, to screen drug candidates targeting a purified kinase. Quantitative measurement of protein phosphorylation has become essential for the development of kinase-inhibiting drugs aimed at therapy of various metabolic diseases. Since kinases are a major source of drug targeting, complex but reliable assay technologies that quantify phosphorylation will continue to be in demand. Biochemical assays that rely on antibodies for assay function are limited by the availability of phosphor-specific antibodies with high affinity and specificity. While many phosphospecific antibodies exist, most are unsuitable for use in quantitative assays due to poor sensitivity or nonspecificity. Alternative methods such as mobility shift, IMAP (a variation of fluorescence polarization that employs nanoparticles bearing immobilized trivalent metal co-ordination complexes that bind specifically to phosphate groups), IQ (using as signal a peptide comprised of an amino acid sequence recognized by the desired kinase that is synthesized with a fluorophore end-label) and light-speed assays (the signal is generated from a polystyrene microsphere that is coated with a modified fluorescent polyelectrolyte) do not rely on antibodies and allow assessment of targets for which no suitable antibodies exist. As a result, these formats will find wider use in the future^[53].

CONCLUSION

As repeatedly emphasized, inflammation is the common mechanism underlying obesity, MS, NAFLD^[54], longevity, CHD and perhaps some cancers. The chicken-and-egg dilemma of IR being cause or effect of inflammation is unsolved at present. Further studies are warranted of anti-inflammatory drugs such as aspirin, anti IL-6 receptors, immune-modulators (calcineurin inhibitors)^[55], substances enhancing the expression of HSPs (which protect cells from ER stress-induced apoptosis), and anti-JNKs in well-designed trials to try to minimize the high impact of these illnesses, and the different expressions of the diseases, on the whole population^[56].

Abstract

Minimally invasive surgery started spreading worldwide in 1987, when the first laparoscopic cholecystectomy was performed. Meanwhile, improvement of endoscopic equipment and instruments allowed gastroenterologists to attempt more aggressive endoluminal interventions, even beyond the wall barrier. The first transgastric peritoneoscopy, in 2004, brought to light the concept of natural orifice transluminal endoscopic surgery (NOTES). The idea of incisionless surgery is attractive and has become a new goal for both surgeons and other people interested in this field of investigation. The authors present a review of all developments concerning NOTES, including animal studies and human experience.

INTRODUCTION

Surgery has experienced a huge development in the past three decades after Dr. Philippe Mouret performed the first laparoscopic cholecystectomy in 1987. Since then, minimally invasive surgery has begun to spread worldwide^[1]. This was largely in part due to patient demands for laparoscopic surgery's advantages - shorter hospital stays, less pain, and smaller, less disfiguring scars^[2]. The improvement of available equipment and instruments allowed more and more surgical procedures to be made through a minimally invasive approach, rapidly becoming a standard practice in most procedures.

At the same time, progresses in gastrointestinal endoscopy have made it an indispensable and multifaceted instrument for diagnosis and therapy. Besides endoluminal procedures, gastroenterologists attempted some interventions beyond the wall barrier, such as pseudocyst drainage^[3] and percutaneous endoscopic gastrostomy^[4]. However, it was not until 2004 that Kalloo *et al*^[5] published the first report of a true transluminal procedure, a transgastric peritoneoscopy in a porcine model, which brought to light the concept of natural orifice transluminal endoscopic surgery (NOTES). The idea of incisionless surgery was attractive and has now become a new goal for both surgeons and other people interested in this field of investigation.

The term NOTES describes novel endoscopic interventions on internal organs performed through natural orifices^[6]. In this new approach, endoscopes enter the abdominal and thoracic cavities *via* any single or combination of natural orifices - mouth, urethra, vagina, and anus. Depending on the orifice, rigid or flexible equipment can be used. The lower “short-ways” (bladder, colon or vagina) allow the easy passage of rigid or flexible instruments into the abdominal cavity, but the upper “long-ways” (esophagus and stomach) require flexible equipment^[7] (Figure 1).

The main goal for NOTES is avoiding skin incisions. Other theoretical advantages include: decreased post-operative pain, reduction/elimination of general anesthesia, performance of procedures in an outpatient or even office setting, and possibly cost reduction. Moreover, eliminating skin incision avoids associated complications such as wound infections and hernias, as well as reduction in hospital stay, faster return to bowel function, improved cosmetic outcomes, and increased overall patient satisfaction^[2].

WHAT DID THE INVESTIGATION ACHIEVE SO FAR?

The first challenge in NOTES is getting good and clean access to the cavity we want to “scope” (Table 1). The first mention of natural orifice procedure dates back to the 1940s, when culdoscopies were performed using an endoscope passed through the recto-uterine pouch to view pelvic organs, as well as to perform sterilization procedures^[8]. At that time, these procedures did not gain much popularity and were restricted to some gynecological procedures. Recently, however, they were recovered by NOTES development. In 2002, Gettman *et al*^[9] published one pure transvaginal nephrectomy along a series of hybrid transvaginal nephrectomy in a porcine model.

Taking advantage of the great developments in gastrointestinal endoscopy, some pioneers began working on the transgastric approach to the abdominal cavity. The first published description of transgastric peritoneoscopy was in 2004 by Kalloo *et al*^[5], in a porcine model. Since then, a number of successful transgastric procedures have been attempted and performed^[10-20]. These initial studies also identified major limitations of the isolated transgastric approach, mainly in more complex procedures such as cholecystectomy, first described in 2005 by Park *et al*^[21]. Lack of triangulation and platform stability were the main problems identified. Searching for solutions to these problems, researchers tried other ways of entering the abdominal cavity. Fong *et al*^[22-24] published the first transcolonic peritoneoscopy followed by a series of transcolonic procedures. The access from below gives a good, direct view of the upper abdominal cavity. Having that in mind, Lima *et al*^[25] published the first transvesical endoscopic peritoneoscopy. And subsequently our group used a combination of transgastric and transvesical approaches to solve the problem of

triangulation, and managed to do a series of cholecystectomies and nephrectomies in porcine models^[26,27].

To accomplish NOTES procedures in the thorax, Sumiyama *et al*^[28] proposed the transesophageal access. Transvesical-transdiaphragmatic thoracoscopy^[29], transgastric-transdiaphragmatic thoracoscopy^[30], and transtracheal thoracoscopy^[31] have been suggested as well. Although the transesophageal method has been preferred as a direct entry to the thorax and posterior mediastinum, this permitted several simple thoracic procedures in porcine models^[32-38].

CURRENT CHALLENGES

Despite the enthusiasm for NOTES, there are still some hurdles to be overcome. The initial concern is the potential for intra-abdominal infection and spillage from the viscerotomy. Infection must first be prevented by using a clean access site. Most transgastric protocols also follow a 24 h liquid formula diet, intravenous antibiotics and stomach irrigation with sterile water and antibiotic solution. Despite these precautions, even a sterile overtube used to protect the endoscope from oral contamination becomes contaminated on oral insertion and can transport bacteria to both the stomach and the peritoneal cavity^[2]. Surprisingly, Narula *et al*^[39] reported no infections after gastrotomy in patients undergoing diagnostic transgastric peritoneoscopy without previous gastric decontamination. The authors considered that the same degree of contamination of the peritoneal cavity is expected as in any operation performed with an open viscus.

There is also some controversy about the need for endoscope sterilization. In a recent literature review, Spaun *et al*^[40] concluded that, although difficult, it is possible to terminally sterilize flexible endoscopes. Steris System 1™ that uses 0.2% peracetic acid was the cheapest and fastest sterilization method and scored second in the risk of recontamination. Ethylene oxide gas sterilization has the lowest risk of recontamination, but is the slowest and most expensive method. The authors recommend sterile instrumentation for clinical NOTES until well-designed and randomized clinical trials are available and guidelines are published.

Concerning viscerotomy closure, gastrotomy has been the most studied and the methods under investigation could also be applied to the colon, esophagus or bladder, depending on the circumstances. Several methods have been proposed for stomach closure, including: conventional endoscopic clips, over-the-scope clip (OTSC) system, septal occluders, T-tags, T-bars for tissue opposing, as well as more complex suturing devices such as the Eagle Claw VII, NDO Plicator, USGI Endosurgical Operating System, and linear endoscopic staplers. Most of these devices still have limitations that need improving, but OTSC shows the most promising results^[41]. More recently, the Padlock-G clip have been described as also showing promising results^[42]. Colonic closure in animal studies has been performed using the

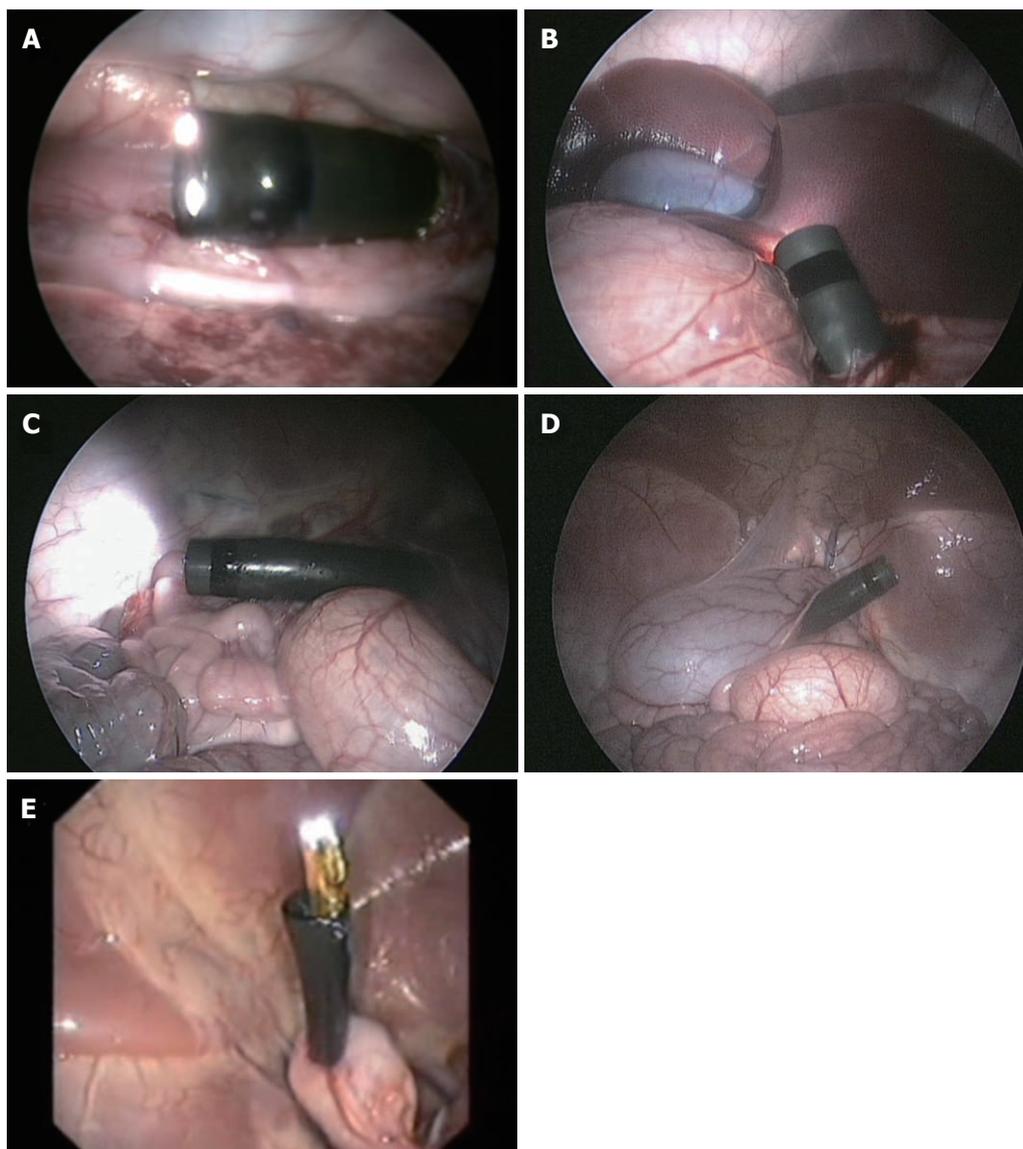

Figure 1 Internal view of natural orifice transluminal endoscopic surgery access (porcine model). A: Trans-thoracic view of transesophageal access; B: Transabdominal view of transgastric access; C: Transabdominal view of transcolonic access; D: Transabdominal view of transvaginal access; E: Transgastric view of transvesical access.

same techniques and devices as those used for gastrotomy closure. Transanal endoscopic microsurgery has been used for a long time, and has been useful for colonic closure in hybrid NOTES procedures in humans^[43]. For vesicotomy closure, Lima *et al*^[44] recently reported the first successful endoscopic closure using a suturing kit (T-fasteners with a locking clinch). Easy and safe closure has been the main advantage for transvaginal route acceptance. Closure after transvaginal access is readily and routinely performed by using standard surgical techniques. Even if closure were to fail, there would be little, if any, clinical significance, because of the extremely low risk of infection or hernia.

Concerning adequate exposure and visualization, pneumoperitoneum is a key component. Air insufflated in an uncontrolled manner through the endoscope results in wide fluctuations in intraperitoneal pressures, overdistension of the abdomen, and adverse hemodynamic effects. Insufflated air can also leak around the endoscope resulting in bowel overdistension^[2]. Many authors are now using a Veress needle to inject carbon

dioxide and safely control its pressure inside the abdomen^[45]. Despite this, new insufflators are being adapted to both deliver and monitor carbon dioxide through the endoscope^[46]. There is a great debate whether CO₂ or room air should be used. The effect of CO₂ with respect to laparoscopy has suggested an overall attenuated inflammatory response that may provide a further immunologic benefit. The acidic environment created has been the main contributing factor believed to facilitate this physiologic result. Conversely, “room air” laparoscopy has been shown to generate a greater inflammatory response, but a recent case-control study did not find a significant difference between the peritoneal inflammatory response of NOTES *vs* laparoscopy with carbon dioxide and air pneumoperitoneum^[47].

As previously stated, maintaining spatial orientation and triangulation of instruments is challenging when using a flexible endoscope. Moreover, flexible endoscopes are difficult to stabilize inside the abdominal cavity and can only pass flexible instruments which are too flaccid for retraction. This challenge can be overcome with

Table 1 Major features of the different natural orifice transluminal endoscopic surgery access for thoracic and abdominal cavities

	Transesophageal	Transgastric	Transvesical	Transvaginal	Transcolonic
Rigid instruments	No	No	Yes	Yes	Yes
Available in both genders	Yes	Yes	Yes	No	Yes
Sterility	No	No	Yes	No	No
Size	Wide	Wide	Up to 6 mm	Wide	Wide
Closure	Endoscopic (in study)	Endoscopic (in study)	Endoscopic (in study)	Direct suture	Endoscopic (in study)
Specimen retrieval	Not reported	Possible	Not reported	Possible	Possible

adequate training, a combination of different routes, and with the constant development of new instruments. Transvaginal, transcolonic and transvesical routes allow the introduction of rigid equipment, and except in the transvesical route, the instruments can be used either through a rigid endoscope or in parallel with a flexible endoscope. Additionally, these access routes coming from the lower abdomen permit a good direct visualization of the upper abdomen. In some cases, one can use an additional transabdominal port. This has been named hybrid NOTES and has been seen as an intermediate step of great help in the training and development of NOTES^[48]. Recently, magnets are being managed to provide the vigorous traction and countertraction required to advance NOTES procedures^[49]. A new magnetic anchoring and guidance system allows concurrent use of multiple working instruments and control of an intra-abdominal camera. It has been used to perform transvaginal, single-port cholecystectomy^[50]. Finally, one of the hurdles of NOTES is getting solid organs out of the thoracic and abdominal cavities. Excision of larger organs such as a kidney, or a gallbladder filled with stones through a small trocar orifice is a huge challenge. The transvaginal access has a big advantage in this matter and has been used for specimen retrieval in most NOTES procedures. On the other hand, transvaginal access is only an option in female patients.

HUMAN EXPERIENCE

In 2003, Rao and Reddy^[51] performed the first NOTES procedure in humans. The authors carried out a transgastric appendectomy in a male patient presenting severe burn lesions in his abdominal wall using a conventional flexible endoscope with two working channels. Only in 2007, was there the first published human NOTES procedure. Marks *et al*^[52] performed a transgastric rescue of a prematurely dislodge gastrostomy tube. The authors advanced a standard gastroscope through the previous gastrostomy, a performed peritoneoscopy, and suctioned away intra-abdominal free fluid. In that same year, another case reported the first human transvesical peritoneoscopy using a flexible ureteroscope during a standard laparoscopic robot-assisted prostatectomy^[53].

The first natural orifice transluminal cholecystectomy in humans was performed in Strasbourg, France^[54]. A

30-year-old woman with symptomatic cholelithiasis was submitted to cholecystectomy using a standard double-channel flexible gastroscope and standard endoscopic instruments. A 2-mm transabdominal needle port was used to insufflate carbon dioxide, to monitor the pneumoperitoneum, and to retract the gallbladder. Colpotomy was closed using conventional instruments. The patient had no post-operative pain and no scars, and was discharged on the second post-operative day. Shortly after that, the same technique was used by a team in Brazil, and by another in Italy^[55,56].

In 2007, a group of investigators from Ohio, United States used transgastric peritoneoscopy after standard laparoscopy to diagnose pancreatic masses^[57]. In 9 out of 10 patients, transgastric abdominal exploration corroborated the decision to proceed to open exploration made during traditional laparoscopic exploration. The average time of diagnostic laparoscopy was 12.3 min, compared to the 24.8 min taken for the transgastric route. Closure of the gastrotomy was obviated through its integration into the primary operation, whether that involved a resection with curative intent or palliation. No cross-contamination of the peritoneum or infectious complications was noted.

Other procedures using exclusively natural orifice transluminal procedures in humans have been performed - transgastric and transduodenal pancreatic necrosectomy^[58], transvaginal incisional hernia repair^[59], transvaginal liver, diaphragm, ovaries, and peritoneum biopsies^[60], and transvaginal appendectomy^[61]. This last one is especially important, as two of the three cases presented had an umbilical port inserted in order to complete appendectomy. As seen before in cholecystectomy, the use of a transabdominal port is essential to make natural orifice approaches feasible or at least easier at this time. Hybrid NOTES procedures are seen as a safe way to accomplish pure NOTES in the future. For this aim, hybrid procedures are developing in humans and achieving new goals like transvaginal nephrectomy^[62], transrectal rectosigmoidectomy^[63], sleeve gastrectomy^[64], transvaginal liver resection^[65], transvaginal splenectomy^[66], transgastric cholecystectomy^[67], transanal rectal cancer resection^[43], intragastric stapled cystogastrostomy of a pancreatic pseudocyst^[68], and adjustable gastric banding^[69].

In 2009, de Sousa *et al*^[70] published the first series of pure NOTES transvaginal cholecystectomies. The authors performed four cholecystectomies using two

endoscopes introduced simultaneously in the abdominal cavity through a transvaginal incision. Dissection was accomplished with conventional endoscopic instruments. Ligation of the cystic duct and artery was performed using endoscopic clips. Vaginal closure was achieved using the direct-vision suture technique. More recently, Bessler *et al*^[71] described a different technique for pure NOTES cholecystectomy in a 35-year-old-woman. Instead of using two endoscopes, the authors used an extra-long 5-mm articulating retractor placed into the abdomen *via* a separate colpotomy made under direct vision using the flexible endoscope in a retroflexed position. This method overcame the retracting limitations that obliged the use of a transabdominal port.

Despite all the enthusiasm around NOTES, other clinical advantages besides the absence of skin incision remain to be fully proven. Although most studies claim that greater operative time would be compensated by shorter hospital stays, prospective control studies are lacking^[72]. Hensel *et al*^[73] reported a retrospective case-control study where hybrid transvaginal cholecystectomy group showed a lower need for analgesics, faster mobilization, more comfortable recovery and a shorter hospital stay than the conventional laparoscopy group.

Finally, patients' perspectives and expectations about NOTES are not yet fully understood. An interesting questionnaire-based study was derived to identify their preferences between different available surgical options upon a hypothetical scenario of an acute appendicitis^[74]. Single port surgery (SPS) was the most popular method followed by conventional laparoscopy. Open surgery and NOTES were the least preferred. Choosing between SPS and NOTES only, 80.6% opted for SPS, 11.8% NOTES, and 5.6% declined surgery. The most popular route of access for NOTES was oral (37.7%). Another study asked women about their concerns and opinions regarding transvaginal surgery^[75]. The majority of women (68%) indicated that they would want a transvaginal procedure in the future because of decreased risk of hernia and decreased operative pain (90% and 93%, respectively), while only 39% were concerned with the improved cosmesis of NOTES surgery. Of the women polled, nulliparous women and those under age 45 years were significantly more often concerned with how transvaginal surgery may affect healthy sexual life and fertility issues. Of the women who would not prefer transvaginal surgery, a significant number indicated concerns over infectious issues.

THE FUTURE OF NOTES

NOTES promises a new and innovative era of minimal access surgery based on traditional laparoscopic and endoscopic techniques. Researchers all over the world are investigating ways to improve NOTES procedures in order to make it easier and safer. With careful development of new equipment and techniques, NOTES may be a reasonable option to conventional laparoscopic procedures. It may even become the method of choice for selected surgical procedures in the future.

Abstract

AIM: To investigate the efficacy of rebamipide in a rat model of colitis and restitution of intestinal epithelial cells *in vitro*.

METHODS: Acute colitis was induced with trinitro-

benzene sulfonic acid (TNBS) in male Wistar rats. Rats received intrarectal rebamipide treatment daily starting on day 7 and were sacrificed on day 14 after TNBS administration. The distal colon was removed to evaluate the various parameters of inflammation. Moreover, wound healing assays were used to determine the enhanced restitution of rat intestinal epithelial (RIE) cells treated with rebamipide.

RESULTS: Intracolonic administration of rebamipide accelerated TNBS-induced ulcer healing. Increases in the wet weight of the colon after TNBS administration were significantly inhibited by rebamipide. The wound assay revealed that rebamipide enhanced the migration of RIE cells through phosphorylation of extracellular signal-regulated kinase (ERK) and activation of Rho kinase.

CONCLUSION: Rebamipide enema healed intestinal injury by enhancing restitution of RIE cells, *via* ERK activation. Rebamipide might be a novel therapeutic approach for inflammatory bowel disease.

Rebamipide promotes healing of colonic ulceration through enhanced epithelial restitution. *World J Gastroenterol* 2011; 17(33): 3802-3809 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i33/3802.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i33.3802>

INTRODUCTION

Inflammatory bowel disease (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), is a chronic and recurrent intestinal inflammatory disorder whose precise pathogenesis remains unknown^[1]. In patients with IBD, a variety of cells and soluble factors mediate extensive mucosal damage, and epithelial cell damage is frequently observed^[2]. Generally, after sustaining mucosal injury, the intestinal epithelium rapidly reestablishes its integrity *via* restitution, proliferation, and differentiation of epithelial cells^[3]. Among these three steps, restitution is thought to be most critical for intestinal mucosal healing^[4]. Therefore, the promotion of restitution remains an important therapeutic target. Along these lines, various molecules involved in regenerating the intestinal epithelium are currently under consideration for clinical use^[5].

Rebamipide is an amino acid derivative of 2(1H)-quinolinone, and is a gastric mucosal protective and ulcer-healing agent that has been widely used for treatment of acute and chronic gastritis and gastric ulcer. It is already known that rebamipide has anti-inflammatory properties including scavenging of free radicals, suppression of pro-inflammatory cytokine production, inhibition of inflammatory cell migration and adherence, and promotion of prostaglandin and mucus production^[6]. Recently, rebamipide has been used as a gastric protective agent and for treatment of UC^[7]. First, Makiyama *et al.*^[8] have reported that rebamipide enema had an anti-inflammatory effect in a patient with proctitis-type UC. They also have reported the efficacy of rebamipide enemas in active distal UC and proctitis in a prospective study^[9]. Furthermore, it has been demonstrated that rebamipide enema is safe and useful in corticosteroid-refractory or -dependent patients with the active distal type of UC^[10]. In addition, Matsumoto *et al.*^[11] have reported that rebamipide enema ameliorates disease activity in patients with left-side ischemic colitis. Thus, these clinical data suggest that rebamipide shows promise in terms of its potential for repairing intestinal injury. However, the detailed molecular mechanism of action of rebamipide against intestinal inflammation remains unclear.

Therefore, in the present study, we aimed to assess the effect of rebamipide in intestinal inflammation by using the trinitrobenzene sulfonic acid (TNBS)-induced colitis model, a well-accepted IBD model. Furthermore, we analyzed the possible mechanisms involved in rebamipide-mediated mucosal restitution by using a well-established model of intestinal epithelial wound healing *in vitro*^[12,13].

MATERIALS AND METHODS

Reagents

All chemicals were prepared immediately before use. Rebamipide {2-(4-chlorobenzoylamino)-3[2-(1H)-quinolinon-4-yl] propionic acid} was a kind gift from Otsuka Pharmaceutical Co. Ltd. (Tokyo, Japan). TNBS and 3, 3', 5, 5'-tetramethylbenzidine were obtained from

Wako Pure Chemicals (Osaka, Japan). We used MEK1/2 inhibitor as an extracellular signal-regulated kinase (ERK) inhibitor (U0126; BIOMOL International LP, Plymouth Meeting, PA, United States) and Y27632 [(1)-(R)-*trans*-4-(1-aminoethyl)-N-(4-pyridyl)cyclohexanecarboxamide dihydrochloride] as the Rho kinase inhibitor (Biaffin GmbH and Co KG, Kassel, Germany). All other chemicals were of the highest quality commercially available.

In vivo study animals

Male Wistar rats weighing 180-200 g were obtained from Shimizu Laboratory Supplies Co. Ltd. (Kyoto, Japan). The animals were housed at 22 °C in a controlled environment with 12 h of artificial light per day, and were allowed access to rat chow and water *ad libitum*. The animals were maintained and all experimental procedures were carried out in accordance with the National Institutes of Health (NIH) guidelines for the use of experimental animals. All experimental protocols were approved by the Animal Care Committee of the Kyoto Prefectural University of Medicine (Kyoto, Japan).

Induction of colitis

TNBS-induced colitis was established using the method of Morris *et al.*^[14]. The rats were lightly anesthetized with pentobarbital following a 48-h fast, and then a rubber catheter (outer diameter, 2 mm) was inserted *via* the anus, such that the tip was 8 cm from the anus. TNBS dissolved in 50% ethanol (120 mg/mL) was instilled into the lumen of the colon *via* the catheter (volume, 0.25 mL). Following the instillation of TNBS at 30 mg per rat, the anus was occluded with a clip for 1 h.

Treatment protocol

All animals were randomized into groups that received rebamipide or physiological saline vehicle. We focused on the effects of rebamipide during healing after colonic mucosal injury. One percent rebamipide was intrarectally administered (2 mL/kg) twice daily starting on day 7 after induction of colitis, until day 14.

Evaluation of colonic damage

The rats were sacrificed on day 14 and the distal colon was removed and opened by longitudinal incision. The wet colon weight was measured immediately thereafter. As indices of inflammation, damage was estimated macroscopically as the sum of the mucosal score. The mucosal score was rated on a six-point scale (0-5) according to the criteria established by Morris *et al.*^[14] (Table 1). The degree of colitis was evaluated by an independent observer who did not have previous knowledge of the treatment. For the histological examination, formalin-fixed tissue was stained with hematoxylin and eosin. The colon histological score was evaluated using the histopathological grading system of Ameho *et al.*^[15] by an observer blinded to the treatment. This grading, which takes into account the degree of infiltration, the presence of erosion, ulceration, or necrosis, and the depth and

Table 1 Criteria for scoring gross morphological damage of the colon^[12]

Mucosal score	Gross morphology
0	No damage
1	Localized hyperemia, but no ulcers
2	Liner ulcers with no significant inflammation
3	Liner ulcers with inflammation at one site
4	Two or more sites of ulceration and/or inflammation
5	Two or more major sites of inflammation and ulceration extending > 1 cm along the length of the colon

surface of the lesion, is scaled from 0 to 6.

***In vitro* study of intestinal epithelial cell line**

Non-transformed rat intestinal epithelial (RIE) cells were grown in a 1:1 mixture of Dulbecco's Modified Eagle's Medium and Ham's F12 medium supplemented with 5% heat-inactivated fetal bovine serum, 2 mmol/L glutamine, 100 U/mL penicillin, 100 µg/mL streptomycin, and 0.25 µg/mL amphotericin. The cells were incubated at 37 °C in a humidified atmosphere supplemented with 5% CO₂. RIE cells were trypsinized and seeded into 60-mm culture dishes. Experiments were performed when the cells reached confluency.

Wound assay

Wound assays were performed using a previously described method with minor modifications^[16]. Confluent monolayers of RIE cells in 60-mm culture dishes were washed with phosphate-buffered saline, and cells were cultured for an additional 24 h in serum-free medium. Subsequently, cell monolayers were disrupted using an extra long 10-µL pipette tip (Pelican Life Sciences, San Diego, CA, United States), followed by a cycle of washing in serum-free medium to yield a cell-free zone in the culture dishes. The process of migration was monitored using an inverted phase-contrast microscope at 0, 6 and 12 h after induction of the artificial wound. Changes in the cell-free zone were analyzed with the ImageJ software (Wayne Rashband; NIH, Bethesda, MD, United States), and this analysis was performed by the same individual under blind conditions to prevent observer bias. To investigate the effects of rebamipide on RIE cell migration, the cells were co-incubated with rebamipide (2 mmol/L) after wound induction. Furthermore, to investigate involvement of the ERK signaling pathway and the Rho kinase pathway, cells were co-treated with U0123 (10 µmol/L) or Y27632 (1 µmol/L) after wounding.

Western blotting analysis

To determine whether rebamipide was involved in the ERK signaling pathway, proteins were obtained from RIE cells at 0, 5, 15 and 20 min after stimulation with 2 mmol/L rebamipide. The total proteins were mixed with SDS sample buffer. The samples were then subjected to 10% SDS-PAGE and blotted onto a polyvinylidene fluoride membrane (Atto Corporation, Tokyo, Japan). The membrane was blocked with 2% bovine serum albumin in Tris-

buffered saline that contained 0.1% Tween (TBS-T) at room temperature for 30 min. Western blotting analysis was carried out using rabbit polyclonal anti-p44/42, phospho-p44/42 (1:1000), and actin antibody (1:1000) as an internal control at room temperature for 1 h. After three washes with TBS-T, the membrane was incubated with anti-rabbit IgG-horseradish peroxidase (1:3000; GE Healthcare UK Ltd., Little Chalfont, Bucks, United Kingdom) at room temperature for 45 min. The signals were visualized using an ECL kit (GE Healthcare) according to the manufacturer's instructions.

Statistical analysis

Results are presented as the mean ± SE. Overall differences between groups were determined by one-way ANOVA. Whenever one-way ANOVA was significant, differences between individual groups were analyzed by Bonferroni's multiple comparisons test. Differences of $P < 0.05$ were considered significant. All analyses were performed using the GraphPad Prism 4 program (San Diego, CA, United States) for a Macintosh computer.

RESULTS

Therapeutic effect of rebamipide on TNBS colitis

In rats exposed to TNBS, macroscopic findings in the colon demonstrated severe colitis with hyperemia, edema, thickening, ulceration, and necrosis. It has already been demonstrated that the lesion area reaches its maximum on day 2 or 3 after TNBS treatment, after which it decreases in a time-dependent manner^[13,17]. In order to focus on the effects of mucosal healing by rebamipide enema, all rats were administered either placebo or rebamipide solution starting on day 7 after induction of TNBS, until day 14. On day 14, severe colitis with thickening of the mucosa and ulceration were still observed in the placebo group (Figure 1A). In contrast, rats treated with 1% rebamipide showed smaller erosions and mild edema in the colon (Figure 1A). Thus, the colonic mucosal damage score on day 14 had significantly increased due to TNBS administration in the sham-treated group. Increases in the mucosal damage score were significantly inhibited by treatment with 1% rebamipide (Figure 1B). Furthermore, the colonic wet weight was significantly increased in the TNBS colitis group. This increase was significantly decreased by treatment with 1% rebamipide (Figure 1C).

The therapeutic effects of 1% rebamipide enema were also confirmed by histological examination. Figure 2A shows the representative histological features of a normal colon (day 0) and those of the control group (day 14) and the rebamipide-treated group (day 14). TNBS administration induced marked thickening of the colonic wall, with transmural infiltration and aggregation of numerous inflammatory cells (Figure 2A), which is in contrast to the features of the normal colon, which does not show transmural infiltration or aggregation of inflammatory cells (Figure 2A). On the contrary, in rats treated with 1%

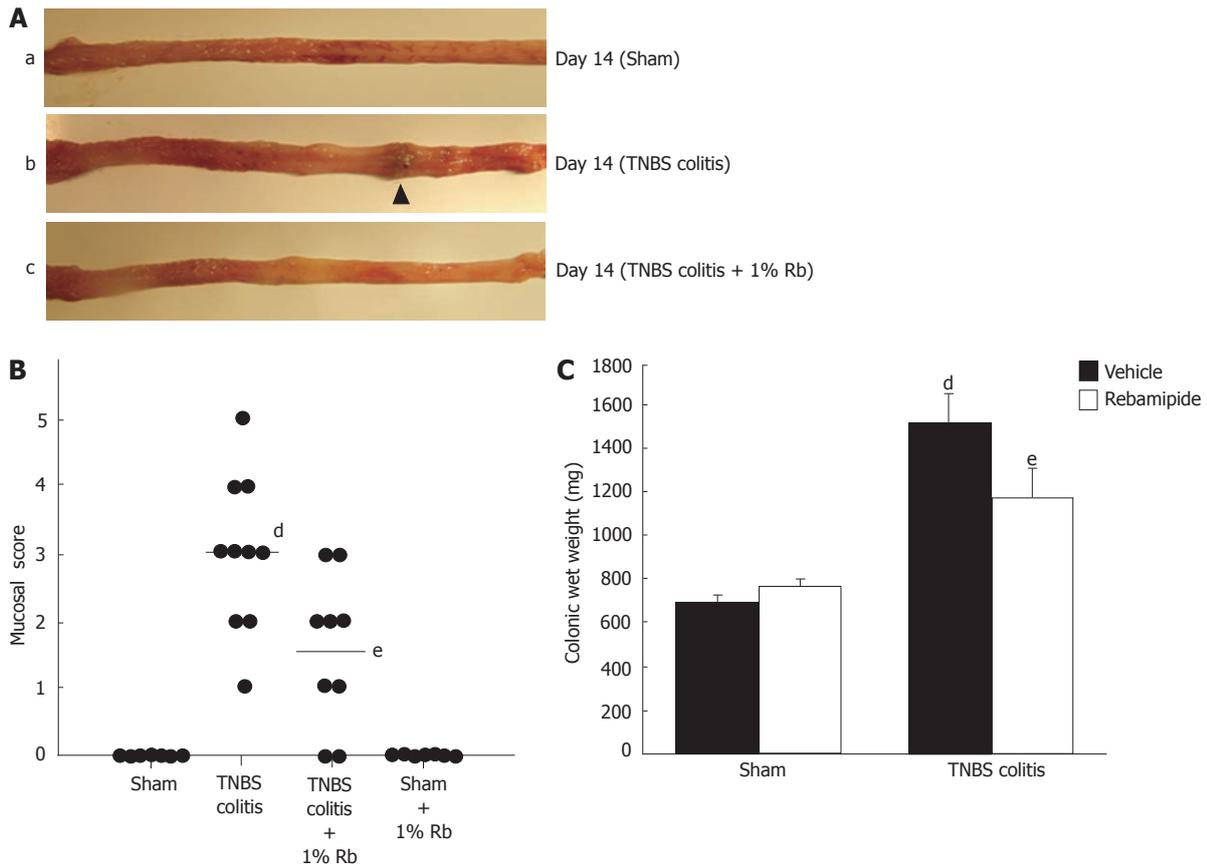

Figure 1 Effects of 1% rebamipide on macroscopic findings, mucosal damage score, and wet colon weight on day 14 after trinitrobenzene sulfonic acid-induced injury. A: Severe colitis was induced with hyperemia, edema, thickening, ulceration, and necrosis in trinitrobenzene sulfonic acid (TNBS)-colitis rats (b) compared to sham-operated rats (a). These changes were reduced in rats treated with 1% rebamipide (TNBS-colitis rats treated with 1% rebamipide) (c). B: A 1% rebamipide enema was administered twice daily starting on day 7 after induction of colitis, until day 14. Rats were sacrificed on day 14, and the mucosal damage score was evaluated. Data are expressed as a scatter plot. ^a*P* < 0.01 vs sham-treated rats. ^b*P* < 0.05 vs TNBS-induced colitis rats receiving the vehicle. C: Rats were sacrificed on day 14 and the distal colon was removed, after which, the wet colon weight was immediately measured. Data represent the mean ± SE of seven rats. ^d*P* < 0.01 vs sham-treated rats receiving the vehicle. ^e*P* < 0.01 vs TNBS-induced colitis rats receiving the vehicle.

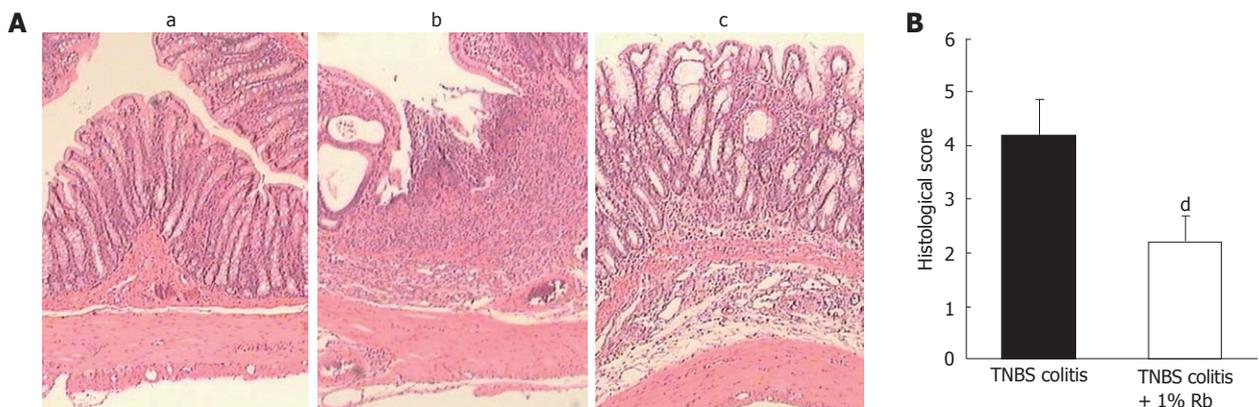

Figure 2 Effects of 1% rebamipide on histological findings in the colon on day 14 after trinitrobenzene sulfonic acid-induced injury. A: Histological appearance of colonic tissue in sham-operated rats (a), trinitrobenzene sulfonic acid (TNBS)-colitis rats (b), and TNBS-colitis rats treated with 1% rebamipide (c). Histological examination revealed that TNBS administration induced marked thickening of the colonic wall, which was associated with transmural infiltration of inflammatory cells. In contrast, both mural wall thickening and infiltration of inflammatory cells were inhibited in rats treated with 1% rebamipide. Hematoxylin and eosin staining (× 40). B: Histological score was evaluated. Data represent the mean ± SE of six rats. ^a*P* < 0.01 vs TNBS-colitis rats receiving the vehicle.

rebamipide, inhibition of both mural wall thickening and inflammatory cell infiltration was observed (Figure 2A). More importantly, rebamipide enema promoted restit-

tion of the colonic epithelium in the ulcerative area. The histological score was increased in the TNBS colitis group, and this increase was significantly inhibited by treatment

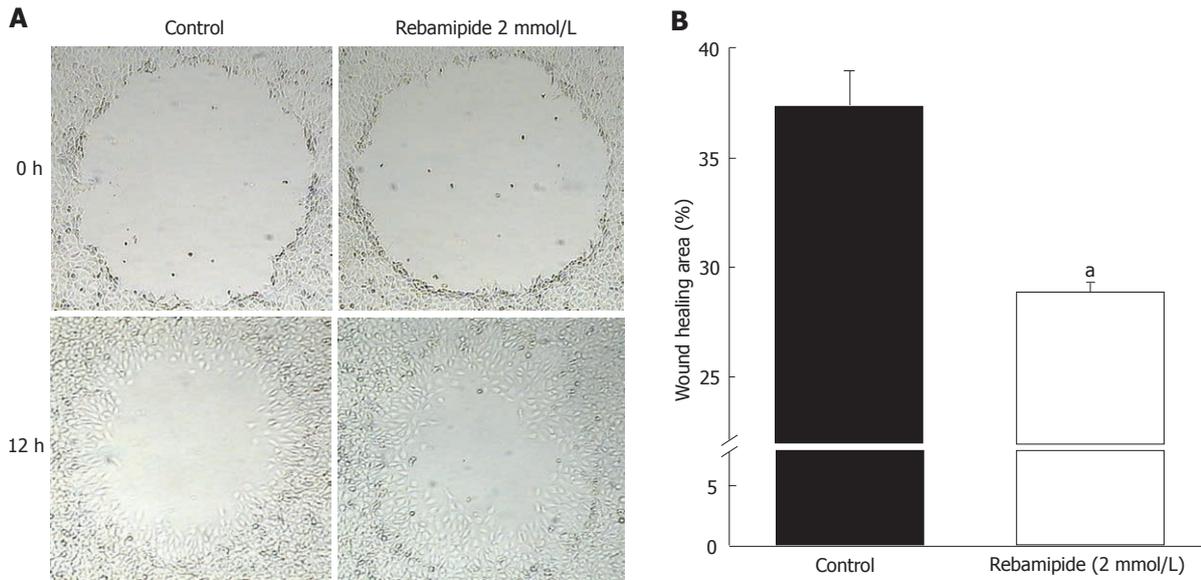

Figure 3 Restitution of rat intestinal epithelial cells around an artificially created wound in control and rebamipide-treated groups. A: Restitution of rat intestinal epithelial (RIE) cells was evaluated using a wound assay. The denuded area of RIE cells recovered in a time-dependent manner after wound induction. Restitution of the denuded area was promoted by rebamipide at 12 h after wound induction. B: To investigate the effects of rebamipide on RIE cell migration, cells were co-cultured with 2 mmol/L rebamipide after wound induction. Wound repair in 2 mmol/L rebamipide-treated cells occurred significantly earlier than it did in the controls. Datas represent the mean \pm SE of four experiments. ^a $P < 0.05$ vs controls.

with 1% rebamipide (Figure 2B).

Effects of rebamipide treatment as determined by wound assay using RIE cells

To investigate the effect of rebamipide on restitution of the intestinal epithelium, we performed a wound assay using RIE cells. The cell-free area at the wound site gradually decreased in a time-dependent manner, and complete recovery was observed 15 h after wound induction (data not shown). Restitution was significantly enhanced by rebamipide treatment (Figure 3A). Treatment with 2 mmol/L rebamipide accelerated wound healing compared to the control group (Figure 3B).

To investigate whether the promotion of restitution by rebamipide was involved in ERK signaling, RIE cells were stimulated with 2 mmol/L rebamipide by using a specific ERK inhibitor (U01263). As shown in Figure 4A, the ERK inhibitor blocked the promotion of wound healing by rebamipide. Moreover, to confirm the involvement of the ERK signaling pathway in the enhanced restitution associated with rebamipide treatment, we performed western blot analysis using phosphorylation-status-dependent and -independent antibodies against ERK1/2 (44 and 42 kDa) at 0, 5, 15 and 20 min after treatment with 2 mmol/L rebamipide. The western blots revealed ERK phosphorylation in RIE cells 5 min after rebamipide treatment (Figure 4B). Furthermore, to examine the role of Rho kinase in rebamipide-enhanced restitution, RIE cells were stimulated with rebamipide by using Y27632, a Rho kinase inhibitor (1 μ mol/L). The inhibition of Rho kinase canceled the promotion of wound healing by rebamipide treatment.

DISCUSSION

In the present study, we demonstrated that rebamipide enema promoted wound healing in rats with TNBS-induced colonic ulceration. In this model, the area of colonic ulceration peaked on day 2 or 3 after TNBS treatment, and subsequent amelioration was observed in a time-dependent manner. In this study, rats were treated with 1% rebamipide enema starting on day 7 after TNBS injury induction, until day 14. Rebamipide clearly accelerated colonic wound healing under these conditions. These findings are consistent with previous results showing the beneficial effects of rebamipide enema in patients with active UC^[7-10], as well as with the results of a study using another experimental colitis model treated with rebamipide enema^[18-20].

Rebamipide is a gastric protective and ulcer healing agent that was developed in Japan. It is used clinically in Japan in combination with acid suppressive agents for gastric mucosal protection, acute and chronic gastritis treatment, and gastroduodenal ulcer healing. More interestingly, accumulating evidence suggests that rebamipide exerts protective and healing effects on other tissues. In fact, rebamipide has been shown to be effective in the treatment of patients with UC. In addition, the therapeutic effect of rebamipide may not be limited to the colon alone: indeed, this agent has been demonstrated by both clinical and basic research as effective for the treatment of stomatitis^[21] and pulmonary^[22], renal^[23] and liver damage^[24-26], and it also provides corneal protection^[27-29].

The mechanisms responsible for amelioration of colitis by rebamipide have not been fully elucidated but may involve inhibition of reactive oxygen species produc-

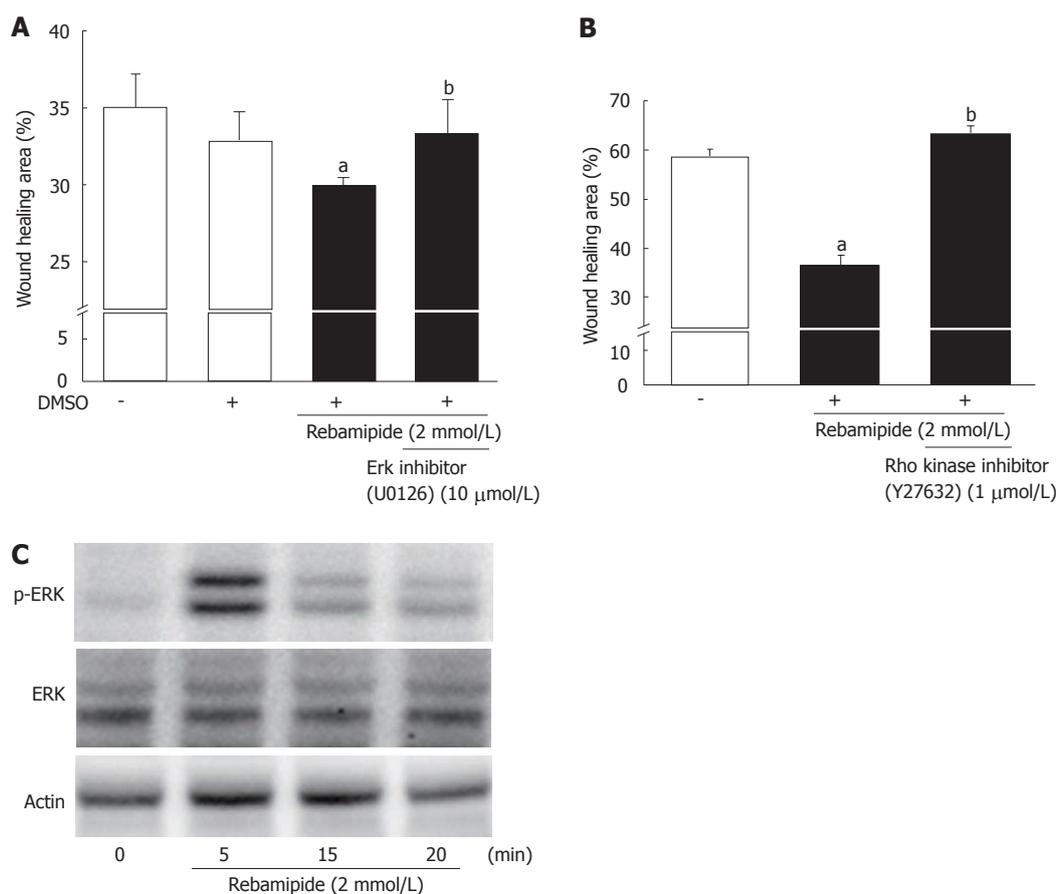

Figure 4 Involvement of extracellular signal-regulated kinase and Rho in rebamipide-treated rat intestinal epithelial cells. **A:** Rat intestinal epithelial (RIE) cells were treated with rebamipide (2 mmol/L) with or without an extracellular signal-regulated kinase inhibitor (U01263, 10 μmol/L) after wound induction. The wound healing area (12 h later) was then monitored. Data represent the mean ± SE of four experiments. ^a $P < 0.05$ vs controls. ^b $P < 0.05$ vs the 2 mmol/L rebamipide-treated group. **B:** Expression of p44/42 and phospho-p44/42 in RIE cells incubated with rebamipide (2 mmol/L) was measured using western blot analysis. Actin antibody was used as an internal control. Representative data from three observations is shown. **C:** RIE cells were treated with rebamipide (2 mmol/L) with or without Rho kinase inhibitor (Y27632, 1 μmol/L) after wound induction. The wound healing area (6 h later) was then monitored. Data represent the mean ± SE of four experiments. ^a $P < 0.05$ vs controls. ^b $P < 0.05$ vs the 2 mmol/L rebamipide-treated group. DMSO: Dimethyl sulfoxide.

tion^[19,20,30], suppression of neutrophil accumulation^[31,32], increases in trans-epithelial electrical resistance^[33], and induction of hepatocyte growth factor expression^[34]. However, it remains unclear whether rebamipide enhances restitution of RIE cells. It is already known that rebamipide enhances gastric epithelial restitution, but the same has yet to be proven in intestinal epithelial restitution. In cases of intestinal mucosal injury, restitution is an important step in re-establishing mucosal integrity, and restitution is the most rapid post-injury response; in effect, restitution restores the continuity of the intestinal epithelial layer, primarily by redistribution of epithelial cells. This process is completed by the migration of local epithelial cells along the underlying matrix, which does not require epithelial cell proliferation^[35,36]. In this study, to assess the effects of rebamipide on intestinal epithelial restitution, the round wound assay was evaluated using RIE cells. Our results showed that 2 mmol/L rebamipide treatment promoted the restitution of RIE cells.

With regard to the role of the ERK signaling pathway in epithelial restitution, several studies have been reported in which activation of the ERK signaling path-

way played an important role in epithelial wound closure. In the present study, rebamipide promoted ERK phosphorylation. This result is in agreement with the results of Gazel *et al.*^[37] and Wang *et al.*^[38]. Moreover, rebamipide-promoted restitution was suppressed by U01263, a specific ERK inhibitor. These data indicate that accelerated restitution by rebamipide is at least partly mediated by the ERK pathway. Tanigawa *et al.*^[39] have demonstrated that rebamipide induces ERK phosphorylation in gastric cancer cells and inhibits cell growth through Smad signaling. Although they used gastric cancer cells, they also found that rebamipide induced phosphorylation of ERK.

Furthermore, we investigated whether rebamipide-promoted restitution was related to Rho kinase activation. Rho kinase has been identified as one of the effectors of the small GTP-binding protein Rho. Accumulating evidence has demonstrated that the Rho/Rho kinase pathway plays an important role in various cellular functions, including cell contraction, cell proliferation, gene expression, and especially cell migration^[40,41]. With regard to restitution of IE cells, Santos *et al.*^[42] have found that

Rho protein is one of the essential elements of a mechanism by which growth factors induce cell migration to restore mucosal integrity, and Rao *et al.*^[43] have demonstrated that activation of Rho kinase results in increased phosphorylation of the myosin light chain, which leads to cell migration. In this investigation, we used Y27632, which has been widely used as a specific inhibitor of the Rho-associated coiled-coil forming protein serine/threonine kinase family of protein kinases^[44]. Co-treatment with Y27632 cancelled the effect of rebamipide on the restitution of RIE cells. These data indicate that rebamipide enhanced the restitution of RIE cells *via* ERK phosphorylation and Rho kinase activation. However, the detailed mechanism of rebamipide-induced ERK and Rho kinase activation remains unknown. Further investigations are needed to elucidate this mechanism.

In summary, the present study indicates that treatment with rebamipide can promote the healing of TNBS-induced intestinal injury, which is associated with acceleration of intestinal epithelial restitution. The present results suggest that rebamipide has great potential as a new therapeutic agent for the treatment of inflammation-associated intestinal injury.

COMMENTS

Background

Ulcerative colitis (UC) is a chronic and recurrent disorder of the colon and rectum. While the precise pathogenesis of UC remains unknown, medical management of patients with acute exacerbation of UC symptoms focuses on achieving remission by inhibiting intestinal inflammation and repairing mucosal injury. However, some patients with inflammatory bowel disease do not respond, or respond incompletely, to the existing treatments. Therefore, it is important to investigate new anti-inflammatory strategies.

Research frontiers

Rebamipide is a gastric mucosal protective and ulcer-healing agent, and has been used for treatment of UC. However, the detailed mechanism of action of rebamipide against intestinal inflammation such as UC remains unclear. In this study, the authors investigated the therapeutic efficacy of rebamipide in an experimental rat model of colitis and evaluated the restitution of intestinal epithelial cells treated with rebamipide *in vitro*.

Innovations and breakthroughs

The present study indicated that treatment with rebamipide could promote the healing of trinitrobenzene sulfonic acid-induced intestinal injury, which has been associated with acceleration of intestinal epithelial restitution through extracellular signal-regulated kinase and Rho kinase activation. The present results suggest that rebamipide has great potential as a new therapeutic agent for the treatment of inflammation-associated intestinal injury.

Applications

By understanding how rebamipide inhibits intestinal inflammation and promotes healing of the intestinal injury, rebamipide may represent a future therapeutic agent for treatment of patients with UC.

Terminology

Rho kinase has been identified as one of the effectors of the small GTP-binding protein Rho. Accumulating evidence has demonstrated that the Rho/Rho kinase pathway plays an important role in various cellular functions, including cell contraction, cell proliferation, gene expression, and especially, cell migration.

Peer review

This is an interesting, well-designed study with good documentation of results.

Abstract

AIM: To elucidate the role of dickkopf3 (Dkk3) in human pancreatic cancer cell growth.

METHODS: Dkk3 mRNA and protein expression in human pancreatic cancer cell lines were detected by real-time reverse transcription polymerase chain reaction (real-time RT-PCR), Western blotting and immunofluorescence. Methylation of the Dkk3 promoter sequence was examined by methylation-specific polymerase chain reaction (MSP) and Dkk3 mRNA expression was determined by real-time RT-PCR after 5-aza-2'-deoxycytidine (5-aza-dC) treatment. The effects of Dkk3 on cancer cell proliferation and *in vitro* sensitivity to gemcitabine were investigated by CellTiter 96® AQueous One Solution Cell Proliferation Assay (MTS) after transfecting the Dkk3 expression plasmid into human pancreatic cancer cells. The expression of β -catenin, phosphorylated extracellular signal-regulated protein kinases (pERK) and

extracellular signal-regulated protein kinases (ERK) was also examined by real-time RT-PCR and Western blotting after upregulating Dkk3 expression in human pancreatic cancer cells.

RESULTS: The results show that the expression levels of both Dkk3 mRNA and protein were low in all pancreatic cancer cell lines tested. The Dkk3 promoter sequence was methylated in the MIA PaCa-2 and AsPC-1 cell lines, which showed reduced Dkk3 expression. These two cell lines, which initially had a methylated Dkk3 promoter, showed increased Dkk3 mRNA expression that was dependent upon the dosage and timing of the DNA demethylating agent, 5-aza-dC, treatment ($P < 0.05$ or $P < 0.01$). When Dkk3 expression was upregulated following the transfection of a Dkk3 expression plasmid into MIA PaCa-2 cells, the ability of cells to proliferate decreased ($P < 0.01$), and the expression of β -catenin and pERK was downregulated ($P < 0.01$). Sensitivity to gemcitabine was enhanced in Dkk3 expression plasmid-transfected cells.

CONCLUSION: Our findings, for the first time, implicate Dkk3 as a tumor suppressor in human pancreatic cancer, through the downregulation of β -catenin expression *via* the ERK-mediated pathway.

INTRODUCTION

Pancreatic cancer is the sixth leading cause of cancer death in China^[1]. The overall five-year survival rate is approximately 1%-3%, and the median survival period after diagnosis is only 4 to 5 mo. Pancreatic cancer remains one of the most aggressive human cancers, with an exceedingly poor prognosis because of its late onset of symptoms^[2], rapid progression, frequent metastasis and insensitivity to chemotherapy and radiotherapy. Therefore, recognizing the factors associated with pancreatic cancer progression is critical for its treatment.

Dickkopf (Dkk) family proteins, including Dkk1/2/3/4, are secreted modulators of the canonical Wnt signaling pathway^[3]. Dkk1, Dkk2 and Dkk4, antagonists of Wnt signaling^[4,5], interact with Wnt coreceptors, low-density lipoprotein receptor-related protein 5/6 (LRP5/6) and Kremen^[6,7]. Dkk3 interacts with kremen1 and kremen2, but not with LRP5/6^[8], and has been proposed to act as a tumor suppressor. Dkk3 is downregulated in some tumors, and it inhibits tumor growth^[9-25]. For example, in cervical cancer and malignant glioma, Dkk3 regulates tumor cell growth and decreases β -catenin expression^[16,23]. Dkk3 can induce cancer cell apoptosis by c-Jun-NH2-kinase (JNK) activation in testicular and prostate cancer cells^[9,26]. The Dkk3 promoter sequence is methylated in several tumors, such as breast cancer, hepatoma, bladder cancer and malignant astrocytic gliomas^[27-32]. In lung adenocarcinomas, however, Dkk3 inhibits cancer cell apoptosis by decreasing the intracellular level of reactive oxygen species and functions as an oncogene^[33]. Dkk3 knock-out mice showed no enhanced tumor formation^[34]. Recently, other studies have demonstrated that Dkk3 plays distinct roles in different cells^[8].

To date, no study has investigated Dkk3 expression and its roles in human pancreatic cancer cell behavior. To better understand the role of Dkk3 in pancreatic cancer progression, we investigated Dkk3 expression and promoter sequence methylation in human pancreatic cancer cells. The effects of Dkk3 on cell proliferation and sensitivity to gemcitabine were simultaneously observed after expression was increased in MIA PaCa-2 cells, following transfection with the Dkk3 expression plasmid.

MATERIALS AND METHODS

Cell lines and cell culture

The human pancreatic cancer cell lines PANC-1, MIA PaCa-2, AsPC-1 and BxPC-3 were purchased from the American Type Culture Collection (Manassas, Virginia, United States). AsPC-1 and BxPC-3 cells were cultured in RPMI-1640 medium (Sigma-Aldrich, MO, United States)

and PANC-1 and MIA PaCa-2 cells were cultured in Dulbecco's Modified Eagle's Medium (Sigma-Aldrich, MO, United States). All media were supplemented with 10% fetal calf serum (Tianjin Haoyang Biological Manufacture Co., LTD, China), 100 μ g/mL streptomycin and 100 U/mL penicillin, and the cultures were grown at 37 °C in a humidified atmosphere containing 5% CO₂.

Construction of and transient transfection with a plasmid expressing human Dkk3

Total RNA was extracted from PANC-1 cells using TRIzol reagent (Invitrogen, CA, United States), according to the manufacturer's protocol. The cDNAs were synthesized using the TaKaRa RNA polymerase chain reaction (PCR) Kit (TaKaRa, Japan). A full-length cDNA encoding human Dkk3 was cloned by PCR using 500 ng cDNA as a template and primers containing HindIII and BamHI restriction enzyme sites (Table 1). The PCR products were ligated into pcDNA3.1 (Invitrogen, CA, United States) to create the plasmid pcDNA3.1-Dkk3. MIA PaCa-2 cells were transfected with the pcDNA3.1 vector or pcDNA3.1-Dkk3 using FuGENE (Roche Diagnostic GmbH, Mannheim, Germany), according to the manufacturer's protocol.

Reverse transcription polymerase chain reaction

Total RNA was isolated from the cells using TRIzol reagent (Invitrogen, CA, United States) according to the manufacturer's protocol. The cDNAs were synthesized using the TaKaRa RNA PCR Kit (TaKaRa, Japan). The optimal PCR conditions were 94 °C for 5 min; 35 cycles at 94 °C for 40 s, 61 °C (Dkk3)/52 °C (β -actin) for 40 s, 72 °C for 40 s; and 72 °C for 10 min. PCR products (5 μ L) were separated by electrophoresis in a 2.0% agarose gel. Primer sequences for Dkk3 and β -actin are listed in Table 1.

RNA preparation and real-time reverse transcription polymerase chain reaction

Total RNA was isolated from the cells, with or without 5-aza-2'-deoxycytidine (5-aza-dC) treatment, using TRIzol reagent (Invitrogen, CA, United States) according to the manufacturer's protocol. First-strand cDNA was synthesized from 500 ng of total RNA using the TaKaRa RNA PCR Kit (TaKaRa, Japan). PCR was conducted on a 7500 Real Time PCR System (Applied Biosystems, United Kingdom) in combination with the SYBR green PCR master mix (Applied Biosystems, United Kingdom). Melting curve analyses following amplification were performed to ensure product specificity. The relative expression levels of Dkk3 mRNA and β -catenin mRNA were normalized to mRNA level of the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH) in the same cDNA sample. Δ Ct was calculated by subtracting the Ct of GAPDH mRNA from the Ct of the mRNA of interest. $\Delta\Delta$ Ct was then calculated by subtracting the Δ Ct of the control from the Δ Ct of the sample. The fold change in mRNA was calculated according to the equation $2^{-\Delta\Delta Ct}$. Primer sequences for Dkk3, β -catenin and GAPDH are listed in Table 1.

Bisulfite modification and methylation-specific polymerase chain reaction

Genomic DNA was isolated from pancreatic cancer cell lines using the TIANamp Genomic DNA kit (Tiangen Biotech Co., LTD, Beijing, China). One microgram of genomic DNA was bisulfite-modified using the Cp-Genome™ DNA Modification Kit (Chemicon, MA, United States) according to the manufacturer's protocol. Methylation-specific polymerase chain reaction (MSP) was performed at 95 °C for 5 min, followed by 34 cycles at 94 °C for 30 s, 59 °C for 30 s and 72 °C for 30 s. The final extension was at 72 °C for 10 min. Each PCR reaction was performed using 0.5 units of HotStarTaq Plus DNA Polymerase (Qiagen GmbH, Hilden, Germany). The primers are listed in Table 1. The specificity of the MSP primers in detecting the Dkk3 methylation status was demonstrated using unmethylated and methylated DNA as a template (EpiTect Control DNA Set; Qiagen GmbH, Hilden, Germany).

5-aza-dC treatment

Cells were seeded at a density of 4×10^4 cells/well in a six-well plate. After overnight incubation, the cells were treated with 10 μmol/L and 20 μmol/L of the DNA demethylating agent 5-aza-dC (Sigma-Aldrich, Steinheim, Germany) for 48 h or 72 h. Control cells were incubated with dimethyl sulfoxide and fresh medium.

Immunofluorescence and confocal microscopy

Cells grown on coverslips were washed and fixed with 4% paraformaldehyde, followed by washing with 0.2% Triton X-100. Coverslips were incubated with nonimmune animal serum to reduce nonspecific binding. The coverslips

were subsequently incubated at 4 °C overnight with an anti-Dkk3 rabbit polyclonal antibody (1:100, Santa Cruz, CA, United States). Rhodamine-conjugated AffiniPure goat anti-rabbit IgG was used as the secondary antibody (1:200, Zhongshan Goldenbridge Biotechnology Co., LTD, Beijing, China). Counterstaining was performed using 1 μg/mL 4',6-diamidino-2-phenylindole. Expression and localization of Dkk3 were observed under a confocal microscope (Leica, Mannheim, Germany).

Western blotting

The cells in culture were washed twice with ice-cold PBS, and proteins were extracted with M-PER mammalian protein extraction reagent (Pierce Biotechnology, Rockford, United States). Samples were centrifuged at $14000 \times g$ for 10 min. Aliquots of cell lysates containing 40 μg protein were separated on a 12% SDS-polyacrylamide gel and transferred to PVDF membranes (Millipore, MA, United States). The membranes were blocked with 10% skim milk and incubated with Dkk3 antibody (1:1500, Santa Cruz, CA, United States), β-catenin antibody (1:1500, BD Transduction Laboratories, San Diego, United States), phosphorylated extracellular signal-regulated protein kinase antibody (pERK antibody, 1:2000, Cell Signaling, MA, United States), extracellular signal-regulated protein kinase antibody (ERK antibody, 1:2000, Cell Signaling, MA, United States) and β-actin antibody (1:2000, Santa Cruz, CA, United States) at 4 °C overnight, followed by their corresponding secondary antibodies (1:2000, Zhongshan Goldenbridge Biotechnology Co., LTD, Beijing, China) at room temperature for 2 h. The membrane-bound proteins were detected using the Pierce ECL Western blotting substrate (Pierce Biotechnology, Rockford, United States).

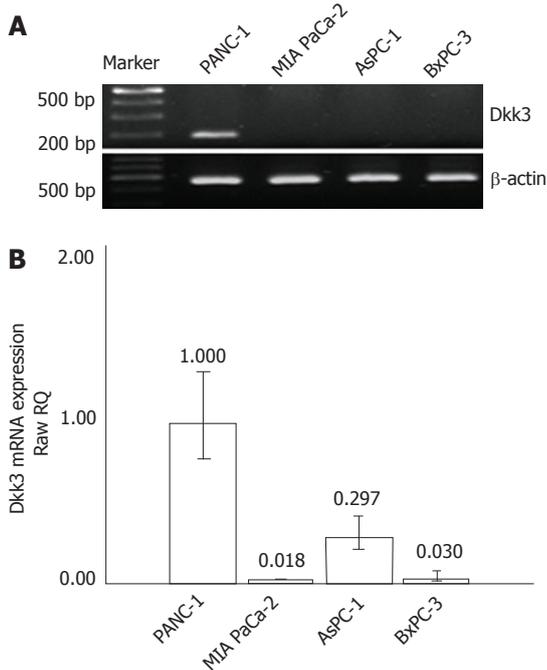

Figure 1 Dickkopf3 expression in human pancreatic cancer cell lines (PANC-1, MIA PaCa-2, AsPC-1 and BxPC-3). A, B: Dickkopf3 (Dkk3) mRNA expression was detected by reverse transcription polymerase chain reaction (RT-PCR) and real-time RT-PCR. Dkk3 mRNA expression was low in all cell lines examined. Dkk3: Dickkopf3; RQ: Relative quantitation.

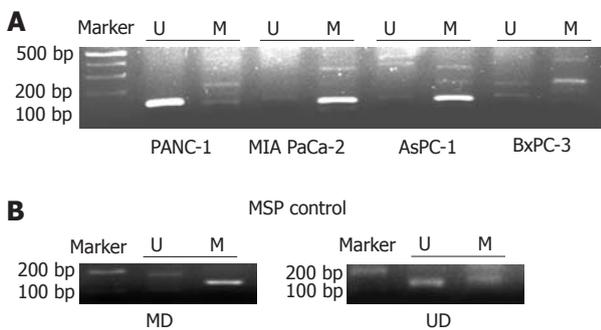

Figure 2 Dickkopf3 promoter methylation analysis in human pancreatic cancer cell lines. A: Methylation-specific PCR (MSP) was performed with bisulfite-treated DNA from pancreatic cancer cells. The Dickkopf3 (Dkk3) promoter was significantly methylated in MIA PaCa-2 and AsPC-1 cells; B: MSP controls demonstrate the specificity of the Dkk3 primers used. Methylated bisulfite-converted DNA exclusively yields amplification products with primers specific to methylated Dkk3 promoter sequences; unmethylated bisulfite-converted DNA yields exclusively amplification products with primers recognizing unmethylated Dkk3 promoter sequences. MD: Methylated bisulfite-converted DNA; UD: Unmethylated bisulfite-converted DNA; U: PCR products amplified with primers recognizing unmethylated Dkk3 promoter sequences; M: Amplification generated with methylation-specific primers.

Determination of dose-response curve

For determination of the dose-response curve, MIA PaCa-2 cells were transfected with pcDNA3.1-Dkk3 or pcDNA3.1. Six hours after transfection, cells were seeded in 96-cell plates in triplicate at a density of 3000 cells/well and were allowed to adhere. Gemcitabine (LILLY, France) was added to the medium 24 h after transfection.

Cell proliferation was determined 72 h after gemcitabine addition using the CellTiter 96[®] AQueous One Solution Cell Proliferation Assay (MTS, Promega, WI, United States), according to the manufacturer's protocol. The spectrophotometric absorbance of each sample was measured at 490 nm using the TECAN spectra (Thermo, Austria). Percent proliferation relative to the controls was calculated based on the MTS read-out; the IC₅₀ value was defined as the concentration of drug that produced a 50% reduction in absorbance relative to the control.

Cell growth assay

For the cell growth assay, MIA PaCa-2 cells were transfected with pcDNA3.1-Dkk3 or pcDNA3.1. At 6 h after transfection, cells were seeded in 96-well plates in triplicate at a density of 1000 cells/well and were allowed to adhere overnight. At 24 h, 48 h and 72 h, cell proliferation was determined using MTS (Promega, WI, United States) according to the manufacturer's protocol. The spectrophotometric absorbance of each sample was measured at 490 nm using the TECAN spectra (Thermo, Austria).

Statistical analysis

Statistical analysis was performed using SPSS 16.0 software. Unless otherwise indicated, the level of significance for differences between data sets was assessed using *t* test and one-way analysis of variance. Data are expressed as the mean \pm SD. *P* < 0.05 was considered statistically significant.

RESULTS

Dkk3 is downregulated in pancreatic cancer cell lines

Dkk3 expression was assessed in four human pancreatic cancer cell lines (PANC-1, MIA PaCa-2, AsPC-1, BxPC-3). A low level of Dkk3 mRNA was observed in all cell lines, although Dkk3 expression in PANC-1 cells was slightly higher than in the other three cell lines (Figure 1). Dkk3 protein expression was too low to detect by Western blotting or immunofluorescence (data not shown).

Methylation of the Dkk3 promoter in pancreatic cancer cell lines

Through the use of MSP, we found that the Dkk3 promoter sequence was significantly methylated in MIA PaCa-2 and AsPC-1 cells, which were the cell lines with reduced Dkk3 expression. Conversely, the Dkk3 promoter sequence was unmethylated in the PANC-1 cells, which had slightly higher Dkk3 expression (Figure 2).

Demethylation of the Dkk3 promoter

Because methylation of the Dkk3 promoter sequence was detected in MIA PaCa-2 and AsPC-1 cells, we chose to treat these two cell lines with 10 μ mol/L and 20 μ mol/L, respectively, of the DNA methyltransferase inhibitor 5-aza-dC. After treatment with 5-aza-dC, for 48 h or 72 h, the cells were harvested to determine Dkk3 mRNA expression by real-time reverse transcription PCR. The results showed that these two cell lines with methylated Dkk3 promoters showed increased Dkk3 mRNA expression,

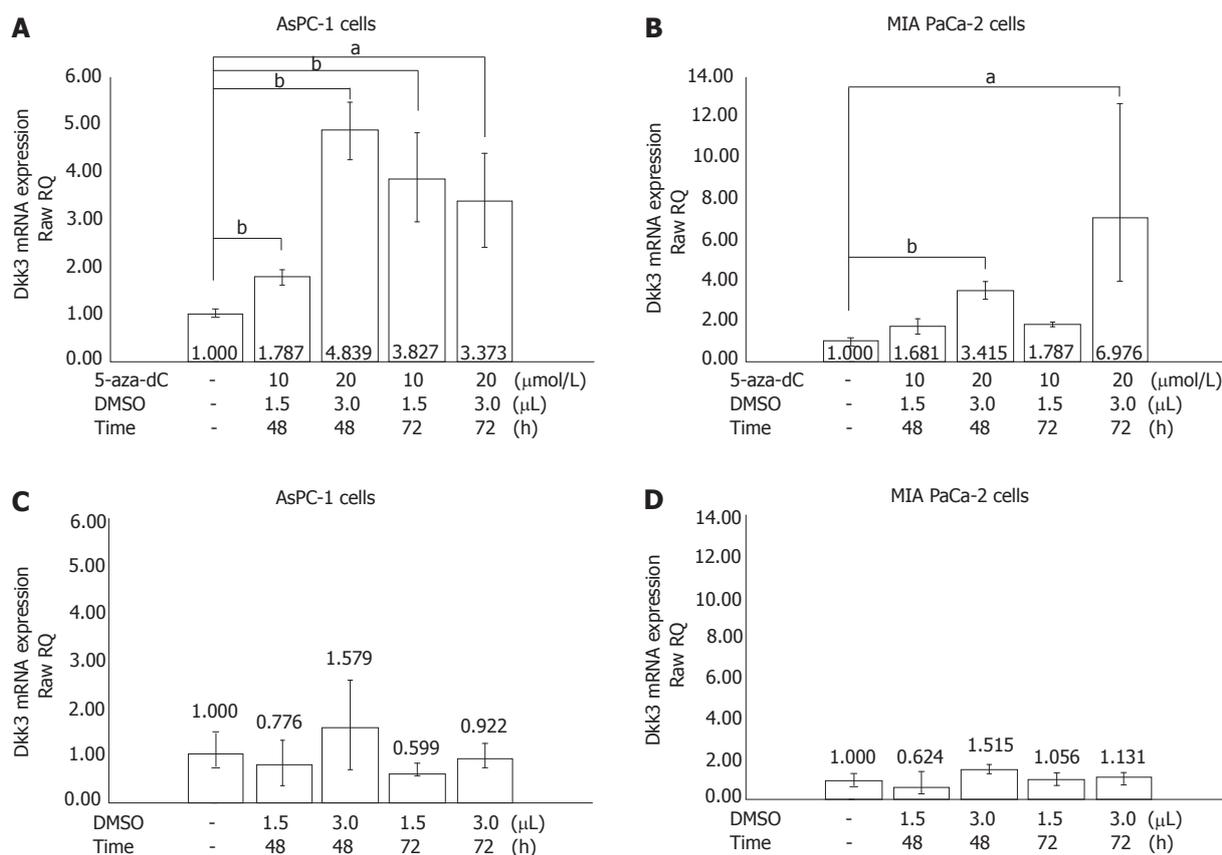

Figure 3 Dickkopf3 mRNA expression after demethylation *in vitro*. A, B: AsPC-1 and MIA PaCa-2 cells were treated with 10 μmol/L and 20 μmol/L of the DNA demethylating agent, 5-aza-dC, for 48 h or 72 h, respectively. The results show that these two cell lines, in which the Dickkopf3 (Dkk3) promoter was initially heavily methylated, had increased Dkk3 mRNA expression that was dependent on the dosage and timing of 5-aza-dC treatment (^a*P* < 0.05 vs untreated MIA PaCa-2 cells or untreated AsPC-1 cells, ^b*P* < 0.01 vs untreated MIA PaCa-2 cells or untreated AsPC-1 cells); C, D: Control cells were incubated with dimethyl sulfoxide and fresh medium. RQ: Relative quantitation; Dkk3: Dickkopf3; DMSO: Dimethyl sulfoxide.

which was dependent on the dosage and timing of 5-aza-dC treatment (*P* < 0.05 or *P* < 0.01) (Figure 3).

Overexpression of Dkk3 suppresses pancreatic cancer cell growth and β-catenin expression

To study the roles of Dkk3 in the progression of pancreatic cancer, MIA PaCa-2 cells were transfected with pcDNA3.1-Dkk3 or pcDNA3.1. After transfection, Dkk3 mRNA and protein levels significantly increased in the pcDNA3.1-Dkk3-transfected cells (*P* < 0.01), while no significant changes were observed in the pcDNA3.1-transfected cells (Figure 4A and B). At 48 h and 72 h after transfection, the β-catenin mRNA and protein expression levels were significantly decreased in the pcDNA3.1-Dkk3-transfected cells (*P* < 0.01) (Figure 4B and C). The protein expression of pERK was also decreased, but there was no significant change in total ERK expression (Figure 4B). The results of the MTS assay showed that in the pcDNA3.1-Dkk3-transfected cells, proliferation capacity was lower than in the pcDNA3.1-transfected cells (*P* < 0.01) (Figure 4D).

Sensitivity of Dkk3-overexpressing pancreatic cancer cells to gemcitabine

A dose-response curve was constructed, and the IC₅₀ val-

ues were compared to determine the influence of Dkk3 overexpression in pancreatic cancer cells on the effect of gemcitabine on cell growth. MIA PaCa-2 cells were transfected with pcDNA3.1-Dkk3 or pcDNA3.1. Seventy-two hours after gemcitabine addition, the IC₅₀ values for gemcitabine were 0.621 μmol/L for pcDNA3.1-Dkk3-transfected cells and 1.877 μmol/L for pcDNA3.1-transfected cells (Figure 4E). These results show that the IC₅₀ value of the Dkk3-overexpressing cells was significantly lower than that of the control cells.

DISCUSSION

Dkk3 is expressed in many normal human tissues^[35]. It was previously reported that Dkk3 expression is generally low in some tumors, such as sporadic epithelial ovarian cancer, cervical cancer, mammary tumors, malignant melanoma, hepatoma and kidney, pancreas, gastric and lung cancers^[12,15,16,18,19,31,32]. Additional studies also revealed the association between Dkk3 expression and cancer metastasis or prognosis in gastric cancer, renal cancer and head and neck squamous cell carcinoma^[36-38]. However, Dkk3 expression and its roles in pancreatic cancer remain unknown. In this study, we detected Dkk3 expression in human pancreatic cancer cells. We found that both Dkk3

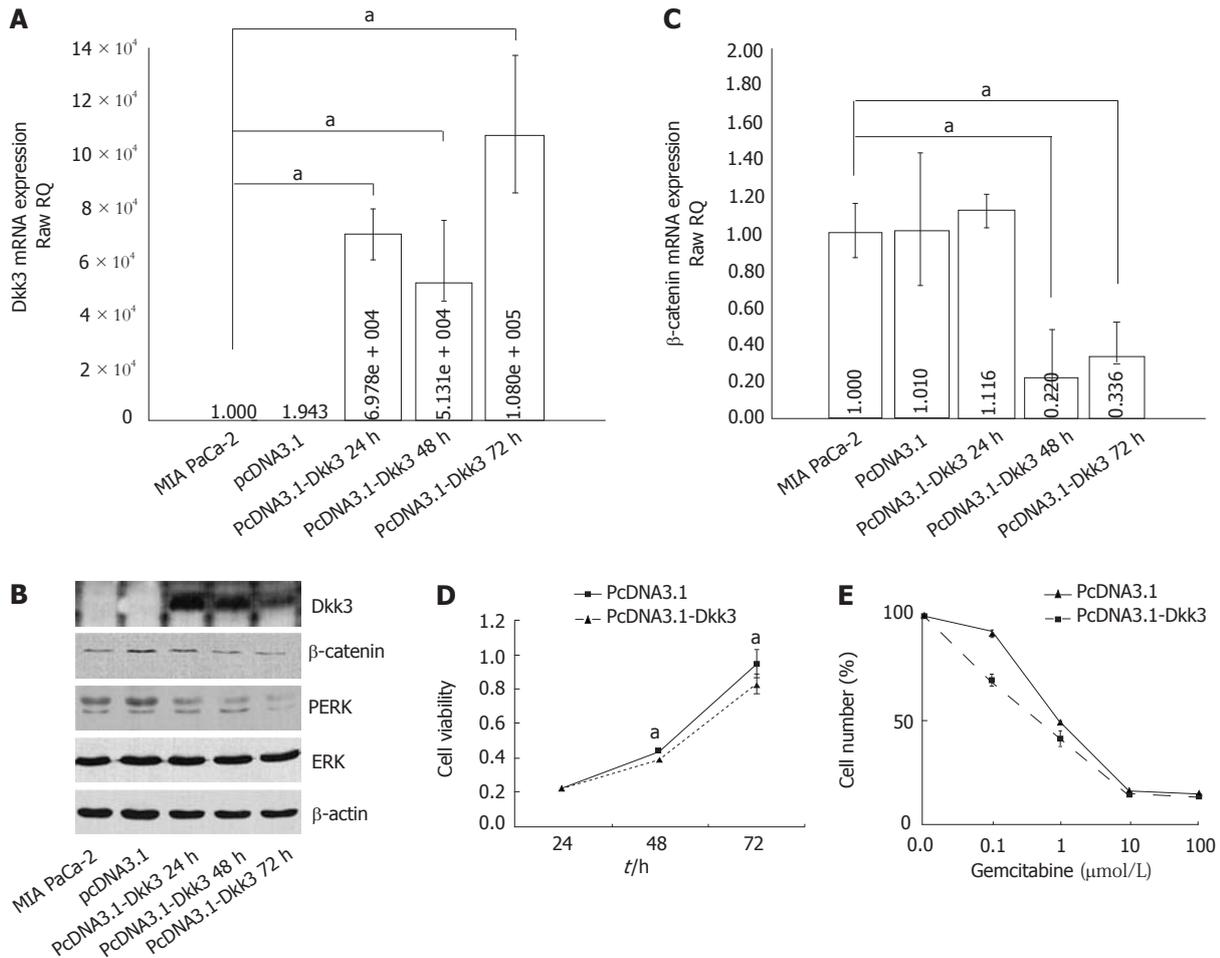

Figure 4 The effects of dickkopf3 overexpression on pancreatic cancer cells. MIA PaCa-2 cells were transfected with pcDNA3.1-dickkopf3 (Dkk3) or pcDNA3.1 vector. A, B: After transfection, Dkk3 mRNA and protein expression were examined by real-time reverse transcription polymerase chain reaction (real-time RT-PCR) and Western blotting. The results show that in the pcDNA3.1-Dkk3-transfected MIA PaCa-2 cells, Dkk3 expression was significantly upregulated ($P < 0.01$, $^aP < 0.01$ vs MIA PaCa-2 cells). B, C: β -catenin expression was examined by real-time RT-PCR and western blotting. β -catenin expression was downregulated 48 h and 72 h after transfecting pcDNA3.1-Dkk3 into MIA PaCa-2 cells ($P < 0.01$, $^aP < 0.01$ vs MIA PaCa-2 cells). B: The expression of extracellular signal-regulated protein kinases (ERK) and phosphorylated extracellular signal-regulated protein kinases (pERK) was examined by western blotting. The expression of pERK was simultaneously downregulated, without a significant change in total ERK expression. D: MTS assay results showed that the proliferative ability of pcDNA3.1-Dkk3-transfected cells was lower than that of pcDNA3.1-transfected cells ($P < 0.01$, $^aP < 0.01$). E: Dose-response analysis of pcDNA3.1- or pcDNA3.1-Dkk3-transfected MIA PaCa-2 cells with gemcitabine treatment. Seventy-two hours after gemcitabine addition, the IC50 values for gemcitabine were 0.621 $\mu\text{mol/L}$ for pcDNA3.1-Dkk3-transfected cells and 1.877 $\mu\text{mol/L}$ for pcDNA3.1-transfected cells. PERK: Phosphorylated extracellular signal-regulated protein kinases; ERK: Extracellular signal-regulated protein kinases; RQ: Relative quantitation; Dkk3: Dickkopf3; DMSO: Dimethyl sulfoxide.

protein and mRNA expression levels were low in all cell lines examined. Our results are partly in agreement with those of Takahashi N *et al*^[39].

Methylation of the Dkk3 promoter has been observed in hepatocellular carcinoma, breast cancer, malignant astrocytic glioma, acute myeloid and lymphoblastic leukemia and gastrointestinal and bladder cancers^[27-30,40-44]. Our MSP results showed that the Dkk3 promoter was methylated in MIA PaCa-2 and AsPC-1 cells, in which Dkk3 expression was low. After treatment with the DNA methyltransferase inhibitor 5-aza-dC, MIA PaCa-2 and AsPC-1 cells, which initially bore heavily methylated Dkk3 promoters, showed increased Dkk3 mRNA expression. In the present study, we demonstrated for the first time that decreased Dkk3 gene expression was associated with promoter methylation in two human pancreatic cancer cell lines (MIA PaCa-2 and AsPC-1). The inhibition

of DNA methyltransferase activity by 5-aza-dC led to a reversion of methylation and upregulated expression of the previously downregulated gene.

Additional studies have recently demonstrated that Dkk3 has distinct roles in regulating the malignant behavior of cancer cells, depending on which cells are examined. For example, Dkk3 can reduce malignancy in mouse prostate cancer RM9 cells *in vitro* and *in vivo*^[25]. Dkk3 can induce apoptosis or cell death in human bladder cancer, prostate cancer, breast cancer and lung cancer cells^[9,20,24,45]. Dkk3 can inhibit tumor growth and metastasis in an orthotopic prostate cancer model^[10]. While Jung *et al*^[33] found that Dkk3 acts as an antiapoptotic molecule in lung adenocarcinoma, our results show that Dkk3 overexpression inhibited pancreatic cancer cell growth. The results revealed that in the pcDNA3.1-Dkk3-transfected MIA PaCa-2 cells, β -catenin mRNA and protein expres-

sion levels were both downregulated. Phosphorylation of ERK was decreased. These data demonstrate that Dkk3 suppressed MIA PaCa-2 cell growth by inhibiting β -catenin expression. Our results were consistent with the findings of Yue *et al.*^[45] in lung cancer. We hypothesize that Dkk3 acts as a Wnt signal transduction inhibitor in human pancreatic cancer cells.

Gemcitabine is the most commonly used chemotherapy drug for pancreatic cancer. Notably, our results show that gemcitabine's IC₅₀ value for pcDNA3.1-Dkk3-transfected cells was significantly lower than that for the control cells. Dkk3 overexpression enhanced the sensitivity of pancreatic cancer cells to gemcitabine.

In summary, our results suggest that Dkk3 acts as a tumor suppressor in human pancreatic cancer cells by downregulating β -catenin expression *via* the ERK-mediated pathway. Dkk3 may be a valid adjunctive target of gemcitabine for the treatment of human pancreatic cancer.

COMMENTS

Background

Pancreatic cancer is the sixth leading cause of cancer death in China. The overall five-year survival rate is approximately 1%-3%. Pancreatic cancer remains one of the most aggressive human cancers. Recognizing the factors associated with pancreatic cancer progression is critical for its treatment.

Research frontiers

Dickkopf family proteins are secreted modulators of the canonical Wnt signaling pathway. Dickkopf 3 (Dkk3) is a member of the dickkopf family proteins. Dkk3 is downregulated in some tumors, and its overexpression inhibits tumor growth. The Dkk3 promoter sequence is methylated in several tumors. However, in lung adenocarcinomas, Dkk3 functions as an oncogene. Recently, other studies have demonstrated that Dkk3 plays distinct roles in different cells.

Innovations and breakthroughs

To date, no study has investigated Dkk3 expression and its roles in human pancreatic cancer cell behavior. In this study, the authors investigated Dkk3 expression and promoter sequence methylation in human pancreatic cancer cells. The effects of Dkk3 on cell proliferation and sensitivity to gemcitabine were simultaneously observed after expression was increased in MIA PaCa-2 cells, following transfection with the Dkk3 expression plasmid. According to the experimental results, the authors for the first time, confirmed that Dkk3 acts as a tumor suppressor in human pancreatic cancer cells by downregulating β -catenin expression *via* the ERK-mediated pathway. Dkk3 overexpression enhanced the sensitivity of pancreatic cancer cells to gemcitabine.

Applications

This study indicates that Dkk3 may be a valid adjunctive target of gemcitabine for the treatment of human pancreatic cancer.

Peer review

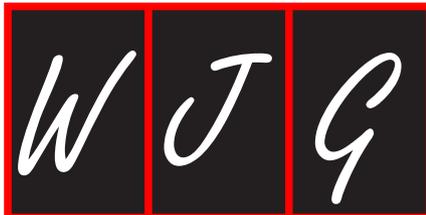

This is a paper that reports that Dkk3 is a tumor suppressor gene in pancreatic cancer. The findings are interesting, and overall writing is good.

Abstract

AIM: To assess the efficacy and safety of a balanced approach using midazolam in combination with propofol, administered by non-anesthesiologists, in a large series of diagnostic colonoscopies.

METHODS: Consecutive patients undergoing diagnostic colonoscopy were sedated with a single dose of midazolam (0.05 mg/kg) and low-dose propofol (starter bolus of 0.5 mg/kg and repeated boluses of 10 to 20 mg). Induction time and deepest level of sedation, adverse and serious adverse events, as well as recovery times, were prospectively assessed. Cecal intubation and adenoma detection rates were also collected.

RESULTS: Overall, 1593 eligible patients were included.

The median dose of propofol administered was 70 mg (range: 40-120 mg), and the median dose of midazolam was 2.3 mg (range: 2-4 mg). Median induction time of sedation was 3 min (range: 1-4 min), and median recovery time was 23 min (range: 10-40 min). A moderate level of sedation was achieved in 1561 (98%) patients, whilst a deep sedation occurred in 32 (2%) cases. Transient oxygen desaturation requiring further oxygen supplementation occurred in 8 (0.46%; 95% CI: 0.2%-0.8%) patients. No serious adverse event was observed. Cecal intubation and adenoma detection rates were 93.5% and 23.4% (27.8% for male and 18.5% for female, subjects), respectively.

CONCLUSION: A balanced sedation protocol provided a minimalization of the dose of propofol needed to target a moderate sedation for colonoscopy, resulting in a high safety profile for non-anesthesiologist propofol sedation.

INTRODUCTION

Colorectal cancer (CRC) represents a major cause of morbidity and mortality in western countries^[1]. Despite the fact that it has been shown to be highly effective in preventing CRC incidence, colonoscopy is usually perceived as an invasive and potentially painful procedure, resulting in a low uptake rate when compared with less invasive options, such as fecal tests or flexible sigmoidoscopy^[2-4].

To improve acceptability and tolerability of colonoscopy, different protocols of sedation have been adopted^[5]. Such regimens have been mainly restricted to benzodiazepines alone or in combination with opioids, because of the relatively high safety of these substances. Although these drugs result in a substantial improvement of patients' and endoscopists's experiences, some drawbacks have been observed. In particular, due to a relatively long half-life, a slow induction of sedation and a delayed discharging time with significant cost of monitoring have been reported^[6]. Moreover, a significant proportion of patients are quite dissatisfied by the sub-optimal degree of sedation provided by this protocol, and morbidity and mortality as a result of respiratory depression have also been reported^[7,8].

Propofol represents a short-acting sedative agonist of gamma-aminobutyric acid receptor in the central nervous system, and it is mainly used for the induction and maintenance of deep sedation during surgical procedures^[9]. Because of its short half-life (2-4 min) and high lipid solubility, propofol has the distinct advantages of a rapid induction of sedation and a fast recovery. When applied to gastrointestinal (GI) endoscopy, patient satisfaction with propofol has been shown to be equivalent or superior to that of benzodiazepines and/or narcotics^[7]. Propofol, however, is a respiratory depressant with a narrow therapeutic range and without a reversal agent, resulting in a significant risk of inducing a too deep level of sedation, complicated by hypoventilation, apnea or cardiovascular depression. Moreover, it lacks a reversal agent. For this reason, propofol is largely administered by anesthesiologists or anesthesiologist nurses^[10]. When considering the very high number of colonoscopies performed worldwide - 14 million every year in the United States alone^[11] - anesthesiologist capacity is, however, likely to be insufficient to assure propofol sedation for this procedure.

It has been recently shown that propofol may be an effective and safe agent when used by non-anesthesiologists to target an adequate level of sedation^[12]. A recent systematic review of the literature, including 646 080 cases, provided adequate evidence to the American Gastroenterological Association for them to support propofol administration by non-anesthesiologists (NAP), because of the extraordinary rarity of life-threatening episodes^[13]. Most of these series were based on the use of propofol alone, during which NAP targeted a deep level of sedation. To further improve the safety profile, it has been suggested that a substantial reduction of the

propofol dose may be achieved by administering this drug in association with other sedative agents, such as midazolam or meperidine^[14,15]. This protocol has been defined as balanced propofol sedation (BPS), and, differently from NAP, it targets a moderate level of sedation.

No study has addressed the use of propofol by non-anesthesiologists for colonoscopy in Italy, and very few in Europe^[13]. This is largely related to the product label of the drug which allows its administration only by physicians trained in general anesthesia. Due to the lack of an adequate anesthesiologist capacity and the low fee of reimbursement for a colonoscopy in the public system, virtually all the procedures are performed without propofol.

Only a few colonoscopy series have addressed the efficacy and safety of BPS for colonoscopy, most of them including only a few hundred of patients^[14,15,17-23]. The purpose of this study was to prospectively assess the safety and the efficacy of endoscopist-administered BPS to target a moderate level of sedation for colonoscopy in a large series of consecutive patients.

MATERIALS AND METHODS

From February 2008 to December 2009, outpatients who presented to our unit for diagnostic colonoscopy were eligible for the study if they were between 18 and 75 years of age, American Society of Anesthesiology (ASA) class I or II, and capable of providing written informed consent for study participation. Exclusion criteria were inability to provide informed consent, history of allergic reactions or hypersensitivities to midazolam, propofol, eggs, or soybeans, high-risk head and neck anatomy (Mallampati score > 2) that could complicate airway rescue, sleep apnea syndrome, ASA class > II.

The use of propofol by non-anesthesiologists in Italy is, at the time being, prevented by the specification in the product label that the use of this drug is exclusively allowed for anesthesiologists or intensive care unit physicians. For this reason, the administration of propofol within the present study has been performed under a study protocol that was supported by our Institution (Istituto Clinico Humanitas) and approved by the institutional review board. Nine endoscopists participated in this protocol, being authorized to administer propofol.

Patients underwent BPS administered by an endoscopist who was not involved in the endoscopic procedure. The physicians administering sedation were certified in advanced cardiac life support and had also successfully completed an intensively structured training program in propofol administration and laryngeal mask use under an anesthesiologist tutorship. The same anesthesiologist was always on call during the procedure time. Baseline vital signs (heart rate, blood pressure, oxygen saturation) were obtained in all patients before induction of sedation. Endoscopy-dedicated nurses also attended the procedure.

BPS was structured as follows: after a single dose of midazolam (0.05 mg/kg; Hameln pharmaceuticals gmbh, Hameln, Germany), a starter bolus of 0.5 mg/kg

Table 1 Scale for assessing Alertness/Sedation

Responsiveness	Score
Responds readily to name spoken in normal tone	5
Lethargic response to name spoken in normal tone	4
Responds only after name is called loudly and/or repeatedly	3
Responds only after mild prodding or shaking	2
Responds only after painful trapezius squeeze	1
Does not respond to painful trapezius squeeze	0

of propofol (Diprivan, Astra-Zeneca, Stockholm, Sweden) was administered. Repeated boluses of 10 to 20 mg of propofol were then administered on-demand with a 30-60 s interval for the entire duration of the procedure. Propofol bolus frequency and dose were titrated to the patient response, including vital signs and manifestations of restlessness or discomfort. The maximum dose allowed to be administered was 200 mg. Throughout the procedure, all patients received oxygen 2 L/min by nasal cannula. Continuous pulse oximetry, heart rate, electrocardiography, and end-expiratory carbon dioxide were monitored, with blood pressure being assessed at 5-min intervals. Level of sedation was evaluated according to the Scale for assessing Alertness/Sedation (MOAA/S), as reported in Table 1. In detail, deep sedation was defined as MOAA/S 1, moderate as MOAA/S 2-4, and minimal as MOAA/S 5. The following parameters were recorded: patient demographics, procedure indication and duration, midazolam dose, propofol dose, induction time, recovery time, cecal intubation rate, and polyp detection rate. The baseline values and changes in vital signs or oxygen saturation (SpO₂) from the baseline were also recorded. Adverse events were defined as hypoxia (i.e., a reduction in oxygen saturation < 90% for more than 20 s) requiring supplemental oxygen (O₂) by nasal cannula (NC) in excess of 2 L/min; and transient hypotension (< 90 mmHg) or bradycardia (< 60 beats/min) not requiring any active medical treatment. Serious adverse events were defined as hypoxia requiring positive pressure ventilation or laryngeal mask use; hypotension (< 90 mmHg) or bradycardia (< 60 beats/min) requiring medical treatment (i.e., infusion of liquid) other than propofol titration; and any event requiring the administration of a benzodiazepine antagonist (flumazenil). After the procedure, the patients were transported to the recovery room where blood pressure, SpO₂ and heart rate were measured continuously until discharge. Discharge was possible when blood pressure was within 20% of the initial value, SpO₂ > 90%, and the patient was able to drink and walk autonomously. Recovery time was measured from the time the patient entered the recovery area until departure by the recovery room nurse.

RESULTS

During the study period, 1593 eligible patients were in-

cluded. Of these, 789 (49%) were male, the median age being 60 years (range: 22-75 years). Clinical indication for colonoscopy was evaluation of symptoms in 876 (55%) cases, screening or surveillance of a previous neoplastic lesion in 542 (34%), work-up of a positive fecal test in 96 (6%), and follow up of inflammatory bowel diseases in the remaining 79 (5%) cases.

Baseline mean heart rate and mean blood pressure were 71 ± 13 beats per min and 103 ± 16 mmHg, respectively. BPS was administered to all the patients. The median dose of midazolam was 2.3 mg (range: 2-4 mg), and the median dose of propofol administered was 70 mg (range: 40-120 mg). The median induction time of sedation (i.e., between the initiation of sedation and colonoscope insertion) was 3 min (range: 1-4 min). The deepest level of sedation was moderate in 1561 (98%) patients and deep in the remaining 32 (2%) cases. General anesthesia was not observed in any patient.

There was no serious adverse event related to any of the 1593 patients. The only adverse events observed with BPS were episodes of transient oxygen desaturation requiring O₂ supplementation by NC in excess of 2 L/min in 8 (0.46%; 95% CI: 0.2%-0.8%) patients. No patient required mask ventilation or endotracheal intubation. Although a transient decrease in blood pressure was common (446 patients, 28%), no episodes of sustained hypotension or bradycardia requiring active therapy were observed. No patient required administration of a benzodiazepine antagonist. Median recovery time was 23 min (range: 10-40 min).

The overall cecal intubation rate was 93.5%, corresponding to 1491 complete colonoscopies. Incomplete procedures were due to poor bowel cleaning in 72 (4.5%) patients and sigmoid strictures in 30 (2%) cases. The median procedural time was 11.3 min (range: 9-22 min), consisting of a median intubation time of 4 min (range: 3-9 min) and a median withdrawal time of 6.3 min (range: 4.2-11.9 min). Adenoma detection rate was 23.4% (27.8% for male, and 18.5% for female subjects). No major procedure-related complication occurred.

DISCUSSION

Our study showed that a BSP protocol, based on the co-administration of propofol with benzodiazepine, was a feasible, effective and safe approach for colonoscopy in a large series of consecutive patients. In particular, following a careful and rigid selection of the patients, BSP was successfully administered by non-anesthesiologist endoscopists without requiring anesthesiologist intervention in any of the cases. No BSP-related serious adverse event occurred in the study population, as outlined by the evidence that a midazolam-reversal agent was not needed in any patient. A transient oxygen desaturation was observed in only 0.5% of the study population, and it was treated conservatively in all cases.

The high safety profile of the BSP observed in our study appears to be strictly related to the very low dose

of propofol needed to target a moderate sedation, because of the additional effect of midazolam. Despite the fact that this was a non-randomized study in which a propofol-alone arm was not included, the median dose of propofol shown in the present study, corresponding to 70 mg per patient, appeared to be much lower than the 200-400 mg range described in previous propofol-alone series^[16]. A similarly low propofol dose was also reported in previous series in which BSP was adopted^[14,15,17-23]. When considering the potential legal implications related to NAP, the ability to minimize the dose of propofol needed appears as an attractive goal for the endoscopists. The very low rate of oxygen desaturation observed in our study may also be related to the systematic adoption of capnography to monitor our patients. It has been suggested that capnography may anticipate the diagnosis of propofol-induced hypoventilation as compared to the simple assessment of oxygen saturation^[24].

It could be argued, however, that co-administration of midazolam could reduce the propofol-related advantages. In particular, the slow metabolism of benzodiazepines could result in a prolonged recovery time, reducing the efficiency of an endoscopic turnover system. The median recovery time in our series was consistently lower than 30 min. This value favorably compares with previous accounts of midazolam alone, in which a recovery time as long as 70 min was reported^[25]. Such a difference in favor of the BSP regimen is presumably due to the relatively low dose of midazolam administered, the median being 2.1 mg per patient. Moreover, midazolam was administered only at the beginning of the procedure as a bolus, so that the drug started to be metabolized during the procedure itself, lasting on average 11 min.

Quality of colonoscopy procedures in our series appeared to reach the required standards, showing no interference of BSP in the diagnostic or operative procedures. In particular, the adjusted cecal intubation rate of 93.5% in a mixed setting with symptomatic and screening indications is remarkably superior to the 80.7% recently reported in an Italian survey, in which the use of propofol was not reported^[26]. Of note, in a similarly designed Italian study, it was observed that the intubation rate in sedation-assisted colonoscopies was superior to that of those performed without sedation^[27].

It could be argued that the results of our study were not unexpected; the safety of BSP having already been shown in previous studies. However, most of these series included only 100-200 patients^[14,15,17-23], so that a greater confirmation of BSP safety in over 1500 subjects was needed. Moreover, this is the first Italian study in which NAP was applied to colonoscopy, and, more generally, to adults. This would appear to be of major importance when considering that the use of propofol in Italy is prevented by an unequivocal recommendation in the product label stating that only anesthesiologists are allowed to administer such a drug. The safety profile of BSP in our study should call for dedicated studies aiming to ascertain whether such a recommendation is really a protection for the patients and whether it is consistent

with literature data or simply represents an obstacle preventing a safe propofol-assisted colonoscopy to most patients. Indeed, in Italy, due to the lack of anesthesiologist capacity, virtually all the colonoscopies are performed without propofol, using at best benzodiazepines and/or narcotics^[25].

There are limitations to the present analysis. Our main target was to evaluate BSP efficacy in targeting a moderate level of sedation when administered by non-anesthesiologists, whilst we did not assess the level of satisfaction of patients or endoscopists with our sedation protocol. However, there is enough evidence regarding a higher satisfaction level with propofol as compared to midazolam^[16]. Moreover, the short induction time clearly reflects a propofol type of sedation rather than the effect of midazolam. Secondly, we did not compare the propofol/midazolam BSP with other protocols, such as propofol alone or propofol with narcotics with or without midazolam. However, most of the propofol-related toxicity is associated with its narrow therapeutic window, so that it is unlikely that such a high safety profile would be achieved by protocols based on doses of propofol substantially larger than those reached in our experience. Thirdly, we did not blind the discharging nurse regarding the type of sedation, so that we cannot exclude a bias in the computation of the recovery time. Fourthly, we did not assess the alertness level after several hours from discharge, so that we cannot exclude a prolonged effect of midazolam bolus in our series. Fifthly, although our study included over 1500 subjects, we cannot exclude extremely rare events that have been associated with the use of propofol, such as neurologic injuries or even death. However, the lack of severe episodes of respiratory or cardiovascular depression reassures us about the safety of BSP. Moreover, no death has been reported up to now with the use of NAP in colonoscopy; all the cases having been associated with upper GI endoscopy or biliary maneuvers^[13]. According to the study protocol, we systematically used a non-anesthesiologist physician for monitoring propofol administration. It could be argued that this represents a waste of resources, requiring two endoscopists to perform one procedure. However, this simply reflects a prudent choice within the study protocol to prevent eventual litigation for an off-label use of the drug. It has already been shown that appropriately trained nurses may assist the endoscopist in propofol administration and sedation monitoring with a clear saving of resources. Finally, we did not use specific scales of recovery after the completion of the colonoscopy, considering discharge possible on the basis of blood pressure, SpO₂, and the patients' ability to drink and walk autonomously.

In conclusion, we report a large consecutive series showing the efficacy and safety of BSP for colonoscopy, when administered by non-anesthesiologists. When considering the controversy regarding NAP use for GI endoscopy, the very low dose of propofol allowed by the co-administration of midazolam appears to be a rational approach to maximize sedation efficacy and to minimize

propofol toxicity at the same time.

ACKNOWLEDGMENTS

We are indebted to Dr. Larry Cohen for his valuable support in reviewing and commenting on the present manuscript.

COMMENTS

Background

Non-anesthesiologists propofol administration (NAP) represents an effective and safe alternative to sedation with benzodiazepines/narcotics for colonoscopy. NAP generally involves the administration of propofol alone to target a deep level of sedation. By associating propofol with other sedative agents, such as midazolam, a moderate level of sedation may be targeted, resulting in a substantial reduction of the propofol dose.

Research frontiers

Despite being validated in small controlled trials, such a balanced propofol sedation has never been tested in a large cohort.

Innovations and breakthroughs

In a large prospective study involving 1593 patients, a balanced propofol sedation consisting of the co-administration of propofol and midazolam resulted in a moderate level of sedation in 98% of colonoscopies. Recovery time also appeared to be favorably short. Such a balanced protocol of sedation appeared to be highly safe, the only serious event being a transient oxygen desaturation requiring further oxygen supplementation in less than 1% of the patients. The median dose of propofol administered was 70 mg, being less than 120 mg in the entire series. The overall cecal intubation and adenoma detection rates were 93.5% and 23.4%, respectively. No major procedure-related complication occurred.

Applications

A balanced administration of propofol by non-anesthesiologists may be safely implemented in dedicated centers.

Peer review

The paper assessed the efficacy and safety of a balanced approach using midazolam in combination with propofol administered by non-anesthesiologists in a large series of diagnostic colonoscopies. It is very interesting.

Abstract

AIM: To find out if by combining 2 ultrasound based elastographic methods: acoustic radiation force impulse (ARFI) elastography and transient elastography (TE), we can improve the prediction of fibrosis in patients with chronic hepatitis C.

METHODS: Our study included 197 patients with chronic hepatitis C. In each patient, we performed, in the same session, liver stiffness (LS) measurements by means of TE and ARFI, respectively, and liver biopsy (LB), assessed according to the Metavir score. 10 LS measurements were performed both by TE and ARFI; median values were calculated and expressed in kilopascals (kPa) and meters/second (m/s), respectively. Only TE and ARFI measurements with IQR < 30% and

SR \geq 60% were considered reliable.

RESULTS: On LB 13 (6.6%) patients had F0, 32 (16.2%) had F1, 52 (26.4%) had F2, 47 (23.9%) had F3, and 53 (26.9%) had F4. A direct, strong correlation was found between TE measurements and fibrosis ($r = 0.741$), between ARFI and fibrosis ($r = 0.730$) and also between TE and ARFI ($r = 0.675$). For predicting significant fibrosis ($F \geq 2$), for a cut-off of 6.7 kPa, TE had 77.5% sensitivity (Se) and 86.5% specificity (Sp) [area under the receiver operating characteristic curve (AUROC) 0.87] and for a cut-off of 1.2 m/s, ARFI had 76.9% Se and 86.7% Sp (AUROC 0.84). For predicting cirrhosis ($F = 4$), for a cut-off of 12.2 kPa, TE had 96.2% Se and 89.6% Sp (AUROC 0.97) and for a cut-off of 1.8 m/s, ARFI had 90.4% Se and 85.6% Sp (AUROC 0.91). When both elastographic methods were taken into consideration, for predicting significant fibrosis ($F \geq 2$), (TE \geq 6.7 kPa and ARFI \geq 1.2 m/s) we obtained 60.5% Se, 93.3% Sp, 96.8% positive predictive value (PPV), 41.4% negative predictive value (NPV) and 68% accuracy, while for predicting cirrhosis (TE \geq 12.2 kPa and ARFI \geq 1.8 m/s) we obtained 84.9% Se, 94.4% Sp, 84.9% PPV, 94.4% NPV and 91.8% accuracy.

CONCLUSION: TE used in combination with ARFI is highly specific for predicting significant fibrosis; therefore when the two methods are concordant, liver biopsy can be avoided.

INTRODUCTION

Liver fibrosis evaluation in patients with hepatitis C virus (HCV) infection is essential for prognosis assessment and also for a decision regarding therapy. In many centers, liver biopsy (LB) is the “normal” means of fibrosis assessment. In the last few years, non-invasive methods for the evaluation of liver fibrosis have become more and more popular, especially in France and, subsequently, throughout the world.

Non-invasive methods for liver fibrosis assessment are: biological (serological) tests^[1-5], ultrasound based (elastographic) methods, such as transient elastography (TE)^[6-9], real time elastography^[10-12] and acoustic radiation force impulse (ARFI) elastography^[13-15] and magnetic resonance imaging (MRI) elastography^[16,17]. Each method has certain advantages: only a few milliliters of blood are required for the serological tests, a special “ultrasound” examination is required for the elastographic methods and finally, a MRI examination reveals information about many abdominal organs and at the same time evaluates the liver stiffness (LS). All these methods have some disadvantages, the major one being that they are not 100% sensitive or 100% specific compared to the LB which is still considered the “gold standard”.

Some authors have proposed to combine different noninvasive methods for liver fibrosis evaluation, hoping to increase the accuracy or maybe to decrease the number of LBs needed to solve unclear cases^[18]. Some years ago, Castera^[18] proposed to use only ALT for the evaluation of liver activity in patients with chronic hepatitis C, and for fibrosis to combine a FibroTest with a FibroScan. If these noninvasive tests are concordant, then LB can be avoided. In this study, when the FibroScan and FibroTest results agreed, significant fibrosis ($F \geq 2$) was confirmed by LB in 84% of the cases, severe fibrosis ($F \geq 3$) in 95% of cases, and cirrhosis ($F = 4$) in 94% of the cases.

The purpose of this study is to find out if, by combining 2 ultrasound based elastographic methods: ARFI elastography and TE, we can improve the prediction of fibrosis severity in patients with chronic HCV hepatitis.

MATERIALS AND METHODS

Patients

We performed a bicentric study in two university hospitals (Timisoara and Cluj-Napoca) that included 197 patients with chronic HCV hepatitis (anti HCV antibodies positive, with or without cytology for at least 6 mo, PCR HCV RNA

Figure 1 Acoustic radiation force impulse measurement in the liver.

positive). In all these patients, in the same session, LS was evaluated by means of TE (FibroScan[®]) and ARFI elastography, and LB was performed in order to assess the fibrosis stage. Patients with other causes of chronic hepatitis (HBV infection, chronic alcohol abuse, cholestatic chronic hepatitis, nonalcoholic steatohepatitis, autoimmune chronic hepatitis, haemochromatosis, Wilson’s disease) were excluded from our study. Informed consent was obtained from each patient included in the study and the study protocol was approved by the local ethical committee.

TE

TE was performed in all patients with a FibroScan[®] device (EchoSens[®] - Paris, France) by experienced physicians (more than 500 TE), blinded to the results of LB and ARFI measurements. In each patient, 10 valid measurements were performed, after which a median value of LS was obtained, measured in kilopascals (kPa). Only patients in which LS measurements by means of TE had a success rate of at least 60%, with an interquartile range (IQR) < 30%, were included in our study. The success rate was calculated as the ratio of the number of successful acquisitions over the total number of acquisitions. IQR is the difference between the 75th percentile and the 25th percentile, essentially the range of the middle 50% of the data.

ARFI elastography

ARFI elastography was performed in all the patients with a Siemens Acuson S2000TM ultrasound system. The ultrasound probe automatically produces an acoustic “push” pulse that generates shear-waves which propagate into the liver. Their speed, measured in meters/second (m/s), is displayed on the screen. The propagation speed increases with fibrosis. The operator can select the depth at which the liver elasticity is evaluated by placing a “measuring box” (10 mm long and 5 mm wide) in the desired place (Figure 1). The patients were examined in left lateral decubitus, with the right arm in maximum abduction. Scanning was performed between the ribs in the right liver lobe in order to avoid cardiac motion (approximately in the place where we usually perform LB), 1 cm under the capsule, with minimal scanning pressure applied by the operator, while the patients were asked to stop breathing for a mo-

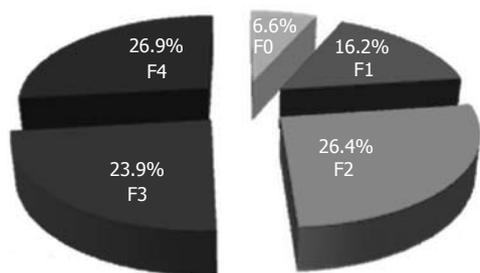

Figure 2 Severity of fibrosis in the studied group.

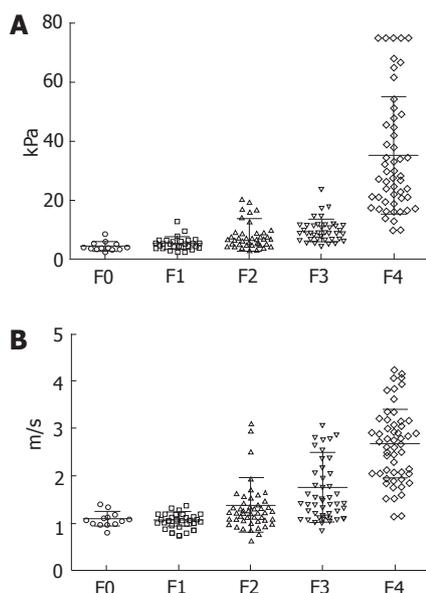

Figure 3 Liver stiffness measurements by means of transient elastography (A) and acoustic radiation force impulse elastography (B) for various stages of fibrosis.

ment, in order to minimize breathing motion.

We performed 10 measurements in every patient, and a median value was calculated, the result being measured in m/s. Only patients in which LS measurements by means of ARFI had a success rate of at least 60%, with an IQR < 30%, were included in our study. Operators were blinded to the results of LB and TE measurements.

LB

LB was performed in all the patients using echoguided TruCut technique, with a 1.8 mm (14 G) diameter automatic needle device-Biopty Gun (Bard GMBh), or echoassisted, using Menghini type modified needles, 1.4 and 1.6 mm in diameter. Only LB fragments including at least 6 portal tracts were considered adequate for pathological interpretation and included in our study. The LBs were assessed, according to the Metavir score, by a senior pathologist (one in each center) blinded to the results of TE and ARFI measurements. Fibrosis was staged on a 0-4 scale: F0-no fibrosis; F1-portal fibrosis without septa; F2-portal fibrosis and few septa extending into lobules;

F3-numerous septa extending to adjacent portal tracts or terminal hepatic venules and F4-cirrhosis.

Statistical analysis

The data we obtained from our patients were collected in a Microsoft Excel file, the statistical analysis being performed using MedCalc and GraphPad Prism programs. The predictors for the stage of fibrosis (ARFI and TE measurements) were numeric variables, so the mean and standard deviation were calculated.

Associations between assay results and fibrosis stage according to the Metavir scoring system (range: 0-4, ordinal scale), were described using the Spearman rank correlation coefficient (*r*).

The diagnostic performances of ARFI and TE were assessed by using receiver operating characteristics (ROC) curves. ROC curves were thus built for the detection of significant fibrosis ($F \geq 2$ Metavir) and cirrhosis ($F = 4$ Metavir). Optimal cut-off values were chosen to maximize the sum of sensitivity (Se) and specificity (Sp). Se and Sp were calculated according to standard methods. Exact confidence intervals of 95% were calculated for each predictive test.

RESULTS

Our study group included 197 patients, 119 women and 78 men, mean age 50 ± 9.8 years. On LB 13 (6.6%) patients had F0, 32 (16.2%) had F1, 52 (26.4%) had F2, 47 (23.9%) had F3 and 53 (26.9%) had F4 (Figure 2).

We obtained valid TE measurements in 187/197 patients (94.9%) and valid ARFI measurements in 191/197 patients (96.9%).

A direct, strong correlation was found between the values of liver stiffness evaluated by TE and fibrosis ($r = 0.741$) (Figure 3A), between the values of liver stiffness measured by ARFI and fibrosis ($r = 0.730$) (Figure 3B) and also between the values of liver stiffness evaluated by means both of TE and ARFI ($r = 0.675$).

The predictive values of TE and ARFI, alone, for $F \geq 2$ and F4, respectively, are presented in Table 1.

By combining the two elastographic methods (values both for TE and ARFI above the mentioned cut-offs) the specificity increased, statistically significant as compared to ARFI ($F \geq 2$: 93.3% vs 86.7%, $P = 0.04$; $F = 4$: 94.4% vs 85.6%, $P = 0.007$) but not as compared to TE ($F \geq 2$: 93.3% vs 86.7%, $P = 0.05$; $F = 4$: 94.4% vs 89.6%, $P = 0.12$), of course with lower sensitivity (Table 2), with very good positive predictive value (PPV) (96.3%) for significant fibrosis ($F \geq 2$ Metavir). By combining the two elastographic methods for F4, we obtained a very high negative predictive value (NPV), along with very good PPV and accuracy (Table 2).

The accuracy of the combined tests (TE + ARFI) was statistically significant better than ARFI alone for predicting cirrhosis (91.8% vs 83.4%, $P = 0.02$), but not as compared to TE alone (91.8% vs 91.4%, $P = 0.96$).

DISCUSSION

Discussions regarding the replacement of LB in the evaluation of liver fibrosis with non-invasive methods are currently very active. Arguments in favor of maintaining LB are: it allows a correct evaluation of fibrosis as well as of the activity of the disease; it can provide arguments for the etiology (Mallory bodies, *etc*) or it can evaluate the presence and severity of hepatocytes' fatty infiltration. Arguments against this method are: it is an invasive one (there is a risk for complications, even if it is low); it is usually a stressful method for the patients; in some cases, good quality histological specimens are not obtained and, also, there are some questions regarding sampling variability.

In some countries, such as France, the non-invasive methods for fibrosis assessment have replaced the LB in a large number of cases. To become accepted worldwide, these non-invasive methods must be very accurate, in order to replace a well recognized method such as LB.

TE measures the liver stiffness of a fragment that is approximately a cylinder 1 cm in diameter and 4 cm long, 500 times bigger than the specimen obtained by LB. This examination is more or less blind, but the other method that we used for the elastographic evaluation of the liver, ARFI, is performed under clear ultrasonographic visualization of the area of interest (the operator being able to choose the area to be examined).

The criticism, especially of TE, is that it is not able to differentiate between contiguous stages of fibrosis (F0 vs F1, or F1 vs F2). On the other hand, from the point of view of the clinician, it is important to know if the patient has only mild fibrosis (probably with no need for treatment in HCV patients), or moderate or severe fibrosis. And for this purpose, TE is quite a good method (the following AUROCs were reported: 0.79 for $F \geq 2$, 0.91 for $F \geq 3$ and 0.97 for $F = 4$)^[7].

The other elastographic method, ARFI technology,

involves targeting an anatomic region to be interrogated for elastic properties, with the use of a region of-interest cursor, while performing real-time B-mode imaging. Tissue from the region of interest is mechanically excited by using short-duration (262 μ s) acoustic pulses with a fixed transmit frequency of 2.67 MHz to generate localized tissue displacements. The displacements result in shear-wave propagation away from the region of excitation and are tracked by using US correlation-based methods^[19]. The shear-wave propagation velocity is proportional to the square root of tissue elasticity. Results are expressed in meters per second (m/s). The technique is new and published data suggest that ARFI and TE have a similar predictive value for fibrosis assessment.

In a study performed by Friedrich-Rust *et al*^[9] in which ARFI was compared to LB and blood markers in 86 patients with chronic hepatitis (HBV or HCV), the Spearman correlation coefficients between the histological fibrosis stage and ARFI, TE, FibroTest and APRI score were statistically significant: 0.71, 0.73, 0.66 and 0.45 respectively ($P < 0.001$).

In the study performed by Lupşor *et al*^[14], 112 patients with chronic hepatitis were evaluated. All the patients underwent LB (fibrosis stage assessed according to the Metavir scoring system), ARFI and FibroScan. The mean ARFI values for different stages of fibrosis were: 1.079 ± 0.150 m/s (F0-F1), 1.504 ± 0.895 m/s (F2), 1.520 ± 0.575 m/s (F3) and 2.552 ± 0.782 m/s (F4). The mean values were statistically significant different only between F3 and F4. The following cut-off values were proposed for various stages of fibrosis: $F \geq 1: 1.19$ m/s; $F \geq 2: 1.34$ m/s; $F \geq 3: 1.61$ m/s; and $F \geq 4: 2$ m/s.

Since both types of elastographic evaluation are available in our Department, we tried to see if by combining them we can improve their predictive value for fibrosis assessment. Firstly, we evaluated their predictive value alone for significant fibrosis ($F \geq 2$ Metavir) and cir-

rhosis ($F = 4$), after which we evaluated their predictive value in combination. If both methods were concordant ($TE \geq 6.7$ kPa and $ARFI \geq 1.2$ m/s), we obtained a high specificity (93.3%) for predicting significant fibrosis ($F \geq 2$), also with a very good positive predictive value (96.8%), so in those cases there was no need to perform LB before initiating treatment. In our study group, 152/197 patients had significant fibrosis ($F \geq 2$ Metavir) on LB. TE and ARFI were concordant for significant fibrosis in 92 of 152 patients. Therefore, we could avoid 60.5% of the LBs in our group of patients.

Also, by combining the two elastographic methods for predicting cirrhosis (F4) ($TE \geq 12.2$ kPa and $ARFI \geq 1.8$ m/s), the results were very good, with 94.4% Sp, 94.4% NPV and 91.8% accuracy, so the combined methods are excellent for confirming, but also for excluding the presence of cirrhosis. In our study group, 53 patients had cirrhosis ($F = 4$ Metavir on LB). TE and ARFI were concordant for liver cirrhosis in 45 from the 53 patients with $F = 4$ on LB (84.9%).

Other published data tried to combine different non-invasive methods for a better evaluation of liver stiffness. In a study published in 2005 by Castera *et al.*¹⁸, 183 patients with chronic HCV hepatitis were evaluated by LB, TE, FibroTest and APRI. The best performance was obtained by combining FibroScan and FibroTest, with areas under the ROC curve of 0.88 for $F \geq 2$, 0.95 for $F \geq 3$, and 0.95 for $F = 4$. When FibroScan and FibroTest results agreed, significant fibrosis ($F \geq 2$) was confirmed by LB in 84% of the cases, severe fibrosis ($F \geq 3$) in 95% of cases, and cirrhosis ($F = 4$) in 94% of the cases.

In another study published in 2010, Castera *et al.*²⁰ evaluated two algorithms for liver fibrosis prediction: one combined TE and FibroTest (Castera) and the other APRI and FibroTest (SAFE biopsy). In all patients a LB was performed. Significant fibrosis ($F \geq 2$ Metavir) was present in 76% of patients and cirrhosis (F4) in 25%. TE failure was observed in eight cases (2.6%). For significant fibrosis, the Castera algorithm saved 23% more liver biopsies than SAFE biopsy (71.9% *vs* 48.3%, respectively, $P < 0.0001$), but its accuracy was significantly lower (87.7% *vs* 97.0%, respectively; $P < 0.0001$). Regarding cirrhosis, the accuracy of the Castera algorithm was significantly higher than that of SAFE biopsy (95.7% *vs* 88.7%, respectively; $P < 0.0001$). The number of saved liver biopsies did not differ between the two algorithms (78.8% *vs* 74.8%, $P = NS$).

Shahenn²¹ published a meta-analysis which compared the performances of TE and FibroTest for the prediction of liver fibrosis in patients with chronic HCV hepatitis. Thirteen studies were identified, 9 regarding FibroTest (1679 patients) and 4 regarding TE (546 patients). In heterogeneous analysis for significant fibrosis, the AUROC curves for FibroTest and TE were 0.81 and 0.83, respectively. At a threshold of approximately 0.60, the sensitivity and specificity of FibroTest were 47% (35%-59%) and 90% (87%-92%). For TE (threshold approximately 8 kPa), corresponding values were 64% (50%-76%) and 87% (80%-91%), respectively. However, the diagnostic ac-

curacy of both tests was associated with the prevalence of significant fibrosis and cirrhosis in the study populations. For cirrhosis, the summary AUROCs for FibroTest and FibroScan were 0.90 and 0.95 (0.87-0.99).

In a study published in 2010 by Cross *et al.*²², 187 patients with chronic HCV hepatitis were evaluated by means of LB, TE and the King score. Liver fibrosis was scored using the Ishak score; significant fibrosis was defined as Ishak fibrosis stage F3-F6, and cirrhosis defined as Ishak fibrosis F5-F6. The AUROCs for TE, the King score and TE + King score for the diagnosis of Ishak F3-F6 were 0.83, 0.82 and 0.85, respectively and 0.96, 0.89 and 0.93, respectively, for the diagnosis of cirrhosis ($F \geq 5$ Ishak). The negative predictive values for the diagnosis of cirrhosis, using the optimal cut-off results for TE (10.05 kPa), the King score (24.3) and the two combined (26.1), were 98%, 91% and 94%, respectively.

Our study tried to establish whether the combination of TE and ARFI could provide some advantages for the evaluation of significant fibrosis in patients with chronic hepatitis C in comparison with a single elastographic method. By combining the two elastographic methods (values both for TE and ARFI above the mentioned cut-offs), the specificity increased (of course with lower sensitivity), with very good PPV (96.3%) for significant fibrosis ($F \geq 2$ Metavir). In our study group, 152/197 patients had significant fibrosis ($F \geq 2$ Metavir) on LB. TE and ARFI were concordant for significant fibrosis in 92 of 152 patients. Therefore, we were able to avoid 60.5% of LB in our group of patients.

Also, by combining the two elastographic methods for predicting cirrhosis (F4) ($TE \geq 12.2$ kPa and $ARFI \geq 1.8$ m/s), the results were very good, with 94.4% Sp, 94.4% NPV and 91.8% accuracy, so the combined methods are not only able to confirm, but also to exclude the presence of cirrhosis.

In conclusion, LS measurements assessed by means of both TE and ARFI strongly correlate to histological fibrosis in HCV patients. TE used in combination with ARFI is highly specific (approximately 93%) for predicting significant fibrosis ($F \geq 2$ Metavir), so that in patients with higher LS measurements than the proposed cut-offs for both methods, liver biopsy could be avoided. Also, in patients suspected of having severe fibrosis, if both methods are concordant, they are very good for confirming and excluding the presence of cirrhosis (94.4% Sp, 94.4% NPV).

COMMENTS

Background

Non-invasive methods for fibrosis assessment in chronic hepatitis, such as transient elastography (TE), are accepted more and more, tending to replace the invasive methods, especially in hepatitis C virus (HCV) chronic hepatitis. In the last few years, studies were published regarding the use of acoustic radiation force impulse (ARFI) elastography for fibrosis assessment in chronic hepatitis.

Research frontiers

Studies were published regarding the benefits of combining non-invasive methods for fibrosis evaluation (serological tests with or without TE), but not regarding a combination of elastographic methods (TE and ARFI).

Innovations and breakthroughs

The aim of this study was to find out if by combining ARFI and TE the prediction of fibrosis in patients with chronic HCV hepatitis can be improved, and the authors concluded that TE used in combination with ARFI is highly specific for predicting significant fibrosis; therefore when the two methods are concordant liver biopsy can be avoided.

Applications

In this study that included 197 patients with chronic C hepatitis, LS measurement by means of both TE and ARFI strongly correlated to the histological fibrosis. TE used in combination with ARFI was highly specific (93.3%) for predicting significant fibrosis ($F \geq 2$ Metavir); therefore in patients with higher LS measurements than the proposed cut-offs for both methods, liver biopsy could be avoided (positive predictive value 96.8%).

Terminology

TE (FibroScan) is an ultrasound-based method that uses the transmission of low-frequency vibrations to create an elastic shear wave that propagates into the liver, followed by the detection wave propagation velocity, which is proportional to the tissue stiffness, with faster wave progression occurring through stiffer tissue. ARFI technology involves targeting an anatomic region to be interrogated for elastic properties, with the use of a region-of-interest cursor, while performing real-time B-mode imaging. Tissue from the region of interest is mechanically excited to generate localized tissue displacements. The displacements result in shear-wave propagation away from the region of excitation and are tracked by using US correlation-based methods. The shear-wave propagation velocity is proportional to the square root of tissue elasticity.

Peer review

This is a well written paper that looks at TE (a well studied technology for liver fibrosis) and acoustic radiation impulse force (a technology for which there is much less clinical data). The data is well displayed.

Abstract

AIM: To demonstrate that CD14⁺ cells are an important source of the growth factor YKL-40 in acute and chronic liver damage.

METHODS: Rats were inoculated with one dose of CCl₄ to induce acute damage. Liver biopsies were obtained at 0, 6, 12, 24, 48 and 72 h. For chronic damage, CCl₄ was administered three days per week for 6 or 8 wk. Tissue samples were collected, and cellular

populations were isolated by liver digestion and purified by cell sorting. YKL-40 mRNA and protein expression were evaluated by real-time polymerase chain reaction and western blot.

RESULTS: Acute liver damage induced a rapid increase of YKL-40 mRNA beginning at 12 h. Expression peaked at 24 h, with a 26-fold increase over basal levels. By 72 h however, YKL-40 expression levels had nearly returned to control levels. On the other hand, chronic damage induced a sustained increase in YKL-40 expression, with 7- and 9-fold higher levels at 6 and 8 wk, respectively. The pattern of YKL-40 expression in different subpopulations showed that CD14⁺ cells, which include Kupffer cells, are a source of YKL-40 after acute damage at 72 h [0.09 relative expression units (REU)] as well as after chronic injury at 6 wk (0.11 REU). Hepatocytes, in turn, accounted for 0.06 and 0.01 REU after 72 h (acute) or 6 wk (chronic), respectively. The rest of the CD14⁺ cells (including T lymphocytes, B lymphocytes, natural killer and natural killer T cells) yielded 0.07 and 0.15 REU at 72 h and 6 wk, respectively. YKL-40 protein expression in liver was detected at 72 h as well as 6 and 8 wk, with the highest expression relative to controls (11-fold; $P \leq 0.05$) seen at 6 wk. Macrophages were stimulated by lipopolysaccharide. We demonstrate that under these conditions, these cells showed maximum expression of YKL-40 at 12 h, with $P < 0.05$ compared with controls.

CONCLUSION: Hepatic CD14⁺ cells are an YKL-40 mRNA and protein source in acute and chronic liver injury, with expression patterns similar to growth factors implicated in inflammation-fibrogenesis.

INTRODUCTION

YKL-40 glycoprotein (Chi3L1) is a growth factor named for its N-terminal amino acid sequence and molecular weight. It is related to 18-glycosylhydrolases, but lacks enzymatic activity^[1,2]. Under physiological conditions, human YKL-40 is secreted in small quantities by synovocytes and chondrocytes^[3,4]. However, *in situ* experiments demonstrated increased tissue mRNA and protein levels in osteoarthritis and rheumatism as well as in patients with inflammatory joint disease, where activated monocytes and macrophages are the main source.

The biological function of YKL-40 is unclear because no receptors have been identified to date. However, it has been reported that YKL-40 binds to stabilin type 1 and heparin sulfate *in vivo*. Furthermore, YKL-40 stimulates the proliferation and migration of connective tissue cells and fibroblasts through activation of the mitogen-activated protein kinase signaling pathway, suggesting that YKL-40 modulates fibrogenesis and tissue remodeling^[5,6].

Several studies have found elevated YKL-40 concentrations in sera of patients with liver diseases, such as hepatic fibrosis by hepatitis C virus^[7]. Serum concentrations of YKL-40 correlated with extracellular matrix (ECM) products secreted by hepatic stellate cells (HSCs) and fibroblasts (e.g., P11NP, hyaluronan, MMP-2, and TIMP-1). It has been suggested that YKL-40 concentrations reflect the degree of liver fibrosis. However, extensive clinical evaluation is still required, and other inflammatory diseases have to be excluded as potential causes of YKL-40 elevations.

In hepatic tissue, immunohistochemical analyses show strong YKL-40 staining around fibrotic areas^[3]; however, in this study it was not possible to discriminate the cells that produce YKL-40. Notably, HSCs from fibrotic liver tissue by *S. japonica* showed an increase of YKL-40 mRNA^[8].

Currently, the kinetics and source of YKL-40 in the liver under damage conditions are unknown. This study addressed these issues as part of a broader effort to elucidate the role of this molecule in hepatic inflammation and tissue repair.

MATERIALS AND METHODS

Animals

Rats were treated according to the guidelines for reproduction, care and use of laboratory animals stated by the Norma Oficial Mexicana (NOM-066-ZOO-1999). Twenty-seven male Wistar rats weighing 250 g each were selected for treatment with CCl₄ and divided into nine groups of three animals each. One group was untreated and used as controls. Six groups were inoculated with a single intragastric dose of 0.5 mL/100 g of CCl₄ (Sigma, 319961, United States) mixed 1:1 with mineral oil (Sigma, M5409, United States) to establish acute injury. These animals were sacrificed at time 0, 6, 12, 24, 48 and 72 h. To establish chronic liver injury, two groups were inoculated three times per week with an i.p. injection of 0.1 mL/100 g CCl₄: mineral oil at ratios of 1:6, 1:5, 1:4 (one week for each), then 1:3 until the animals were sacrificed at week 6 or 8.

Tissue samples

Procedures were performed under ether anesthesia. Livers were washed with PBS (Gibco, 70013-032, United Kingdom) at 4 °C, sectioned into small 100 mg pieces and stored in tubes at -70 °C. Samples for RNA extraction were stored in 500 µL of TRIzol (Invitrogen[®] BRL 15596-026, United States) at -70 °C.

RNA extraction

Liver tissue and cells were homogenized in 500 µL of TRIzol (Invitrogen[®] BRL United States). Chloroform (Sigma, C2432, United States) was added, and the samples were centrifuged for 15 min at 10 000 g and 4 °C. Total RNA was precipitated with isopropanol (Sigma, 19516, United States). The RNA pellet was washed with 75% ethanol and dissolved in RNase-free water. The final concentrations and quality of the RNA were determined by spectrophotometry.

Reverse-transcriptase polymerase chain reaction

Approximately 1 µg of total RNA was reverse-transcribed to cDNA in a 20 µL reaction using murine leukemia virus reverse transcriptase M-MLV (Invitrogen[®] BRL, 28025-013, United States). The mixture was prepared with 1 µg of RNA, 125 ng/µL of random primers (Invitrogen[®] BRL, 48190011, United States), 1 µL of 10 mmol/L dNTP mix and 12 µL of sterile distilled water. The mixture was heated for 5 min at 65 °C and quick chilled on ice. Four µL of 5X First Strand Buffer, 2 µL of 0.1 mol/L DTT and 1 µL of RNaseOUT (Invitrogen[®] BRL, 10777019, United States) were added, and the reaction was incubated at 37 °C for 2 min. Finally, 200 U/µL of M-MLV were added, and the total reaction was incubated at 25 °C for 10 min and then at 37 °C for 50 min. The reaction was inactivated by heating at 70 °C for 15 min^[9].

Real-time polymerase chain reaction

Real-time polymerase chain reaction (PCR) was performed

with an ABI Prism 7300 thermocycler (Applied Biosystems, United States). Each 20 μ L reaction contained 2 μ L of cDNA and TaqMan Universal PCR master mix (Applied Biosystems, 4364338, United States). The primers and probe set sequences were specific for 18S rRNA (constitutive gene; Applied Biosystems, FG18S RNA, United States) and YKL-40 (inducible gene; Applied Biosystems, Rn0149065, United States). All reactions were run in duplicate at universal thermocycler conditions for TaqMan[®] Gene Expression Assays (2 min at 50 °C, 10 min at 95 °C and 40 cycles at 95 °C for 15 s and 60 °C for 1 min). Results were analyzed with ABI Prism software^[9].

YKL40 expression in cell subpopulations

Male Wistar rats were anesthetized, and livers were perfused *via* the portal vein with calcium-free Gey's solution (Sigma, 69779, United States) supplemented with 100 U/mL of heparin. A second perfusion was done with calcium-free Gey's solution containing 100 U/mL of heparin, 0.06% collagenase (Fluka, 27678, United States) and 0.01% DNase (Roche, 13035000, Sweden). Liver tissues were extracted, homogenized and placed in a bottle containing Gey's solution, 0.005% collagenase and 0.001% DNase, and stirred gently for 30 min at 37 °C. The resultant suspension was filtered in 106 Nylon mesh, and 4 mL of MEM (Invitrogen[®] BRL, 11095, United States) supplemented with 10% fetal bovine serum (Invitrogen[®] BRL, 1082-139, United States) were added. The homogenates were centrifuged at 50 G for 2 min at 4 °C to precipitate hepatocytes. The supernatant was recovered and centrifuged at 400 G for 7 min at 4 °C. The pellet was resuspended with Gey's solution plus 25% albumin (Sigma, A7906, United States) and centrifuged at 350 G for 10 min at 4 °C to obtain non-parenchymal cells (NPCs). NPCs were washed, resuspended with Gey's solution, placed on a lymphoprep (Axis-Shield, LYS3773, Oslo, Denmark) gradient and centrifuged at 1800 *g* for 25 min. The white ring of mononuclear cells was recovered. Cells were washed and then divided into aliquots of 1×10^6 per tube for sorting. Next, cells were incubated with a CD14 primary antibody (Santa Cruz Biotechnology, M305, United States, 1:25) for 30 min in the dark at 4 °C. Cells were then washed and incubated with a FITC secondary antibody (Jackson ImmunoResearch, 71813, United Kingdom, 1:2000) for 30 min at 4 °C in the dark. Marked cells were washed and sorted (BD FACSAria) by CD14 protein surface marker expression.

Western blotting

Protein extraction from whole liver tissue and cellular populations was performed with the NE-PER (Pierce, 78833, United States) extraction reagent according to the manufacturer's instructions. Protein concentrations were quantified with the BioRad protein assay (BioRad, 500-13, 14, 15; United States). Sodium dodecyl sulfate polyacrylamide gel electrophoresis was done at 12%, and the proteins were transferred to a polyvinylidene fluoride (PVDF) membrane at 30 V overnight at 8 °C. The PVDF membrane was washed twice in tris buffered

saline (TBS) and blocked with 5% of non-fat milk used for 1 h at room temperature with constant stirring. The membrane was then incubated for 1 h at room temperature with primary antibodies against YKL-40 (Santa Cruz Biotechnology, sc-31722, United States, 1:200) or [-Actin (Santa Cruz Biotechnology, sc-47778, United States, 1:500)]. Membranes were then washed twice with tris buffered saline Tween-20 (TBST) and incubated for 30 min with an HRP-conjugated donkey anti-goat secondary antibody (Santa Cruz Biotechnology, sc-2020, United States, 1:4000) to detect YKL-40 or goat anti-mouse for [-actin (Roche, 11520709001, Sweden, 1:500)]. Membranes were then washed twice in TBST and TBS. The signal was detected with the BM chemiluminescence Western Blotting kit (Roche, 1520709, Sweden) according to the manufacturer's instructions. Relative expression units (REU) were calculated from densitometric values of YKL-40 and β -actin (Kodak MI SE 4.5 software, Kodak, United States).

In vitro overexpression of YKL-40

Alveolar macrophage cells (ATCC, NR8383) were cultured in RPMI 1640 medium (Invitrogen[®] BRL, 21870084, United States) supplemented with 10% fetal calf serum and 1% antibiotic-antimycotic (Invitrogen[®] BRL, 15240062, United States). Upon reaching 70% confluence, cells were stimulated with LPS (Sigma, L4005, United States, 100 ng/L) for 3 h or 12 h; the medium was then discarded, and the cells were lysed in Trizol/TRIZOL reagent for mRNA extraction and evaluation of YKL-40 mRNA expression by real-time PCR.

Statistical analysis

The statistical analysis was performed with SPSS 10.0 software (SPSS Inc., United States), and significance was calculated by ANOVA. Data were expressed as mean \pm SD. We considered $P \leq 0.05$ to be significant.

RESULTS

YKL-40 mRNA expression

Real-time PCR was performed on liver tissue samples after acute or chronic injury to evaluate changes in YKL-40 mRNA expression. In all experiments, healthy animals served as the control group. At 6 and 12 h after CCl₄ administration, YKL-40 expression was increased 2- and 10-fold, respectively, compared to controls ($P \leq 0.05$). Maximum expression (26-fold) relative to healthy tissue samples occurred at 24 h. At 72 h, YKL-40 mRNA expression levels declined to a level close to that of the 0-h and healthy groups (Figure 1).

In the chronic liver injury model, YKL-40 mRNA expression was significantly increased relative to controls at both 6 and 8 wk (8 and 10 REU, respectively, $P < 0.05$) (Figure 1).

YKL-40 protein expression

We next investigated the presence of YKL-40 protein in whole liver tissue from healthy, acute and chronic

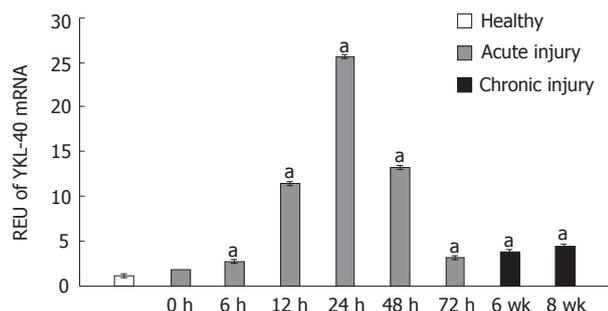

Figure 1 YKL-40 mRNA expression in whole liver tissue samples with acute and chronic injuries induced by CCl₄. After acute injury, YKL-40 mRNA increased in a gradual and constant pattern and then fell to control levels. The maximum 26-fold increase was reached at 24 h in the acute damage model. For the chronic injury model, at 6 and 8 wk, YKL-40 mRNA levels were increased 7- and 9-fold compared to controls, respectively. ^a*P* ≤ 0.05. REU: Relative expression units.

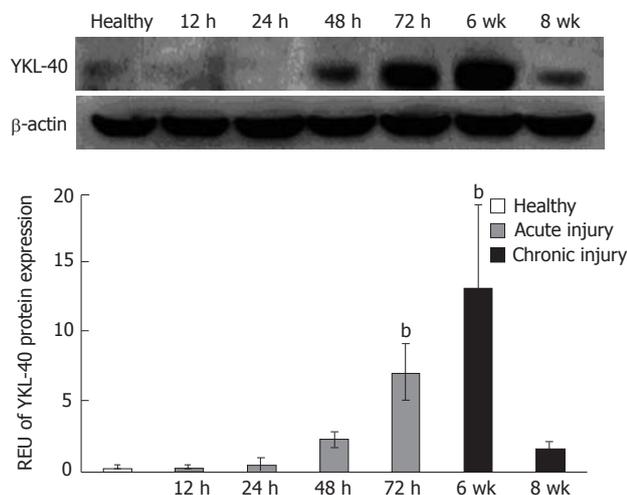

Figure 2 YKL-40 protein levels show a gradual increase. The maximum peak was at 72 h in the acute damage model and 6 wk in the chronic injury model, with 2.01 and 6.35-fold increases, respectively. ^b*P* ≤ 0.05 respect to the control group. REU: Relative expression units.

injury samples. In livers with acute injury, we observed that YKL-40 protein levels peaked at 72 h, with an increase of 2.0-fold compared to controls. At 12 and 24 h, YKL-40 levels were similar to those of healthy livers. In contrast, in the chronic injury model the maximum peak was observed at 6 wk with a significant decline apparent by 8 wk (*P* < 0.05) (Figure 2).

CD14⁺ cells are a source of YKL-40 protein

Based on their high levels of YKL-40 protein expression in whole liver samples, the 72-h group from the acute model and the 6-wk group from the chronic model were chosen for evaluation of protein expression in isolated cells. It has been reported that CD14⁺ cells population, which includes Kupffer macrophages, synthesize the largest amount of cytokines and growth factors. Additionally, they are found in abundance in the liver, accounting for about 20%-25% of NPCs^[10] and 80%-90% of macrophages in the whole body. Therefore, we evalu-

ated YKL-40 protein expression in this subpopulation.

Hepatocytes, CD14⁺ cells and CD14⁻ cells isolated from healthy animals did not show significant YKL-40 protein expression, with no statistical significance between groups (Figure 3A). However, when these cells types were isolated from CCl₄-treated animals, YKL-40 protein expression was elevated up to 4-fold compared with healthy animals. The highest level (0.09 REU) was detected in CD14⁺ cells in the acute damage model (Figure 3B). In the chronic injury model, both CD14⁺ and CD14⁻ cells were significant sources of YKL-40, with 0.15 and 0.11 REU, respectively (*P* < 0.05 compared to control cells) (Figure 3C).

Lipopolysaccharide induces YKL-40 mRNA expression in rat alveolar macrophages

Previous studies reported that CCl₄ induces damage to the intestinal tissue architecture^[11]. CCl₄ promotes translocation of bacteria and associated compounds like Lipopolysaccharide (LPS) towards the liver by portal blood flow. Here, LPS is taken up by Kupffer cells, which then synthesize cytokines and growth factors. To demonstrate this effect, rat alveolar macrophage cells were stimulated with LPS for 3 or 12 h. Our results showed that YKL-40 mRNA levels were increased 9- and 11-fold, respectively, compared with control cells without LPS stimulation (*P* ≤ 0.05). However, no significant difference was detected between the 3- and 12-h groups (Figure 4).

DISCUSSION

Several studies have found a correlation between serum YKL-40 levels and liver fibrosis stages^[10,12,13]. However, other studies have reported contradictory findings^[14-18]. Nevertheless, in the first set of studies, procollagen III peptide and hyaluronic acid showed better correlations with fibrosis than YKL-40, likely because these molecules are scar components. YKL-40 is presumably a growth factor that indirectly contributes to fibrosis by stimulating proliferation of the cells that produce ECM proteins. For this reason, we considered it important to study the expression kinetics and source of YKL-40 in models of acute and chronic liver injury.

Although liver fibrosis and cirrhosis are characterized by inflammatory infiltration, a process in which a great number of cells participate, Johansen *et al.*^[3] showed that the liver was a possible source of YKL-40. This study noted that strong YKL-40 immunostaining could be detected around fibrotic areas in liver tissue samples where fibrosis had been induced by alcohol and viral hepatitis, but it was impossible to distinguish the cellular source^[3].

We used the CCl₄ damage model because it resembles alcohol damage^[14] and because the kinetics of damage is well characterized. Our results show that YKL-40 mRNA levels began to increase at 12 h, with a maximum peak at 24 h (Figure 1). In the CCl₄ fibrosis model, increased mRNA levels of growth factors such as TGF-β and PDGF at 48 and 72 h after intoxication suggest their participation in the fibrogenic process through their bio-

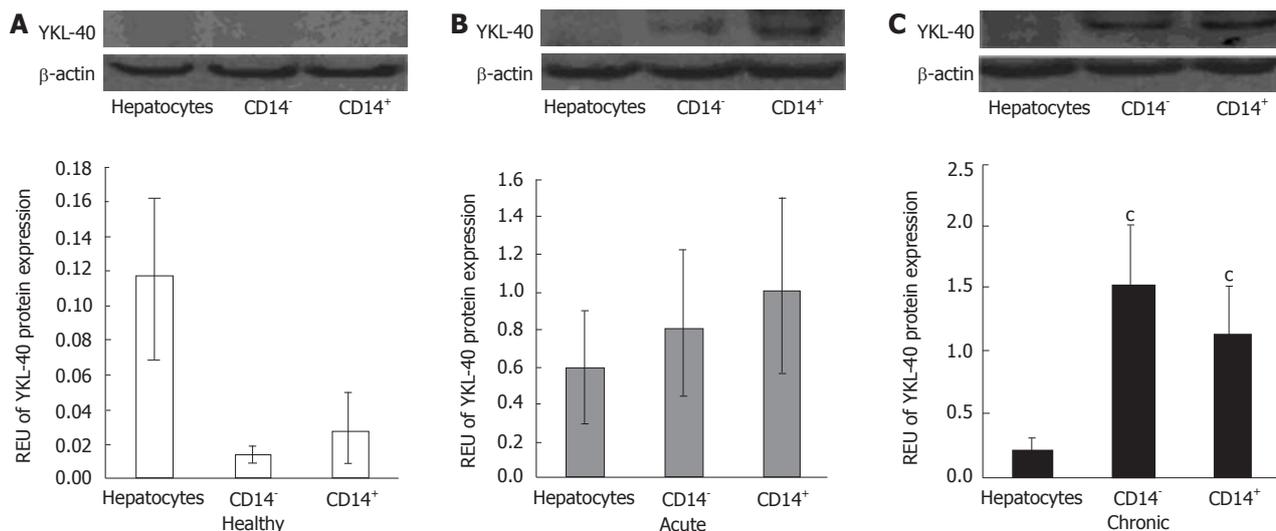

Figure 3 YKL-40 protein expression in cellular populations isolated from liver tissue. A: In healthy livers, expression of YKL-40 protein was lower in CD14⁺ and CD14⁻ subpopulations. B: In cells from livers exposed to acute damage, YKL-40 protein levels were higher in CD14⁺ cells. C: In the chronic injury model, hepatocytes showed low levels of YKL-40, with significant difference between CD14⁺ and CD14⁻ cells against hepatocytes (^c*P* < 0.05). REU: Relative expression units.

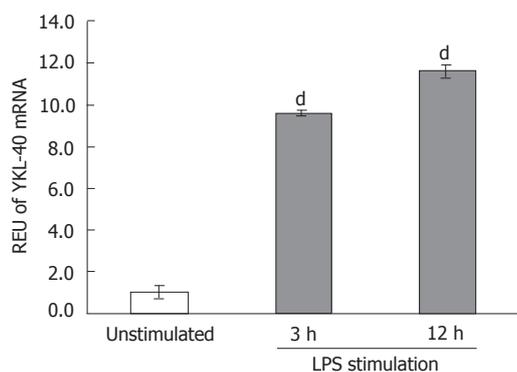

Figure 4 YKL-40 mRNA expression was induced by lipopolysaccharide in cell culture. After 3 and 12 h of stimulation with lipopolysaccharide, YKL-40 mRNA levels were increased by 9- and 11-fold, respectively, in a rat alveolar macrophage cell line (^d*P* < 0.05). Unstimulated cells were used as controls. REU: Relative expression units. LPS: Lipopolysaccharide.

logical activities of ECM synthesis and HSC-fibroblast proliferation respectively^[15,19]. Like PDGFβ, YKL-40 might activate the proliferating cell signaling pathway PI3K-AKT^[20].

Kupffer cells were the natural candidate source of YKL-40 because previous studies of joint, lung, kidney and skin inflammatory diseases^[2,5] identified macrophages as the main producer of this protein. In our study, CD14⁺ cells were a source of YKL-40, exhibiting 0.9 and 0.11 REU in the acute and chronic damage models, respectively. However, it is important to note that CD14⁻ cells also produced YKL-40 protein, with 0.7 and 0.15 REU in the acute and chronic injury models, respectively. This population includes immune cells such as natural killer (NK) and natural killer T (NKT) cells, which represent about 37% and 26% of non-parenchymal cells respectively. These cells are the first line of defense in liver infections and consequently have immunoregulatory properties: they can synthesize cytokines

(e.g., IFN-γ, TNF-α, IL-4, IL-10 and IL-13) (NK cells) or induce direct cellular destruction by TLR or CD1D molecules (NKT cells)^[11].

LPS might also be a trigger of YKL-40 gene expression. Carbon tetrachloride and alcohol injure the upper gastrointestinal tract, forming lesions in gastric and duodenal mucosa. This promotes increased intestinal permeability to endotoxins, notably LPS, peptidoglycan, flagellin and zymosan, which are found in liver blood influx as well. These antigens are taken up by monocytes and Kupffer cells^[12,13], which express TLR 1-8. LPS is known to be a ligand for TLR-4, a toll-like receptor widely expressed in monocytes and macrophages. This ligand-receptor interaction induces larger quantities of TNF-α, TGF-β and IL-10 cytokines^[12,13]. Considering that the type of intestinal and liver damage induced by CCl₄ is similar to that of ethanol consumption, we stimulated alveolar macrophages *in vitro* with 100 ng/L and found increases in YKL-40 mRNA levels of about 9- and 12-fold at 3 and 12 h, respectively. These results indicate that LPS could act as a direct stimulus to induce YKL-40 in macrophages during the establishment of damage.

COMMENTS

Background

Hepatic diseases are a major cause of death in the world; some have, as a singular characteristic, the presence of fibrosis. Hepatic fibrosis is difficult to diagnose because a hepatic biopsy is needed, and the condition of patients frequently makes it impossible to perform a biopsy. For several years, researchers have been looking for fibrosis markers in the blood in order to avoid having to perform a hepatic biopsy. One of these is YKL-40, a protein produced by several tissues under conditions causing stress and damage, such as alcohol consumption. YKL-40 has been used as a fibrosis marker with controversial results, particularly since it is not known precisely which cells produce this protein.

Research frontiers

The focus of this article is to elucidate which cells in the liver are producing YKL-4 and to try to understand the role of YKL-40 in the process of repairing

fibrotic hepatic tissue and the maintenance of a healthy liver.

Innovations and breakthroughs

Until the present moment, there has not been a study that describes in which cells and at what time YKL-40 is produced. Several research protocols in humans have been made: in 2003 Nojgaard detected YKL-40 and successfully related this protein with hepatic fibrosis, however in recent years other research has shown contradictory results. Johansen in 2000 published that, in liver biopsies, cells were producing YKL-40; however, with the methodology used it was impossible to distinguish which cells types were actively producing YKL-40. This work was initiated because the authors thought that it was necessary to know more about YKL-40 production and to focus on the hepatic cellular source.

Applications

The hepatic cells that produce YKL-40 are CD14⁺ and CD14⁻ at different times. This helps the authors to better understand how serum YKL-40 could be increased at different stages of disease, and attempt to better understand YKL-40 as a blood fibrosis marker and how this molecule participates in the process of hepatic health and illness.

Terminology

YKL-40: Protein produced by cells that helps to augment cell growth and to stimulate proteins that form the extracellular environment. CD14: Molecules in the cell membrane useful to classify and distinguish cells.

Peer review

A research study about a model of hepatic injury in the rat that is relevant since nowadays liver cirrhosis/fibrosis is a health problem worldwide. Many treatment modalities have been suggested to prevent the development of fibrosis but, unfortunately, none of them have uniformly yielded promising results. Therefore, a better knowledge of the pathogenic mechanisms involved in the inflammatory response developed during acute and chronic liver diseases makes possible the use of more effective therapeutic approaches in these patients.

Abstract

AIM: To examine the influence of ghrelin on the regenerative potential of gastrointestinal (GI) epithelium.

METHODS: Damage to GI epithelium was induced in mice by two intravenous injections of doxorubicin (10 and 6 mg/kg). Some of the doxorubicin-treated mice received a continuous subcutaneous infusion of ghrelin (1.25 µg/h) for 10 d *via* implanted mini-osmotic pumps. To label dividing stem cells in the S-phase of the cell cycle, all mice received a single intraperitoneal injection of 5'-bromo-2'-deoxyuridine (BrdU) one hour before sacrifice. The stomach along with the duodenum were then removed and processed for histological examination and immunohistochemistry using anti-BrdU antibody.

RESULTS: The results showed dramatic damage to the GI epithelium 3 d after administration of chemotherapy which began to recover by day 10. In ghrelin-treated mice, attenuation of GI mucosal damage was evident in the tissues examined post-chemotherapy. Immunohistochemical analysis showed an increase in the number of BrdU-labeled cells and an alteration in their distribution along the epithelial lining in response to damage by doxorubicin. In mice treated with both doxorubicin and ghrelin, the number of BrdU-labeled cells was reduced when compared with mice treated with doxorubicin alone.

CONCLUSION: The present study suggests that ghrelin enhances the regenerative potential of the GI epithelium in doxorubicin-treated mice, at least in part, by modulating cell proliferation.

INTRODUCTION

Ghrelin is a novel 28-amino acid peptide which was simultaneously discovered by two independent research

groups more than 10 years ago^[1,2]. It was initially found to be a secretory product of a subset of enteroendocrine cells predominantly present in the stomach with a decreasing gradient toward the small intestine and the colon^[1,2]. It was also found to be produced in small amounts by several other organs such as the brain, pancreas, pituitary, kidney, lung and placenta^[3].

Functional studies revealed that ghrelin is involved in a wide variety of biological activities including growth hormone release^[4], stimulation of food intake and body weight gain^[5,6], gastrointestinal (GI) motility^[7], and modulation of cardiovascular function^[8]. Furthermore, it has been shown that ghrelin may also control proliferation and differentiation programs of neuronal and mesenchymal stem cells^[9] and modulate cell proliferation of some tissue progenitors^[10,11] and cell lines^[12-14].

In the stomach, while ghrelin has been shown to modulate the secretory activity of parietal cells^[15,16], it is not known whether this hormone is involved in the regulation of epithelial cell proliferation. It was shown earlier that parietal cells are the source of some instructive signals and their ablation in mice modulates the proliferation and differentiation program of gastric epithelial stem/progenitor cells^[17] and with age cause gastric carcinoma^[18]. Therefore, modulation of the secretory activity of these cells might also affect the proliferation/differentiation program of the epithelial progenitors. Surprisingly, when ghrelin knockout mice were examined, no abnormalities were reported in the GI mucosa^[19]. Recently, there has been increasing evidence to suggest a role for ghrelin in protection against gastric mucosal damage^[20,21]. The mechanism of mucosal protection was mainly attributed to the release of nitric oxide^[22].

The aims of this study were to determine whether ghrelin can be used to protect against GI mucosal damage induced by doxorubicin, and to test whether ghrelin protection, if any, is associated with modulation of cell proliferation in the progenitor cell zone of the GI epithelium.

MATERIALS AND METHODS

Animals

In this study, female BALB/c mice (2-3 mo old) were evaluated after being housed in sterile microisolator cages with sterile bedding, food, and water ad libitum. The animals were kept under a 12-h light/dark cycle and at room temperature (22-24 °C). The protocols described in this study were approved by the Animal Research Ethics Committee of the Faculty of Medicine, UAE University.

Chemotherapeutic treatment

To establish the experimental protocol of this study, we initially injected age-matched mice ($n = 40$) with a single dose of 5-fluorouracil (100 mg/kg body weight) or doxorubicin (10 mg/kg). Mice were then sacrificed at different time periods varying from 1 to 16 d. Gastro-duodenal tissues were collected to identify any changes

in mucosal integrity.

Experimental protocol

Mice ($n = 9$) were divided into three equal groups. Mice in the first group received ghrelin (Sigma, St. Louis, MO, United States) through Alzet micro-osmotic pumps (Durect Co, Cupertino, CA, United States) implanted subcutaneously which released ghrelin at a rate of 1.25 mg/h for 14 d. The pumps were prepared for implantation according to manufacturer's instructions and our previously published procedure^[23]. On the 8th and 9th day of ghrelin perfusion, mice received two intravenous injections of doxorubicin (10 and 6 mg/kg, respectively). In the second group, mice were subcutaneously infused with saline instead of ghrelin and then received two intravenous injections of doxorubicin on two consecutive days as in the first group. The third group of mice served as controls and, instead of ghrelin and doxorubicin, received only saline by infusion pump and by intravenous injections, respectively. To label dividing cells in the S-phase of the cell cycle, mice in all 3 groups received a single intraperitoneal injection of 5'-bromo-2'-deoxyuridine (BrdU, 120 mg/kg) one hour before sacrifice. At day 4 post-doxorubicin (or saline) second injection, the stomach along with the duodenum were removed under ether anesthesia and processed for morphological and immunohistochemical analysis.

Morphological analysis

To examine the histopathological changes that occurred in the wall of the GI tract, the stomach and proximal part of the duodenum were dissected from all mice under anesthesia and immediately processed for conventional histological examination^[23]. The tissues were fixed immediately in Bouin solution, dehydrated in ethanol, and infiltrated/embedded in paraffin. Five-micron-thick sections were mounted on slides and stained with periodic acid schiff and hematoxylin.

BrdU immunolabeling

To examine cell proliferation and estimate the number of cells in the S-phase of the cell cycle, paraffin tissue sections from all mice were processed to determine the localization of cells which incorporated BrdU^[23]. Briefly, tissue sections were first deparaffinized, hydrated, and incubated with 3% hydrogen peroxide to block endogenous peroxidase. The anti-BrdU antibody used was goat polyclonal^[24]. Biotinylated anti-goat immunoglobulin G was used as a secondary antibody which was identified by avidin-peroxidase and then di-aminobenzidine as a coloring agent. Immunoprobed tissue sections were scanned using the Olympus microscope to quantify BrdU-labeled cells. In each mouse, the numbers of BrdU-labeled cells per gastric gland or crypt-villus unit were averaged.

Statistical analysis

Data are presented as mean \pm SD. Differences between groups were evaluated using the Student *t* test. $P < 0.05$ was taken as statistically significant.

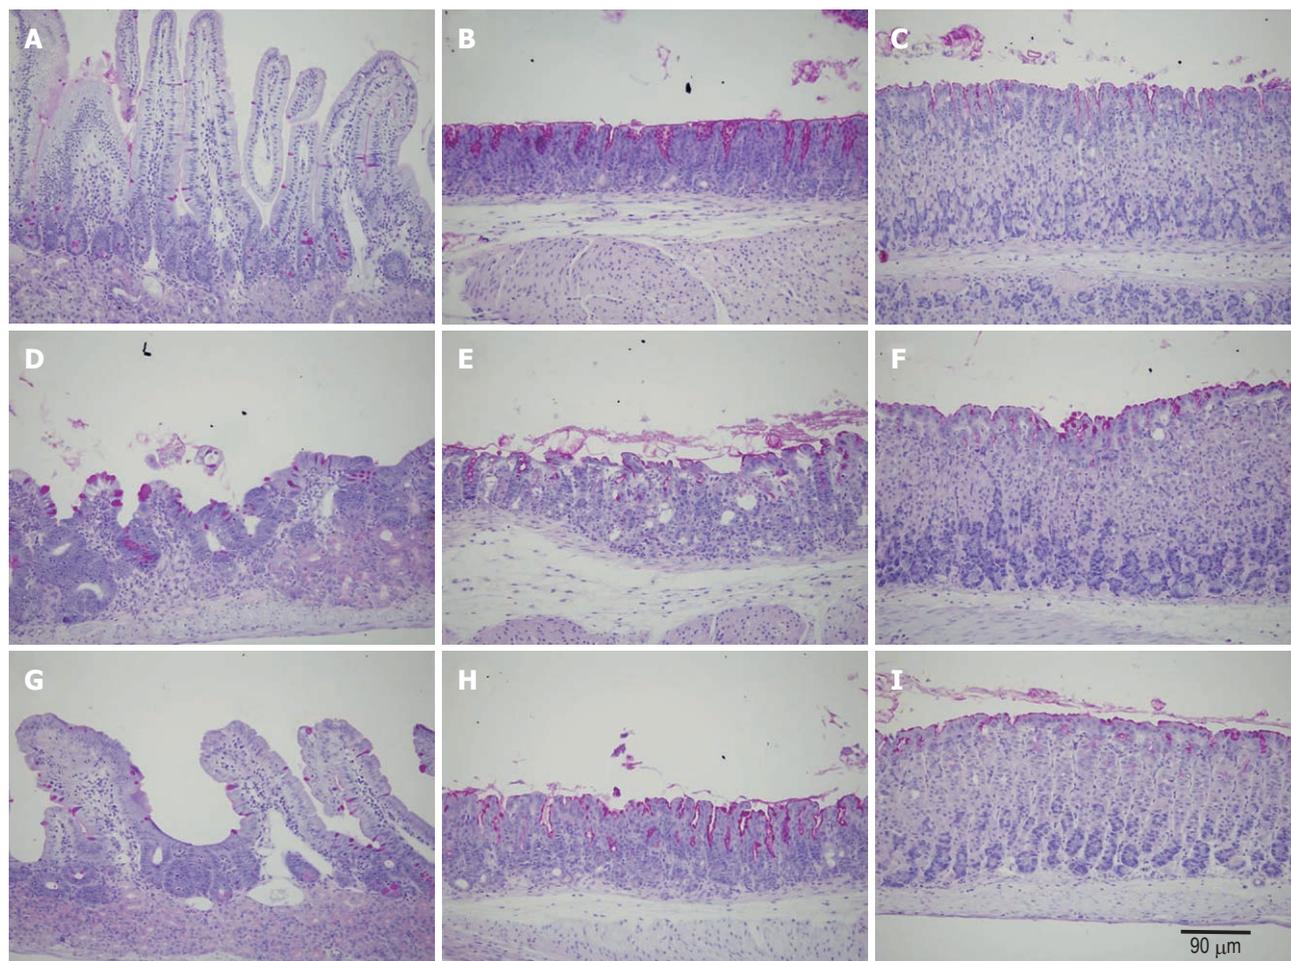

Figure 1 Light micrographs showing tissue sections obtained from the duodenum (A, D, G), pyloric antrum (B, E, H) and gastric corpus (C, F, I) of control (A-C), doxorubicin-treated (D-F) and ghrelin-plus-doxorubicin-treated (G-I) mice. All tissue sections were stained with periodic acid schiff and hematoxylin. Note that while there are apparent mucosal changes in D and E due to doxorubicin treatment, the tissues in G and H are more or less similar to control.

RESULTS

A single injection with chemotherapeutic agent induces mild effects in the GI mucosa

The damaging effect of the chemotherapeutic agents on GI mucosa was followed by microscopic examination of tissue sections. The dose regimen used for 5-fluorouracil showed inconsistent damaging effects in the mucosal tissues in the form of occasional vacuolation of the lining GI epithelial cells. Doxorubicin treatment induced a slightly more pronounced and consistent effect. Therefore, it was decided to use two intravenous injections of doxorubicin for the experimental protocol.

Protection of GI mucosa by ghrelin against the damaging effects of doxorubicin

Microscopic examination of gastroduodenal mucosa of control mice revealed the expected histological features of intact long oxyntic glands of the corpus region, short mucous glands of the pyloric antrum, and the very long crypt-villus units of the duodenum (Figure 1) as previously described^[25]. In the second group of doxorubicin-treated mice, while little changes were observed in the oxyntic glands in the form of a few scattered cells with vacuolated

cytoplasm, the antral glands showed more aggressive changes which induced dilations of the glandular lumen. Massive mucosal changes in the duodenum were observed (Figure 1D-F). The villi appeared blunt or much shorter and broader than those of control mice. In addition, the integrity of the villus epithelium was not intact. Signs of vacuolation and cell damage were evident throughout. In the ghrelin-plus-doxorubicin-treated mice, the glands in the corpus and antral regions appeared similar to those of control mice. Even the duodenal villi appeared intact, long and populated mainly by absorptive and goblet cells as in control mice (Figure 1G-I).

Modulation of BrdU-labeling in doxorubicin- and ghrelin-treated mice

To correlate the morphological changes with cell proliferation, we used the BrdU labeling method. BrdU was made available to cells in the S-phase of the cell cycle one hour before sacrifice. Gastroduodenal tissue sections were then immunolabeled using anti-BrdU antibody (Figure 2). In control mice, BrdU-labeled cells in the corpus and antral mucosae were located at the pit-gland junction close to the luminal surface (corpus) or the gland bottom (antrum). Counts revealed the presence of

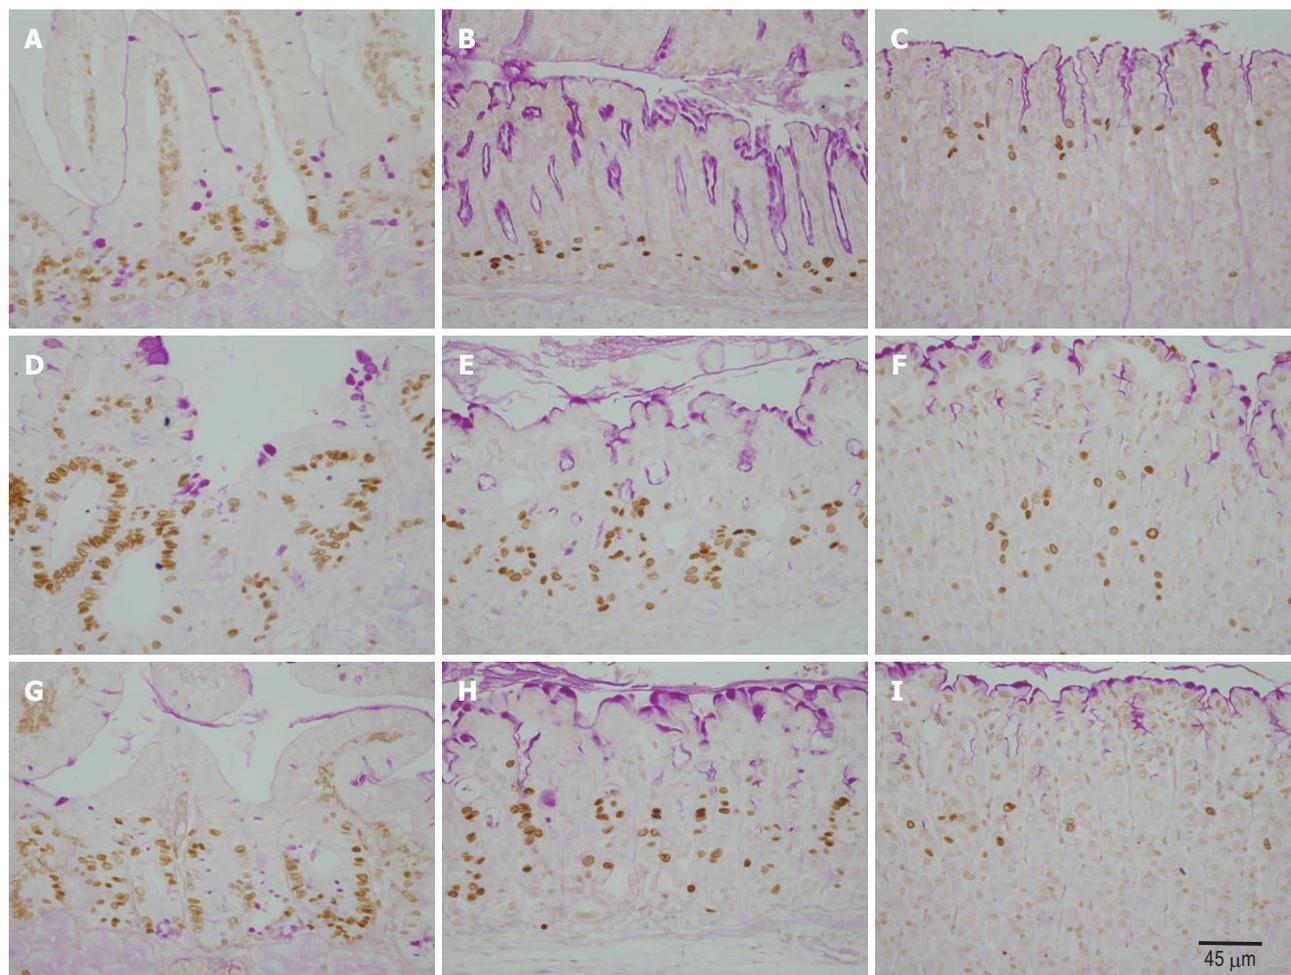

Figure 2 Immunohistochemical analysis of S-phase cells using anti-5'-bromo-2'-deoxyuridine antibody and tissue sections obtained from the duodenum (A, D, G), pyloric antrum (B, E, H) and gastric corpus (C, F, I) of control (A-C), doxorubicin-treated (D-F) and ghrelin/doxorubicin-treated (G-I) mice. Note that BrdU-labeled cells (brown nuclei) of doxorubicin-treated tissues in D, E and F appear more expanded when compared with control tissues in A, B and C. BrdU-labeled cells in G and H are still more expanded than in the control, but less prominent than in D and E.

3.5 ± 0.18 and 5.5 ± 0.18 cells per gland in the corpus and antrum, respectively (Figure 3). In the duodenum, dividing BrdU-labeled cells were in the lower portion of the crypts and averaged 10.7 ± 0.85 (Figure 3).

In doxorubicin-treated mice, the labeling pattern of BrdU-immunoreactive cells was altered in the corpus, antrum and duodenum. There was a general increase in the number of BrdU-labeled cells in the gastroduodenal mucosa. In addition, the distribution of BrdU-labeled cells was expanded and tended to be more scattered rather than localized to the gastric isthmus (Figure 2E, F). Counts revealed an increase in the number of BrdU-labeled cells up to 31.2 ± 4.07 , 12.1 ± 0.59 , 4.3 ± 0.18 in the duodenum, antrum and corpus, respectively. Each of these values was significantly higher than its corresponding value in control mice ($P > 0.01$).

Ghrelin-treated mice which also received doxorubicin showed an usual pattern in the distribution of dividing cells, however, the number of BrdU-labeled cells in the antrum and duodenum remained at a higher level than the control (Figures 2G, H, 3). These findings were confirmed when all mice were examined and BrdU-labeled

cells were quantified. When compared with control, the data showed a significant increase in the number of BrdU-labeled cells in the pyloric antrum and duodenum (9.6 ± 0.38 and 27.6 ± 2.75 , respectively). However, when these values were compared with those obtained from the second group of mice (treated only with doxorubicin), there was a decrease in S-phase labeled cells, but this was only significant in the antrum ($P > 0.02$).

DISCUSSION

Despite the tremendous effort in modern drug discovery and development, dyspepsia and GI mucosal damage remain frequent complications affecting life quality in cancer patients receiving chemotherapy. The available data demonstrate that ghrelin could be a potential protective agent against these complications. In rats treated with cisplatin, it was demonstrated that ghrelin can be used to prevent delayed gastric emptying, early satiety, anorexia, nausea and vomiting, all characteristic of cancer-associated dyspepsia syndrome^[26]. In the present study we induced GI mucosal damage using doxorubicin and

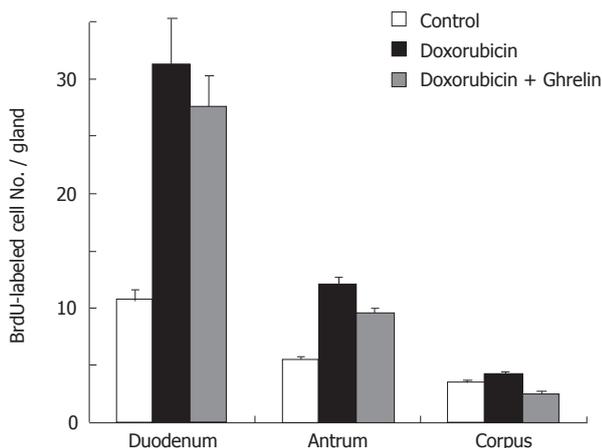

Figure 3 Analysis of 5'-bromo-2'-deoxyuridine-labeled cell counts in the duodenum, antrum and corpus of control, doxorubicin-treated and ghrelin/doxorubicin-treated mice.

demonstrated that ghrelin administration can also prevent the damaging effects of this chemotherapeutic agent.

Ghrelin appears to be a potent GI mucosal protective agent. Its effect on maintaining GI mucosal integrity was achieved using different experimental animal models. A recent series of studies showed that administration of ghrelin to rodents attenuated gastric mucosal lesions induced by ethanol^[20], stress^[21], ischemia-reperfusion^[27,28] and even HCl administration^[29]. The ghrelin effects on ethanol and stress models were mediated by release of nitric oxide as they were prevented by blocking nitric oxide synthase activity^[22]. The effects of ghrelin on the HCl-model was mediated not only by growth hormone secretagogue receptor, but also histamine H3 receptor, suggesting the involvement of histamine release in ghrelin-induced protection^[29].

It has been suggested that ghrelin is involved in several cell biological processes *via* different modes of actions: endocrine, paracrine and autocrine. We speculate that ghrelin exerted its GI mucosal protection *via* a paracrine effect. Examination of the GI mucosae of mice treated with two intravenous injections of doxorubicin revealed degenerative changes in their epithelial cell lining. However, mice which received ghrelin by continuous subcutaneous infusion showed minimal effects and appeared more or less similar to control mice when treated with the same dosage regimen of doxorubicin. The available data from the present study may suggest a mechanism which involves modulation of the cell cycle and induction of cell differentiation to substitute for the damaging effect of doxorubicin.

Several lines of evidence suggest that ghrelin modulates the proliferation of various cell types. It has been demonstrated that ghrelin stimulates proliferation of osteoprogenitor cells in bone tissue^[30] and neuronal progenitor cells in the spinal cord^[31]. Since cell proliferation and epithelial renewal are regarded as one of the protective mechanisms against GI mucosal damage, the question arises whether ghrelin also modulates prolifera-

tion of GI epithelial cells and hence could protect their integrity against noxious agents (such as chemotherapy). To answer this question we injected all mice used in our experiments with BrdU to label dividing cells during the S-phase of the cell cycle using immunohistochemistry. As expected, control mice showed BrdU-labeled cells in the isthmus regions of gastric glands and at the bottom of intestinal crypts. Doxorubicin-treated mice showed many more BrdU-labeled cells in both the gastric glands and intestinal crypts, probably to compensate for the damaged cells. However, in the presence of excess ghrelin, the damaging effects of doxorubicin were minimal and the number of BrdU-labeled cells was reduced, perhaps due to enhancement of cell differentiation. The other possibility is that ghrelin enhances cell differentiation and the increased proliferating cells observed in doxorubicin-treated mice were instructed by ghrelin to differentiate and migrate to restore the normal organization of the epithelium.

The protective effect of ghrelin against tissue damage is not restricted to the GI mucosa. Recent studies suggested that ghrelin promotes neuroprotective effects *via* stimulation of the regenerative potential of hippocampal neuroprogenitor cells to form new neurons. Incidentally, the expression of GHS-R was also demonstrated in the hippocampus^[10,11].

In conclusion, this study demonstrates the protective effect of ghrelin against GI mucosal damage induced by doxorubicin and provides an addition justification for its potential use during chemotherapy in cancer patients to improve their quality of life.

COMMENTS

Background

Normal gastrointestinal (GI) mucosa is characterized by its regenerative potential following damage. However, cancer patients receiving chemotherapy develop severe GI complications due to mucosal damage. Ghrelin has been suggested to play a protective role against these mucosal damaging effects.

Research frontiers

It is important to define the factors involved in GI mucosal protection and regulation of stem cell proliferation and differentiation. Here the authors provide evidence in support of the role of ghrelin in GI mucosal protection.

Innovations and breakthroughs

This study provides evidence that ghrelin protects against GI mucosal damage caused by doxorubicin.

Applications

The findings of this article could help in designing new modalities for GI mucosal protection and regeneration in cancer patients undergoing chemotherapy.

Peer review

This is an interesting and elegant experimental paper examining the effect of ghrelin on the intestinal tract of doxorubicin-treated mice. The investigators showed that ghrelin protects against doxorubicin-induced epithelial damage. In addition, they showed it modulates epithelial proliferation.

ACKNOWLEDGEMENT

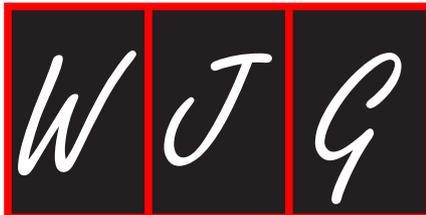

This paper is dedicated to our colleague Dr. H Kataya who initiated this collaborative study and suddenly passed away before its completion. The authors acknowledge the

Research Affairs section of the United Arab Emirates University which funded this interdisciplinary project.

Abstract

AIM: To outline the appropriate diagnostic methods and therapeutic options for acquired bronchobiliary fistula (BBF).

METHODS: Literature searches were performed in Medline, EMBASE, PHMC and LWW (January 1980-August 2010) using the following keywords: biliobronchial fistula, bronchobiliary fistula, broncho-biliary fistula, biliary-bronchial fistula, tracheobiliary fistula, hepatobronchial fistula, bronchopleural fistula, and biliptysis. Further articles were identified through cross-referencing.

RESULTS: Sixty-eight cases were collected and reviewed. BBF secondary to tumors (32.3%, 22/68), including primary tumors (19.1%, 13/68) and hepatic metastases (13.2%, 9/68), shared the largest proportion of all cases. Biliptysis was found in all patients, and other symptoms were respiratory symptoms, such as irritating cough, fever (36/68) and jaundice (20/68). Half of the patients were treated by less-invasive methods such as endoscopic retrograde biliary drainage. Invasive approaches like surgery were used less frequently (41.7%, 28/67). The outcome was good at the end of the follow-

up period in 28 cases (range, 2 wk to 72 mo), and the recovery rate was 87.7% (57/65).

CONCLUSION: The clinical diagnosis of BBF can be established by sputum analysis. Careful assessment of this condition is needed before therapeutic procedure. Invasive approaches should be considered only when non-invasive methods failed.

Management of acquired bronchobiliary fistula: A systematic literature review of 68 cases published in 30 years. *World J Gastroenterol* 2011; 17(33): 3842-3849 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i33/3842.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i33.3842>

INTRODUCTION

Bronchobiliary fistula (BBF) is a rare disorder, first reported by Peacock in 1850^[1]. It consists of abnormal interconnection between the biliary tract and bronchial trees. Unlike congenital bronchobiliary fistula, acquired BBF is usually regarded as a consequence of local infection, such as hydatid or amebic disease of the liver, hepatic abscess, trauma, obstruction of biliary tract and neoplasm^[1-58]. However, management of this condition can be very difficult and is often associated with a high rate of morbidity and mortality. Up to now, there has

been no widely accepted management strategy in this field. We searched the literature to outline the appropriate diagnostic methods and therapeutic options for acquired BBF.

MATERIALS AND METHODS

Data searching strategy

Literature searches were performed in Medline, EMBASE, PHMC and LWW (January 1980–August 2010), using the following keywords: biliobronchial fistula, bronchobiliary fistula, biliary-bronchial fistula, tracheobiliary fistula, hepatobronchial fistula, bronchopleural fistula and biliptysis. Two reviewers searched the literature independently in order to identify articles appropriate for inclusion in this review. Further articles were identified through cross-referencing. As a result, 68 cases were collected and reviewed.

Study criteria

Case reports and case series associated with acquired BBF and full texts of case reports in English were included. Cases did not provide basic information such as age, gender, primary diseases and etiological, clinical manifestation, therapeutic method, outcome and follow-up duration were excluded.

The clinical outcome was defined as cured when clinical symptoms such as biliptysis, fever and jaundice disappeared without use of drainage tube or with closure of the fistula. In addition, an adequate follow-up period (at least 2 mo) was necessary in patients without tumors. Treatment failure was defined as persistence of symptoms, and death due to bronchobiliary fistula or complications from the treatment.

RESULTS

General data

A summary of published case reports in recent 30 years concerning acquired BBF is shown in Table 1^[1–58]. Sixty-eight cases were retrieved. Information regarding the demographics, clinical data and other variables were not reported in a few cases, thus the denominator varies in the following proportion of cases. Forty-two (61%) of the patients were men. The median age of onset was 48.3 years (range, 14–87 years) (Table 1). Fistula involving both lungs has not been reported so far. Only one case reported by Weis^[2] showed that the BBF orifice was opened in the left lung (Figure 1).

Pre-existing conditions

According to the data, BBF secondary to tumors (32.3%, 22/68) including primary tumors (19.1%, 13/68) and hepatic metastases (13.2%, 9/68) shared the largest proportion. Bile duct obstruction (30.8%, 21/68), including biliary stenosis (17.6%, 12/68) and cholangiolithiasis (13.2%, 9/68) took the second position. Although liver tumor or chronic pancreatitis is associated with different degrees of biliary obstruction, it is considered as an independent

etiology. Hepatic hydatidosis had been regarded as the most common primary disease in developing countries for a long time, but only 8 (11.7%, 8/68) cases have been reported in recent 30 years. Other causes were trauma (10.2%, 7/68) and chronic pancreatitis (2.9%, 2/68). One case of hepatic abscess, subphrenic abscess, syphilis gummosa and acute cholecystitis each in a suprahepatic gall bladder as other single primary diseases has been respectively reported. Four cases were complicated with multiple primary diseases in this review (Figure 2).

Symptoms

Biliptysis was presented in all the 68 patients (Figure 3). The volume of scant bile-staining of the sputum and the expectoration of copious volumes of bile ranged from 200 mL to 600 mL and reached a maximum of 1.2 L daily. Respiratory symptoms, such as irritating cough, fever and jaundice, were other clinical features of BBF. More than half of the patients (36/68) presented with fever. The highest body temperature exceeded 39.0 °C. Abdominal pain was present in 14 patients and most in the right upper quadrant, but chest pain occurred in only eight patients. Respiratory disorders occurred in eight cases, including six cases of dyspneic disease. Symptoms like hepatic decompensation, portal hypertension, anorexia, anemia, nausea, vomiting and diabetes were sporadic. Pneumonia as the most common comorbidity was diagnosed in 10 patients, but bacteriologic results were only provided in two cases.

Therapeutic options

Less-invasive procedures had a tendency to be employed in treatment of BBF. Half of the patients underwent therapeutic endoscopy (49.2%, 33/67), including endoscopic retrograde biliary drainage (ERBD) in 24 cases, sphincterotomy in 16 cases, endoscopic nasobiliary drainage (ENBD) in 3 cases and endoscopic stone extraction in three cases. Percutaneous drainage was conducted in 5 cases. Percutaneous transhepatic cholangial drainage (PTCD) was used as a main treatment only in two patients.

Surgical procedures are invasive, and usually used as a final choice. In this review, 28 patients received open operations (41.7%, 28/67), including pulmonary lobectomy, resection and kprosthesis of fistulous tract in diaphragm, heplobectomy, hepaticocenterostomy and abscess drainage alone or in combination.

With the advance of modern medical techniques, histoacryl embolization under bronchoscopic guidance and n-Butyl cyanoacrylate *via* a bronchial approach brought new insights into this field. However, only one case each by the two techniques was reported by Kim JH and Goldman SY, respectively, and both patients died in the following four months because of hepatic failure or cancer^[6,14].

Clinical outcome and follow-up

The outcome at the end of follow-up period (range from 2 wk to 72 mo) was good in most of the 28 cases,

Table 1 Basic data collected from case reports in the literature published over past 30 years

and the recovery rate was 87.7% (57/65). Therapeutic endoscopy was safer than surgery, as 96.8% (30/31) *vs* 76.9% (20/26). Intraoperative complications as the cause of death occurred in one patient and recurrent BBF was found in four cases. Among the recurrent cases, one was cured by open surgery, one by percutaneous drainage and the other two cases by ERBD.

DISCUSSION

Local infection has been considered as a classic cause of BBF since Peacock's report in 1850^[1,59]. According to this review, tumor is the major cause of BBF. It should

be emphasized that the disease spectrum is changing. It may be correlated with the development of radical surgery and its complications. Primary tumors were all liver cancers in BBF patients as noticed in this review. Among the seven cases with information of tumor location, only two cases had the tumor near diaphragm surface and one case had diaphragm invasion. Metastatic tumors derived from gastrointestinal tract were reported in nine cases of BBF. The pathogenesis of BBF is various. It may involve the iatrogenic damage, diaphragm invasion, intrahepatic or extrahepatic biliary obstruction and tumor cachexia. Although biliary obstruction is the most common pathogeny in literature^[57], its nature is not easy to

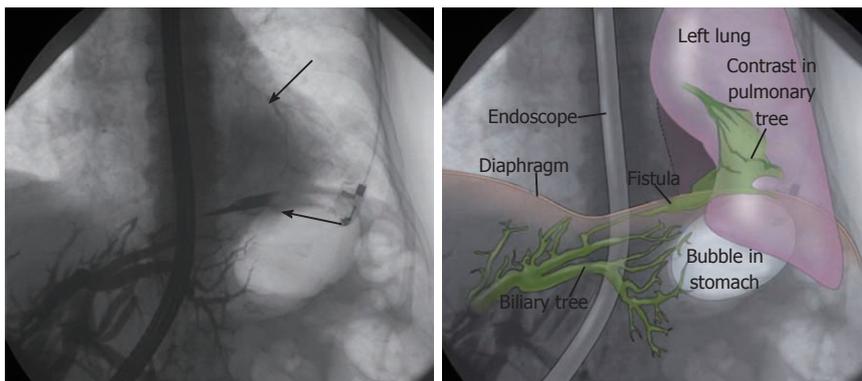

Figure 1 Picture reprint from the article of Weis^[2]. The arrows show the bronchobiliary fistula involving the left lung.

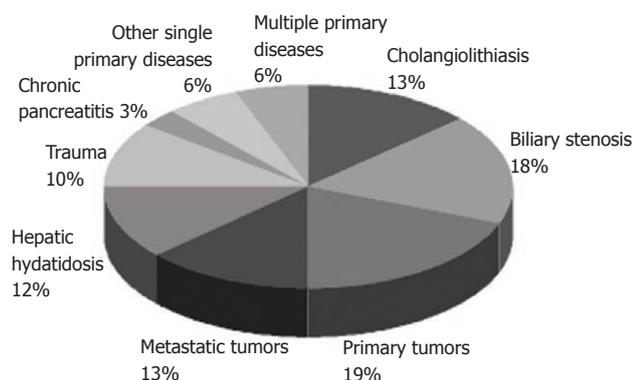

Figure 2 Primary diseases of bronchobiliary fistula. Multiple primary diseases include liver abscess and biliary stenosis, cholangiolithiasis and chronic pancreatitis, metastatic liver tumors and cholangiolithiasis, hepatic abscess and chronic pancreatitis.

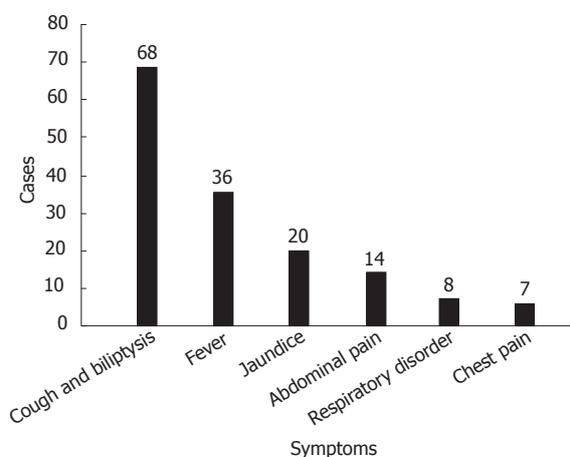

Figure 3 Clinical manifestations of bronchobiliary fistula.

define, and in most cases, it resulted from the presence of severe inflammation close to the primary lesion or in the hilus of the liver. The obstruction of the bile duct is often due to lithiasis, tumor, hydatid cyst, or postoperative stricture.

It should be emphasized that the recent surgery or invasive therapies before bilioptysis appearance was observed in 51 cases (75%). And in seven cases, the operation induced the stenosis of bile duct. It is considered that the stress, especially the iatrogenic damage is correlated with bronchobiliary fistula. We also found a congenital case^[60]. Therefore, we suspect that congenital fragile structure in diaphragma may be the basic pathogenesis in some cases.

Clinical diagnosis is usually made by bilioptysis. In some cases, it is inappropriately diagnosed as acute pneumonitis or chronic irritable cough producing greenish sputum^[59]. Patients having a long history of biliary tract disease can be diagnosed quite easily. However, some patients exhibited minimal signs of this disease. Sutherland *et al*^[61] described false bile ptyalism in patients with sickle cell diseases and hemolytic crisis. In the patients without these conditions, the presence of bile in the sputum is defined as pathognomonic bronchobiliary fistula. Conventionally, endoscopic retrograde cholangio-pancreatography

(ERCP) or percutaneous transhepatic cholangio (PTC) provided direct photographic evidence. This has been the most preferred choice for BBF. But, contrast-enhanced magnetic resonance cholangio (MRC) and hepatobiliary imino-diacetic acid (HIDA) scan not only ensures a definite diagnosis, but also has distinct advantage over other conventional non-invasional techniques^[62,63].

In terms of medical treatment, somatostatin and its analogues were often used for treating BBF, because it reduced its secretion in the gastrointestinal tract. But, up till now, not a single case has been completely cured only with medical treatment^[28]. Many patients complained that posture had an adverse impact on the volume of bilioptysis. But only few doctors considered this factor while treating these patients. Therefore, we suggest that doctors should instruct BBF patients, especially those without biliary obstruction, to refrain from bile postural drainage. In other words, patients should be advised to take orthostatic position and avoid supine position. To alleviate the symptoms and accelerate concrescence of the fistula, bile reflux should be decreased. In addition, electrolyte disturbances and digestive system disturbances occurred when a significant amount of bile is lost. Therefore, supporting therapy should be administered with appropriate prophylactic attention.

Recently, when resolution of a distal biliary obstruction was accomplished, non-surgical interventions *via* ERCP or PTC were successfully conducted. ERBD became much more prevalent. It was considered in more than 60% (24/39) of cases for non-surgical treatment in this review. Based on this review, its single application recovery rate is also much higher than traditional surgery (95.8%:76.9%). Although PTC and ENBD may lead to severe electrolyte disturbances and disturbances of the digestive system triggered by bile loss, it is convenient to recheck the healing of fistula using the radiographic technique with contrast media injection *via* drainage tube. This is practically more advantageous for managing the disease. In the past few years, histoacryl embolization under bronchoscopic guidance or the n-Butyl Cyanoacrylate *via* a bronchial approach were reported as new therapeutic methods^[6,14]. However, these methods should be proved by more clinical cases.

The open surgery should be the first choice when interventional techniques have failed or BBF secondary to tumors, biliary obstruction and trauma occurred. The type of operation depends on the primary tumor type, BBF location and involvement. The following surgical procedures were performed in BBF: drainage of right subphrenic or hepatic abscess, closure of fistula, resection of hydatid cysts or tumor, biliary drainage using T-tube, and bilioenteric anastomoses (e.g., Roux-en-Y hepaticojejunostomy). In case of diaphragmatic, pleural, bronchial, or pulmonary damages, closure of the diaphragm, pleural drainage, decortication or different pulmonary resections have been used. Gugenheim *et al.*^[59] recommended a two-stage approach for treating BBF: (1) external biliary drainage by percutaneous or surgical drainage of subphrenic abscess and/or direct percutaneous drainage of the intrahepatic biliary tract; and (2) treatment of the underlying cause. In the patients with biliary obstruction, the priority management was to treat the biliary disease.

Early diagnosis and treatment can alleviate the patient's sufferings. But there has been no evidence as to whether they can improve the prognosis of these patients. We have not obtained any information about the prevention of this disease.

In conclusion, we reviewed limited information of BBF published in the past 30 years. We could not completely understand its etiology and pathogenesis. The published experience suggests that ERCP or PTC should be a priority. But new diagnostic techniques such as contrast-enhanced MRC and HIDA scan have greater advantages. While considering the medical treatment, quite a few doctors have advocated non-operative therapy as the preferred choice. Individualized and multidisciplinary treatment should be emphasized in patients with primary diseases as the condition of each individual patient is quite different and complex.

COMMENTS

Background

Bronchobiliary fistula (BBF) is an uncommon disorder involving biliary channels

and the bronchial tree. Acquired BBF without proper management can induce death. With the improvement of non-invasive approaches, more satisfying outcome can be expected.

Research frontiers

Increasing non-invasive and less-invasive approaches to the management of acquired BBF can offer promising benefits to the patients with this condition. In this literature review, the authors point out that the definite procedure such as surgery should be considered only when the non-invasive methods failed.

Innovations and breakthroughs

Invasive procedure such as surgical excision of the fistula has been used widely, while less-invasive methods like external and internal stenting which can reduce biliary obstruction are of more value, since they are much safer and easier. The authors of this review searched the literature, provided more diagnostic and therapeutic options in management of acquired BBF.

Applications

BBF is rare and easily misdiagnosed as respiratory disease. Patients with this disease usually had poor outcome. However, there has been no guideline in BBF treatment up to date. This study reviewed the management strategy of BBF and summarized the experience from literatures in the past 30 years. It may contribute to the clinical treatment of BBF.

Terminology

Hepatobiliary imino-diacetic acid scan is a nuclear imaging procedure to evaluate the status of the gallbladder. N-Butyl cyanoacrylate is a tissue adhesive that applied as a monomer to moist tissue and polymerizes to form a bond. It is biodegradable slowly and used in all kinds of surgeries.

Peer review

This paper is a review of the world literature regarding BBF. Authors presented a spectrum of case reports concerning BBF. Idea of the summary about the knowledge of BBF is interesting.

Abstract

AIM: To improve the diagnosis of heterotopic pancreas by the use of contrast-enhanced computed tomography (CT) imaging and CT virtual endoscopy (CTVE).

METHODS: A total of six patients with heterotopic pancreas, as confirmed by clinical pathology and immunohistochemistry in the Sixth Affiliated People's Hospital of Shanghai Jiao Tong University, Shanghai, China, were included. Non-enhanced CT and enhanced CT scanning were performed, and the resulting images were reviewed and analyzed using three-dimensional post-processing software, including CTVE.

RESULTS: Four males and two females were enrolled. Several heterotopic pancreas sites were involved; three occurred in the stomach, including the gastric antrum ($n = 2$) and lesser curvature ($n = 1$), and two were in the duodenal bulb. Only one case of heterotopic pancreas lesion occurred in the mesentery. Four cases had a solid yet soft tissue density that had a homogeneous pat-

tern when viewed by enhanced CT. Additionally, their CT values were similar to that of the pancreas. The ducts of the heterotopic pancreas tissue, one of the characteristic CT features of heterotopic pancreas tissue, were detected in the CT images of two patients. CTVE images showed normal mucosa around the tissue, which is also an important indicator of a heterotopic pancreas. However, none of the CTVE images showed the typical signs of central dimpling or umbilication.

CONCLUSION: CT, enhanced CT and CTVE techniques provide useful information about the location, growth pattern, vascularity, and condition of the gastrointestinal wall around heterotopic pancreatic tissue.

INTRODUCTION

Heterotopic pancreas is a condition in which pancreatic tissue is found outside the boundaries of the normal pan-

Table 1 Clinical and computed tomography scanning data for the six patients with heterotopic pancreas

Case	Gender	Age	Symptom	Location	Growth pattern and modality
1	M	60 yr	Carcinoid syndrome	Duodenal bulb	Exogenous, superficially lobulated, well-defined border, subserosal outer boundary was rough
2	F	59 yr	Epigastric pain (3 wk)	Gastric antrum	Circumscribed tissue, ill-defined border
3	M	68 yr	Epigastric pain (1 yr)	Gastric antrum	Circumscribed tissue, superficially lobulated, ill-defined border
4	F	3 mo	Identified during choledochal cystectomy	Mesentery	No obvious abnormality detected by computed tomography
5	M	60 yr	Abdominal distension (2 mo)	Lesser curvature aspect of gastric antrum	Superficially lobulated, well-defined border
6	M	38 yr	Cachexia	Duodenal bulb	Exogenous, well-defined border

creas; such tissue is regarded as aberrant pancreas or an accessory pancreatic lesion. This tissue has no anatomical, vascular or neuronal connection with the main pancreas. Such anomalies can become apparent at any age, but they are most commonly found in the fourth, fifth and sixth decades of life, with a slight male predominance. Heterotopic pancreas frequently occurs in association with the gastrointestinal tract (stomach, duodenum, jejunum, ileum) but is also found associated with Meckel's diverticulum, mesentery, omentum, spleen, and gallbladder^[1]. In mice, the formation of a heterotopic pancreas may be caused by inactivation of the gene *IPF-1* (also known as *IDX-1*, *STF-1* or *PDX*), which leads to errors in embryological development that can result in the total absence of the pancreas^[1]. Symptoms are dependent on the location of the ectopic tissue, although the most common symptoms are epigastric pain, pyloric obstruction, cholecystitis, and intussusception^[1,2]. Some cases are identified as a result of such symptoms, but others are identified incidentally, such as during an unrelated surgery or during autopsy^[1,3,4].

Cases of heterotopic pancreas have been reported in recent years following descriptions of the general characteristics of the condition observed by endoscopic ultrasonography (EUS). However, recent improvements in multi-slice computed tomography (CT) technology and the wide use of enhanced CT scanning have provided a new approach for identifying heterotopic pancreas. In this study, we present six cases of heterotopic pancreas and highlight the associated CT features^[5].

MATERIALS AND METHODS

Patients

We retrospectively analyzed our database of all patients (about 350 000 patients) who underwent CT scanning at the Shanghai 6th People's Hospital Affiliated with Shanghai Jiao Tong University from January 2000 to December 2010. Six cases (four males, two females) were selected who were definitively diagnosed with heterotopic pancreatic tissue postoperatively by pathological examination and immunohistochemistry. With the exception of one patient aged 3 mo and another aged 38 years, the subjects were all aged between 59 and 68 years (Table 1). Three

patients complained of epigastric pain or abdominal distension, and two others presented with cachexia or carcinoid syndrome. The other case was identified incidentally (Table 1). This study was reviewed and approved by the Shanghai 6th People's Hospital Affiliated with Shanghai Jiao Tong University.

CT scanning procedure

Multi-slice CT scanning was performed in all of the six cases using the LightSpeed VCT (GE) or Sensation CT (SIEMENS). No abnormality was detected in one of the female patients who therefore did not undergo contrast-enhanced CT scanning. The other five cases underwent enhanced CT scanning after standard CT scanning. With the exception of the 3-mo-old infant, the patients were asked to hold their breath during the scan in order to reduce artifacts. The thickness of the scanning slices was either 5 mm or 7 mm. The CT data of some patients was further refined using reconstruction software, which enabled thinner slice data to be obtained. The reconstruction software was all supplied by multi-slice CT; this was one function of the multi-slice CT. After the reconstruction the thinnest slice was 0.625 mm.

Each patient received the contrast agent iopromide (dose, 50-70 mL) through the median cubital vein. The arterial phase scan was produced approximately 30 s after the start of the injection. Coronal and sagittal images were obtained, and scanning data were analyzed on the GE workstation ADW 4.3. Lesion sizes were measured, and CT values were calculated (Table 1). Images were analyzed by application of three-dimensional post-processing software, including CT virtual endoscopy (CTVE).

RESULTS

Clinical findings

The six patients comprised four males (aged 38, 60, 60 and 69 years) and two females (aged 3 mo and 59 years). All five adult patients had experienced symptoms over a period of time ranging from weeks to years. Three of the patients presented with symptoms that were directly indicative of gastrointestinal disease, which made the lesions

Table 2 Detailed data from non-enhanced and enhanced computed tomography images of five of the six patients with heterotopic pancreas

Case	Lesion dimensions (cm ³)	CT scanning		Enhanced CT scanning		Properties	Enhancement pattern
		Lesion	Pancreas	Lesion ¹	Pancreas ¹		
1	1.8 × 1.2 × 2.1	38.2	44.3	93.2	97.4	Solid	Homogeneous, highly enhanced
2	1.2 × 1.0 × 2.1	28.2	44.7	80	106.9	Solid	Homogeneous, slightly enhanced

6	1.9 × 1.3 × 1.0	43.3	47.1	29.1	106.6	Solid	Homogeneous, highly enhanced

Hu is the unit value for computed tomography (CT). ¹The CT values of both the lesion and the pancreas were measured during the arterial phase.

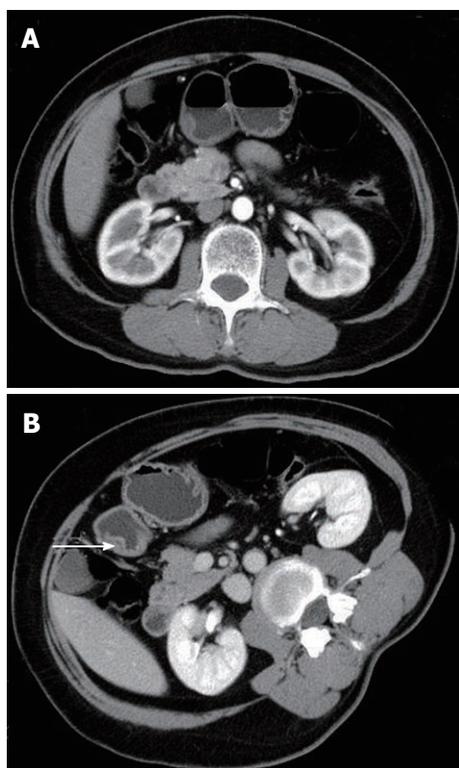

Figure 1 Heterotopic pancreas in the gastric antrum of a 59-year-old woman. A: Arterial phase image showing gastric antrum wall thickening. There is a circumscribed border of the lesion below the mucosal layer. The density at the center of the lesion is slightly lower than at the periphery. B: Each patient was asked to lie on their right side during venous phase scanning. The central area of the low-density region (white arrow) is obvious.

simpler to identify. However, two of the patients had non-specific symptoms, including carcinoid syndrome or cachexia associated with other systemic diseases. As these symptoms did not directly indicate a heterotopic pancreas, the lesions were more difficult to identify. They were discovered after physical examination and other tests. The 3-mo-old girl was jaundiced, and although CT scanning revealed the presence of a choledochal cyst, the heterotopic pancreatic tissue that indeed was later found to be

present in the mesentery was not detected (Table 1).

CT techniques

The CT values of the heterotopic pancreatic tissues were calculated, and these ranged from -47.8 to 43.3 Hu (Table 2). The density measured in four cases was indicative of soft tissue, and this density correlated with the fatty tissue in only one case. The lesions were frequently superficially lobulated, with circumscribed borders, and they protruded into the gastrointestinal cavity or peritoneal cavity. After carrying out contrast-enhanced CT, the CT value of each lesion was based on the arterial phase scanning data. The three soft tissue lesions were homogeneously enhanced to varying extents. The other two lesions were heterogeneously enhanced (Table 2).

The scanning data were analyzed in depth using the GE workstation. The lesions could be seen from any angle in addition to the traditional axial, coronal, and sagittal views. Post-processing software was used to reveal further detail. In two cases, there was a strip of low density, which could be seen in both the axial and sagittal images; this may have represented the duct of the heterotopic pancreas (Figures 1 and 2).

CTVE imaging of each entire lesion revealed structural features of the mass, such as a spherical shape and superficial lobulation, amongst others. This also aided in identifying the layer of the gastrointestinal wall in which the lesion was located, and it showed that the mucosa around the lesion was normal (Figure 3).

DISCUSSION

The incidence of heterotopic pancreas is low, with only 40% of patients experiencing symptoms and 60% of cases being found incidentally during surgery for other disorders^[6-9]. Although CT scanning is a highly sensitive technique, it can still be difficult to detect this abnormality. In this study, a heterotopic pancreas was detected in five of six patients by means of CT scanning. Moreover, contrast-enhanced CT scanning should always be per-

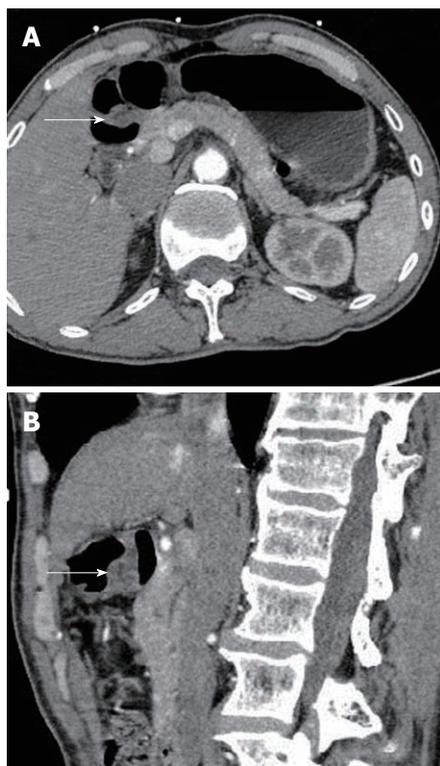

Figure 2 Heterotopic pancreas in the gastric antrum of a 68-year-old woman; the lesion is protruding into the stomach cavity. This heterotopic pancreas is of lower density than the pancreas, is heterogeneous, and slightly enhanced. In both the axial (A) and sagittal images (B), there is a low-density strip (white arrow) in the center of the lesion, which may represent the duct of the heterotopic pancreas. From the sagittal image (B), it can be seen that although the heterotopic pancreas tissue lies in the gastric antrum wall, the wall is still well defined. This suggests that the lesion does not violate the surrounding tissues and organs.

formed, when possible. Heterotopic pancreatic tissue was not observed in only one patient - the infant. For that patient, we postoperatively analyzed the CT images, but the lesion was still undetectable. As the intestines had expanded due to gas and liquid accumulation, as is commonly seen in infants, some of the intestines congregated at the mesenteric root.

In this study, 83.3% (five of six lesions) of the heterotopic pancreas lesions we observed occurred in the stomach, duodenum, and jejunum. In the stomach, 80%-90% of the lesions occurred in the antrum, within 5 to 6 cm of the pylorus^[1,10,11]. Two of the three lesions that occurred in the stomach were located in the antrum (Figure 1). Heterotopic pancreas rarely occurs outside the gastrointestinal wall in tissues such as the liver, lung, omentum, mesentery, umbilicus, mediastinum, and fallopian tube^[1,11-14].

Histologically, heterotopic pancreas is composed of ductal components, acinar cells, and islet cells. Because of differences in the proportions of the three components, however, the density of heterotopic pancreas tissue can vary^[15]. In our study, lesions in four cases were composed of solid soft tissue, which was the commonest type. With the borders being defined to a variable extent, the density was similar to that of the main pancreas in 75% (3/4)

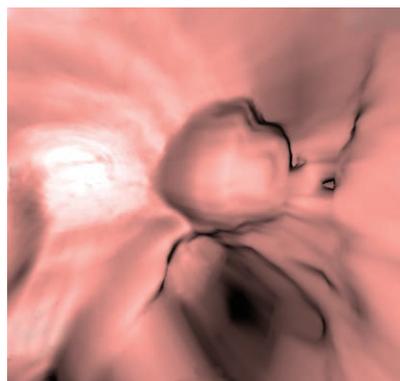

Figure 3 Heterotopic pancreas at the lesser curvature aspect of a 60-year-old man, the lesion is located below the mucosal layer. Computed tomography virtual endoscopy image showing that the lesion is round and superficially lobulated with a depression on one side.

of the cases of this type. Both the non-enhanced and contrast-enhanced CT images were analyzed, and the CT value of each lesion was measured (Table 2). These tissues were also homogeneously enhanced and were similar to the pancreas^[16]. Only one case had a heterogeneous enhancement density that was typical of fatty tissue, and this was initially misdiagnosed as a lipoma. Therefore, lesions of the gastrointestinal tract having a density equivalent to fat should be additionally screened for a potential diagnosis of heterotopic pancreas.

Besides the density types discussed above, there is also a less common mixed-density cyst/solid type that was not observed in our study. This has also been considered as a complication of heterotopic pancreas^[7,17]. Kim *et al.*^[14] reported that heterotopic pancreas with predominantly pancreatic acini shows a homogeneous enhancement pattern, whereas lesions with a mixed composition of acini and ducts show a heterogeneous enhancement. In our study, two cases showed a low-density strip of tissue with a well-defined border in the middle of the heterotopic pancreas lesion. In one case, the low-density strip was peripherally enhanced and so may have been the duct of the heterotopic pancreas^[13].

Further thin-slice image data were obtained using the multi-slice CT, showing more details of each lesion, such as the interior density, enhancement pattern, location, and the duct. The thin-slice images also yielded high-quality two-dimensional and three-dimensional representations. With selection of the optimal viewing angle for the two-dimensional image, the low-density strip was shown to a greater extent; the presence of this strip is thus one of the characteristics of a heterotopic pancreas. Using EUS, Ryu *et al.*^[18] also identified the anechoic duct structure in some cases of heterotopic pancreas. Other work has shown that EUS may be more useful than CT in visualizing the pancreatic ducts^[19]. In our study, however, the very small, narrow ducts were detectable only upon analysis of thin-slice two-dimensional contrast-enhanced images, and they were not detectable by EUS in the same patients. Therefore, we found that CT images were more sensitive

for detecting the heterotopic pancreas duct.

CTVE is a three-dimensional display technology used in the post-processing of CT scanning data to reconstruct three-dimensional cavity surface images of hollow organs, and it provides images that are similar in detail to those obtained by endoscopy (Figure 3). The mucosa around all lesions we observed was normal. The gastrointestinal mucosa seemed to be undamaged and enhanced^[14]. This was an important sign in the diagnosis of heterotopic pancreas.

The features of the heterotopic pancreas have been confirmed by endoscopy^[20]. The lesions we observed were superficially lobulated, but none of the cases in our study exhibited typical heterotopic pancreas features, such as central dimpling or umbilication^[21]. Notably, Ryu *et al.*^[18] also did not observe such umbilication. Hazzan *et al.*^[10] suggested that, although central umbilication of the lesion is one of the characteristic features of a heterotopic pancreas, it is difficult to diagnose because umbilication is often absent in tumors of less than 1.5 cm in diameter. This may explain why umbilication was not observed in our study, i.e., because the lesions were small.

In conclusion, CT scanning, contrast-enhanced CT scanning and CTVE provide useful information about heterotopic pancreas tissue and reveal some of its characteristic features. This combined-technique approach represents a novel way of recognizing and diagnosing the disease. Although these techniques have some limitations, they have been shown to be beneficial for preoperative diagnosis of heterotopic pancreas and therefore may influence the choice of surgical procedure. Resection of heterotopic pancreas tissue is advisable in order to avoid later complications and a second operation^[22,23,25].

COMMENTS

Background

Heterotopic pancreas has a low incidence, and most affected individuals are asymptomatic. Previous reports describe the identification of heterotopic pancreas through endoscopic ultrasonography, but few studies have focused on the potential benefits of computed tomography (CT) and contrast-enhanced images. With the improvement in multi-slice CT technology and the widely used post-processing software, this approach provides a new way to detect the features of heterotopic pancreas.

Research frontiers

In recent years, an increasing number of studies have focused on the application of contrast-enhanced CT scanning, post-processing software, and Computed tomography virtual endoscopy (CTVE) technology for the diagnosis of heterotopic pancreas.

Innovations and breakthroughs

CT scanning revealed the location and enhanced features of the lesion. CTVE showed the location, size, and shape of lesions as well as the organs with which they were associated; it also could visualize lumen stenosis and the surrounding mucosa. CTVE is also a reliable way to show the duct of heterotopic pancreas tissue. The advantages of this approach are that it is non-invasive and can reveal the extent of disease.

Applications

The findings of this study will be advantageous for the preoperative diagnosis of heterotopic pancreas. The approach also demonstrates a new use of CTVE.

Peer review

It is an interesting proposition, even though founded on retrospective analysis.

Abstract

Clostridium septicum (*C. septicum*) gas gangrene is well documented in the literature, typically in the setting of trauma or immunosuppression. In this paper, we report a unique case of spontaneous clostridial myonecrosis in a patient with Crohn's disease and sulfasalazine-induced neutropenia. The patient presented with left thigh pain, vomiting and diarrhea. Blood tests demonstrated a profound neutropenia, and magnetic resonance imaging of the thigh confirmed extensive myonecrosis. The patient underwent emergency hip disarticulation, followed by hemicolectomy. *C. septicum* was cultured from the blood. Following completion of antibiotic therapy, the patient developed myonecrosis of the right pectoral muscle necessitating further debridement, and remains on lifelong prophylactic antibiotic therapy.

INTRODUCTION

Clostridium septicum (*C. septicum*) gas gangrene is not uncommonly described in the literature, invariably in the immunosuppressed patient. Though historically described as a complication of war wounds, in the present time it is usually associated with postoperative infections^[1]. Crohn's disease is an inflammatory bowel disease with variable luminal and extra-luminal manifestations. Because of the autoimmune nature of the disease, treatment is immunomodulatory in nature and common side effects include marrow suppression. We describe the development of *C. septicum* gas gangrene in a patient with Crohn's disease, who was neutropenic as a result of treatment with sulfasalazine.

CASE REPORT

A 26-year-old man presented to the emergency department with the complaint of a few hours of feeling unwell with vomiting, diarrhea and pain in the left anterolateral thigh. His background history included longstanding diarrhea secondary to Crohn's colitis diagnosed by colonoscopy 2 mo previously. The colitis was predominantly cecal, and the patient had been commenced on sulfasalazine treatment. Sulfasalazine had however been stopped 2 wk prior to presentation due to lack of efficacy, and prednisone was substituted.

On initial examination the patient looked unwell and was tachycardic (150 bpm), though afebrile and normotensive. Respiratory and abdominal examinations were unremarkable, and the left anterolateral thigh was tender

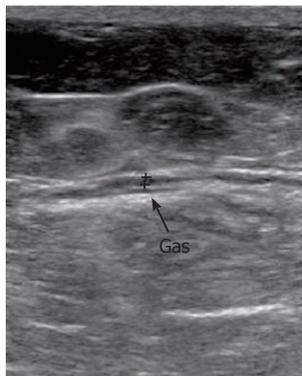

Figure 1 Ultrasound scan of left anterior thigh demonstrating gas. Princess Alexandra Radiology Department, 2007.

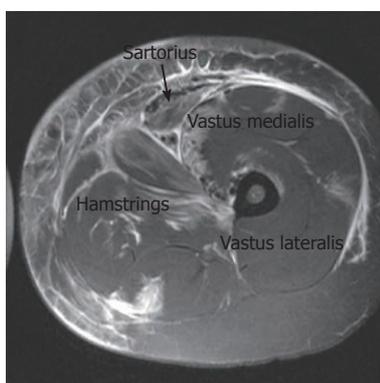

Figure 2 T2 fat suppressed magnetic resonance imaging of the left thigh, demonstrating changes of necrotizing myositis and gas formation. Princess Alexandra Hospital Radiology Department, 2007.

to palpation but otherwise normal in appearance. An initial ultrasound scan of the thigh also excluded any abnormality. Within 2 h the patient developed a fever to 38.5 °C and marked erythema of the left thigh with pustular formation. Initial laboratory investigations demonstrated a profound neutropenia (neutrophil count $0.2 \times 10^9/L$, white blood cell count $1.6 \times 10^9/L$) and myoglobinuria. An urgent repeat ultrasound scan of the anteromedial aspect of the left thigh demonstrated several small collections corresponding to pustule sites on the skin and visualized free gas near the obturator foramen (Figure 1). Magnetic resonance imaging confirmed extensive necrotic myositis and extensive gas formation in the left vastus medialis down to the extensor tendon and neurovascular bundle and in the rectus femoris (Figure 2). A presumptive diagnosis of infective myonecrosis was made. The patient underwent emergency left hip disarticulation and exploratory laparotomy. Two days later an abdominal computed tomography (CT) scan was performed for investigation of induration of the abdominal wall, and demonstrated cecal edema with free gas in the cecal wall. Right hemicolectomy was then performed for colitis and gangrene. *C. septicum* was cultured from blood samples taken at initial presentation. Antibiotic treatment of intravenous lincomycin, meropenem and penicillin was given.

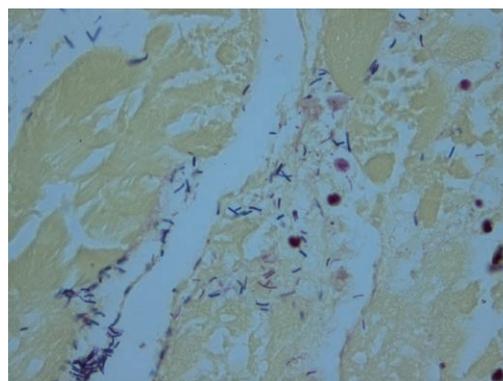

Figure 3 Necrotic chest wall muscle, with *Clostridium septicum* species. Pathology Queensland, Queensland Health-Princess Alexandra Hospital, 2007.

Routine hip stump washouts were performed and excluded progression of the necrotizing myositis. His recovery was complicated by a right pleural effusion requiring drainage. The patient was discharged from hospital on oral amoxicillin after a 3-wk stay. Two weeks after completion of the amoxicillin treatment the patient again presented with pain and erythema over the right pectoral muscle. A CT scan demonstrated an enlarged right pectoralis major muscle with inflammation of the overlying subcutaneous fat. The patient was taken to theatre where the necrotic pectoralis major muscle was debrided. *C. septicum* was cultured from the intraoperative specimen (Figure 3). Antibiotic treatment during the perioperative period was intravenous benzylpenicillin, and the patient was also treated with hyperbaric oxygen therapy postoperatively. He had an uneventful recovery, and now remains on lifelong oral ampicillin prophylaxis.

DISCUSSION

C. septicum is a large, spore-forming, gram-positive anaerobic bacillus^[2-4] found in the gastrointestinal tract of approximately 2% of the healthy population^[5]. *C. septicum* is typically found in the cecum and ileocecal area, where factors including poor vascular supply, local redox potential, pH and the osmotic and electrolyte environment provide an environment conducive to proliferation^[5-7]. The rapid proliferation and systemic toxicity that *C. septicum* causes is thought to be attributed to the production of four exotoxins^[4]. The alpha toxin causes intravascular hemolysis, necrosis of host tissue, and increases capillary permeability, thus producing tachycardia and hypotension^[2]. A hallmark of clostridial myonecrosis is a paucity of inflammatory cells in the affected tissue^[2,5,8]. The necrotic process spreads rapidly to adjacent healthy tissue, causing massive necrotizing gangrene within hours^[2].

C. septicum gas gangrene can be traumatic or non-traumatic. Traumatic gas gangrene historically complicated war wounds, and is now usually associated with postoperative infections^[1]. Non-traumatic clostridial infections nearly always occur in the immunosuppressed patient,

commonly in the setting of hematological or gastrointestinal cancer^[5,7]. Diagnosis in a patient with spontaneous myonecrosis is often difficult as systemic symptoms are vague, and early localized findings can be mistaken for cellulitis. However, in a novel presentation, the triad of pain, tachycardia out of proportion to fever and crepitus is highly suggestive of clostridial myonecrosis^[2,5].

We propose that in our patient, the ulcerated cecum allowed entry of *C. septicum* into the abdominal cavity, and this in concert with neutropenia secondary to sulfasalazine provided an environment predisposing to rapid proliferation of the bacilli.

Sulfasalazine is a medication commonly used in the treatment of inflammatory bowel disease, and a not uncommon complication is neutropenia. Mortality is high in *Clostridium* sepsis in the neutropenic milieu, and death usually occurs within 24 to 48 h^[4,8]. For this reason, early diagnosis followed by immediate, aggressive surgical debridement is critical to survival^[2,9]. It is therefore advisable that blood counts be monitored in patients who are commenced on this treatment, and that neutropenic patients receive emergency management should symptoms of sepsis arise.

Acknowledgments to reviewers of World Journal of Gastroenterology

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Antonio Basoli, Professor, General Surgery "Paride Stefanini", Università di Roma-Sapienza, Viale del Policlinico 155, Roma 00161, Italy

Chris Briggs, MB ChB, MRCS(Ed), Department of Hepatobiliary and Pancreatic Surgery, K Floor, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF, United Kingdom

Jeff Butterworth, MB, FRCP, Dr, Department of Gastroenterology, Shrewsbury and Telford Hospital NHS Trust, Mytton Oak Road, Shrewsbury, Shropshire SY3 8XQ, United Kingdom

Herwig R Cerwenka, Professor, Department of Surgery, Medical University of Graz, Auenbruggerplatz 29, A-8036 Graz, Austria

Events Calendar 2011

- January 14-15, 2011
 AGA Clinical Congress of Gastroenterology and Hepatology: Best Practices in 2011 Miami, FL 33101, United States
- January 20-22, 2011
 Gastrointestinal Cancers Symposium 2011, San Francisco, CA 94143, United States
- January 27-28, 2011
 Falk Workshop, Liver and Immunology, Medical University, Franz-Josef-Strauss-Allee 11, 93053 Regensburg, Germany
- January 28-29, 2011
 9. Gastro Forum München, Munich, Germany
- February 4-5, 2011
 13th Duesseldorf International Endoscopy Symposium, Duesseldorf, Germany
- February 13-27, 2011
 Gastroenterology: New Zealand CME Cruise Conference, Sydney, NSW, Australia
- February 17-20, 2011
 APASL 2011-The 21st Conference of the Asian Pacific Association for the Study of the Liver Bangkok, Thailand
- February 22, 2011-March 04, 2011
 Canadian Digestive Diseases Week 2011, Vancouver, BC, Canada
- February 24-26, 2011
 Inflammatory Bowel Diseases 2011-6th Congress of the European Crohn's and Colitis Organisation, Dublin, Ireland
- February 24-26, 2011
 2nd International Congress on Abdominal Obesity, Buenos Aires, Brazil
- February 24-26, 2011
 International Colorectal Disease Symposium 2011, Hong Kong, China
- February 26-March 1, 2011
 Canadian Digestive Diseases Week, Westin Bayshore, Vancouver, British Columbia, Canada
- February 28-March 1, 2011
 Childhood & Adolescent Obesity:
- A whole-system strategic approach, Abu Dhabi, United Arab Emirates
- March 3-5, 2011
 42nd Annual Topics in Internal Medicine, Gainesville, FL 32614, United States
- March 7-11, 2011
 Infectious Diseases: Adult Issues in the Outpatient and Inpatient Settings, Sarasota, FL 34234, United States
- March 14-17, 2011
 British Society of Gastroenterology Annual Meeting 2011, Birmingham, England, United Kingdom
- March 17-19, 2011
 41. Kongress der Deutschen Gesellschaft für Endoskopie und Bildgebende Verfahren e.V., Munich, Germany

- December 1-4, 2011
 2011 Advances in Inflammatory Bowel Diseases/Crohn's & Colitis Foundation's Clinical & Research Conference, Hollywood, FL 34234, United States

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copy-right" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Disturbance of the inflammatory response in the gut is important in several clinical diseases ranging from inflammatory bowel disease to postoperative ileus. Several feedback mechanisms exist that control the inflammatory cascade and avoid collateral damage. In the gastrointestinal tract, it is of particular importance to control the immune response to maintain the balance that allows dietary uptake and utilization of nutrients on one hand, while preventing invasion of bacteria and toxins on the other hand. The process of digestion and absorption of nutrients requires a relative hyporesponsiveness of the immune cells in the gut to luminal contents which is not yet fully understood. Recently, the autonomic nervous system has been identified as an important pathway to control local and systemic inflammation and gut barrier integrity. Activation of the pathway is possible *via* electrical or *via* pharmacological interventions, but is also achieved in a physiological manner by ingestion of dietary lipids. Administration of dietary lipids has been shown to be very effective in reducing the inflammatory cascade and maintaining intestinal barrier integrity in several experimental studies. This beneficial effect of nutrition on the in-

flammatory response and intestinal barrier integrity opens new therapeutic opportunities for treatment of certain gastrointestinal disorders. Furthermore, this neural feedback mechanism provides more insight in the relative hyporesponsiveness of the immune cells in the gut. Here, we will discuss the regulatory function of the autonomic nervous system on the inflammatory response and gut barrier function and the potential benefit in a clinical setting.

INTRODUCTION

Disturbance of the inflammatory response in the gut is important in several clinical diseases ranging from inflammatory bowel disease (IBD) to postoperative ileus (POI)^[1,2]. Although a fierce response to pathogens, ischemia, trauma and other forms of injury is necessary, the inflammatory cascade needs to be tightly controlled to avoid local tissue damage or systemic effects such as shock, organ failure or even death^[3,4]. Especially in the gastrointestinal tract a delicate equilibrium is required; on one hand there needs to be a state of relative hyporesponsiveness to commensal bacteria, dietary antigens and biological toxins that are ingested along with nutrients, and on the other hand potential pathogens must be recognized and neutralized when necessary^[5].

An unrestrained inflammatory response is not desired since it may cause local damage to healthy tissue, cause acute and chronic inflammatory diseases and even evolve into critical systemic inflammatory syndromes such as sepsis.

Controlling the inflammatory response has been a therapeutic target for many gastrointestinal diseases for a long time. For IBD, control of the intestinal inflammatory response *via* an anti-inflammatory therapy using tumour necrosis factor- α (TNF- α) antibodies has been proven to be very successful in the clinical situation^[6,7]. For other syndromes such as POI, only experimental evidence is available that shows a positive effect of an anti-inflammatory therapy^[8].

In the last decade, a new anti-inflammatory pathway has been discovered involving the autonomic nervous system. Several experimental studies have shown that stimulation of the autonomic nervous system can dampen the inflammatory response and prevent loss of gut barrier integrity^[9-11]. In this way, activation of the autonomic nervous system can potentially ameliorate inflammation-based diseases and prevent complications. Both IBD and POI have been shown to be reduced effectively in experimental models using activation of the autonomic nervous system^[8,12]. A more physiological and less invasive way of activating this anti-inflammatory vagal pathway is by administration of nutrition^[13-15]. Nutrition and specifically dietary lipids activate the autonomic nervous system *via* afferent vagal nerve fibres and release of neuro-endocrine hormones^[16,17]. In this way nutrition may be used as therapy to prevent excessive inflammation and the accompanying local tissue damage. Although the beneficial effect of nutrition on inflammation has been recognized by many for a long time in several clinical settings, this vagal feedback mechanism gives more insight in the mode of action of nutrition and individual food components and helps to develop new nutritional therapies.

THE INFLAMMATORY RESPONSE

Release of proinflammatory cytokines by macrophages and neutrophils is essential in the initial and rapid innate immune response. Additionally, exposure to bacterial ligands elicit a complex orchestrated network of responses in which complement, chemokines, adhesion molecules, heat shock proteins and other late mediators play a role^[18]. One of the key mediators released early after exposure to bacterial structures is TNF- α ^[19]. This pleiotropic cytokine causes activation of macrophages and stimulates neutrophils. Inhibition of this cytokine has been shown to be therapeutic in IBD and rheumatoid arthritis, although it may also be detrimental in patients carrying certain pathogens while also in sepsis^[20]. Other rapidly released pro-inflammatory mediators include interleukin-6, interleukin-1 β and interleukin-8. The inflammatory response is often triggered by bacteria or bacterial products that have distinctive characteristics called pathogen-associated molecular patterns that

are recognized by immune cells *via* Toll-like receptors (TLRs)^[21]. There are several ligands for TLRs including endotoxin, the major constituent of Gram-negative bacteria (TLR4), bacterial DNA (TLR9) and peptidoglycans (TLR2). Activation of TLRs triggers several intracellular signalling pathways leading to translocation of the transcription factor nuclear factor- κ B (NF- κ B) to the nucleus and ultimately resulting in the release of inflammatory mediators^[22]. To prevent an exaggerated inflammatory response and to manage the collateral damage caused by release of proinflammatory mediators, several control systems are activated at all levels. This so-called “anti-inflammatory response”, consists of numerous anti-inflammatory mediators, including cytokines, neuromediators, hormones and stress molecules released to restore homeostasis. Interleukin-10 (IL-10) and transforming growth factor- β are important anti-inflammatory cytokines. For example, IL-10 has been shown to play a pivotal role in the intestinal recovery following surgery^[23]. Another important pathway in the anti-inflammatory response is triggered by the catabolism of heme by the enzyme heme-oxygenase 1. This results in induction of biliverdin which has been shown to protect against polymicrobial sepsis in cecal ligation and puncture^[24]. Furthermore, carbon monoxide is formed which has been shown to ameliorate development of postoperative ileus *via* reduction of the inflammatory response and induction of IL-10^[25].

To prevent an exaggerated inflammatory response several control systems are activated at all levels. This so-called “anti-inflammatory response”, consists of numerous anti-inflammatory mediators, including cytokines, neuromediators, hormones and stress molecules. IL-10 and transforming growth factor- β are the main identified anti-inflammatory cytokines.

The complex of these counter-regulatory mechanisms to severe infection of injury is also called the “compensatory anti-inflammatory response syndrome” (CARS). CARS was at first considered to be a global deactivation of the immune system following systemic inflammatory response syndrome. However, new insights suggest that it is rather a reprogramming of leucocytes leading to a compartmentalized control to prevent excessive inflammation upon infection and injury^[26].

INTESTINAL BARRIER INTEGRITY

The intestinal lumen is an important reservoir of bacteria that is strictly separated from the sterile environment of the host *via* a physical/anatomical and immunological barrier. Changes or defects in certain components of the intestinal barrier may lead to activation of the inflammatory system potentially leading to known gastrointestinal diseases such as inflammatory bowel disease^[27].

The physical/anatomical barrier of the gut is formed by a monolayer of epithelial cells, originating from multipotent stem cells present in the crypt. These cells differentiate into several subclasses, amongst which are absorptive enterocytes, that make up > 80% of all

small intestinal epithelial cells, Paneth cells and goblet cells^[28,29]. The intestinal cells are bound together with several protein complexes including occluding, claudin and zonula occludens proteins, also called tight-junctions^[30]. Breakdown of this barrier potentially leads to the translocation of luminal antigens, bacteria and their toxic products into the circulation^[31,32]. In the case of transmural damage to all intestinal layers (mucosa, submucosa, muscularis and serosa) luminal content may pass into the abdominal cavity leading to detrimental effects as sepsis.

The immunological barrier is formed by enterocytes that are considered to actively participate as innate immune sensors of microbial pathogens and commensal organisms. Host recognition of microbial components is achieved by pattern recognition receptors, like the cytoplasmic NOD-like receptors and membrane-bound TLRs. Crypt Paneth cells secrete defensins (e.g., antimicrobial peptides) into the villous crypt, thereby maintaining its sterility and regulating microbial homeostasis^[33]. It has also been shown that Paneth cells are equipped with the proper molecules to recognize and signal endotoxin, the major component of Gram-negative bacteria^[34]. Goblet cells secrete mucus (composed of glycoproteins and water) providing a filter overlying the intestinal epithelium and secrete trefoil peptides; small proteins needed for epithelial growth and repair. Gut-associated lymphoid tissue is present in the lamina propria and provides immune surveillance. Finally, sampling of luminal antigens occurs by M-cells and dendritic cells, which present antigens to T and B cells, thereby inducing the acquired immune system. This response includes secretion of large amounts of IgA by plasma cells. This secretory IgA covers the mucosal surface and has a major role in excluding antigen from passing the epithelium^[35].

Interestingly, the process of digestion and metabolism of nutrients requires a physiological breach of the intestinal barrier, without noticeable activation of the immune response. This relative hyporesponsiveness to luminal contents during the process of food uptake is not fully understood. The autonomic nervous system may be important in regulation of this process.

THE CENTRAL NERVOUS SYSTEM AND INNATE IMMUNITY

Excessive release of inflammatory mediators following activation of inflammatory cells by bacterial products is (amongst other pathways) controlled by the central nervous system. Supposedly, inflammatory mediators such as TNF- α and interleukins activate afferent vagal pathways leading to a variety of responses. The hypothalamic-pituitary-adrenal signalling pathway is activated causing an instantaneous release of serum corticosteroids that leads to inhibition of (excessive) inflammation. In addition to this afferent or sensory function during inflammation, the efferent vagal system is also involved in regulation of the inflammatory response^[36]. Previous studies have

shown that stimulation of efferent vagal fibres increases release of acetylcholine, the principal neurotransmitter of the vagus nerve. Acetylcholine subsequently binds to specific $\alpha 7$ nicotinic receptors ($\alpha 7$ nAChR) leading to activation of an intracellular pathway^[37]. It has been shown that the transcription factor STAT3 is phosphorylated by tyrosine kinase Jak2, leading to the anti-inflammatory effect *via* NF- κ B^[12]. Ultimately this results in a decreased release of both early inflammatory mediators such as TNF- α but also late mediators such as HMGB-1^[9,38,39]. Stimulation of this neural feedback loop is efficient in reducing the inflammatory response in several experimental models. Direct electrical stimulation or pharmacological stimulation of nicotinic receptors *via* agents such as CNI-1493 significantly reduces the systemic inflammatory response to endotoxic shock^[40]. Furthermore, activation of this neural anti-inflammatory pathway, the so-called cholinergic anti-inflammatory pathway reduces the inflammatory response and its sequelae during septic peritonitis and following hemorrhagic shock^[11]. Interestingly, recent evidence indicates that vagus nerve signalling has a dual effect in macrophages. Besides inhibiting cytokine secretion, the cholinergic nervous system also enhances endocytosis and phagocytosis of bacteria by macrophages^[41]. This effect on phagocytosis is caused by stimulation of the nAChR $\alpha 4/\beta 2$ rather than $\alpha 7$ nAChR. The spleen has also been implicated in the anti-inflammatory cholinergic pathway; however the underlying mode of action at this stage is elusive. The vagus nerve conveys signals from the brain to the immune cells residing in the spleen *via* the celiac-superior mesenteric plexus ganglia and the splenic nerve^[42]. The requirement of the nicotinic acetylcholine receptor $\alpha 7$ in this process is not yet clear.

NUTRITIONAL STIMULATION OF THE AUTONOMIC NERVOUS SYSTEM

Besides electrical or pharmacological stimulation, the autonomic nervous system can also be stimulated in a physiological way *via* nutrition, more specifically *via* dietary lipids and proteins/peptides. Ingestion of dietary lipids, proteins and peptides triggers release of cholecystokinin (CCK)^[43]. CCK binds to CCK-1 and CCK-2 receptors, leading to a rapid activation of the autonomic nervous system *via* the afferent vagal pathway^[44]. Subsequently the efferent vagal pathway is activated resulting in release of acetylcholine. Binding of acetylcholine to $\alpha 7$ nicotinic receptors on inflammatory cells then leads to a decreased release of inflammatory cytokines. Such a nutritional intervention with dietary fat has been proven to be very efficient in reducing the systemic inflammatory response, ameliorate tissue damage and preserve intestinal barrier function^[13-15]. Interestingly, the protective effects of dietary lipids were shown to be efficient when given before an inflammatory trigger. Even when the nutritional intervention is started after the inciting event it still is effective^[45]. This is especially of interest in

acute clinical settings such as trauma in which changes in intestinal barrier integrity are clinically important and may be related to associated complications^[46].

The fact that such a negative feedback mechanism exists seems logical and functional during feeding. During digestion and absorption of vital nutrients, a fierce immune response to temporally present bacterial toxins, antigens and destructive endogenous lysozymes accompanying nutrition needs to be avoided. Next to the dampening effect of lipid enriched nutrition on the inflammatory response, intestinal barrier integrity is also preserved in various experimental models. This beneficial effect on gut barrier integrity may be explained twofold. First of all, release of acetylcholine can prevent intestinal damage *via* a decreased release of inflammatory cytokines. Both TNF- α and IFN- γ have long since been known to modulate the epithelial barrier in the intestine^[47,48]. Interestingly, lipid rich nutrition preserves intestinal barrier function early on, suggesting that local inflammation may be of importance^[49]. Another route may be through enteric glia cells since ablation of these enteric glia cells has been shown to directly affect gut barrier function and may result in inflammation^[50]. The effects of lipid rich nutrition on these cells however needs to be further investigated.

NEW THERAPEUTIC STRATEGIES

Stimulation of the autonomic nervous system may be useful as a therapeutic target in acute inflammatory based conditions. There have been many experimental studies showing a beneficial effect of electrical or pharmacological stimulation of the autonomic nervous system. However, general activation of nicotinic receptors may also have a wide scope of unwanted effects on other cells or cell systems besides inflammatory cells, which have yet to be determined.

Enteral administration of dietary fat provides a physiologic way to stimulate the cholinergic anti-inflammatory pathway and administration of nutrition is considered to be safe. Early enteral nutrition is successfully implemented in fast-track programs such as the Enhanced Recovery After Surgery program in which both hospital stay and the complication rate following colorectal surgery are reduced^[51].

Surgical patients are an interesting intervention group since the timing of surgery (and therefore the trigger for the immune response) is predetermined. Dampening the postoperative local and inflammatory response is expected to have important effects on related complications such as POI, but potentially also on other parameters.

Future clinical trials with dietary lipids as a means to stimulate the anti-inflammatory cholinergic pathway will provide more clarity to these questions.

CONCLUSION

The autonomic nervous system is an endogenous path-

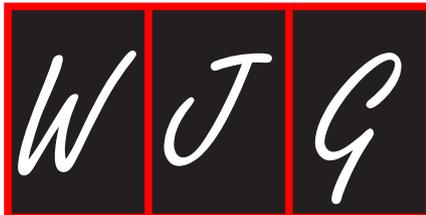

way that dampens the inflammatory response and regulates intestinal barrier function. Further delineation of this pathway may help to understand the relative hyporesponsiveness in the intestine to luminal contents. Furthermore, nutritional stimulation of this anti-inflammatory neurogenic feedback may be used as an important therapeutic target in several inflammatory based diseases.

Abstract

Cholangioscopy remains another modality in the investigation of biliary strictures. At cholangioscopy, the "tumour vessel" sign is considered a specific sign for malignancy. Through its ability to not only visualise mucosa, but to take targeted biopsies, it has a greater accuracy, sensitivity and specificity for malignant strictures than endoscopic retrograde cholangiopancreatography guided cytopathological acquisition. Cholangioscopy however, is time consuming and costly, requires greater technical expertise, and should be reserved for the investigation of undifferentiated strictures after standard investigations have failed.

INTRODUCTION

Multiple modalities are now available for the investigation of obstructive jaundice: endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance cholangiopancreatography, endoscopic ultrasound (EUS), computed tomography (CT) and transabdominal ultrasound (TUS). TUS is accurate in identifying biliary obstruction, but is less accurate in identifying the aetiology^[1-3]. Whilst there have been refinements in techniques in the other aforementioned imaging modalities, making a conclusive diagnosis in the setting of a biliary stricture or intraductal tumour may be difficult^[4,5]. Biliary strictures may be caused by benign and malignant tumours, as well as inflammatory processes. Management strategies with optimal outcomes are clearly dependent on knowing the correct diagnosis. Whilst features suggestive of malignancy are assessed for on cholangiography and EUS, these criteria are known to be non specific^[6] and histopathology remains the gold standard for diagnosis.

Conventional tissue sampling during ERCP is routinely performed in the investigation of biliary strictures; however it remains sub-optimal in making a diagnosis. Brush cytology remains the mainstay of obtaining a cytological sample from a biliary stricture at ERCP. It is simple to perform and reported to have few complications^[7]. Brush cytology performed at the time of ERCP has a sensitivity of 30% to 57%^[8-10] and is thought to be limited by the poor cellular yield.

Cholangioscopy involves direct visualisation of the biliary tree *via* a fibre optic or video scope. It may be performed percutaneously or "peroral", where a scope is passed down the therapeutic channel of a duodenoscope, and has become an additional modality in the investiga-

tion and management of biliary disease. Initially, the percutaneous approach was favoured because these cholangioscopes were larger than the operating channel of a conventional therapeutic duodenoscope. Subsequently, cumbersome mother daughter systems were developed to visualise the biliary tree *via* the ampulla. Peroral cholangioscopy (POCS) was first described in the in 1976 by Kawai *et al*^[11]. Initially the domain of specific tertiary hospitals, the clinical use of cholangioscopy is expanding. Our focus is to review the utility of cholangioscopy in biliary strictures: in particular details of cholangioscopes available, the evidence available in relation to the diagnostic realms of cholangioscopy, cholangioscopy assisted biopsy and the utility of chromocholangioscopy (CC) and POCS with narrow band imaging (NBI).

INSTRUMENTS

Peroral cholangioscopes

Peroral cholangioscopes are passed down the 4.2 mm working channel of a therapeutic duodenoscope to visualise the biliary tree. There are currently devices available from Olympus, Pentax, and Boston Scientific.

Olympus and Pentax provide reusable fibre optic and video cholangioscopes. There are four different sized diameter per-oral cholangioscopes available - 2.6, 2.8, 3.1 and 3.4 mm. The 2.6 and 2.8 mm diameter cholangioscopes have a 0.75 mm working channel that allows the passage of a 0.025 inch guide wire. The 2.8, 3.1 and 3.4 mm diameter cholangioscopes with a 1.2 mm working channel permit use of 1.9-3 French electrohydraulic lithotripsy fibers, 0.035 inch guide wire and biopsy forceps. These cholangioscopes come in 187, 190 and 200 cm lengths and have bi-directional (up-down) movement.

These scopes consist of a dial for two way tip deflection, air/water buttons and suction channels. The core of the cholangioscope is predominantly fibre optic cables through which the image is transmitted from the tip of the endoscope to the eyepiece, with a light guide for illumination, angulation wires for tip deflection, an air/water nozzle and a working channel.

There are newer 3.4 and 5.3 mm cholangioscopes available using charge couple device (CCD) technology and a NBI system incorporated into a video cholangioscope (Olympus Inc., CHF-B260 and CHF-BP260). They are currently still undergoing FDA approval and have not yet been used in North America^[12,13].

The Spyglass Direct Visualization System (Microvasive Endoscopy, Boston Scientific Co., Natick, Mass, United States) is composed of a reusable optical probe that traverses a disposable access and delivery catheter (Figure 1). The 3.4 mm diameter disposable catheter consists of the optical probe port, an irrigation port and 1.2 mm accessory channel. The 0.77 mm, 6000 pixel, reusable optic probe, is a collection of light fibers and optical fiber bundles. This system offers 4-way deflected steering, and a specific miniature biopsy forceps (Spybite[®]) which is commercially

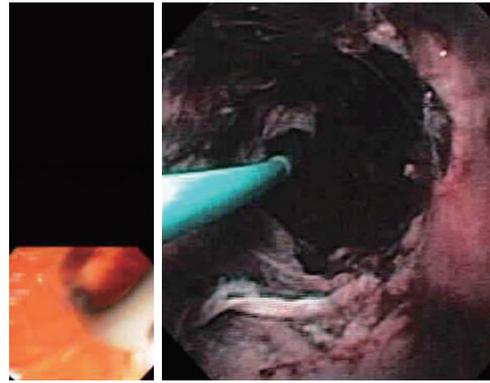

Figure 1 Video cholangioscopy of benign common hepatic stricture secondary to primary sclerosing cholangitis.

available with this system.

Percutaneous/intraoperative cholangioscopes

Percutaneous/intraoperative cholangioscopes used are usually shorter (35, 38, 45 and 70 cm) working length, wider diameter (4.8, 4.9 and 6.0 mm) and have a larger accessory channel (2.0, 2.2 and 2.6 mm). This wider channel facilitates instrumentation with more therapeutic devices - intraductal lithotripsy fibers, baskets, and forceps.

Paediatric endoscopes

Paediatric endoscopes have also been used to directly visualise the biliary tree intubated under fluoroscopic and endoscopic guidance, and the use of a biliary placed guidewire or balloon catheter^[14,15]. These techniques overcome the disadvantages of using the “mother daughter” system which is relatively expensive in capital expenditure, time consuming, cumbersome, usually requires two endoscopists, is fragile and has a smaller working channel. This method has been reported with a variable success (45.5%-100%) of biliary intubation, but is currently not routinely performed^[14,15].

A double balloon enteroscope overtube (TS 13140, total length 1450 mm, Fujinon Corp., Omiya, Japan) has been used in combination with an Olympus paediatric gastroscope (GIF-N230 or N260; Olympus Optical Co, Ltd, Tokyo, Japan) to perform cholangioscopy. The gastroscope was used to intubate the duodenum, the overtube advanced over the gastroscope and post-insufflation used as an anchor whilst the gastroscope intubated the biliary tree under endoscopic and fluoroscopic guidance. In this single case series of 12 patients, the device had a success of 83.3%^[16]. Lithotripsy and biopsies were able to be performed through the working channel of the paediatric gastroscope.

Wilson Cook Inc. (Winston Salem, NC, United States) has released a cholangioscopy access balloon. These are 315 cm long 4 Fr catheters with either a 15 or 20 mm balloon that is inserted into the biliary tree through the duodenoscope. The balloon is then insufflated, securing its position, and the duodenoscope is exchanged for a paediatric

atric gastroscope with tension on the catheter to prevent looping. After intubation of the biliary tree, the balloon may be deflated if biopsies are to be taken or therapeutic intervention needs to be performed. At this current time, there are no clinical trials evaluating the use of this device and it awaits FDA approval for clinical use.

Peroral vs percutaneous cholangioscopy

Percutaneous cholangioscopy (PTC) was often the favoured method of cholangioscopy. Wider, shorter and more maneuverable scopes enabled biopsies for diagnosis and therapeutic devices to be advanced through the working channel in a less cumbersome manner. The procedure itself requires only one endoscopist. The drawbacks of PTC are that it is performed through an operatively placed T-tube tract or a percutaneous transhepatic biliary drain (PTBD). To use the T-tube, 3 to 5 wk must be waited for the maturation of the tract, with inherent time delays. To perform PTCs *via* the PTBD, 2 to 4 wk must be allowed for a tract to mature after an internal/external 7 to 8 French pigtail catheter is initially deployed, with sequential dilatation commencing after several days to eventually deploy a 16 French diameter catheter across the tract. The final step before introduction of the cholangioscope is a pre-procedure dilation. A percutaneous plastic peel-away sheath (Wilson Cook Inc, Winston Salem, NC, United States) or metal sheath (Olympus Co., Tokyo, Japan) may be used for direct access if these time delays are not feasible. Drawbacks of this approach are the necessity for long hospitalization, cumbersome management of a drainage catheter and possible complications of bleeding/hemobilia, seeding metastasis along the sinus tract of percutaneous transhepatic drainage and risk of intraperitoneal metastasis^[17].

POCS is usually performed with two experienced endoscopists and has a long procedure time. Alternatively a specially designed external cholangioscope fixation device or nurse/assistant may be used. ERCP is usually performed to delineate the biliary tree and pathology, and the cholangioscope is placed down the working channel of the duodenoscope and may be inserted freehand through the previously sphincteromised ampulla or it may be inserted over a long 450 cm guidewire that has been backloaded into the channel of the daughter scope. The cholangioscope is fragile and judicious use of the elevator is advised, with the latter method trying to overcome the need for vigorous use of the elevator. Maneuverability is technically more challenging due to the length of the POCS, and two way tip deflection and limitations also arise from traversal of the duodenoscope. Passage of the biopsy forceps can also be difficult due to the length and angles of the cholangioscope required to arrive at the target lesion.

Cholangioscopic findings in biliary strictures

Numerous studies have evaluated the use of cholangioscopy in undifferentiated strictures^[18-22]. In a case series of 111 patients with biliary tumours/strictures, they aimed

to correlate cholangioscopic findings with histopathology from cholangioscopic guided biopsies or surgically resected specimens^[23]. They classified the cholangioscopic findings of cholangiocarcinoma into three categories: nodular, papillary and infiltrative types^[23]. Nodular type cholangiocarcinoma is described to have nodular mucosa causing luminal narrowing, with the mucosa being irregular with intense neovascularization. This type of cholangiocarcinoma is short in length. Papillary type cholangiocarcinoma is described to have papillary mucosal projections, superficially spreading and neovascularization is usually not a feature. These papillary projections usually caused obstruction and were intermingled with pus and sludge. The authors describe a mucin secreting cholangiocarcinoma, that on cholangioscopy appear similar to papillary type cholangiocarcinoma with papillary or villous mucosal projections. The mucin secretion is thought to cause marked proximal ductal dilatation. Infiltrative type cholangiocarcinoma was not usually associated with a mass lesion. This malignancy has a smooth tapered narrowing, with the mucosa being white with subtle elevations on the margin of tumour vessels. Neovascularization was not described to be as predominant as with the nodular type cholangiocarcinoma. There have been no studies to prospectively evaluate if the cholangiographic type of cholangiocarcinoma prognosticates the clinical outcome.

Benign strictures were described in this case series to have a smooth surface mucosa and tapered luminal narrowing with no definite neovascularization^[23]. Biliary papillomatosis consists of papillary projections into the lumen with intervening normal areas of mucosa, and is thought to predispose to papillary adenocarcinoma. The authors conclude that it is difficult to cholangiographically differentiate papillary adenoma from papillary adenocarcinoma; however they suggest that the degree of luminal obstruction may correlate to the risk of overt malignancy.

ASSESSMENT OF NEOVASCULARIZATION OR THE "TUMOUR VESSEL" SIGN

The "tumour vessel" is an abnormally proliferating and tortuous vascular structure on the mucosa adjacent to the stricture. Synonymous terms include "capillary sign", neovascularization and vascular dilatation. A prospective study of patients with biliary strictures without a luminal mass in or around the stricture diagnosed at ERCP or percutaneous transhepatic cholangiography, evaluated the sensitivity and specificity of the "tumour vessel" sign for malignancy as seen at PTC^[24]. In total, 63 patients were enrolled in the study. Malignancy was confirmed when malignant cells were seen in PTC directed biopsies and in the surgically resected specimen. A stricture was deemed benign if the resected specimen had no evidence of malignant cells or, after the 1 year follow up, there was no clinical or radiological evidence of disease progression.

They found the sensitivity of this sign for malignancy to be 61% (25/41) and specificity was 100%. PTC directed biopsies had a sensitivity of 80% (33/41) and specificity of 100%. Concordance between two endoscopists for the “tumour vessel” sign was 100%. Six of eight strictures with a positive “tumour vessel” sign had false negative biopsies. The majority of these malignant strictures were infiltrative type cholangiocarcinomas, which is thought to spread beneath the epithelium, and the abundant fibrosis may lead to higher rates of falsely negative biopsies. For this particular reason, the authors suggested cholangioscopy be considered in patients with non diagnostic cytological specimens gathered at ERC in particular to assess for this specific sign.

THE CLINICAL UTILITY OF CHOLANGIOSCOPY

In a case series of 97 patients with biliary filling defects and strictures, Fukuda *et al*^[20] evaluated the additional benefit of POC to ERCP and biopsies or brushings. Patients were excluded if there was an ampullary or pancreatic (based on CT or TUS) mass or in subjects with negative cytology who were not clinically followed up for a minimum of 12 mo. Criteria used to assess strictures for malignancy included: (1) the presence of tumour vessels; (2) easy oozing; and (3) irregular surface.

Patients were deemed to have malignancy if they had positive surgical specimens, evidence of malignant cytology by other means, or clinical progression at follow up. Of 76 strictures, 38 were malignant and 28 benign. ERCP and tissue sampling correctly identified 22 of the 38 malignant strictures giving sensitivity, specificity, accuracy, and a positive and negative predictive value of 57.9%, 100%, 78.1%, 100% and 68.6%, respectively. In comparison, the addition of POCS to ERCP and tissue sampling correctly identified all 38 malignant strictures and 33 of the 38 benign strictures. This improved the sensitivity to 100%; however the specificity was 87.2%. The five false positive strictures identified on POCS had abnormal tortuous dilated vessels present, which was previously thought to be specific for malignancy. The authors conclude that POCS without POCS directed biopsy is a useful adjunct to ERCP in the management of biliary strictures^[20].

Shah *et al*^[19] assessed the clinical utility of POCS and cholangioscopic assisted/directed biopsies in the investigation of indeterminate biliary strictures. Sixty-two patients were referred with a combination of non diagnostic cytology taken at ERCP and/or non specific imaging by CT, magnetic resonance imaging or positron emission tomography scanning. Eighteen patients had a final diagnosis of malignancy and 16 were diagnosed with cholangioscopy. One of the malignancies missed was proximal to a benign appearing biliary stricture secondary to primary sclerosing cholangitis and diagnosed intraoperatively in the caudate lobe. The other malignancy was a hilar cholangiocarcinoma diagnosed in the explanted liver, 7 mo after cholangioscopy with negative cholangioscopic

assisted and directed biopsies. Based on cholangioscopy, two patients were incorrectly diagnosed with malignancy. Both had negative cholangioscopic assisted and directed biopsies and normal intraoperative biopsies. In the 16 patients correctly diagnosed with malignancy at cholangioscopy, biopsies were positive in 10 patients (63%). Overall the sensitivity for detecting malignancy by cholangioscopy with and without biopsy based on this cohort was 89%, specificity 96%, positive predictive value 89% and negative predictive value 96%. These studies suggest that cholangioscopy without biopsy has a relatively high sensitivity and specificity for malignant strictures as compared with ERCP and cytopathological acquisition. Whilst there are no head to head studies comparing ERCP and cholangioscopy, it is not unreasonable to consider cholangioscopy in the setting of a non diagnostic ERCP.

IMAGE ENHANCED VIDEO CHOLANGIOPANCREATOSCOPY

New techniques currently being evaluated in the investigation of biliary strictures include CC and NBI.

Chromocholangioscopy

Chromoendoscopy is commonly used in assessment, particularly of the borders of gastrointestinal malignancies. Methylene blue chromocholangioscopy has been evaluated in two studies in patients with biliary strictures^[25,26]. Hoffman *et al*^[26] performed per oral chromoendoscopy by injecting 15 mL of 0.1% methylene blue down the working channel of the cholangioscope. Excess dye was then removed with suction after 2 min. In 55 patients who underwent chromoendoscopic cholangioscopy for biliary strictures or filling defects, dye spray added on average 18 min to the procedure (range 10–45 min). Chromocholangioscopic images were correlated with cholangioscopic directed biopsies. In this pilot study, different staining patterns of methylene blue were seen in normal, inflammatory (diffuse uptake) and dysplastic mucosa (irregular uptake). In particular, the authors suggested the uptake of stain in inflammatory tissue helped to distinguish fibrotic from inflammatory strictures, especially in patients with primary sclerosing cholangitis. The authors report that most lesions were identifiable with white light cholangioscopy^[26]. Whilst this study demonstrated clear difference in patterns, this has not been repeated, nor is chromocholangioscopy practice widespread.

Narrow band imaging

The NBI system developed by Olympus medical system is based on modifying/narrowing the bandwidth of spectral transmittance resulting in optical colour separation. The filter is placed in the optical illumination system and removes all light wavelengths except for two narrow wavelengths. The central wavelengths of each band are 415 nm and 540 nm. This is available on two video cholangioscopes (CHF-B260 and CHF-BP260). The shorter band is thought to give information about

the capillary and pit patterns of the superficial mucosa, whilst the 540 nm wavelength gives more information about thicker capillaries in slightly deeper tissues. To date, published literature in relation to narrow band imaging cholangioscopy is limited to case reports and small case series^[12,27-30]. The largest case series is of 21 lesions in 12 patients who underwent POCS with narrow band imaging^[12]. Their aim was to comparatively assess the clinical feasibility of using POCS with NBI, and the ability of POCS with NBI to identify biliary lesions in comparison to conventional white light POCS. In particular they assessed the ability to determine distal and if possible, proximal margins, and surface vasculature. In this small case series, only two POCS with conventional white light cholangioscopies were rated as “excellent” in comparison with 12 lesions with NBI. NBI identified four strictures not seen with standard POCS. The authors suggest observation of surface structure and mucosal vessels was as good as or better than, conventional observation and that video cholangioscopy with NBI may be helpful in differentiating benign from malignant strictures and bile duct tumours showing superficial spread^[12]. A limitation of NBI cholangioscopy is that bile and blood both appear as dark red fluid, possibly limiting views. These preliminary findings need to be further evaluated with randomized controlled studies.

CONCLUSION

Cholangioscopy remains another modality in the investigation of biliary strictures. Through its ability to visualise mucosa and take targeted biopsies, it has a greater accuracy, sensitivity and specificity for malignant strictures than ERCP guided cytopathological acquisition^[19,20]. Cholangioscopy however, is time consuming and costly, requires greater technical expertise, and should be reserved for the investigation of undifferentiated strictures after standard investigations have failed. There is still a paucity of literature with regards to image enhanced cholangioscopy and its role, which remain promising, in imaging technologies that require further investigation.

Abstract

Adult stem cells represent the self-renewing progenitors of numerous body tissues, and they are currently classified according to their origin and differentiation ability. In recent years, the research on stem cells has expanded enormously and holds therapeutic promises for many patients suffering from currently disabling diseases. This paper focuses on the possible use of stem cells in the two main clinical settings in gastroenterology, i.e., hepatic and intestinal diseases, which have a strong impact on public health worldwide. Despite encouraging results obtained in both regenerative medicine and immune-mediated conditions, further

studies are needed to fully understand the biology of stem cells and carefully assess their putative oncogenic properties. Moreover, the research on stem cells arouses fervent ethical, social and political debate. The Italian Society of Gastroenterology sponsored a workshop on stem cells held in Verona during the XVI Congress of the Federation of Italian Societies of Digestive Diseases (March 6-9, 2010). Here, we report on the issues discussed, including liver and intestinal diseases that may benefit from stem cell therapy, the biology of hepatic and intestinal tissue repair, and stem cell usage in clinical trials.

INTRODUCTION

In recent years stem cells (SCs) have become increasingly important in all fields of modern medicine. Different types of SCs are eligible for cell therapy, such as mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs) and adult liver stem/progenitor cells (LPCs). Although the clinical usefulness of the related lines of research remains to be ascertained in human trials, there is fascinating potential for growth in the use of SCs as a

therapeutic option. It is now well known that adult SCs are the self-renewing progenitors of numerous body tissues, classified according to their origin and ability to differentiate, and functionally responsible for the development and regeneration of tissues and organs, including the gastrointestinal tract and liver^[1]. Embryonic stem cells would probably be the best cells to use in clinical research, but their use raises many ethical controversies, therefore the researchers' attention has shifted instead to adult stem cells as a potential therapeutic tool.

SCs have recently gained great importance in gastroenterology and hepatology regarding both the pathogenesis and the treatment of liver diseases and inflammatory or immune-mediated bowel diseases, two clinical fields with a great impact for people worldwide.

But the other side of the presence of SCs in the gastrointestinal tract and liver needs to be carefully considered since the self-renewing properties characteristic of SCs may sometimes give them a key role in the processes of carcinogenesis^[2].

Discussion on the therapeutic applications of SCs in gastroenterology (and other fields) was first prompted by a previously-published paper^[3]. The Italian Society of Gastroenterology (SIGE) consequently sponsored a workshop on SCs in Verona during the Congress of the Federation of Italian Societies of Digestive Diseases (FISMAD) (March 6-9, 2010). The present paper reports on the issues analyzed, ranging from which liver and intestinal diseases may benefit from stem cell therapy to the biology of liver and intestinal tissue repair, and stem cell usage in clinical trials.

AUTOLOGOUS STEM CELLS IN THE TISSUES REPAIR PROCESS

Regeneration

The liver and gastrointestinal epitheliums are known to have great regenerative potential in response to injuries and normal cell turnover^[4,5].

The intestine consists of rapidly-proliferating tissue, in which cell turnover occurs every 2-7 d under normal circumstances, and even more rapidly following tissue damage^[3]. This rapid regenerative potential is possible thanks to a consistent proliferation of progenitor cells that occurs in crypts. Indeed, unlike most other mammalian tissues, the stem cells of the intestine are strictly compartmentalized in crypts. Two hypotheses exist regarding the exact identity and localization of SCs. The principal hypothesis, developed in the late 1950s and experimentally supported by Potten in the 1977^[6], is the so-called “+4 position model”. According to this theory, SCs are found directly above the Paneth cells, in position 4 starting from the bottom of the crypt. From there, the SCs move up and differentiate into Goblet cells, enterocytes and enteroendocrine cells, or they move down to become Paneth cells^[7]. The second, and more recent, hypothesis is the “SCs zone model”, which is based on the identification of the crypt base columnar (CBC) cells

hidden between the Paneth cells^[8]. In 2007, Berker and colleagues demonstrated that CBC cells express a peculiar marker, the *Lgr5*, a Wnt target gene that encodes an orphan G protein-coupled receptor characterized by a large leucine-rich extracellular domain and seven transmembrane domains^[9]. Using lineage tracing experiments, they demonstrated that the *Lgr5*⁺ cells are multipotent, giving rise to all the different intestinal epithelial cells types, and are very long-lived. Similar observations were made also in the colon, suggesting that the CBC *Lgr5*⁺ cells are authentic intestinal SCs^[10]. Consequently, *Lgr5* can be identified as a definitive marker of crypt SCs^[11,12].

Other than the resident intestinal SCs, recent studies have suggested that mesenchymal cells derived from bone marrow (BM) have a crucial role in intestinal repair and fibrosis^[13-15]. Studies conducted on both experimental animals and humans given sex-mismatched BM-derived SCs (BM-SCs) transplants showed that a population of myofibroblasts (MFs) derived from the male donor populated the mucosa in the female host intestine, and the sub-epithelial compartment in particular^[16]. Given the importance of these MFs in orchestrating epithelial cell turnover and function, it may be that they have a positive therapeutic effect on gastrointestinal functions. Further studies demonstrated that donor-derived cells were able to repopulate the host's intestinal epithelium with cells expressing all four lineage markers (goblet cells, Paneth cells, enteroendocrine and enterocytes^[4]). The donor BM-SCs were also able to differentiate into all the cell types needed for neo-angiogenesis (i.e. pericytes, endothelial cells and vascular smooth muscle cells), thus contributing to tissue repair. However, the mechanisms by which SCs take effect in gut injury are still under debate. Some researchers believe that BM-SCs differentiate into intestinal SCs or progenitor epithelial cells, while others have demonstrated that a fusion with resident cells takes place. Protection against injury can be achieved even in the absence of SC differentiation, giving the impression that SCs aid native tissues via cell-cell interaction or by releasing protective substances as they transit through injured tissues^[4].

In the liver, regeneration mainly involves mature hepatocytes, highly differentiated cells with a long lifespan that can re-enter the cell cycle and restore the liver mass in response to parenchymal loss^[5]. If the hepatocytes' replication is impaired, or experimentally inhibited, then regeneration can be accomplished by the activation, expansion, and differentiation of LPCs putatively located within the canals of Hering (CoH). LPCs are responsible for the so-called “ductular reaction” in humans, which corresponds to the oval cell (OC) response seen in specific rodent models of liver injury^[17]. Numerous studies have shown that both OCs and LPCs are highly clonogenic and bipotent cells (capable of differentiating into hepatocytes and cholangiocytes), and that they co-express biliary and hepatocytic markers, as well as HSC-associated antigens, such as CD34 and c-kit^[18]. LPCs are

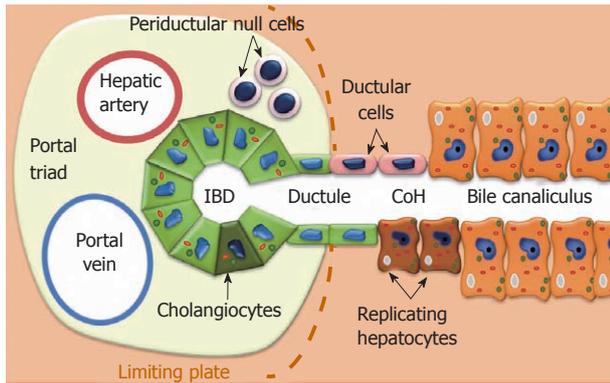

Figure 1 Hepatic cell populations with stemness potential and their location within the liver. IBD: Inflammatory bowel diseases; CoH: Canal of Hering.

a heterogeneous population with a variable stemness potential and notable phenotypic discrepancies, depending on the experimental conditions^[19]. Using a functional assay, Kuwahara *et al.*^[20] found 4 possible hepatic cell populations with a stemness potential: (1) replicating hepatocytes at the parenchymal/stromal interface; (2) ductular cells of the CoH; (3) cholangiocytes of the intralobular bile ducts; and (4) periductular null cells (devoid of hepatocytic and biliary markers). The asymmetrically-dividing cells that populate these sites may represent some form of lineage hierarchy within the LPC population: periductular null cells might give rise to the cytokeratin-positive cells of the CoH, which in turn could generate the intraductal cells and periductular hepatocyte-like cells^[21] (Figure 1).

In some cases the LPC are supported in the regeneration process by stem cells mobilized from BM. Various studies have in fact reported that stem cells from BM can contribute to liver regeneration through their release into the circulation, migration to the liver and differentiation into hepatocytes. However, the extents to which this occurs and the mechanisms involved remain highly controversial issues^[1,22].

Estimates of liver repopulation by HSCs vary widely, ranging from 0.01% to 40%^[23-34]. Petersen *et al.*^[24] originally reported that BM-SCs transplanted into sublethally irradiated rats repopulate the BM and then migrate to the liver and “transdifferentiate” into hepatocytes by entering the liver OC progenitor pathway. BM-SCs are believed to have the ability to expand clonally and to have a bipotential capacity that enables them to differentiate into both hepatocytes and bile duct epithelial cells^[35,36]. This mechanism was generally accepted until studies by Wang *et al.*^[37] using lacZ marking showed that BM cells did not enter the OC pool in wild-type mice treated with DDC, nor did they contribute to liver repopulation by OCs in mouse recipients. Dabeva *et al.*^[38] also showed that BM cells transplanted into rats contributed less than 1% to the OCs expanded after inducing damage with 3 different methods: (1) 2-acetylaminofluorene/partial hepatectomy (PH); (2) retrorsine/PH; or (3) D-galactosamine-induced liver injury. The debate is still open.

Fibrosis

Fibrosis is the progressive accumulation in the tissues of fibrillary extracellular matrix (ECM), but - for its pathophysiological role to be fully understood - it should be seen as a process of chronic wound healing taking place in a tissue continually subjected to injury.

Intestinal fibrosis is a potentially severe complication of inflammatory bowel diseases (IBD), such as Crohn’s disease, and its pathophysiology is still unclear. The presumably key events in the development of IBD-associated fibrosis are the exposure of MFs to inflammatory mediators, and the subsequent production of ECM and tissue remodeling^[29]. Intestinal fibrosis is characterized by myofibroblast accumulation secondary to their local proliferation, migration and recruitment from the BM. Different studies have shown that BM-SCs frequently engraft in the intestine and differentiate into MFs in the lamina propria. *In situ* hybridization was used to detect Y-chromosomes in these cells and their myofibroblastic phenotype was confirmed by their immunostaining positivity for alpha-smooth muscle actin (α -SMA) and negativity for desmin, the mouse macrophage marker F4/80, and the hematopoietic precursor marker CD34. These results were confirmed in mice as early as 1 wk after BM transplantation, and were also seen 2 and 6 wk after cell transplantation, indicating that transplanted BM cells are capable of withstanding a sustained turnover of the MF cells in the lamina propria^[39].

Intestinal MFs can also derive from alternative sources however, such as circulating fibrocytes and the process of “epithelial-mesenchymal transition (EMT)”. Fibrocytes are BM-derived circulating mesenchymal progenitors that co-express hematopoietic and mesenchymal cell markers, and produce ECM components^[30]. In inflammatory processes, fibrocytes are released from the BM and migrate to the sites affected where they differentiate into epithelial, endothelial, neuronal and mesenchymal cells^[30]. In several systems, significant numbers of fibroblasts may be generated by the transformation of non-mesenchymal into mesenchymal cells in a process termed EMT^[40], during which epithelial cells lose their expression of E-cadherin and other components of epithelial cell junctions and acquire a mesenchymal cell phenotype^[41]. This process has a role in the genesis of the fibroblasts that contribute to fibrosis in adult tissues.

In the liver, fibrosis is a multicellular, integrated process requiring a close cross-talk between hepatocytes, cholangiocytes, and non-parenchymal cells (including infiltrating inflammatory cells, Kupffer cells, hepatic stellate cells and sinusoidal endothelial cells)^[42]. Nearly all forms of chronic liver disease can cause fibrosis, though its rate of progression and likelihood of leading to cirrhosis differs in the various etiologies.

All forms of fibrogenesis develop in the context of tissue damage, where hepatocytes and non-parenchymal cells produce signals that target hepatic stellate cells and other fibrogenic MFs, leading to the accumulation of ECM. The generation of reactive oxygen species and

non-oxidant products of oxidative stress exacerbates the hepatocellular damage, promoting inflammation and Kupffer cell activation. Oxidative stress also directly provides pro-fibrogenic stimuli to hepatic MFs^[43].

Hepatic stellate cell activation is considered the major source of MFs in liver damage, but other ECM-producing cells contribute to liver fibrosis, including fibroblasts and portal tract MFs, smooth muscle cells localized in the vessel walls, and MFs located around the centrilobular vein^[42]. Recent studies have demonstrated, moreover, that epithelial cells (both hepatocytes and bile duct epithelial cells) have the ability to acquire myofibroblastic features in the process of EMT, as in the intestine^[44], although the extent to which this process contributes to the development of fibrosis remains controversial.

The role of BM-SCs in the pathogenesis of liver fibrosis has recently been the object of considerable interest. It is usually impossible to track the lineage of cells in humans, although this was done in a study by Forbes *et al.*^[45] in a series of male patients with sex-mismatched liver transplants who subsequently developed graft fibrosis, and in one female patient who developed cirrhosis after receiving a BM transplant from a male. The authors used Y chromosome tracking to identify the origin of the cells participating in liver fibrosis. Substantial numbers of scar-associated MFs in fibrotic areas were found to derive from BM. Using a mouse model of liver fibrosis in which sex-mismatched BM transplants were performed, the same group found clear evidence of a BM contribution to the MFs in fibrotic scars^[46], and provided evidence that the BM contributes to both the macrophage and stellate cells populations in the injured liver^[47]. By subfractionating the BM-SCs compartment, it was demonstrated that, although HSCs contribute to the inflammatory cell infiltrate, the BM-derived MF-like cells originate from MSCs. Intriguingly BM-SCs are widely distributed in the scar tissue in advanced fibrosis. This suggests that, whatever the origin and topography of the injury in chronic disease, BM-derived MFs gradually begin to replace local MF recruitment. Evidence of a functional role of BM-derived MFs was provided by transplanting BM from mice bearing a reporter transgene for collagen, before inducing fibrosis, showing that the recruited MFs transcribe this gene. Also, when wild-type mice were transplanted with BM from a transgenic mouse that develops a characteristic liver scarring pattern (because it expresses a form of collagen I not susceptible to degradation by matrix metalloproteinases), CCl₄ administration induced liver scarring, with characteristics similar to those seen in the BM donor mouse. These data indicate that the transfer of genetically modified BM alters the phenotype of the liver fibrosis, making it reflect the genotype of the BM donor rather than that of the recipient mouse. The same study also provided conclusive evidence that recruited cells contribute directly to fibrosis through the expression, synthesis, and secretion of collagen^[47].

Despite the available evidence for the contribution of BM-SCs, the matter is still widely disputed. Indeed,

a recent paper revealed an unexpectedly limited role of BM-derived cells in collagen production in two mechanistically distinct models of liver fibrosis^[48]. Although some of the BM-derived cells exhibited a mesenchymal morphology resembling that of MFs, the number of BM-derived α -SMA-positive cells was much smaller than previously reported. More importantly, specific and quantitative analyses of collagen type I alpha 2 promoter activation, using a combination of enhanced green fluorescent protein and luciferase reporter genes, clearly showed that BM-derived cells produce little, if any, type I collagen during hepatic fibrogenesis.

STEM CELLS AS A THERAPEUTIC TOOL FOR LIVER AND INTESTINAL DISEASES

Stem cell therapy in intestinal diseases

It is well recognized that inflammatory and immune-mediated bowel diseases, such as Crohn's disease and celiac disease, are due to a dysregulation of the immune response in genetically susceptible individuals. Both these conditions have a strong impact on public health due to their increasing prevalence and incidence in Western populations.

Medical therapy for these disorders has improved dramatically in the last decade with the introduction of targeted biological therapies, the optimization of older therapies and a better understanding of the mucosal immune system and genetics involved in the pathogenesis of IBD. Nevertheless, a considerable number of patients remain refractory to therapy, or become unresponsive to, or intolerant to therapy^[49]. Unconventional strategies have consequently been investigated, identifying the use of SCs as an effective alternative approach to IBD.

The possibility that SCs might represent an effective treatment in IBD and celiac disease initially emerged from several case reports of remission being induced in patients undergoing hematopoietic stem cell transplantation (HSCT) for concomitant hematological malignancies. Theoretically, allogeneic HSCT could be beneficial by replacing the genetic predisposition to IBD, and autologous HSCT might also offer the advantage of a more intense immunosuppression than would otherwise be given, thereby clearing the body of committed lymphocyte clones. On this basis, two phase I clinical trials were carried out on a total of 16 patients who underwent autologous HSCT for refractory Crohn's disease^[50,51]. The results were promising, with remission observed in 14/16 patients, but the adverse effects were far from negligible. As for celiac disease, autologous HSCT was used in a phase I clinical trial to treat 7 patients suffering from refractory celiac disease type II, prompting a significant reduction in the number of aberrant T cells and an improvement in both clinical and serological parameters in 6/7 cases after a mean follow-up of 15.5 mo^[52]. In contrast, when 15 patients with enteropathy-associated T cell lymphoma as a complication of celiac disease were treated with autologous HSCT in three phase I trials, 10

patients died of progressive disease, indicating that the HSCT afforded no benefit in prognostic terms^[53-55].

MSCs can be isolated from various tissues, such as BM, adipose or muscle tissue, fetal tissues and perivascular tissue, and they can support hematopoiesis and differentiation towards adipogenic, osteogenic^[56], and myogenic lineages^[57]. These cells are identified by their expression of a particular panel of surface molecules, e.g., CD105, CD73, CD90, and the absence of CD14, CD34, CD45, and HLA-DR. They elicit no proliferative response from alloreactive lymphocytes because of the negligible levels of extracellular MHC class I and II determinants (though they are present intracellularly). MSCs are also endowed with important immunomodulatory functions in all the cells involved in both the innate and adaptive immune responses^[58]. *In vitro* studies have demonstrated that MSCs can inhibit or suppress several T cell functions, such as proliferation after mitogen and antigen stimulation and inducing cell cycle arrest, probably *via* the release of chemokines, nitric oxide and the enzyme indoleamine 2, 3-dioxygenase. MSCs also do not preferentially target any T cell subset and their inhibition can also extend to B cells, NK cells, and dendritic cells. More precisely, dendritic cells cultured in the presence of MSCs have an impaired T cell stimulatory activity in a mixed lymphocyte reaction, with a shift from predominantly pro-inflammatory Th1 to anti-inflammatory Th2 cells, thus skewing the immune response to T-cell tolerance. Combined, these results support a role for MSCs in preventing rejection after organ transplantation and in the treatment of immune-mediated diseases.

A parallel series of *in vivo* studies conducted on animal models of gastrointestinal injury (gastric and colonic ulcers, and IBD), such as dextran sulfate sodium- and trinitrobenzene sulfoxide-induced colitis, showed beneficial effects of MSCs after both systemic infusion and topical injection^[59-61]. These studies showed that MSCs preferentially homed onto areas of mucosal injury, promoted tissue repair and neo-angiogenesis, reduced inflammation, and restored the immune cell balance.

To date, over 60 MSC clinical trials have been registered and/or are underway according to the website (www.clinicaltrials.gov) in the fields of immune-mediated and cardiovascular diseases, orthopedics, and organ transplantation. As for gastrointestinal diseases, MSCs were used in a single systemic infusion in an open-label phase 2 trial testing Prochymal (*ex vivo* cultured human MSCs, Osiris Therapeutics) for the treatment of refractory Crohn's disease. All 10 patients treated had a statistically significant, mean 105-point reduction in their CDAI score by day 28, and there appeared to be a positive correlation between the dose of cells infused and the clinical response, with patients on high doses achieving a better response^[62]. The most impressive results, however, emerged from a multicenter, phase II trial in which patients with severe, acute GvHD refractory to conventional therapies were treated with two MSC infu-

sions, resulting in an overall survival rate of 53% two years later^[63].

Given the immunomodulatory function of MSCs and their ability to home onto sites of tissue injury, the Ciccocioppo group in Pavia demonstrated that BM-derived MSCs from Crohn's disease patients can be isolated and expanded, and that this cell population exhibits the same biological characteristics as those from healthy controls. MSCs from Crohn's disease patients may therefore be considered for use in cell therapy in an autologous setting.

In general, the convenient isolation procedure, the lack of significant immunogenicity (which allow for allogeneic transplantation without using immunosuppressive drugs), the absence of ethical controversies, the potential to differentiate into tissue-specific cell types with a trophic activity, and their immunosuppressive and immunomodulatory effects make MSCs particularly interesting with a view to their potential uses in regenerative therapy in many gastrointestinal diseases^[64].

Stem cell therapy in liver diseases

Liver disorders affect hundreds of millions of patients worldwide. Liver failure can be defined as the inability of the liver to perform its normal, physiological synthetic and metabolic functions due to severe hepatic injury. Classically, liver failure is divided into acute (ALF) and chronic forms (CLF). ALF is characterized by the sudden onset of hyperbilirubinemia, hepatic encephalopathy and coagulopathy with no underlying liver disease; this remains a dramatic, unpredictable condition, with high morbidity and mortality rates^[65]. CLF usually occurs in the context of hepatic cirrhosis, which can be the result of many possible causes, including excessive alcohol consumption, chronic hepatitis B or C, autoimmunity, or metabolic disorders. The natural course of chronic liver disease is often complicated by acute episodes of potentially reversible decompensation, triggered by a precipitating event, such as infection or upper gastrointestinal bleeding; this situation is frequently called acute-on-chronic liver failure (AoCLF)^[66].

With the help of intensive care and artificial liver support, a substantial proportion of ALF patients may recover spontaneously, but orthotopic liver transplantation (OLT) is the only curative option for end-stage liver diseases and remains the final resort of proven benefit for ALF too, raising the one-year survival rate of ALF patients from 50% to 75%^[67]. Organ shortage remains a major limitation however, and alternative solutions are being examined. Hepatocyte transplantation, or the use of these cells in bioartificial livers^[68,69], have attracted attention in the past three decades, but their exploitation in clinical practice still poses considerable problems, including the difficulty of obtaining hepatocytes and particularly of maintaining their viability and differentiated function when cultured *in vitro*. These issues have been investigated with the aim of improving results^[70,71], but the use of SCs and/or growth factors seems to be

a more appealing and applicable solution for promoting liver repair^[3,72,73].

The possible therapeutic value of BM-SCs was first investigated by intraportally transplanting autologous CD133⁺ cells in patients with liver cancer undergoing portal embolization prior to extensive liver resection (LR)^[74]. A significant improvement in Child-Pugh score and albumin levels was reported in 9 cirrhotic patients given a portal vein infusion of unsorted autologous BM-SCs^[75]. Improved liver function after LR was also recently documented in patients with cirrhosis and hepatocellular carcinoma (HCC) after they underwent autologous BM-SCs transplantation prior to surgery^[76].

Other clinical approaches rely on the administration of G-CSF in combination with leukocyte apheresis and reinfusion of mobilized HSC. The feasibility, safety and BM-SCs mobilization patterns following G-CSF treatment has been assessed in patients with cirrhosis^[77]. Yannaki *et al*^[78] reported on the successful use of boost infusions of mobilized CD34⁺ cells after a standard G-CSF regimen in 2 patients. A significant biochemical and histopathological improvement was achieved by infusing G-CSF-mobilized CD34⁺ HSCs in a patient with drug-induced ALF^[79]. In a phase I clinical trial on 5 patients with AoCLF, administering G-CSF and then reinfusing the CD34⁺ cells improved liver function in more than 50% of cases during a 60-d follow-up^[80]. The same patients were then monitored for up to 18 mo, during which time the procedure was judged to be safe and the beneficial effects lasted around 12 mo^[81]. In 9 patients with alcohol-related cirrhosis, the reinfusion of CD34⁺ HSCs (collected after G-CSF mobilization and expanded *in vitro*) was well tolerated and beneficial to liver function^[82]. In another trial, 40 patients with HBV-related cirrhosis were randomized to receive G-CSF alone or in combination with the reinfusion of peripheral blood monocytes in the hepatic artery. During a 6-mo follow-up, a significant biochemical and clinical improvement was seen in both groups^[83]. Finally, G-CSF has been used alone to treat end-stage liver diseases in a few small clinical trials: overall, the procedure proved safe and was well tolerated, though these studies were too small to draw any conclusions regarding patient survival or treatment efficacy^[77,84-86]. It is worth noting, however, that G-CSF administration was associated with the induction of endogenous liver SCs proliferation within 7 d in the largest randomized trial published to date, conducted by Sphar *et al*^[86].

Most of the above-mentioned clinical trials have their limitations, having been conducted on small groups of patients, with no controls, and using outcome parameters that are easily biased, as mentioned elsewhere^[87,88]. It seems likely that the main role for SC-based therapies in hepatology will be as a bridge to transplantation, or as a way to maintain patients who are not eligible for OLT, using repeated infusions of SCs and/or growth factors to stabilize their liver function. Some conceptual and technical issues nonetheless continue to restrict the diffusion of such treatments in clinical practice^[87,89] and, until these open questions have been properly answered,

SC-based therapies for liver diseases should be limited to well-designed and adequately powered clinical trials.

THE DARK SIDE OF STEM CELLS: THE CANCER STEM CELLS THEORY

The cellular origin of most solid tumors is largely unknown, but different tumor subtypes seem to reflect different origins at the time of cancer initiation. Cells within the tumor population also often exhibit different phenotypic and functional characteristics, which lend heterogeneity to the tumor mass^[90].

At least two models have been proposed to account for the heterogeneity and inherent differences in tumor-generating capacity of SCs, including the cancer stem cells (CSCs) and the clonal evolution models^[91,92]. In the CSCs model, based on a cell hierarchy within the tumor, only a minority of tumor cells can generate a tumor, based on their self-renewal properties and enormous proliferative potential. The clonal evolution model, on the other hand, postulates that genetic and epigenetic changes can occur stochastically over time in individual cancer cells, giving them a selective advantage in proliferating and forming a tumor mass. These two models are not mutually exclusive in cancers following a stem cell model, because CSCs would be expected to evolve via the clonal evolution of transformed SCs^[2]. The hypothesis that stem cells could be targets of malignant transformation has led to an awareness of the similarities between CSCs and normal SCs, including their surface marker phenotype and molecular machinery relating to self-renewal and differentiation. In the last ten years, evidence has been accumulating to indicate that CSCs are not only involved in the perpetuation of hematopoietic tumors, but also play a part in various solid cancers, including those of the breast, brain, prostate, colon, and liver.

Colorectal cancer is the second leading cause of cancer-related death in the western world. A number of studies have produced evidence of the existence of colon CSCs and demonstrated that the tumorigenic cell population of colorectal cancer can be isolated from its expression of specific cell surface biomarkers. The existence of colon CSCs was first reported by the Dick and De Maria research groups^[93,94], each of which identified a small population of cancer cells capable of initiating tumor growth in immunodeficient mice and staining positive for the marker CD133. This marker (also known as prominin-1) was initially identified as a marker of *Drosophila* neuroblasts^[95]. Although it is expressed on different types of stem cell and may play a part in cell polarity, it has no known key role in stem cell function. CD133 is reportedly a potential marker of CSCs in various tumors^[96], but its role as a marker of colorectal cancer was recently questioned by Shmelkov *et al*^[97], who showed that both CD133-positive and CD133-negative metastatic colon cancer cells can initiate a tumor. For the time being it is not clear whether all reported markers really do mark CSCs or merely lead to their enrichment,

and whether these markers are directly linked to stem cell functions. So the search for the perfect CSC marker, which could be useful as a therapeutic target, goes on.

The cellular origin of HCC has long been debated, but whether it originates from mature hepatocytes or stem/progenitor cells, or both, remain to be seen. It has been suggested that intrahepatic stem cells can give rise to human HCC and cholangiocarcinoma (CC)^[98], since oval cell activation has been demonstrated in rodent models of HCC and CC^[99,100]. A role for intrahepatic stem cells in carcinogenesis is also supported by a histological subtype of liver malignancy that displays features of both HCC and CC (HC-CC), combined with the presence of numerous liver progenitor cells^[101,102].

Putative CSCs have recently been isolated from both cancer cell lines and primary HCC tissue using different cell surface markers specific for normal stem cells (Table 1). CD133 seems to play a crucial part in HCC too. Cells positive for CD133 have been reported to exhibit a greater tumorigenicity than the corresponding CD133-negative cells in HCC cell lines^[103,104]. Another frequently-used CSCs marker for isolating liver CSCs is EpCAM^[105,106]. As mentioned earlier, the classification of HCC patients based on EpCAM expression has a prognostic significance. In addition, the prospectively isolated EpCAM cells exhibited an adult SC-like gene expression profile. Given that the heterogeneity of human liver cancer may be related to its CSC origin, hepatic CSCs cannot be identified by the expression of a single marker. A clear liver CSCs profile has yet to be established, and Colombo *et al.*^[107] recently implemented a long-term culture system for isolating and characterizing human liver CSCs. Different HCC cell lines and clones from single HCC specimens were obtained, probably generated from different clonogenic cells, some of which had SC-like features. These HCC cell lines revealed a different morphology, antigen profile, proliferative potential, and *in vitro* antitumor drug resistance. The progenies of clone-initiating cells tend to reproduce the original population over time, suggesting the existence of hierarchically different cells and thus supporting the CSCs model. On the other hand, other HCC cell lines, which showed less aggressive features *in vivo* and were unable to generate different clones *in vitro*, seem to support the clonal evolution model. Taken together, these preliminary data appear to indicate that liver cancer heterogeneity can be explained by a model incorporating both the cancer stem cell hypothesis and clonal evolution mechanisms.

CONCLUSION

Stem cells may have the potential for replacing cells lost as a result of many devastating diseases, such as acute and chronic liver diseases and inflammatory or immune-mediated bowel diseases. There is little doubt that this potential benefit underpins the huge interest in stem cell research. Nonetheless, despite encouraging results obtained in regenerative medicine and the promise of

Table 1 Immunophenotypes of putative hepatocellular carcinoma stem cells reported in literature

future therapies, more studies are needed to thoroughly understand the biology of stem cells, overcome barriers related to immune response, and assess their oncogenic properties. Moreover, some conceptual and technical issues still restrict the diffusion of such treatments in clinical practice. There is still no consensus on the best methods to use for stem cell purification, the ideal route of delivery, amount of cells to infuse, and timing of infusions. Moreover, the risk of malignant transformation and/or pro-fibrogenic effects of SC-based therapies cannot be ruled out, and this imposes the need for a careful evaluation and longer follow-up periods to ascertain the safety and efficacy of SCs in therapeutic applications. Finally, while stem cell experimentation is appealing to researchers and medical specialists, it is also arousing fervent ethical, social and political debate.

Adopting scientific methods based on randomized and controlled trials should produce the necessary results on the real therapeutic role of stem cells. Indeed, the latest findings and ongoing technical improvements entitle researchers to have high hopes for the near future. The scientific researchers and physicians of today continue to hope that the mythological idea of regeneration in the story of Prometheus can be made real by developing therapies to restore lost, damaged or aging cells and tissues in the human body^[3]. Much has been done, but there is still a lot to do. The future is open and promising.

Abstract

Hepatitis B virus (HBV) reactivation represents an emerging cause of liver disease in patients undergoing treatment with biologic agents. In particular, the risk of HBV reactivation is heightened by the use monoclonal antibodies, such as rituximab (anti-CD20) and alemtuzumab (anti-CD52) that cause profound and long-lasting immunosuppression. Emerging data indicate that HBV reactivation could also develop following the use of other biologic agents, such as tumor necrosis factor (TNF)- α inhibitors. When HBV reactivation is diagnosed, it is mandatory to suspend biologic treatment and start antiviral agents immediately. However, preemptive antiviral therapy prior to monoclonal antibody administration is crucial in preventing HBV reactivation and its clinical consequences. Several lines of evidence have shown that risk of HBV reactivation is greatly reduced by the identification of high-risk patients and

INTRODUCTION

Hepatitis B virus (HBV) infection remains a major public health issue, and represents an important cause of liver-related morbidity and mortality. It is estimated that one third of the world's population has been infected with HBV and 350 million people worldwide are affected by chronic HBV infection. HBV reactivation is a well-known phenomenon in chronic HBV carriers and it represents a life-threatening complication following cytotoxic or other immunosuppressive anticancer therapy^[1-3]. The liver damage due to HBV reactivation is characterized by two pathogenetic phases. Initially, during the stage of intense immunosuppressive therapy, there is markedly enhanced viral replication, as reflected by increases in serum levels

of HBV DNA, which results in widespread infection of hepatocytes. Following completion of immunosuppressive therapy and subsequent restoration of immune function, there is a rapid cytotoxic-T-cell-mediated destruction of HBV-infected hepatocytes, which is clinically characterized by development of hepatitis, hepatic failure, and even death.

The risk of clinical manifestations is mainly seen in overt carriers of HBV, but hepatitis might be observed also in subjects with occult HBV infection, who are positive for markers of previous exposure to the virus. The most commonly reported types of chemotherapy related to HBV reactivation are those used for the treatment of hematological malignancy, especially malignant lymphoma^[4,5]. Recently, the risk of HBV reactivation has been heightened by the use of biologic therapy, such as rituximab (anti-CD20) and alemtuzumab (anti-CD52) that cause profound and long-lasting immunosuppression^[6]. Emerging data indicate that HBV reactivation could also develop following the use of other monoclonal therapies, such as tumor necrosis factor (TNF)- α inhibitors^[7,8].

In the present article, we discuss the current trends for the management of HBV reactivation in immunosuppressed patients receiving biologic therapy, such as rituximab, alemtuzumab and TNF- α blockers.

HBV REACTIVATION: DEFINITION AND CLINICAL IMPLICATIONS

HBV reactivation is usually defined as an increase in HBV viral replication in patients with chronic or past HBV infection. The chance of HBV reactivation is closely linked to the serological profile of the infected patient^[9]. The risk is highest in patients who are positive for HBV surface antigen (HbsAg) (the so-called overt carriers of HBV)^[10]. Nevertheless, HBV reactivation can occur also in HBsAg-negative patients who have only markers of previous exposure to HBV [hepatitis B core antibody (HBcAb)-positive with or without hepatitis B surface antibody (HBsAb)] (the so-called occult carriers of HBV)^[11,12]. In such patients, a low level of HBV replication persists in the liver and in peripheral blood mononuclear cells for several years. The timing of HBV reactivation in patients undergoing monoclonal antibody therapy is not uniform. In overt carriers with high HBV viral load, hepatitis may occur during immunosuppressive treatment. However, in most cases, reactivation occurs following the cessation of biological treatment^[10]. At present, the most reliable and easy test used in clinical practice to diagnose HBV reactivation is the demonstration of an increase in serum HBV DNA levels. Serological tests, such as serum IgM HBcAb, are not sufficiently specific to discriminate between acute HBV infection and reactivation in patients with chronic HBV infection.

HBV reactivation may be symptomatic or asymptomatic. Hepatitis should be ascribed to HBV reactivation if it is preceded or accompanied by enhanced HBV viral replication (demonstrable increase in HBV DNA by at

least 10-fold, or an absolute increase to $> 10^8$ IU/mL). The time interval between the peak of HBV DNA viral load and hepatitis onset is variable. Classical features of hepatitis, including fatigue, jaundice, ascites, hepatic encephalopathy and coagulopathy, may be present. Patients with pre-existing cirrhosis are more likely to develop liver failure. Although some subjects can recover spontaneously, the mortality of HBV reactivation is reported as 5%-40%^[3].

IMMUNOSUPPRESSION AND RISK OF HBV REACTIVATION FOLLOWING MONOCLONAL ANTIBODY THERAPY

In recent years, the effective management of various hematological malignancies and immune-mediated inflammatory diseases has included the use of monoclonal antibody therapy. Rituximab (anti-CD20), alemtuzumab (anti-CD52) and TNF- α inhibitors represents a modern therapeutic approach that has greatly improved the prognosis and outcome of several malignant and non-malignant conditions. However, these biologic agents induce a profound immunosuppression and their use has been reported to be associated with development of severe infections, including HBV reactivation^[13,14].

Rituximab (anti-CD20 monoclonal antibody)

Rituximab therapy represents one of the most important advances in the treatment of lymphoproliferative disorders in the past 30 years. Rituximab is the archetype of this new class of compounds that is being currently used for the treatment of CD20-positive B-cell lymphoma, chronic lymphocytic leukemia (CLL) and autoimmune conditions, such as immune thrombocytopenia and collagenopathy. It is a chimeric murine-derived monoclonal antibody that is engineered by grafting the variable regions that target the CD20 antigen from a murine anti-CD20 antibody into human constant regions^[15]. Binding of rituximab to B cells activates complement and promotes C3b deposition in close proximity to cell-bound rituximab. In addition to antibody dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity, rituximab also induces apoptosis through activation of caspase-3 and sensitizes cells to pro-apoptotic stimuli, which appears to be crucial in rituximab-induced cell killing. Treatment with rituximab is not commonly associated with severe opportunistic infections, while the risk of HBV reactivation is significantly higher if compared to conventional chemotherapy. There are increasing reports of HBV reactivation after rituximab therapy, either when used alone or in combination with chemotherapy^[3,16,17]. HBV infection has been reported to be the most common viral infection in patients affected by lymphoma and treated with rituximab. Aksoy *et al.*^[18] have shown that rituximab-related HBV infections are associated with a mortality rate of 50% compared to 33% observed in patients with other infections. In a recent retrospective

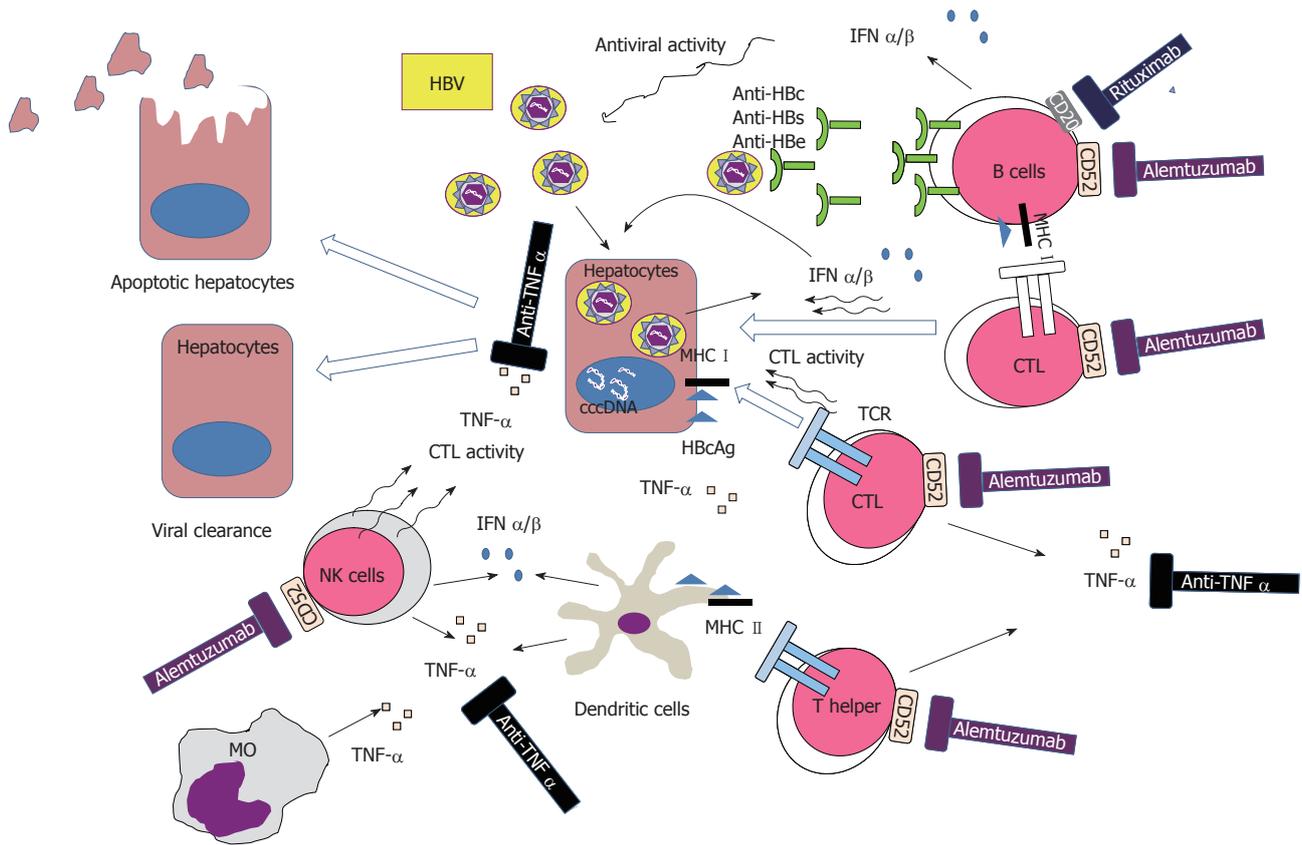

Figure 1 Pathogenetic hypothesis of hepatitis B virus reactivation following monoclonal antibody treatment. IFN: Interferon; TNF: Tumor necrosis factor; MHC: Major histocompatibility complex; NK: Natural killer; MO: Monocytes; TCR: T-cell receptor; CTL: Cytotoxic T lymphocyte; HBV: Hepatitis B virus; HBcAg: HBV core antigen.

study, 80% of HBV carriers without lamivudine prophylaxis experienced HBV-related hepatitis, including one fatal hepatic failure. Moreover, about 4% of HBsAg-negative patients developed *de novo* HBV hepatitis and two died of fulminant hepatitis^[10]. The profound and durable depletion of circulating population of B cells induced by the drug lead to dysregulation in host immunity to HBV and represents the main pathogenetic factor involved in viral replication and reactivation^[19]. The control of HBV infection is mediated mainly by HBV-specific cytotoxic T lymphocytes; nevertheless, B lymphocytes are still essential for antigen presentation. The failure in antigen presentation related to the prolonged depletion of B cells by rituximab may allow the HBV to escape the cytotoxic T lymphocyte control, hence leading to development of viral hepatitis reactivation (Figure 1).

Alemtuzumab (anti-CD52 monoclonal antibody)

Alemtuzumab is a humanized chimeric lymphocytotoxic monoclonal antibody that recognizes the antigen CD52, a 21- to 28-kDa heavily glycosylated membrane-anchored glycoprotein that is abundantly expressed on B and T cells, as well as on natural killer cells and macrophages). Typically, granulocytes, platelets, erythrocytes, and hematopoietic stem cells (HSCs) lack CD52 expression. CD52 is expressed on all CLL cells and indolent lymphomas. CD52 is not shed, internalized, or modulated and is

therefore an ideal antigen for targeted immunotherapy. However, the ubiquitous expression of CD52 on lymphocytes and monocytes is predictive of the increased neutropenia, lymphopenia and infectious complications observed with alemtuzumab therapy. Alemtuzumab was first used in the allogeneic HSC transplantation as *ex vivo* treatment of donor HSC or *in vivo* as part of combination chemotherapy or for the conditioning regimen of patients undergoing HSC transplantation^[20], with the aim to prevent graft-*vs*-host disease. More recently, alemtuzumab was approved for the treatment of high-risk patients with CLL. Most treated patients manifest profound peripheral-blood lymphopenia by 2-4 wk, which may persist for > 1 year. The effector mechanisms of alemtuzumab are not fully understood but may include ADCC, complement-mediated cell lysis, and induction of apoptosis (Figure 1). Alemtuzumab therapy is known to be associated with a high risk of serious bacterial, viral and fungal infections and should be used with great caution^[21]. The risk of severe infection, e.g., *Pneumocystis jirovecii* pneumonia, adenovirus infection and parvovirus B19 infection have also been reported. Although the risk of HBV reactivation after anti-CD52 monoclonal-antibody-mediated immunosuppression is not well defined, there have been multiple reports on the development of HBV reactivation after alemtuzumab therapy. In particular, alemtuzumab-containing chemotherapy regimens are as-

sociated with a high risk (29%) of reactivation of occult HBV infection and severe HBV-related hepatitis^[14,21,22]. Considering the degree and duration of immunosuppression induced by alemtuzumab, chronic HBV-infected patients should be treated with pre-emptive anti-HBV therapy before commencement of an alemtuzumab-containing chemotherapy regimen.

TNF- α antagonists

Emerging data suggest a potential risk of HBV reactivation in patients treated with anti-TNF- α agents^[8]. Currently, five TNF- α antagonists are approved in the United States for treatment of various immune-mediated inflammatory diseases, such as rheumatoid arthritis, psoriasis, psoriatic arthritis, ankylosing spondylitis, and Crohn's disease. Four are antibodies directed against TNF- α : infliximab, a chimeric mouse/human monoclonal antibody; adalimumab and golimumab, humanized monoclonal antibodies; and certolizumab, a pegylated Fab fragment of humanized monoclonal antibody. The fifth drug, etanercept is a protein that blocks the TNF- α receptor on human cells. The critical role of TNF- α in mediating inflammation, particularly granulomatous inflammation, has led to an increased susceptibility to infections by intracellular pathogens, such as *Mycobacterium tuberculosis*, *Mycobacterium avium* complex, *Histoplasma capsulatum*, *Cryptococcus neoformans*, *Coccidioides* species, and possibly *Pneumocystis*, *Listeria*, and *Aspergillus*^[23,24]. To date, no consensus exists about the safety of anti-TNF- α in patients with chronic HBV infection. The 2008 American College of Rheumatology recommendations contraindicate the use of anti-TNF- α in patients with hepatitis^[25]. A recent consensus statement on biologic agents for treatment of rheumatic diseases recommends that patients should be screened for HBV before anti-TNF- α initiation^[26]. Specific warnings about HBV reactivation have been added to the American label by the FDA, recommending that antiviral therapy should be used in patients in whom HBV infection is diagnosed during anti-TNF- α therapy. Various case reports have suggested that TNF- α inhibition facilitates HBV reactivation and replication, with fulminant hepatic failure or fatal outcomes^[8]. HBV reactivation resulting in acute or subfulminant hepatitis is more likely in active HBV carriers. The risk of viral reactivation in occult HBV carriers seems to be significantly lower, and it is seen especially in patients with intense immunosuppression. In a large study of 88 patients with potential occult HBV infections exposed to TNF- α blockers, a small number of cases of HBV reactivation was observed^[27]. It is currently unknown if the risk of HBV reactivation is homogeneous within the family of TNF- α inhibitors. Among different anti-TNF- α agents, infliximab seems to be more frequently associated with viral reactivation, although the reasons for this are still unclear^[28]. In chronic HBV infection, TNF- α has a dual role: it protects the hepatocytes by decreasing transcriptional activity of the HBV core promoter gene; and the cytokine can augment hepatocyte apoptosis and eventual liver fibrosis through different mechanisms. Thus, paradoxically,

TNF- α blockade may be potentially beneficial, because long-term inhibition of this cytokine could have a protective effect on the hepatocytes; sparing them from injury and the liver from progressive fibrosis. However, failure to secrete appropriate amounts of TNF- α and impairment in the circulating CD8⁺ T-cell responses is associated with decreased clearance of HBV (Figure 1). This phenomenon raises concern regarding the safety of TNF- α inhibitors in patients with underlying liver disease^[7].

ANTIVIRAL STRATEGIES FOR MANAGEMENT OF HBV REACTIVATION

When HBV reactivation is diagnosed, it is mandatory to suspend all chemotherapy and start treatment with antiviral agents immediately. However, pre-emptive antiviral therapy prior to monoclonal antibody administration is crucial in preventing HBV reactivation and its clinical consequences. Several lines of evidence have shown that risk of HBV reactivation is greatly reduced by the identification of high-risk patients and the use of prophylactic antiviral therapy^[9,29]. The early identification of patients at risk of HBV reactivation before they receive monoclonal antibody therapy is crucial for avoiding the serious morbidity associated with disease reactivation. Virological screening is recommended in all patients at risk of HBV reactivation, who are planned to receive monoclonal antibody therapy (Figure 2). Testing for HbsAg, HBcAb and HBsAb could allow identification of patients with chronic, occult or resolved infection^[30]. HBsAg-positive patients, including both the active carriers (detectable HBV DNA with the presence of liver damage) and the inactive carriers (undetectable HBV DNA with no liver damage), should be treated immediately, in order to block viral replication and disease progression before monoclonal antibody therapy is given.

Recommendations for standard management are less clear in patients with occult HBV infection (HBsAg-negative/HBcAb-positive with or without HBsAb and undetectable HBV DNA). Indeed, in these patients, the risk of disease reactivation is significantly lower if compared with HBsAg-positive individuals. Therefore, it has been proposed that HBsAg-negative patients with positive HBcAb and undetectable HBV DNA should be strictly monitored by measurement of alanine aminotransferase (ALT) and serum HBV DNA; in case of HBV reactivation, as assessed by significant increase in HBV-DNA levels, they should be promptly treated with antiviral drugs, possibly before ALT elevation. Nevertheless, this approach is not universally accepted because a delay in the administration of antiviral treatment might expose the patient to the risk of severe hepatic failure during occult HBV infection^[29]. In our opinion, considering the relative safety of newer oral antiviral agents, prophylactic treatment represents a reasonable strategy; especially in high-risk patients receiving a rituximab-based regimen (Figure 2).

The optimal timing and duration of antiviral prophylaxis should be individualized, taking into consideration

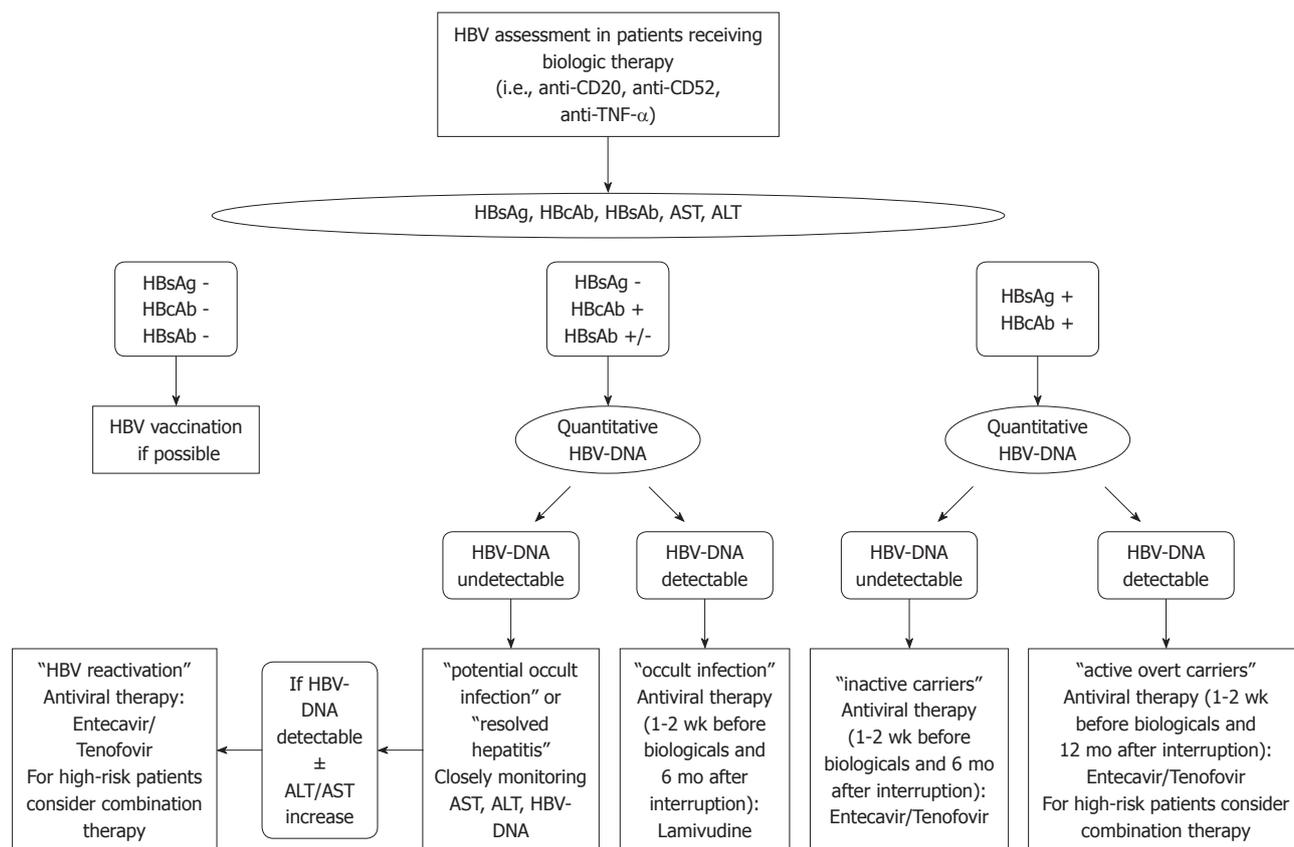

Figure 2 Proposed algorithm for the management of hepatitis B virus-infected patients requiring biologic therapy. HBV: Hepatitis B virus; TNF- α : Tumor necrosis factor α ; HbsAg: HBV surface antigen; HBcAb: Hepatitis B core antibody; HBsAb: Hepatitis B surface antibody; ALT: Alanine transaminase; AST: Aspartate transaminase.

viral and host factors. Starting antiviral treatment before immunosuppressive regimen and proceeding until the immune system has fully restored might be the most reasonable approach. In general, antiviral drugs should be initiated 1-2 wk before monoclonal antibody therapy and should be provided for at least 6 mo after the biologic treatment is stopped (Figure 2). Nevertheless, close monitoring of HBV DNA and ALT is strongly recommended after stopping prophylaxis to prevent severe HBV flare.

SELECTION OF ANTIVIRAL REGIMEN

Drugs used for treatment of HBV infection include interferon therapy and nucleos(t)ide analogs. Standard interferon (IFN)- α or pegIFN- α is contraindicated for treatment of HBV reactivation following biologic therapy.

Currently, five oral nucleos(t)ide antiviral drugs are approved for the treatment of chronic HBV infection: lamivudine, adefovir, entecavir, tenofovir, and telbivudine. The most commonly used antiviral drug in HBV reactivation is lamivudine^[31,32]. However, prognosis of patients undergoing a chemotherapeutic regimen including rituximab remains severe despite lamivudine therapy. Furthermore, lamivudine efficiency is hampered by the high rate of drug resistance mutations within HBV polymerase, which are associated with treatment failure^[33]. Lamivudine monotherapy can also select HBV strains associated with

resistance to entecavir^[34] and adefovir^[35]. To date, current treatment guidelines no longer recommend lamivudine monotherapy as primary treatment for chronic hepatitis B^[30]. This drug may have still a role in the prevention of HBV reactivation in patients with occult HBV infection (Figure 2). Nevertheless, considering the high rate of mortality associated with HBV reactivation during monoclonal antibody therapy, the use of more potent and effective antiviral drugs needs to be evaluated. Adefovir has been used in patients with established HBV reactivation and individuals treated with lamivudine prophylaxis who have developed drug resistance. However, primary treatment failure occurs in $\geq 10\%$ of patients treated with adefovir, and viral resistance occurs in nearly 30% of patients with hepatitis B e antigen-negative disease after 5 years of therapy^[36]. Entecavir and tenofovir are more potent and effective antiviral drugs that now represent the current preferred options for the management of treatment-naïve patients with chronic HBV infection^[2]. These new-generation HBV polymerase inhibitors exhibit very low rates of resistance in nucleoside-naïve patients when given as monotherapy. To date, there is no or very limited experience on the use of these drugs in the management of HBV reactivation in immunosuppressed patients undergoing monoclonal antibody therapy^[37]. There are a few case reports on telbivudine safety in HBV reactivation but there are no reports on tenofovir efficacy in

HBV reactivation.

The best evidence for antiviral prophylaxis of HBV reactivation is still for lamivudine (Figure 2), but there are few data on the use of entecavir. In two recent case reports, entecavir was successfully used as a first-line treatment for HBV reactivation following chemotherapy containing rituximab^[38,39]. However, in another study, it has been shown that entecavir increases mortality of patients with HBV reactivation, by increasing lactic acidosis and encephalopathy^[40]. Recently, we described a case of HBV reactivation in a patient with non-Hodgkin's lymphoma following a rituximab-based regimen: he was successfully treated with a combination antiviral treatment including entecavir and tenofovir^[41]. Antiviral treatment with entecavir was immediately initiated when the patient had HBV reactivation, and a rapid reduction of viral replication with normalization of transaminases was obtained. However, after a few months, the patient again presented with virological and biochemical breakthrough; probably related to the persistent and severe immune impairment of T- and B-cell function. We obtained full viral suppression and stable normalization of liver enzymes only after starting a combination strategy that included entecavir and tenofovir. Anti-HBV combination therapy has been considered in HBV-infected patients with decompensated cirrhosis and following liver transplantation^[57]. In our opinion, the combined use of antiviral drugs should be further evaluated for the management of HBV reactivation; especially in patients with severe impairment of the immune system (Figure 2), although safety data in different groups of patients are needed.

CONCLUSION

HBV reactivation represents an important medical issue in HBV-infected patients receiving biological treatment with monoclonal antibodies, such as rituximab, alemtuzumab or TNF- α antagonists. The identification of high-risk patients with active, inactive and occult HBV infection and the use of prophylactic antiviral treatment is crucial in avoiding the serious morbidity associated with HBV disease reactivation. Finally, studies examining the safety and efficacy of the latest generation anti-HBV drugs in sequential monotherapy, or in combination, for the management of HBV reactivation should be strongly encouraged.

Abstract

Melatonin is a hormone with endocrine, paracrine and autocrine actions. It is involved in the regulation of multiple functions, including the control of the gastrointestinal (GI) system under physiological and pathophysiological conditions. Since the gut contains at least 400 times more melatonin than the pineal gland, a review of the functional importance of melatonin in the gut seems useful, especially in the context of recent clinical trials. Melatonin exerts its physiological effects through specific membrane receptors, named melatonin-1 receptor (MT1), MT2 and MT3. These receptors can be found in the gut and their involvement in the regulation of GI motility, inflammation and pain has been reported in numerous basic and clinical studies. Stable levels of melatonin in the lower gut that are unchanged following a pinealectomy suggest local synthesis and, fur-

thermore, implicate physiological importance of endogenous melatonin in the GI tract. Presently, only a small number of human studies report possible beneficial and also possible harmful effects of melatonin in case reports and clinical trials. These human studies include patients with lower GI diseases, especially patients with irritable bowel syndrome, inflammatory bowel disease and colorectal cancer. In this review, we summarize the presently available information on melatonin effects in the lower gut and discuss available *in vitro* and *in vivo* data. We furthermore aim to evaluate whether melatonin may be useful in future treatment of symptoms or diseases involving the lower gut.

Distribution, function and physiological role of melatonin in the lower gut. *World J Gastroenterol* 2011; 17(34): 3888-3898 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i34/3888.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i34.3888>

INTRODUCTION

Melatonin (N-acetyl-5-methoxytryptamine), discovered in 1917, is found in humans, animals, plants and microbes. It is a lipophilic compound diffusing rapidly through biological membranes and is involved in many regulatory processes, such as biological rhythms, intestinal reflexes, protection against inflammation, metabolism and repro-

duction. Additionally, melatonin may act as a mediator of inter-organ communication, e.g., between gut and liver^[1].

In animals, melatonin was first reported in the bovine pineal gland in the year 1958, and in the gut it was first identified in the human appendix in 1974^[2]. Melatonin is synthesized in the pineal gland and secreted in a circadian pattern, with highest amounts released during nighttime^[3]. The light/dark information regulating the secretion of melatonin by the pineal gland is received in the supra-chiasmatic nuclei *via* retinal photosensitive ganglionic cells. Melatonin released into the bloodstream acts as an endocrine hormone and controls biological functions with circadian rhythms, e.g., the sleep-wake cycle. Melatonin is also involved in the regulation of food intake and digestion^[4].

Following the detection of the melatonin-synthesizing enzymes N-acetyltransferase and hydroxyindole-O-methyltransferase in the gut^[5], the possibility of additional extra-pineal melatonin synthesis was considered^[6]. Melatonin produced in the gut is believed to act as a paracrine hormone which can be secreted in both a continuous or a cyclic fashion. Melatonin is also synthesized by a variety of other extra-pineal cells, such as bone marrow cells, lymphocytes, mast cells and epithelial cells, and it is unclear to what extent melatonin from these sources contributes to gut melatonin levels. Release of melatonin from all these extra-pineal sources seems to be independent of the photoperiod^[7-9].

Melatonin has been studied in different areas of medicine in numerous clinical trials. In the lower gut, the roles of melatonin are complex and largely uncharacterized. This review will focus on the gastrointestinal (GI) localization of melatonin, the role of melatonin in the lower gut and the mechanisms involved. Animal and benchside research, as well as translational human research, will be discussed with a special emphasis on summarizing all available human data related to the lower gut.

MELATONIN PRESENCE IN THE LOWER GUT

Bubenik *et al.*^[10] were the first to report the presence of melatonin in the mucosa of the gut. This observation was later confirmed by studies using immunohistochemistry and radioimmunoassay techniques^[11]. In the mammalian gut, melatonin exhibits striking differences in regional distribution, with the highest levels in the rectum and the colon and the lowest levels in the jejunum and the ileum. These regional differences in tissue distribution were confirmed in other species including rabbit, mouse and human^[12]. Moreover, specific antibodies against melatonin in rat identified melatonin-like immunoreactivity in all parts of the gut, and after administering exogenous melatonin the most pronounced accumulation of melatonin was seen in the colon and the rectum^[13]. Furthermore, melatonin was detected in luminal fluids of the gut. This melatonin may originate from food, mucosal sources, or organisms populating the gut. Finally, luminal melatonin may also be of biliary origin, but at the present time its

sources have not been elucidated.

Melatonin is synthesized in the enterochromaffin (EC) cells throughout the gut^[14,15], and the EC cells have been reported to be the major source of L-tryptophan-induced increase of circulating melatonin. Interestingly, the distribution of melatonin is comparable to the density of EC cells in the gut. Oral administration of L-tryptophan caused a rapid and dose-dependent elevation of circulating melatonin in rats or chickens^[16]. L-tryptophan-induced melatonin synthesis was greater following oral than following intraperitoneal administration. This indicates that L-tryptophan is a crucial precursor in gut melatonin synthesis.

Some melatonin detected in the gut is of pineal origin through accumulation from circulating sources, and the digestive tract, especially in the lower gut, might act as a store for pineal-derived melatonin particularly at nighttime^[17]. Melatonin levels in the gut are independent of pineal production, since in rats pinealectomy had no influence on gut melatonin concentrations^[18]. Interestingly, at any time of the day or night, the gut contains at least 400 times more melatonin than the pineal gland, once again emphasizing the functional importance of melatonin in the gut. No photoperiodic cyclical secretion of melatonin was observed in the gut, which is in contrast to the typical secretion pattern for melatonin from the pineal gland. In diabetic rats, lower melatonin levels were observed in the pancreas, the kidneys and the duodenum, but no change of melatonin level was detected in the colon, when compared to non-diabetic control rats^[19]. The relevance of these observations has yet to be determined.

Melatonin concentrations in the gut vary depending on age. In the postnatal rat, GI melatonin levels peaked at birth and then declined to stable levels at the age of 21 d^[13]. This decline in melatonin concentrations was more pronounced in the jejunum, ileum and colon compared to the stomach^[20]. However, later in life the levels of melatonin increase; it has been shown that melatonin concentration in the mucosa of the ileum and distal colon is 126% higher in older mice (22-24 mo) compared to younger mice (2-5 mo)^[21]. Remarkably, the same study provided evidence that most of the daytime levels of melatonin in the blood are of GI origin. It was also shown in pigs that the serum melatonin levels correlate well with the levels of melatonin in the lower gut^[22]. Food restriction increases melatonin concentrations in the gut and in the brain in mice^[23]. These distinct changes in melatonin levels suggest that there may be a physiological role for melatonin in the regulation of digestion and in the control of food intake. On the contrary, the melatonin levels in the lower gut may be influenced by luminal contents and may thus depend on the movement of digesta, but this notion remains speculative at the present stage.

MELATONIN RECEPTORS ARE LOCALIZED IN THE ILEUM AND THE COLON

Melatonin exerts some of its physiological effects through

activation of specific membrane receptors. According to their pharmacological properties, these receptors have been classified as Mel1A, Mel1B and Mel1C^[24,25]. Two of these, Mel1A and Mel1B, were recently renamed melatonin-1 receptor (MT1) and MT2 receptors. Both MT1 and MT2 receptors are members of the G-protein coupled receptor family and share a common seven transmembrane structure. MT1 and MT2 show high homology at the amino acid level, with a 55% overall homology and a 70% homology within the transmembrane domains. They also share some specific short amino acid sequences, suggesting that they represent a specific subfamily^[26,27]. However, MT1 and MT2 receptors activate very distinct intracellular signaling pathways^[28,29]. It has been shown that the MT1 melatonin receptor is coupled to G proteins that mediate adenylate cyclase inhibition and phospholipase C beta activation. The MT2 receptor couples to a number of signal transduction pathways, including phosphoinositol production, inhibition of adenylate cyclase and the inhibition of soluble guanylate cyclase pathway^[30-32]. Luzindole acts as an antagonist at both receptors and is used in numerous studies^[33-35]. 4-P-PDOT is a selective antagonist at MT2^[36]. For the MT1 receptor no highly selective antagonist has been reported yet.

The third melatonin binding site MT3 (formerly Mel1C) is an enzyme named quinone reductase 2 (QR2). MT3 can be blocked by prazosin. Activation of MT3/QR2 by melatonin may explain the protective effect of melatonin against oxidative stress in different animal models, since MT3/QR2 has potent antioxidant properties.

The melatonin receptors display regional tissue and cell specific variations, reflecting the overall complexity of melatonin signaling^[37]. Functional assays, as well as receptor binding studies, have demonstrated the presence of high affinity binding sites for melatonin on cell membranes, for example in the hypothalamus, medulla oblongata, hippocampus, cerebellum, parietal cortex and striatum of rats. Interestingly, the density of these binding sites varies depending on the time of the day and physiological conditions, including age^[38,39].

Furthermore, there exists a group of nuclear melatonin receptors. These nuclear receptors for melatonin belong to the retinoid Z receptor (RZR) or retinoid orphan receptor (ROR) subfamilies, which include three subtypes (α , β , γ), encoded by three different genes^[40,41]. An interaction between membrane and nuclear melatonin receptors was suggested by the observation that the expression of ROR/RZR mRNA is decreased in blood mononuclear cells with reduced MT1 receptor expression. Finally, melatonin can directly interact with intracellular proteins such as calmodulin, calreticulin or tubulin, extending the list of potential sites of binding and action for melatonin^[42-44].

All three MT receptors can be found in the gut and the data on localization are summarized in Table 1. The subcellular distribution of melatonin binding is highest in the nuclear fraction, followed by the microsomal and the mitochondrial fractions, and is lowest in the cytosolic fraction.

Melatonin MT1 receptor mRNA has been detected

Table 1 Localization of melatonin membrane receptors in the ileum and the colon of rodents

	MT1	MT2	MT3
Ileum	+	+	+
Colon	+	+	+
Mucosa	+	No data	No data

in rat small and large intestine. The highest MT1 mRNA expression was found in the rat duodenum, with lower expression in the jejunum and ileum. No circadian changes were found in MT1 mRNA expression in gut tissues. In the duck gut, there was found to be a significant variation in the densities of 2-iodo (¹²⁵I)-melatonin binding sites in different regions of the gut, with the following descending order of density: ileum, jejunum > duodenum, colon > cecum > esophagus^[45]. Short-term fasting increased the expression of MT1 in the sub-epithelial layer of the rat small and large intestine, but no changes in MT1 expression were detected in other gut layers. During long-term fasting this increase in MT1 expression persisted only in distal colon, while in the remainder of the colon and in the small intestine MT1 expression returned to normal levels^[46-48].

A study using tissues from rat pancreas, stomach, duodenum and colon found the highest levels of MT2 in the colon by using western blot analysis^[49]. In the same study, the most intense MT2 immunoreactivity was observed in the muscularis mucosae and in the circular and longitudinal muscle layers of rat gut. Detection of MT2 receptors in the gut muscle layers suggests an involvement of MT2 in the regulation of intestinal motility. Comparable to MT1, the expression of MT2 receptors does not vary with food intake.

Pharmacological studies suggested the presence of the melatonin MT3 receptor in guinea pig colon^[50] and later MT3 was found in monkey (*Macaca fascicularis*) gut^[51]. However, presently it is unclear in which gut layer MT3 is expressed.

In addition, in blood vessels of both rodent and human colon, a high density of melatonin-binding sites was reported. *In vitro* preparations of arterial smooth muscle of the porcine colon relax in response to melatonin and melatonin receptor agonists, although these effects were seen at rather high concentrations of melatonin^[52]. Based on *in vitro* experiments on rat arteries, it has been suggested that a vasoconstrictive effect of melatonin is mediated *via* MT1 and a vasodilatory effect is mediated *via* MT2 receptors^[53]. The effects of melatonin in the gut may be dose-dependent and reflect actual MT1/MT2 ratio in muscle layers of gut segments.

Whereas data are available for the localization and expression of MT receptors in the gut, the presence of nuclear melatonin binding sites remains unresolved. One

study has suggested that melatonin nuclear receptors are present in murine colon cancer cells, but the relevance of this observation and localization remains unclear^[54].

ACTIONS OF MELATONIN IN THE ILEUM AND THE COLON

In contrast to the central nervous system, the function of melatonin in the gut is less clear. In the gut it seems that melatonin plays significant roles in regulating intestinal motility, the immune system, GI secretion, and the release of peptides involved in energy balance such as peptide YY^[55]. Melatonin was also shown to protect the colon in different pathophysiological conditions; frequently these protective effects involve activation of antioxidative mechanisms or the regulation of blood vessel tone and thus modification of perfusion^[56,57]. Another effect of melatonin is the alteration of gut flora and potential anti-microbiotic actions; melatonin was shown to influence *E. coli* O157:H7 growth *in vitro* and *in vivo* in infected wethers^[58].

Motility

Melatonin is known to be involved in the regulation of GI motility. Melatonin is produced in EC cells of the GI tract and has high lipophilicity, and therefore may diffuse into deeper layers through mucosa and submucosa, to finally act in the muscularis mucosae or the myenteric plexus. In these actions, muscular and neuronal sites are involved. Contractile and relaxant effects of melatonin in the GI tract have been reported in numerous species^[59-61]. The involved sites of action and the mechanism of melatonin action in the GI tract are not poorly characterized. Involvement of melatonin receptors and/or ion channels located on GI smooth muscle cells and/or neurons have been suggested and details are discussed below.

Melatonin alters GI motility by activating melatonin receptors. The most likely sites of melatonin action in the GI smooth muscle cells are the membrane-bound melatonin receptors and there is strong evidence that MT₂ receptors are involved. *In vivo* animal studies showed that melatonin exerted both excitatory and inhibitory effects on the gut depending on the dose of melatonin. Small doses of melatonin accelerated the intestinal transit in rats, while high doses reversed this effect. These effects were blocked by luzindole, suggesting the involvement of intestinal melatonin receptors^[62].

Early *in vitro* research showed that melatonin reduces the force of spontaneous contractions of ileum and colon segments of rat intestine, while the frequency of intestinal contractions remained unchanged^[61]. In the GI tract, the cyclic generation of electrical currents is one fundamental mechanism of coordinated smooth muscle contraction. Slow waves and spiking activity are organized in myoelectric migrating complexes (MMC). Depending on the report, endogenous and exogenous melatonin inhibits pre- and postprandial irregular spiking activity of intestinal motility. Furthermore, pinealectomy suppressed the regular phase of MMCs, and adminis-

tration of exogenous melatonin could restore a regular phase MMC activity in rat ileum^[63]. These changes may depend on the action of melatonin on the GI neurons. In one study focusing on gastric emptying, melatonin partly inhibited gastric motility by activating sympathetic neurons. In the stomach, melatonin also reduces nitrergic myenteric innervation^[64]. In electrophysiological experiments it was shown that the nitrergic component of the smooth muscle inhibitory junction potential was reduced by melatonin and this may be a consequence of direct inhibition of nitric oxide synthase (NOS) activity by melatonin at enteric synapses. Other studies suggest that the effect of melatonin may be related to the blockade of nicotinic channels by melatonin, or due to an interaction between melatonin and Ca²⁺-activated K⁺ channels^[65]. Furthermore, it was demonstrated that the inhibitory effect of melatonin is apamin-sensitive and thus involves Ca²⁺-activated K⁺ channels^[66]. One study also showed that the melatonergic attenuation of acetylcholine-induced contractions of intestinal strips from goldfish is dependent on extracellular calcium^[67].

Moreover, a beneficial effect of melatonin in reversing lipopolysaccharide-induced motility disturbances, which involves a reduction in lipid peroxidation and an increase of mitogen-activated protein kinase activation, nuclear factor kappaB (NF-κB) activation, inducible NOS (iNOS; NOS-2) expression and finally nitrite production^[68], was reported. Additionally, melatonin was shown to modulate the cholecystokinin action on ileal motility and to reduce the duration of cholecystokinin stimulatory effects on GI smooth muscle in rats^[69].

Other possible sites of melatonin action are 5-HT receptors. One study suggested that high doses of melatonin in the GI tract interact with cholecystokinin-2 and 5-HT₃ receptors on the vagal afferent fibers, and thus induce vago-vagal inhibitory reflexes^[70]. In some reports, the relaxant effect of melatonin through 5-HT receptor antagonism was proven^[71], but other pathways may also be involved. Recently, it was demonstrated that melatonin can inhibit the activity of the serotonin transporter, which controls the reuptake of 5-HT in intestinal epithelial cells and inhibits NK₂ receptor-triggered 5-HT release from guinea pig colonic mucosa by acting at a MT₃ melatonin receptor located directly on the mucosal layer^[72]. These actions may at the same time affect gut secretion.

Secretion

Melatonin is involved in the regulation of intestinal ion transport. Exogenous melatonin reduced diarrhea in rats with colitis, but the involved mechanisms have not been fully elucidated^[73]. In the colon, melatonin is thought to play a role in regulating Cl⁻ secretion^[74]. Melatonin can affect the expression of COX-2 and iNOS and melatonin modulates secretion elicited by prostaglandin E₂ and sodium nitroprusside in rat distal colon. Some of these secretory effects seem to be localized in the colonic epithelium and involve cAMP pathways, while others involve the enteric neuronal system^[75]. According to these studies,

melatonin is a physiological modulator of ion transportation in the lower gut and many mechanisms are involved.

Immune system

Melatonin has numerous effects on the immune system. It increases natural killer cell activity and Th2 cell-mediated immune responses^[76,77]. Melatonin was reported to regulate gene expression of several cytokines including IL-2, IL-2R and IFN- γ released by human CD4 T cells^[78,79]. The effects on other functions of the immune system, such as lymphoproliferation and cytokine production by human lymphocytes, have also been studied. Melatonin protects human and murine CD4⁺ T cells from apoptosis by inhibiting CD95 ligand mRNA and protein up-regulation in response to TCR/CD3 stimulation^[80]. Additionally, the melatonin/IL-2 relationship may be particularly relevant for immune tolerance. Melatonin can affect T-cell tolerance *via* IL-2^[81]. At the same time, melatonin acts as an immunomodulator and these effects are mediated by melatonin receptors located on immunocompetent cells^[82]. Melatonin synthesized in human lymphocytes is involved in the physiological regulation of IL-2/IL-2R expression through mechanisms comprising both membrane and nuclear melatonin receptors^[83].

The majority of melatonin effects described for lymphocytes seem to be mediated through MT1 receptors^[84]. However, some evidence shows that melatonin-induced enhancement of immune function is also mediated *via* MT2 receptors^[85]. Antagonists at the MT2 receptor or the nuclear RZR/ROR were found to reduce human lymphocyte IL-2 production, proving the involvement of these binding sites in IL-2 production^[86].

Experimental inflammation

By preserving the mucosal cell integrity and inhibiting the accumulation of neutrophils, melatonin exerts protective effects against inflammation in the gut^[87]. Melatonin was shown to reduce the severity of intestinal inflammatory pathologies such as colitis in animal models^[88]. Pentney *et al.*^[89] reported that daily melatonin administration reduced the severity of dextran sodium sulphate (DSS)-induced colitis in mice. In these experiments, serum melatonin levels were more than 10 times higher in mice that received DSS, as compared to controls. It is presently unclear what causes the significant improvement of inflammation in melatonin-treated mice, as no receptor antagonists were employed in this study and no downstream mechanisms were investigated. Melatonin has been reported to reduce the severity of experimental colitis in mice and rats and though *in vitro* and *in vivo* studies suggest numerous pathways involved, the exact mechanism of action remains unclear^[90]. In experimental colitis in rats, melatonin reduced colon injury by influencing numerous events including the enzyme activities of matrix metalloproteinase-9 (MMP-9), MMP-2 and caspase-3, by suppressing the activities of cyclooxygenase-2 (COX-2) and iNOS, inhibiting the expression of NF- κ B and acting as a radical scavenger^[91-95].

Moreover, the regulation of macrophage activity^[96] and the reduction of bacterial translocation in trinitrobenzene sulfonic acid (TNBS)-induced colitis have been reported^[97]. Melatonin treatment also causes a substantial reduction of *FasL* gene activation, which is known to induce a pro-inflammatory response characterized by a release of IL-1b, macrophage inflammatory protein-1a (MIP-1a), MIP-1b and MIP-2. Blocking the action of these cytokines has been shown to delay the onset of experimental colitis, to suppress inflammation and to ameliorate colonic damage^[98]. But melatonin does not exert unanimously protective effects. Marquez *et al.*^[99] reported that acutely administered melatonin is protective against TNBS-induced colitis in rats, whereas chronic melatonin treatment exaggerates colitis. Future studies are needed to clarify the full extent of melatonin protection against colitis and to characterize the involved mechanisms.

ROLE OF MELATONIN IN DISEASES INVOLVING THE ILEUM AND THE COLON

Irritable bowel syndrome

Irritable bowel syndrome (IBS) is a functional GI disorder characterized by abdominal pain and is diagnosed following the Rome III criteria. Multiple factors are involved in the pathophysiology of IBS; amongst others IBS has been associated with abnormal GI motor functions, visceral hypersensitivity, as well as psychosocial factors^[100,101].

Some studies suggest a possible role of melatonin in the pathophysiology of IBS. For example, disturbances in melatonin metabolism and secretion may be involved in different GI diseases including IBS^[102]. In a clinical trial involving patients with IBS, the beneficial effects of melatonin were obvious in the relief of symptoms such as abdominal pain, abdominal distension and abnormal sensation of defecation^[103]. Melatonin may exert its beneficial effects in IBS through effects on the central nervous system, *via* an enhancement of the cellular and humoral immune systems, or by antagonizing corticoid- and serotonin-mediated effects^[104,105]. However, melatonin does not influence sleep pattern or psychological well-being in patients with IBS. Recently, it has been shown that the antinociceptive effects of melatonin are not mediated through melatonin receptors, but through a supra-spinal process linked to the central opioidergic system, as pre-treatment with naltrexone or luzindole blocked the antinociceptive effect of melatonin in TNBS-treated rats^[106].

According to recent clinical trials, melatonin may be a future therapeutic option for IBS management (Table 2). In one placebo-controlled, randomized clinical trial in 40 patients with IBS, daily administration of melatonin 3 mg orally at bedtime for two weeks significantly alleviated abdominal pain^[107]. Patients treated with melatonin for two weeks significantly increased rectal thresholds towards balloon pressure and volume, ameliorating rectal sensitivity to pain and urgency. In another clinical trial, 17 female

Table 2 Clinical trials using melatonin in patients with irritable bowel syndrome

Authors	n	Study design	Dose	Conclusion
Lu <i>et al.</i> ^[110]	17	Randomized, crossover placebo-controlled (8 wk) ¹	3 mg/od	CTT did not change significantly in IBS patients with melatonin treatment
Saha <i>et al.</i> ^[109]	18	Randomized, placebo-controlled (8 wk) ¹	3 mg/od	Significant symptomatic benefit on bowel symptoms, extra-colonic symptoms, and quality of life
Lu <i>et al.</i> ^[108]	17	Randomized, crossover placebo-controlled (8 wk) ¹	3 mg/od	Significant symptomatic benefit on IBS scores, anxiety, well-being, and depression scores
Song <i>et al.</i> ^[107]	40	Randomized, placebo-controlled (2 wk) ¹	3 mg/od	Significantly attenuated abdominal pain and reduced rectal pain

¹Treatment duration; od: Once daily; CTT: Colonic transit time; IBS: Irritable bowel syndrome.

IBS patients were randomized to receive either melatonin 3 mg or placebo at bedtime for 8 wk, followed by a 4-wk washout period^[108]. Improvements in mean IBS scores were significantly greater during treatment with melatonin compared to placebo. Additionally, sleep, anxiety and depression scores improved. Saha *et al.*^[109] randomly assigned 18 IBS patients to receive either melatonin 3 mg or placebo at bedtime for 8 wk and they found that melatonin significantly improved overall IBS scores and quality of life scores. All these trials suggest that melatonin has beneficial effects in patients with IBS, but larger clinical trials in patients with IBS are needed. Another clinical trial was interested in colonic transit time (CTT) in IBS patients. These patients were randomized and received either melatonin 3 mg or placebo daily for 8 wk^[110]. Neither in healthy controls, nor in IBS patients, were stool texture or CTT changed, but the tests used may not be sensitive enough to detect motility or secretory changes and thus these data need to be interpreted cautiously.

In some of these clinical trials it has been shown that the beneficial effects of melatonin in IBS may be related to its action on gut sensory pathways. In this context it would be interesting to know whether melatonin alters visceral hypersensitivity or whether it acts as a general analgesic and would reduce rectal sensations in healthy volunteers as well. It is presently not clear whether this melatonin effect on rectal sensation is short-lasting or holds over longer periods of time. Although only a few clinical studies have shown its efficacy, melatonin appears to have a significant role in reduction of abdominal distension and rectal pain in treatment of IBS.

Inflammatory bowel disease

Despite the numerous animal studies showing protective effects of melatonin in colitis models, there are only limited clinical data available on the therapeutic role of melatonin in inflammatory bowel disease (IBD). To our knowledge, there are three published case reports of the self-administration of melatonin in IBD (Table 3). However, no clinical trials have been performed in IBD patients.

In one case report, after the self-administered use of melatonin as a self directed treatment for jet lag on international flights, the patient observed that his ulcerative colitis (UC) symptoms were virtually absent^[111,112]. Once his flare-ups were more troublesome requiring continu-

ous topical mesalamine therapy, he self-administered melatonin 3 mg/d, and according to the report he was symptom-free for a period of 3 mo. His symptoms recurred within 1 wk of running out of melatonin tablets. In contrast, other cases showed melatonin exacerbated symptoms associated with UC or Crohn's disease^[113,114]. One patient decided to take melatonin capsules (3 mg) at bedtime. Two months later, the patient started to experience the symptoms of active UC, including bloody mucous diarrhea. He continued taking melatonin and received corticosteroids orally and rectally. Since the symptoms did not calm down, the patient was hospitalized and stopped consuming melatonin; 48 h later there was a complete remission of the UC symptoms. Another patient decided to take melatonin capsules (3 mg) at bedtime. Four days later, the patient started to experience the symptoms of active Crohn's disease, such as diarrhea and abdominal cramps. She then stopped taking melatonin, and 24 h later there was a complete remission of symptoms. Clinical trials should be performed to evaluate a possible beneficial or detrimental effect of melatonin in IBD; presently available literature is inconclusive, though basic studies strongly suggest beneficial effects.

Colon cancer

Following the identification of melatonin binding sites in human colon tissue from patients with carcinoma of the rectum and the colon, a possible role of melatonin in colorectal cancer was addressed in several studies. ¹²⁵I-melatonin binding sites were identified in the mucosa and the submucosa of the human colon and radioimmunoassays revealed melatonin concentrations of 467 ± 99 pg/g tissue in non-cancer control patients, while daytime melatonin concentrations in the colon of patients with colorectal carcinoma were 3147 ± 87.8 pg/g tissue^[115]. The relevance of the diurnal variation of melatonin levels to colon cancer has yet to be determined. Colorectal carcinoma patients showed significant decrements in the peak amplitude of melatonin secretion, as well as a reduction in overall melatonin output^[116]. Some studies suggest that melatonin may be involved in cancer risk or protection from cancer development^[117]. For example, following pinealectomy, increased colonic crypt cell proliferation was reported in rats, suggesting melatonin pathways being involved in carcinogenesis in the co-

Table 3 Case reports of melatonin self administration in patients with ulcerative colitis and Crohn's disease

Authors	Age, gender, disease	Treatment	Dose	Result
Maldonado <i>et al</i> ^[113]	56, male, UC	Added melatonin to the otherwise unchanged drug treatment (salazosulfapyridine, corticosteroids)	3 mg/od	Two months later, the patient started to experience the symptoms of active UC, including bloody diarrhea
Jan <i>et al</i> ^[111] Mann ^[112]	47, male, UC	Added melatonin to an existing medication of mesalamine due to ongoing bloody diarrhea	3 mg/od	Symptoms resolved fast (2-3 d) and the beneficial effect was long lasting
Calvo <i>et al</i> ^[114]	35, female, CD	After becoming pregnant, the patient interrupted the treatment with melatonin, corticoids and salazosulfapyridine and symptoms of CD emerged again	3 mg/od	Recurrence of diarrhea and abdominal cramps within 4 d

od: Once daily; UC: Ulcerative colitis; CD: Crohn's disease.

lon^[118]. Another study in rats showed that small bowel crypt cell hyperplasia occurred several weeks after pinealectomy, but again the exact mechanisms were not identified. Recently, melatonin showed a great potential to control the preneoplastic patterns induced by constant light in the colon^[119].

The suggested colon cancer controlling mechanism of melatonin involves inhibition of tumour angiogenesis, modulation of the mitotic and apoptotic indices, and maintenance of the intracellular level of glutathione^[120,121]. Although no effects of melatonin on *in vitro* cell growth were found, a statistically significant and progressive suppression of *de novo* DNA synthesis was found following melatonin application^[122]. Other melatonin effects related to the control of tumour growth are the modulation of estrogen receptors, direct effects on the cell cycle, influence on several growth factors, increasing of gap junctions and enhancing the level of antioxidants^[123,124]. The anti-oxidative and anti-inflammatory actions of melatonin, changing the oxidative status and reducing the production of nitric oxide by cultured colon cancer cells, may also be directly involved in the onco-static properties of melatonin^[125]. Some studies suggest that for colon adenocarcinoma, membrane-bound and nuclear melatonin receptors are involved in these onco-static actions^[126,127]. Melatonin binds to receptors on T helper cells and monocytes, stimulating the production of IFN γ and interleukins 1, 2, 6 and 12, which in turn up-regulates immune responses resulting in a restoration of immunodeficiency states^[128]. Melatonin in this context also modulates the expression of NF- κ B, TNF- α , IL-1 β and STAT3^[129]. The activation of lymphocytes and monocytes/macrophages by melatonin is one of the mechanisms by which melatonin as an immunosurveillant prevents tumor development^[130,131]. For example, patients with advanced GI carcinoma treated with a combination of IL-2 and melatonin exhibited a significantly higher number of lymphocytes, T lymphocytes, NK cells and CD4⁺ cells than those receiving IL-2 alone^[132].

In clinical trials, melatonin was shown to have cytoprotective effects that may be involved in increasing the efficacy of cancer chemotherapy and improving survival. Melatonin co-treatment was also shown to reduce the adverse toxicities of chemotherapy and radiotherapy in

several studies, including in patients with colorectal carcinoma^[133,134]. For example, the efficacy of weekly low-dose CPT-11 in pretreated metastatic colorectal cancer patients may be enhanced by a concomitant daily administration of melatonin (20 mg/d, orally)^[135]. Other clinical studies showed that melatonin co-treatment with IL-2, *Aloe vera* or fish oil partly enhanced the effect of chemotherapy and reduced the toxicity in colorectal carcinoma^[136-139]. However, melatonin did not have any protective effect on irradiation-induced lymphocytopenia in patients with colorectal carcinoma (Table 4)^[140].

Clinical trials using melatonin in the context of colorectal cancer are small and unfortunately not of high quality. Presently, these studies have to be carefully interpreted and the studies seem, if anything, to be hypothesis-generating. Controlled clinical trials are needed to establish the potential role of melatonin in cancer treatment.

CONCLUSION

Melatonin found in the lower gut comes largely from intestinal sources, such as the EC cells and, to only a minor extent, from extra-intestinal sources such as the pineal gland. Melatonin levels in the ileum and the colon are dependent on food intake and digestion, but in contrast to systemic melatonin levels, the GI melatonin level is independent of light or the circadian rhythm.

Melatonin regulates the motility of the lower gut by acting on membrane melatonin receptors and all known MT1-3 were found to be localized in the GI tract, though their exact involvement in the regulation is not fully characterized. Additionally, actions of melatonin on 5-HT receptors have been reported, adding to the complexity of melatonin involvement in the regulation of GI function.

Melatonin was recently suggested to be a promising future drug for IBS treatment. Presently available basic and clinical data indicate that it is particularly effective in alleviating hypersensitivity and pain in patients with IBS, but larger clinical trials, ideally double-blinded and placebo-controlled, are needed.

Melatonin is furthermore involved in immunomodulatory functions throughout the GI tract. The protective actions of melatonin in mouse models of intestinal inflammation or in models of GI cancer are promising

Table 4 Clinical trials using melatonin in patients with colorectal cancer

Authors	n	Disease	Study design	Dose	Results and conclusion
Lissoni <i>et al</i> ^[140]	18	Rectal cancer	Randomized to melatonin, melatonin + 5-methoxytryptamine or melatonin + IL-2, 5 wk	20 mg/od	Melatonin had no effect on radiation-induced lymphocytopenia
Lissoni ^[133]	152	CRC	Randomized to oxaliplatin/5-Fu or CPT-11/FS/5-Fu with or without melatonin	20 mg/od	Melatonin significantly reduced the occurrence of cachexia, thrombocytopenia, neurotoxicity and asthenia
Persson <i>et al</i> ^[139]	8	CRC	Randomized to fish oil or melatonin (4 wk) followed by 4 wk fish oil with melatonin	18 mg/od	Melatonin had no effect on serological inflammation markers
Cerea <i>et al</i> ^[135]	30	CRC	Randomized to CPT-11 or CPT-11 plus melatonin 9 wk	20 mg/od	Disease-control higher in CPT-11 + melatonin group
Lissoni <i>et al</i> ^[120]	7	CRC	Daily melatonin for at least 2 mo	20 mg/od	Melatonin may control tumor growth by reducing VEGF secretion
Lissoni <i>et al</i> ^[134]	25	CRC	Randomized to 5-Fu/FS or 5-Fu/FS + melatonin. 5 cycles of 28 d	20 mg/od	Melatonin reduces toxicity and increases efficacy of 5-Fu/FS chemotherapy
Lissoni <i>et al</i> ^[138]	8	CRC	Randomized to melatonin or melatonin + <i>Aloe vera</i> tincture until progression	20 mg/od	Melatonin + <i>Aloe vera</i> stabilized disease and increased survival in end-stage patients
Barni <i>et al</i> ^[137]	50	CRC	Randomized to BSC or BSC combined with low-dose IL-2 + melatonin 4 wk	40 mg/od	Low-dose IL-2 + melatonin induced tumor regression and prolonged survival in second-line treatment
Lissoni <i>et al</i> ^[136]	19	CRC	Randomized to IL-2 or IL-2 + melatonin 4 wk	40 mg/od	Melatonin enhanced the activity of IL-2, induced tumour regression, prolonged progression-free survival and overall survival

CRC: Colorectal cancer; od: Once daily; BSC: Best supportive care; VEGF: Vascular endothelial growth factor.

and warrant further research. The translation of these observations to humans is less well characterized.

localized application into HepG2 tumor *in vivo*.

METHODS: Different hepatoma and colon carcinoma cell lines (HepG2, HuH7, Chang liver, LoVo, RKO, SW-48, SW-480) were grown in minimal essential medium supplemented with 10% fetal bovine serum and 1% antibiotic/antimycotic solution and maintained in a humidified 37 °C incubator with 5% CO₂. These cells were pretreated with BSO for 24 h and then with AZA for different times. We examined the effects of this combination on some proteins and on cellular death. We also studied the efficacy and the safety of AZA (6 mg/kg per day) and BSO (90 mg/kg per day) in HepG2 tumor growth *in vivo* using athymic mice. We measured safety by serological markers such as amino-transferases and creatine kinase.

RESULTS: The *in vitro* studies revealed a new mechanism of action for the AZA plus BSO combination in the cancer cells compared with other thiopurines (6-mercaptopurine, 6-methylmercaptopurine, 6-thioguanine and 6-methylthioguanine) in combination with BSO. The cytotoxic effect of AZA plus BSO in HepG2 cells resulted from necroptosis induction in a mitochondrial-dependent manner. From kinetic studies we suggest that glutathione (GSH) depletion stimulates c-Jun amino-terminal kinase and Bax translocation in HepG2 cells with subsequent deregulation of mitochondria (cytochrome c release, loss of membrane potential), and proteolysis activation leading to loss of membrane integrity, release of lactate dehydrogenase and DNA degradation. Some of this biochemical and cellular changes could be reversed by N-acetylcysteine (a GSH replenisher). *In vivo* studies showed that HepG2 tumor growth was inhibited when AZA was combined with BSO.

CONCLUSION: Our studies suggest that a combination of AZA plus BSO could be useful for localized

Abstract

AIM: To evaluate the efficacy and the safety of azathioprine (AZA) and buthionine sulfoximine (BSO) by

treatment of hepatocellular carcinoma as in the currently used transarterial chemoembolization method.

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is increasing, and currently there are approximately 1 million new cases annually worldwide^[1]. Classical curative options available are surgical resection or liver transplantation^[2]. For unresectable HCC, an effective treatment is transarterial chemoembolization (TACE)^[3]. In TACE, the branch of the hepatic artery supplying the tumor is occluded at the time of arteriography by injection of lipidol and/or gelatin-sponge particles, which results in necrosis of the tumor. To increase that effect, chemotherapeutic agents (e.g., doxorubicin, epirubicin, mitomycin c, cisplatin or 5-fluorouracil) are often mixed with lipidol^[3]. A significant number of patients benefit from treatment with TACE^[3]. For further progress in this encouraging treatment, other antitumor drugs are needed. One of the problems in treating HCC is chemoresistance, therefore the majority of systemic therapies have been disappointing. For years researchers have observed that an elevation in intracellular glutathione (GSH) has been associated with resistance to irradiation and to chemotherapy, and correspondingly, the diminution of GSH levels is associated with sensitization to both types of therapy^[4]. Azathioprine (AZA) and buthionine sulfoximine (BSO) are medicines which decrease GSH levels by different mechanisms. Azathioprine belongs to the family of thiopurines with cytostatic activity, which is used in the treatment of autoimmune diseases, organ transplantation and in acute lymphoblastic leukemia^[5]. The first step in AZA activation consumes GSH, leading to release of 6-mercaptopurine from the imidazole moiety in an enzymatic reaction catalyzed by several glutathione-S-transferase (GST) isoforms^[5]. BSO is a competitive inhibitor of γ -glutamylcysteine synthetase (GCS), the rate-limiting step in the biosynthetic pathway

of GSH production^[6]. With the aim of treating tumors that overexpress glutathione (e.g., hepatocarcinoma), several groups undertook phase I clinical studies with BSO to evaluate whether modulation of GSH could be clinically useful^[7]. In these preliminary studies, the drug proved to be well tolerated and safe, which prompted us to study the effect of BSO combined with AZA: (1) on cell death of HCC cell lines (Hep G2, Huh7 and Chang cells) in culture; and (2) on the volume of the tumor obtained by injection of HepG2 into athymic mice *in vivo*. These results were compared with colon cancer cell lines (Lovo, SW-480, RKO and SW-48).

MATERIALS AND METHODS

Materials

AZA was a gift from UCB Pharma SA (Madrid, Spain). Antibodies against phospho-p54/46 JNK (c-jun N-terminal kinase), p-p38 MAPK (mitogen-activated protein kinase), JNK, p38 MAPK and α -tubulin were from Cell Signaling Technology Inc. (Beverly, Massachusetts) and antibodies against Bax, Bid, Bad, Bcl-2, cytochrome c, procaspase-3, GCS, nucleoporin and poly (ADP-ribose) polymerase (PARP) were from Santa Cruz Biotechnology Inc. (Santa Cruz, CA). p-38 MAPK inhibitor [SB203580, 4-(4-fluorophenyl)-2-(4-methylsulfinylphenyl)-5-(4-pyridyl)-1H-imidazole], JNK inhibitor (SP600125, 1,9-pyrazoloanthrone) were from Calbiochem (Barcelona, Spain). 3-(4,5-dimethylthiazol-2-yl)-2,5 diphenyl tetrazolium bromide (MTT), DL-buthionine-[S,R]-sulfoximine (BSO), 6-mercaptopurine and 6-methylmercaptopurine were from Sigma Chemical Co. (Madrid, Spain). 2-amino-6-mercaptopurine and 2-amino-6-methylmercaptopurine were from ICN Biomedicals Inc. (Ohio, United States). Z-VAD-mfk caspase-3 inhibitor was from Bachem (Heidelberg, Germany). Ac-DEVD-AMC was from Alexis Biochemicals (San Diego, California). OxyBlot™ Protein Oxidation Kit was from Millipore (Billerica, Massachusetts). All other reagents were of the highest grade of purity available.

Cell culture

HepG2, HuH7 and Chang cells, LoVo, SW-480, RKO and SW-48 cells were from ATCC and were grown in minimal essential medium (MEM) supplemented with 10% fetal bovine serum and 1% antibiotic/antimycotic solution and maintained in a humidified 37 °C incubator with 5% CO₂.

Metabolic activity and cell viability

The MTT reduction assay was performed as described previously^[8]. Cell viability was determined by the trypan blue exclusion assay as previously described^[9].

Analysis of GSH

Intracellular GSH levels were determined fluorometrically as described previously^[10].

Lactate dehydrogenase release assay

Cellular supernatants were mixed with lactate dehydro-

genase (LDH) substrate (0.2 mol/L Tris-HCl buffer, pH 8.2, containing 2.5 mg/mL L-lactate, 2.5 mg/mL NAD⁺, 0.1% (v/v) Triton X-100, 1-methoxyphenazine methosulfate and MTT). The formazan formed was measured at a wavelength of 570 nm and reference of 655 nm^[8].

DNA fragmentation gel assay

The study of DNA fragmentation was performed as previously described^[11].

Western blotting

Total cell protein was extracted as described previously^[11]. The proteins were determined by the Bradford method and were loaded onto sodium dodecyl sulfate polyacrylamide gel electrophoresis gel and transferred to nitrocellulose membranes overnight at 25 V and 4 °C. The immunoblots were developed as previously described^[11].

Cytometry

Mitochondrial impairment was estimated using a JC-1 probe (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide/chloride) as previously described^[12]. Cell cycle analysis using propidium iodide staining was performed as described previously^[12].

Caspase-3 activity analysis

Cells were lysed in 10 mmol/L Tris-HCl buffer (pH 7.5) containing NaH₂PO₄/NaHPO₄ (10 mmol/L), Triton-X-100 (1%), NaCl (130 mmol/L) and sodium pyrophosphate (10 mmol/L). The cell lysates were incubated for 60 min at 37 °C in a 20 mmol/L HEPES buffer (pH 7.5) containing, glycerol (10%), DTT (2 mmol/L) and the specific fluorogenic substrate Ac-DEVD-AMC. Cleavage of the fluorescent caspase-3 substrate was monitored using a fluorescence plate reader at excitation/emission wavelengths of 355/460 nm.

Analysis of in vivo tumor growth inhibition

Nude mice were subcutaneously inoculated with 10⁷ HepG2 cells. After solid tumor formation (i.e., tumor volume 100 mm³), the tumor-bearing nude mice were randomized into four experimental groups, each one with eight mice. These groups were treated by peritumoral injection with 0.1 mL dimethyl sulfoxide (DMSO) (5%), BSO (90 mg/kg per day), AZA (6 mg/kg per day) or BSO (90 mg/kg per day) plus AZA (6 mg/kg per day), respectively. The BSO treatment was daily, while the AZA treatment was given on alternate days for a total of 12 d. Tumor size was measured every day. At the end of the experiment, all the animals were sacrificed. Plasma levels of creatine kinase, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were also determined, following the procedures stated by the provider (Spinreact).

Statistical analysis

Statistical analysis was performed using the GraphPad Prism package (GraphPad Software Inc., San Diego,

CA). Values are reported as mean ± SE and evaluated by the analysis of variance. The statistical significance was set at $P < 0.05$.

RESULTS

Effect of AZA treatment on viability and metabolic activity of HepG2 cells

We treated HepG2 cells for 24 h, 48 h or 72 h with DMSO (0.2%) or AZA (75, 150, 300, 600 or 1000 μmol/L) dissolved in 0.2% DMSO. Figure 1A shows that AZA decreased cell viability (measured by Trypan blue exclusion assay) at 600 μmol/L and 1000 μmol/L without significant changes in cell viability at lower drug concentrations. Similarly, azathioprine significantly inhibited metabolic activity (measured by the MTT assay) in a dose- and time-dependent manner (Figure 1B). The metabolic activity was more sensitive to the effect of AZA than the cell viability. In fact with AZA at 300 μmol/L we observed a loss in metabolic activity without changes in cell viability compared with control cells (DMSO). The comparison of MTT and Trypan blue exclusion assays, suggest that AZA produced inhibition of cell proliferation and/or loss of mitochondrial activity up to 300 μmol/L and induced toxicity at higher concentrations (600 μmol/L and 1000 μmol/L). In any case, our results show that HepG2 cells are very resistant to AZA treatment unlike human hepatocytes in culture (data not shown).

Sensitization of HepG2 cells to azathioprine by BSO pretreatment

When HepG2 cells were pretreated for 24 h with BSO (500 μmol/L) and then co-treated with AZA (0, 75 μmol/L, 150 μmol/L, 250 μmol/L, 300 μmol/L, 600 μmol/L or 1000 μmol/L) for 24 h (Figure 1C), metabolic activity noticeably decreased (IC₅₀ = 80 μmol/L) with respect to those cells treated with AZA alone (IC₅₀ = 800 μmol/L). The pretreatment with BSO potentiated the efficiency of azathioprine 10-fold in decreasing the metabolic activity of HepG2 cells. In the same way, HepG2 pretreated cells for 24 h with BSO (500 μmol/L) and then co-treated with AZA (100 μmol/L) for 3 h, 6 h, 12 h or 24 h showed a time-dependent inhibition of metabolic activity, in contrast to those cells that did not receive BSO (Figure 1D). Pretreatment with BSO significantly decreased basal levels of GSH (Figure 1E). Kinetic studies underlined that AZA treatment decreased GSH content in a time-dependent manner both in BSO-pretreated cells and in control cells (Figure 1F). However, the effect of AZA on GSH levels was higher in BSO-sensitized cells compared with control cells, which suggested that the compounds had synergic effects in regulation of GSH levels.

In order to localize the compartment affected by GSH depletion, we studied the presence of oxidized proteins (by OxyBlot) in different cellular fractions (cytosol, mitochondria and nucleus) obtained from drug-treated cells (Figure 2A). The treatment with AZA (300 μmol/L) plus BSO (500 μmol/L) increased the oxidized proteins

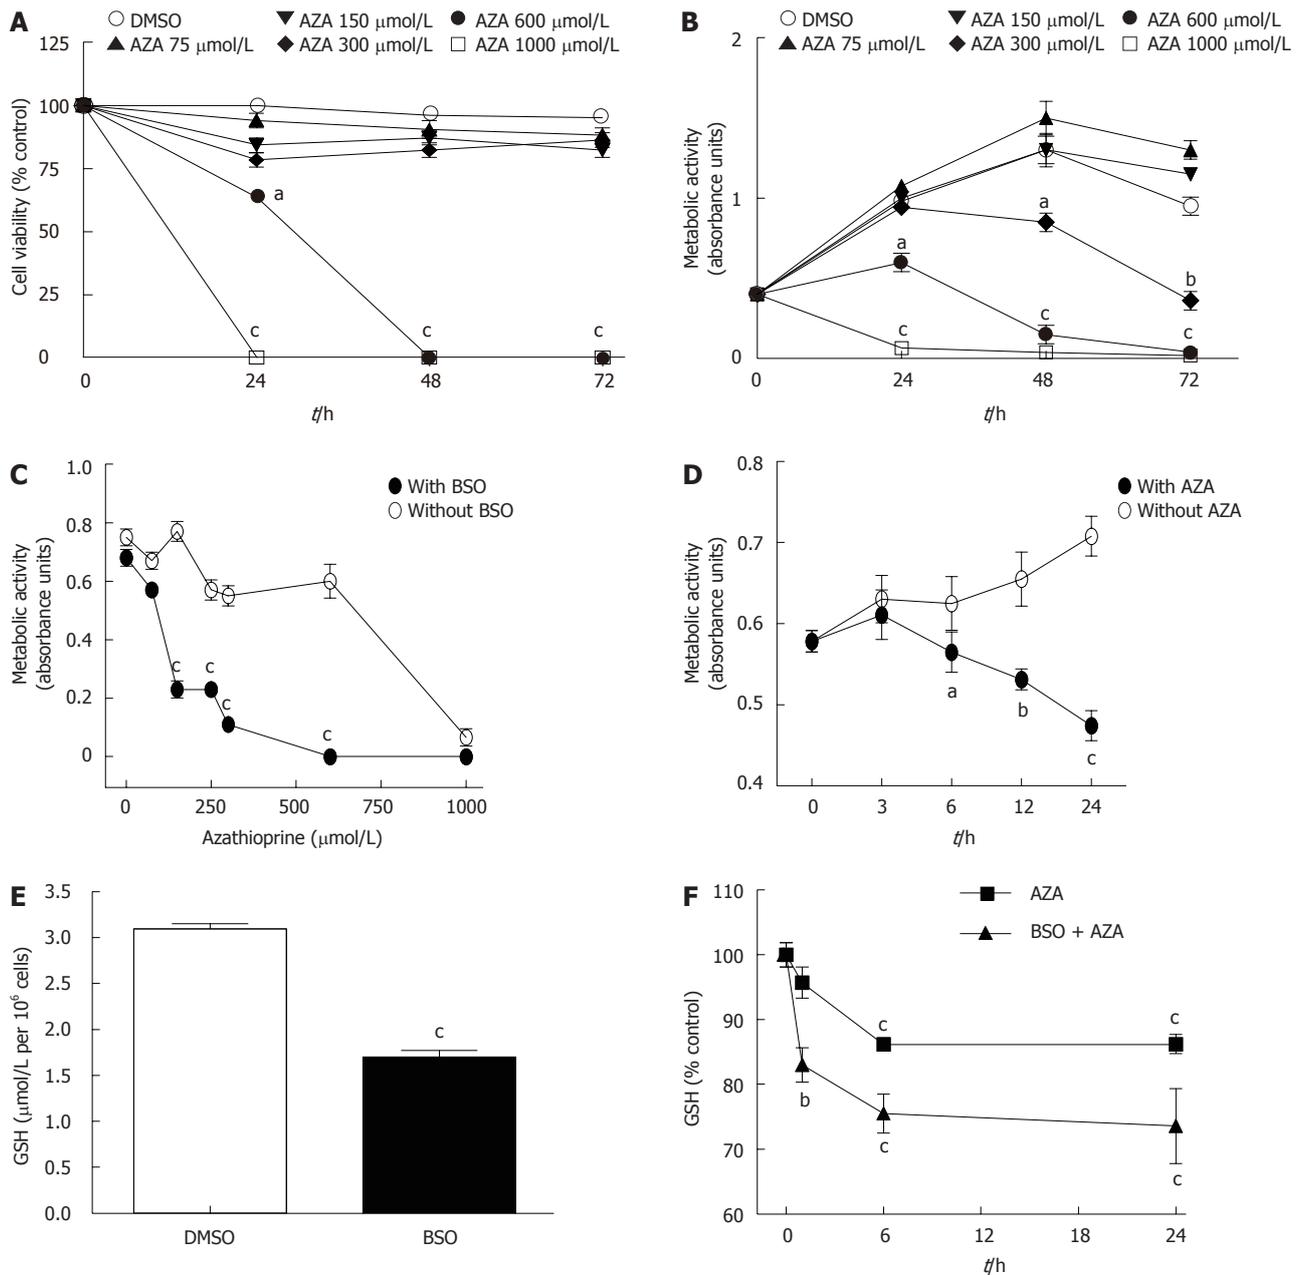

Figure 1 Effect of azathioprine treatment in HepG2 cells and sensitization of HepG2 cells by buthionine sulfoximine pretreatment. A: Cell viability (by trypan blue exclusion assay); B: Metabolic activity (by MTT assay) of HepG2 cells treated at different times with dimethyl sulfoxide (DMSO) or azathioprine (AZA) at different concentrations; C: Metabolic activity of cultured HepG2 cells pretreated for 24 h without or with buthionine sulfoximine (BSO) (500 $\mu\text{mol/L}$) and then cotreated with AZA at different concentrations for 24 h, or D with AZA (100 $\mu\text{mol/L}$) at different times; E: Glutathione (GSH) content of HepG2 cells pretreated for 24 h with DMSO or BSO (500 $\mu\text{mol/L}$); F: GSH content of HepG2 cells pretreated for 24 h with DMSO or BSO (500 $\mu\text{mol/L}$) and then cotreated with AZA (300 $\mu\text{mol/L}$) for different times. The significant differences with respect to control were statistically analyzed by analysis of variance with the Bonferroni post hoc test. ^a $P < 0.05$; ^b $P < 0.01$; ^c $P < 0.001$.

in all fraction studied compared with cells treated with BSO (500 $\mu\text{mol/L}$). This effect was partially reversed by cotreatment with N-acetylcysteine (NAC, 1.5 mmol/L), a GSH replenisher. The levels of nucleoporin, PARP and cytochrome c were used as markers for the nucleus (nucleoporin and PARP) and mitochondria (cytochrome c). Interestingly, treatment with AZA plus BSO induced the depletion of nucleoporin and cytochrome c in the nucleus and in the mitochondria, respectively (Figure 2A). These effects were partially reversed by NAC.

Effect of AZA plus BSO combined on the metabolic activity of HCC cell lines and colon cancer lines

Treatment with AZA (300 $\mu\text{mol/L}$) plus BSO (500 $\mu\text{mol/L}$), decreased the metabolic activity in all cell lines (HepG2, Huh-7, Chang cells, LoVo, SW-480, RKO, SW-48) tested in comparison with control treatment (DMSO) (Figure 2B).

Effect of thiopurines plus BSO combined on the metabolic activity of HepG2 and colon cancer lines

Pretreatment with BSO (24 h) and subsequent treatment

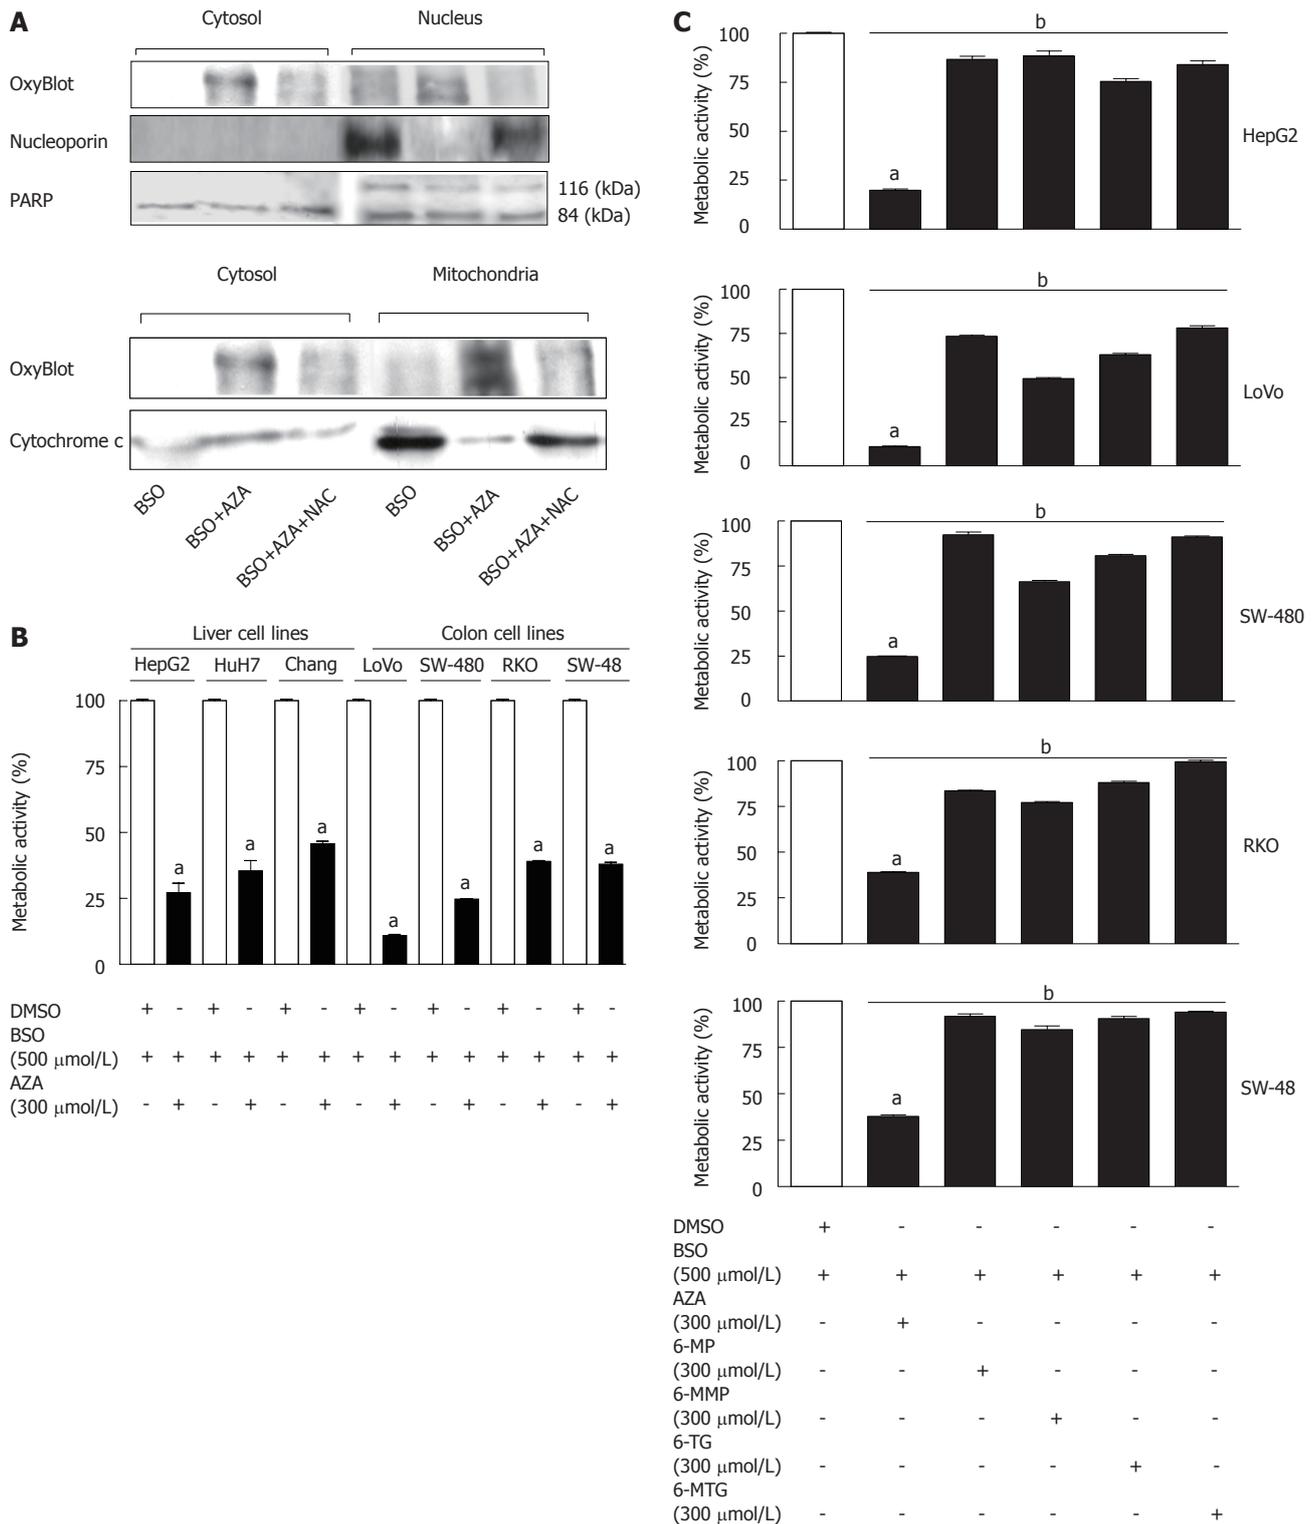

Figure 2 Effect of the treatment with thiopurines plus buthionine sulfoximine in cancerous cell lines. A: Western blotting of several proteins from enriched fractions of cytosol, nucleus and mitochondria obtained from HepG2 cells pretreated with buthionine sulfoximine (BSO) (500 μmol/L, 24 h), or pretreated with BSO (500 μmol/L, 24 h) and then cotreated with azathioprine (AZA) (300 μmol/L) for 6 h with or without N-acetylcysteine (NAC) (1.5 mmol/L); B: Metabolic activity (by MTT assay) in different cancer cell lines from liver and colon pretreated with BSO (24 h) and then cotreated with dimethyl sulfoxide (DMSO) or with AZA for 12 h; C: Metabolic activity (by MTT assay) in different cell lines pretreated with BSO (24 h) and then cotreated with AZA or with different thiopurines for 12 h. Significant differences with respect to control (DMSO plus BSO) were statistically analyzed by analysis of variance with the Bonferroni *post hoc* test. ^a*P* < 0.001, BSO plus AZA vs control. ^b*P* < 0.001, BSO plus AZA vs BSO plus different thiopurines.

with thiopurines (6-mercaptopurine, 6-methylmercaptopyrimidine, 6-thioguanine or 6-methylthioguanine) for

12 h caused a slight decrease in the metabolic activity of HepG2 cells with respect to control (cells treated with

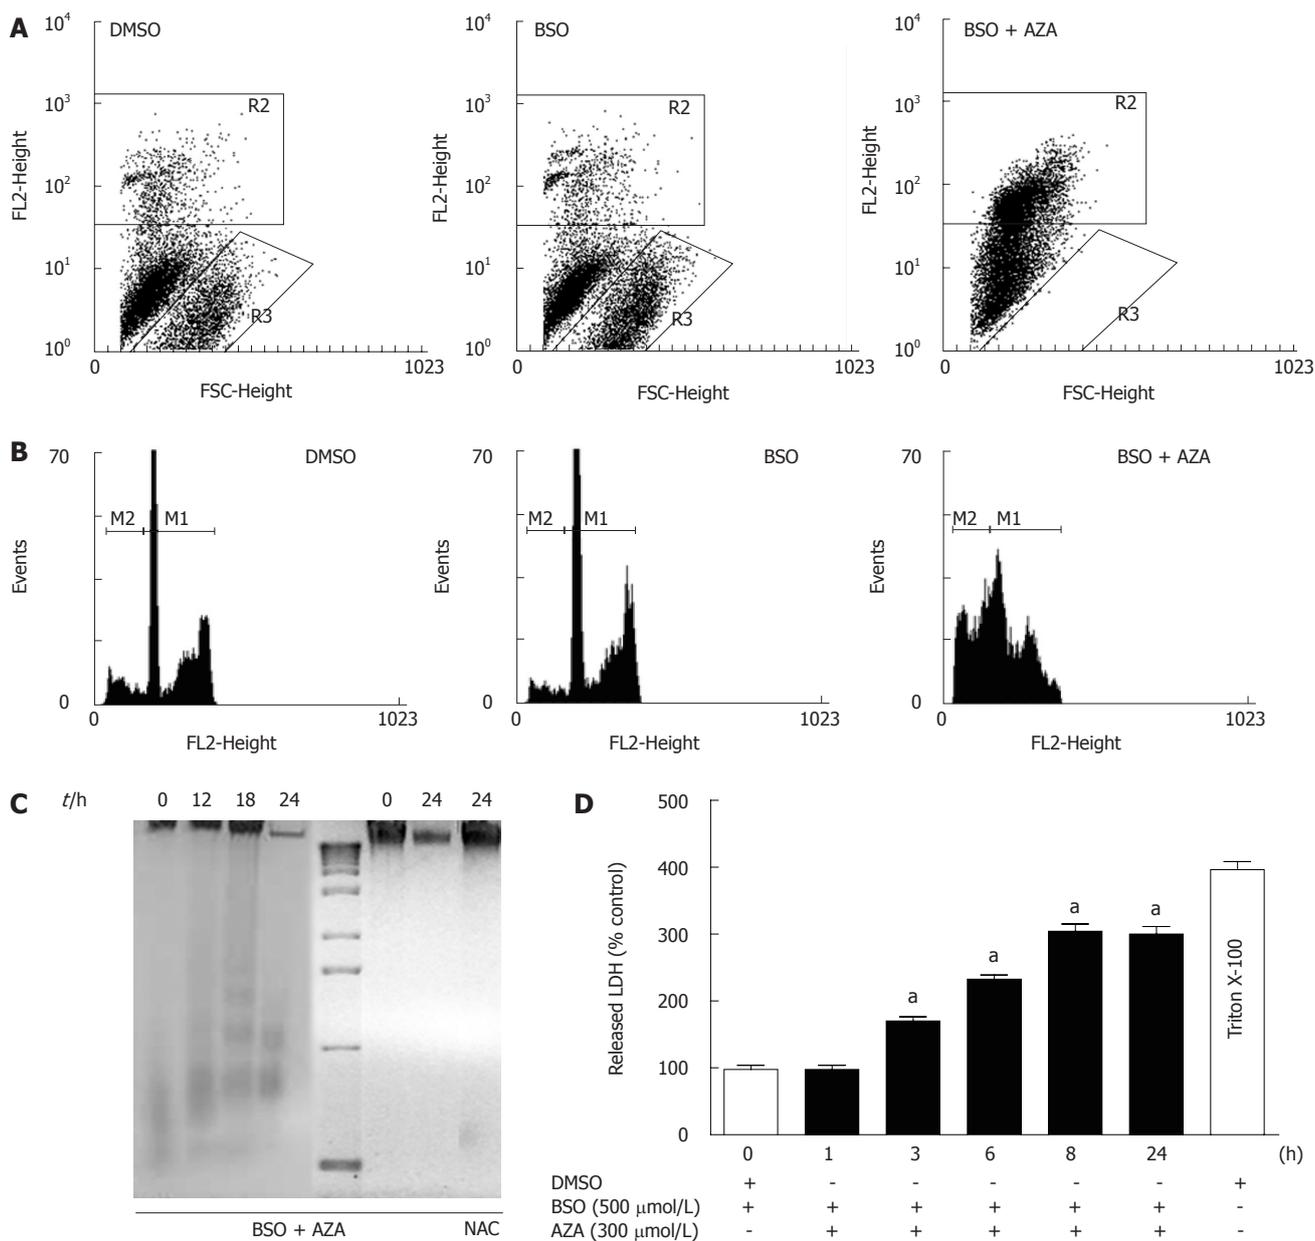

Figure 3 Effect of azathioprine plus buthionine sulfoximine treatment on cell viability, DNA fragmentation and lactate dehydrogenase release. A: Cell viability of HepG2 cells treated with dimethyl sulfoxide (DMSO) (24 h), buthionine sulfoximine (BSO) (500 $\mu\text{mol/L}$, 24 h) or pretreated with BSO (500 $\mu\text{mol/L}$, 24 h) and then cotreated with azathioprine (AZA) (300 $\mu\text{mol/L}$, 24 h); B: Study of cell cycle of HepG2 cells treated in the same conditions; C: DNA fragmentation of HepG2 cells pretreated with BSO (500 $\mu\text{mol/L}$, 24 h) and then cotreated with AZA (300 $\mu\text{mol/L}$) at different times with or without N-acetylcysteine (NAC) (1.5 mmol/L); D: Time course of lactate dehydrogenase (LDH) released by HepG2 cells pretreated with BSO (24 h) and then cotreated with AZA at different times. Triton X-100 (0.2%) used as control. Significant differences with respect to control (DMSO plus BSO) were statistically analyzed by analysis of variance with the Bonferroni *post hoc* test. ^a $P < 0.001$.

BSO) (Figure 2C); the effect of the preceding treatment with thiopurines on metabolic activity was very modest compared with the effect of AZA (Figure 2C). We observed significant differences between AZA and the other thiopurines studied. Subsequent studies were performed using AZA.

Effect of AZA plus BSO on necrosis and apoptosis parameters

Pretreatment of HepG2 cells for 24 h with BSO (500 $\mu\text{mol/L}$) and subsequent treatment with AZA (300 $\mu\text{mol/L}$)

for 24 h resulted in a significant loss of cell viability with respect to cells treated with BSO or with DMSO, as measured by staining of live cells with propidium iodine (Figure 3A). The R₃ area corresponded to viable cells and R₂ to non viable cells. Pretreatment of HepG2 cells with BSO (500 $\mu\text{mol/L}$) did not significantly change their viability compared with DMSO-treated cells (Figure 3A). To determine the mode of cell death, cell cycle analysis was performed by staining Triton X-100 permeabilized cells with propidium iodine followed by flow cytometry analysis (Figure 3B). In the presence of BSO

(500 $\mu\text{mol/L}$) and AZA (300 $\mu\text{mol/L}$), we observed a significant increase in the sub-G1 population (M2) with respect to cells treated with BSO or with DMSO alone. No significant differences were observed between cells treated with DMSO or with BSO (Figure 3B). These data suggested that the significant decrease in both metabolic activity and viability of cells treated with BSO and AZA was due in part to an increase in nuclear fragmentation characteristic of late apoptosis and early necrosis. To quantify the contribution of apoptosis and necrosis in cell death induced by BSO (500 $\mu\text{mol/L}$) plus AZA (300 $\mu\text{mol/L}$), we studied oligonucleosomal DNA fragmentation (Figure 3C) and LDH release (Figure 3D), respectively. The combined drug treatment induced a slight DNA laddering at 18 h treatment. After this period of time, treatment with BSO plus AZA induced extensive DNA degradation which was characteristic of necrosis. This degradation was prevented by the presence of NAC (1.5 mmol/L) (Figure 3C). Next we studied LDH release (Figure 3D). Our results showed that LDH release was statistically significant after 3 h combined drug treatment compared with control treatment. After 8 h treatment in the same conditions, we observed approximately 75% of necrotic cell death compared with control necrosis (HepG2 cells in the presence of Triton X-100) (Figure 3D). To obtain a new insight in the role of mitochondria in the cell death induced by the combination of BSO (500 $\mu\text{mol/L}$) and AZA (150 $\mu\text{mol/L}$ or 300 $\mu\text{mol/L}$), we evaluated: (1) annexin V bound to phosphatidylserine on the surface of Hep G2 cells; and (2) the mitochondrial functionality through JC-1 probe aggregation. Figure 4 shows that treatment of cells with BSO plus AZA: (1) increased the percentage of cells positive for annexin V (Q2 quadrant) in a dose-dependent manner: from 37% in control cells (DMSO), to 64% in cells treated with 500 $\mu\text{mol/L}$ BSO plus 150 $\mu\text{mol/L}$ AZA, then to 92% in cells treated with 500 $\mu\text{mol/L}$ BSO plus 300 $\mu\text{mol/L}$ AZA; and (2) decreased the percentage of cells with intact mitochondrial membrane potential, in a dose-dependent manner: from 85% in control cells (DMSO) to 68% in 500 $\mu\text{mol/L}$ BSO plus 150 $\mu\text{mol/L}$ AZA, then to 2% in 500 $\mu\text{mol/L}$ BSO plus 300 $\mu\text{mol/L}$ AZA. Annexin V staining was calculated as a percentage of R1 (cells with the mitochondrial membrane potential intact). R2 represented cells without an intact membrane potential mitochondrial. We obtained very similar proportions of cells stained with annexin V and JC-1 after treatment with DMSO (control cells) or with BSO (500 $\mu\text{mol/L}$) (data not shown).

It is very interesting to emphasize the recovery effect of NAC. Cells treated with BSO (500 $\mu\text{mol/L}$) and AZA (300 $\mu\text{mol/L}$) in the presence of NAC (1.5 mmol/L) showed a larger percentage of cells with intact mitochondrial membrane potential (68%) than cells treated with BSO and AZA in the absence of NAC (2%). However, a high percentage (82%) of annexin V-positive cells were observed in the NAC-treated cells, which suggest that they were at the beginning of apoptosis (Figure 4).

Effect of AZA plus BSO in cellular signaling

HepG2 cells were pretreated for 24 h with MEM or BSO (500 $\mu\text{mol/L}$), then were treated with or without SP600125 (a JNK specific inhibitor) or SB203580 (a p38 specific inhibitor), in the presence or in the absence of AZA (300 $\mu\text{mol/L}$) for 1 h (Figure 5A). In contrast to BSO, treatment with AZA induced p38 phosphorylation, which indicated enzyme activation. This effect increased in those cells treated with both AZA and BSO, and JNK1/JNK2 phosphorylation was also observed. The treatment of cells with SB203580 decreased both p38 and JNK1/JNK2 phosphorylation. SP600125 decreased JNK1/JNK2 phosphorylation and also p38 phosphorylation, which suggests a linked control mechanism between both pathways. On the other hand, NAC treatment inhibited both p38- and JNK1/JNK2-induced phosphorylation by AZA and BSO (Figure 5A).

In the next set of experiments (Figure 5B), we pretreated HepG2 cells for 24 h with BSO (500 $\mu\text{mol/L}$) and then with AZA (300 $\mu\text{mol/L}$) at different times (1, 3, 6, 8, 12 h), and we found that Bad, Bid and Bcl-2 remained constant, but Bax increased at 1 h and 3 h. There was general protein degradation at 24 h of treatment that affected Bad, Bid and β -tubulin (Figure 5B). Also we studied cytochrome c release from mitochondria. The maximum release of occurred at 3 h of AZA treatment and was attenuated by cotreatment with NAC (1.5 mmol/L) (Figure 6A). Next we examined the oxidation of proteins, with "OxyBlot kit", in cells pretreated with BSO (500 $\mu\text{mol/L}$) for 24 h and cotreated with AZA (300 $\mu\text{mol/L}$) at different times. The experiment showed oxidation of 53 kDa and 67 kDa bands at 6 h, but after this period of time, we observed decreased protein oxidation (Figure 6B). The protein oxidation was reversed by NAC (Figure 6D).

We studied the proteolysis of procaspase-3, GCS and PARP by Western blotting (Figure 6B). Pretreatment with BSO (500 $\mu\text{mol/L}$, 24 h) and then cotreatment with AZA (300 $\mu\text{mol/L}$) at different times, induced procaspase-3 dimerization (65 kDa band) but we did not observe fragmentation. The substrates of caspase-3, GCS and PARP, were fragmented with the combined treatment of BSO (500 $\mu\text{mol/L}$) plus AZA (300 $\mu\text{mol/L}$) (Figure 6B), however their proteolysis profiles did not correlate with those obtained in a classical model of caspase-3 activation, as observed for Hep G2 cells treated with actinomycin D (0.8 $\mu\text{mol/L}$) plus tumor necrosis factor- α (35 pmol/L) for 18 h (Figure 6C). We observed that NAC inhibited the proteolysis of procaspase-3, GCS and PARP induced by AZA plus BSO (Figure 6E). However, Z-VAD-mfk (a caspase-3 inhibitor) did not have any significant effect on proteolysis of procaspase-3, GCS and PARP (Figure 6E). The protective role of GSH in Hep G2 cell death induced by BSO plus AZA treatment and the absence of caspase-3 activation in this model is shown in Table 1.

Effect of AZA plus BSO in the development of the xenograft in nude mice

HepG2 cells were subcutaneously injected into nude mice,

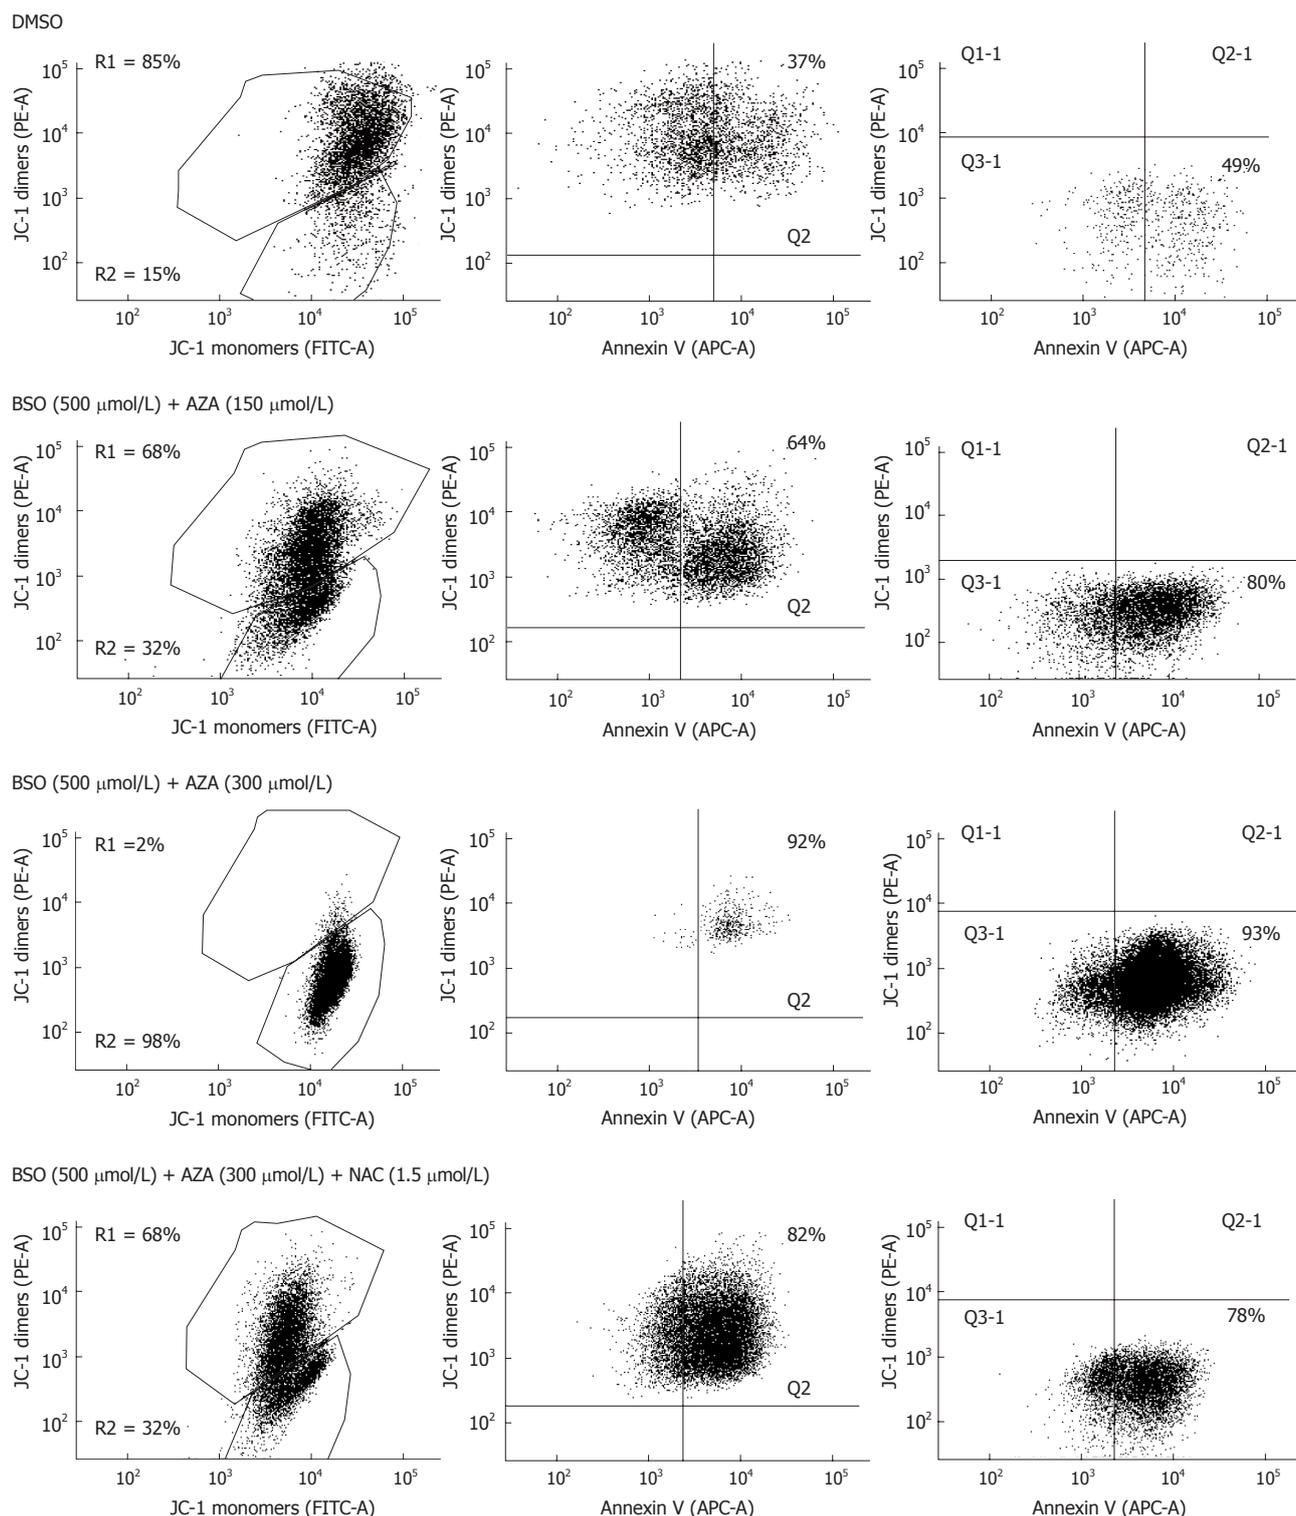

Figure 4 Analysis by flow cytometry of HepG2 cells apoptosis (annexin V) and of mitochondrial functionality (JC-1). Cells treated with dimethyl sulfoxide (DMSO) (24 h), or pretreated with buthionine sulfoximine (BSO) (24 h) and then cotreated with azathioprine (AZA) (24 h) in absence or presence of N-acetylcysteine (NAC). This experiment is representative of three others with similar results.

and the tumor size was measured every day. From the 7th day of BSO (90 mg/kg per day) plus AZA (6 mg/kg per day) treatment, the tumor volume was significantly decreased by a mean of 35% when compared with vehicle, DMSO (Figure 7A). These results showed no statistically significant differences ($P > 0.05$) between control (DMSO)

and BSO (90 mg/kg per day) treatment or between control (DMSO) and AZA (6 mg/kg per day) treatment (Figure 7A). GSH levels decreased in the tumors in BSO and AZA plus BSO groups compared with the corresponding control group (DMSO) (Figure 7C). Tumor cytolysis in the AZA plus BSO group was accompanied by a signifi-

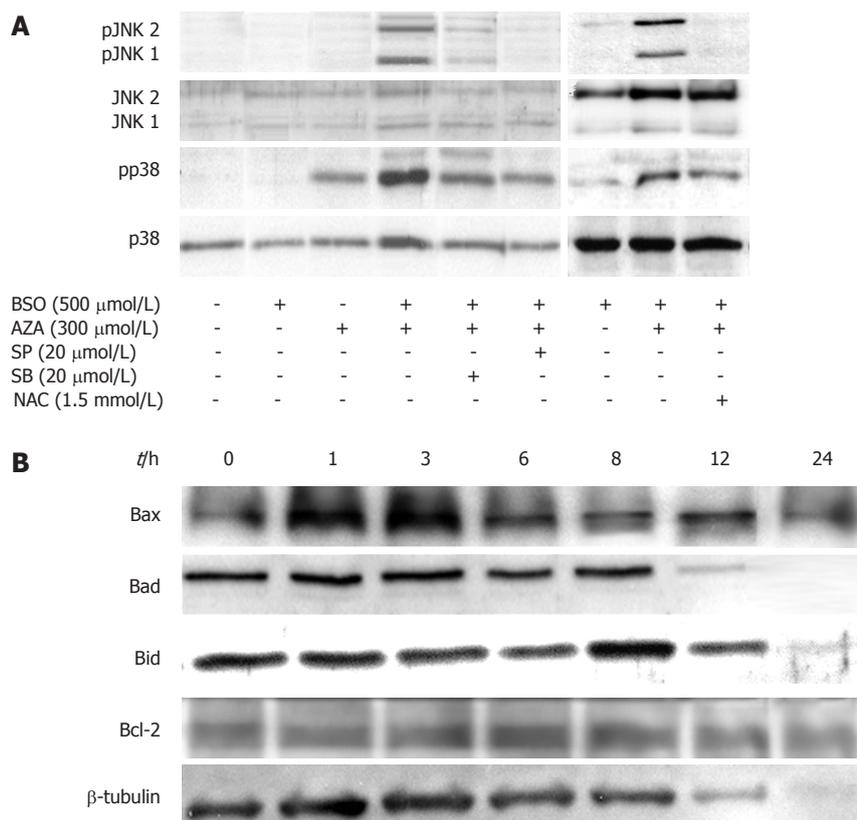

Figure 5 Effect of azathioprine plus buthionine sulfoximine treatment on cellular signaling. A: Stress activated kinases from HepG2 cells pretreated with buthionine sulfoximine (BSO) (24 h) and then cotreated with different combinations of azathioprine (AZA) with SP600125, SB203580 or N-acetylcysteine (NAC) for 1 h; B: Time course of mitochondrial regulatory proteins from HepG2 cells pretreated with BSO (500 $\mu\text{mol/L}$, 24 h) and then treated with AZA (300 $\mu\text{mol/L}$) at different times. This set of experiments is representative of three others with similar results.

Table 1 HepG2 cells metabolic activity and caspase-3 activity

	Metabolic activity (absorbance units)	Caspase-3 activity (% of CRL)			
		0 h	6 h	12 h	18 h
BSO/DMSO	0.833 \pm 0.016	100.00 \pm 6.62	-	-	-
BSO/AZA	0.544 \pm 0.046 ^a	-	95.87 \pm 8.56	92.79 \pm 6.09	-
BSO/AZA/NAC	0.933 \pm 0.059	-	93.29 \pm 4.03	98.87 \pm 2.64	-
BSO/AZA/Z-VAD-mfk	0.680 \pm 0.034 ^a	-	94.85 \pm 6.81	102.60 \pm 7.30	-
TNF- α (35 pmol/L)/ActD (0.8 $\mu\text{mol/L}$)	-	-	-	-	143.00 \pm 5.77 ^b
TNF- α (700 pmol/L)/ActD (0.8 $\mu\text{mol/L}$)	-	-	-	-	141.30 \pm 4.33 ^b

Cells were treated with buthionine sulfoximine (BSO) (500 $\mu\text{mol/L}$, 24 h), or pretreated with BSO (500 $\mu\text{mol/L}$, 24 h) and then cotreated for 12 h with: (1) azathioprine (AZA) (300 $\mu\text{mol/L}$), (2) AZA (300 $\mu\text{mol/L}$) plus N-acetylcysteine (NAC) (1.5 $\mu\text{mol/L}$) or (3) AZA (300 $\mu\text{mol/L}$) plus Z-VAD-mfk (50 $\mu\text{mol/L}$). tumor necrosis factor (TNF)- α plus actinomycin D (ActD) treatment for 18 h was used as a positive control (CRL). Significant differences with respect to control [(BSO plus dimethyl sulfoxide (DMSO))] were statistically analyzed by analysis of variance. ^a $P < 0.05$; ^b $P < 0.05$.

Table 2 Summary of enzyme levels in mice

Enzyme	DMSO	BSO	AZA	BSO/AZA
AST (IU/L)	91.07 \pm 8.36	62.79 \pm 3.89	124.90 \pm 10.56	154.30 \pm 19.75 ^a
ALT (IU/L)	31.50 \pm 9.12	22.36 \pm 2.85	36.17 \pm 5.44	42.29 \pm 9.04
CK (IU/L)	598.60 \pm 112.10	416.00 \pm 89.28	904.40 \pm 129.40	918.50 \pm 128.70

Enzyme activity of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and creatine kinase (CK) in plasma of nude mice transplanted with HepG2 cells at the end of the experiment (12 d of treatment in similar conditions as in Figure 7). Significant differences with respect to control animals [dimethyl sulfoxide (DMSO)] were statistically analyzed by analysis of variance. ^a $P < 0.001$. BSO: Buthionine sulfoximine; AZA: Azathioprine.

cant reduction in procaspase-3 compared with control (DMSO) (Figure 7D). Plasma creatine kinase, ALT and AST did not show marked changes in the AZA plus BSO group compared with control (DMSO) and with the other groups studied (Table 2). This implied that a combination of AZA plus BSO did not induce toxicity in the hosts.

DISCUSSION

New drug combinations are needed for treatment of patients with cancer, particularly those refractory to stan-

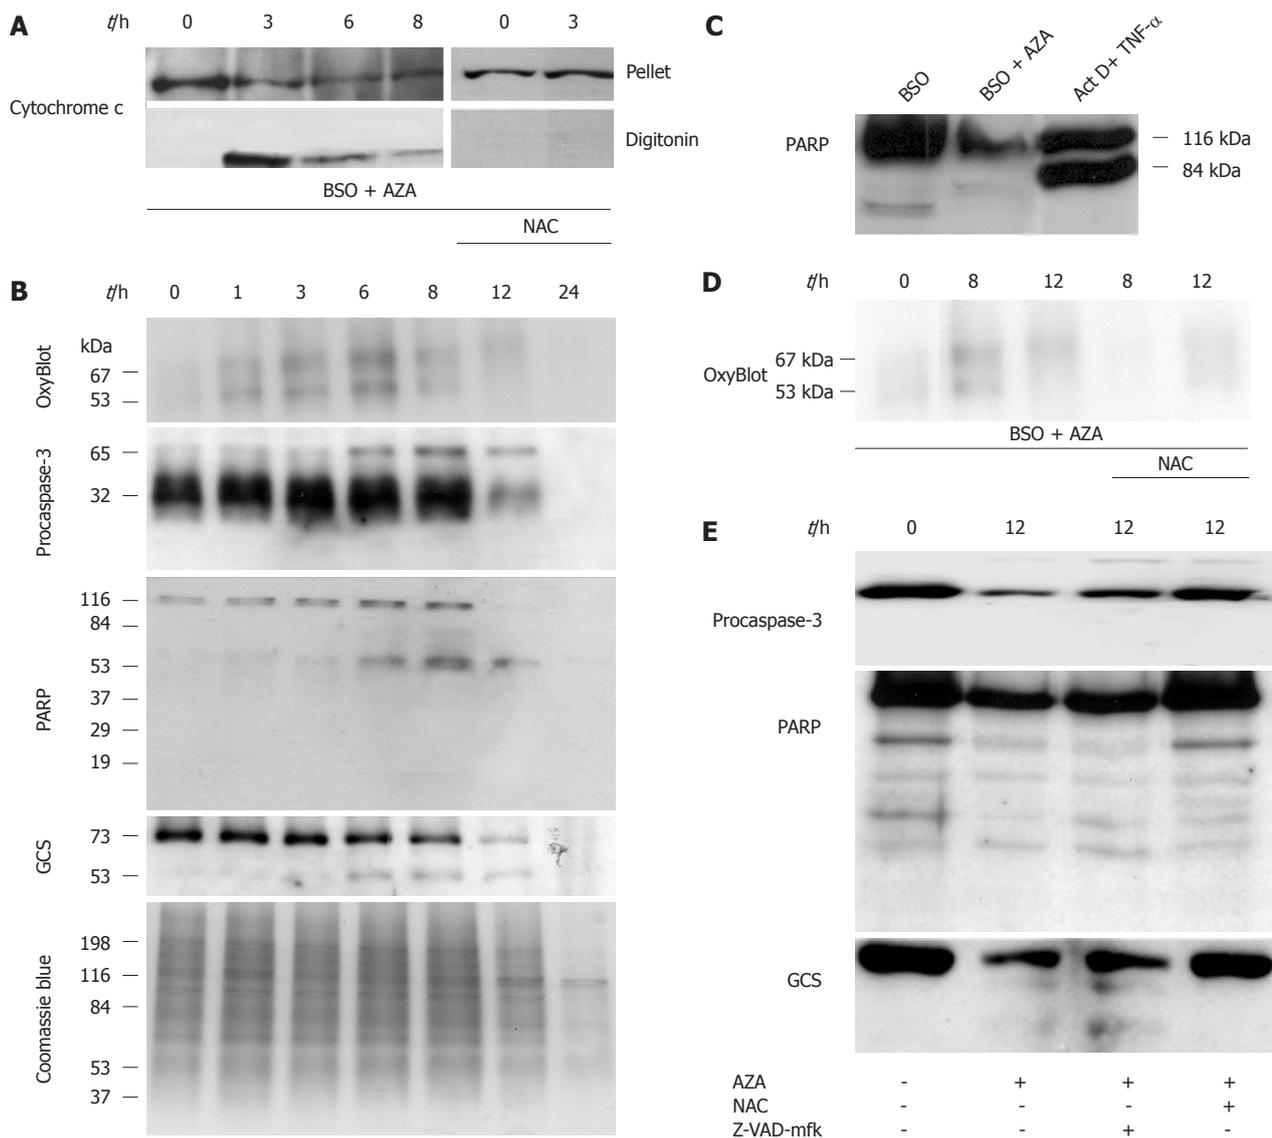

Figure 6 Effect of azathioprine plus buthionine sulfoximine treatment on biochemical markers of apoptosis. A: Time course of cytochrome c release from HepG2 cells pretreated with buthionine sulfoximine (BSO) (500 $\mu\text{mol/L}$) during 24 h and then cotreated with azathioprine (AZA) (300 $\mu\text{mol/L}$) at different times. N-acetylcysteine (NAC) (1.5 mmol/L) was added at the same time as AZA; B: Time course of apoptosis-related proteins in HepG2 cells pretreated with BSO (500 $\mu\text{mol/L}$) for 24 h and then cotreated with AZA (300 $\mu\text{mol/L}$) at different times; C: Western blotting of poly(ADP-ribose) polymerase (PARP) from HepG2 cells treated with BSO (500 $\mu\text{mol/L}$, 24 h), or pretreated with BSO (500 $\mu\text{mol/L}$, 24 h) and then cotreated with AZA (300 $\mu\text{mol/L}$, 12 h). HepG2 cells treated with actinomycin D (0.8 $\mu\text{mol/L}$) plus tumor necrosis factor (TNF)- α (35 pmol/L) for 18 h were used as positive control; D: Time course of the oxidized proteins from HepG2 cells treated in similar conditions as in panel A; E: Time course of apoptosis-related proteins from HepG2 cells treated in similar conditions as in panel A. NAC (1.5 mmol/L) or Z-VAD-mfk (50 $\mu\text{mol/L}$) were added at the same time as AZA. This set of experiments is representative of three others with similar results.

dard therapy. **Unresectable HCC is treated by TACE^[3,13]**, in which tumor necrosis is induced by hypoxia and by classic (doxorubicin, epirubicin, mitomycin c, cisplatin or 5-fluorouracil) or new (zinostatin stimalamer) drugs^[13]. Our preclinical results suggest that a new combination of old drugs could be useful in locoregional treatment of HCC. The AZA plus BSO combination offers the advantage of a new mechanism of action to the previous one used in TACE therapy, as we showed in the present paper. Moreover, our results revealed that AZA plus BSO may have a new spectrum of activity in comparison with the parent molecules, 6-mercaptopurine and 6-thioguanine. The localized application of AZA (6 mg/kg per day) and BSO (90 mg/kg per day)

produced a decrease in the volume of the HepG2 tumor xenograft that was not achieved by AZA or BSO alone. The doses used in the nude mouse model are comparable to those used for AZA in liver transplantation^[14] and in clinical trials of BSO^[7]. The therapeutic effect was produced with only minor changes in biochemical parameters used in the evaluation of the drug safety profile. Our results suggested that the AZA plus BSO combination induced necroptosis by JNK activation. Necroptosis is a caspase-independent regulated cell death, that results in morphological features resembling necrosis. Our data suggested that AZA and BSO can induce HepG2 cell death by depletion of the different pools of GSH, which could explain the synergistic effect of the compounds on

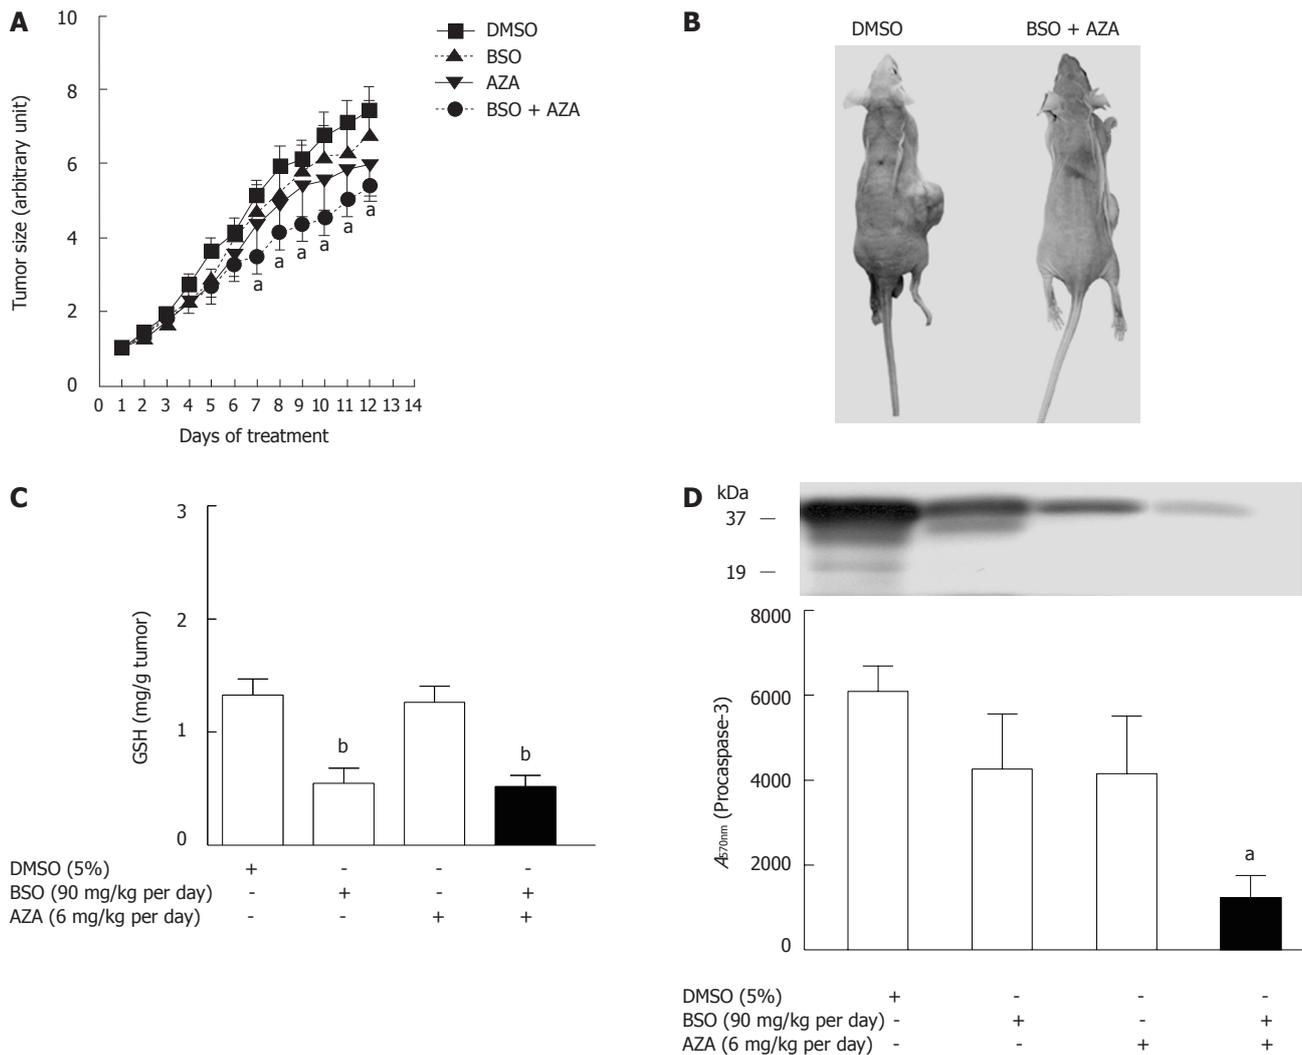

Figure 7 Effect of azathioprine plus buthionine sulfoximine treatment on tumor volume of nude mice. A: Inhibition of tumor growth by buthionine sulfoximine (BSO) (90 mg/kg per day) plus azathioprine (AZA) (6 mg/kg per day), AZA (6 mg/kg per day) or BSO (90 mg/kg per day). HepG2 cells (107) were implanted subcutaneously into nude mice as described in Materials and Methods; B: Representative animals of the groups treated with dimethyl sulfoxide (DMSO) or BSO plus AZA after 12 d of treatment. Levels of glutathione (GSH) (C) and of procaspase-3 (D) in the tumors of nude mice after 12 d of treatment with the corresponding drugs. There were eight mice in each group. Data points represent the mean \pm SE. ^a*P* < 0.05; ^b*P* < 0.01.

cell cytotoxicity. This suggestion is based on: (1) AZA decreases GSH levels in pretreated cells with BSO; (2) AZA kinetics on GSH depletion is more rapid and profound in cells pretreated with BSO than in control cells; (3) AZA is able to activate p38 by a GSH-dependent mechanism, while BSO is not; (4) AZA is able to stimulate JNK activity in cells GSH-depleted by BSO; this last effect is completely reversed by NAC; (5) AZA is able to stimulate the oxidation of cytosolic, nuclear and mitochondrial proteins by a GSH-dependent mechanism as demonstrated by the reversal by NAC; and (6) AZA treatment depletes both nucleoporin and cytochrome c in cells pretreated by BSO; these effects are reversed by NAC. From kinetic studies, we suggest that GSH depletion induced by AZA plus BSO stimulates JNK, Bax translocation and subsequent deregulation of mitochondria and activation of a cytotoxic cascade in HepG2 cells. The mitochondrial crisis is demonstrated by cytochrome c release and an increase in oxidized proteins. Classically, a link has been

observed between mitochondria and caspase-3 activation^[15]. Our results demonstrated the proteolysis of procaspase-3, PARP, γ -glutamylcysteine synthetase, the loss of membrane integrity, the release of LDH and DNA degradation after treatment with AZA plus BSO. Several of these cellular and biochemical changes are characteristic of apoptosis and of necrosis. We observed (Figure 8) at short times (0 to 6 h) of drug treatment, rapid regulatory changes associated with GSH levels, such as JNK activation and Bax translocation, which are followed by mitochondrial cytochrome c release and protein oxidation, all parameters classical hallmarks of apoptosis. However, cytochrome c release did not lead to caspase-3 activation and subsequent PARP proteolysis in 89 kDa fragments, as observed in control experiments performed in the presence of tumor necrosis factor- α and actinomycin-D. In addition, caspase-3 activity did not increase in the presence of BSO plus AZA. The absence of caspase-3 activation is corroborated using Z-VAD-mfk, because this caspase-3 in-

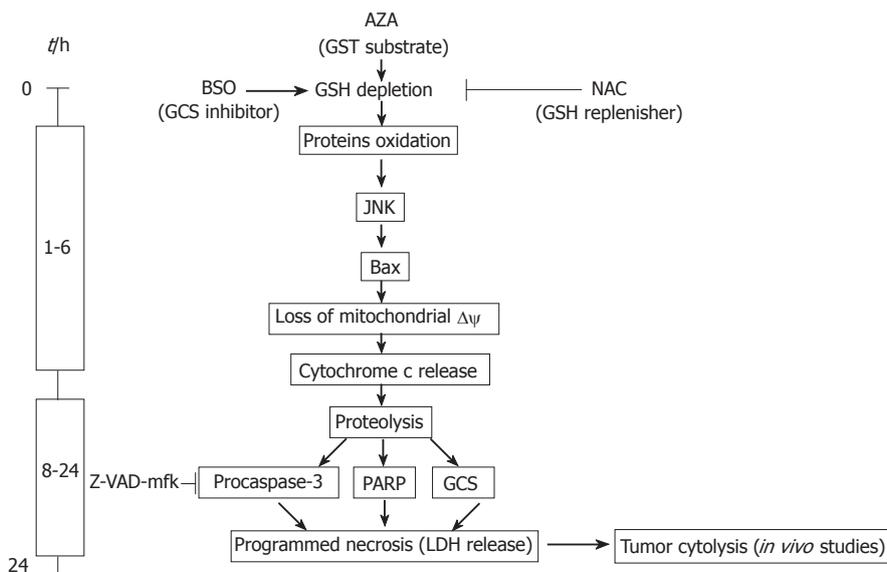

Figure 8 Time course of the events in our molecular model. AZA: Azathioprine; GST: Glutathione-S-transferase; GSH: Glutathione; GCS: γ -glutamylcysteine synthetase; BSO: Buthionine sulfoximine; NAC: N-acetylcysteine; PARP: Poly (ADP-ribose) polymerase; LDH: Lactate dehydrogenase.

hibitor did not protect against AZA plus BSO-induced cytotoxicity. These data exclude the involvement of caspase-3 in the cell death induced by the combination of both compounds. We observed at longer periods (6 to 24 h) of treatment with both compounds (Figure 8), a generalized protein degradation which affected structural (β -tubulin), regulatory (Bad, Bid, procaspase-3), metabolic (GCS) and DNA binding (PARP) proteins. Interestingly, Bcl-2 levels did not change with AZA plus BSO treatment which rules out apoptosis as the mechanism of cell death. Recently, a novel form of cell death called necroptosis or programmed necrosis has been proposed^[15], which like apoptosis, can be executed by a regulated mechanism. The first steps are common or similar to apoptosis but the inactivation of caspases causes a shift from apoptosis to mixed cell death (necrotic/apoptotic) or to full-blown necrosis^[15]. Our results suggest a role for GSH in the shift between apoptosis and necrosis induced by AZA plus BSO, because the addition of NAC to the drug combination reversed the majority of the cytotoxic effects induced by AZA plus BSO (JNK activation, cytochrome c release, protein oxidation, extensive proteolysis, mitochondrial membrane depolarization, and DNA fragmentation), but it did not inhibit annexin V-staining, which is characteristic of the early step of apoptosis. Recently, the importance of GSH has been shown in the induction of cell death by regulation of the cascade GST-JNK. The JNK activity is inhibited by binding with GST and, in this molecular model, a decrease in GSH causes oxidation of Cys47 and Cys101 in the GST protein, which in turn induces JNK release and subsequent activation^[16]. Our results suggest a similar model of activation of JNK by AZA plus BSO. In contrast, JNK activation in HepG2 cells by staurosporin, H₂O₂, etoposide or ultraviolet light induces classical apoptosis^[17]. In some instances, it may be desirable to trigger necrotic cell death, for example in hepatocarcinoma treatment, necrosis is the target of all

effective locoregional therapies^[3]. Our results provide important insights for the comprehensive understanding of the mechanism cell death induced by AZA and BSO in HepG2 cells and in other cancerous cells from the liver (HuH7, Chang cells) and from the colon (LoVo, SW-48, RKO, SW-48). To be considered as a therapeutic agent, the administered doses of AZA plus BSO must be compatible with those used in clinical practice; in this respect we observed that the doses of both compounds locally injected in the xenograft were able to reduce the tumor volume without any serious side effects. This combined therapy has an additional advantage, in that the presence of NAC can protect major organs from unexpected damage. The effectiveness of BSO in the treatment of solid tumors has been observed previously in combination with arsenic trioxide^[18], sodium borocaptate^[19] or melphalan^[6]. Interestingly, in this last paper BSO was administered efficiently by infusion into the hepatic artery, as in TACE. Our results provide experimental evidence to support the clinical use of the combined treatment of AZA and BSO in liver cancer.

COMMENTS

Background

The incidence of human liver carcinoma is increasing and is the fifth most common cancer in the world. Unfortunately, the disease is often diagnosed too late. For unresectable liver carcinoma, an effective treatment is transarterial chemoembolization (TACE). One way to progress with this encouraging treatment is to find a synergistic combination of classical drugs.

Research frontiers

One of the problems in treating hepatocarcinoma is chemoresistance, thus the majority of systemic therapies have been disappointing. Researchers for years have observed that elevation of intracellular glutathione (GSH) has been associated with resistance to irradiation and to chemotherapy and correspondingly the diminution of GSH levels is associated with sensitization to both types of therapy. Buthionine sulfoximine (BSO) is a competitive inhibitor of γ -glutamylcysteine synthetase, the rate-limiting step in the biosynthetic pathway of GSH production, and reduces their levels. In this study, the authors demonstrate that azathioprine (AZA) plus BSO could induce: (1) cell death of several cancer lines *in vitro* by activation of JNK; and (2) HepG2 cell death in a xenograft model.

Innovations and breakthroughs

The results point out the role of GSH in the synergism observed by the combination of AZA plus BSO, because the addition of N-acetylcysteine (NAC) reversed JNK activation, cytochrome c release, protein oxidation, extensive proteolysis, mitochondrial membrane depolarization and DNA fragmentation observed in the presence of AZA plus BSO. However, NAC was not able to inhibit annexin V staining which is characteristic of the early step of apoptosis. The modulation of the shift between apoptosis and necrosis induced by AZA plus BSO, in the presence or in absence, respectively, of NAC may be important in overcoming the chemoresistance observed during treatment of liver tumors.

Applications

The present findings may provide: (1) a new drug combination for the treatment of liver neoplasms; (2) identification of molecular targets to inhibit chemoresistance of cancer. These two pathways could be promising in the treatment of liver cancer.

Terminology

AZA is an immunosuppressant for clinical use belonging to the family of the thiopurines. It is used in organ transplantation and treatment of autoimmune diseases. BSO is an inhibitor of glutathione synthesis that is being evaluated clinically as an adjuvant in the treatment of cancer.

Peer review

The paper is of interest and deserves consideration for publication.

Abstract

AIM: To determine if anesthesiologist-monitored use of propofol results in improved detection of adenomas when compared with routine conscious sedation.

METHODS: This retrospective study was conducted at two separate hospital-based endoscopy units where approximately 12 000 endoscopic procedures are performed annually, with one endoscopy unit exclusively using anesthesiologist-monitored propofol. Three thousand two hundred and fifty-two patients underwent initial screening or surveillance colonoscopies. Our primary end point was the adenoma detection rate, defined as the number of patients in whom at least one adenoma was found, associated with the type of sedation.

RESULTS: Three thousand two hundred and fifty-two

outpatient colonoscopies were performed by five selected endoscopists. At least one adenoma was detected in 27.6% of patients (95% CI = 26.0-29.1) with no difference in the detection rate between the anesthesiologist-propofol and group and the gastroenterologist-midazolam/fentanyl group (28.1% vs 27.1%, $P = 0.53$).

CONCLUSION: The type of sedation used during colonoscopy does not affect the number of patients in whom adenomatous polyps are detected.

Conscious or unconscious: The impact of sedation choice on colon adenoma detection. *World J Gastroenterol* 2011; 17(34): 3912-3915 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i34/3912.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i34.3912>

INTRODUCTION

Colonoscopy is recognized as the gold standard examination in screening for colon polyps. Adenomas can be precursors to colon cancer and their removal by polypectomy prevents the development of cancer in many instances^[1,2]. However, adenomas may be missed in up to 24% of exams according to studies employing same day, tandem colonoscopies^[3,4]. Among the factors shown to affect polyp detection rates are: quality of preparation, withdrawal time, image enhancements (high definition, narrow band imaging), increased visualization of the

colonic mucosa with the Third Eye Retroscope and even the time of day that the exam is performed^[5-9].

Two methods of sedation are commonly used for colonoscopy exams: conscious sedation with gastroenterologist-monitored use of fentanyl and midazolam, and modified anesthesia with anesthesiologist-monitored use of propofol. Advantages of the latter method include a deeper level of sedation with less patient movement and awareness. Also, with anesthesiologist controlled propofol sedation, the endoscopist is freed from making decisions regarding the level of sedation and, therefore, can fully focus on the examination. A 5-year review of the Clinical Outcomes Research Initiative database showed that more large (> 9 mm) adenomas were detected during average risk screening colonoscopy exams using deep sedation with propofol than with moderate conscious sedation^[10]. Given that the smaller adenomas comprise most of the ones missed on colonoscopies, we determined in this study whether anesthesiologist-monitored use of propofol was associated with increased adenoma detection rate, regardless of size, compared to nurse-gastroenterologist monitored fentanyl and midazolam. Such a finding would help justify the higher cost of monitored use of propofol.

MATERIALS AND METHODS

Study design

This retrospective study was conducted at two separate hospital-based endoscopy units where approximately 12 000 endoscopic procedures are performed annually, with one endoscopy unit exclusively using anesthesiologist-monitored propofol. Two CRNAs staff the unit, each using the same method of administering propofol with an induction bolus followed by smaller bolus doses as required. The second unit serves both inpatients and outpatients. In this unit, gastroenterologist-controlled fentanyl and midazolam is the predominant method of sedation. Initial sedation with both medications is supplemented by small doses (0.5 to 1.0 mg midazolam or 25 mcg fentanyl) of either or both agents at the discretion of the gastroenterologist. We studied the adenoma detection rates of five experienced gastroenterologists who had each performed at least 10 000 colonoscopy exams and worked in both endoscopy units. All exams were performed using standard definition white light colonoscopes from the CF-Q160AL and CF-180AL series (Olympus America, Inc.) with standard definition flat screen monitors. The study was approved by the Norwalk Hospital Institutional Review Board.

Study sample

The study population consisted of consecutive outpatients undergoing initial screening or surveillance colonoscopy by one of the five endoscopists between January 1, 2008 and May 31, 2009. Patients were included if they met standard guidelines for screening and surveillance colonoscopy^[11]. Patients were excluded if they had a personal history of inflammatory bowel disease, a familial

history of a polyposis syndrome (familial adenomatous polyposis, hereditary non-polyposis colon cancer, juvenile polyposis, *etc.*) or had an inadequate bowel preparation.

Patients were assigned to the endoscopy units using either propofol or midazolam/fentanyl groups based on the day of the week. Each endoscopist spent the same day each week in the anesthesiologist-propofol unit. We recorded using the electronic medical record patient demographics including: age, (segmented into 5 groups: 20-49 years, 50-64 years, 65-74 years, 75-84 years and 85 years and older), gender, ethnicity, the indication for colonoscopy (screening or surveillance), the total number of adenomas detected and the number of adenomas detected in each patient.

Outcomes

Our primary end point was the adenoma detection rate, defined as the number of patients in whom at least one adenoma was found, associated with the type of sedation.

Statistical analysis

We conducted bivariate analyses to describe the differences in patient characteristics and adenoma detection between the use of anesthesiologist-propofol and gastroenterologist-midazolam/fentanyl sedation across all 5 endoscopists. Chi-square test was used for comparing categorical variables and *t*-test for comparing continuous variables. The hierarchical generalized linear model (HGLM) approach was used to assess the differences in adenoma detection between the two types of sedation by modeling the log-odds of adenoma detection as a function of patient demographics and the use of propofol. To determine the influence of various patient characteristics on the adenoma detection and incidence rates, we also fitted an HGLM without adjusting for those patient characteristics. All of the HGLM were constructed with a random endoscopist-specific effect, which accounts for a within-endoscopist correlation of the observed outcomes and separates within-endoscopist variation from between-endoscopist variation. The 95% CI was also calculated for each estimate obtained from the models and all statistical testing was 2-sided at a significance level of 0.05. All analysis was done using STATA version 10.0 (STATA Corporation, College Station, TX).

RESULTS

Patient characteristics

The study population consisted of 3252 outpatients having colonoscopy performed by one of the five selected endoscopists. Individual procedural volumes among the endoscopists ranged from 396 to 938 over the study period. The mean age was 61 years, predominately being 87.6% Caucasian (Table 1) and 53% male. The group receiving propofol was nine months older than the group receiving midazolam/fentanyl ($P = 0.037$). There were no statistical differences between the two sedation groups in terms of gender, ethnicity or indications for colonoscopy.

Adenoma detection rates

Overall, at least one adenoma was detected in 27.6% of patients (95% CI: 26.0-29.1) with no difference noted in the detection rate between the anesthesiologist-propofol group and the gastroenterologist-midazolam/fentanyl group (28.1% *vs* 27.1%, *P* = 0.53). Although there was substantial variation in overall adenoma detection rates among the individual endoscopists (ranging from 35.1% to 12.9%), the type of sedation used was not associated with differences in rates of adenoma detection (Table 2).

Because patient assignment to either the propofol or midazolam/fentanyl sedation group was not randomized, HGLM was used to determine whether any of the patient characteristics (age group, ethnicity, gender or indication for colonoscopy) contributed to the observed adenoma detection rates. Using midazolam/fentanyl sedation as the reference standard, the odds ratio for the detection of adenomas does not differ when propofol is used and the results are adjusted for patient and physician characteristics (Table 3). Using the model, no difference in adenoma detection rates was identified when each of the five patient age groups were examined individually.

DISCUSSION

This study shows that anesthesiologist-monitored propofol sedation was not associated with an overall significant difference in adenoma detection rate compared to gastroenterologist-monitored sedation with midazolam and fentanyl. Adjustments for patient characteristics and variation in endoscopist detection rates also failed to show an overall advantage for the detection of adenomas associated with propofol sedation.

Clear benefits of the use of propofol do exist. Anesthesiologist-monitored propofol sedation allows colonoscopy to be performed more efficiently with a more rapid onset of sedation and shorter patient recovery times. This type of sedation also frees the endoscopist from making decisions regarding the level of sedation and patient monitoring, allowing full concentration on the endoscopic task at hand. A 5-year review of the Clinical Outcomes Research Initiative database showed that more large (> 9 mm) polyps were detected during average risk screening colonoscopy exams using deep sedation with propofol than with moderate conscious sedation^[10]. In this study, 20% more polyps were detected and multivariate analysis found no factors other than propofol sedation to account for the difference. In contrast, our study examined the detection of potentially pre-cancerous adenomatous polyps of any size, and did not find a benefit to the use of propofol. Both studies were retrospective in nature.

Polyp detection rates vary with the time spent examining the colonic mucosa during withdrawal of the instrument, the quality of the preparation and optical enhancements such as high definition scopes and monitors and narrow band imaging. In our study, procedural technique and daily patient volume were the same for each endoscopist in both the anesthesiologist-propofol and gastroenterologist - midazolam/fentanyl endoscopy units. All preparations were graded good to excellent and the exams

were performed with a mix of Olympus CF-Q160AL and CF-180AL series instruments, the latter with narrow band imaging capability. High definition instruments were not in use in our units at the time of the study.

Our arrangement with 2 endoscopy suites, one providing exclusively anesthesiologist-monitored propofol and the other providing predominantly gastroenterologist-controlled fentanyl and midazolam, provided a convenient, albeit non randomized method to compare whether type of sedation was associated with adenoma detection rates. The fact that each physician worked in the propofol unit on the same day each week introduced a potential confounding variable, however, we are not aware of any literature correlating adenoma detection rates with the day of the week the procedure is performed.

While retrospective, this study represents the 'real world' practice of colonoscopy with experienced clinicians performing both screening and surveillance exams on patients who are receiving either anesthesiologist or operator controlled sedation. Our data show that the detection rate of adenomatous polyps of all sizes is not increased by the use of anesthesiologist monitored propofol sedation compared to gastroenterologist monitored sedation with midazolam/fentanyl. While the use of propofol based anesthesia is certainly associated with increased patient satisfaction, the detection rate of adenomatous colon polyps is not enhanced.

COMMENTS

Background

Colonoscopy is the gold standard examination in screening for colon polyps. Adenomas can be precursors to colon cancer and their removal by polypectomy prevents the development of cancer in many instances. Yet it has been shown that adenomas may be missed up to 24% of the time.

Research frontiers

Many factors have been shown to affect polyp detection rates including: quality or preparation, withdrawal time, image enhancement, polyp size, increased visualization with Third Eye Retroscope and time of day. However, few studies have shown any adenoma detection rate differences in the type of sedation used.

Innovations and breakthroughs

This is one of the first studies of its kind to investigate whether or not anesthesiologist monitored use of propofol would affect the adenoma detection rate when compared to gastroenterologist-monitored use of fentanyl and midazolam. The data suggest that anesthesia monitored propofol sedation was not associated an overall significant difference in adenoma detection rate compared to gastroenterologist monitored sedation with midazolam and fentanyl.

Applications

The data suggest that the detection rate of adenomatous polyps of all sizes is not increased by the use of anesthesiologist monitored propofol sedation compared to gastroenterologist monitored sedation with midazolam/fentanyl. While the use of propofol based anesthesia is certainly associated with increased patient satisfaction, the detection rate of adenomatous colon polyps is not enhanced. This study could have future financial implications given the cost of anesthesiologist monitored propofol sedation.

Terminology

Propofol is a short-acting, intravenously administered hypnotic agent. Its uses

include the induction and maintenance of general anesthesia, sedation for mechanically ventilated adults, and procedural sedation. Midazolam is a short-acting drug in the benzodiazepine class that is used for treatment of acute seizures, moderate to severe insomnia, and for inducing sedation and amnesia before medical procedures. Fentanyl is a strong agonist on the μ -opioid receptors and is commonly used before procedures as an anesthetic in combination with a benzodiazepine.

Abstract

AIM: To evaluate the treatment of pediatric functional chronic intestinal constipation (FCIC) with a probiotic goat yogurt.

METHODS: A crossover double-blind formula-controlled trial was carried out on 59 students (age range: 5-15 years) of a public school in Belo Horizonte, MG, Brazil, presenting a FCIC diagnostic, according to Roma III criteria. The students were randomized in two groups to receive a goat yogurt supplemented with 10^9 colony forming unit/mL *Bifidobacterium longum* (*B.*

longum) (probiotic) daily or only the yogurt for a period of 5 wk (formula). Afterwards, the groups were intercrossed for another 5 wk. Defecation frequency, stool consistency and abdominal and defecation pain were assessed.

RESULTS: Both treatment groups demonstrated improvement in defecation frequency compared to baseline. However, the group treated with probiotic showed most significant improvement in the first phase of the study. An inversion was observed after crossing over, resulting in a reduction in stool frequency when this group was treated by formula. Probiotic and formula improved stool consistency in the first phase of treatment, but the improvement obtained with probiotic was significantly higher ($P = 0.03$). In the second phase of treatment, the group initially treated with probiotic showed worsening stool consistency when using formula. However, the difference was not significant. A significant improvement in abdominal pain and defecation pain was observed with both probiotic and formula in the first phase of treatment, but again the improvement was more significant for the group treated with *B. longum* during phase I ($P < 0.05$). When all data of the crossover study were analyzed, significant differences were observed between probiotic yogurt and yogurt only for defecation frequency ($P = 0.012$), defecation pain ($P = 0.046$) and abdominal pain ($P = 0.015$).

CONCLUSION: An improvement in defecation frequency and abdominal pain was observed using both supplemented and non-supplemented yogurt, but an additional improvement with *B. longum* supplementation was obtained.

Pediatric functional constipation treatment with *Bifidobacterium*-containing yogurt: A crossover, double-blind, controlled trial. *World J Gastroenterol* 2011; 17(34): 3916-3921 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i34/3916.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i34.3916>

INTRODUCTION

The worldwide prevalence of childhood constipation in the general population ranges from 0.7% to 29.6%^[1], and the wide range indicates differences in definition and selection of patients. This functional defecation disorder is characterized by infrequent defecation less than three times per week, frequent episodes of fecal incontinence, the periodic passage of large and painful stools which clog the toilet, and retentive posturing. Upon physical examination a palpable fecal mass is often found in the abdomen and the rectum. Accompanying symptoms may include irritability, decreased appetite, and/or early satiety. In the vast majority of cases (90% to 95%), no underlying organic cause is found and functional constipation is diagnosed^[2].

The standard treatment consists of disimpaction and the administration of laxatives to achieve a normal bowel habit of passing a soft stool without pain. Even though the traditional treatment is well established and safe, for many patients it does not provide a satisfying improvement, prompting interest in other therapeutic strategies^[3].

Probiotics are increasingly being used as an alternative in the management of constipation. Probiotics are defined as live microorganisms which when administered in adequate amounts confer a benefit on the host health^[4]. In a recent review, the efficacy and safety of probiotic supplementation for the treatment of constipation was evaluated^[5]. Studying 5 randomized controlled trials, with a total of 377 subjects (three trials with adults and two trials with children), the data suggests a favorable effect of some strains of *Lactobacillus*, *Bifidobacterium* and *Escherichia coli* (*E. coli*). Only one of the randomized controlled trials described the ineffectiveness of *Lactobacillus rhamnosus* Goldin and Gorbach as an adjunct to lactulose for the treatment of constipation in children^[6]. The authors of the review concluded that until more data are available, the use of probiotics for the treatment of constipation should be considered investigational. More recently, *Lactobacillus reuteri* administered in infants with chronic constipation had a positive effect on frequency of bowel movements, but not on stool consistency^[7] and the intake of mixed probiotic strains [*Lactobacillus plantarum*, *Bifidobacterium breve*, *Bifidobacterium animalis* subspecies *lactis* (*B. animalis* var. *lactis*)] was able to relieve evacuation disorders and hard stools in healthy adults^[8].

In the present study, the ingestion of goat yogurt containing a *Bifidobacterium longum* (*B. longum*) strain was evaluated for the treatment of functional chronic intestinal constipation (FCIC) in children and adolescents.

MATERIALS AND METHODS

Subjects and eligibility criteria

Children aged 5-15 years and with FCIC, referred to a public school in the central area of the city of Belo Horizonte, Minas Gerais, Brazil, were eligible for study entry. Constipation was characterized according to Rome III criteria as presenting at least two out of six of the following symptoms for two or more months: two or fewer defecations per week; at least one episode of fecal incontinence per week; history of retentive posturing or excessive volitional stool retention; history of painful or hard bowel movements; presence of a large fecal mass in the rectum; history of wide diameter stools that may obstruct the toilet^[2]. Exclusion criteria were the use of any oral laxative < 4 wk before intake, metabolic disease, a history of gastrointestinal surgery and fecal incontinence. Patients with fecal incontinence were excluded in order to make the sample more homogeneous in relation to disease severity. The follow-up protocol included defecation frequency, stool consistency, and abdominal and defecation pains recorded daily by the adolescents or parents. All children older than 12 years and/or parents gave informed consent. The study was approved by the Ethical Committee in Research of the Universidade Federal de Minas Gerais (COEP/UFMG, number ETIC0506/08).

Yogurt and bacterium

The *B. longum* strain used in the trial was isolated from the feces of a healthy child and identified by Multiplex Polymerase Chain Reaction. This strain was selected as a candidate for probiotic use based on technological (aerotolerance and high growth rate) and beneficial (wide antagonistic spectrum against pathogenic indicators, few antimicrobial resistance) criteria. The bacterium was grown in de Man, Rogosa and Sharp broth (Difco, Sparks, United States) for 48 h at 37 °C in an anaerobic chamber (Forma Scientific Company, Marietta, United States) containing N₂ 85%, H₂ 10% and CO₂ 5%. After growth, the culture was concentrated by centrifugation and resuspended in peptone sterile water. An aliquot of 1 mL of the concentrated bacterium suspension was added to 9 mL of a commercial goat yogurt (Capril Jacomé, Contagem, Brazil) to obtain a final concentration of 10⁹ colony forming unit (CFU)/mL. The control formula was prepared by addition of 1 mL of peptoned water to 9 mL of goat yogurt. The goat yogurt contained the two classical yogurt starters, *Lactobacillus delbrueckii* subspecies *bulgaricus* and *Streptococcus thermophilus* from the YF-L812 commercial culture (DVS - Christian Hansen Laboratory, Horsholm, Denmark). Both yogurts were maintained at 4 °C until use and for a maximum of one week. During this period, the *Bifidobacterium* cells remained viable at 10⁹ CFU/mL levels.

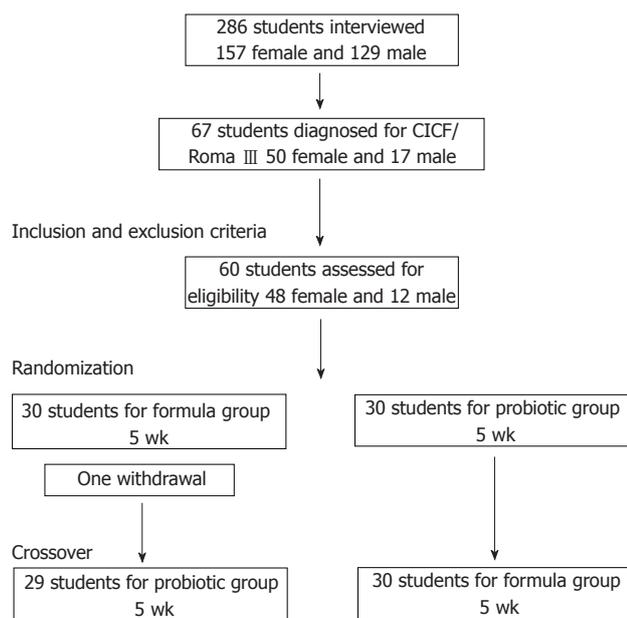

Figure 1 Participant flow diagram.

Study intervention

This study was carried out using a crossover double-blind, formula-controlled design with two parallel groups. In order to determine the sample size, a preliminary trial was done with 15 children to evaluate the average and variance of the difference in defecation frequency between formula and probiotic groups. To guarantee that the sample size calculation considered the crossover design, an equation for the comparison between averages of difference^[9] was used considering a significance level set at 0.05, a power of 80%, a difference average of 0.75 and a variance difference of 3.15. Under the assumptions made here, the smallest sample size was 22 for each group. The students were randomized in two groups to receive 1 mL of goat yogurt supplemented with 10⁹ CFU/mL *B. longum* (probiotic) daily or the same dose of goat yogurt daily for a period of 5 wk (formula). Afterwards, the groups were crossed over to alternate intervention for another 5 wk. Defecation frequency, stool consistency and abdominal or defecation pain were assessed at the first (A1), third (A2) and fifth week (A3) before crossing over, and the first (B1), third (B2) and fifth week (B3) after crossing over. The stool consistency was characterized using the Bristol Stool Scale^[10]. To describe feces consistency, the subjects and/or their parents received instructions with a stool illustration and explanation in advance for the purpose of objectively selecting the stool form. The two products, goat yogurt with or without *B. longum* were identical in weight, color, smell, taste and package. All doctors and children involved were unaware of the treatment administered. Children were instructed to maintain their ordinary dietary habits, but were asked to avoid consuming other fermented dairy products or yogurts during the study. The allocation sequence and randomization list were computer-generated using the Epi Info Program.

Statistical analysis

Pearson exact test and Wilcoxon test were used to compare the variables (defecation frequency, stool consistency and abdominal and defecation pain) between the two groups. Differences in the variable distributions at each moment of each sequence of intervention were used for these analyses. The data were analyzed using the software Statistical Package for Social Sciences (SPSS 15.0). Normality was evaluated by Shapiro Wilk test. All tests were two sided, and *P* < 0.05 was considered statistically significant. All analyses were performed on an intention-to-treat basis.

RESULTS

The participant flow diagram (Figure 1) shows that among 286 students interviewed, 67 (23.4%) were diagnosed with FCIC following the Roma III criteria. Seven of them were excluded based on the exclusion criteria, and the remaining students were randomized to receive the probiotic or formula treatment. After the beginning of the trial only one parental withdrawal occurred in the formula group. There was no adverse effect due to the interventions in the present study protocol.

Table 1 summarizes the subjects' baseline demographic and clinical characteristics. The two groups were comparable in regard to age, sex, and baseline features of constipation. More female subjects than male were present in the two groups and at a similar frequency (79.3% and 80.0% in formula and probiotic groups, respectively)

Figure 2A shows and compares the evolution of the two groups for hard stool consistency (Bristol scale < 4) during the trial. An improvement was observed with both

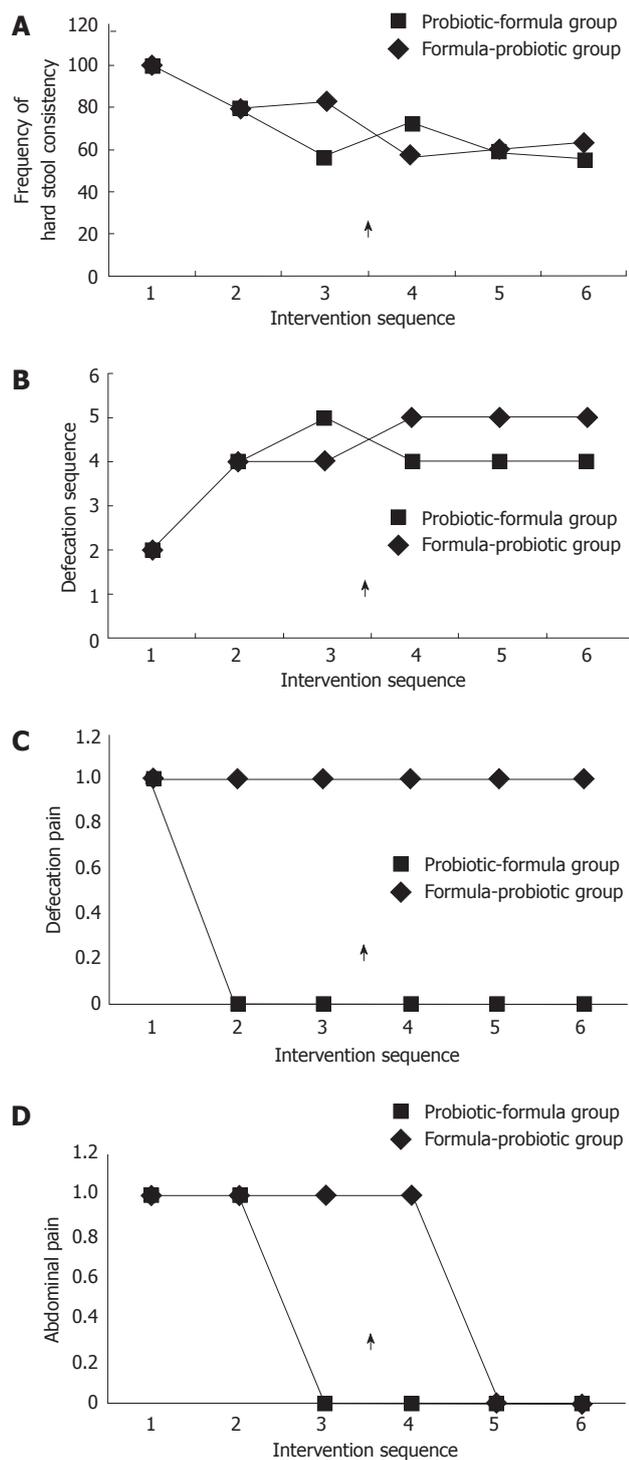

Figure 2 Evolution of hard stool consistency (Bristol scale < 4) (A), defecation frequency (B), defecation pain (C) and abdominal pain (D) during the intervention sequence. 1: A1; 2: A2; 3: A3; 4: B1; 5: B2; 6: B3. Arrow shows the moment of inversion in the intervention sequence.

treatments as compared to baseline. This improvement was greater in the probiotic group during the first part of the intervention when a significant difference ($P = 0.03$) was observed between the two groups after 5 wk of treatment (A3 phase). After crossing over, an inversion was observed, but this was not statistically significant.

Figure 2B shows and compares the evolution of the two groups for defecation frequency during the trial. A

significant improvement in defecation frequency was also noted for both groups when compared to baseline with a tendency to a slight additional improvement at the end of the first intervention when *B. longum* was supplemented, and an inversion after crossing over.

Figure 2C shows and compares the evolution of defecation pain in the two groups during the trial. An improvement was observed for both treatments in relation to the baseline, but with a better evolution for the probiotic group. However, a significant difference ($P = 0.009$) between formula and probiotic was observed only for phase B1, and contrarily to Figures 1 and 2 an inversion was not observed after crossing over.

Figure 2D shows and compares the evolution of abdominal pain in the two groups during the trial. When the symptomatology was compared before and after the intervention, a significant improvement was noted for both groups as compared to baseline, but again with better results for the probiotic group. However, at the end of the second intervention after crossing over, the symptomatology was similar for the two groups.

When all data of the crossover study were analyzed, significant differences were observed between probiotic yogurt and yogurt only for defecation frequency ($P = 0.012$), defecation pain ($P = 0.046$) and abdominal pain ($P = 0.015$).

DISCUSSION

The prevalence of FCIC observed in the present study (23.4%) was similar to the data cited in the literature^[1]. The predominance of FCIC in female subjects (about 80%) was also described in the literature^[1].

Within the first week of intervention, a significant improvement in all constipation symptoms was observed in both treatment groups (yogurt or yogurt plus *B. longum*) when compared to the baseline. However, when the yogurt was supplemented with the probiotic, further improvement was obtained when compared to the yogurt only. Yogurt is generally considered to alleviate gastrointestinal conditions such as constipation and diarrhea^[11]. However, regarding the effect of yogurt alone on constipation, few reports are available in the literature, and the results reported are contradictory. Additionally, in most of the clinical trials comparing the effect of probiotic yogurt with control yogurt, the starter lactic acid bacteria are heat-killed in the second situation, which does not correspond to the reality. In the few studies where viability of the starter strains was maintained in the control yogurt, improvement of constipation symptoms was observed in both probiotic and control groups with an increment in the first one^[12].

There are several hypotheses to explain how probiotics might have therapeutic potential for the treatment of constipation. Firstly, quite old and well known observations showed that the absence of gut microbiota in germ-free animals result in abnormal characteristics of the intestinal morphology and function such as increased transit time of contents, altered myenteric neurons, impaired intestinal muscle function and decreased intestinal

mass^[13,14]. Interestingly, the mono-association of germ-free animals with *Lactobacillus acidophilus* or *Bifidobacterium bifidum* reduced the migrating myoelectric complex period and accelerated the small intestinal transit. Inversely, some *E. coli* strains presented an inverse effect when mono-associated in gnotobiotic animals^[14]. Short-chain fatty acids (SCFAs), main metabolic products derived from the fermentative activity of the gut microbiota, have a direct influence on intestinal motility through the Gpr41 receptor^[15]. In colonized Gpr41 knockout mice, an increased intestinal transit rate was associated with a reduced expression of peptide YY, an enteroendocrine cell-derived hormone that normally inhibits gut motility^[16]. Secondly, there are some data suggesting differences in the intestinal microbiota of healthy individuals and patients with chronic constipation^[17,18]. The main features were an increased number of clostridia and enterobacteria, and a decrease in bifidobacteria and lactobacilli. These differences have an influence on the metabolic profile of the gut environment, and particularly on SCFA pattern^[19]. However, a key question is if this dysbiosis is a secondary manifestation of constipation, or is a factor contributing to constipation. Another set of data favoring the microbiota influence describes the higher defecation frequency and softer stool consistency in breast-fed than in formula-fed infants in the first four months of life, which can be due to the higher fecal levels of bifidobacteria in breast-fed infants^[20]. Thirdly, studies involving the administration of *Bifidobacterium animalis* subspecies *lactis* DN-173010 have shown improved colonic transit times, both in a healthy population^[21] and in constipated patients^[22]. Another study showed that the intake of probiotic (*Lactobacillus helveticus* and *B. longum*) can modify the gut microbial ecology and metabolic profiles^[23]. Finally, in a study using a guinea-pig isolated tissue model, results showed that cytoplasmatic fraction of probiotic bacteria (*Lactobacillus*, *Bifidobacterium*) stimulated the contraction of the ileum segment and induced proximal colon relaxation^[24].

In conclusion, an improvement in constipation symptoms was observed using both supplemented and non-supplemented yogurt. An additional improvement with *B. longum* supplementation was suggested in the present intercrossed double-blind formula-controlled study.

COMMENTS

Background

The worldwide prevalence of childhood constipation in the general population ranges from 0.7% to 29.6%, and the standard treatment that consists of disimpaction and administration of laxatives does not provide satisfying improvement in 40% of the children. Development of new therapeutic strategies is necessary to treat these patients more effectively, and probiotics are increasingly being used as one of such alternatives in the management of constipation.

Research frontiers

There is growing interest in the use of probiotics in organic and functional gastrointestinal disorders. A limited number of studies have been published about the effects of probiotics on constipation in children, and encouraging results have been obtained. But so far there is no hard evidence to recommend this use in children, and a general consensus in the scientific literature recommends more clinical trials. In the present intercrossed double-blind formula-controlled study, an additional improvement in constipation symptoms was observed using yogurt supplemented with *Bifidobacterium longum* when compared to non-supplemented yogurt.

Innovations and breakthroughs

Recent reports have highlighted that the administration of probiotics could be recommended as an adjunctive therapy of chronic constipation. It is well known that the indigenous digestive microbiota affects intestinal motility and accelerates small intestinal transit. Among the components of this microbial ecosystem, bacteria of the *Bifidobacterium* genus seems to be involved in the phenomenon and therefore are microorganisms of choice for use as probiotics.

Applications

The results of the present clinical trial suggest that the ingestion of a goat yogurt supplement with a *Bifidobacterium* strain may represent an alternative strategy in the treatment of pediatric functional constipation.

Peer review

A clearcut, well conducted trial showing how the addition of a specific probiotic agent can improve intestinal symptoms in children and adolescent with constipation.

Abstract

AIM: To investigate the inhibitory role and the underlying mechanisms of sorafenib on signal transducer and activator of transcription 3 (STAT3) activity in hepatocellular carcinoma (HCC).

METHODS: Human and rat HCC cell lines were treated with sorafenib. Proliferation and STAT3 dephosphorylation were assessed. Potential molecular mechanisms of STAT3 pathway inhibition by sorafenib were evaluated. *In vivo* antitumor action and STAT3 inhibition were investigated in an immunocompetent orthotopic rat HCC model.

RESULTS: Sorafenib decreased STAT3 phosphorylation

at the tyrosine and serine residues (Y705 and S727), but did not affect Janus kinase 2 (JAK2) and phosphatase shatterproof 2 (SHP2), which is associated with growth inhibition in HCC cells. Dephosphorylation of S727 was associated with attenuated extracellular signal-regulated kinase (ERK) phosphorylation, similar to the effects of a mitogen-activated protein kinase (MEK) inhibitor U0126, suggesting that sorafenib induced S727 dephosphorylation by inhibiting MEK/ERK signaling. Meanwhile, sorafenib could also inhibit Akt phosphorylation, and both the phosphatidylinositol-3-kinase (PI3K) inhibitor LY294002 and Akt knockdown resulted in Y705 dephosphorylation, indicating that Y705 dephosphorylation by sorafenib was mediated by inhibiting the PI3K/Akt pathway. Finally, in the rat HCC model, sorafenib significantly inhibited STAT3 activity, reducing tumor growth and metastasis.

CONCLUSION: Sorafenib inhibits growth and metastasis of HCC in part by blocking the MEK/ERK/STAT3 and PI3K/Akt/STAT3 signaling pathways, but independent of JAK2 and SHP2 activation.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most frequent cause of cancer-related death globally. Although prognosis of patients with HCC has increased in recent decades, long-term survival remains unsatisfactory because of the high rate of recurrence and metastasis^[1]. Advances in treating this disease are likely to develop from a better understanding of its biology and behavior, which are affected by multiple molecular pathways controlled by transcription factors^[2,3].

Signal transducer and activator of transcription 3 (STAT3) plays a critical role in transcriptional regulation of genes that are involved in tumor cell proliferation, survival and invasion^[4]. Constitutive activation of STAT3 is observed in 72.4% of human HCC^[5] and in a wide variety of other cancer types^[6,7]. Overexpression of constitutively activated forms of STAT3 induces the formation of foci *in vitro* and tumors in mouse models. Moreover, inhibiting STAT3 function *via* RNA knockdown, peptide inhibition, and expression of dominant-negative forms in cancer cells leads to a decrease in tumor progression^[8]. Our group has also reported that knockdown of STAT3 with antisense oligonucleotides inhibits tumor growth and metastasis in a mouse xenograft model of HCC^[9]. In human HCC tissues, constitutive activation of STAT3 is a significant predictor of overall survival^[5]. Thus, targeting of STAT3 activation may prove to be an effective approach to controlling HCC.

Sorafenib (Nexavar, BAY 43-9006) is a multikinase inhibitor that has shown anti-tumor activity against a wide variety of cancers including HCC^[10,11]. Sorafenib blocks tumor cell proliferation and angiogenesis by targeting the Raf/mitogen-activated protein kinase kinase (MEK)/extracellular signal-regulated kinase (ERK) signaling pathway and receptor tyrosine kinases (RTKs), such as vascular endothelial cell growth factor receptor (VEGFR)-2, VEGFR-3, platelet-derived growth factor receptor- β , fms-like tyrosine kinase receptor-3 (FLT3), RET, and c-KIT^[10,11]. Recently, sorafenib has been shown to suppress tumor growth by decreasing STAT3 phosphorylation in a group of human malignancies^[12-15]. In HCC, sorafenib has also been suggested to overcome TRAIL resistance through the inhibition of STAT3^[16]. However, thus far, the exact molecular mechanisms by which sorafenib inhibited STAT3 have not been fully elucidated.

Here, we found that sorafenib decreased STAT3 phosphorylation at both tyrosine and serine residues (Y705 and S727), which were independent of Janus kinase 2 (JAK2) and phosphatase shatterproof 2 (SHP2) activity. We further demonstrated that inhibition of the phosphatidylinositol-3-kinase (PI3K)/Akt and MEK/ERK path-

ways was responsible for Y705 and S727 dephosphorylation, respectively, by sorafenib. Consistent with these findings, sorafenib markedly inhibited STAT3 dephosphorylation, suppressed tumor growth and metastasis in an immunocompetent orthotopic rat HCC model.

MATERIALS AND METHODS

Reagents and cell lines

Sorafenib (BAY 43-9006, Bayer Pharmaceutical Corporation) was dissolved in sterile dimethyl sulfoxide (DMSO) for *in vitro* experiments, and in Cremophor EL (Sigma) and 95% ethanol (50:50) for *in vivo* experiments. DMSO was added to cultures at 0.1% (v/v) final concentration as a vehicle control. Primary antibodies, STAT3 and phosphorylated STAT3 (p-STAT3; Y705 and S727); Akt and phosphorylated Akt (p-Akt; S473); JAK2 and phosphorylated JAK2 (p-JAK2; Y1007/1008); ERK1/2 and phosphorylated ERK1/2 (p-ERK1/2; T202/Y204); SHP2 and phosphorylated SHP2 (p-SHP2; Y580) were purchased from Cell Signaling Technology. Cyclin D1 was from Abcam. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was purchased from Millipore. Human or rat Akt small interfering RNA (siRNA), control siRNA, were obtained from Shanghai GenePharma Co. (Shanghai, PR China). LY294002, a PI3K inhibitor, and U0126, a MEK inhibitor, were purchased from Cell Signaling Technology.

Two human HCC cell lines, HCCLM3^[17,18] and HepG2 (ATCC), and a rat HCC cell line, Morris hepatoma 3924A (MH) cells (German Cancer Research Center Tumor Collection)^[19], were maintained in high-glucose DMEM supplemented with 10% heat-inactivated fetal bovine serum, L-glutamine, 100 units/mL penicillin, and 100 μ g/mL streptomycin. Cell lines were cultured at 37 °C in a humidified incubator in 5% CO₂.

MTT assay

The effect of sorafenib on HCC cell growth was determined with the 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazoliumbromide (MTT) assay. Cells were seeded into 96-well flat-bottom plates (1×10^3 /well) and cultured for 24, 48 or 72 h in medium supplemented with sorafenib (0, 0.05, 0.1, 1, 5, 10 or 20 μ mol/L; 6 wells/dose), and each experiment was repeated at least three times. After sorafenib treatment, cells were incubated with MTT (20 μ L/well) at 37 °C for 4 h, and then 200 μ L DMSO was added. The absorbance of individual wells was determined at 570 nm.

Western blotting analysis

Western blot analysis was performed as previously described^[20]. Briefly, total cell lysates were prepared, and proteins were separated by SDS-PAGE, followed by transfer to polyvinylidene difluoride membranes. The membranes were washed, blocked, and incubated with the specific primary antihuman antibodies against p-STAT3-Y705 (1:1000), p-STAT3-S727 (1:1000), STAT3

(1:1000), p-Akt (1:1000), Akt (1:1000), p-ERK1/2 (1:1000), ERK1/2 (1:1000), p-JAK2 (1:1000), JAK2 (1:1000), p-SHP2 (1:1000), SHP2 (1:1000), cyclin D1 (1:1000), or GAPDH (1:5000), followed by incubation with horseradish peroxidase-conjugated secondary antibodies. Proteins were detected by enhanced chemiluminescence assay (Pierce-Thermo Scientific).

Quantitative reverse transcription-polymerase chain reaction

Cells were plated and treated with 10 $\mu\text{mol/L}$ sorafenib. The cells were harvested after 24 h, and total RNA was extracted with Trizol Reagent (Invitrogen) according to the manufacturer's protocol. Total RNA was reverse transcribed with RevertAid™ first-strand cDNA synthesis kit (Fermentas). Human and rat STAT3 mRNA levels were determined by qPCR using SYBR Premix Ex Taq (TaKaRa, Dalian, China) and normalized to human and rat β -actin respectively, using the following primers: β -actin (human) forward, 5'-CAA CTG GGA CGA CAT GGA GAA AAT-3' and reverse, 5'-CCA GAG GCG TAC AGG GAT AGC AC-3'; β -actin (rat) forward, 5'-TCC ACC CGC GAG TAC AAC CTT CTT-3' and reverse, 5'-GGC CCG GGG AGC ATC GTC-3'; STAT3 (human) forward, 5'-CCC CCG CAC TTT AGA TTC AT-3' and 5'-GGT AGG CGC CTC AGT CGT AT-3'; STAT3 (rat) forward, 5'-GGT GAT GAG TTT CCG AGT GTG TCT GA-3' and reverse, 5'-AAA GCG CCT GCG CCT GCG ATA AAG TTC T-3'. Relative gene expression was calculated with the $2^{-\Delta\Delta C_t}$ method.

Akt silencing by siRNA

Akt siRNA and negative control mismatch sequences were transfected into HepG2 and MH cells using Lipofectamine™ 2000 (Invitrogen) according to the manufacturer's instructions. The following sense and anti-sense siRNA strands were used: Akt (human) GUG CCA UGA UCU GUA UUU ATT (sense), UAA AUA CAG AUC AUG GCA CTT (anti-sense); Akt (rat) GCU CAG AUG AUC ACC AUC ATT (sense), UGA UGG UGA UCA UCU GAG CTT (anti-sense). After 72 h, cells were lysed, and protein was analyzed by Western blotting.

Animal experiments

Male ACI rats (Harlan Inc., Indianapolis, IN, United States; 200-220 g) were maintained in laminar-flow cabinets under specific pathogen-free conditions and a 12-h dark-light cycle. The animals were cared for and handled according to recommendations of the NIH guidelines for care and use of laboratory animals. The Shanghai Medical Experimental Animal Care Committee approved the experimental protocol. Intrahepatic tumor implantation with Morris Hepatoma fragments was performed under aseptic conditions as previously described^[21].

The rats were randomly assigned to 3 groups ($n = 10$ per group): vehicle control, sorafenib early treatment, and sorafenib late treatment. Sorafenib treatment groups were given 30 mg/kg sorafenib in 500 μL carrier solu-

tion once daily by gavage. The dose of sorafenib was based on doses commonly used in murine models^[11,22]. Treatment was started on days 5 and 17 after tumor implantation in the sorafenib early and late treatment groups, respectively. On day 17, the HCC xenografts reached approximately 700 mm^3 , which was demonstrated in our preliminary experiment. Control rats received an equal volume of carrier solution by gavage. The rats were sacrificed at day 38 after tumor implantation. At necropsy, tumor volume was calculated as $V = \pi/6 \times \text{length} \times \text{width} \times \text{height}$. Lung and lymph node metastasis, as well as peritoneal seeding, were denoted as the visually positive tumor nodules. For Western blot analysis, tumor tissues were homogenized in tumor lysis buffer. For immunohistochemical staining, tumors were fixed in paraformaldehyde for 24 h and embedded in paraffin for sectioning.

Immunohistochemistry

Tissue sections (4 μm) were stained with hematoxylin and eosin for histologic analysis and with the specific primary antihuman antibodies against p-STAT3-Y705, p-STAT3-S727, p-Akt, p-ERK and cyclin D1 for immunohistochemistry. Briefly, after microwave antigen retrieval, tissues were incubated with primary antibodies overnight at 4 °C, followed by 30-min incubation with the secondary antibody. The reaction was visualized with diaminobenzidine, and tissues were counterstained with hematoxylin.

The tissue sections were viewed at $\times 200$ magnification and images were captured. Five fields per section were analyzed, excluding peripheral connective tissue and necrotic regions. Scoring for p-STAT3-Y705 and p-STAT3-S727 was assigned based on both staining proportion and intensity as previously described^[5]. For expression intensity of p-Akt, p-ERK and cyclin D1, the integrated absorbance and the area in a photograph were measured using Image-Pro Plus v6.0 software (Media Cybernetics, Inc.). A uniform setting of color segmentation was loaded for counting the integrated absorbance of all the pictures, and the mean p-Akt, p-ERK or cyclin D1 density was calculated as the product of the integrated absorbance/total area.

Detection and quantitation of apoptosis

The terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) method was based on the specific binding of terminal deoxynucleotidyl transferase to the 3'-OH ends of DNA, ensuring the synthesis of a polydeoxynucleotide polymer. For this purpose, the In Situ Cell Death Detection kit-Peroxidase (Roche) was used according to the manufacturer's directions.

Capture of the photographs and measurement of positive staining density were performed as described previously^[11,22]. Briefly, the tissue sections were viewed at $\times 200$ magnification and images were captured. The Apoptosis Index was determined by counting at least 1000 cells in 5 randomly selected fields, using Image-Pro Plus v6.0

Table 1 Sorafenib suppresses tumor growth and metastasis *in vivo* *n* (%)

Groups (<i>n</i> = 10)	Tumor volume (mm ³)	Lung metastasis	Lymph node metastasis	Peritoneal seeding	Ascites
Vehicle	12795.71 ± 2980.56	9/10 (90)	7/10 (70)	3/10 (30)	4/10 (40)
Sorafenib (early)	351.26 ± 97.58 ^a	0/10 (0) ^b	0/10 (0) ^b	0/10 (0) ^c	0/10 (0) ^c
Sorafenib (late)	2248.33 ± 971.68 ^a	4/10 (40) ^b	0/10 (0) ^b	0/10 (0) ^c	0/10 (0) ^c

^a*P* < 0.001, Student *t* test (*vs* vehicle group); ^b*P* < 0.05, Fisher's exact test (*vs* vehicle group); ^c*P* < 0.05, Fisher's exact test (*vs* vehicle group).

software (Media Cybernetics, Silver Spring, MD).

Statistical analysis

Statistical analysis was performed with SPSS 16.0 software (SPSS, Chicago, IL). Measurement values were expressed as mean ± SD. The Student *t*-test and Fisher's exact test were used as appropriate. Two-tailed *P* < 0.05 were considered significant.

RESULTS

Sorafenib inhibits tumor growth *in vitro*

To determine the growth inhibition effect of sorafenib in HCC, HCC cell lines HCCLM3, HepG2 and MH were incubated for 24, 48 and 72 h with sorafenib (0.01–20 μmol/L). As shown in Figure 1A, sorafenib inhibited tumor cell growth in both a time- and dose- dependent manner.

Sorafenib inhibits STAT3 phosphorylation independent of JAK2

Given that STAT3 is constitutively activated in HCC, we next evaluated whether sorafenib could induce HCC growth arrest by inhibiting STAT3. We found that sorafenib inhibited phosphorylation of STAT3 at both Y705 and S727 in a dose-dependent manner. Furthermore, inhibition was evident as early as 2 h after treatment and lasted for 24 h (Figure 1B and 1C) in all HCC cell lines, which corresponded with sorafenib-induced growth inhibition as assessed by MTT assay.

JAK2 is considered as one of the most common activators of STAT3. We therefore determined the effects of sorafenib on JAK2. Western blot analysis showed that JAK2 phosphorylation was not reduced during the 24-h sorafenib treatment (Figure 1B and 1C). In addition, total STAT3 protein and mRNA expression levels also remained unchanged during the 24-h treatment (*P* > 0.05 for all; Figure 1C and 1D).

Sorafenib-induced S727 dephosphorylation is dependent on MEK/ERK

Because 24 h treatment with 10 μmol/L sorafenib significantly inhibited S727 and ERK phosphorylation in HCC lines, we evaluated the effect of the selective MEK inhibitor U0126 in HepG2 and MH cells to determine whether MEK was involved in this effect (Figure 2A). Dephosphorylation of S727, not Y705, was associated with attenuated ERK phosphorylation by U0126, suggesting that sorafenib induced S727 dephosphorylation (but not Y705), at least partly, through inhibiting MEK/

ERK phosphorylation.

Sorafenib-induced Y705 dephosphorylation is dependent on PI3K/Akt

A 2-h treatment with the PI3K inhibitor, LY294002, significantly inhibited phosphorylation of Y705, but not S727, in a dose-dependent manner (Figure 2B). This inhibitory effect lasted for 24 h after treatment (Figure 2B), which was in parallel with results of sorafenib treatment. Similarly, we found that knockdown of Akt expression and activation by siRNA also significantly inhibited phosphorylation of Y705, but not S727, in HepG2 and MH cell lines (Figure 2C), suggesting that the PI3K/Akt may be responsible for Y705 phosphorylation in HCC. We further found that sorafenib could inhibit Akt activation in HCC cell lines, mainly at lower concentrations (Figure 2D). Collectively, these results suggested that sorafenib could downregulate Y705 phosphorylation in part by blocking the PI3K/Akt pathway.

Apart from PI3K/Akt, some other effectors, such as SHP2^[23], may also take an active part in Y705 dephosphorylation. Here, we also determined the effects of sorafenib on SHP2. Western blot analysis showed that SHP2 phosphorylation was not affected during the 24 h sorafenib treatment (Figure 2E). Cyclin D1 is an important target gene of STAT3. Our data also showed that the expression of cyclin D1 decreased in HCC cells treated with sorafenib (Figure 2E).

Sorafenib inhibits HCC tumor growth and metastasis *in vivo*

Various manifestations exhibited by our immunocompetent rat model of HCC including local growth, regional invasion, spontaneous metastasis to lungs, lymph nodes, and peritoneal seeding (Figure 3A), as well as molecular signatures like constitutively active JAK2, SHP2, STAT3, Akt and ERK, are similar to those observed in HCC patients.

As shown in Table 1, sorafenib significantly reduced tumor volume (mean tumor volume: vehicle control group, 12795.71 ± 2980.56 mm³; sorafenib late treatment group, 2248.33 ± 971.68 mm³; *P* < 0.001). Furthermore, the primary tumor volume was even lower in the sorafenib early treatment group (mean tumor volume: 351.26 ± 97.58 mm³; *P* < 0.001). Sorafenib treatment (early and late) also suppressed lung and lymph node metastasis compared with the vehicle control (*P* < 0.05; Figure 3A and 3B). Sorafenib treatment reduced peritoneal seeding and bloody ascites, but these differences

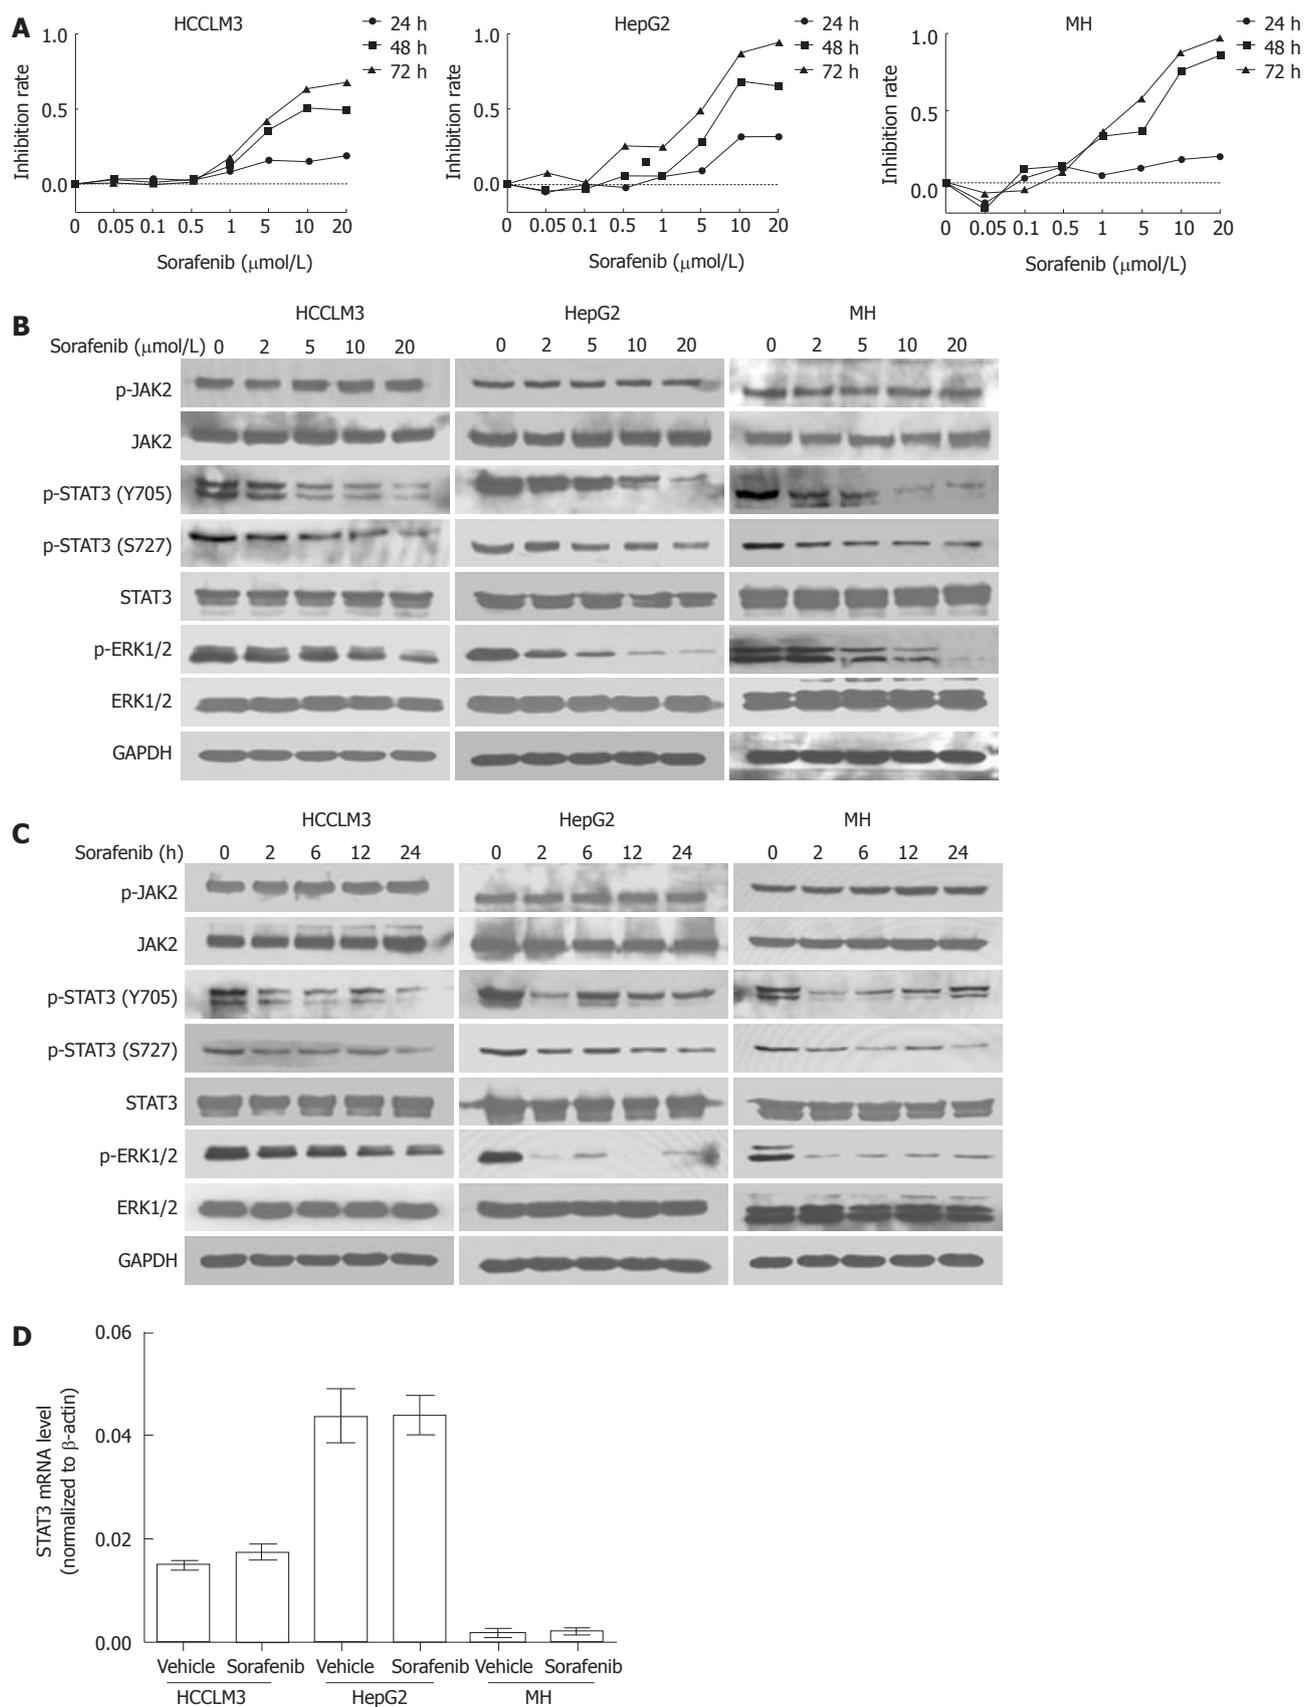

Figure 1 Inhibition of signal transducer and activator of transcription 3 signaling by sorafenib is associated with reduced cell proliferation. A: Sorafenib inhibited cell proliferation in a time and dose-dependent manner, as assessed by the MTT assay; B: Sorafenib inhibited phosphorylation of signal transducer and activator of transcription 3 (STAT3) and extracellular signal-regulated kinase 1/2, but not janus kinase 2 (JAK2), in a dose-dependent manner. Hepatocellular carcinoma (HCC) cells were exposed to sorafenib for 2 h, and proteins were analyzed by Western blot; C: Sorafenib durably inhibited phosphorylation of STAT3 and ERK1/2 but not JAK2. HCC cells were treated with 10 μmol/L sorafenib for different durations, and cell lysates were analyzed by Western blotting; D: Sorafenib did not affect STAT3 mRNA levels in HCC cell lines ($P > 0.05$ for all). After 24-h sorafenib treatment (10 μmol/L), STAT3 mRNA levels were analyzed by qRT-PCR.

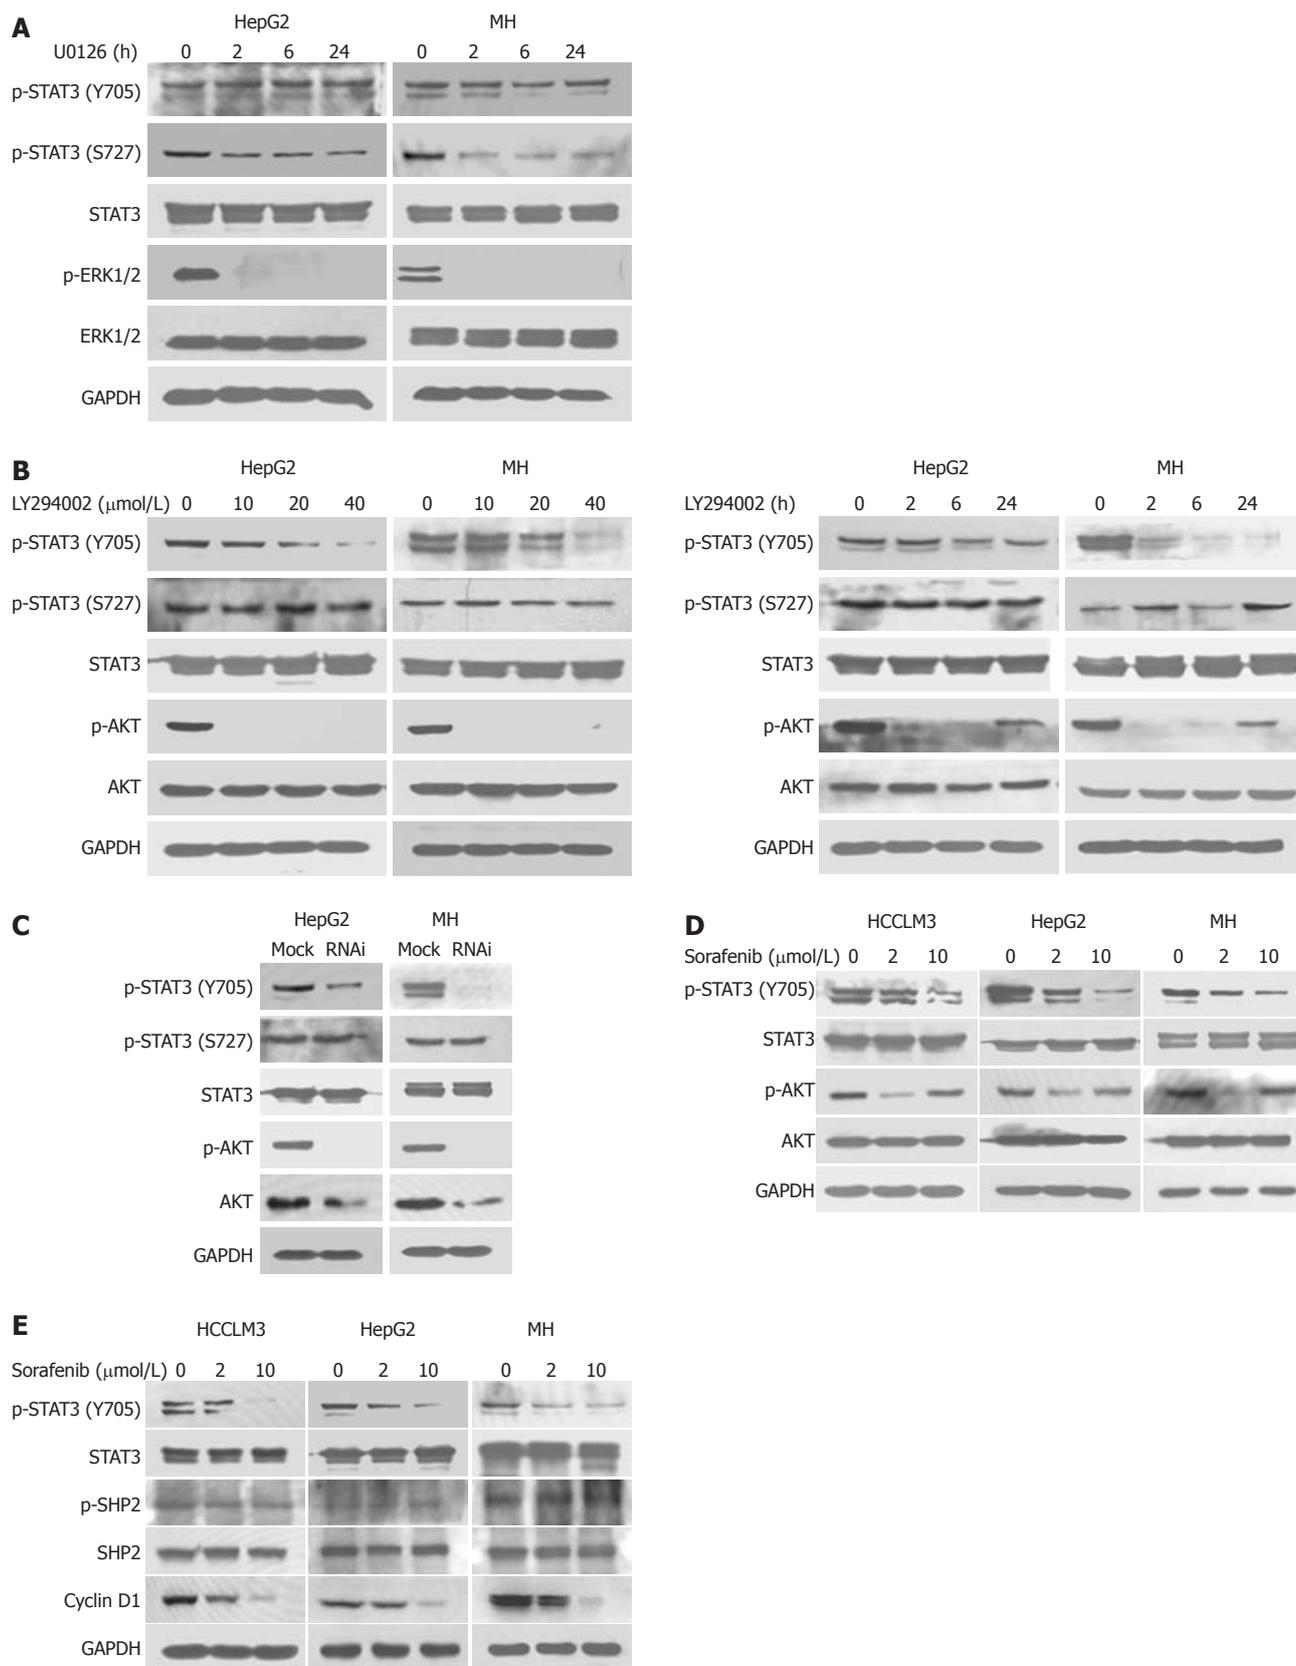

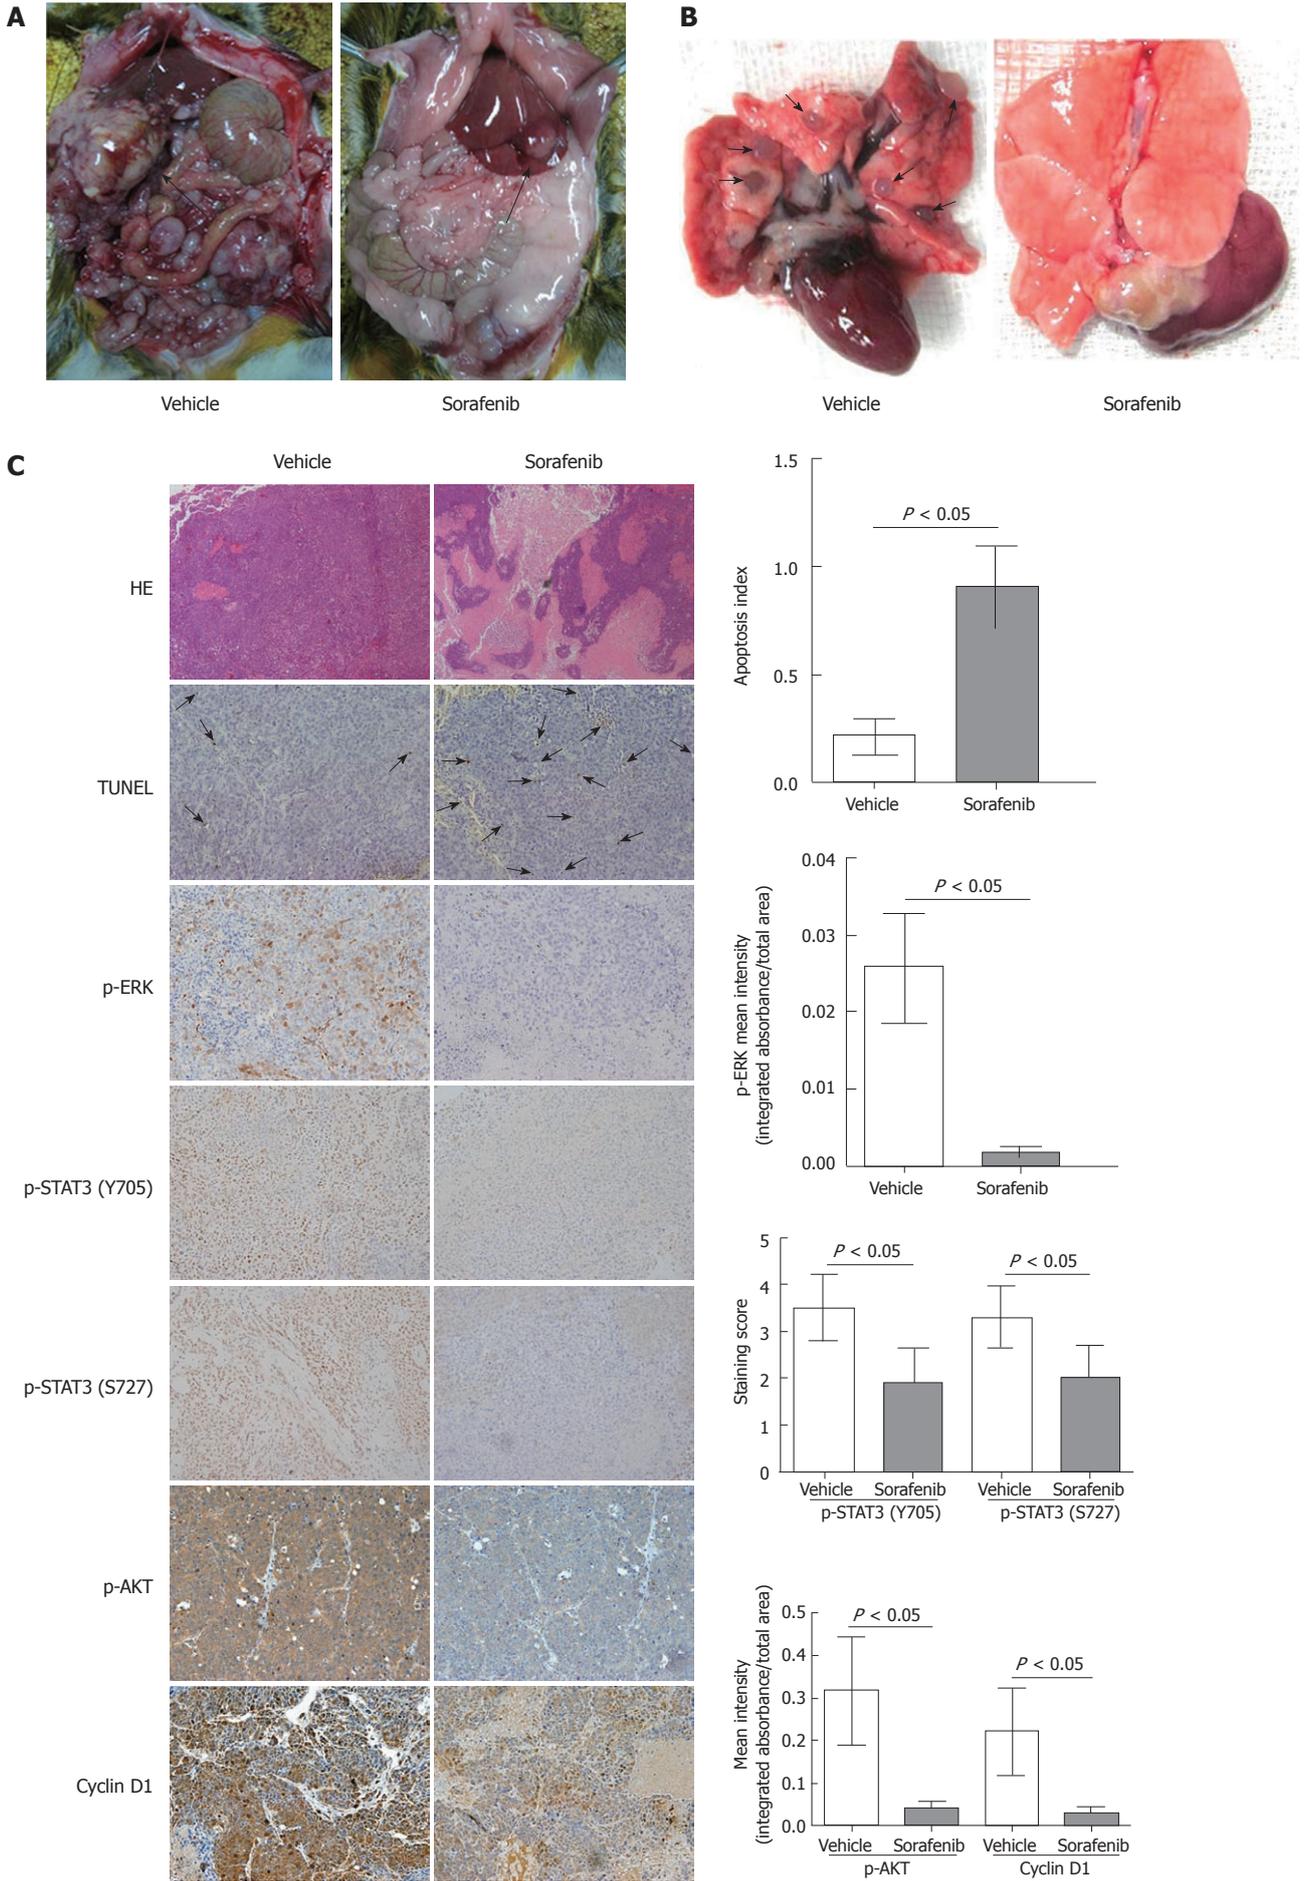

Figure 2 Inhibition of signal transducer and activator of transcription 3 signaling in hepatocellular carcinoma. A: U0126 (20 $\mu\text{mol/L}$) durably inhibited phosphorylation of signal transducer and activator of transcription 3 (STAT3) (S727) in HepG2 and Morris hepatoma (MH) cell lines; B: A 2-h exposure to LY294002 inhibited phosphorylation of STAT3 (Y705) in HepG2 and MH cells in a dose-dependent manner (left). LY294002 (20 $\mu\text{mol/L}$) durably inhibited phosphorylation of STAT3 (Y705) in HepG2 and MH cells (right); C: Akt silencing by siRNA inhibited phosphorylation of STAT3 (Y705, but not S727) in HepG2 and MH cells; D: A 2-h exposure to sorafenib inhibited phosphorylation of Akt, mainly at low concentration (2 $\mu\text{mol/L}$) in HCCLM3, HepG2, and MH cells; E: Sorafenib promoted Y705 dephosphorylation and obviously reduced the expression levels of cyclin D1 regardless of shatterproof 2 (SHP2).

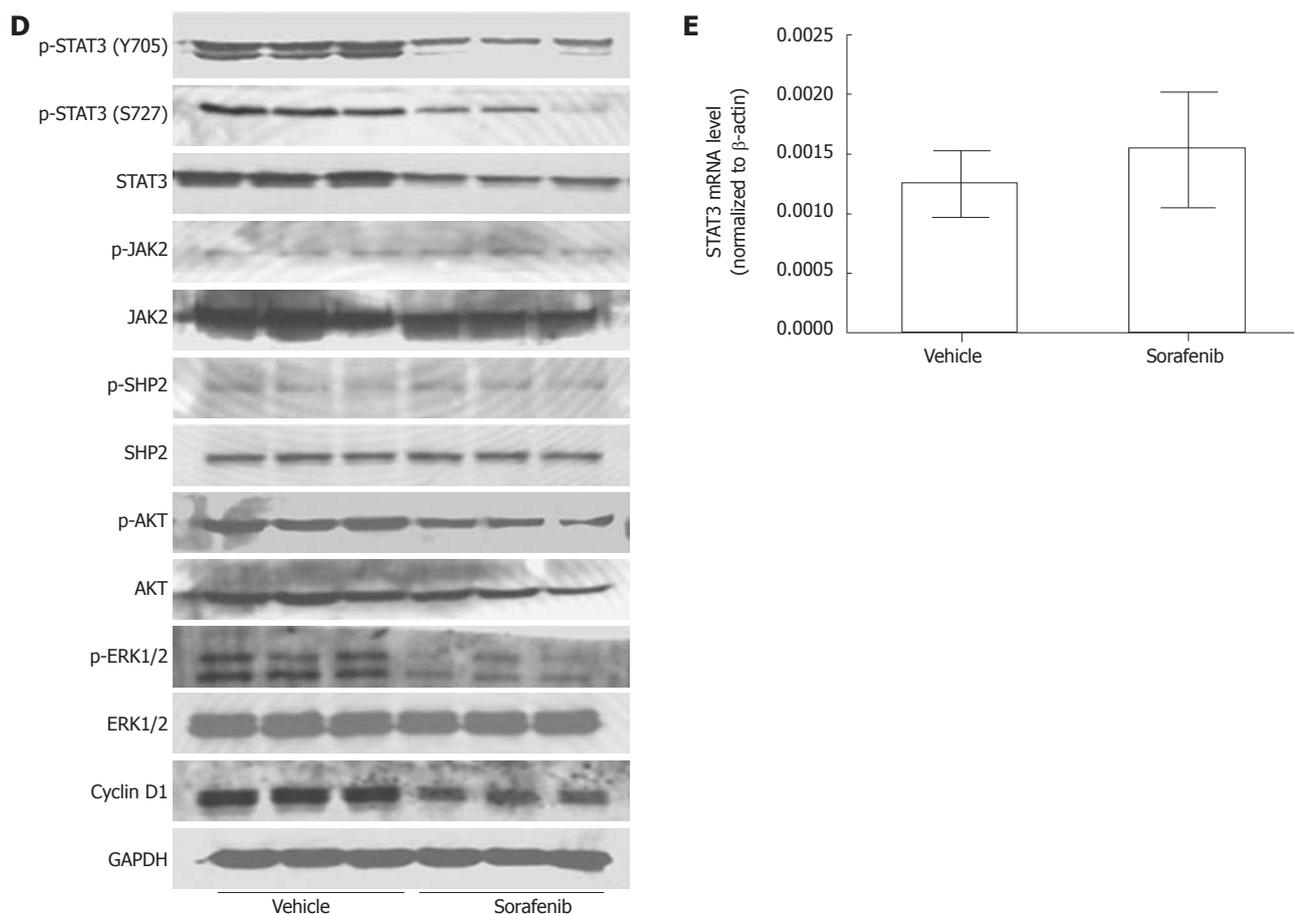

Figure 3 Inhibition of tumor growth and metastasis by sorafenib *in vivo*. Rats with morris hepatoma (MH) tumors were treated with vehicle or sorafenib (30 mg/kg per day) starting on day 17 after tumor implantation. Tumors were removed on day 38 following implantation; A: Tumor growth and abdominal lymph node metastasis were reduced by sorafenib treatment (arrows); B: Sorafenib treatment reduced lung metastasis (arrows); C: Significant tumor necrosis in the sorafenib-treated group was visualized by hematoxylin-eosin staining (magnification, $\times 40$). As shown by TUNEL (arrows), sorafenib also induced tumor cell apoptosis significantly (apoptosis index, 0.217 ± 0.825 vs 0.909 ± 0.189 ; $P < 0.05$; magnification, $\times 200$). Immunohistochemical analysis showed that the expression levels of cyclin D1 and phosphorylation of signal transducer and activator of transcription 3 (STAT3) (Y705 and S727), Akt, and extracellular signal-regulated kinase (ERK) were significantly reduced by sorafenib treatment ($P < 0.05$ for all; magnification, $\times 200$); D: Sorafenib reduced phosphorylation of STAT3, Akt, and ERK, but not Janus kinase 2 and shatterproof 2. Sorafenib also reduced the expression levels of cyclin D1 significantly; E: Sorafenib did not affect STAT3 mRNA levels in rat tumor tissues ($P > 0.05$).

were not significant ($P > 0.05$). Obvious weight loss or death (data not shown) was not observed in sorafenib-treated rats, suggesting that sorafenib was well tolerated and effective in this rat HCC model.

Significant tumor necrosis in the sorafenib treatment group was visualized by hematoxylin-eosin staining (Figure 3C). As shown by TUNEL, sorafenib also induced tumor cell apoptosis significantly (apoptosis index, 0.217 ± 0.825 vs 0.909 ± 0.189 ; $P < 0.05$; Figure 3C). Immunohistochemistry confirmed that phosphorylation of STAT3 (Y705 and S727), Akt and ERK was much lower in the sorafenib treatment group than in the vehicle control ($P < 0.05$ for all; Figure 3C). Western blot analysis also indicated that the dose of sorafenib used in this study was sufficient to inhibit phosphorylation of Akt, ERK and STAT3 in tumors (Figure 3D), which was consistent with its antitumor effects. As with *in vitro* results, sorafenib *in vivo* treatment did not reduce the STAT3 mRNA level ($P > 0.05$; Figure 3E), nor JAK2 and SHP2 phosphorylation (Figure 3D). In addition, expression of STAT3-related cyclin D1 was reduced in the sorafenib

late treatment group ($P < 0.05$; Figure 3C and 3D).

DISCUSSION

STAT3 is constitutively active in most tumor cells and not in normal cells, and hence represents an attractive molecular target^[24]. Here, we showed that sorafenib inhibited STAT3 phosphorylation: (1) at S727 through the MEK/ERK signaling pathway; (2) at Y705 by blocking PI3K/Akt signaling pathways; and (3) independent of JAK and SHP2, thereby inhibiting HCC tumor growth *in vitro* and *in vivo*. Although some studies have reported that sorafenib inhibits STAT3 signaling in some cancers including HCC^[12-16], to the best of our knowledge, this is the first report demonstrating the full inhibition of STAT3 activity on 2 phosphorylating residues by sorafenib acting on distinct underlying mechanisms in HCC (Figure 4).

Phosphorylation of STAT3 at Y705 enables its dimerization, nuclear translocation, DNA binding, and gene transcription^[25], whereas phosphorylation of an-

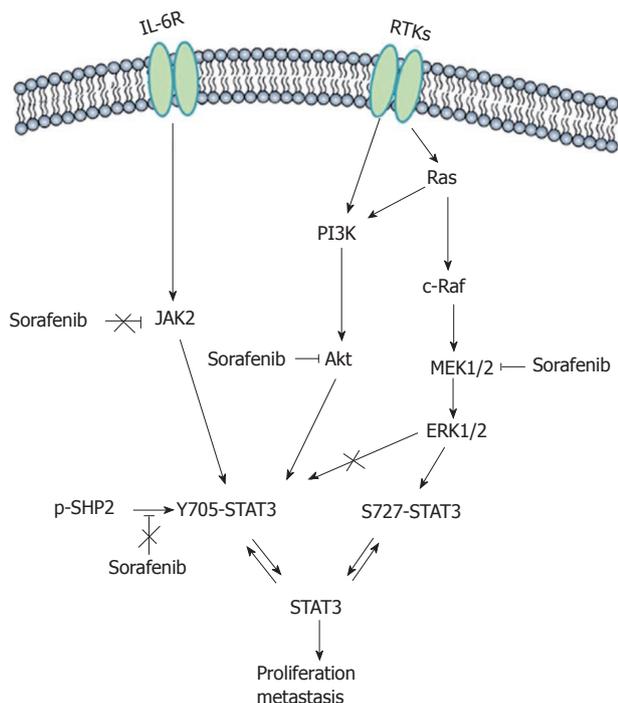

Figure 4 Signaling pathways involved in sorafenib-induced inhibition of signal transducer and activator of transcription 3 phosphorylation. In hepatocellular carcinoma, extracellular signal-regulated kinase-related pathways regulate signal transducer and activator of transcription 3 (STAT3) phosphorylation at S727, and phosphatidylinositol-3-kinase (PI3K)/Akt can be responsible for phosphorylation at Y705. Thus, sorafenib inhibits STAT3 phosphorylation in part through blockade of the mitogen-activated protein kinase kinase (MEK)/extracellular signal-regulated kinase (ERK)/STAT3 and PI3K/Akt/STAT3 signaling pathways, regardless of the Janus kinase 2 and phosphatase shatterproof 2.

other conserved STAT3 residue, S727, enhances STAT3 transcriptional activity^[26]. Cooperation of tyrosine and serine phosphorylation is necessary for the full activation of STAT3^[27]. We found that STAT3 was constitutively phosphorylated at Y705 and S727 in HCC and sorafenib inhibited phosphorylation of the both sites among HCC cells that exhibited different molecular or genetic characteristics. The inhibition was evident as early as 2 h after treatment and lasted for 24 h, suggesting the actions of sorafenib are relatively rapid and prolonged. Furthermore, we identified the potential mechanisms involved in blocking STAT3 signaling.

First, we observed that sorafenib induced STAT3 dephosphorylation at S727 was accompanied by simultaneously blocked MEK/ERK signaling. Similar results were observed with the MEK inhibitor U0126, indicating that ERK-related pathways participate in the regulation of STAT3 in HCC. We reasoned that sorafenib-induced S727 dephosphorylation may be mediated through the MEK/ERK/STAT3 pathway. However, the phosphorylation of both S727 and Y705 were inhibited by sorafenib, whereas U0126 produced no obvious effects on Y705. Therefore, yet unidentified signaling pathways may be involved in sorafenib-induced Y705 dephosphorylation of STAT3.

To clarify this point, we exposed HCC cells to both

the PI3K inhibitor LY294002 and Akt knockdown, and found these treatments resulted in Y705 dephosphorylation. We thus inferred that PI3K/Akt pathway was involved in Y705 dephosphorylation in HCC. Furthermore, we found sorafenib could also inhibit Akt phosphorylation, suggesting that sorafenib could down-regulate Y705 phosphorylation in part by blocking the PI3K/Akt pathway. Given that the PI3K/Akt pathway is an important downstream effector of RTKs^[10], and that RTKs are the major well established targets of sorafenib, we propose that RTK inhibition by sorafenib may be responsible for Akt dephosphorylation in HCC. However, to some extent, Akt dephosphorylation was not correlated well with the inhibition of Y705 phosphorylation by sorafenib. Some other mechanisms, besides PI3K/Akt, may also be involved in Y705 dephosphorylation by sorafenib that need further investigation.

In addition, as a first attempt to elucidate the STAT3 signaling pathways involved in sorafenib-treated HCC cells, we examined the effect of sorafenib on JAK2 and SHP2 activation. JAK2 is a typical non-RTK involved in interleukin-6 intracellular signaling that activates STAT3^[28]. SHP2, a cytoplasmic tyrosine phosphatase, has been recently shown to operate in sorafenib induced STAT3 dephosphorylation in cholangiocarcinoma^[29]. However, both sorafenib-treated and untreated HCC cells contained constitutively activated JAK2 and SHP2, indicating that sorafenib promoted STAT3 dephosphorylation regardless of JAK2 and SHP2. Meanwhile, we did not find that total STAT3 protein expression and mRNA levels were affected.

Because host immune responses play a critical role in hepatocarcinogenesis, invasion and dissemination^[30,31], we chose an immunocompetent model for our *in vivo* studies. In this model, sorafenib increased tumor necrosis, induced tumor cell apoptosis and decreased tumor growth, as compared with control treatment. Importantly, consistent with *in vitro* results, *in vivo* sorafenib treatment significantly inhibited STAT3 activity at both Y705 and S727 with concomitant dephosphorylation of Akt and ERK, while dephosphorylation of JAK2 and SHP2 was not observed. In addition, the expression levels of cyclin D1, an important target gene of STAT3, were also reduced accordant with STAT3 inhibition both *in vitro* and *in vivo*.

In conclusion, we demonstrated that sorafenib is capable of inhibiting HCC growth and metastasis by suppressing STAT3 activity. PI3K/Akt and MEK/ERK signaling pathways may be collectively involved in inhibiting STAT3 activity, independent of SHP2 and JAK2. Our findings not only elucidate an additional potential molecular target of sorafenib, but also provide a rational basis for the development of combination strategies to maximize the HCC response.

COMMENTS

Background

Recent studies have shown that signal transducer and activator of transcription 3 (STAT3) is constitutively activated in hepatocellular carcinoma (HCC) and

may be an attractive molecular target. Sorafenib is a multikinase inhibitor that has shown efficacy against advanced HCC. This study investigated the molecular mechanisms of STAT3 inhibition by sorafenib in HCC.

Research frontiers

STAT3 plays a critical role in transcriptional regulation of genes that are involved in tumor cell proliferation, survival and invasion, thus targeting of STAT3 activation may prove to be an effective approach to controlling HCC. Recently, sorafenib has been shown to suppress tumor growth by decreasing STAT3 phosphorylation in a group of human malignancies including HCC. However, thus far, the exact molecular mechanisms by which sorafenib inhibited STAT3 were not fully elucidated.

Innovations and breakthroughs

Although some studies have reported that sorafenib inhibits STAT3 signaling in some cancers including HCC, to the best of our knowledge, this is the first report demonstrating that sorafenib inhibits growth and metastasis of HCC by the full inhibition of STAT3 activity on 2 phosphorylating residues involved in the distinct underlying mechanism of HCC.

Applications

The findings not only elucidate an additional potential molecular target of sorafenib, but also provide a rational basis for the development of combination strategies to maximize the HCC response.

Terminology

STAT3, an important transcription factor, plays a critical role in transcriptional regulation of genes that are involved in tumor cell proliferation, survival and invasion. STAT3 is constitutively activated in diverse cancer cell types and has been shown to be an essential signaling molecule in tumorigenesis through its transcriptional activity on tumor-associated genes.

Peer review

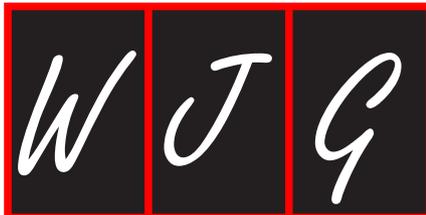

In this manuscript, the authors showed the mechanisms of the suppression of HCC growth by sorafenib *in vivo* and *in vitro*. The study is organized well, the results are interesting and the manuscript is written properly.

Abstract

AIM: To investigate the expression of Erythropoietin (Epo) and its receptor (EpoR) in gastric adenocarcinoma (GAC) and the correlation with angiogenesis and clinicopathological features.

METHODS: The expressions of Epo, EpoR and vascular endothelial growth factor (VEGF), as well as microvessel density were evaluated in 172 GAC biopsies by immunohistochemical staining. The correlations between these parameters and patient's clinicopathological features were analyzed statistically.

RESULTS: The proportion of Epo and EpoR alterations in GAC was higher than that in adjacent normal mucosa ($P = 0.035$ and 0.030). Epo high-expression was associated with EpoR high-expression, Lauren type, extensive

lymph node metastasis and advanced stage of GAC ($P = 0.018$, 0.018 , 0.004 and 0), while EpoR expression was linked with older age, World Health Organization type, extensive lymph node metastasis and advanced stage ($P = 0.001$, 0.013 , 0.008 and 0.001). VEGF high expression was significantly correlated with EpoR low-expression, Lauren type, extensive lymph node metastasis and advanced stage ($P = 0.001$, 0.001 , 0.001 and 0.007). The expression of Epo or EpoR was associated with microvessel density ($P = 0.004$ and 0.046). On multivariate analysis, only lymph node metastasis, abnormal Epo expression and tumor nodes metastases stage were independently associated with survival. In addition, a strong association with the immunohistochemical expression of EpoR and the angiogenic protein, VEGF, was noted.

CONCLUSION: Increased expression of Epo and EpoR may play a significant role in the carcinogenesis, angiogenesis and progression of GAC. Epo may be an independent prognostic factor.

INTRODUCTION

Gastric adenocarcinoma (GAC) is one of the common-

est fatal malignancies in the world. The incidence varies considerably between geographical areas, with a higher incidence in China and other Asian countries than in Western Europe and the United States^[1]. Patients with tumors limited to the mucosa and submucosa have an excellent prognosis, with a 5-year survival rate of over 90% after surgery^[2]. In contrast, the prognosis for patients with advanced cancers is less predictable and generally poorer. At present, therapeutic decisions are based on clinical-pathological parameters, including age, tumor nodes metastases (TNM) stage and histological grade. Although useful, these factors often fail to differentiate more aggressive tumor types from less aggressive types^[3]. As a result, there is an urgent need to find special markers, which are closely related to biologic characteristics, outcome of gastric adenocarcinoma and performance of antigen-specific therapeutic targeting strategy.

Erythropoietin (Epo) is a low-molecular-weight glycoprotein hormonal stimulator of erythropoiesis produced in the fetal liver and subsequently in the adult kidney^[4]. Epo exerts its action through its specific receptor (EpoR), a member of the cytokine receptor superfamily, which is mainly expressed on erythroid colony-forming units^[5]. The presence of an autocrine-paracrine Epo-EpoR system in tumors and the possible effects of Epo on the tumor microenvironment and angiogenesis are consistent with a complex biology for Epo-EpoR signaling in cancer.

Epo is a pleiotropic cytokine that exerts diverse biological effects in many non-hematopoietic tissues. There is increasing evidence suggesting a wider biological role for Epo/EpoR unrelated to erythropoiesis. Angiogenesis, the process by which new blood vessels arise from pre-existing vessels, has been shown to be one of the extra-hematopoietic functions of Epo^[6]. The precise role of Epo in angiogenesis has not been clarified, although many critical functions of Epo have been reported. Endothelial cells from some sources express EpoR^[7]. Moreover, Epo induces endothelial cell proliferation and migration^[7-9] and has been shown to stimulate angiogenesis in rat aortic rings *in vitro*^[10]. The expression of EpoR in tumor vascular endothelium suggests that Epo may affect the tumor microenvironment, perhaps by stimulating tumor angiogenesis^[6]. In addition, Epo was considered to inhibit endothelial cell apoptosis induced by high glucose^[11]. A clinical trial demonstrated that EpoR level correlated with angiogenesis and progression of patients with gastric carcinoma, and that Epo might have a trophic effect on the vasculature of the gastrointestinal tract^[12].

The angiogenic potential of Epo was found to be similar to that of vascular endothelial growth factor (VEGF) when stimulating human adult myocardial endothelial cells^[13]. VEGFs, as the main regulators in angiogenesis, have chemotactic effects and promote the division of cells. Many studies have identified that the expression levels of VEGFs in malignant tumor were strongly correlated with their malignant grading, mi-

crovessel density and prognosis^[14].

In the present study, we investigated the expression of Epo and EpoR in human gastric adenocarcinomas and assessed their possible association with various histopathological features, microvascular density and expression of the *VEGF* gene. Moreover, the association between Epo/EpoR expression and prognosis was evaluated.

MATERIALS AND METHODS

Patient data

Tumor specimens were obtained from 172 patients (108 males and 64 females; mean age 55.9 years; range 24 to 82 years) who underwent surgery for gastric adenocarcinomas from November 2005 through April 2008. None had received prior chemotherapy or radiotherapy. All patients provided written informed consent.

Clinical and pathological records and slides were available for all cases. HE-stained slides of gastric adenocarcinomas were reviewed and one block with tumor and adjacent normal mucosa (ANM) tissue was selected for immunohistochemical staining. Histopathological examination indicated that 64 GAC samples were intestinal type according to Lauren-type classification, 70 were diffusal type and 38 were mixed type, respectively. According to World Health Organization (WHO) histological classification, 142 patients were diagnosed as tubular type, 12 patients were diagnosed as mucinous type, 4 patients were diagnosed as papillary type, and 14 patients were diagnosed as signet ring cell type. According to TNM classification, there were 10 cases at stage I, 18 at stage II, 80 at stage III and 64 at stage IV, respectively.

Processing of specimens and immunohistochemistry

Sections (4 μ m) of tissue blocks were transferred to an adhesive-coated slide. A 3-step immunoperoxidase technique using streptavidin-peroxidase (S-P) was employed for Epo, EpoR and VEGF detection. All the sections were routinely deparaffinized and rehydrated, then the sections were rinsed in phosphate-buffered saline (PBS, pH = 7.4), and were subsequently treated for antigen retrieval (10 min, microwave oven, 800 W, citrate buffer, pH = 6.0). After cooling at room temperature for 20 min, the sections were rinsed in PBS, and then immersed in 3% H₂O₂ for 15 min to block the endogenous enzymes. Thereafter, the sections were incubated with normal goat serum at 37 °C for 15 min to block non-specific antibodies. The primary antibodies were a polyclonal goat antiserum for Epo (polyclonal, N-19, Santa Cruz, United States), a polyclonal rabbit antiserum for EpoR (polyclonal, H-194, Santa Cruz, United States), monoclonal rabbit antiserum for VEGF (monoclonal, ZA-0509, Zhongshan, China) and a mouse monoclonal antibody against the human endothelial cell marker CD34 (monoclonal, ZM-0046, Zhongshan, China), which were diluted at 1:50 dilution. They were used for overnight incubation at 40 °C. The sections were then rinsed in PBS and incubated with biotinylated secondary

antibodies (SP kit, Zhongshan, China) and rinsed in PBS again. After interaction with streptavidin-HRP (SP kit, Zhongshan, China) and then rinsed in PBS, the sections were visualized by reaction with 3, 3'-diaminobenzidine and counterstained with hematoxylin. For both antibodies, adequate positive controls of kidney and liver were used according to the manufacturer's recommendations, and normal goat serum and PBS substituting the primary antibody were used as negative controls.

Scoring of the results

The immunostaining results were evaluated and scored independently by two pathologists without knowledge of the clinical data of patients. Antibody staining results were scored according to the percentage of cytoplasmic positive cells as follows: (-), < 10%; (+), 11%-20%; (++) , > 21%. Only epithelial labeling was scored. Epo, EpoR and VEGF high-expression was defined as > 20% tumor cells with positive staining, whereas low-expression was < 20%.

Microvessel density

The counting of microvessels in GAC was evaluated by a previously reported method^[15]. Briefly, intratumoral microvessel density (IMD) was observed in areas of most intense neovascularization or hotspots in tumor by light microscopy. After determining the area of highest neovascularization, single microvessels were manually counted on a 200 × field by two different observers without knowledge of patient outcome. Any brown-stained endothelial cell or cell cluster clearly separated from adjacent microvessels was considered as a single, countable microvessel.

Statistical analysis

All statistical analyses were performed with SPSS 13.0 software for Windows. The chi-square test was used to assess Epo, EpoR and VEGF expression with clinicopathological characteristics. Univariate analysis by Student's *t* test was used to assess protein expression in relation to angiogenesis of GAC. The survival curve of patients was determined using the Kaplan-Meier method and Cox regression, and statistical evaluation was performed using the log rank test. *P* < 0.05 was considered statistically significant.

RESULTS

Expression of Epo, EpoR in GAC biopsies, and their correlation

Epo and EpoR expression were strong on the cell membrane and in the cytoplasm of GAC cells (Figure 1A and B). However, the signals were weak in ANM cells. Of the sections with ANM, only 12 (6.98%) of 172 cases were stained positively with Epo antibodies and 15 (8.72%) were stained positively with EpoR antibodies. 74.4% (128/172) of carcinomas stained positively for Epo, and 60.5% (104/172) of carcinomas stained positively for EpoR. A stronger positivity was found in GAC than in ANM for both Epo and EpoR ($\chi^2 = 4.434$, *P* =

Table 1 Correlation between expression of erythropoietin, erythropoietin receptor and vascular endothelial growth factor

EpoR	Epo		<i>P</i> value	VEGF		<i>P</i> value
	Low expression	High expression		Low expression	High expression	
0	24	44	0.018	22	46	0.001
1	20	84		60	44	

EpoR: Erythropoietin receptor; Epo: Erythropoietin; VEGF: Vascular endothelial growth factor.

0.035 and $\chi^2 = 4.719$, *P* = 0.030, respectively).

Epo and EpoR were detected in concomitant expression in the same portion of tumor cell on serial sections. Epo expression was found to be closely related to the expression of EpoR in tumor (Table 1).

Epo, EpoR and VEGF expression in correlation with clinicopathological parameters in GAC

Epo high-expression (74.4%, 128/172) was significantly correlated with Lauren type, extensive lymph node metastasis and advanced stage of GAC. However, no significant correlation between Epo high-expression and older age, gender or WHO type was observed. High-expression of EpoR (60.5%, 104/172) was found to have a significant positive correlation with older age, WHO type, extensive lymph node metastasis and advanced stage. No significant correlation between EpoR high-expression and gender or Lauren type was observed (Table 2).

Positive VEGF expression was found in 52.3% of (90/172) tumor tissues (Figure 1C). VEGF high-expression was significantly correlated with Lauren type, extensive lymph node metastasis and advanced stage of GAC. However, no significant correlation between VEGF high-expression and gender or WHO type was observed (Table 2). VEGF and EpoR were detected in concomitant expression in the same portion of tumor cell on serial sections. VEGF expression was found to be closely related to the expression of EpoR in tumor (Table 1).

Relationship of Epo, EpoR and VEGF expression with microvessel density

Microvessels in GAC, indicated by CD34 immunostaining, were observed to be scattered in the tumor cell nests (Figure 1D), and were scored as IMD. The correlation between IMD and protein expression in GAC is shown in Figure 2. Mean IMD value was 31.62 ± 14.01 and 31.57 ± 14.01 in the cases with high Epo or EpoR expression, respectively, which were significantly higher than those in the cases with low Epo or EpoR expression (24.82 ± 11.74 and 27.29 ± 13.06 , *P*-values were 0.004 and 0.046, respectively). We examined the relationship between other clinicopathological characteristics and IMD in tumors; however, no significant correlations were found. Therefore, angiogenesis in GAC seemed to be independent of gender, age, WHO type, lymph node metastasis, TNM stage and VEGF expression in patients.

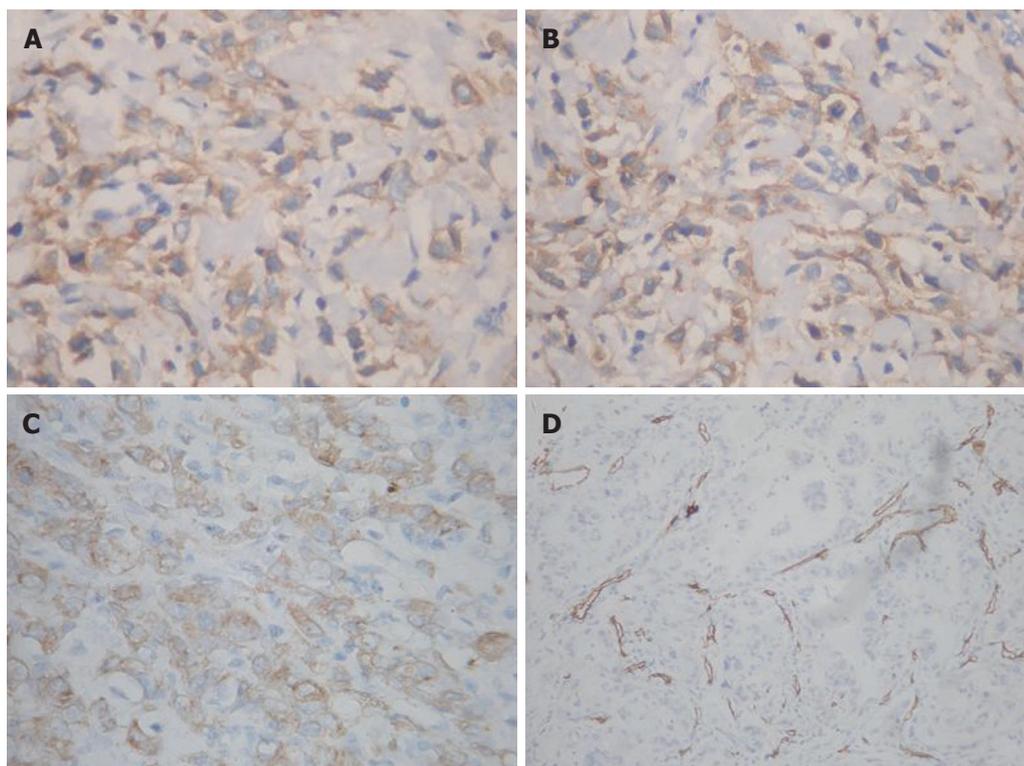

Figure 1 Erythropoietin, erythropoietin receptor, vascular endothelial growth factor and CD34 expression in biopsies from gastric adenocarcinoma patients. A, B: Erythropoietin and erythropoietin receptor positive immunostaining signals were localized in the cytoplasm of tumor cells with a scattered distribution pattern in most cases; C: Vascular endothelial growth factor immunoreactivity was detected in the cytoplasm of gastric adenocarcinoma. Original magnification: $\times 200$; D: Microvessels in tumor were highlighted by staining endothelial cells for anti-CD34. Any brown-staining endothelial cell or cell cluster that was clearly separated from adjacent microvessels was considered as a single, countable microvessel. Original magnification: $\times 100$.

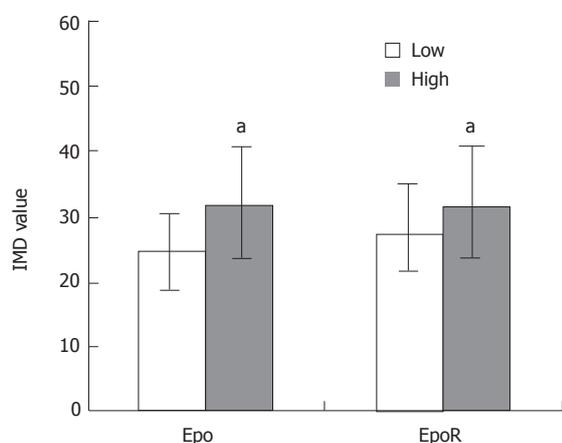

Figure 2 Correlation between intratumoral microvessel density and protein expression in gastric adenocarcinoma. The mean intratumoral microvessel density in the high-expressed erythropoietin (Epo) and erythropoietin receptor (EpoR) cases was significantly increased compared to that of low-expressed cases ($^aP < 0.05$). IMD: Intratumoral microvessel density.

Association of Epo, EpoR and VEGF expression with survival of GAC patients

In this study, 150 cases had adequate follow-up data for the final analysis, whereas 22 cases were excluded from survival analysis because the patients were lost to follow-up. The 150 cases were followed up for 1 to 56 mo (mean 27.4 mo), and 98 patients (65.3%) died of tumor during this period.

Univariate survival analysis demonstrated that patients with high Epo immunoreactivity, had a significantly worse overall survival compared to patients with low Epo immunoreactivity (log rank test: $P = 0.0167$, Figure 3B). Median survival time of patients with low Epo expression was 45 mo, which was much longer than patients with high positivity whose median survival time was 14 mo.

Patient survival was also associated with lymph node metastasis and advanced clinical stage ($P = 0.000$ and $P = 0.0006$, Figure 3A, 3C). The difference in survival rate was not significant between the GAC patients with different EpoR expressions ($P = 1.0000$). When patients were stratified according to tumor high-expression of both Epo and EpoR (84 cases), the difference in survival rate was not significant between the patients with both high-expression of Epo and EpoR compared with patients with low-expression of both Epo and EpoR or single protein high-expression ($P = 0.5306$). In addition, the difference in survival rate was not significant between the patients with different VEGF expression status in tumor cells ($P = 0.9756$).

On multivariate analysis, only lymph node metastasis (hazard ratio, 1.672; 95% confidence interval, 1.2199-2.2916, $P = 0.0014$), abnormal Epo expression of GAC tumor cells (hazard ratio, 1.6517; 95% confidence interval, 0.9979-2.7338, $P = 0.0509$) and TNM stage (hazard ratio, 1.4292; 95% confidence interval, 1.0403-1.9636, $P = 0.0276$)

Epo: Erythropoietin; LN: Lymph node.

were independently associated with survival (Table 3).

DISCUSSION

Epo is used to manage anemia in cancer patients^[16,17]. Patients treated with recombinant human Epo not only have increased levels of hemoglobin, but their performance status also improves significantly, and they enjoy a significantly enhanced quality of life^[17]. The expression of the Epo-EpoR system in tumor vascular endothelium suggests that this system may affect the tumor microenvironment, perhaps by stimulating tumor angiogenesis^[6,18,19]. In this study, we found a correlation between the expression of Epo or EpoR and CD34 in vascular endothelial cells using immunohistochemistry. Compared with that in cases with low Epo or EpoR expression, microvessel density in tumor in the cases with high Epo or EpoR expression was significantly higher. These results suggested that the Epo-EpoR system is an important factor in gastric adenocarcinoma angiogenesis. The possible effects of Epo/EpoR

on tumor angiogenesis are consistent with the complex biology of Epo-EpoR signaling in cancer. Thus, the potential role of the Epo-EpoR system in angiogenesis may be considered as a subsidiary of its possible function in improving overall tissue oxygenation^[11].

Epo and EpoR were detected in solid tumors of the brain^[20], breast^[21,22], kidney^[23], female genital tract^[24], squamous cell carcinoma of the uterine cervix and tongue^[25,26], and were implicated in tumor growth, invasion and metastasis. In the present study, we clearly demonstrated the presence of Epo and EpoR proteins in a series of GAC by immunohistochemistry. Epo and EpoR were highly expressed in GAC as compared to ANM. These results suggest that Epo and EpoR may be involved in the pathogenesis of GAC.

Nakamatsu *et al*^[27] demonstrated that Epo was not detectable in normal or cirrhotic liver tissues without tumors using radioimmunoassay, while immunoreactive EpoR was detectable in the endothelium of intervening vessels of all hepatic tumors using immunohistochemistry. The reason for selective expression of EpoR in the tumor vessels is unclear. The immature nature of tumor vessels compared with mature hepatic vessels may be related to the selective expression of EpoR. In the present study, Epo expression was significantly associated with Lauren type, while EpoR expression was significantly associated with WHO type. These results may suggest that the signaling pathway of Epo is different from that of EpoR in GAC. The most interesting finding of this

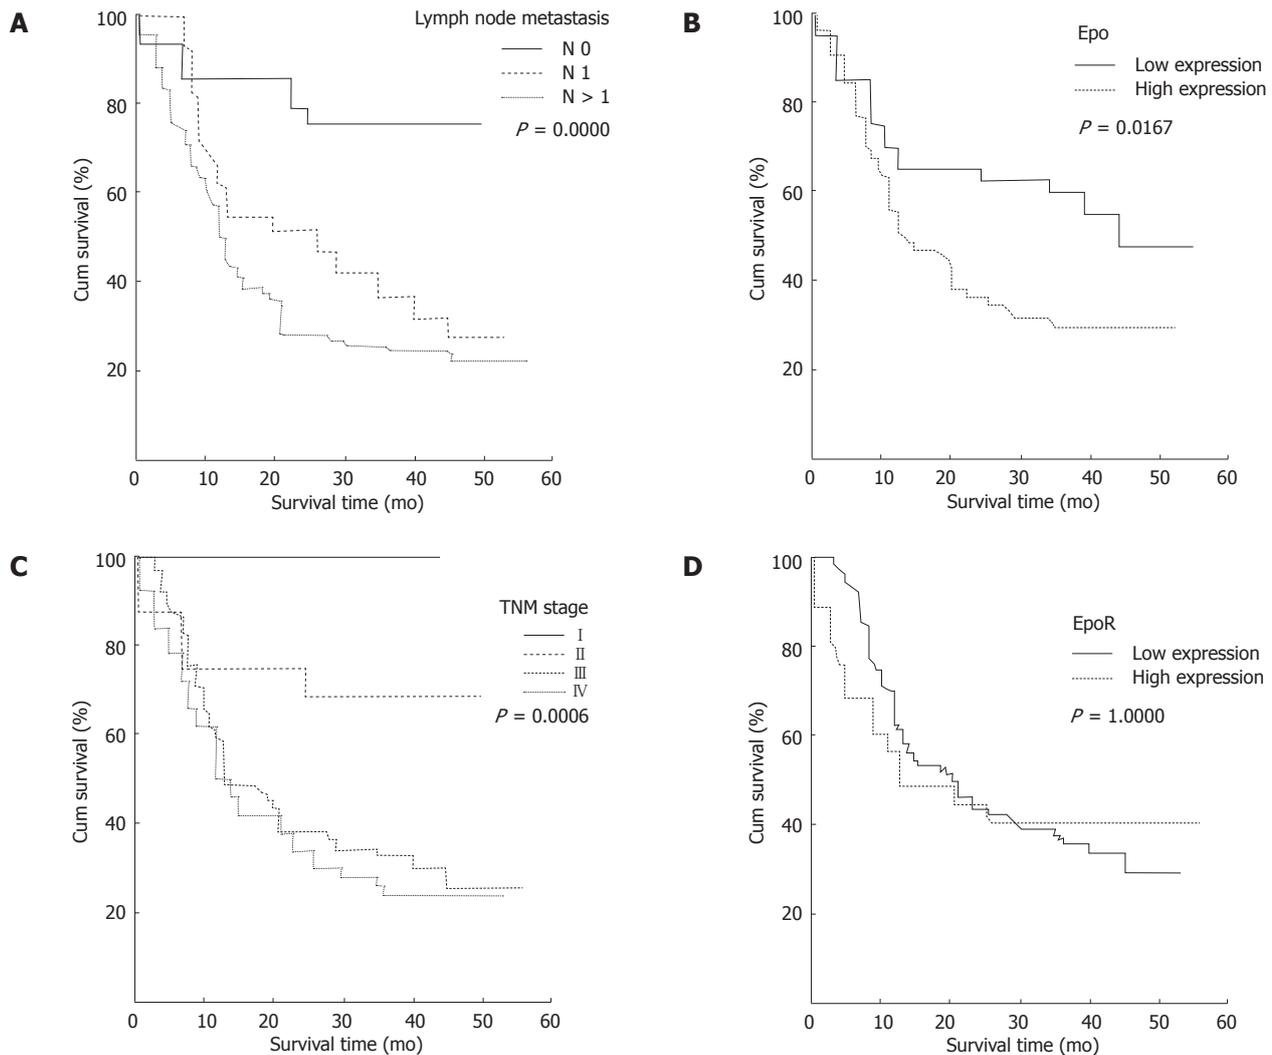

Figure 3 Kaplan-Meier survival analyses of gastric adenocarcinoma patients. A: Kaplan-Meier curve showing that patients with lymph node metastasis ($N \geq 1$) have a lower survival rate than those without lymph node metastasis (N0); B: A significant difference in survival rate was found between gastric adenocarcinoma (GAC) patients with high and low erythropoietin expression in tumor; C: A significant difference in survival rate was found between different clinical stages; D: No significant difference in survival rate was found between GAC patients with high and low erythropoietin receptor expression in tumor.

study is the association between EpoR expression and age. EpoR expression was higher in older patients than in younger patients. The reason for such selective expression in GAC is not clear.

Phenotypic traits of malignant tumor may be caused by microenvironmental selection pressure during carcinogenesis. Hypoxia can drive a tumor towards more malignant phenotypes^[28], such as invasion and migration of tumor cells, which may be the basis for lymph node metastasis and distant metastasis. Our previous study demonstrated that increased levels of Epo and EpoR promote invasiveness and lymph node metastases of human tongue squamous cell carcinoma^[26]. In the current study, the observed relationship between high Epo or EpoR expression and lymph node metastasis as well as advanced tumor stage indicated that Epo or EpoR might be possible mediators that contribute to the extensive lymph node metastasis and accelerated progression of GAC.

In the Epo-EpoR system, both pathways were important in executing their multifunctions. The co-expression

of Epo and EpoR in tumor cells suggests the involvement of an autocrine Epo-EpoR signaling loop. However, in the survival analysis, although high Epo expression in tumor cells was closely associated with lower survival rate of patients with GAC, high EpoR expression was not. Moreover, on multivariate analysis of prognostic factors in GAC, only high Epo expression emerged as an independent factor which influenced the prognosis of GAC patients. These results indicate that the tumor-cell-derived Epo-EpoR system may contribute, in part, to metastasis of lymph node and progression of GAC through an autocrine pathway. Epo is an independent prognostic factor in predicting the prognosis of GAC.

Epo is a hypoxia-inducible stimulator of erythropoiesis. Acting *via* its receptor (EpoR), Epo up-regulates bcl-2 and inhibits apoptosis of erythroid cells, and then, rescues neurons from hypoxic damage^[29]. Although we did not detect expression and regulation of bcl-2 in GAC tumor cells, it is reasonable to believe that only abnormal Epo expression, including absent and endocytosed

expression resulting in dysfunction of Epo complexes, plays important roles in metastasis and progression of GAC. Yasuda *et al.*^[30] blocked Epo signaling in xenografts of stomach choriocarcinoma in nude mice by ip injections of EpoR antagonist, and found inhibition of angiogenesis and tumor cells, and destruction of tumor masses. The mechanism of Epo and EpoR protein over-expression in GAC merits further investigation to establish these proteins as therapeutic targets.

The expression, regulation and biological significance of the Epo/EpoR system and VEGF in malignant tumor are complicated. It is well known that VEGF induced by hypoxia might mediate hypoxia-initiated angiogenesis^[31], while hypoxia could rapidly activate hypoxia inducible factor-3 α (HIF-3 α) gene expression^[32]. Under hypoxic stimulation, HIF-1 has been shown to activate the transcription of Epo^[30]. Epo and EpoR gene expressions are under the direct control of hypoxia through stabilization of the HIF1 α transcription factor that binds to the hypoxia-responsive element of the *Epo* gene^[33]. Nakano *et al.*^[34] demonstrated the important roles of the vascular EpoR system, including induction of postischemic angiogenesis, secretion of VEGF from ischemic muscle and BM-derived cells, and enhancement of VEGFR-2 in ischemic tissue. These results suggested that EpoR might be important for VEGF secretion and angiogenesis.

In the current study, VEGF expression was significantly correlated with Lauren type, lymph node metastasis, TNM stage and EpoR reactivity. To the best of our knowledge, this is the first study to demonstrate a tight relationship between EpoR and VEGF expression in GAC. High EpoR reactivity was linked with low VEGF expression, possibly as a result of an intracellular signal overflow. Thus, we infer a rivalry action existing between EpoR and VEGF when combining with the receptor on tumor surface.

COMMENTS

Background

Gastric adenocarcinoma is one of the commonest fatal malignancies worldwide especially in China and other Asian countries. The prognosis for patients with advanced cancers is generally poor. There is an urgent need to find special markers closely related to tumor outcome and therapy.

Research frontiers

Erythropoietin (Epo) and its specific receptor (EpoR) are members of the cytokine receptor superfamily. The possible effects of Epo on tumor microenvironment and angiogenesis are consistent with the complex biology of Epo-EpoR signaling in cancer. However, the precise role of Epo-EpoR in gastric adenocarcinoma is still not clear. In this study, the authors demonstrate that the Epo-EpoR system is an important factor in gastric adenocarcinoma angiogenesis.

Innovations and breakthroughs

Epo and the EpoR have been implicated in some solid tumors. However, there are very few data in the medical literature regarding the role of Epo and the EpoR in the carcinogenesis or progression of gastric adenocarcinoma. This study demonstrates that Epo and EpoR are over-expressed in gastric adenocarcinoma. Furthermore, the authors suggest that Epo or EpoR might be possible mediators that contribute to the extensive lymph node metastasis and accelerated progression of gastric adenocarcinoma.

Applications

By understanding the important roles of the Epo-EpoR system in metastasis

and progression of gastric adenocarcinoma, this study may represent a future strategy for therapeutic intervention in the treatment of patients with gastric adenocarcinoma.

Terminology

Epo is a pleiotropic cytokine that exerts diverse biological effects in many non-hematopoietic tissues such as stimulating tumor angiogenesis. Epo exerts its action through EpoR.

Peer review

The authors examined the expression of Epo and EpoR in gastric adenocarcinoma and the correlation with angiogenesis and clinicopathological features. It revealed that Epo and EpoR system provides advantage to the carcinogenesis, angiogenesis, and malignant progression of gastric adenocarcinoma. The results are interesting and indicate that Epo might be an independent prognostic factor in gastric adenocarcinoma.

Abstract

AIM: To assess the association between *Interleukin-10* (IL-10) gene IL-10-1082 (G/A), IL-10-592(C/A), IL-10-819 (T/C) polymorphisms and hepatocellular carcinoma (HCC) susceptibility.

METHODS: Two investigators independently searched the Medline, Embase, China National Knowledge Infrastructure, and Chinese Biomedicine Database. Summary odds ratios (ORs) and 95% confidence intervals (95% CIs) for IL-10 polymorphisms and HCC were calculated in a fixed-effects model (the Mantel-Haenszel method) and a random-effects model (the DerSimonian and Laird method) when appropriate.

RESULTS: This meta-analysis included seven eligible

studies, which included 1012 HCC cases and 2308 controls. Overall, IL-10-1082 G/A polymorphism was not associated with the risk of HCC (AA vs AG + GG, OR = 1.11, 95% CI = 0.90-1.37). When stratifying for ethnicity, the results were similar (Asian, OR = 1.12, 95% CI = 0.87-1.44; non-Asian, OR = 1.10, 95% CI = 0.75-1.60). In the overall analysis, the IL-10 polymorphism at position -592 (C/A) was identified as a genetic risk factor for HCC among Asians; patients carrying the IL-10-592*C allele had an increased risk of HCC (OR = 1.29, 95% CI = 1.12-1.49). No association was observed between the IL-10-819 T/C polymorphism and HCC susceptibility (TT vs TC + CC, OR = 1.02, 95% CI = 0.79-1.32).

CONCLUSION: This meta-analysis suggests that IL-10-592 A/C polymorphism may be associated with HCC among Asians. IL-10-1082 G/A and IL-10-819 T/C polymorphisms were not detected to be related to the risk for HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC), which is the fifth most common cancer and the third leading cause of cancer-

related death worldwide, is a global health problem^[1,2]. The estimated annual number of cases exceeds 500 000, with a mean annual incidence of around 3%-4%^[3]. Patients with HCC have a poor prognosis, with a five-year survival rate of 5% in developing countries in 2002^[1] because of the lack of effective therapy in most patients^[4]. Aetiologically, carcinogenesis of HCC is a complex, multistep and multifactor process, in which many factors are implicated. As we know, chronic infection with hepatitis B virus (HBV) or hepatitis C virus (HCV) is the most well-established environmental risk factor for HCC worldwide. However, only a fraction of HBsAg carriers eventually develop HCC and only 2.5% of HCV infected individuals develop HCC later in life^[5]. The exact mechanism of hepatocarcinogenesis is still incompletely understood, and the risk factors for HCC still need to be further elucidated.

Interleukin-10 (IL-10), whose encoding gene is located on chromosome 1 (1q31-1q32), is an immunoregulatory cytokine produced by Th2 cells, monocytes/macrophages, and regulatory T cells. It plays an anti-inflammatory action by inhibiting the synthesis of cytokines such as IL-1 α , IL-1 β , IL-6, IL-8, IL-12 and tumor necrosis factor- α (TNF- α) in activated macrophage and interferon gamma (IFN γ) by T cells^[6], and it also has some antifibrotic properties^[7]. The risk for HCC increases with the severity of hepatic inflammation and chronic inflammation developing through the action of various inflammatory mediators is known as a cofactor of carcinogenesis^[8,9]. It also has been suggested that chronically HCV-infected patients who received either short- or long-term therapy with recombinant IL-10 showed a decrease in hepatic inflammation and fibrosis^[10,11]. The production of cytokines (including IL-10) is under genetic control and varies among individuals as a function of polymorphisms within the regulatory regions of the various genes that determine the transcriptional activation^[12-15]. The promoter of the *IL-10* gene contains three biallelic polymorphisms at positions -1082 (base G to A, dbSNP No. rs1800896), -819 (base C to T, dbSNP No. rs1800871), and -592 (base C to A, dbSNP No. rs1800872) from the transcription start site, and these influence the capacity to produce IL-10^[16]. *IL-10* gene polymorphisms have been reported to be associated with breast cancer^[17], cervical cancer^[18], multiple myeloma^[19], cutaneous malignant melanoma^[20], oral squamous cell carcinoma^[21] and gastric carcinoma^[22].

Over the last decade, a number of studies have assessed the association between the *IL-10* gene polymorphism and HCC risk in different populations; however, the results are inconsistent and inconclusive^[23-29]. Different methodologies have been used, but, in particular, most of the studies used a small sample size and it is therefore not surprising that there has been a lack of replication in the various studies. By using all the available published data to increase the statistical power, it was hypothesized that a meta-analysis might allow plausible candidate genes to be excluded and causative genes to be

identified with reliability. We have therefore taken a meta-analysis in which all the published case-control studies are processed to confirm whether the polymorphisms of *IL-10* gene promoter increased the risk of HCC.

MATERIALS AND METHODS

Literature search strategy

We searched the PubMed, Embase, China National Knowledge Infrastructure and Chinese Biomedicine databases for all articles on the association between *IL-10* polymorphisms and HCC risk (last search update 30th November 2010). The following key words were used: "Interleukin-10" or "IL-10", "liver cancer" or "hepatocellular carcinoma", and "polymorphism" or "variant". The search was without restriction on language, conducted on human subjects. The reference lists of reviews and retrieved articles were hand searched at the same time. We did not consider abstracts or unpublished reports. If more than one article was published by the same author using the same case series, we selected the study where the most individuals were investigated.

Inclusion and exclusion criteria

We reviewed abstracts of all citations and retrieved studies. The following criteria were used to include published studies: (1) evaluating the association between *IL-10* gene polymorphism and HCC; (2) case-control design; and (3) sufficient genotypes data were presented to calculate the odds ratio (OR) and confidence interval (CI). Participants could be of any age. Studies were excluded if one of the following existed: (1) the design was based on family or sibling pairs; (2) the genotype frequency was not reported; or (3) there was insufficient information for extraction of data. The HCC definition used in the individual studies was accepted and we documented this in our analysis.

Data extraction

All data were extracted independently by two reviewers (Wei Y and Liu F) according to the inclusion criteria listed above. Disagreements were resolved by discussion between the two reviewers. The following characteristics were collected from each study: first author, year of publication, country of the first or corresponding author, ethnicity, number of cases and controls, genotyping methods, matching variables, and evidence of Hardy-Weinberg equilibrium (HWE) (Table 1). Different ethnicities descents were categorized as Asian and non-Asian.

Statistical analysis

The statistical analysis was conducted using STATA 11.0 (Stata Corp LP, College Station, TX, United States); $P < 0.05$ was considered statistically significant. HWE in the controls was tested by the chi-square test for goodness of fit, and a $P < 0.05$ was considered as significant disequilibrium. For *IL-10*-1082 polymorphism and *IL-10*-819 polymorphism, analyses were performed for AA vs AG + GG

genotype and TT *vs* TC + CC genotype, respectively. Because lack of separated AG and GG genotype frequency for two studies, A allele *vs* G allele could not be performed for IL-10-1082 polymorphism. Similarly, T allele *vs* C allele could not be performed for IL-10-819 polymorphism. For IL-10-592 polymorphism, we examined the contrast of the allelic effect of C (minor allele) *vs* A (common allele), and also examined the contrast of CC *vs* AC + AA genotypes. These contrasts correspond to the recessive and dominant effects of the C allele, respectively.

The OR and 95% CI were estimated for each study in a random-effects model or in a fixed-effects model. Heterogeneity among studies was examined with the χ^2 -based Q testing and I^2 statistics^[30]. $P < 0.1$ was considered significant for the χ^2 -based Q testing and I^2 was interpreted as the proportion of total variation contributed by between-study variation. If there was a significant heterogeneity ($P < 0.1$), we selected a random-effects model (the DerSimonian and Laird method) to pool the data. If not, we selected a fixed-effects model (the Mantel-Haenszel method) to pool the data. Publication bias was examined with funnel plots and with the Begg's and Egger's tests^[31-33]. If there is evidence of publication bias, the funnel plot is noticeably asymmetric. For the Begg's and Egger's tests the significance level was set at 0.05.

RESULTS

Studies included in the meta-analysis

There were 72 papers relevant to the search words. *Via* the steps of screening the title and reading the abstract, eight studies were identified^[23-29,34]. Of these, one study was excluded because of no allele or genotype frequency; thus, seven eligible studies^[23-29] which included 1012 HCC cases and 2308 controls were found to match our inclusion criteria. Four of seven publications indicated HWE in their subjects^[23-25,27]; we calculated HWE for the remained three publications and found that only Migita's study relating to IL-10-1082 polymorphism was inconsistent with Hardy-Weinberg disequilibrium ($P = 0.004$). The flow chart of selection of studies and reasons for exclusion is presented in Figure 1. Studies had been carried out in China, Japan, Korea, Tunisia and the United States. Characteristics of studies included in the meta-analysis are presented in Tables 1 and 2.

Evaluation of IL-10 gene polymorphisms and association with HCC

There were six case-control studies^[23,24,26-29] which had been performed to study the IL-10-1082 A/G polymorphism and HCC risk. Of these, four studies were performed in Asians, one study in Americans and one in Africans. Because adequate sample populations were unavailable for the American and African groups, we performed ethnicity-specific meta-analysis in the Asian and non-Asian populations. The combined results based on all studies showed that there was no association between IL-10-1082 A/G polymorphism and HCC risk (AA *vs* AG + GG, OR = 1.11, 95% CI = 0.90-1.37). When

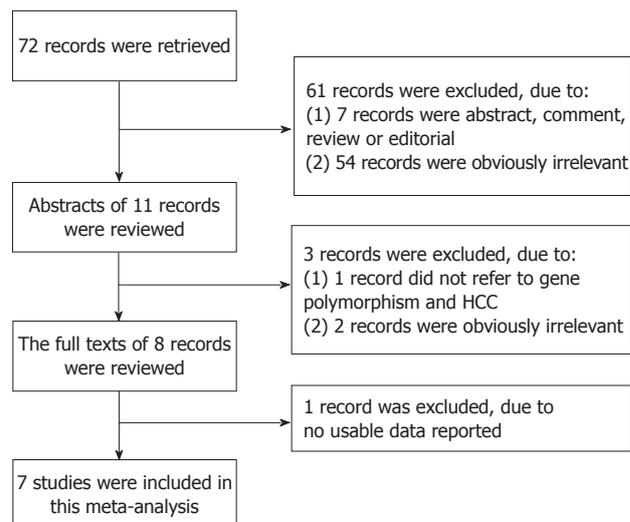

Figure 1 Flow chart of selection of studies and specific reasons for exclusion from the meta-analysis.

stratifying for ethnicity, the results were similar (Asian, OR = 1.12, 95% CI = 0.87-1.44; non-Asian, OR = 1.10, 95% CI = 0.75-1.60) (Figure 2).

There were four case-control studies^[25,26,28,29] which had been performed to study the IL-10-592 C/A polymorphism and HCC risk. Of these, all studies were performed in Asians. The combined results based on all studies showed that C allele carriers had an increased risk of HCC *vs* A allele carriers (OR = 1.29, 95% CI = 1.12-1.49) (Figure 3). Meanwhile, CC genotype carriers had an increased risk of HCC *vs* AC and AA genotype carriers (OR = 1.68, 95% CI = 1.25-2.26).

Only three studies were performed to study the IL-10-819 T/C polymorphism and HCC risk. The combined results based on all studies showed that there was no association between IL-10-819 T/C polymorphism and HCC risk (TT *vs* TC + CC, OR = 1.02, 95% CI = 0.79-1.32).

Sensitivity analysis

The influence of a single study on the overall meta-analysis estimate was investigated by omitting one study at a time, and the omission of any study made no significant difference, indicating that our results were statistically reliable.

Evaluation of heterogeneity and publication bias

Statistically significant heterogeneity was not observed between trials for all analysis with the χ^2 -based Q testing and I^2 statistics. Review of funnel plots could not rule out the potential publication bias for all analyses. Publication bias was not evident when the Begg's rank correlation method and the Egger's weighted regression method were used except for analyzing IL-10-1082 polymorphism and HCC risk (Table 3).

DISCUSSION

It has been recognized that the most important risk fac-

OR: Odds ratio.

tor for the development of HCC is cirrhosis^[35]. Chronic infections with HBV and HCV are the most frequent causes of cirrhosis worldwide. A large number of cohort and case-control studies have shown that alcohol consumption causes liver cirrhosis and is an independent risk factor for HCC^[36,37]. Epidemiological studies reported elevated HCC risks associated with exposure to aflatoxins after adjustment for HBV exposure^[38]. Cigarette smoking has been causally associated with the risk of HCC^[37]. Although so many environmental factors are

found to correlate with the tumorigenesis of HCC, there still are a portion of patients without known risk factors who eventually developed HCC^[39]. Previous study had shown an interaction of environmental factors and genetic predisposition in the development of HCC^[40]. Therefore, genetic predisposition may contribute to the process of tumorigenesis.

A genetic predisposition to HCC has been suggested by many studies^[41,42]. Recent studies suggest that single nucleotide polymorphism may be related to the tu-

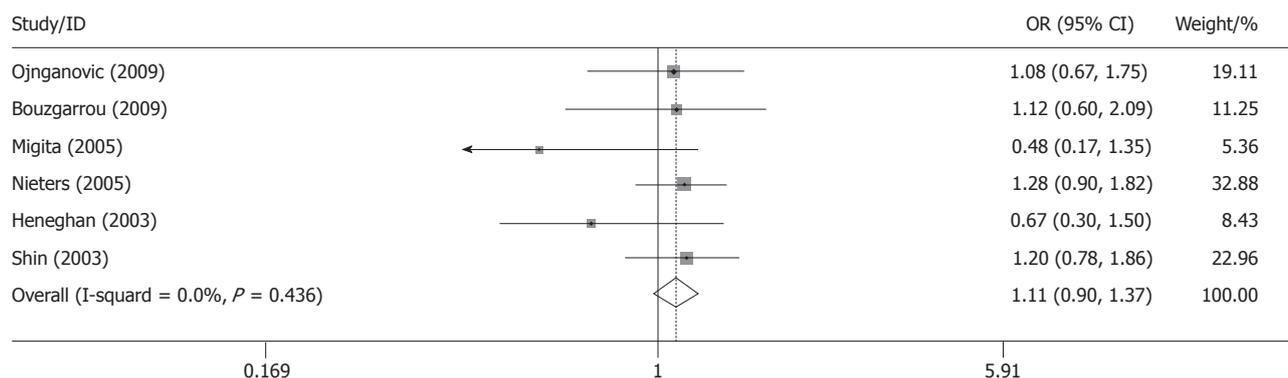

Figure 2 Odds ratios and 95% CI of individual studies and pooled data for the association of the Interleukin-10-1082 A/G polymorphism and hepatocellular carcinoma risk comparing AA genotype with AG + GG genotype.

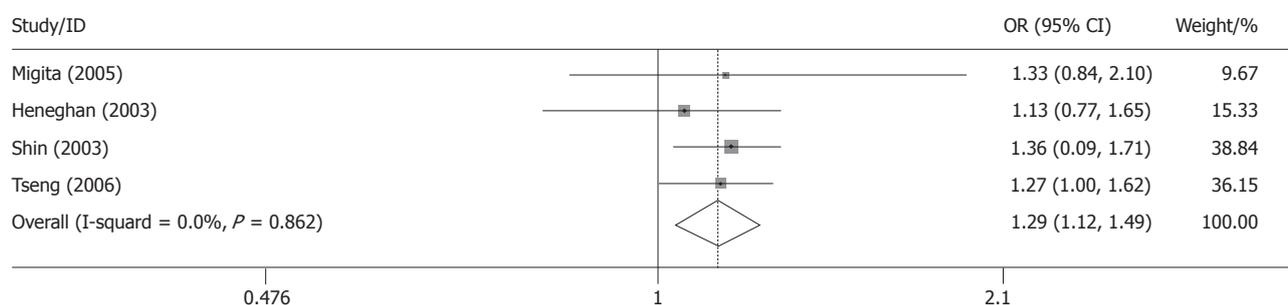

Figure 3 Odds ratios and 95% CI of individual studies and pooled data for the association of the Interleukin-10-592 C/A polymorphism and hepatocellular carcinoma risk comparing any C allele with A allele.

morigenesis of liver cancer^[43,44]. The *IL-10* gene and its encoded protein is an immunoregulatory cytokine that plays an anti-inflammatory action, which has three SNPs at positions -1082, -592 and -819 promoter region. Until recently, a number of studies had been performed to analyse *IL-10* polymorphisms and HCC risk. However, most of these studies were based on small sample sizes. Moreover, there were still some conflicting results. As a powerful statistical method, meta-analysis can provide a quantitative approach for pooling the results of different research on the same topic, and for estimating and explaining their diversity^[45,46].

The data from this meta-analysis clearly suggest that the *IL-10*-592 C allele is a genetic contributor to overall HCC susceptibility. We also observed that the C/C homozygote had a stronger association with HCC susceptibility than the C/A heterozygote and AA homozygote. Given the important roles of *IL-10* in inflammation and tumor development, it was biologically plausible that *IL-10*-592 C/A polymorphism was associated with the risk of HCC by modulating *IL-10* expression. Such evidence on the functionality of this polymorphism might lead to a better understanding of this association. The risk for HCC increases with the severity of hepatic inflammation and chronic inflammation developing through the action of various inflammatory mediators is known as a cofactor of carcinogenesis^[8,9]. As mentioned above, the function of *IL-10* is to inhibit immune response and inflammation. Meanwhile, previous studies

suggested that *IL-10*/-592*C allele may be a marker for lower *IL-10* production^[29,47]. The genetic polymorphism may affect the severity of hepatic inflammation and cause higher HCC risk due to lower *IL-10* production. In addition, this meta-analysis also suggests that *IL-10*-1082 A/G polymorphism was not associated with the risk of HCC. When stratifying for ethnicity, the results were similar. Similarly, no association was found between HCC susceptibility and *IL-10*-819 T/C polymorphism.

As previously described, ethnicity can strongly influence the distribution of cytokine gene polymorphisms^[48]. This suggests that there are racial differences in genetic risk; the different genetic backgrounds and different environments the different ethnicities lived in may contribute to the ethnic discrepancy. In the meta-analysis, studies comprising *IL-10* polymorphism (at position -592 and -819) and HCC risk were all performed in Asians. For *IL-10*-1082 polymorphism and HCC susceptibility, we stratified the result by race (Asian and non-Asian population), but the results were similar. This is probably because the number of studies from non-Asian populations were too small to detect the ethnic discrepancy, thus, caution should be adopted when explaining our results.

One of the major concerns in a sound meta-analysis is the degree of heterogeneity that exists between the component studies because non-homogeneous data are liable to result in misleading results. In the present study, the Q testing and I^2 statistics were carried out to test the

significance of heterogeneity. Fortunately, statistically significant heterogeneity was not observed between trials for all analysis with the χ^2 -based Q testing and I^2 statistics. Moreover, we performed a sensitivity analysis by removing one study each time and rerunning the model to determine the effect on each overall estimate. The estimates changed little, which implied that our results were statistically reliable.

However, there are still some limitations in this meta-analysis. (1) We did not test for gene-to-environment interactions because of the issue of multiple testing and the lack of sufficient studies. It is possible for specific environmental and lifestyle factors to alter those associations between gene polymorphisms and HCC risk; (2) as in most meta-analyses, these results should be interpreted with caution because the populations from 5 countries and controls were not uniform; (3) the number of studies and the number of subjects in the studies included in the meta-analysis by specific subgroups were small, thus, caution should be adopted when explaining our results; and (4) meta-analysis is retrospective research that is subject to methodological limitations. In order to minimize the bias, we developed a detailed protocol before initiating the study, and performed a meticulous search for published studies by using explicit methods for study selection, data extraction and data analysis. Nevertheless, our results should be interpreted with caution.

This meta-analysis suggests that the IL-10-592 C/A polymorphism may be associated with HCC among Asians. The pooled ORs in this study - both with respect to the IL-10-592*C allele and the IL-10-592/CC homozygote - suggest a modest but definite genetic effect. It is critical that larger and well-designed multicentre studies based on different ethnic groups are needed to confirm our results.

COMMENTS

Background

Interleukin-10 (IL-10) is an immunoregulatory cytokine produced by Th2 cells, monocytes/macrophages, and regulatory T cells. The promoter of the *IL-10* gene contains three biallelic polymorphisms at positions -1082 (base G to A, dbSNP No. rs1800896), -819 (base C to T, dbSNP No. rs1800871), and -592 (base C to A, dbSNP No. rs1800872) from the transcription start site. These changes have been implicated as risk factors for hepatocellular carcinoma (HCC), but individual studies have been inconclusive or controversial. The aim of this meta-analysis was to clarify the effect of IL-10 polymorphisms on the risk of HCC.

Research frontiers

To date, a number of studies have assessed the association between the *IL-10* gene polymorphism and HCC risk in different populations; however, the results are inconsistent and inconclusive. No quantitative summary of the evidence has ever been performed.

Innovations and breakthroughs

IL-10-592 A/C polymorphism may be associated with HCC among Asians, while IL-10-1082 G/A and IL-10-819 T/C polymorphisms could not alter susceptibility to HCC.

Applications

It can be seen from this paper that IL-10-592 A/C polymorphism could alter susceptibility to HCC. It suggests that a common variant in the functional region of a definitively meaningful gene had an effect on human disease, such as cancer.

Peer review

The meta-analysis aimed at assessing the association between *IL-10* gene polymorphisms and HCC. This is an appealing issue, leading to interesting results.

Abstract

Systemic mastocytosis (SM) is a heterogeneous disease of the bone marrow characterized by abnormal growth, accumulation and activation of clonal mast cells (MCs). We report a case of SM with multi-organ involvement. A 30-year-old man presented with diarrhea, flushing, maculopapular rash with itching and weight loss. The upper and lower gastrointestinal endoscopies showed macroscopic involvement of stomach and duodenum; mucosal samples from stomach, duodenum, colon and distal ileum showed mucosal infiltration by large, spindle-shaped MCs with abnormal surface molecule expression (CD2 and CD25), a picture fully consistent with SM, according to the World Health Organization diagnostic criteria. A computed tomography scan showed diffuse lymphadenopathy, hepatosplenomegaly and diffuse small bowel involvement. Bone marrow aspirate and biopsy were diagnostic for SM; serum tryptase levels were increased (209 ng/mL, normal values < 20 ng/mL). The conclusive diagnosis was smouldering SM. There were

INTRODUCTION

Systemic mastocytosis (SM) is a heterogeneous disease of the bone marrow characterized by abnormal growth, accumulation and activation of clonal mast cells (MCs)^[1-3]. In most patients, SM is caused by mutations in the KIT oncogene (D816V, present in more than 80% of patients), which encodes for a tyrosine kinase protein involved in differentiation and proliferation of MCs. This mutation determines an abnormal differentiation, proliferation and clustering of neoplastic progenitors of MCs^[1-8]. Clinical features are related to histamine release (e.g., flushing, urticaria, itching, diarrhea, etc) or to uncontrolled growth and infiltration of clonal MCs in different organs (such as liver, spleen and bone marrow). The latter clinical findings must be divided into B- (Borderline Benign-Be watchful) and C-symptoms (Consider Cytoreductive therapy) (Table 1)^[2-5].

Bone marrow aspirate and biopsy represent the main diagnostic step when SM is suspected^[1-5,7,8]. According

to the World Health Organization (WHO) diagnostic criteria (Table 2), SM is diagnosed when the major and at least one minor criterion or three minor criteria are satisfied^[2,3].

At present there is no effective therapy for SM and the medical approach is aimed at symptomatic relief and improvement of quality of life. SM patients should avoid triggers for MC degranulation (e.g., exposure to heat, cold, acute emotional stress, very strenuous exercise, alcohol). Commonly used symptomatic drugs are H1 and H2 histamine receptor blockers, ketotifen, cromolyn sodium and anti-leukotriene drugs. Cytoreductive regimens (interferon alpha-2b, cladribine, tyrosine kinase inhibitors and hydroxyurea) are indicated in SM with C findings^[2,5,7-13].

CASE REPORT

A 30-year-old man presented with a ten-year history of maculopapular rash with itching and a six-month history of diarrhea (3-4 bowel movements per day with loose stools), flushing and weight loss.

The medical history was otherwise unremarkable, except for a non-steroidal anti-inflammatory drug-induced anaphylaxis.

Relevant findings at physical examination were represented by a diffuse maculopapular rash with itching (termed “urticaria pigmentosa”) (Figure 1), hepatomegaly (with the lower hepatic edge 3 cm below the costal margin), splenomegaly (with the lower splenic edge 2 cm below the costal margin) and a diffuse, superficial, painless lymphadenopathy, ranging from 2 to 4 cm in diameter.

Complete blood count, renal function tests, plasma electrolytes, liver function tests, clotting and thyroid function tests were normal as was plasma protein gel electrophoresis.

Serological and stool tests for bacterial and parasitic infections were negative. Past or current hepatitis B virus (HBV), hepatitis C virus (HCV) and human immunodeficiency virus (HIV) infections were ruled out by determining HBsAg and anti-HBc, anti-HCV and anti-HIV antibodies. Celiac disease was excluded on the basis of negative anti-endomysial and anti-transglutaminase antibodies with normal total IgA concentration. The panel for gastrointestinal neuroendocrine tumors was negative. Serum calcitonin levels were normal. Conversely, serum tryptase level was 209 ng/mL (reference value ≤ 20 ng/mL).

Abdominal ultrasonography showed hepatomegaly, splenomegaly, diffuse lymphadenopathy and diffuse small bowel dilatation with wall edema (Figure 2A and 2B). At upper and lower gastrointestinal endoscopy, there was a diffuse hyperemia with superficial erosions. Gastric, duodenal, distal ileal and colonic histology (Figure 3A, 3B and 3C) revealed diffuse mucosal MC infiltration, with spindle-shape and with abnormal surface molecule expression (CD2 and CD25) fully consistent with SM according to WHO criteria^[2,3].

In line with the current guidelines^[1-3,5], the patient

Table 1 Systemic mastocytosis findings related to mast cell infiltration and proliferation (modified from Valent *et al.*^[3])

B symptoms (Borderline benign-be watchful)
Hepatomegaly
Splenomegaly
Lymphadenopathy
Hypercellular marrow
Mast cell infiltration in bone marrow > 30%
Serum tryptase levels > 200 ng/mL
C symptoms (Consider cytoreductive therapy)
Anemia (Hb < 10 g/dL)
Thrombocytopenia (< 100 000/mm ³)
Neutropenia
Hepatopathy with ascites or portal hypertension
Splenomegaly with hypersplenism
Malabsorption with weight loss
Osteolysis with pathological bone fractures

Table 2 World Health Organization diagnostic criteria for systemic mastocytosis (modified from Valent *et al.*^[3])

Major criterion
Multifocal dense infiltrates of MCs (> 15 MCs in aggregates) in bone marrow biopsy and/or in sections of other extracutaneous organ(s)
Minor criteria
(1) > 25% of all MCs are atypical cells on bone marrow smears or are spindle-shaped in MC infiltrates detected on sections of extracutaneous organ(s)
(2) c-kit point mutation at codon 816 in the bone marrow or in another extracutaneous organ
(3) MCs in the bone marrow or in another extracutaneous organ express CD2 and/or CD25
(4) Serum tryptase levels > 200 ng/mL (this criterion is valid only if AHNMD-SM has been excluded)

MCs: Mast cells; AHNMD-SM: Associated hematopoietic clonal non-MC lineage disease systemic mastocytosis.

underwent a bone marrow aspirate and biopsy with evidence of diffuse MC infiltration, fully consistent with SM (Figure 4A, 4B and 4C). D816V mutation detection in the KIT oncogene was negative.

Disease staging was performed by both total body computed tomography scan, which confirmed hepatosplenomegaly, diffuse abdominal lymphadenopathy and diffuse small bowel involvement, and total skeleton X-ray, negative for osteolytic lesions. Osteoporosis was diagnosed on the basis of reduced bone mineral density.

In accordance with the diffuse organ involvement, serum tryptase levels > 200 ng/mL and B-findings (hepatosplenomegaly, lymphadenopathy, diarrhea and osteoporosis), the final diagnosis was of smouldering SM^[2-4]. No indication was given for cytoreductive regimen; the patient was instructed to avoid MC degranulation triggers and was given H1-H2 histamine receptor blockers and cromolyn sodium. A strict follow-up was planned aimed at early recognition of an aggressive SM evolution^[2-4,7,8,14]. The patient was evaluated at quarterly intervals for a nine-month period and then, because of clinical stability, twice a year.

Figure 1 Maculopapular rash (“urticaria pigmentosa”) in a systemic mastocytosis patient.

DISCUSSION

Systemic mastocytosis, a rare disease whose prevalence is unknown, can affect people at any age, with a slightly higher frequency in young men^[1-3].

According to the WHO classification, four SM variants have been identified^[1-3,5]: (1) **indolent SM** represents the most common form and is characterized by cutaneous and bone marrow involvement, without B or C findings; its prognosis is usually good. A rare subvariant, possibly progressing to a more aggressive SM type, is smoldering SM, characterized by B findings, diffuse organ involvement and serum tryptase levels > 200 ng/mL; (2) **aggressive SM**: this form affects 5% of SM patients and is characterized by the lack of cutaneous involvement. C findings are present and the prognosis is usually poor; (3) **associated hematopoietic clonal non-MC lineage disease SM (AHNMD-SM)** represents the second most frequent subtype of SM. To be diagnosed, WHO criteria for both SM and AHNMD must be fulfilled. Underlying blood disease is represented by myeloid disease in 80%-90% of cases and by lymphatic malignancy in the remaining 10%-20%. The prognosis is influenced both by AHNMD and SM subtype; and (4) **mast cell leukemia**: a very rare SM subtype characterized by C findings, percentage of neoplastic MCs at bone marrow biopsy > 20% and circulating neoplastic MCs. Its prognosis is usually poor.

As indicated by WHO diagnostic criteria, SM is diagnosed when the major criterion and at least one minor criterion or at least three minor criteria are satisfied^[2,3]. Based on the low disease prevalence and its wide clinical spectrum, SM can be difficult to diagnose.

Bone marrow aspirate and biopsy represent the cornerstones for SM diagnosis, the hallmark being the presence of multifocal, dense MC aggregates^[2,3]. To further improve MC recognition in bone marrow samples, immunohistochemical markers have been introduced. Among them, tryptase reactivity is considered the most sensitive, allowing the detection of even small MC infiltrates^[15,16]. Considering that virtually all MCs, irrespective of their maturation stage, activation status or tissue of localization, express tryptase, staining for this marker

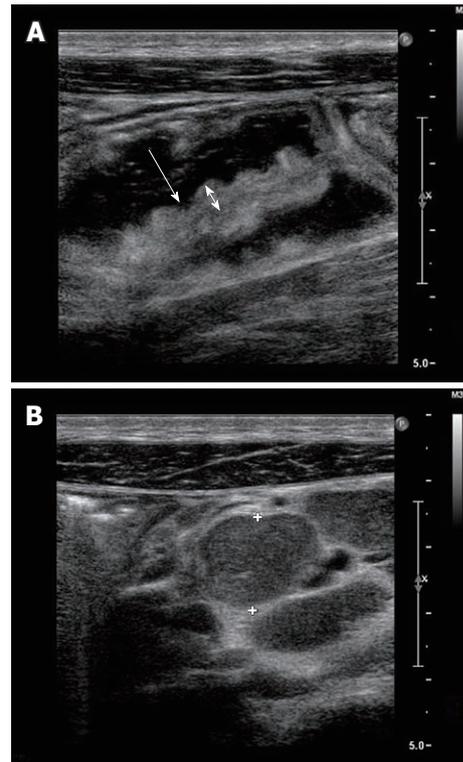

Figure 2 Abdominal ultrasound. A: Small bowel dilatation (white arrow) and wall edema (duble arrow) at ultrasonography (US). B: Abdominal lymphadenopathy at US (crosses refer to lymph node enlargement, 5 cm).

detects even those infiltrates that are primarily comprised of immature, nongranulated MCs^[17]. However, it must be emphasized that neither tryptase nor other immunohistochemical markers (e.g., CD 117) can distinguish between normal and neoplastic MCs^[18]. Conversely, immunohistochemical detection of aberrant CD2 or CD25 expression on bone marrow MCs appears to be a reliable diagnostic tool in SM, given its ability to detect abnormal MCs in all SM subtypes^[17]. The expression of even one of these two antigens represents a WHO minor diagnostic criterion.

Johnson *et al*^[19] enrolled 59 patients with clinically suspected SM; all of them underwent bone marrow examination, including immunophenotyping by immunocytochemistry and/or flow cytometry and molecular studies for KIT exon 17 mutations, and determination of serum tryptase level. Using the WHO criteria, in patients with suspected SM based on clinical and laboratory findings, the diagnosis of SM was possible in 90% of the cases. However, the major criterion was only observed in nearly 70% of patients. In an additional 30%, the diagnosis of SM could only be obtained by using ancillary testing, as specified by the WHO minor criteria. Noteworthy, the series from Johnson *et al*^[19] support the relevance of ancillary testing in obtaining the diagnosis of SM by bone marrow examination.

A further comment is warranted regarding the controversial role of serum tryptase level in the diagnostic SM algorithm. Tryptase is an enzyme stored in MC granules and released after MC degranulation. It is activated by acidic pH and presence of heparin. The bio-

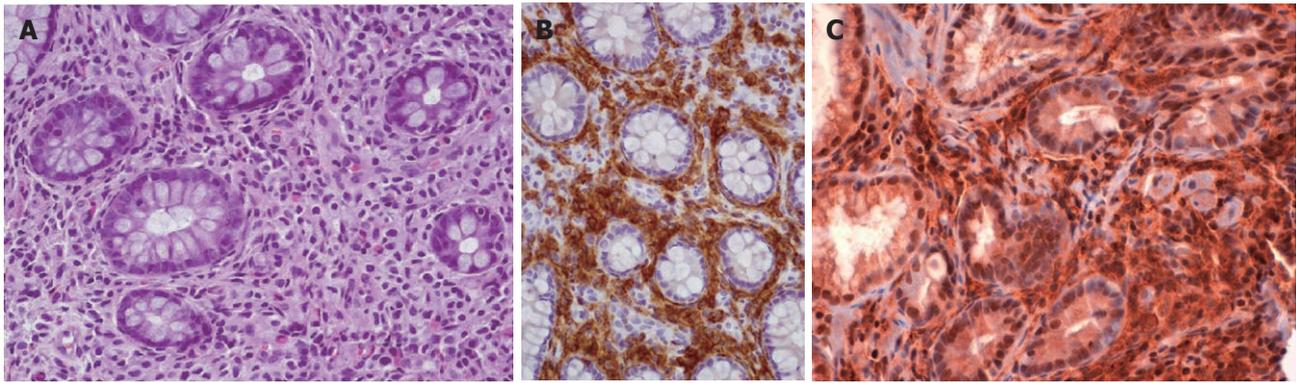

Figure 3 Colon biopsy in a systemic mastocytosis patient. A: Diffuse mast cell (MC) infiltrate (Hematoxylin-eosin, $\times 10$); B: The dense infiltrate is represented by MCs, whose detection is increased by positive immunohistochemical marker CD117; C: The dense infiltrate is represented by MCs, whose detection is increased by positive immunohistochemical marker CD25.

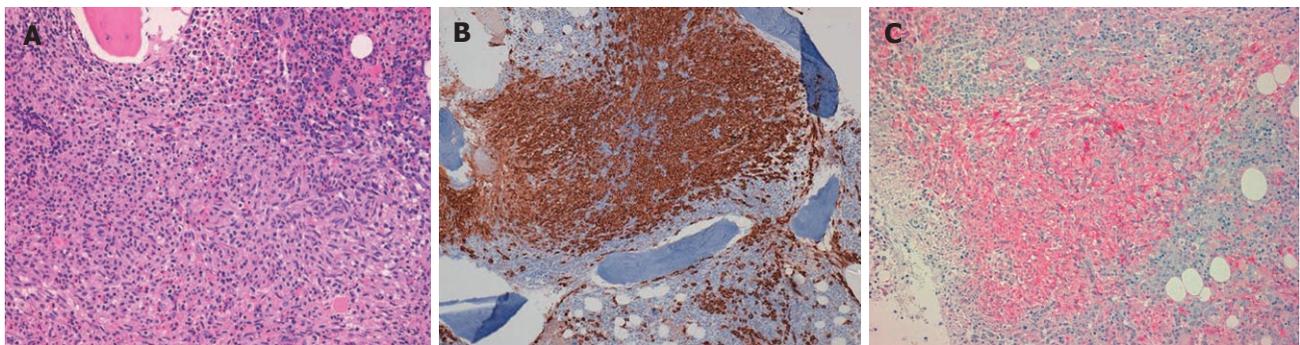

Figure 4 Bone marrow biopsy in a systemic mastocytosis patient. A: Diffuse mast cell (MC) infiltrate (Hematoxylin-eosin, $\times 10$); B: The dense infiltrate is represented by MCs, whose detection is increased by positive immunohistochemical marker CD117; C: The dense infiltrate is represented by MCs, whose detection is increased by positive immunohistochemical marker CD25.

logic activity of enzymatically active tryptase is still uncertain. Many potential substrates have been defined *in vitro*: anticoagulation, fibrosis and fibrolysis, kinin generation and destruction, enhancement of vascular permeability, airway smooth muscle hyperreactivity. However, it must be underlined that the *in vivo* relevance of these potential activities remains to be defined. Serum tryptase levels increase as a consequence of acute systemic anaphylaxis, SM and myeloproliferative diseases. In SM, serum tryptase levels represent a minor diagnostic criterion according to the WHO, but only if AHNMD-SM has been excluded^[20,21]. Valent *et al*^[3,5] have recently suggested that patients with clinical suspicion of SM having high serum tryptase levels should undergo a bone marrow examination in order to confirm the diagnosis. Furthermore, as tryptase levels are related to the burden of neoplastic MCs, their determination is of relevance in following up those SM patients given a cytoreductive regimen.

Abstract

Gastrointestinal involvement of neurofibromatosis type 1 (NF1, Von Recklinghausen's disease) is generally associated with the upper gastrointestinal tract. Abdominal manifestation of NF1 includes several tumors such as malignant peripheral nerve sheath tumors, gastrointestinal stromal tumors and ampulla of Vater tumors. However, colonic involvement in NF1 patients is rare. We report a case of a patient presenting with dysphagia, weight loss, intermittent abdominal pain and constipation caused by a single cecal neurofibroma obstructing the ileocecal valve. Also gastrointestinal involvement of the lower tract should be considered in patients with NF1 presenting with abdominal complaints.

INTRODUCTION

Neurofibromatosis type 1 (NF1) or Von Recklinghausen's disease is an autosomal dominant genetic disorder with an incidence of 1 in 2600-3000 individuals^[1,2]. Neurofibromas are benign tumors arising from Schwann cells, caused by a mutation of the tumor suppressor gene NF1^[3,4]. Diagnosis of NF1 is made on clinical criteria, originally described by the National Institutes of Health Consensus Development Conference in 1987^[5]. The most typical features are café-au-lait macules and neurofibromas of the skin. Other organ systems can also be affected, including the cardiovascular system, eyes, bones and the gastrointestinal system. In this report we present a case of a patient with NF1 and recurrent abdominal complaints, caused by a neurofibroma in the cecal wall.

CASE REPORT

A 69-year-old woman with a history of Von Recklinghausen's disease was presented to the gastroenterologist with weight loss (9 kg in 3 mo), dysphagia and anorexia for several weeks. She also suffered from intermittent central abdominal pain for more than 1 year. There was no history of nausea, vomiting or pyrosis. For many years she had constipation, without visible blood loss or melaena. She underwent an appendectomy and a laparoscopic cholecystectomy at the age of 20 and 60, respectively. Despite her NF1, which affected her skin and bones, no other medical history was known. She did

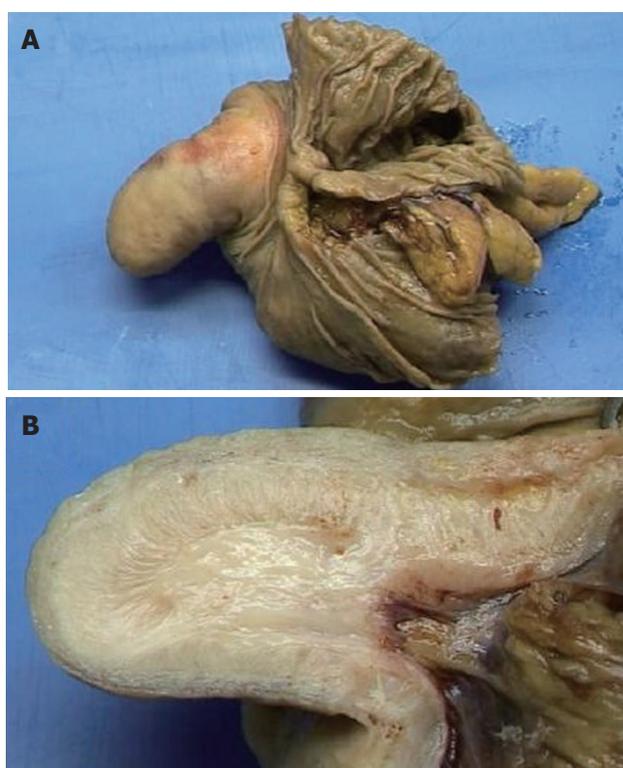

Figure 2 Opened resection specimen (A) and cut surface of the polyp (B).

not use any medication. Physical examination revealed no abnormalities of the abdomen, other than neurofibromas on her skin. Laboratory studies were normal.

Since the most prominent complaints were dysphagia and weight loss, a gastroduodenoscopy was performed, which did not show any abnormalities of the esophagus, stomach or duodenum. An abdominal ultrasound, however, demonstrated a 3.4 cm large tumorous process in the right lower quadrant. A computed tomography-scan of the abdomen showed the same process, localized in the cecal wall, invaginating into the cecal lumen (Figure 1). There were no signs of bowel obstruction or metastasis in mesenteric lymph nodes or liver.

Before a planned colonoscopy the clinical presentation deteriorated; our patient developed severe abdomi-

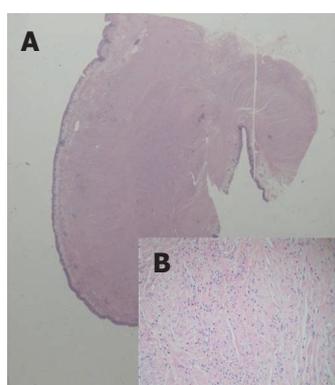

Figure 3 Overview of the polyp (A) and detail of the submucosal tumor (B), HE staining; original magnification, $\times 100$.

nal pain and a laparoscopic procedure was performed. Macroscopic inspection of the cecum revealed a palpable tumor inside the lumen. Further visual inspection of the abdominal cavity revealed no pathologic findings, such as mesenteric masses or liver metastasis. A laparoscopic right-sided hemicolectomy with an extracorporeal primary side-to-side anastomosis was performed. She recovered well and was discharged after five days. Soon her normal appetite returned, she regained her normal weight and had no more abdominal pain.

Pathologic study of the specimen revealed a polypoid cecal tumor of 3 by 5.5 cm (Figure 2), with a submucosal and intramucosal growing pattern. The lesion contained foci of spindle cells with a bundle-like growing pattern. Ganglion cells were absent. The lesion was positive for CD34, SMA and S100, but negative for P53. The morphological and immunohistochemical characteristics were consistent with the diagnosis of neurofibroma type 1 (Figures 3 and 4). The tumor was negative for CD117 and DOG-1 thus excluding a diagnosis of gastrointestinal stromal tumors (GIST).

DISCUSSION

NF1 can affect multiple organ systems, causing skin lesions, malignant peripheral nerve sheath tumors, intra-

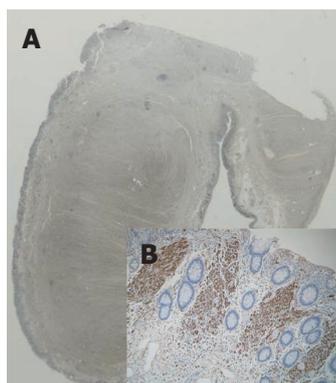

Figure 4 Overview of the polyp (A) and detail of the submucosal tumor (B), S100 staining; original magnification, $\times 100$.

cranial tumors and cranial vascular deformities, optic pathway gliomas, bone deformities, heart problems, hypertension and abdominal tumors^[1].

Five categories of abdominal neoplasms in association with NF1 have recently been described^[6]. The first category is benign or malignant neurogenic tumors, with neurofibromas as the most common and often asymptomatic (65%) neoplasm, originating from the mesenteric plexus. Several cases with abdominal neurofibroma have been described^[7-11]. Other neurogenic tumors are plexiform neurofibromas, malignant peripheral sheath tumors and ganglioneuromas^[6]. The second category is neuroendocrine tumors as carcinoids, pheochromocytomas and paragangliomas. In particular ampulla of Vater carcinoids are associated with NF1^[12,13]. The third category is GIST, which have been reported in up to one third of all patients with NF1^[14,15]. The pathogenesis of GIST is different from sporadic tumors^[3]. The fourth category is embryonal tumors, such as Wilms tumor, neuroblastoma and rhabdomyosarcoma. Finally, adenocarcinomas of the gastrointestinal tract have been detected in patients with NF1. Wood *et al.*^[6] (2005) reported a patient with NF1 and colon carcinoma and presented older reports suggesting an association between NF1 and colon carcinoma.

Gastrointestinal involvement of NF1 in patients is reported in 25% of all cases, almost always affecting the upper gastrointestinal tract. The jejunum and stomach are common sites of neurofibromas or associated tumors such as GISTs and ampulla of Vater carcinoids^[12,13]. Oesophagus and colon are rarely involved^[7]. We found 5 case reports and 1 patient in a series of 10 patients with a colonic neurofibroma^[7-11,17]. The most common presenting signs are abdominal pain, gastrointestinal bleeding, obstruction and palpable masses. The presence of one or more intestinal neurofibromas, however, does not imply that a patient has NF1. Only in 15% of cases where intestinal neurofibromas were found was the patient diagnosed with NF1^[7].

Pathologic study of a neurofibroma in the gastrointestinal tract reveals a tumor consisting of a mixture of spindle cells with wavy nuclei and strands of collagen as

well as Schwann cells, perineurial fibroblasts, endothelial cells and mast cells. Tumors positive for S100 are very suggestive for neurofibromas. These tumors must be distinguished from GISTs, schwannomas, perineuromas and leiomyomas^[18].

In this report we present a case of a patient with NF1 and recurrent abdominal complaints caused by a large cecal neurofibroma. Gastrointestinal involvement of NF1 can be found in patients with NF1 and abdominal pain, particularly in the upper gastrointestinal tract, but also colonic localisation has to be considered. Evaluation by endoscopic assessment or radiological imaging of the gastrointestinal tract is advised. Also a higher incidence of gastrointestinal malignancies in patients with NF1 has to be considered.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copy-right" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Baishideng Publishing Group Co., Limited

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, WJG requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantumms can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Instructions to authors

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Hormone-stimulated pancreatic function tests (PFTs) are considered the gold standard for measuring pancreatic exocrine function. PFTs involve the administration of intravenous secretin or cholecystokinin, followed by collection and analysis of pancreatic secretions. Because exocrine function may decline in the earliest phase of pancreatic fibrosis, PFTs are considered accurate for diagnosing chronic pancreatitis. Unfortunately, these potentially valuable tests are infrequently performed except at specialized centers, because they are time consuming and complicated. To overcome these limitations, endoscopic PFT methods have been developed which include aspiration of pancreatic secretions through the suction channel of the endoscope. The secretin endoscopic pancreatic function test (ePFT) involves collection of duodenal aspirates at 15, 30, 45 and 60 min after secretin stimulation. A bicarbonate concentration greater than 80 mmol/L in any of the samples is considered a normal result. The secretin ePFT has demonstrated good sensitivity and specificity compared with various reference standards, including the "Dreiling tube" secretin PFT, endoscopic ultrasound, and surgical histology. Furthermore, a standard autoanalyzer can be used for bicarbonate analysis, which allows the secretin ePFT to be performed at any hospital. The secretin ePFT may complement imaging tests like endoscopic ultrasound (EUS) in the diagnosis of early chronic pancreatitis.

This paper will review the literature validating the use of ePFT in the diagnosis of exocrine insufficiency and chronic pancreatitis. Newer developments will also be discussed, including the feasibility of combined EUS/ePFT, the use of cholecystokinin alone or in combination with secretin, and the discovery of new protein and lipid pancreatic juice biomarkers which may complement traditional fluid analysis.

INTRODUCTION

Direct hormone-stimulated pancreatic function tests (PFTs) are the most sensitive and specific tests for assessing the pancreatic exocrine reserve^[1]. They involve administration of a gastrointestinal hormone, followed by collection and analysis of the resulting pancreatic secretions. Direct PFTs are categorized based on the hormonal stimulants used. The secretin PFT measures bicarbonate and volume, a reflection of duct-cell function. The cholecystokinin (CCK) PFT measures enzymes (e.g, lipase and trypsin), a reflection of acinar-cell function.

Direct PFTs have been performed for over 80 years using double-lumen gastroduodenal collection tubes (Dreiling tubes). The tubes are placed through the mouth, and positioned with the weighted tip passed the ligament of Treitz. The gastric lumen sits in the greater curvature of the stomach and collects gastric secretions to prevent acid contamination of the duodenum. The duodenal lu-

men collects the pancreatic secretions. In secretin PFT protocols, fluid is analyzed for bicarbonate concentration or output for an estimation of duct cell secretion. In CCK PFT protocols, fluid is analyzed for enzyme output for an estimation of acinar cell capacity. Dreiling tubes are long, floppy, and often difficult to place properly. Accurate placement requires prolonged manipulation under fluoroscopy, or endoscopic guide-wire placement^[2]. It is not uncommon for the test to take 2-3 h because of the long time required for tube placement and an additional 60-90 min required for fluid collection. Sophisticated laboratory techniques may be required for fluid analysis, which may not be universally available. Even among the few centers that perform PFTs, the test protocols are not standardized. Various combinations of hormones or analogs, dosing regimens, collection times, laboratory techniques, parameters for analyses, and diagnostic thresholds are used, making it difficult to compare results and assess the tests' performance. Although direct PFTs have been labeled the "gold standard" tests for assessing exocrine function, there is no "gold standard" direct PFT. Based on these limitations, direct PFTs are rarely performed, despite their potential usefulness for diagnosing mild and moderate exocrine insufficiency.

ENDOSCOPIC METHODS

Recently, endoscopes have been used to collect pancreatic fluid under direct visualization. Some investigators have collected pancreatic secretions using a catheter placed in the pancreatic duct at the time of endoscopic retrograde cholangiopancreatography (ERCP)^[3,4]. One potential advantage of this method is that pure pancreatic fluid is obtained, preventing contamination by other fluids found in the duodenum (e.g, bile, mucous, or food). In addition, a pancreatogram can be performed to detect structural abnormalities. A major limitation is that cannulation of the pancreatic duct is required, imparting a risk of acute pancreatitis. The time of fluid collection must also be relatively short (10-15 min). Bicarbonate secretion may not reach maximum until 25-40 min after secretin; thus, false positives are common^[5]. More recently, investigators have performed endoscopic methods in which fluid is aspirated through the suction channel of the endoscope. A common secretin ePFT protocol is as follows: Secretin is administered as an intravenous bolus dose of 0.2 mcg/kg. After sedation, the endoscope is passed through the mouth into the stomach. Gastric fluid is aspirated as completely as possible to prevent contamination of the duodenal contents. The scope is advanced into the duodenum and residual duodenal fluid is thoroughly suctioned. Timed aspirates of duodenal fluid (5-10 mL) are obtained through the suction channel into a fluid collection trap at 15, 30, 45, and 60 min. The fluid samples are placed on ice and taken to the hospital laboratory. The samples are analyzed using a chemistry autoanalyzer for bicarbonate concentration. The maximum bicarbonate concentration from all the samples is termed the peak bicarbonate. A peak bicarbonate concentration less than 80 millimolar is

considered abnormal. The following section will review the literature regarding the endoscopic secretin pancreatic function test (ePFT).

SECRETIN ePFT

Most of the recent validation studies of the ePFT have used secretin for hormonal stimulation. Ceryak *et al*^[6] were the first group to publish the results of a purely endoscopic secretin PFT, in a pilot study of 11 patients who had undergone ERCP for evaluation of abdominal pain. Duodenal aspirates were obtained every 10 min for one hour following intravenous secretin administration. In seven patients with a normal pancreatogram, the peak bicarbonate concentration was greater than 80 mmol/L. Conversely, three of the four patients with ductal changes of chronic pancreatitis (CP) did not achieve the 80 mmol/L threshold. Note that 80 mmol/L is a widely accepted bicarbonate threshold used in most Dreiling tube PFT protocols^[7]. In a similar study, secretin ePFT results were compared in patients with abdominal pain and low suspicion of CP, suspected early CP, and advanced CP^[8]. All patients in the low risk category had a bicarbonate concentration greater than 80 mmol/L. Most patients with calcific pancreatitis had bicarbonate concentrations less than 60 mmol/L. Most of the patients in the early CP category had values between 60 and 80 mmol/L. These studies suggested the feasibility of the secretin ePFT, and demonstrated that it distinguishes the presence or absence of CP when using the cut-off point of 80 mmol/L.

Validation of any new tests requires comparison with a gold standard method. Our group performed crossover studies comparing the secretin ePFT and Dreiling PFT in healthy subjects^[9] and patients evaluated for CP^[10]. The mean difference in peak bicarbonate was 0 mmol (95% CI-3, 9). There was a strong correlation between peak bicarbonate obtained by ePFT and Dreiling PFT ($r = 0.77$, $P < 0.001$). In addition, the time required to perform the ePFT was significantly less compared with the Dreiling PFT.

Structural and functional tests may be used synergistically in the diagnosis of pancreatitis. Past studies comparing PFT with ERCP have shown less than optimal concordance of structural and functional abnormalities. In a recent study, we compared endoscopic ultrasound (EUS) to secretin ePFT^[11]. We found significant inverse correlations of the EUS score with the secretin ePFT peak bicarbonate. However, the concordance of EUS with secretin ePFT in the group with mild EUS changes was only 72%.

The ePFT has been compared to the secretin magnetic resonance cholangiopancreatography (MRCP) in patients evaluated for CP^[12]. Among 24 patients with a normal ePFT, 15 had a normal MRCP pancreatogram, while nine patients had an abnormal MR pancreatogram. Among 12 patients with abnormal ePFT, seven had an abnormal MR pancreatogram, while five patients had a normal MR pancreatogram. Again, this suggests suboptimal correlation of structural and functional tests in the early phase of CP. Utilizing the MRCP functional assessment (duodenal fill-

ing after secretion), all 24 patients with normal ePFT had normal duodenal filling, and all 15 patients with abnormal ePFT had abnormal duodenal filling.

The secretin ePFT has been compared to histology in one retrospective study^[13]. Seventeen patients underwent a secretin ePFT within 12 mo before surgical resection or biopsy of the pancreas. There was a significant negative correlation between the ePFT peak bicarbonate concentration and the histological fibrosis score (Spearman $r = -0.57$). The ePFT was 86% sensitive and 67% specific for the diagnosis of fibrosis. The sensitivity and specificity were similar to those of EUS in the detection of histological fibrosis.

NEW DEVELOPMENTS

Shortened ePFT

A considerable limitation of the secretin ePFT is that it takes approximately 1 h to perform, with fluid collections at 0, 15, 30, 45, and 60 min after secretin injection. As such, we and others have studied shortened ePFT methods^[14,15]. In a retrospective analysis of 240 ePFT results, we found that measuring bicarbonate at 30 and 45 min provides 94% accuracy compared with the full hour long test. We currently administer secretin in the admitting area before transport to the endoscopy suite. By the time the patient is sedated, the scope inserted, and the stomach cleared of gastric fluid, we are able to efficiently collect duodenal aspirates at the 30 and 45 min time points. A careful luminal examination is performed between collections.

Combined EUS/PFT

A combination of structural and functional testing may be required to diagnose CP. We often perform a combined EUS and ePFT in the same endoscopic session. This involves performance of EUS following secretin stimulation, with collection of duodenal fluid at 15, 30, and 45 min. In 252 patients evaluated for suspected minimal change CP (no calcifications), 160 (63.5%) had concordant normal EUS and ePFT results, “ruling out” CP. Thirty-two patients (12.7%) had concordant abnormal EUS and ePFT results, “ruling in” the diagnosis^[16]. The remaining 60 patients had discordant results, which are more difficult to interpret. Patients with abnormal EUS and normal ePFT may have CP with preserved exocrine function. The significance of normal EUS with abnormal ePFT is uncertain, but may suggest a very early form of CP prior to the development of overt structural changes. Long-term studies are needed to better understand the significance of minimal or discordant functional and endosonographic changes.

Use of CCK for ePFT

Many pancreatic referral centers advocate that the CCK PFT is the most sensitive method for detecting early acinar cell loss from pancreatic fibrosis. Most CCK PFT protocols require continuous collection of pancreatic fluid using a gastroduodenal collection tube, with measurement of total enzyme output. Measurement of enzyme output

requires an accurate assessment of volume. Most CCK protocols use a second orogastric tube to perfuse an inert non-absorbable marker, such as polyethylene glycol (PEG). Measurement of recovered PEG from the duodenal juice produces a more accurate volume estimate.

Unlike more labor intensive methods that utilize perfusion markers, ePFT methods do not quantify volume, which would allow an accurate estimation of enzyme outputs. Instead, the ePFT collects timed samples of fluid and relies on concentration measurements. Studies of a CCK ePFT utilizing lipase concentrations have yielded mixed results. A pilot study found a threefold increase in lipase concentrations in healthy volunteers following continuous CCK stimulation (40 ng/kg per hour), with a mean peak lipase value of 1778847 IU^[17]. A subsequent study demonstrated that a peak lipase value of 780000 IU provided 83% sensitivity and 87% specificity for differentiating healthy subjects from patients with established CP^[18]. In a third study, CCK-stimulated endoscopic and Dreiling tube PFTs were compared with measurement of lipase concentrations^[19]. Both collection methods produced excellent discrimination between healthy volunteers and patients with moderate to advanced CP based on the ERCP Cambridge classification. A more recent study of the CCK ePFT yielded less satisfactory results^[11]. Although there was good separation between controls and those with advanced CP, there was substantial overlap in lipase results with the group with suspected early CP.

We have recently studied an ePFT using combined secretin and CCK to assess both duct-cell and acinar-cell function. The bicarbonate and enzyme results from the combined ePFT were compared using EUS as a reference standard^[20]. Of all the diagnostic parameters, peak bicarbonate and amylase appeared to optimize discrimination. Using logistic regression, a predictive score was developed including peak bicarbonate and peak amylase for prediction of CP. A predictive score threshold of 1213 yielded 82.8% sensitivity and 88.9% specificity. Further validation of this combined test is currently underway.

Use of autoanalyzers for bicarbonate measurement

In the secretin PFT, the standard technique for bicarbonate measurement has been back titration. Back titration involves gradual addition of defined quantities of hydrochloric acid to the pancreatic fluid sample until a pre-specified pH is obtained, allowing calculation of the original bicarbonate content of the fluid. Back titration is cumbersome and not available in most hospitals, whereas, chemistry autoanalyzers are widely available in all hospitals. We compared back titration versus an autoanalyzer for bicarbonate measurement in pancreatic fluid^[21]. There was high concordance between the methods (Lin's concordance coefficient = 0.96), suggesting that the autoanalyzer is a satisfactory method for bicarbonate measurement.

Measurement of proteins and lipids

Fluid analysis for PFTs has focused on the products of pancreatic exocrine secretion (bicarbonate and enzymes).

However, CP is disease of inflammation and fibrosis, not simply functional loss. Therefore, measurement of the byproducts of inflammation may be useful in diagnosing early CP, even before functional decline occurs. A recent study demonstrated the feasibility of measuring the entire complement of proteins from pancreatic fluid using gel electrophoresis followed by tandem mass spectrometry.^[22] The known functions of the discovered proteins were ascertained using gene ontology analysis. In this study, a total of 134 proteins were isolated from the pancreatic fluid, the majority of which were found in multiple samples. Further studies are underway to refine this proteomics approach, and to better understand the discriminative ability of these newly elucidated biomarkers for diagnosis.

Oxidative stress is known to have a role in pancreatic inflammation. Reactive oxidative molecules can cause damage to lipid membranes. Therefore, measurement of oxidized fatty acids may represent a useful biomarker for early CP. We have used a “lipidomics” approach to quantifying oxidized fatty acids in the serum and expressed pancreatic fluid during secretin ePFT, combined with tandem mass spectrometry. Oxidized fatty acids were differentially expressed in both the serum and fluid, suggesting a promising biomarker for early CP^[23,24]. Further work is needed to validate the use of protein or lipid measurement from pancreatic secretions.

ROLE OF THE ePFT

Endoscopic methods have simplified direct PFTs, and made them more accessible to clinicians and patients. However, there are acknowledged limitations. First, even when shortened protocols are used, the ePFT remains a time-consuming test, requiring 30-45 min of prolonged endoscopy. Second, the inability to accurately quantify fluid volume prevents calculation of enzyme output, arguably the optimal measure of acinar capacity. Finally, although intravenous sedation in low doses does not appear to substantially affect exocrine secretion, the effect of higher levels of sedation, as required for many patients with CP, has not been adequately studied.

The actual role of ePFT in the care of patients has yet to be defined. PFT has been considered a diagnostic test for early CP because mild changes in functional capacity may represent an early biomarker for pancreatic fibrosis. However, this is not universal in all patients. Past studies have shown that most patients with mild and severe CP have evidence of exocrine loss. However, some patients with advanced structural changes of CP have preserved exocrine function. We believe the ePFT serves as a complementary diagnostic modality with structural testing, as seen with the combined EUS/ePFT.

The ePFT may also be useful in investigating the cause of malabsorptive diarrhea. We frequently perform a fecal elastase test in the initial workup of patients with malabsorptive diarrhea. Fecal elastase levels are quite useful in diagnosing moderate and advanced exocrine insufficiency. However, if the fecal elastase result is equivocal or if mild exocrine insufficiency is considered, we often proceed

to secretin ePFT. We typically obtain secretin-stimulated duodenal aspirates before obtaining a small intestinal mucosal biopsy in patients evaluated for steatorrhea. In 12 patients who presented with painless steatorrhea, and who lacked structural features of CP on imaging tests, two patients (20%) were found to have concordant abnormal results, suggesting early CP with exocrine insufficiency^[16]. Conversely, 10 patients had a concordant normal EUS and ePFT, ruling out pancreatic insufficiency. Several of these patients were found to have other causes of steatorrhea, such as celiac disease or bacterial overgrowth.

Secretin ePFT may also be considered in patients with established CP to “stage” the disease and determine the need for exogenous enzymes. In our series of 38 patients with established severe CP who underwent EUS/ePFT, there were five patients (13.2%) who had a normal ePFT^[16]. These patients also lacked postprandial diarrhea. Based on the normal ePFT results, these patients were spared the cost and nuisance of taking pancreatic enzymes.

CONCLUSION

Endoscopic fluid collection has made hormone-stimulated pancreatic function tests much more accessible for routine clinical care. The incremental diagnostic utility of the secretin ePFT in the context of other sensitive structural tests, such as EUS and MRCP, remains to be proven. We have found the ePFT to be most useful in patients with suspicion of CP, but with minimal or equivocal radiographic abnormalities. In these patients, a combined secretin ePFT and endoscopic ultrasound is often performed as an efficient structural and functional assessment of the gland. We have also found the ePFT helpful in the workup of malabsorptive diarrhea, allowing a simultaneous small intestinal biopsy to screen for mucosal diseases that cause malabsorption. Further studies are underway to optimize ePFT protocols and to better define their role in the clinical care of patients.

Abstract

Gastrointestinal (GI) bleeding refers to any hemorrhage ascribed to the pathologies of the gastrointestinal tract, extending from the mouth to the anal canal. Despite the recent improvements in the endoscopic, hemostatic and adjuvant pharmacologic techniques, the reported mortality is still around 5%-10% for peptic ulcer bleeding and about 15%-20% for variceal hemorrhages. Although endoscopic management reduces the rates of re-bleeding, surgery, and mortality in active bleeding; early recurrence ratios still occur in around 20% of the cases even with effective initial hemostatic measures.

In this quest for an alternative pro-hemostatic agent for the management of GI bleedings, Ankaferd blood stopper (ABS) offers a successful candidate, specifically for "difficult-to-manage" situations as evidenced by data presented in several studies. ABS is a standardized mixture of the plants *Thymus vulgaris*, *Glycyrrhiza glabra*, *Vitis vinifera*, *Alpinia officinarum*, and *Urtica dioica*. It is effective in both bleeding individuals with normal hemostatic parameters and in patients with deficient primary and/or secondary hemostasis. ABS also modulates the cellular apoptotic responses to hemorrhagic stress, as well as hemostatic hemodynamic activity. Through its effects on the endothelium, blood cells, angiogenesis, cellular proliferation, vascular dynamics, and wound healing, ABS is now becoming an effective alternative hemostatic medicine for gastrointestinal bleedings that are resistant to conventional anti-hemorrhagic measurements. The aim of this review is to outline current literature experience suggesting the place of ABS in the management of GI bleeding, and potential future controlled trials in this complicated field.

INTRODUCTION AND BACKGROUND OF ANKAFERD BLOOD STOPPER

Ankaferd is a traditional herbal medicine that has been used in Anatolia as a hemostatic agent for centuries^[1]. Ankaferd is a standardized mixture of the plants *Thymus vulgaris*, *Glycyrrhiza glabra*, *Vitis vinifera*, *Alpinia officinarum*, and *Urtica dioica*, each of which have some effects on the endothelium, blood cells, angiogenesis, cellular proliferation, vascular dynamics, and/or cell mediators^[1-4]. Ankaferd blood stopper (ABS), a novel topical hemostatic agent, has been approved in Turkey for clinical hemorrhages, when the conventional control of bleeding by ligation and/or conventional hemostatic measures is ineffective^[5,6]. ABS is clinically effective in bleeding individuals with normal hemostatic parameters and in patients with deficient primary hemostasis and/or secondary hemostasis^[7-10]. ABS modulates the cellular apoptotic responses to hemorrhagic stress as well as its hemostatic hemodynamic activity^[11], and has many effects on proteins of the tissue and blood. Dose-dependent reversible PAR-1 down-regulation is mediated by ABS and also induces sustained PAR-1 down-regulation in the presence of lipopolysaccharides (LPS). These findings are compatible with other investigations focusing on the endothelial hemostatic molecules, endothelial cell protein C receptor (EPCR) and PAI-1. ABS may act as a topical biological response modifier as along with its anti-hemorrhagic effects^[10].

Gastrointestinal (GI) bleeding is a potentially life-threatening condition and a common cause of hospitalization. Despite effective endoscopic treatments, it is responsible for a significant societal burden due to the associated morbidity, mortality and financial implications^[12]. Although endoscopic management does diminish the rates of re-bleeding, surgery, and mortality in active hemorrhage, early recurrence still occurs in around 20% of cases despite the effective initial hemostasis. Hence, there is an ongoing intensive search for novel techniques or treatments that are effective, safe and “potentially life-saving” in the distinct settings of GI bleedings. During the search for a complementary pro-hemostatic agent for the management of GI hemorrhages, accumulated evidence suggested that ABS could have an efficient place for the “difficult-to-manage” subtypes of GI bleedings^[13-22]. ABS may serve as an adjuvant and/or primary agent for this complicated area.

The aim of this review is to outline the current literature suggesting the place of ABS in the management of GI bleeding, and potential future controlled trials in this complicated field. Currently established standard medical and endoscopic therapeutic options with hemostatic approaches do not represent the primary scope of this paper.

ABS AS A MODERN TOPICAL HEMOSTATIC AGENT

The basic mechanism of action for ABS appears to be the formation of an encapsulated protein network that provides focal points for erythrocyte aggregation. Rather than affecting an individual clotting factor, this protein mesh af-

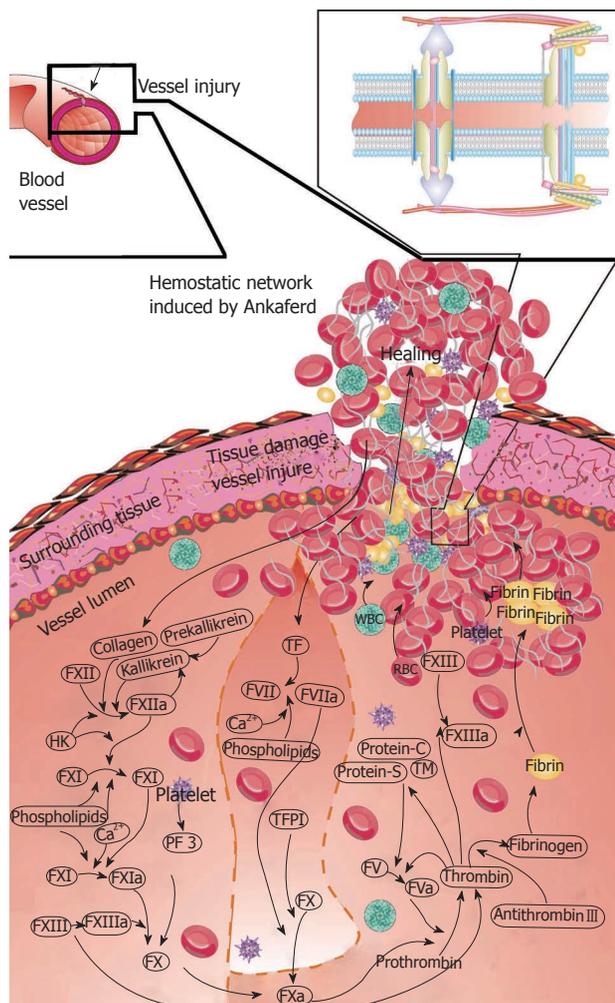

Figure 1 The basic mechanism of action for ankaferd blood stopper is the formation of an encapsulated protein network that provides focal points for erythrocyte aggregation. Ankaferd blood stopper (ABS)-induced formation of the unique protein network within the vital erythroid aggregation covers the entire physiological haemostatic process. Red blood cell (RBC) elements (such as spectrin and ankrin surface receptors, and internal ferrochelatase enzyme), related transcription factors (such as GATA-1) and RBC-related proteins (such as urotensin II) are the main targets of ABS. Those proteins and the required adenosine triphosphate bioenergy are included in the protein library of Ankaferd^[1].

fects the entire physiological hemostatic process that controls bleeding^[1,2]. Blood cells, particularly erythrocytes and activated leukocytes, were found to aggregate rapidly in the presence of ABS, thereby participating in the network formation (Figure 1). Macroscopic hemostatic actions of ABS may be explained by its rapid (< 1 s) induction of a protein network in human plasma and serum samples^[23]. ABS-induced formation of the protein network with vital erythroid aggregation covers the entire physiological hemostatic process^[1,2]. There are distinct important components of the ABS-induced hemostatic network. Vital erythroid aggregation takes place with the spectrin and ankyrin receptors on the surface of red blood cells. Those proteins, and the required ATP bioenergy, are included in the ABS protein library. Ankaferd also upregulates the GATA/FOG transcription system affecting erythroid functions. Urotensin-II is also an essential component of Ankaferd and represents the link between injured vascular endothe-

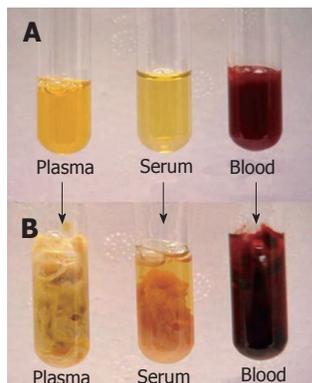

Figure 2 Ankaferd blood stopper-induced protein network formation with in less than 1 s. Plasma under the light microscopy before (A) and just after (B) Ankaferd application^[1].

lium, adhesive proteins, and active erythroid cells^[1,2]. These concepts have been developed *via* matrix-assisted laser desorption/ionization time of flight proteomic molecular analyses, cytometric arrays, transcription analysis, and Scanning electron microscopy ultrastructural examinations, as well as numerous investigations interacting with *in vivo* research settings^[23-26].

In vitro tests demonstrated that coagulation proteins were not individually affected by the addition of ABS to fresh normal plasma or serum, whereas plasma fibrinogen activity decreased from 302 to < 10 mg/dL, and fibrinogen antigen decreased from 299 mg/dL to < 30 mg/dL in parallel with thrombin time prolongation. Total protein, albumin and globulin levels decreased after the addition of ABS to fresh serum^[2,23]. These studies suggested that the ABS-induced network formation depends upon interactions between ABS and blood proteins, such as fibrinogen, and that ABS might affect fibrinogen and other proteins *via* agglutination of these molecules. Figure 2 depicts the macroscopic appearance of the protein network formation before and after adding ABS to human plasma, serum and whole blood.

Dose-dependent reversible PAR-1 down-regulation is mediated by ABS inside the human umbilical vein endothelial cells. ABS induces sustained PAR-1 down-regulation in the presence of LPS. These findings are compatible with our previous investigation focusing on the endothelial hemostatic molecules, EPCR and PAI-1. ABS has dual diverse dynamic reversible actions on EPCR and PAI-1 inside vascular endothelial cells also in the model of human umbilical vein endothelial cells. Sudden anti-hemorrhagic efficacy of ABS *via* immediate enhanced expression of pro-hemostatic PAI-1 and down-regulated anti-coagulant EPCR upon the exposure of ABS have been recognized as the unique hemostatic effects of ABS. The hemostatic function of PAR-1 is mainly prothrombotic. Significant PAR-1 down-regulation mediated by ABS indicated that ABS has balanced effects on global hemostasis^[2,26,27]. Coagulation proteins, namely factor II, V, VII, VIII, IX, X, XI and XIII, were not affected *in vitro* individually by ABS^[17]. Likewise, prothrombin time (PT) and activated partial thromboplastin time (aPTT) were normal

via the application of ABS. However, prolonged thrombin time (TT) was evident^[2]. Since PAR-1 is the most important thrombin receptor, depression of PAR-1 with ABS could explain the prolonged TT due to ABS^[10,27].

UPPER GASTROINTESTINAL BLEEDING

Peptic ulcer disease

Peptic ulcer is the most common cause of acute hemorrhage in the upper gastrointestinal tract, accounting for 28%-59% of all episodes of upper GI bleeding^[28,29]. Endoscopy with hemostatic therapy has clearly been shown to aid in proper diagnosis, prognosticate requirement for blood transfusions and, in the majority of instances, obviates the need for surgical intervention^[30,31]. Despite the improvements in achieving hemostasis, recurrent bleeding still occurs in about 15% to 20% of GI bleeding cases. Moreover, the reported mortality for patients with a bleeding peptic ulcer still amounts to 15%^[32]. Early effective hemostatic intervention is of great importance in the treatment of bleeding peptic ulcer disease, due to the high risk of morbidity and mortality. However, additional development is eagerly awaited for the therapeutic armamentarium of GI bleeding, which is safe, effective and easy applicable in difficult or intolerant patients^[33,34]. In this setting, ABS could be the candidate hemostatic agent in the controlling of peptic ulcer bleeding, based on the previous successful anecdotal reports in GI bleeding with various clinical outcomes^[13-22].

There is growing evidence in favor for the use of ABS in distinct states of GI bleeding, particularly in patients with bleeding due to peptic ulcer disease. In an observational study of "intention-to-treat" analysis by Ozaslan *et al.*^[35], five adult patients with bleeding peptic ulcer disease, in which ABS was used as a primary hemostatic agent due to difficulties or inappropriateness of the conventional measures, were reported to attained success in controlling of the bleeding within minutes. Similarly, Purnak *et al.*^[36] reported a successful hemostasis control in a patient with a bleeding peptic ulcer complicated with defective hemostasis. In this reported case, at the time of bleeding, the patient was under-treated with a cytotoxic chemotherapeutic agent leading to thrombocytopenia. Furthermore, platelet dysfunction and prolonged PT due to neutropenic sepsis had further complicated the hemostatic status. This "difficult-to-manage" situation was effectively controlled with topical ABS application and provided a critical time gain to the clinician until hemostasis could be returned to the normal level. Since ABS performs cellular hemostasis mainly through erythrocytes, it is reasonable to suggest that bleeding due to defective hemostasis (such as from a low platelet count, due to a warfarin overdose or because of chronic nonsteroidal anti-inflammatory drug use) could be controlled more efficiently with ABS as in this reported case^[36]. Likewise, the *in vivo* hemostatic effect of ABS with defective hemostasis, due to aspirin and low-molecular weight heparin administration, has been investigated in experimental models and ABS was found to be effective in shortening the bleeding duration and decreasing the amount of bleeding^[37]. Fur-

thermore, the first pediatric experience with ABS in an infant with bleeding peptic ulcer was recently demonstrated by Yarali *et al.*^[38]. Both of these reports seem to be encouraging for the justification of the use of ABS in peptic ulcer bleeding based on future controlled clinical trials.

Neoplastic upper GI bleedings

GI bleedings due to tumoral lesions (primary gastrointestinal tumors, direct local invasion by other malignancies, or metastatic disease to the gastrointestinal tract) are among the frequently encountered causes of GI bleeding, accounting for nearly 5% of severe upper GI bleeding cases^[39]. Severe bleeding is a bad prognostic sign for upper GI tumors, and endoscopic hemostasis in this setting is often a temporary measure prior to staging and surgical resection. Several methods have been used to control bleeding from gastroduodenal malignant lesions, including thermal contact probes (tumor probe, bipolar probes, or heater probe), epinephrine injection, laser coagulation and injection of sodium tetradecyl sulphate with a success rate of 66%-100%^[39-41]. Unfortunately, these intervention modalities were associated with high re-bleeding rates; up to 80% in a 1 mo period^[39,40].

In the setting of malignant GI bleeding, ABS was effectively used previously in several reports. Application of ABS successfully controlled GI bleeding within seconds in a patient with major GI bleeding from a recurrent lesion at the hepaticojejunostomy anastomosis following surgery for distal cholangiocellular carcinoma^[42]. In a case series by Kurt *et al.*^[43], topical application of ABS in seven patients with neoplastic upper GI hemorrhages, with appropriate bleeding control and post-procedural complications, were documented. In their summary, complete hemostasis was achieved in all of those patients within seconds of the endoscopic topical application of ABS, with no immediate complications. A recent report by Ozaslan *et al.*^[44] also supported the effectiveness of ABS in tumoral GI bleedings as a primary hemostatic agent. In their observational study, six patients suffering from malignant GI bleeding were reported to achieve hemostasis with topically applied ABS during endoscopy by a sclerotherapy needle or a heater probe catheter. The control of bleeding was obtained with ABS in five cases during the first endoscopic session, while the remaining one required a second application.

Apart from the mechanical hemostasis achieved by ABS, Turhan *et al.*^[45] disclosed that ABS decreases tumor vascularization in bleeding gastrointestinal carcinomas. In this report, topical ABS was applied in two patients with distinct tumoral GI bleedings due to gastric and rectal cancer. Tumor neo-vascularization/angiogenesis before and after the application of ABS were measured as tumor microvessel density (MVD). Topical ABS administration to the tumoral lesion resulted in complete control of the bleeding. Furthermore, ABS significantly decreased MVD measurements in both of the GI neoplastic tissues in comparison to the MVDs from the biopsy specimens before the ABS administration and the unexposed native neoplastic tissues of the stomach and rectum^[45]. Based on these preliminary findings, the authors suggested the

presence of a secondary, more sustained, mechanism of hemostasis induced by ABS beyond the initial protein network.

Although the management of tumoral GI bleeding in a pediatric population is a difficult to manage situation, ABS was also shown to be effective in a 10-year-old boy with esophageal tumor bleeding related to disseminated intravascular coagulation (DIC) during the post-chemotherapy period^[46]. Since the endoscopic procedure was contraindicated due to DIC and associated co-morbidities in this patient, nasogastric tubes were used for the topical application of ABS. The bleeding was stopped within a very short period of time following the 6 milliliters of topical ABS application, with no observation of re-bleeding or side effects.

Sphincterotomy bleeding

Endoscopic sphincterotomy (EST), which has become an essential procedure in therapeutic endoscopy for the management of pancreatic and biliary problems, raises concerns about procedure-related complications, such as hemorrhages, pancreatitis, cholangitis and perforation^[47]. Hemorrhage is one of the most frequently encountered, and sometimes fatal, complications of EST and the incidence is reported as 1%-10%^[47]. Though delayed hemorrhage may develop several days after EST, most of the bleedings occur just after EST. For this reason, effective control of intra-procedural hemorrhage is of great importance for the prevention of late post-EST bleedings. Several methods were suggested to control EST-related bleedings, with various grades of success^[48]. The classical therapeutic methods for the EST-induced hemorrhages are endoscopic, surgical and radiological interventions. The reported means of endoscopic management consist of: argon plasma coagulation, electrocoagulation, injection therapy with various agents, and hemoclipping^[49,50]. Since complete control of hemorrhages are not always possible *via* using those methods, novel hemostatic agents like ABS offer promising results in controlling post-sphincterotomy bleedings. We have recently reported the successful application of ABS in a 43-year-old woman that has underwent ERCP for cholangitis due to multiple bile duct stones^[13]. After mild sphincterotomy, early bleeding from the sphincterotomy site was observed. Despite management with electrocoagulation and injection therapy with epinephrine, the bleeding remained uncontrolled. Subsequently, we injected 3 mL of ABS *via* the working channel of the duodenoscope to the bleeding areas. After a rapid and effective hemostatic response was successfully achieved, the procedure was terminated. Figure 3 shows an early bleeding during the endoscopic sphincterotomy, which has been controlled *via* the topical application of ABS.

Mallory-Weiss syndrome

Mallory-Weiss syndrome (MWS) was determined to be the cause of upper GI bleeding in 3%-10% of cases^[51]. Bleeding in MWS usually stops spontaneously and patients can benefit from conservative medical treatment. Unfortunately, patients, especially those with stigmata of active

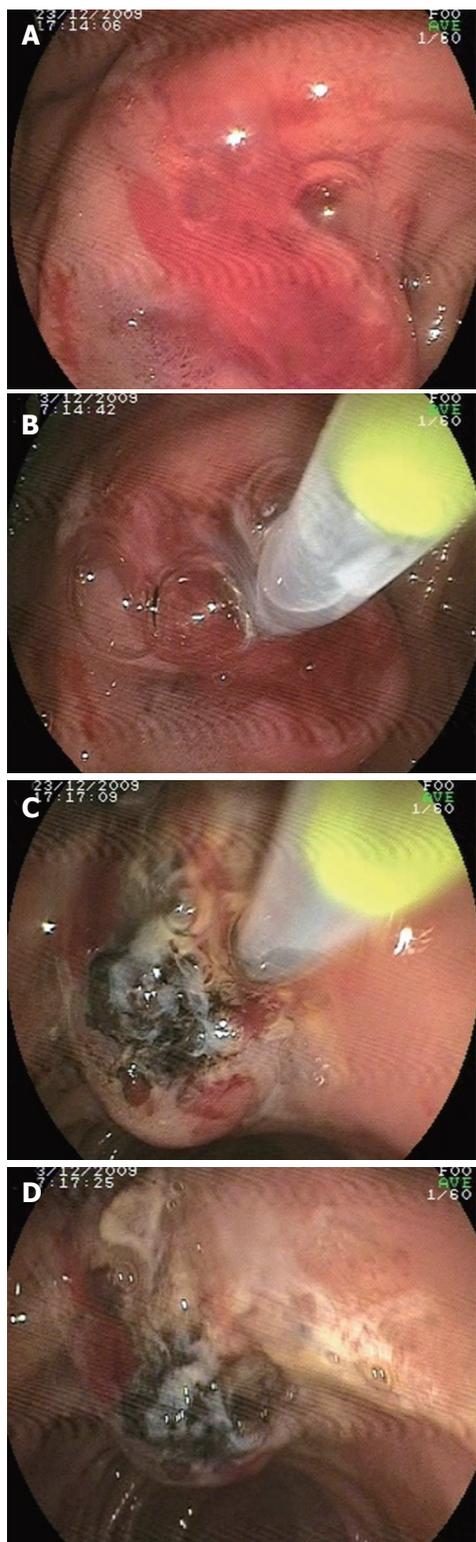

Figure 3 Ankaferd application during endoscopic sphincterotomy. A: Early bleeding during the endoscopic sphincterotomy; B: Ankaferd blood stopper (ABS) topically applied to the bleeding area; C: Hemorrhage was immediately controlled just after topical ABS administration; D: The bleeding site was covered by the hemostatic network related with the ABS application and hemorrhage was stopped.

bleeding and unstable vital signs at admission and/or associated co-morbid diseases, may require hemostatic intervention like hemoclip application, adrenaline injection and

band ligation^[52-54]. In a report by Ozaslan *et al.*^[35], a 62-year-old man with bleeding MWS was successfully treated with 13 mL of ABS. In another report, topical administration of ABS after unsuccessful combined endoscopic treatment in a warfarin-treated patient with bleeding MWS resulted in successful control after 7 mL of ABS application^[22]. This case demonstrates the effectiveness of ABS even in patients receiving anticoagulant therapy, which could possibly broaden the use of ABS in distinct states of gastrointestinal bleeding with hemorrhagic diathesis.

Dieulafoy's lesion

Dieulafoy's lesion (DL) is an uncommon, but important, cause of upper gastrointestinal bleeding consisting of a submucosal ectatic artery in the gastrointestinal tract and has a high mortality rate when diagnosis and treatment are delayed. It accounts for 0.3%-6.7% of all causes of upper GI bleeding^[55-57]. Endoscopic therapy is the current "standard-of-care" for patients with DL, because the lesions are commonly in an accessible localization with upper GI endoscopy^[56]. Unfortunately, endoscopic therapy sometimes fails to control active bleeding, resulting in hemorrhagic shock, circulatory collapse associated with increased morbidity, and even mortality. The first experience with ABS in a 63-year-old patient with DL was reported by Kurt *et al.*^[21]. In a recent paper, ABS was also shown to be effective in bleeding DL as an adjuvant modality in two patients^[22].

Variceal upper gastrointestinal bleeding

Variceal bleeding is one of the most serious and life-threatening complications of cirrhosis and portal hypertension, with mortality exceeding 50% in severe or advanced liver disease in acute variceal hemorrhage^[42]. Gastroesophageal varices are present in approximately 50%-60% of patients with cirrhosis. The prevalence of variceal hemorrhage is approximately 5%-15% yearly, and early variceal rebleeding has a rate of occurrence of 30%-40% within the first 6 wk^[29]. Despite urgent endoscopic and/or pharmacological therapy, variceal bleeding cannot be controlled, or recurs early, in about 10%-20% of patients with considerable morbidity and mortality rates^[58]. Although, endoscopic band ligation (EBL) and sclerotherapy are the choice of endoscopic treatment modalities for both active variceal bleeding and for secondary prophylaxis, application difficulties during active bleeding necessitated a search for new techniques and agents that are effective and safe. Furthermore, ease of administration, not requiring much experience and non-toxicity (even if the endoscopist could not locate the exact bleeding site), and injecting ABS to the close proximity to the suspected bleeding area may stop the variceal bleeding immediately. For that reason, ABS seems to offer a practical alternative in the setting of gastroesophageal variceal bleeding. Recently Tuncer *et al.*^[14] reported a patient with a fundal variceal hemorrhage that was effectively treated with 6 mL of ABS. Immediate hemostasis was achieved in 18 s without any further treatment. Control endoscopy was performed on day 5 that revealed clean surface

fundal varices and a successful variceal obscuration by cyanoacrylate injection that was performed subsequently. Similarly, in a case report by Ozaslan *et al*^[15], a patient with alcoholic cirrhosis who developed severe bleeding during an elective EBL session due to immediate band slippage underwent endoscopic topical application of ABS, which was then associated with the cessation of the hemorrhage. Although both of these reports seem to be encouraging, further controlled randomized studies are required to validate the effectiveness of ABS in the therapy of gastroesophageal varices. Current data regarding the use of ABS in GI bleedings is summarized in Table 1.

LOWER GASTROINTESTINAL BLEEDING

Post-polypectomy bleeding

Bleeding following endoscopic polypectomy is the most common complication of colonic polypectomy^[59], occurring in 0.3%-6.1% of polypectomies in various reports^[60-62]. Bleeding can occur immediately following polypectomy or be delayed for hours or even up to 29 d^[63]. Acute bleeding is due to the involvement of an underlying artery or inadequate coagulation of the polyp stalk and is usually self limiting, although active arterial bleeding can occur acutely.

The effectiveness of ABS for post-polypectomy bleeding was shown by Karaman *et al*^[16] in 7 patients with post-polypectomy bleeding (5 cases of colonic, 2 cases of gastric

polypectomy). ABS application was reported to be performed as a first choice in 5 cases, and after failed attempts with endoscopic interventions in 2 patients. Bleeding following polypectomy was stopped with ABS application in all of the cases without any other complication or re-bleeding. In a recent case series by Kurt *et al*^[22], ABS application in a total of 11 patients (8 gastroduodenal, 3 colonic) with post-polypectomy bleeding resulted in the successful control of active bleeding.

Radiation colitis

Radiation proctitis (RP) is a relatively common late complication of pelvic radiation, commonly given for prostate, rectal, and gynecologic malignancies. The main symptoms of chronic RP are hematochezia (sometimes quite severe), urgency, constipation, tenesmus, diarrhea, and rectal pain. While mild cases may settle spontaneously over some months, severe hemorrhagic RP may require repeated blood transfusions and is difficult to treat with medical therapy such as sulfasalazine, corticosteroid enemas, and sucralfate (given orally or as an enema)^[64,65]. Currently, argon plasma coagulation (APC) and local application of formalin are being used as main successful measures for therapy of RP, while APC treatment offers a safe non-contact method of delivering hemostasis compared to formalin^[64-66]. Although complete healing of RP is not expected, even with APC or formalin, the measurement of efficacy with current treatments have been reported

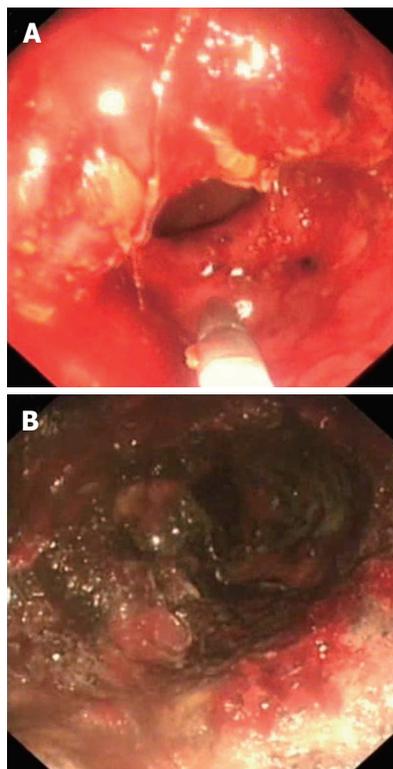

Figure 4 Endoscopic images of the distal rectum in a patient with radiation proctitis. A: Before Ankaferd blood stopper (ABS) application with fresh bleeding; B: After ABS application with grayish-yellow coagulum formation covering the diseased area.

as decreased rectal bleeding, reduced transfusion requirement, improvements in endoscopic appearance and quality of life for the patients. In this setting, ABS may offer an exciting alternative in the treatment of RP, due to its ease of application, non-toxicity, and speed of action. It has a short procedure time and very simple technique (only spraying targeted or even just close to the bleeding area), and does not require expensive equipment like APC. Moreover, it offers two unique advantages to other modalities that are used in APC therapy; it doesn't require precise localization of the site of bleeding when applied, and simple topical application over the whole lesion could suffice for the entire coating of the affected mucosa (Figure 4). The first case of successful ABS application in radiation colitis was reported by Ozaslan *et al*^[17] in a 71-year-old woman who had undergone pelvic radiotherapy due to cancer of the cervix. A total of 20 mL ABS was used with a sclerotherapy needle on the lesion and resulted in a greyish-yellow discoloration of the affected mucosa with cessation of bleeding. Three further sessions were carried out on a weekly basis to complete the healing with no signs of re-bleeding in the following days. At follow-up, the giant ulcerated lesion was reported to have almost disappeared, with only mild residual erosions and friability remaining. A difficult case of radiation proctitis that was managed by ABS was also reported by Shorbagi *et al*^[18] in a 70-year-old patient with failed management of both medical and endoscopic interventions with APC. In this report, approximately 20 mL of ABS solution was applied to the affected areas by using a disposable washing pipe,

which resulted in the immediate control of bleeding. The authors concluded that ABS would be a useful adjuvant to APC since, by controlling the active bleed, it may help to better localize and target telangiectasias. Kurt *et al*^[22] reported 3 patients with radiation colitis which was primarily managed with APC. Adjuvant application of ABS in these patients resulted in a more sustained control of bleeding. Aside from these reports, an observational study was also conducted in 8 patients with bleeding due to chronic RP in which ABS was applied as a primary therapy^[19]. In this study, ABS was instilled onto the bleeding areas by sclerotherapy needle or heater probe catheter, once a week, at a dose of 20-30 mL per session. ABS-induced hemostasis lasted for 1-8 d per session, and was achieved in seven of eight cases. In the eighth case, bleeding was only lessened. However, recurrence of bleeding was seen in all patients and ABS was found to be ineffective on telangiectasia at the last follow-up. As a result, ABS was only found to be effective in healing radiation-induced ulcers with no prolonged effect on bleeding telangiectasias due to RP.

Based on current observations, ABS may lead to the apparent healing of ulcers, but it might not be useful for the healing of telangiectasia or as a definitive therapy for bleeding in patients with chronic RP.

Solitary rectal ulcer

Solitary rectal ulcer (SRU) is a rare rectal disorder that can be present with bleeding, passage of mucus, straining during defecation, and a sense of incomplete evacuation^[67]. Although bleeding due to a rectal ulcer commonly stops spontaneously, re-bleeding is a major matter of concern, despite effective endoscopic interventions. Recently in a paper by Ibis *et al*^[20], topical application of 10 mL of ABS onto the ulcer through a disposable washing pipe resulted in successful control of the bleeding. Furthermore, complete healing of a bleeding SRU located adjacent to the anal canal prevented a potential risk for infection with fecal passage.

Neoplastic lower gastrointestinal bleeding

Colon cancer is the predominant cause of neoplastic bleeding. It accounts for up to 2%-9% of cases of hematochezia and is, by far, the most frequent cause of iron-deficiency anemia and the source of chronic lower GI bleeding^[68]. The bleeding is usually low-grade and recurrent, occurring as a result of erosions and ulceration on the surface of the tumor and often exacerbated by the use of NSAIDs. Although several endoscopic treatment modalities can be used to achieve hemostasis, when the bleeding tumoral lesion is identified in a colonoscopic examination, the majority of patients require surgical management due to increased re-bleeding rates, which can be as high as 80% up to 1 mo after the procedure. For that reason, alternative approaches are required, especially in inoperable cases or as a bridge to elective surgery. In this setting, ABS as a novel hemostatic agent could have a potential benefit in controlling bleeding from GI tumors. In a retrospective analysis, the effectiveness of ABS in lower GI bleeding due to rectal carcinoma was shown in three patients^[43]. Hemostasis was achieved in all three patients

within seconds following ABS application, with no adverse events.

CONCLUSION

ABS, which has long been used as a traditional folkloric medicinal plant extract, represents an effective alternative treatment modality as a modern topical hemostatic agent for GI bleeding either as an adjuvant or primary agent complementing conventional methods. Although ABS is still in the early developmental stages as a drug, observations from published series with encouraging results provide evidence for the preliminary safety and efficacy of ABS in distinct states of GI bleeding as a haemostatic agent^[13-22,35,42-46]. Future randomized controlled trials will elucidate whether ABS would be as much of a novel, safe and effective treatment option in the setting of GI bleeding.

Abstract

With the rising prevalence of antimicrobial resistance, the treatment success of standard triple therapy has recently declined to unacceptable levels (i.e., 80% or less) in most countries. Therefore, several treatment regimens have emerged to cure *Helicobacter pylori* (*H. pylori*) infection. Novel first-line anti-*H. pylori* therapies in 2011 include sequential therapy, concomitant quadruple therapy, hybrid (dual-concomitant) therapy and bismuth-containing quadruple therapy. After the failure of standard triple therapy, a bismuth-containing quadruple therapy comprising a proton pump inhibitor (PPI), bismuth, tetracycline and metronidazole can be employed as rescue treatment. Recently, triple therapy combining a PPI, levofloxacin and amoxicillin has been proposed as an alternative to the standard rescue therapy. This salvage regimen can achieve a higher eradication rate than bismuth-containing quadruple therapy in some regions and has less adverse effects. The best

second-line therapy for patients who fail to eradicate *H. pylori* with first-line therapies containing clarithromycin, amoxicillin and metronidazole is unclear. However, a levofloxacin-based triple therapy is an accepted rescue treatment. Most guidelines suggest that patients requiring third-line therapy should be referred to a medical center and treated according to the antibiotic susceptibility test. Nonetheless, an empirical therapy (such as levofloxacin-based or furazolidone-based therapies) can be employed to terminate *H. pylori* infection if antimicrobial sensitivity data are unavailable.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is the main cause of gastritis, gastroduodenal ulcer disease, gastric adenocarcinoma and mucosa-associated tissue lymphoma. The Maastricht III Consensus Report has recommended that proton pump inhibitor (PPI)-clarithromycin-amoxicillin

or metronidazole treatment for 7 to 14 d is the first choice treatment for *H. pylori* infection^[1]. As a general rule for the treatment of other infectious diseases, clinicians should prescribe therapeutic regimens that have a per-protocol eradication rate $\geq 90\%$ for anti-*H. pylori* therapy^[2]. However, several large clinical trials and meta-analyses have shown that the eradication rate of the standard triple therapy has generally declined to unacceptable levels (i.e., 80% or less) recently^[3,4]. In some European countries, the success rates are disappointingly low with values of only 25%-60%^[5,6]. The reasons for this fall in efficacy with time are uncertain but may be related to the increasing incidence of clarithromycin-resistant strains of *H. pylori*^[3,4,7,8]. This article will review the most recent literature in an attempt to introduce novel first-line eradication regimens with a per-protocol eradication rate exceeding 90% and rescue regimens with an eradication rate exceeding 80%.

FIRST-LINE THERAPY

The main reasons for eradication failure of *H. pylori* infection include antibiotic resistance, poor compliance and rapid metabolism of PPI^[3]. Clarithromycin resistance is the major cause of eradication failure for standard triple therapy^[8]. Pooled data from 20 studies involving 1975 patients treated with standard triple therapy showed an eradication rate of 88% in clarithromycin-sensitive strains *vs* 18% in clarithromycin-resistant strains^[8]. Therefore, the background rate of clarithromycin resistance is critically important as its presence negatively impacts the efficacy of standard triple therapy. A systemic review showed that the rate of clarithromycin-resistant strains ranged from 49% (Spain) to 1% (Netherlands) worldwide^[9]. In areas with clarithromycin resistance of $< 10\%$ [i.e., Netherlands, Sweden, Ireland, Germany, Malaysia, Taiwan (South)], it is still possible to employ a standard triple therapy to achieve a per-protocol eradication rate $> 90\%$. However, standard triple therapies should be abandoned in areas with clarithromycin resistance $\geq 20\%$ [i.e., Spain, Turkey, Italy (Central), Alaska, China, Japan, Cameroon] because the per-protocol eradication rates of standard therapies are often less than 85% and the intention-to-treat eradication rates are usually less than 80%^[2-8,10].

Recently, several studies showed that a novel 10-d sequential therapy can achieve a promising success rate of 90%-94%^[11-13]. The regimen consists of a 5-d dual therapy with a PPI (standard dose, *b.i.d.*) and amoxicillin (1 g, *b.i.d.*) followed by a 5-d triple therapy with a PPI (standard dose, *b.i.d.*), clarithromycin (500 mg, *b.i.d.*) and metronidazole (500 mg, *b.i.d.*). Gatta *et al.*^[12] reported a rigorous systematic review that identified 13 trials evaluating 3271 patients. The data showed that sequential therapy achieved a 12% better absolute eradication rate than the standard triple therapy. A randomized, double-blind, placebo-controlled trial demonstrated that the per-protocol eradication rates of sequential therapy and standard triple therapy for clarithromycin-resistant strains were 89% and 29%, respec-

tively^[11]. However, it should be noted that most of the studies concerning sequential therapies were conducted in Italy. A recent trial in Korea showed that the per-protocol eradication rates of sequential therapy and standard triple therapy were 86% and 77%, respectively. The two therapies had comparable eradication rates^[14]. There is, therefore, a clear need for well-designed randomized trials from countries other than Italy to determine the real advantages of this novel therapy.

Concomitant therapy is another novel regimen which was proved successful in the presence of clarithromycin resistance^[15]. This is a 4-drug regimen containing a PPI (standard dose, *b.i.d.*), clarithromycin (500 mg, *b.i.d.*), amoxicillin (1 g, *b.i.d.*) and metronidazole (500 mg, *b.i.d.*) which are all given for the entire duration of therapy. This therapy is superior to standard triple therapy for *H. pylori* eradication^[15]. It is also less complex than sequential therapy as this regimen does not involve changing drugs halfway through. A head-to-head non-inferiority trial of 10-d sequential and 10-d concomitant therapy showed that they were equivalent (93.1% *vs* 93.0% by per-protocol analysis)^[16].

Recently, Hsu *et al.*^[17] reported a hybrid (dual-concomitant) therapy consisting of a dual therapy with a PPI (standard dose, *b.i.d.*) and amoxicillin (1 g, *b.i.d.*) for 7 d followed by a concomitant quadruple therapy with a PPI (standard dose, *b.i.d.*), amoxicillin (1 g, *b.i.d.*), clarithromycin (500 mg, *b.i.d.*) and metronidazole (500 mg, *b.i.d.*) for 7 d. The new therapy extends the duration of amoxicillin treatment to 14 d and concomitantly employs three antibiotics in the last 7 d of the treatment course. In 117 *H. pylori*-infected subjects, the novel therapy provided excellent eradication rates of 99% and 97% according to per-protocol and intention-to-treat analysis, respectively. It is important to note that the new therapy has a high efficacy in the treatment of *H. pylori* strains harboring dual resistance to clarithromycin and metronidazole. Several studies have shown that sequential therapy is ineffective in clearing *H. pylori* with dual resistance^[8]. The prolonged treatment duration of amoxicillin to 14 d in the hybrid therapy might account for the higher eradication rate in the face of *H. pylori* strains with dual resistance to clarithromycin and metronidazole. Further studies in populations with different levels of prevalence of clarithromycin and metronidazole resistance are needed to assess the efficacy of the new regimen.

Bismuth-containing quadruple therapy is an alternative first choice treatment for *H. pylori* infection recommended by the Maastricht III Consensus Report^[1] and the Second Asia-Pacific Consensus Guidelines for *H. pylori* Infection^[18]. Two studies each with more than 100 patients have shown eradication rates of $> 90\%$ with this combination given for 10 d^[19,20]. Recently, Malfertheiner *et al.*^[21] compared the efficacy of a 10-d bismuth-containing quadruple therapy (omeprazole, bismuth, metronidazole and tetracycline) and a 7-d triple therapy (omeprazole, clarithromycin and amoxicillin). The data indicated that the former had a higher eradication rate than the latter (93%

vs 70% by per-protocol analysis). Currently, the optimal treatment duration of bismuth-containing quadruple therapy remains unclear but a 10-14 d course is most commonly employed in clinical practice^[22].

Based on a large body of published clinical trials, a quinolone-based triple therapy is effective in the first-line therapy of *H. pylori* infection. The eradication rates of levofloxacin-based triple therapy ranged from 72% to 96%^[23]. The regimen might be considered in populations with clarithromycin resistance greater than 15%-20% and quinolone resistance less than 10%^[23]. However, a quinolone-based triple therapy is not generally recommended as first-line therapy at the moment due to concerns about the rising prevalence of quinolone-resistant strains in the first-line and second-line anti-*H. pylori* therapies. Furthermore, greater use of quinolone would likely result in the development of more quinolone-resistant pathogens causing respiratory and urogenital tract infections.

SECOND-LINE THERAPY

The Maastricht III Consensus Report recommended a bismuth-containing quadruple therapy regimen comprising a PPI, bismuth, metronidazole and tetracycline as second-line therapy^[1]. This rescue regimen fails in 5%-63% of patients with an average eradication rate of 76% on the basis of a pooled analysis^[24,26]. The prevalence of metronidazole-resistant strains, dose and duration of rescue therapy seem to be important variables for the efficacy of this treatment. In bismuth-containing quadruple regimens, PPI should be prescribed in the usual dose and twice a day, colloidal bismuth subcitrate 120 mg four times a day, tetracycline 500 mg four times a day and metronidazole 500 mg three times a day. A report from Korea showed that the two-week bismuth-containing quadruple therapy was more effective than the 1-wk treatment (83% *vs* 64% by intention-to-treat analysis)^[27].

Levofloxacin-based triple therapy consisting of levofloxacin (500 mg, *q.d.*), amoxicillin (1 g, *b.i.d.*) and a PPI (standard dose, *b.i.d.*) represents an encouraging strategy for second-line therapy. A meta-analysis by Saad *et al.*^[28] showed that a 10-d regimen of levofloxacin-based triple therapy was superior to a 7-d bismuth-based quadruple therapy. Another meta-analysis by Gisbert *et al.*^[29] demonstrated a borderline significance of higher *H. pylori* cure rates with levofloxacin-based triple regimens compared with quadruple therapies (81% *vs* 70%). Additionally, the study revealed fewer adverse effects with levofloxacin than with quadruple regimens (19% *vs* 44%). However, it is noteworthy that levofloxacin-based triple therapies seem less effective in Asia. Two randomized controlled trials from Taiwan and Hong Kong showed that levofloxacin-based triple therapy was comparable to quadruple therapy in the eradication efficacy of second-line therapy.^[30,31] The second-line therapy for patients who fail to eradicate *H. pylori* new first-line therapies (such as sequential therapy, concomitant therapy or hybrid therapy) remains unclear. However, a recent study showed that a le-

vofloxacin-based triple therapy with lansoprazole (30 mg, *b.i.d.*), levofloxacin (250 mg, *b.i.d.*) and amoxicillin (1 g, *b.i.d.*) achieved a high eradication rate in patients who failed to clear *H. pylori* with sequential therapy^[32].

THIRD-LINE THERAPY

Currently, a standard empirical third-line therapy is lacking. The Maastricht III Consensus Report recommended using bacterial culture with antimicrobial sensitivity tests to select antibiotics for third-line regimens^[1]. Cammarota *et al.*^[33] analyzed *H. pylori* isolates from 94 consecutive patients in whom *H. pylori* infection had persisted after two eradication attempts. Ninety-four subjects (100%) were resistant to metronidazole, 89 (95%) to clarithromycin, 29 (31%) to levofloxacin and five (5%) to tetracycline. No resistance to amoxicillin was found in any of the patients. Patients were then treated with a culture-guided, third-line regimen: 89 patients with a 1-wk quadruple regimen including omeprazole, bismuth, doxycycline and amoxicillin, and five patients with a 1-wk triple regimen containing omeprazole, amoxicillin and levofloxacin or clarithromycin. Overall, *H. pylori* eradication was obtained in 90% of subjects treated by the culture-guided therapy.

However, it has been reported that the sensitivity of culture is less than 60%^[34]. Additionally, *in vitro* antimicrobial sensitivity does not necessarily lead to eradication *in vivo* and *vice versa*. Recently, several empirical third-line therapies have been proposed to treat refractory *H. pylori* infection. A 10-d quadruple therapy comprising rabeprazole (20 mg *b.i.d.*), bismuth subcitrate (300 mg, *q.i.d.*), amoxicillin (500 mg, *q.i.d.*), and levofloxacin (500 mg, *q.d.*) achieved an eradication rate of 84% by both intention-to-treat analysis and per-protocol analysis in patients who failed to eradicate *H. pylori* with standard triple therapy and bismuth-based quadruple therapy^[35].

Rifabutin is an antituberculous agent, which can be administered with PPI and amoxicillin for 10-14 d to eradicate *H. pylori*. One study used rifabutin (150 mg, *b.i.d.*), amoxicillin (1 g, *b.i.d.*) and omeprazole (20 mg, *b.i.d.*) for 14 d as a third-line therapy^[36]. Per-protocol and intention-to-treat eradication was achieved in 11/14 patients (79%). It is noteworthy that serious myelotoxicity and ocular adverse events have been reported with rifabutin therapy^[37]. In addition, greater use of rifabutin would likely result in the development of more resistant strains to *Mycobacterium tuberculosis* and *Mycobacterium avium*.

Furazolidone-based therapy is another useful option to treat refractory *H. pylori* infection. A 7-d quadruple therapy consisting of lansoprazole (30 mg, *b.i.d.*), tripotassium dicitratobismuthate (240 mg, *b.i.d.*), furazolidone (200 mg, *b.i.d.*) and tetracycline (1 g, *b.i.d.*) has a high efficacy in third-line therapy with an eradication rate of 90% by both intention-to-treat and per-protocol analysis^[38]. The recommended regimens for *H. pylori* therapies are summarized in Table 1.

In conclusion, with the rising prevalence of antimicrobial resistance, the treatment success of standard

Table 1 Recommended regimens for *Helicobacter pylori* therapy

Treatment	Regimen
First-line therapy	
Standard triple therapy ¹	A PPI (standard dose, <i>b.i.d.</i>), clarithromycin (500 mg, <i>b.i.d.</i>) and amoxicillin (1 g, <i>b.i.d.</i>) for 7-14 d
Sequential therapy	A 5-d dual therapy with a PPI (standard dose, <i>b.i.d.</i>) and amoxicillin (1 g, <i>b.i.d.</i>) followed by a 5-d triple therapy with a PPI (standard dose, <i>b.i.d.</i>), clarithromycin (500 mg, <i>b.i.d.</i>) and metronidazole (500 mg, <i>b.i.d.</i>)
Concomitant therapy	A PPI (standard dose, <i>b.i.d.</i>), clarithromycin (500 mg, <i>b.i.d.</i>), amoxicillin (1 g, <i>b.i.d.</i>) and metronidazole (500 mg, <i>b.i.d.</i>) for 7-10 d
Hybrid therapy	A 7-d dual therapy with a PPI (standard dose, <i>b.i.d.</i>) and amoxicillin (1 g, <i>b.i.d.</i>) followed by a 7-d quadruple therapy with a PPI (standard dose, <i>b.i.d.</i>), amoxicillin (1 g, <i>b.i.d.</i>), Clarithromycin (500 mg, <i>b.i.d.</i>) and metronidazole (500 mg, <i>b.i.d.</i>)
Bismuth-containing quadruple therapy	A PPI (standard dose, <i>b.i.d.</i>), bismuth (standard dose, <i>q.i.d.</i>) tetracycline (500 mg, <i>q.i.d.</i>) and metronidazole (250 mg, <i>q.i.d.</i>) for 10-14 d
Second-line therapy	
Bismuth-containing quadruple therapy	A PPI (standard dose, <i>b.i.d.</i>), bismuth (standard dose, <i>q.i.d.</i>) tetracycline (500 mg, <i>q.i.d.</i>) and metronidazole (500 mg, <i>t.i.d.</i>) for 10-14 d
Levofloxacin-based triple therapy ²	A PPI (standard dose, <i>b.i.d.</i>), levofloxacin (500 mg, <i>q.d.</i>) and amoxicillin (1 g, <i>b.i.d.</i>) for 10 d
Third-line therapy	
Culture-guided therapy	A 10-d quadruple therapy comprising a PPI (standard dose, <i>b.i.d.</i>), bismuth (standard dose, <i>q.i.d.</i>) and two antibiotics selected by antimicrobial sensitivity tests
Levofloxacin-based quadruple therapy	A PPI (standard dose, <i>b.i.d.</i>), bismuth (standard dose, <i>q.i.d.</i>), levofloxacin (500 mg, <i>q.d.</i>) and amoxicillin (500 mg, <i>q.i.d.</i>) for 10 d
Rifabutin-based triple therapy	A PPI (standard dose, <i>b.i.d.</i>), rifabutin (150 mg <i>b.i.d.</i>) and amoxicillin (1 g <i>b.i.d.</i>) for 14 d
Furazolidone-based quadruple therapy	A PPI (standard dose, <i>b.i.d.</i>), tripotassium dicitratobismuthate (240 mg, <i>b.i.d.</i>), furazolidone (200 mg, <i>b.i.d.</i>) and tetracycline (1 g, <i>b.i.d.</i>)

¹Employed in areas with clarithromycin resistance < 10% and abandoned in areas with clarithromycin resistance ≥ 20%. ²Employed in patients who fail to eradicate *Helicobacter pylori* with standard triple therapy, sequential therapy, concomitant therapy or hybrid therapy. PPI: Proton pump inhibitor.

triple therapy has recently declined to unacceptable levels. Novel first-line anti-*H. pylori* therapies in 2011 include sequential therapy, concomitant quadruple therapy, hybrid (dual-concomitant) therapy and bismuth-containing quadruple therapy. After the failure of standard triple therapy, a bismuth-containing quadruple therapy or a levofloxacin-based triple therapy can be employed as rescue treatment. The best second-line therapy for patients who fail to eradicate *H. pylori* with first-line therapies containing clarithromycin, amoxicillin and metronidazole is unclear. However, a levofloxacin-based triple therapy is an accepted salvage treatment. With regard to third-line therapy of *H. pylori* infection, a culture-guided therapy has been recommended. If antimicrobial sensitivity data are unavailable, an empirical therapy (such as levofloxacin-based, rifabutin-based, or furazolidone-based therapies) can be employed to terminate *H. pylori* infection. In spite of many emerging therapies, none have been included into current major consensus so far. Hopefully, the upcoming Maastricht IV meeting will bring a wind of change.

Abstract

AIM: To compare the microRNA (miR) profiles in the primary tumor of patients with recurrent and non-recurrent gastric cancer.

METHODS: The study group included 45 patients who underwent curative gastrectomies from 1995 to 2005 without adjuvant or neoadjuvant therapy and for whom adequate tumor content was available. Total RNA was extracted from formalin-fixed paraffin-embedded tumor samples, preserving the small RNA fraction. Initial profiling using miR microarrays was performed to identify potential biomarkers of recurrence after resection. The expression of the differential miRs was later verified by quantitative real-time polymerase chain reaction (qRT-PCR). Findings were compared between patients who had a recurrence within 36 mo of surgery (bad-prognosis group, $n = 14$, 31%) and those who did not (good-prognosis group, $n = 31$, 69%).

RESULTS: Three miRs, miR-451, miR-199a-3p and miR-195 were found to be differentially expressed in tumors from patients with good prognosis vs patients with bad prognosis ($P < 0.0002$, 0.0027 and 0.0046 respectively). High expression of each miR was associated with poorer prognosis for both recurrence and survival. Using miR-451, the positive predictive value for non-recurrence was 100% (13/13). The expression of the differential miRs was verified by qRT-PCR, showing high correlation to the microarray data and similar separation into prognosis groups.

CONCLUSION: This study identified three miRs, miR-451, miR-199a-3p and miR-195 to be predictive of recurrence of gastric cancer. Of these, miR-451 had the strongest prognostic impact.

MicroRNAs as a potential prognostic factor in gastric cancer. *World J Gastroenterol* 2011; 17(35): 3976-3985 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i35/3976.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i35.3976>

INTRODUCTION

Gastric cancer is a highly aggressive and lethal malignancy. It accounts for 8.6% of all new cancer cases worldwide, and is the second leading cause of cancer deaths. Of the estimated 930 000 people newly diagnosed with gastric cancer each year, some 700 000 will die of the disease^[1]. Although surgery is the standard treatment of localized gastric cancer, the results are often disappointing, with recurrence rates as high as 70% after successful complete (R0) resection. Attempts to improve outcome with adjuvant therapy have yielded only modest success. Trials of postoperative chemoradiation or perioperative chemotherapy report only a 10%-15% absolute reduction in the risk of recurrence^[2,3]. Moreover, the adjuvant therapy regimens used in these studies were themselves associated with significant morbidity and even mortality.

These findings emphasize the need for better selection of patients for the various treatment strategies. For example, patients with a good prognosis may be spared adjuvant therapy whereas those with a poor prognosis may receive such treatment or even be offered investigational programs. However, at present, the prognosis of the individual patient is determined solely by the extent of local tumor spread [Tumor, Node Status, Metastasis (TNM) staging]^[4]. Other factors, such as the patient's age and sex, tumor grade and presence of vascular invasion and perineural spread, add little to the ability of clinicians to distinguish between patients with a good and bad prognosis^[5-7]. A nomogram incorporating multiple clinical and pathological parameters that was created to predict survival after R0 resection, but it has not been adopted by the medical community^[8]. Clearly, novel effective prognostic markers are still lacking in gastric cancer.

MicroRNAs (miRs) are short non-coding RNAs, 17-22 nucleotides in length, which regulate gene expression and thereby play significant roles in human development and various pathological conditions^[9-11]. The expression of miRs is dynamic and corresponds to the physiological situation, raising the possibility that miR profiles derived from tumoral specimens may be able to serve as diagnostic or prognostic biomarkers^[12-15]. Indeed, recent studies have shown an association of miR expression and different malignancies^[16-20]. Their prognostic role in gastric cancer is unknown, but preliminary findings are encouraging^[21-26].

The aim of the present study was to compare the miR profiles in surgically resected primary gastric cancer tumors between patients with and without recurrence to evaluate their prognostic impact.

MATERIALS AND METHODS

Patients

The study population consisted of patients with histologically confirmed adenocarcinoma of the stomach who were operated on and followed-up at the two hospitals of the Rabin Medical Center. Other inclusion criteria were as follows: treatment between 1995 and 2005, to ensure the quality of the surgical specimens on the one hand and adequate follow-up on the other; absence of distant spread; and minimum of 36 mo follow-up in those without recurrence, to reliably estimate disease-free survival. Patients with cardiac tumors extending into the gastroesophageal junction were eligible, but not patients with predominantly esophageal or gastroesophageal junction tumors (Siewert classification I - II)^[27]. All patients underwent potentially curative gastrectomies with clear margins (R0 resection). To isolate a prognostic from a predictive effect, patients who received any adjuvant or neoadjuvant therapy were excluded. Eligible patients were identified from the database of the two Institutes of Oncology at the Rabin Medical Center. The study was approved by the local Institutional Review Board.

Follow-up

The study was retrospective; therefore, the follow-up schedule for the individual patients was determined by the treating physician. At our center, patients with gastric cancer are routinely followed once every 3 to 6 mo in the first three years, regardless of the stage of their disease. Time to recurrence or death is defined from the date of surgery. At each visit, patients undergo a medical history, physical examination, and measurement of serum carcinoembryonic antigen level. Imaging tests and endoscopies are performed when clinically indicated.

For the present study, eligible patients were divided into two groups: those in whom the disease recurred during the first 36 mo of follow-up (bad-prognosis group) and those who did not have a recurrence within this period (good-prognosis group).

Pathology

Formalin-fixed paraffin-embedded blocks of the surgical specimens from the initial gastrectomies of the eligible patients were retrieved from the archives of the two Institutes of Pathology at the Rabin Medical Center. After initial patient identification, all original histological slides were reviewed, and an appropriate block containing > 50% tumor was retrieved. In the cohort used for this study the median tumor content was 78% with a range of 50%-95%. From each block, 10 slices of 10 μ m each were collected in one 1.5mL tube for RNA extraction and miR analysis. Histological type and grade, as well as

other significant tumor features (e.g., perineural invasion), were determined by a pathologist on hematoxylin-eosin-stained slides prepared from the first and/or last sections of the sample.

RNA extraction

Total RNA was extracted as described previously^[28]. Briefly, the sample was incubated several times in xylene at 57°C to remove excess paraffin and then washed several times with ethanol. Protein degradation was performed by incubation of the sample in a proteinase K solution at 45°C for a few hours. The RNA was extracted using acid phenol/chloroform and then precipitated with ethanol; DNase was introduced to digest DNA. Total RNA quantity and quality were measured using a Nanodrop ND-1000 (NanoDrop Technologies, Wilmington, DE).

Array platform

Custom miR microarrays have been described previously^[15]. Briefly, ~900 DNA oligonucleotide probes representing miRs (Sanger database version 10 and additional miRs predicted and validated by Rosetta Genomics) were spotted in triplicate on coated microarray slides (Nexterion[®] Slide E, Schott, Mainz, Germany), using the BioRobotics MicroGrid II microarrayer (Genomic Solutions, Ann Arbor, MI) according to the manufacturer's directions. 3.5 µg of total RNA were labeled by ligation of an RNA-linker, p-rCrU-Cy/dye (Eurogentec Inc., San-Diego, CA; Cy3 or Cy5) to the 3' end. Slides were incubated with the labeled RNA for 12-16 h at 55°C and then washed twice. Arrays were scanned using Agilent DNA Microarray Scanner Bundle (Agilent Technologies, Santa Clara, CA) at a resolution of 10 µm with 100% and 10% laser power. Array images were analyzed using SpotReader software (Niles Scientific, Portola Valley, CA). Microarray spots were combined and signals normalized as described previously^[28]. Two types of positive controls were included in the experimental design: (1) synthetic small RNAs were spiked into each RNA sample before labeling to verify labeling efficiency; and (2) probes for abundant small RNAs were spotted to validate RNA quality.

Signal calculation and normalization

The RNA fluorescence data from the slide corresponding to each patient were loaded into a single database. Microarray spots were combined and signals were normalized as described previously^[15]. Data were log-transformed and analyzed in log-space. Therefore, the expression level or signal of an individual miR referred to the normalized value. The miR profile of each patient was visually compared with the median value for all patients. Eleven samples for which the readings were clearly incomparable (i.e., overall pattern too noisy) were excluded. These samples did not differ in their survival patterns from the 45 samples that were kept for statistical analysis ($P = 0.28$ by log-rank test). Only samples that passed this analysis were included in further analyses.

Polymerase chain reaction validation

For the purposes of signal verification, 15 miRs were selected for quantitative real-time polymerase chain reaction (qRT-PCR) analysis. Nine were selected as differential miR probes and six as non-differential probes, for signal normalization. The six miRs (hsa-let-7c, hsa-miR-222, hsa-miR-22, hsa-miR-15b, hsa-miR-425 and hsa-miR-34a) that were selected for normalization had low variability across all samples in the microarray experiment and were used as endogenous controls. Linear normalization was applied as follows: the mean cycle threshold (C_T) for the miRs used for normalization was calculated for each sample and the difference between the mean C_T for each sample and the mean of the mean C_T s was subtracted from all C_T s measured for that sample. Twenty samples, 10 from the good-prognosis group and 10 from the poor-prognosis group, were analyzed. MiR amounts were quantified using a recently described qRT-PCR method^[29]. RNA was incubated in the presence of poly (A) polymerase (PAP; Takara-2180A), $MnCl_2$ and ATP for 1 h at 37°C. Then, using an oligodT primer harboring a consensus sequence, reverse transcription was performed on total RNA using SuperScript II RT (Invitrogen, Carlsbad, CA). This was followed by cDNA amplification by RT-PCR; the reaction contained a miR-specific forward primer, a TaqMan probe complementary to the 3' of the specific miR sequence as well as to part of the polyA adaptor sequence, and a universal reverse primer complementary to the consensus 3' sequence of the oligodT tail. The C_T , i.e., the PCR cycle at which the probe signal reached the threshold, was determined for each well. To allow comparison with results from the microarray, each value received was subtracted from 50. The $50-C_T$ (50_{CT}) expression for each miR for each patient was compared with the log signal obtained by the microarray method. The microarray and PCR readings for each miR were correlated over all patients. Differential expression analysis for good *vs* bad prognosis, and Kaplan-Meier survival analysis were also performed for the PCR data.

Data analysis and statistics

The clinical and pathological data of the eligible patients whose surgical specimens were deemed suitable for the tissue analysis were entered into an electronic database created for this purpose and anonymized. The miR measurements were performed by trained personnel who were blinded to the patients' clinical data.

Data were split by the prognostic grouping of the patients with or without a recurrence within 36 mo of surgery. A total of 112 miRs had a median signal that passed the minimal threshold of 300 units in at least one group. For each of these, the distributions of readings in the two groups were compared using the Wilcoxon-Mann-Whitney two-sample rank-sum test. The threshold for P -value significance was selected by setting a Benjamin-Hochberg false discovery rate (FDR) of 0.1, yielding a value of 0.0235. The fold-change between the two groups (i.e., the

ratio of the median expression levels) was calculated for

each miR; miRs were deemed differentially expressed if the *P* value was below the significance threshold and the fold-change was at least 2.0.

The cohort was divided into two groups according to the expression signal (above or below the median) of each of the most significant miRs. Kaplan Meier survival curves were then used to compare the two groups, and *P* values were obtained by a log-rank test. Additionally, to adjust for multiple-hypothesis testing, the miR profiles were randomly shuffled between patients. Specifically, miR profiles were randomly associated with clinical data at $N_{\text{repeat}} = 200$ times; in each repeat and for each miR, patients were divided into two groups (i.e., miR signal above/below the median), and log-rank *P* values were recalculated using the (randomly associated) clinical follow-up data. The lowest *P* value for each random set was recorded. The *P* values obtained were ranked, and the placement of the true *P* value within this list ($\text{rank}_{\text{true}}$) was determined, generating an adjusted *P* value, $P_{\text{adjusted}} = \text{rank}_{\text{true}}/N_{\text{repeat}}$. The re-sampling method was used to evaluate conclusions of complex analyses, such as combinations of miRs.

Stepwise Cox regression was used to analyze combined survival patterns (combinations of miRs and combinations of clinical and demographic features) on multivariate analysis. The inclusion criterion was $P < 0.05$, and the exclusion criterion was $P > 0.1$. The coefficients of the Cox fit were used to create a composite risk score for each patient. A score threshold that produced optimal separation between good and bad prognosis was used for Kaplan-Meier analysis.

The overall goal of this research was to reliably predict non-recurrence after surgery, i.e. to achieve a high positive predictive value (PPV, number of patients correctly predicted to have no recurrence/all patients predicted to have no recurrence). After choosing the most relevant miR, its predictive value was optimized by finding the threshold that maximized the PPV with high sensitivity for detection of non-recurrence. The Kaplan-Meier analysis was then repeated on the basis of this separation, and the log-rank test was repeated to measure separation.

RESULTS

Clinical predictors of outcome

A total of 69 patients who fulfilled all the eligibility criteria, and from whom paraffin blocks were available, were identified retrospectively from the database of the Institutes of Oncology of the Rabin Medical Center. Fifty-six of the samples had a tumor content of at least 50% and were analyzed for miR expression using microarrays (see section 2.5). In 45 of them (80%), reliable miR expression data were obtained; these samples were included in the statistical analysis. The samples were derived from 14 patients (31%) who had a recurrence of the disease within 36 mo of surgery (bad-prognosis group), and 31 (69%) who did not (good-prognosis group). Four patients had a recurrence more than 36 mo after surgery and were included in the good-prognosis group. The median duration of follow-up for the patients without recurrence was

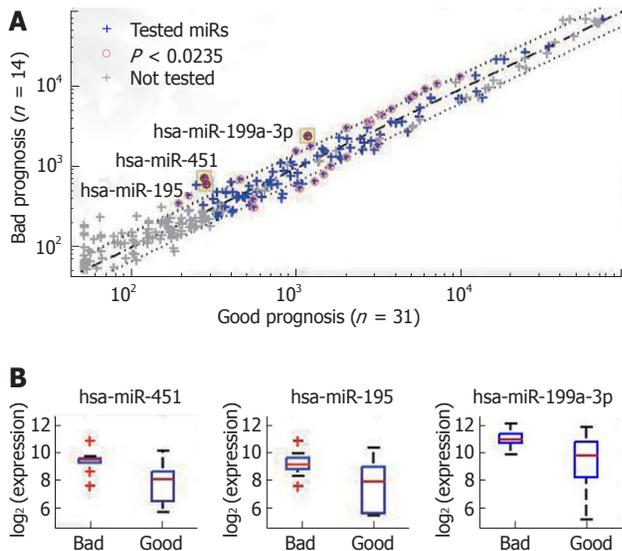

Figure 1 Differential expression of microRNAs between gastric cancer patients with good prognosis (no recurrence within 36 mo from surgery) or bad prognosis (recurrence within 36 mo). A: Median expression data (in normalized fluorescence units) are shown for all microarray probes (crosses). MiRs with low expression (below 300 units) in both groups and control probes were not tested for expression differences (grey crosses); 112 miRs (blue crosses) were tested using a rank-sum (Wilcoxon-Mann-Whitney) test. Twenty-six miRs had a $P < 0.0235$ (pink circles), corresponding to a false discovery rate = 0.1. Of these, three miRs (highlighted) also had a fold-change of > 2 : miR-451, miR-195 and miR-199a-3p. B: Box-plots of the expression levels (in \log_2 normalized fluorescence units) of these three miRs in the good/bad prognosis groups. Plots show the median (horizontal line), 25th to 75th percentile (box), extent of data (“whiskers”, extending up to 1.5 times the inter-quartile range), and outliers (red crosses, values outside the range of the whiskers). miR: MicroRNA.

86 mo (range: 40-194 mo).

The patients’ clinicopathological characteristics are summarized in Table 1. Analysis of the clinical variables with the pathological tumor features of the two groups revealed that TNM stage, T and N stages, and surgery type correlated significantly with bad prognosis. No correlation was noted for patient age, sex, or ethnicity, tumor grade, location, or histological type, or preoperative carcinogenic embryonic antigen level.

Molecular predictors

Three miRs had a significant difference in expression in the tumor samples of the patients with a bad prognosis and in the samples of the patients with a good prognosis: miR-451, miR-199a-3p, and miR-195 (Figure 1 and Table 2). The largest fold-change and the most significant difference were obtained for miR-451, with a P value of 0.0012 (rank-sum test), which is much lower than the P -value significance threshold (0.0235) after correction for multiple hypothesis testing (with FDR = 0.1). Dividing the samples according to the median expression level of miR-451 generated two groups with significantly different rates of disease-free survival ($P = 0.001$, log-rank test). To correct for multiple hypothesis testing, we randomly reassigned the patient follow-up data to the miR expression profiles and then tested all miRs for significance using the log-rank test. Out of the 200 random re-assignments of miR expression patterns, none generated

miR	P value	Fold change	Median value	
			Good prognosis	Bad prognosis
miR-451	0.0002 (0.0046)	2.66 (3.14)	260 (18.9)	690 (20.6)
miR-195	0.0046 (0.017)	2.17 (3.29)	270 (17.6)	580 (19.4)
miR-199a-3p	0.0027 (0.045)	2.15 (1.97)	1100 (20.1)	2300 (21.1)

Comparison between patients with recurrence of gastric cancer within three years from surgery (bad prognosis) and patients without a recurrence (good prognosis). P values were calculated by a Wilcoxon-Mann-Whitney rank-sum test. Only miRs that passed the false discovery rate = 0.1 threshold ($P < 0.0235$) and had a fold-change greater than 2 (in the microarray data) are listed. Values in parenthesis show the same statistics for the quantitative real-time polymerase chain reaction verification set. Cycle threshold (C_t) values are the inverses of the log signals; therefore, median values are given in $50-C_t$ to maintain the same sense as the array data.

a P value as low as that obtained for miR-451 with the real data (hence, an adjusted $P < 0.005$).

To obtain a better predictive value, we optimized the cutoff threshold for miR-451 expression. Using a threshold of 181 normalized fluorescence units, we were able to identify a group of patients ($n = 13$) without a single case of recurrence within 36 mo ($P = 0.0009$, log-rank test; Figure 2A). All 13 were included among the 31 patients in the good prognosis group. The sensitivity for identifying non-recurrence was 42% [13/31, 95% Confidence Interval (CI): 28%-56%] and the specificity was 100% (14/14, 95% CI: 78%-100%). The PPV was 100% (13/13, 95% CI: 75%-100%), and the negative predictive value (NPV) was 44% (14/32, 95% CI: 28%-60%). This group included 3 of the 6 patients (50%) in the good-prognosis group with stage III disease, and 5 of the 11 patients in that group (45%) with stage II disease.

A fair correlation was noted between the differentially expressed miRs ($r \sim 0.6$), except between miR-199a-3p and miR-195 ($r = 0.86$). This finding suggested that these miRs are independent predictors and that their linear combination could increase the predictive value. Indeed, using logistic regression, the combination of miR-451 and miR-199a-3p produced an excellent separation ($P = 0.00003$). In no case, out of 200 random re-assignments, was a combination of any two miRs found to be as good a predictor of prognosis as this combination with the real data (adjusted $P < 0.005$).

Combining clinical and molecular markers

Stage is the most typical and often the strongest clinical predictor of prognosis in gastric cancer. A possible confounding factor could be a correlation of miR expression with stage. Therefore, to remove the effect of stage, we subdivided the patient population by stage. We found that miR-451 was an excellent predictor of poor prognosis even within the subset of patients with stage III cancer (log-rank $P = 0.026$, Figure 2B). For stages I - II alone, the result was not significant owing to lack of statistical power (only one case of recurrence of stage I disease and four cases of stage II).

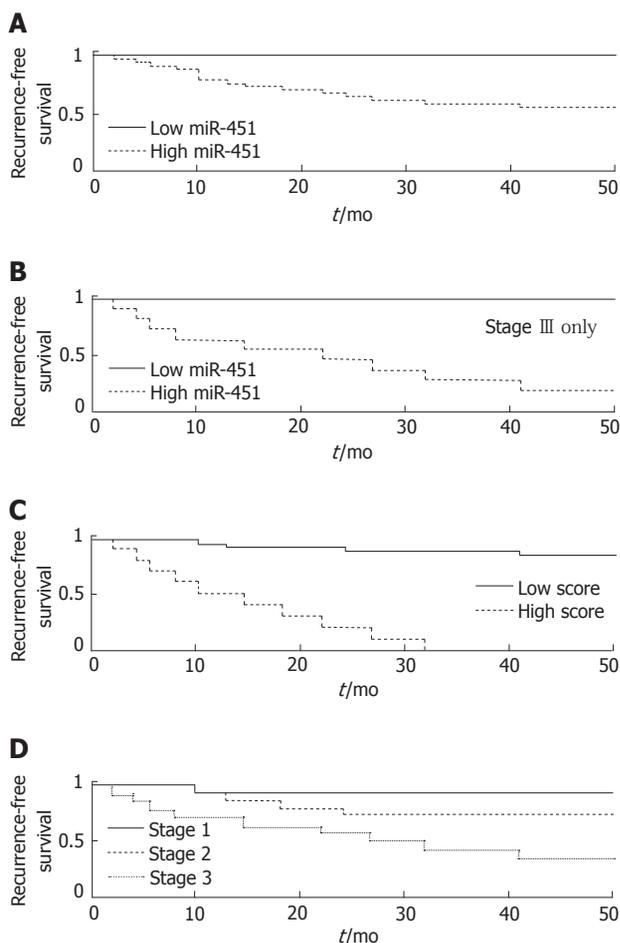

Figure 2 Kaplan-Meier model of disease recurrence for gastric cancer patients, showing the fraction without disease recurrence as function of time from surgery. A: The population was divided into groups with high expression ($n = 32$) or low expression ($n = 13$) of miR-451, based on best separation (log-rank $P = 0.0009$). B: Recurrence for patients with stage III gastric cancer only, grouped by low expression ($n = 3$) or high expression ($n = 11$) expression of miR-451, based on best separation (log-rank $P = 0.026$). C: Population grouped by composite score, calculated as $0.827 \cdot \log_2(\text{miR-451 expression}) + 1.57 \cdot \text{stage}$, using Cox regression coefficients. The threshold used (11.86) maximizes the separation between high score ($n = 10$, poor prognosis) and low score ($n = 35$, good prognosis). Although the positive predictive value with this threshold was lower than obtained using miR-451 alone (panel A), and recurrence-free survival of the good-prognosis group was not 100% as obtained for miR-451 (4 of the 35 patients in the low-score group had a recurrence before 36 mo), the negative predictive value increased to 100% (all 10 cases in the high-score group had recurrence by 36 mo) and the separation was much more significant ($P = 2 \cdot 10^{-10}$). D: Population split by stage. $P = 0.00013$ between stages I and III (log-rank test). miR: MicroRNA.

Using the Cox proportional hazards model, we created a composite score, with improved separation. The most significant separation was obtained for a combination of miR-451 expression with stage; the score was defined by the Cox coefficients as $0.827 \cdot \log_2(\text{miR-451 normalized signal}) + 1.57 \cdot \text{stage}$. Lower scores, corresponding to lower values of miR-451 expression and lower stage, indicated a better prognosis. The separation into prognostic groups based on score values was excellent (log-rank $P = 2 \cdot 10^{-10}$, Figure 2C), and much better than that for either miR alone ($P = 0.0002$, see above) or stage alone ($P = 0.00013$,

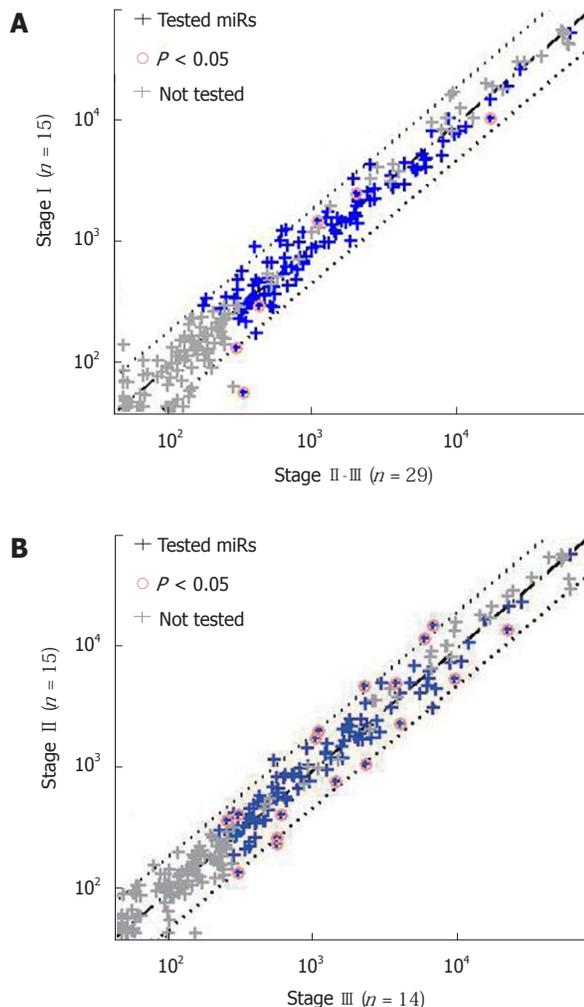

Figure 3 Differential expression of miRs in gastric cancer tumors by clinical disease stage (at surgery). Median expression data (in normalized fluorescence units) are shown for all microarray probes (crosses). MiRs with low expression (below 300 units) in both groups and control probes were not tested for expression differences (grey crosses). A: 112 miRs (blue crosses) were tested by rank-sum test for expression between stage I tumors and stages II-III tumors. None of the miRs passed the false discovery rate (FDR) threshold of 0.2; 6 miRs had a $P < 0.05$ (pink circles). B: 111 miRs (blue crosses) were tested for expression between stage II tumors and stage III tumors. None of the miRs passed the FDR threshold of 0.2; 17 miRs had a $P < 0.05$ (pink circles). Diagonal lines show the equal median expression (dashed line) and the twofold change in median expression (dotted lines). miR: MicroRNA.

Figure 2D). On fine tuning the score threshold, we found that a score of < 9.5 identified a good-prognosis group with a PPV of 100% (17/17, 95% CI: 80%-100%). None of the 17 patients had had a recurrence in 36 mo (sensitivity = 55%, 95% CI: 33%-69%). Among the patients with a score of > 9.5 were all those with a recurrence (14/14, specificity = 100%, 95% CI: 78%-100%), for a NPV of 50% (14/28, 95% CI: 32%-67%). The combination of miR expression with stage was further justified by the finding that miR-451, as well as miR-199a-3p and miR-195, were not differentially expressed between stage I and stages II-III tumors, between stage II and stage III tumors (Figure 3), or between stages I-II and stage III tumors (not shown), with miR-199a-

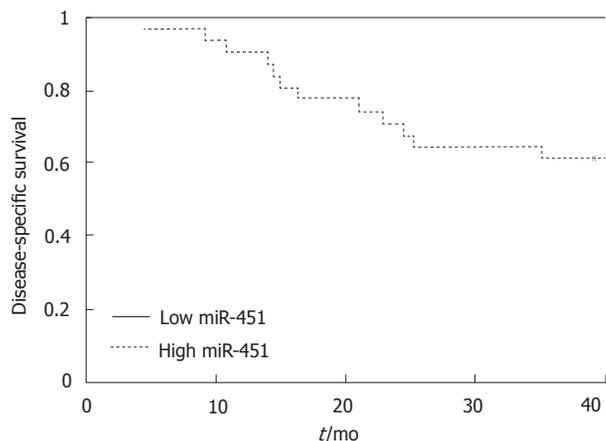

Figure 4 Kaplan-Meier model of disease-specific survival for patients with gastric cancer, grouped by high expression ($n = 32$) or low expression ($n = 13$) of miR-451, using the threshold of miR-451 expression that optimized the positive predictive value (181 normalized fluorescence units, $P = 0.005$). Among the patients whose tumors expressed low levels of miR-451, no disease-specific deaths occurred within 36 mo of surgery.

3p showing a nonsignificant upregulation in stage III.

Survival

Splitting the population by miR451 expression, using the same threshold value of 181 normalized fluorescence units, also led to a clear separation of the patients by survival. All 13 patients with low miR-451 expression survived for 36 mo (PPV = 100%, 95% CI: 75%-100%), whereas 12 of the 32 patients with a high miR-451 expression died within 36 mo (NPV = 37%, CI: 23%-55%; $P = 0.005$, Figure 4). These values suggest a specificity for survival of 100% for miR-451 expression (12/12, 95% CI: 76%-100%) and a sensitivity of 39% (13/33, 95% CI: 25%-56%).

Validation by qRT-PCR

The expression of a subset of miRs in a subset of samples was verified by qRT-PCR. Overall, the same miRs that showed significant differential expression in the microarray analysis were also differentially expressed by qRT-PCR (Table 2, Figure 5A). We focused on the miR with the strongest differential expression in the two prognosis groups, miR-451. The expression levels of miR-451 measured by the two platforms were highly correlated (Figure 5B; Pearson correlation coefficient, 0.83). Patients in the good-prognosis group had a lower expression of miR-451 by both microarray and qRT-PCR analysis. Using a simple threshold on the qRT-PCR signals (at $50_{Ct} = 19$), we found that signals below this threshold were characteristic only of patients with a good prognosis (PPV for non-recurrence of 100%, 95% CI: 53%-100%) and identified half these patients (sensitivity of 50%, 95% CI: 24%-76%), with a specificity of 100% (95% CI: 72%-100%) and NPV of 50% (95% CI: 41%-84%). There was a clear difference in prognosis between patients with signals above or below this threshold (Figure 5C, log-rank test; $P = 0.015$).

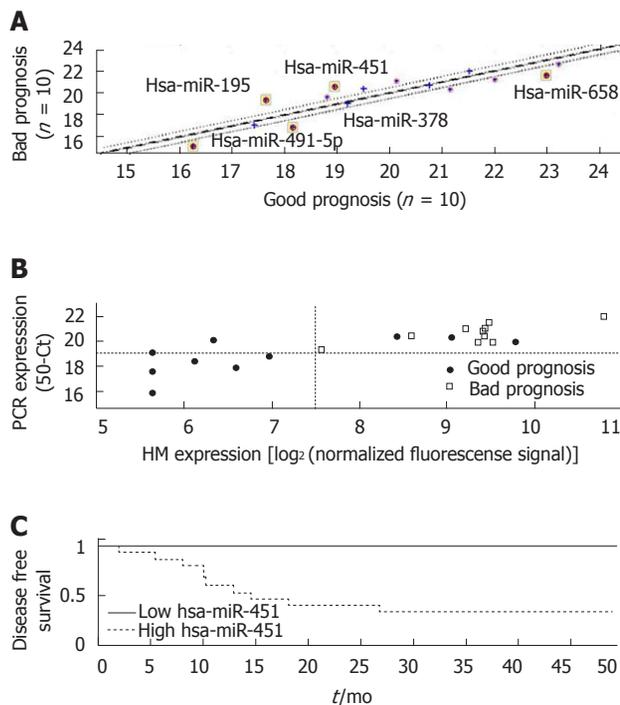

Figure 5 Validation by quantitative real-time polymerase chain reaction: A: Differential expression of microRNAs (miRs) between a subset of the gastric cancer samples from patients with good prognosis ($n = 10$) or bad prognosis ($n = 10$). Median expression data are shown for all probes tested. Cycle threshold (C_T) values are the inverses of the log signals; therefore, median values are given in $50-C_T$ (50_{Ct}) to maintain the same sense as the array data; B: Correlation of expression signals of miR-451 between microarrays (\log_2 normalized fluorescence units) and quantitative real-time polymerase chain reaction (qRT-PCR) (50_{Ct}). Good-prognosis cases are represented by filled circles, bad-prognosis cases by empty squares. Dotted lines indicate the thresholds of the miR-451 signal at normalized fluorescence of 181 units [$\log_2(181) = 7.5$] and at $50_{Ct} = 19$. The correlation coefficient (Pearson) between the signals is 0.83; C: Recurrence in 20 cases, measured by qRT-PCR, grouped by $50_{Ct} < 19$ (solid line, $n = 5$) or $50_{Ct} > 19$ (dotted line, $n = 15$). $P = 0.015$ by log-rank test. MiR: MicroRNA; PCR: Polymerase chain reaction; HM: Human custom microRNA-Microarray.

DISCUSSION

The results of the present study indicate that the expression levels of three miRs, miR-451, miR-199a-3p, and miR-195, may help to differentiate patients with gastric cancer with a good or bad prognosis. Specifically, tumors from patients who remained free of recurrence for at least 36 mo from surgery had significantly lower levels of these miRs than tumors from patients who had a recurrence. The miR with the most significant difference was miR-451, and the combination of the miR-451 with miR-199a-3p values provided even better predictive information. The prognostic role of miR-451 was both independent of, and additive to, the currently most important prognostic factor in gastric cancer, tumor stage. Finally, higher levels of miR-451 were found to be associated not only with recurrence but also with worse survival.

Two recent studies have highlighted the importance of miR-451 in gastric cancer. Takagi *et al.*^[30] evaluated tumor samples from 43 patients and found that miR-451 levels were lower in the gastric cancer cells than in adjacent non-malignant cells. Bandres *et al.*^[22], in a study of

21 patients with stage III disease receiving postoperative chemoradiation, also found lower levels of miR-451 in the gastric cancer cells. The lower levels were correlated with a higher risk of recurrence and death after resection of the primary tumor. These results were confirmed in a cohort of 24 patients with stage I-IV disease. Our study also highlights the role of miR-451 in gastric cancer, but as opposed to the findings of Bandres *et al.*^[22], lower, not higher levels of miR-451 were associated with better outcome. This discrepancy may be explained by the different study populations: in our cohort, only 30% of the patients had stage III disease and none had received postoperative treatment. Therefore, the patients in the earlier study^[22] were at a much higher risk of recurrence. Moreover, given that Bandres *et al.*^[22] were evaluating a treated population, the miR-451 expression in their study may well have had a predictive impact. Indeed, they found that overexpression of miR-451 was associated with increased radiosensitivity. The different results between the studies might also be attributable to differences in the methods of selecting and handling the tissues from which RNA was extracted, and the actual percentage of tumor in the specimens. Bandres *et al.*^[22] did not provide these details, but in the present study, more than 30% of the samples were found to be inadequate for investigation. The correlation of our qRT-PCR results with the microarray platform results suggests not only internal consistency, but also a stable process for miR measurement. Lastly, and probably most importantly, the small sample sizes and the essentially preliminary nature of the results in both studies, and in that of Takagi *et al.*^[30], may explain the inconsistencies among them. For example, other recent studies of the miR expression profile of gastric cancer did not find a differential expression of miR-451 in the malignant cells^[31,32].

While the actual impact of miR-451 on patient outcome is unclear, there are preliminary clues pointing to the possible mechanisms whereby it may influence cell function. In the study by Takagi *et al.*^[30], *in vitro* analysis suggested that miR-451 inhibits tumor growth and induces tumor sensitivity to 5-fluorouracil by interacting with messenger RNAs (mRNAs) of the insulin receptor substrate-1 (IRS-1) and beta-actin. In the study by Bandres *et al.*^[22], overexpression of miR-451 reduced cell proliferation and increased sensitivity to radiotherapy, apparently via downregulation of mRNA and protein levels of the macrophage migration inhibitory factor oncogene. Two other studies have shown that miR-451 is involved in the regulation of the multi-drug resistance 1 (MDR-1) gene and, thereby, in tumor resistance to various chemotherapeutic agents, most notably doxorubicin^[33,34]. However, the studies reported opposite effects: in one study, MDR-1 expression increased in the presence of miR-451^[29], and in the other, it decreased^[34]. Tsuchiya *et al.*^[35] found that miR-451 is essential for epithelial cell polarity by affecting the translocation of the beta-1 integrin protein. Clearly, as a single miR may target multiple mRNAs simultaneously, and several miRs may target a single mRNA

simultaneously, the interactions of miRs with their target mRNAs are expected to be very complex. Hence, it is not surprising that a number of unrelated mechanisms have already been postulated for a single miR such as miR-451, and it is likely that it may indeed be involved in multiple cell processes, like the ones described.

There are several strengths and weaknesses of the present study that need to be addressed. First, the sample size, though small, was nevertheless somewhat larger than in previous studies. Second, we used very strict criteria for selection of the study population: all patients were operated in a single medical center, none received adjuvant therapy, and all were closely followed for at least three years. Third, several statistical tests were performed to reduce the risk of randomly choosing a “statistically significant” biomarker from the hundreds tested, a risk that is typical of studies screening for novel biomarkers (multiple hypothesis testing). Fourth, qRT-PCR was used to verify the appropriate identification of significant signals and suggested a method for future adaptation of our findings in the hospital laboratory setting. Another strong point of this study is that it provides meaningful predictive values, which may have important clinical implications. Informed decision-making using a test with a high PPV can spare patients unnecessary and sometimes toxic treatment. We were able to identify a group of samples with low signals of miR-451 for which the PPV for non-recurrence was 100%. According to the current standard, a substantial proportion of patients with gastric cancer receive adjuvant therapy. Thus, our finding, if validated, suggests that those with low miR-451 expression do not require adjuvant chemotherapy because their risk of recurrence is low. Our sample size was insufficient for adequate independent validation, and further studies, in larger cohorts, are needed. In addition, although the estimated PPV was 100%, our confidence interval was still quite wide. We are currently in the process of formulating a follow-up validation study wherein the prognostic impact of miR-451 will be tested in an independent cohort. The critical importance of such validation is further emphasized by the large variability of the available data on the prognostic role of various miRs in gastric cancer. In fact, there is only a minimal overlap between the different miR signatures that have been reported to have a prognostic impact in gastric cancer^[21,26].

In summary, this study showed that three miRs, miR-451, miR-199a-3p and miR-195, might serve as biomarkers of the risk of recurrence of gastric cancer after resection. One of them, miR-451, seems to hold the most promise for further evaluation. Our results add to the accumulating evidence on the role of miR-451 in gastric cancer. Further research in this direction is warranted. Within this setting, we have recently embarked on a validation study for the results presented here.

tance in analysis of the pathological slides.

COMMENTS

Background

Surgery is the standard treatment of localized gastric cancer but its results are often disappointing. Our current ability to determine the prognosis of such individual patients, and hence their need for adjuvant therapy is limited. MicroRNAs (miRs) are short non-coding RNAs that regulate gene expression and are therefore involved in various physiological and pathological conditions, including cancer.

Research frontiers

The expression of miRs is dynamic and therefore these molecules may serve diagnostic or prognostic biomarkers in various malignancies. Indeed, recent studies have suggested that various miR molecules may have a prognostic role in gastric cancer. In this study, three miRs, miR-199a-3p, miR-195, and especially miR-451, were found to associated with the risk of recurrence after the resection of gastric cancer.

Innovations and breakthroughs

Several attempts have been made to identify miRs that may predict patient outcome in gastric cancer. The current study showed that three miRs might indeed serve as biomarkers for the risk of recurrence of gastric cancer after resection. These results are based on a reasonably sized cohort of 45 patients with strict eligibility criteria, two independent methods to measure miR expression levels, and multiple statistical testing to reduce the risk of randomly choosing a "statistically significant" biomarker. All these have resulted in meaningful predictive values, and most importantly, the authors were able to identify a group of patients who had no risk of recurrence at all.

Applications

The results of this study add to the accumulating data on the prognostic role of miRs in gastric cancer. Once validated, these results may allow a better prognostication of patients after resection of gastric cancer and an improved selection of patients for adjuvant therapy.

Terminology

MiRs are short non-coding RNAs, 17-22 nucleotides in length, which regulate gene expression and thereby play significant roles in human development and various pathological conditions, including cancer.

Peer review

The proposed study is well designed, well written, and uses appropriate methods.

Abstract

AIM: To explore the dynamic changes of prion protein (PrPc) in the process of gastric cancer drug resistance and the role of PrPc expression in the prognosis of gastric cancer patients receiving chemotherapy.

METHODS: A series of gastric cancer cell lines resistant to different concentrations of adriamycin was established, and the expression of PrPc, Bcl-2 and Bax was detected in these cells. Apoptosis was determined using Annexin V staining. Western blotting and immunohistochemistry were performed to detect the expression of PrPc in patients receiving chemotherapy and to explore the role of PrPc expression in predicting the chemosensitivity and the outcome of gastric cancer patients receiving chemotherapy. Follow-up was performed for 2 years.

RESULTS: PrPc expression was increased with the increase in drug resistance. Bcl-2, together with PrPc, increased the level of anti-apoptosis of cancer cells. Increased PrPc expression predicted the enhanced level of anti-apoptosis and resistance to anticancer drugs. PrPc expression could be used as a marker for predicting the efficacy of chemotherapy and the prognosis of gastric cancer. Increased PrPc expression predicted both poor chemosensitivity and a low 2-year survival rate. Contrarily, low PrPc expression predicted favorable chemosensitivity and a relatively high 2-year survival rate.

CONCLUSION: PrPc expression is associated with histological types and differentiation of gastric cancer cells; The PrPc expression level might be a valuable marker in predicting the efficacy of chemotherapy and the prognosis of gastric cancer patients receiving chemotherapy.

INTRODUCTION

Prion protein (PrPc or PrP) is a pathogen that causes bovine spongiform encephalopathy (also known as “mad cow disease”). In 1982, Prusiner^[1] isolated the protease-

and heat-resistant protein from the brains of scrapie-infected hamsters. PrPc is encoded by the host prion gene but not by the prion gene. Thereafter, a new field of biomedicine, prion biology, was founded, and a new concept of pathology, protein conformation diseases, was also established. In 2003, our study showed that PrPc was associated with the multidrug resistance of gastric cancer^[2,3], and thereafter, a series of studies have been conducted to explore the role of PrPc in the differentiation, proliferation and metastasis of cancer cells and to deeply investigate the structural domains of PrPc. These studies have achieved great progress in prion biology and pathogenesis^[4-13]. The present study aimed to investigate PrPc expression in gastric cancer cell lines and its role in predicting the outcome of gastric cancer patients undergoing chemotherapy. Our study may elucidate the clinical significance of PrPc over-expression in cancers and provide a potential indicator for predicting the outcome of cancer patients.

MATERIALS AND METHODS

Materials

Gastric cancer cell lines (KATO III, BGC-823, GES, HGC-27, AGS, SGC7901 and MGC803) were purchased from the Academy of Military Medical Sciences and were maintained in our department. PrPc and β -actin monoclonal antibodies (Sigma, United States), enhanced chemiluminescence (ECL) kit (Amersham Pharmacia) and immunohistochemistry kit (Beijing biodev-tech Co., Ltd) were used in this study.

A total of 185 patients with gastric cancers at stages I to IV (6th edition of the UICC TNM classification and Lauren classification) were recruited. The characteristics of these patients are summarized in Table 1. There were 134 men and 51 women included in this study. The age of these patients ranged from 33 to 76 years, with a mean age of 54.2 years. The cancers of these patients were pathologically proven to be moderately or well-differentiated ($n = 43$), poorly differentiated ($n = 33$), undifferentiated ($n = 46$), mucinous ($n = 16$) and mixed cancers ($n = 47$). In addition, normal gastric tissues without cancer infiltration were used as controls.

Methods

Establishment of adriamycin-resistant gastric cancer cell lines^[10]: Adriamycin-resistant SGC7901 cells were selected by a stepwise increase in adriamycin concentration from 0.04 $\mu\text{g}/\text{mL}$ to 0.6 $\mu\text{g}/\text{mL}$. In brief, the SGC7901 cells were maintained in medium containing 0.04 $\mu\text{g}/\text{mL}$ adriamycin for 48 h. Then, the medium was refreshed with adriamycin-free medium. When normal growth was observed, the medium was replaced with that containing 0.04 $\mu\text{g}/\text{mL}$ adriamycin followed by incubation for 48 h. The above mentioned procedures were repeated 3-5 times, and then the adriamycin concentration was increased once every 6-10 d. Finally, SGC7901 cells that were resistant to 0.04, 0.18, 0.32, 0.46 and 0.6 $\mu\text{g}/\text{mL}$ adriamycin were obtained. Each adriamycin-resistant

SGC7901 cell line was collected and stored in liquid nitrogen for the synchronization of experiments. The sensitivity of cells to adriamycin was determined by methyl thiazolyl tetrazolium assay followed by calculation of the half-maximal inhibitory concentration (IC₅₀). The resistance index (RI) was calculated as follow: $\text{RI} = \text{IC}_{50\text{drug-resistant cells}} / \text{IC}_{50\text{parental cells}}$.

Detection of the expression of PrPc, Bcl-2 and Bax in each adriamycin-resistant SGC7901 cell line by Western blotting:

After recovery from storage in liquid nitrogen, cells were maintained in fresh medium. Total proteins were extracted from cells in the logarithmic growth phase of growth, and the protein concentration was determined. Then, 40 μg total proteins were separated in sodium dodecylsulphate (SDS) polyacrylamide gels and transferred onto nitrocellulose membranes. The primary antibodies used to detect the target proteins were anti-PrP, anti-Bcl-2 and anti-Bax monoclonal antibodies and anti- β -actin polyclonal antibody; horseradish peroxidase-conjugated goat anti-mouse IgG was used as the secondary antibody. The bands were visualized using the ECL system (Amersham Pharmacia Biotech, Piscataway, NJ, United States) according to the manufacturer's instructions, and protein concentration was quantified by densitometry with Total-Lab 2.0 software.

Flow cytometric analysis of apoptosis in each adriamycin-resistant SGC7901 cell line:

Cells in the logarithmic phase of growth were transferred to a 6-well plate. After adherence, cells were maintained in medium with 0.7 $\mu\text{g}/\text{mL}$ adriamycin at 37 °C for 48 h. The medium was then replaced with fresh medium containing 5 μL Annexin V-FITC and 1.5 mmol CaCl_2 , and the cells were incubated for 15 min at 37 °C. Subsequently, the cells were re-suspended in 490 μL binding buffer and 5 μL PI staining solution and incubated for 10 min at 4 °C. Apoptosis was then detected by flow cytometry, and the apoptosis index (AI) was calculated as follows: $\text{AI} = (\text{number of early and late apoptotic cells}) / \text{total number of cells} \times 100\%$.

Detection of PrPc expression in different gastric cancer cell lines by Western blotting:

Gastric cancer cells in the logarithmic growth phase of growth were harvested and the total protein was extracted, after which the proteins were separated on SDS polyacrylamide gels and transferred onto nitrocellulose membranes. The primary antibodies used to detect the target proteins were anti-PrP, anti-Bcl-2 and anti-Bax monoclonal antibodies and anti- β -actin polyclonal antibody; horseradish peroxidase-conjugated goat anti-mouse IgG was used as the secondary antibody. The bands were visualized using the ECL system (Amersham Pharmacia Biotech, Piscataway, NJ, United States) according to manufacturer's instructions.

were used for immunohistochemical detection of PrPc with the StreptAvidin Biotin Complex staining kit according to the manufacturer's instructions. The bands were visualized using diaminobenzidine substrate. The primary antibody was replaced with phosphate-buffered saline as the negative control.

Analysis was performed with Image-Pro Plus 5.0 software. Five high-power fields were randomly selected, and 100 cells were counted. The proportion of PrP-positive cells per sample was calculated, and tissue grading was performed as follows: < 5% as negative (score 0); 5%-25% as "+" (score 1); 26%-50% as "++" (score 2); 51%-75% as "+++" (score 3), and > 75% as "++++" (score 4). Scores of greater than 3 were regarded as strongly positive.

Detection of PrPc expression in gastric cancer tissues by Western blotting: Gastric cancer tissues, including 52 adenocarcinomas, 26 undifferentiated cancers, 33 mixed cancers, 17 poorly differentiated cancers and 11 precancerous lesions (severe atrophic gastritis), were obtained from 139 patients with gastric cancers who underwent biopsy or gastrectomy. Total protein was extracted with Trizol, the protein concentration was determined, and the proteins were separated by SDS-PAGE. Anti-PrP monoclonal antibody (Sigma, Swampscott, MA, United States) and anti- β -actin polyclonal antibody were used as primary antibodies and horseradish peroxidase-conjugated goat anti-mouse IgG as the secondary antibody.

Relationship between PrPc expression and the efficacy of chemotherapy in gastric cancer patients

The treatment strategies included surgery + chemotherapy and surgery + chemotherapy + interventional therapy. The treatment efficacy was recorded as complete remission (CR), partial remission (PR), stable disease, and progressive disease according to the criteria developed by the World Health Organization (WHO). The overall efficacy was calculated as CR + PR. According to the Karnofsky Performance Scale (KPS), the patients were stratified into one of the following groups: the improvement group (the increase in KPS score was greater than 10 after treatment), the deterioration group (the decrease in KPS score was greater than 10 after treatment), and the stability group (the changes in KPS score were less than 10 after treatment). The performance status was evaluated according to Zubrod-ECOG-WHO, and survival was followed up for 2 years. The demographics of these patients

at baseline and after 2 years of follow-up were summarized in Table 1, respectively. PrPc expression in the patient samples was detected by immunohistochemistry and Western blotting, and the patients were divided into PrPc-positive and PrPc-negative groups. The whole protocol was approved by the Institutional Review Board of the Ethics Committee of our hospital. Informed consent was obtained before the study.

Statistical analysis

Statistical analysis was performed using SPSS software. Quantitative data were analyzed using the *t* test, and qualitative data were analyzed using the χ^2 test. A value of *P* < 0.05 was considered statistically significant.

RESULTS

PrPc, Bcl-2 and Bax expression in gastric cancer cells resistant to different concentrations of adriamycin

The RI of gastric cancer cells resistant to adriamycin were increased accompany with the deepened concentrations which the value of RI 0.92 \pm 0.072 *vs* the adriamycin concentration 0 μ g/mL, 1.478 \pm 0.098^a *vs* 0.04 μ g/mL, 3.096 \pm 0.201^a *vs* 0.18 μ g/mL, 4.5 \pm 0.334^a *vs* 0.32 μ g/mL, 5.086 \pm 0.302^a *vs* 0.46 μ g/mL, 6.65 \pm 0.354^a *vs* 0.6 μ g/mL (^a*P* \leq 0.01 *vs* 0 μ g/mL group).

PrPc, Bcl-2 and Bax expression in gastric cancer cells resistant to different concentrations of adriamycin are shown in Figure 1. Analysis indicated that the expression of PrPc and Bcl-2 were markedly increased (*P* < 0.01) in an adriamycin concentration-dependent manner, while that of Bax was significantly reduced (*P* < 0.01). The results indicated that the resistance index was 3.096 when the adriamycin concentration was 0.18 μ g/mL.

Apoptosis of gastric cancer cells resistant to different concentrations of adriamycin

The AI is displayed in Figure 2. A significant difference in the AI was not noted between the 0.04 and 0 μ g/mL adriamycin groups (*P* > 0.05). In SGC7901 cells resistant to 0.18 μ g/mL adriamycin, the anti-apoptotic capability was significantly increased and drug sensitivity markedly decreased with an RI of 3.096 (*P* < 0.001) when compared with SGC7901 cells without adriamycin treatment.

PrPc expression in different gastric cancer cell lines

PrPc expression in different gastric cancer cell lines is

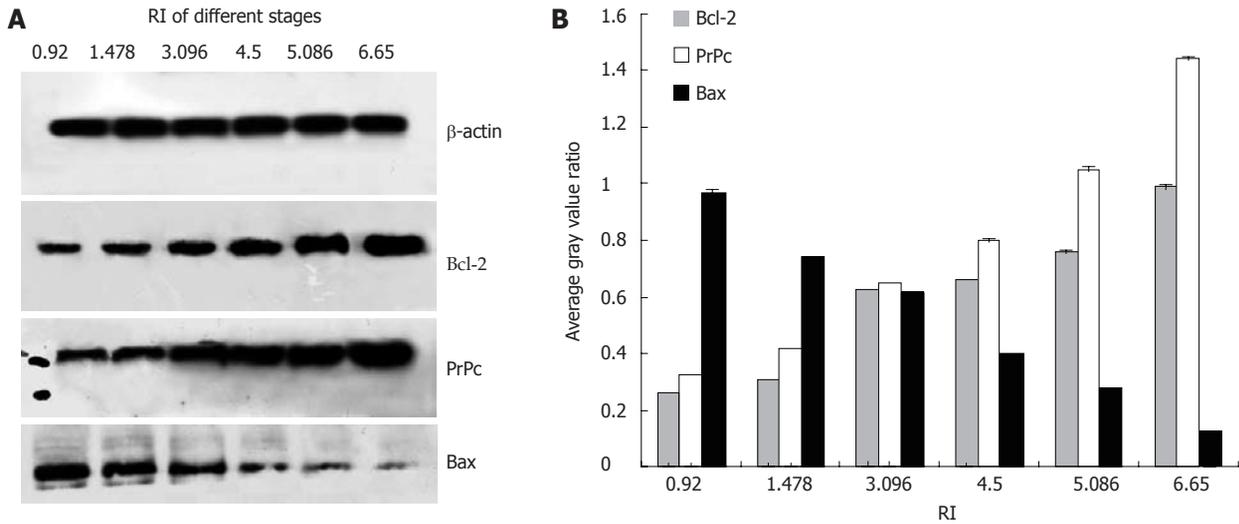

Figure 1 Expressions of PrPc, Bcl-2 and Bax in gastric cancer cells resistant to different concentrations of adriamycin. Analysis indicated that the expressions of PrPc and Bcl-2 were markedly increased ($P < 0.01$), but that of Bax was significantly reduced ($P < 0.01$), which were in an adriamycin concentration dependent manner. Resistance index was 3.096 when the adriamycin concentration was 0.18 $\mu\text{g/mL}$. PrPc: Prion protein; RI: Resistance index.

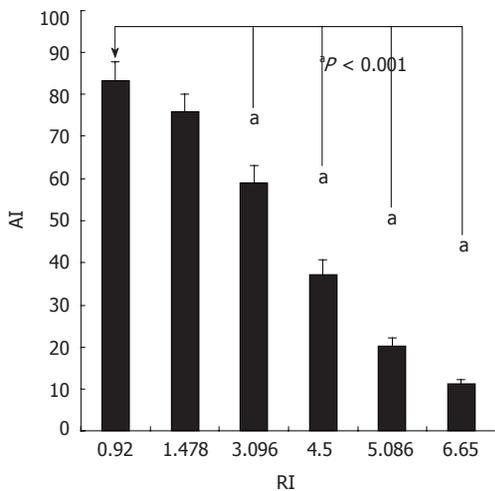

Figure 2 Apoptosis index of gastric cancer cells resistant to adriamycin of different concentrations. In the SGC7901 cells resistant to 0.18 $\mu\text{g/mL}$ adriamycin, the anti-apoptotic capability was significantly increased with the resistance index of 3.096 ($P < 0.001$) when compared with SGC7901 cells without adriamycin treatment. AI: Apoptosis index; RI: Resistance index.

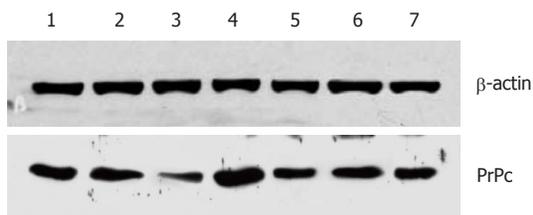

Figure 3 Prion protein expression in different gastric cancer cell lines. 1: KATO III; 2: BGC-823; 3: GES; 4: HGC-27; 5: AGS; 6: SGC7901; 7: MGC80. Results showed that the highest prion protein (PrPc) expression was found in undifferentiated gastric cancer cells (HGC-27), followed by poorly differentiated gastric cancer cells (KATO III), and the lowest PrPc expression in human gastric epithelial immortalized GES-1 cells. PrPc: Prion protein.

presented in Figure 3. Results showed that the highest PrPc expression was found in undifferentiated gastric

cancer cells (HGC-27) followed by poorly differentiated gastric cancer cells (KATO III), and the lowest PrPc expression was in GES-1 immortalized human gastric epithelial cells. These results were consistent with tissue microarray and Western blotting analyses of the cancer tissues. Of note, low PrPc expression was noted in immortalized GES-1 cells, which was different from the results from the tissue microarray analysis.

PrPc expression using tissue microarray assay

PrPc expression in the gastric cancers, precancerous lesions and normal tissues are presented in Figures 3, 4 and 5, respectively. χ^2 tests revealed that the percentage of PrPc-positive cells in gastric cancers and precancerous lesions were dramatically increased when compared with normal tissues ($P < 0.01$). The percentage of PrPc-positive cells in adenocarcinoma, mucinous carcinoma, undifferentiated cancer and poorly differentiated cancer are displayed in Figure 4. Analysis showed that PrPc-positive cells were related to the types of gastric cancer ($P < 0.05$). The proportion of PrPc-positive cells in undifferentiated cancer was significantly higher than that in adenocarcinoma ($P < 0.01$), but no significant differences in PrPc positive cells were found between mucinous carcinoma and poorly differentiated adenocarcinoma (Figure 5).

PrPc protein expression in different types of gastric cancers

PrPc expression in the cancer and normal tissues is shown in Figure 6, and the immunohistochemistry for PrPc in gastric cancer is shown in Figure 7. Results showed that PrPc expression in gastric adenocarcinoma and mixed carcinoma was relatively low, and no significant difference in PrPc expression was observed between the remaining types of gastric cancer. Furthermore, PrPc expression in normal gastric tissues was much lower than that in gastric cancers.

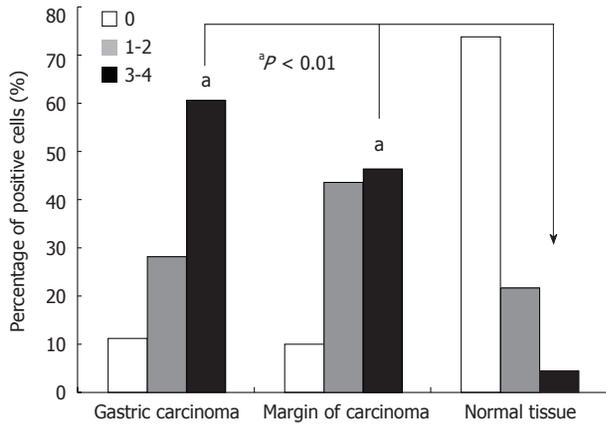

Figure 4 Prion protein expression in gastric cancers, precancerous lesions, and normal tissues. χ^2 test revealed that the number of prion protein positive cells in gastric cancers and precancerous lesions were dramatically increased when compared with normal tissues ($^aP < 0.01$). PrPc: Prion protein.

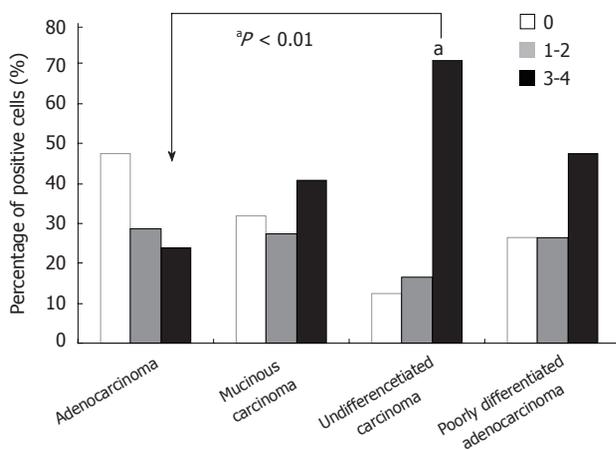

Figure 5 Prion protein expression in different type of gastric cancer. The proportion of prion protein positive cells in undifferentiated cancer was significantly higher than that in adenocarcinoma ($^aP < 0.01$), but no significant difference in PrPc positive cells was found between mucinous carcinoma and poorly differentiated adenocarcinoma. PrPc: Prion protein.

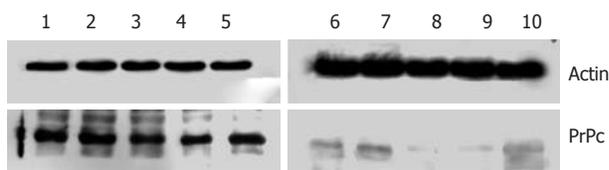

Figure 6 Prion protein expression in gastric cancers and normal tissues. The prion protein (PrPc) expression in gastric adenocarcinoma and mixed carcinoma was relatively low, and no significant difference in PrPc expression was noted between the remaining types of gastric cancer. Furthermore, PrPc expression in normal gastric tissues was much lower than that in gastric cancers. PrPc: Prion protein. 1: Tissue of atrophic gastritis; 2: Tissue of undifferentiated gastric cancer; 3: Tissue of gastric adenocarcinoma; 4: Tissue of mixed type carcinoma; 5: Tissue of poorly differentiated gastric cancer; 6-10: Corresponding normal gastric tissue.

Association of PrPc expression and chemotherapeutic efficacy in gastric cancer patients

The demographics of 185 patients at baseline are presented in Table 1, and those after 2 years of follow-up

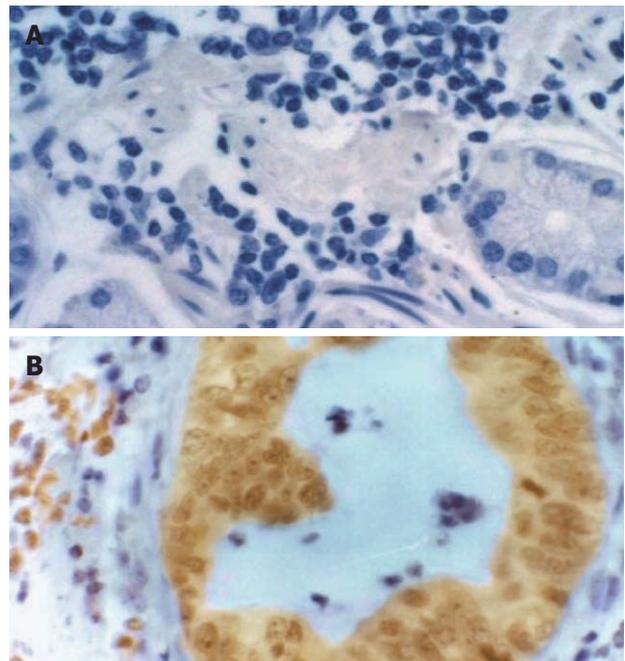

Figure 7 Prion protein expression in human gastric cancer ($\times 200$). A: Negative control; B: Positive results.

PrPc expression	Case	CR	PR	NC	PD	CR + PR (%)
0	59	7	25	18	9	32 (54.24)
1	30	2	8	13	7	10 (33.33)
2	39	1	9	19	10	10 (25.64)
≥ 3	57	0	11	21	25	11 (19.29)

PrPc: Prion protein; CR: Complete remission; PR: Partial remission; NC: Stable disease; PD: Progressive disease.

are presented in Table 2. Analysis showed that PrPc expression was significantly correlated with the pathological type of gastric cancer ($P < 0.05$). PrPc expression in undifferentiated cancers was significantly higher than that in moderately or well-differentiated cancer and mixed cancers ($P < 0.01$). However, no significant difference in PrPc expression was observed between poorly differentiated cancers and mucinous cancer ($P > 0.05$). The relationship between PrPc expression and the efficacy of chemotherapy are shown in Tables 2 and 3. The curative effects, KPS scores, and performance statuses were also evaluated. As shown in Table 2, PrPc expression was associated with the efficacy of chemotherapy. Patients with higher PrPc expression had a poorer response to chemotherapy ($P < 0.05$). As shown in Table 3, PrPc expression was associated with survival ($P < 0.05$). High PrPc expression predicted poorer prognosis, where a lower 2-year survival rate and higher mortality rate were observed when compared with low PrPc expression group. Table 4 showed KPS scores at diagnosis and after 2 years of follow-up in patients with different levels of PrPc expression. Results showed the overall survival status was

Table 3 Survival status of patients with different prion protein expression after chemotherapy

PrPc expression	n	6 mo	1 yr	2 yr	Death mortality n (%)
0	59	0	11	45	3(5.10)
1	30	0	8	20	2(6.67)
2	39	3	7	17	7(17.95)
≥ 3	57	5	12	25	17(29.82)

PrPc: Prion protein.

deteriorated (KPS score was decreased more than 10), and the decrease in KPS score was profound in patients with strongly positive PrPc expression ($P < 0.01$) when compared with other patients.

DISCUSSION

PrPc expression in gastric cancer cells and tissues

The expression of prion protein tends to occur in rapidly regenerating or poorly differentiated tissues^[14-18]. Pammer *et al*^[19] detected PrPc expression in gastrointestinal mucosa by immunohistochemistry, and results showed that PrPc expression was significantly increased in *H. pylori*-induced gastritis, suggesting that prion infection and replication could occur in gastrointestinal epithelial cells. In the present study, PrPc expression was detected through tissue microarray assays in normal gastric tissues, gastric cancers and precancerous lesions. Results revealed weak or no PrPc expression in normal gastric tissues, but hemocytes showed high PrPc expression; this observation could be attributed to normal tissues with some inflammation being used for detection, and positive expression was mainly found in infiltrated lymphocytes. PrPc expression was detected in gastric cancer tissues, adjacent normal tissues and normal tissues using tissue microarray assay based on tissue classification, e.g., negative group, positive group (+ to ++) and strongly positive group (+++ to ++++). χ^2 tests revealed that PrPc expression in gastric cancers and precancerous lesions was dramatically increased when compared with normal tissues ($P < 0.01$). These findings imply that PrPc expression is closely associated with cell status. When cellular functions are active, including malignant transformation and excessive proliferation, PrPc expression is increased, which has been confirmed by Liang *et al*^[9]. Moreover, PrPc expression was related to pathological types of gastric cancer. The proportion of PrPc-positive cells in undifferentiated cancer was significantly higher than that in gastric adenocarcinoma, suggesting that cancer differentiation is also correlated with PrPc expression, and the poorer the differentiation, the higher the level of PrPc expression. These results also indicate the relationship between cellular functions and PrPc expression: more active cellular function results in greater active proliferation and differentiation, and higher grades of malignancy mean higher levels of PrPc expression.

PrPc expression was detected by immunohistochemistry in 185 patients with gastric cancers, and PrPc ex-

Table 4 Karnofsky performance scale score of patients with different prion protein expression levels

PrPc expression	n	Before treatment	2 yr later	Difference
0	59	85.25 ± 11.40	73.90 ± 22.40	11.35
1	30	81.67 ± 17.34	69.33 ± 25.68	12.34
2	39	74.10 ± 18.77	60.77 ± 31.81	13.33
≥ 3	57	63.90 ± 18.87	45.93 ± 32.00	17.97

PrPc: Prion protein.

pression in gastric cancers was significantly higher than that in normal gastric tissues. Strongly positive PrPc expression was found in 26 undifferentiated gastric cancers, while the well-differentiated adenocarcinoma had a low positive rate of PrPc expression (42.45%). However, negative or weak PrPc expression was also observed in gastric cancers, while positive, but not strongly positive, PrPc expression was detected in normal gastric tissues. These results were consistent with the tissue microarray assays.

PrPc expression was detected in different gastric cancer cell lines. The highest PrPc expression was found in an undifferentiated cancer cell line (HGC-27 cells) followed by a poorly differentiated cell line (KATO III cells). The lowest PrPc expression was detected in the immortalized normal human gastric epithelial cell line (GES cells).

In our study, PrPc expression was detected in different types of gastric cancer by immunohistochemistry and western blot and in different gastric cancer tissues from patients and different gastric cancer cell lines using tissue microarray assay. In this study, PrPc expression was associated with cell status and differentiation, which is consistent with previous reports^[9,20].

Dynamic changes in PrPc in the process of anti-cancer drug resistance

PrPc is closely related to tumor development. PrPc expression has been shown to be related not only to cancer cell proliferation but also to drug resistance and cancer cell metastasis^[21]. Meslin *et al*^[22] showed that PrPc gene silencing in ADM-resistant MCF-7 breast cancer cells increased the sensitivity of those cells to TRAIL-induced apoptosis. In addition, Bcl-2 expression was inhibited and pro-apoptotic Bax expression was increased following PrPc gene silencing, resulting in enhanced apoptosis. Our *in vitro* experiments further validated this result. After pulse induction of SGC7901 cells with different concentrations of adriamycin, PrPc, Bcl-2 and Bax expression and apoptosis were determined in adriamycin-resistant cells. Results showed that PrPc expression increased and apoptosis decreased with the increase in resistance to adriamycin. Our experiments not only show the dynamic changes in PrPc, Bcl-2 and Bax expression in gastric cancer cells resistant to various concentrations of adriamycin, but they also reveal that PrPc over-expression decreases apoptosis in cancer cells and reduces their sensitivity to drugs. It has been confirmed that PrPc is an anti-apoptotic gene that can cause synergistic effects with

Bcl-2. PrPc has been shown to be able to dimerize with the C-terminus of Bcl-2^[23,24]. When PrPc expression is up-regulated, the Bcl-2/Bax ratio is increased and is accompanied by the suppression of p53 and Bax, resulting in anti-apoptosis^[25-29]. Bcl-2 is expressed in almost all cell types, while PrPc expression is rarely observed in normal cells. This observation also determines the significance of PrPc expression in clinical practice. Our results confirmed the above findings^[2,10].

In another study, Meslin *et al.*^[22] detected PrPc expression in breast cancer patients that were non-responsive to an estrogen receptor inhibitor. Results of the study of the efficacy of chemotherapy indicated that patients with suppressed PrPc expression show favorable sensitivity to chemotherapy. This study was very important in monitoring the sensitivity of cancers to chemotherapy and drug resistance. In addition, detection of PrPc expression may become an indicator in diagnosing cancers and in monitoring the therapeutic efficacy. Our results confirmed that PrPc over-expression predicts gastric cancer cell drug resistance.

In addition, PrPc expression is closely related to the apoptosis pathway. Up-regulation of PrPc expression reduces apoptosis by increasing Bcl-2 expression^[2,3]. A study showed that the N-terminus of PrPc in metastatic gastric cancer with high PrPc expression could promote invasion and metastasis, which was partially associated with extracellular signal-regulated kinase/mitogen extracellular kinase pathway activation and subsequent transcriptional activation of MMP1^[5]. Furthermore, PrPc over-expression promoted the proliferation of gastric cancer cells and was strongly related to the incidence and development of gastric cancer^[6,7]. These *in vitro* experiments confirmed that the up-regulation of PrPc expression predicted enhanced proliferation and reduced apoptosis in gastric cancer cells, which resulted in drug resistance.

The role of PrPc expression in monitoring the therapeutic efficacy of gastric cancer

In the present study, positive PrPc expression was associated with the pathological type of gastric cancer. Mixed gastric cancer and undifferentiated gastric cancer had relatively high PrPc expression, which was consistent with tissue microarray assay results and the detection of PrPc expression in different gastric cancer cell lines. Results from the follow-up revealed that the patients with strongly positive PrPc expression showed poor sensitivity to chemotherapy and that the 2-year survival rates and KPS scores were significantly decreased. However, those with negative PrPc expression showed high sensitivity to chemotherapy, and the 2-year survival rates and KPS scores were remarkably higher than those with positive PrPc expression. Thus, PrPc could be a marker for the prognosis and response to chemotherapy in gastric cancer patients. In the National Center for Biotechnology Information gene bank (<http://www.ncbi.nlm.nih.gov/geo/>), results show PrPc expression in gastric cancer is higher than that in normal tissues (high-density oligonucleotide microarray, $P < 0.05$), and researchers speculate

PrPc may be a useful resource for future development of therapeutic targets and diagnostic markers for gastric cancer (<http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE2685>)^[30]. This result also confirms our previous findings that PrPc expression in gastric cancer can promote multidrug resistance and metastasis^[2,3] and that PrPc over-expression in gastric cancer patients predicts tolerance to chemotherapy and a low survival rate. Long-term follow-up should be conducted to investigate the chemotherapeutic efficacy.

In summary, we conclude that: (1) PrPc expression is associated with gastric cancer pathological type and cancer cell differentiation; (2) PrPc exerts synergistic effects with Bcl-2 to decrease apoptosis, resulting in drug resistance; (3) Gastric cancer patients with PrPc over-expression are resistant to chemotherapy and have a poor prognosis. We speculate that PrPc might be one of the markers used for monitoring the response to chemotherapy and the prognosis of gastric cancer.

COMMENTS

Background

Prion Protein (PrPc or PrP) is a pathogen causing bovine spongiform encephalopathy (BSE, also known as "mad cow disease"). PrPc is encoded by host prion gene but not by the prion gene. In 2003, the authors' study showed that PrPc was associated with multi-drug resistance of gastric cancer and thereafter a series of studies have been conducted to explore the role of PrPc in the differentiation, proliferation and metastasis of cancer cells and to investigate the structural domains of PrPc. The present study aimed to investigate the PrPc expression in gastric cancer cell lines and the role of PrPc expression in predicting outcome of gastric cancer patients undergoing chemotherapy.

Research frontiers

PrPc is closely related to tumor development. Study has demonstrated PrPc expression is related with not only cancer cell proliferation, but also the drug resistance and metastasis of cancer cells associated with multi-drug resistance of gastric cancer. When PrPc expression is up-regulated, Bcl-2/Bax ratio is increased accompanied by suppression of p53 and Bax resulting in anti-apoptosis. Up-regulation of PrPc expression predicted enhanced proliferation and anti-apoptosis of gastric cancer cells resulting in drug resistance. In the National Center for Biotechnology Information gene bank, results show PrP expression in gastric cancer is higher than that in normal tissues, and researchers speculate PrP may be a useful resource for future development of therapeutic targets and diagnostic markers for gastric cancer.

Innovations and breakthroughs

In the article "Over-expression of PrPc and its antiapoptosis function in gastric cancer" to be published on March 24, 2006, the authors found that PrPc might play a role as an effective antiapoptotic protein through Bcl-2-dependent apoptotic pathways in gastric cancer cells. According to results from this article, the authors conclude that PrPc and Bcl-2 have synergistic anti-apoptotic effects leading to increased resistance to chemotherapy. The PrPc expression level might be a valuable marker in predicting the efficacy of chemotherapy and prognosis of gastric cancer patients receiving chemotherapy. The findings were based on a series of studies which have been conducted to explore the role of PrPc in the differentiation, proliferation and metastasis of cancer cells and to investigate the structural domains of PrPc.

Applications

PrPc expression could be used as a marker for predicting the efficacy of chemotherapy and prognosis of gastric cancer. PrPc over-expression in gastric cancer patients predicts poor chemosensitivity and poor prognosis. Therefore, the PrPc expression level might be a valuable marker in predicting the efficacy of chemotherapy and prognosis of gastric cancer patients receiving chemotherapy.

Terminology

PrPc is a pathogen causing BSE (also known as "mad cow disease"). The prion (from proteinaceous infectious only) is devoid of informational nucleic acids and

consists of an 'infectious' protein that is capable of converting a normal host protein termed PrPc, or simply PrP, into a likeness of itself. PrPc is encoded by host prion gene but not by prion gene.

Peer review

The authors explore the dynamic changes of PrPc in the process of gastric cancer drug-resistance and the role of PrPc expression in the prognosis of gastric cancer patients receiving chemotherapy. The study revealed that: (1) PrPc expression is associated with gastric cancer pathological type of and cancer cell differentiation; (2) PrPc exerts synergistic effects with Bcl-2 to decrease apoptosis, resulting in drug resistance; and (3) Gastric cancer patients with PrPc over-expression are resistant to chemotherapy and have a poor prognosis. These findings suggest that PrPc might be one of the markers used for monitoring the response to chemotherapy and the prognosis of gastric cancer.

cer (CRC) development.

METHODS: Tissue microarrays were prepared from archival paraffin embedded tissue, including 51 colorectal carcinomas, 25 tubular adenomas (TA) and 26 HPs, each with matched normal colonic epithelium. Immunohistochemistry was performed using antibodies against TIF1 γ , Smad4 and TGF β R II. The levels of expression were scored semi-quantitatively (score 0-3 or loss and retention for Smad4).

RESULTS: Overexpression of TIF1 γ was detected in 5/26 (19%) HP; however, it was seen in a significantly higher proportion of neoplasms, 15/25 (60%) TAs and 24/51 (47%) CRCs ($P < 0.05$). Normal colonic mucosa, HP, and TAs showed strong Smad4 expression, while its expression was absent in 22/51 (43%) CRCs. Overexpression of TGF β R II was more commonly seen in neoplasms, 13/25 (52%) TAs and 29/51 (57%) CRCs compared to 9/26 (35%) HP ($P < 0.05$). Furthermore, there was a correlation between TIF1 γ overexpression and Smad4 loss in CRC (Kendall tau rank correlation value = 0.35, $P < 0.05$). The levels of TIF1 γ overexpression were significantly higher in stage III than in stage I and II CRC ($P < 0.05$).

CONCLUSION: The findings suggest that over-expression of TIF1 γ occurs in early stages of colorectal carcinogenesis, is inversely related with Smad4 loss, and may be a prognostic indicator for poor outcome.

INTRODUCTION

Colorectal cancer (CRC) continues to be a significant cause of morbidity and mortality worldwide with over 1 million new cases diagnosed each year^[1]. Recent advances in treatment include both cytotoxic chemotherapies and novel biologic agents targeting specific cellular signaling pathways that regulate cell proliferation, apoptosis, and angiogenesis. The transforming growth factor-beta (TGF- β) signaling pathway is important in colorectal carcinogenesis and provides potential therapeutic molecular targets^[2].

The TGF- β signaling pathway is composed of TGF- β receptor type I (TGF β R I) and type II (TGF β R II) and Smad proteins. TGF- β ligands bind directly to membranous TGF β R II, trans-phosphorylating TGF β R I and enabling the TGF β R I kinase domain to act on cytoplasmic receptor-regulated Smad proteins (R-Smads)^[3,4]. TGF- β plays a unique dual role in growth suppression and cellular proliferation. In the normal colon, TGF- β may act as a tumor suppressor, inhibiting cellular proliferation and inducing apoptosis. Conversely in late stages of CRC, TGF- β acts as a tumor promoter, stimulating invasion and angiogenesis^[5,6]. The specificity in TGF- β activity is determined by R-Smads that propel downstream signaling through nuclear translocation and activation of target transcription genes. Development of hyperplasia, adenoma, CRC, and finally metastasis often involve inactivation of tumor suppressor genes and activation of oncogenes resulting in alterations in cell proliferation, apoptosis, migration, and invasion at the cellular level.

Transcriptional intermediary factor 1 gamma (also termed TIF1 γ /TRIM33/RFG7/PTC7/Ectoderm) functions as a cofactor of the TGF- β signaling pathway. However, TIF1 γ 's precise functional role is not clear. It is proposed to have functions both dependent and independent of R-Smads. TIF1 γ acts as a regulator of the TGF- β pathway through multiple R-Smad dependent mechanisms including by (1) targeting cytoplasmic Smad4 for degradation^[7]; (2) disrupting Smad-Smad complex formation; and (3) targeting nuclear Smad4 for degradation^[8]. In an R-Smad independent model, TIF1 γ is reported to act as a new co-Smad required for TGF- β signaling during human erythropoiesis^[9]. Thus TIF1 γ can function as either a negative regulator or a complementary agonist of TGF- β signaling.

Prior studies have shown that Smad4 deletion occurs in 16%-25% of CRCs and low levels of Smad4 suggest a poor response to therapy and short survival^[10,11]. Both TGF β R II and Smad4 mutations are reported to occur at

the early stage of transition of adenoma to carcinoma^[11]. An inverse relationship between the expression of Smad4 and TIF1 γ has been proposed based on *in vitro* studies^[7], whereas studies on pancreatic cystic tumors suggest that the two factors complement each other in tumorigenesis^[12]. The expression and the role of TIF1 γ in colorectal carcinogenesis remain unknown. This study is designed to analyze the expression of TIF1 γ in CRC and its pre-cancerous lesion (i.e., adenoma) in comparison with non-neoplastic lesions [hyperplastic polyps (HP)] and normal epithelium by immunohistochemical methods, and to assess the prognostic significance of abnormal TIF1 γ expression for CRC.

MATERIALS AND METHODS

Specimens

Formalin-fixed paraffin embedded archival tissue blocks of 51 colorectal carcinomas, 25 tubular adenomas (TA), 26 HPs, excluding sessile serrated polyp/adenoma morphologically with their normal epithelium were retrieved from the Department of Pathology, Tisch Hospital, New York University Medical Center between 2007 and 2009. Normal control tissue from each patient was taken from the margin of the resection specimen and from different parts or adjacent normal (non-neoplastic) tissue in the same patient. The study was approved by Institutional Review Board. Clinical and pathological data of each patient were obtained including age, sex, tumor size, tumor location, grade, type, stage and the status of *Kras* mutation. The type and differentiation of all neoplasms was evaluated by two independent pathologists (Cristina Hajdu and Ru-Liang Xu). Tissue microarrays (TMA) were prepared by using a 3-mm biopsy punch needle. Two representative cores from each lesion and 1 core from normal epithelium were taken from archival paraffin-embedded tissue blocks. Hematoxylin-eosin staining was performed for histological characterization.

Immunohistochemical staining for TIF1 γ , Smad4 and TGF β R II

Immunohistochemistry (IHC) was performed using single label technique by the NexES automated immunostainer and detection system (Ventana Medical Systems, Tucson, AZ, United States). Four micron-thick sections were deparaffinized in xylene, rehydrated through graded alcohols, and rinsed in distilled water. All incubations were carried out at 37 °C unless otherwise noted. After deparaffinization, heat induced epitope retrieval was performed by microwaving sections with 0.01 M, pH 6.0 citrate buffer for 20 min in a 1200 watt microwave oven. Endogenous peroxidase was blocked by application of hydrogen peroxide for 4 min. Monoclonal antibodies against TIF1 γ (TIF1gamma: sc-101179, Santa Cruz), Smad4 (Smad4: sc-7966, Santa Cruz, Biotechnology Inc, Santa Cruz, California, United States) and TGF β R II (TGFbeta2 receptor: ab28382, Abcam) at (1:50), (1:200) and (1:300) dilution respectively were applied to the TMAs followed by adding

a biotinylated goat anti-rabbit for 8 min, and subsequently by the application of streptavidin-horseradish peroxidase for 8 min. The reaction was visualized by applying chromogen, 3,3'-diaminobenzidine/hydrogen peroxide mix for 8 min and copper sulfate for enhancement for an additional 4 min. Slides were then counterstained with hematoxylin, dehydrated, and mounted in permanent media. Primary antibody was omitted in negative controls.

Immunohistochemical labeling for TIF1 γ , Smad4 and TGF β R II was evaluated by three independent authors with the agreement in all cases examined. Cytoplasmic staining of TGF β R II and nuclear staining of TIF1 γ was considered positive. The immunolabeling pattern of each case was scored based on the percentage of cells with positive staining and intensity. Intensity was scored semi-quantitatively as: strong (3+), moderate (2+), weak (1+) and negative (0). Final score was determined as the highest intensity score obtained by > 20% of positively stained cells. Final expression was determined by adjusting for the staining score on corresponding normal epithelium. Overexpression of TIF1 γ and TGF β R II in the neoplasm was considered if the adjusted final score was \geq 1.

For Smad4, the immunostaining pattern of each case was scored as "no loss" (positive) or "loss" (negative). Normal colonic epithelium served as a positive control showing strong nuclear staining. Neoplasms and HP were scored as "no loss" if the neoplastic or hyperplastic epithelium showed any nuclear labeling and as "loss" if they showed no or only faint cytoplasmic staining with total absence of nuclear Smad4 protein.

Kras mutation

Out of 51 CRCs cases, 37 cases had *Kras* mutation data. *Kras* genotyping was performed using polymerase chain reaction with exon 2 flanking primers followed by capil-

lary gel electrophoresis fluorescence detection in the Molecular Diagnostic Laboratory, Genzyme, Inc. This assay analyzes codons 12 and 13 in exon 2 of the *Kras* gene. However, mutations in codon 61 and other sites were not tested. The analytical sensitivity of the assay is approximately 10%, thus mutations present in a low percentage of cells may not be detected.

Statistical analysis

Summary data were expressed as proportions and percentages. Comparisons among groups were performed using χ^2 test. Correlation between the different protein expression and clinical variables was performed by Kendall tau rank correlation test. Probability values of 0.05 or less were considered significant. Linear predictive module was used to predict the stage of the cancer according to different variables.

RESULTS

We studied the expression of TIF1 γ in association with Smad4 and TGF β R II in TA (*n* = 25) and CRC (*n* = 51) in comparison with matched normal control and non-neoplastic lesions or HP (*n* = 26). Of the 51 CRCs 37 (72%) were well-to-moderately differentiated, 8 (15%) poorly differentiated, and 6 (11%) mucinous adenocarcinoma. According to the TNM staging system by the American Joint Committee on Cancer, 16 (31.3%) were stage I, 14 (27.4%) stage II, and the remaining 21 (41.2%) stage III. Lymph node metastases were present in 21 (41.2%) of the CRCs at the time of diagnosis. The clinical and pathologic characteristics of the 51 patients with CRC were collected. The median age of the 51 individuals diagnosed with CRC was 70 \pm 10.8 years (42-85 years), and 27 of 51 (52.9%) were men. Patients showed no sex predilection. Twenty-seven (41%) of the lesions diagnosed as CRCs were located in the proximal colon (right side), 16 (45%) were in the distal colon (left side), while 8 (13%) were in the rectum. None of the patients diagnosed with CRC received neoadjuvant therapy. The mean size of the 51 tumors was 4.3 cm \pm 1.7 cm. The levels of nuclear or cytoplasmic expression of TIF1 γ , TGF β R II, and Smad4 were correlated with patient's clinical and *Kras* mutation status (Table 1).

Increased TGF β R II expression in TA and CRCs

TGF β R II expression was observed in the cytoplasm of the normal epithelium and its intensity varied from 1+ to 2+ in all the cases (Figure 1A, B and C). Increased expression was more commonly seen in neoplastic lesions, TA (13/25 or 52%) and CRC (29/51 or 57%), as compared to HP (9/26 or 35%) (*P* < 0.05) (Figure 2). However, no statistical difference was found in overexpression between CRC and TA. Increased expression of TGF β R II was more frequent in well-to-moderately differentiated carcinomas compared to poorly differentiated lesions (73% vs 25%). Overexpression of TGF β R II was not observed in mucinous type carcinomas. TGF β R II expression in CRC

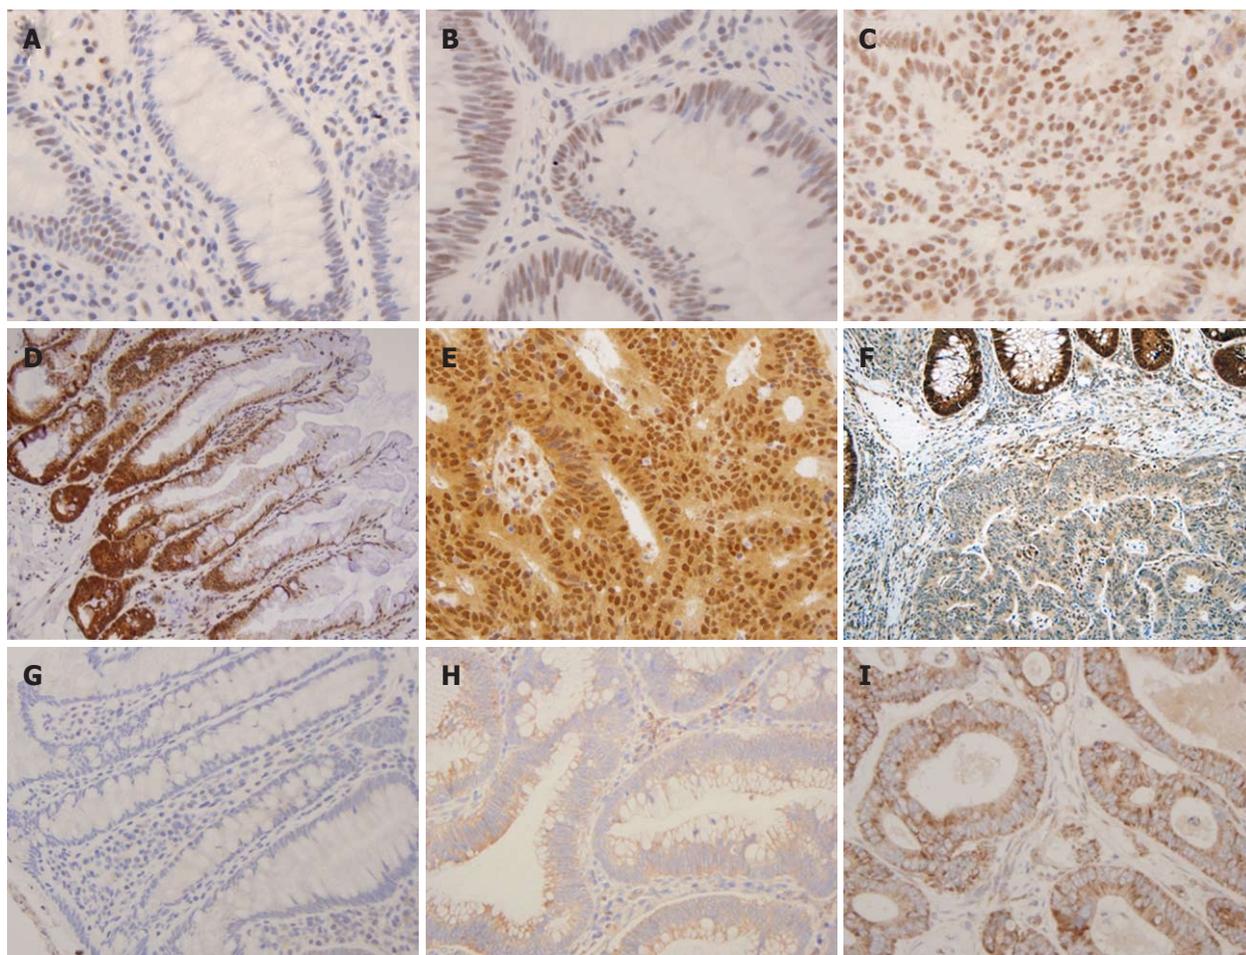

Figure 1 Semi-quantitative immunohistochemistry scoring of transcriptional intermediary factor 1 gamma, Smad4 and transforming growth factor-beta receptor type II overexpression. Immunohistochemistry (IHC) staining for transforming growth factor-beta receptor type II shown in A, B, C: Weak cytoplasmic (0-1+) staining seen in normal colonic mucosa (A). Moderate (2+) cytoplasmic and weak (0-1+) membranous staining in the tubular adenoma (TA) (B). Strong cytoplasmic and focal membranous staining in the cancer cells (C). IHC staining for Smad4 shown in D, E, F: Strong (3+) Smad4 staining seen in normal colonic mucosa (D). Tumour cells showing strong (3+) expression of Smad4 protein in the nucleus and cytoplasm (E). Adenocarcinoma with loss of Smad4 in the nuclei (F). IHC staining for transcriptional intermediary factor 1 gamma (TIF1 γ) shown in G, H, I: Weak (1+) nuclear staining for TIF1 γ seen in normal colonic mucosa (G), moderate (2+) nuclear staining seen in TA (H), strong nuclear staining (3+) in cancer cells (I) (400 \times).

lesions did not correlate with patient age, sex, site, size, stage or *Kras* mutation.

Loss of Smad4 expression in CRC

Normal colonic epithelium displayed uniformly distributed strong (3+) nuclear Smad4 staining but in occasional cases staining was stronger at the bottom of the crypts (Figure 1D, E and F). While none of the HP or TAs showed loss of expression of Smad4 (Table 1), a significant proportion of CRC cases (22/51 or 43%) completely lacked the nuclear expression of Smad4. The lack of Smad4 expression was more frequent in primary CRC with lymph node metastasis (11/21 or 52.4%) than without lymph node metastasis (11/30 or 36.6%). Of 37 cases of CRC with available data of *Kras* mutation status, 11 cases had mutations in codon 12 or 13. The loss of Smad4 expression was significantly higher in CRCs with *Kras* mutations (9/11 or 81.8%) than the cases without (11/26 or 42.3%) ($P < 0.05$). There was no significant difference in the expression loss of Smad4 related to the

age, sex, site, size and grade of CRC.

Overexpression of TIF1 γ in hyperplastic and neoplastic lesions

TIF1 γ protein was located in the nucleus of normal colonic epithelium on IHC with intensity of 1+ to 2+ in the majority (96%) of cases, and 3+ nuclear staining in 4% normal epithelium. The staining was seen predominantly in the lower part of the crypts in comparison to the luminal (Figure 1G, H and I). Increased expression of TIF1 γ was more frequently seen in neoplasms, TA (15/25 or 60%) and CRC (24/51 or 47%) than HPs (5/26 or 19%) ($P < 0.05$). There was no statistical difference in TIF1 γ overexpression between TA and CRC ($P < 0.05$) (Figure 2).

Association of overexpression of TIF1 γ with higher stage CRC

The frequency of TIF1 γ overexpression was significantly higher in stage III CRC in comparison to stage I and II CRC ($P < 0.05$). Using a linear predictive module for

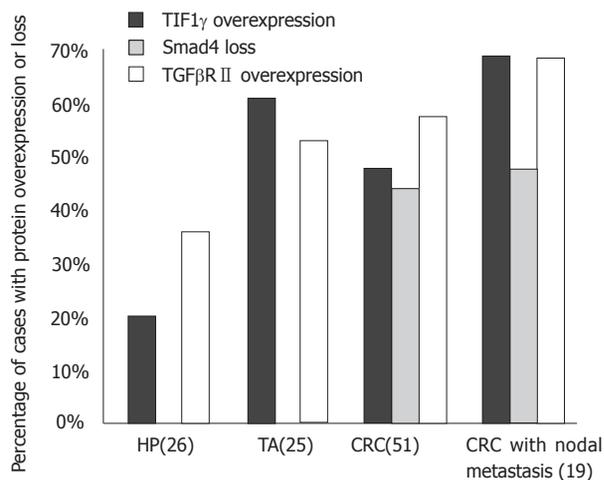

Figure 2 Comparison of transcriptional intermediary factor 1 gamma overexpression, Smad4 loss, and transforming growth factor-beta receptor type II overexpression among hyperplastic polyps, tubular adenomas, and colorectal cancer. HP: Hyperplastic polyps; TA: Tubular adenomas; CRC: Colorectal cancer; TIF1 γ : Transcriptional intermediary factor 1 gamma; TGF β R II: Transforming growth factor-beta receptor type II.

the higher stage (III), the predictivity was 67% by TIF1 γ overexpression in comparison to the marginal predictivity (58%) by loss of Smad4. However, there was no statistical difference in TIF1 γ overexpression between the primary tumors and matched lymph node metastasis ($P > 0.05$). There was no significant difference in the expression of TIF1 γ related to the age, sex, site, size, grade and *Kras* mutation of CRCs ($P > 0.05$) (Table 1).

Correlation between overexpression of TIF1 γ and abnormal expression of Smad4 and TGF β R II in CRC

To determine the relationship among the levels of expression for TIF1 γ , Smad4 and TGF β R II, we performed Kendall tau rank correlation test. In CRC a significant correlation was seen between TIF1 γ overexpression and Smad4 loss (Kendall tau value 0.35, $P < 0.05$). There was no significant correlation between Smad4 loss and TGF β R II overexpression in CRC, or between TIF1 γ and TGF β R II overexpression in CRC, TA or HP.

DISCUSSION

Our study has evaluated the expression of important mediators, TIF1 γ , Smad4 and TGF β R II, in TGF- β signaling pathway in normal epithelium, HP (benign nondysplastic lesion), TA (precursor lesion) and CRC by semi-quantitative IHC analysis. TGF- β , belonging to a ligand-receptor family that also includes bone morphogenetic protein and activin, is often excessively produced in CRCs, presumably owing to loss of feedback inhibition with disruption of its intracellular Smad signaling pathway. The autocrine activity from elevated secretion of TGF- β ligand increases expression of TGF β R II to unmask the interruption of Smad-dependent signaling to suppress tumor growth. A similar phenomenon has been reported previously *in*

in vitro in prostate cancer cells^[13]. Our study also showed increased expression of TGF β R II in TA (52%) and well-to-moderately differentiated CRCs (73%). Functional mutations in TGF β R II have been reported in approximately 30% of CRCs in later stage^[14,15]. Low TGF β R II expression was found in poorly differentiated CRC (25%), similar to previous studies. The finding represents failure of TGF- β antiproliferative and apoptotic effects in advanced CRC and other cancers^[16-18]. Smad4 protein expression was absent in a significant proportion (43%) of CRC cases, which is consistent with literature^[10]. None of normal epithelium, HP and TAs displayed Smad4 loss, supporting that Smad4 loss occurs at a later stage in colorectal carcinogenesis^[19,20].

This is the first report attempting to elucidate the role of TIF1 γ in colorectal carcinogenesis and its interaction with Smad4, a key regulator of TGF- β signaling pathway. TIF1 γ is the third member of the TIF1 gene family observed in the nucleus of normal epithelium and cancer cells and has been shown to selectively bind to receptor-activated Smads 2 and 3^[9]. In the present study TIF1 γ overexpression was seen in non-dysplastic or non-precursor lesion HP (19%), and more frequently found in neoplasms, TA (60%) and CRC (47%) ($P < 0.05$ respectively). This suggests that TIF1 γ is involved in abnormal cell proliferation and early stages of colorectal carcinogenesis, as compared to Smad4 loss which was only seen in later adenoma stage and CRC. This finding is, however, different from the results in human pancreatic ductal adenocarcinoma, which conversely showed down-regulation of TIF1 γ ^[12].

In a mouse model of pancreatic carcinogenesis, TIF1 γ was shown to be in cooperation with *Kras* activation to induce pancreatic tumors, reminiscent of human Intraductal Papillary Mucinous Neoplasms^[12]. In our study, we did not find a positive relationship between the expression of TIF1 γ and common mutations (codon 12 or 13 of exon 2) of *Kras* in CRC, but showed an inverse relationship between Smad4 loss and *Kras* mutation. This may suggest that interaction between TGF- β tumor suppressing pathway and Ras-MAPK pathways is different in colorectal carcinogenesis from in its pancreatic counterpart. However, this observation may be biased because of a relatively small number of samples. A large sample size study and/or an animal model is needed to provide a more definite answer.

A significant correlation between TIF1 γ overexpression and Smad4 loss suggests a mutual interaction between the two molecules similar to the result demonstrated *in vitro* in breast, colon and pancreatic Smad4-defective cancer cell lines^[9]. Recently it has been shown that TIF1 γ acts as a general inhibitor of TGF- β and bone morphogenetic proteins (BMP) signaling pathways by acting as an E3 ubiquitin ligase causing Smad4 ubiquitination and degradation^[7]. Consistent with this hypothesis, our findings suggest that TIF1 γ is overexpressed in early stages, and possibly acts by degradation of Smad4 disrupting its tumor suppressor activity leading to progression of

adenoma-carcinoma sequence. Our results, however, are only based upon immunohistochemical study, and further conformational study is needed to support the above conclusions.

In addition to its role in abnormal proliferation and early carcinogenesis, we found a significantly high expression of TIF1 γ in stage III CRC with nodal metastasis in comparison to stage I and II CRC. Using a linear predictive module for advanced stage III in comparison to stage I/II, Smad4 loss had marginal predictivity (58%) in comparison to 67% by TIF1 γ overexpression. The findings suggest that TIF1 γ might also be involved in tumor progression. Consistent with earlier reports, the frequency of Smad4 loss was also higher in stage III CRC in comparison to stage I/II CRC^[10]. This further indicates that TIF1 γ and Smad4 could possibly act in collaboration with each other during colorectal carcinogenesis. Statistical differences in TIF1 γ and Smad4 expression based on tumor size, site and grade cannot be concluded from the present study. Combined TIF1 γ and Smad4 expression may serve as a marker for high stage disease in colon biopsy specimen. Since a large proportion of CRCs in our patients are located in the left side, further study is needed to clarify the relationship between the microsatellite stability of CRC and TIF1 γ and/or Smad4 expression.

In summary, overexpression of TIF1 γ occurs in association with abnormal proliferation and in early stages of colorectal carcinogenesis. It shows an inverse relationship with Smad4 loss, suggesting that TIF1 γ may have a collaborative effect with Smad4 in colorectal carcinogenesis. Our study also found that overexpression of TIF1 γ is associated with high tumor stage, indicating that it is a poor prognostic factor. Further molecular studies are needed to evaluate the role of TIF1 γ in colorectal carcinogenesis, its interaction with other factors in TGF β /BMP pathways, and utility as a prognostic marker for CRC.

COMMENTS

Background

Colorectal cancer (CRC) continues to be a significant cause of morbidity and mortality worldwide despite recent development of new therapy, mainly because the molecular mechanisms underlining the colorectal carcinogenesis are not completely understood. Transcriptional intermediary factor 1 gamma (TIF1 γ) is a recently identified cofactor of Smad4, a key part of transforming growth factor-beta (TGF- β) signaling pathway. It has been shown that TIF1 γ plays an important role in early embryonic development and potentially is involved in carcinogenesis in some organs or systems. Hitherto, the role of this factor in colorectal carcinogenesis and the significance of the abnormal expression in the gastrointestinal tract are unknown.

Research frontiers

TIF1 γ functions as a cofactor of the TGF- β signaling pathway, acting on Smad4 or Smads complex by ubiquitination. Smad4 as a tumor suppressor has been shown to be a prognostic factor in a subset of patients with CRC. In a mouse model the inactivation of this protein appeared to cooperate with Kras mutation (G12D) to induce cystic tumors of the pancreas, and the down-regulation of this protein was seen in pancreatic ductal carcinoma. This study is designed to analyze the expression of TIF1 γ in CRC and its precancerous lesion (i.e., adenoma) in comparison with a non-neoplastic lesion (hyperplastic polyps)

and normal epithelium by an immunohistochemical method, and to explore the prognostic significance of abnormal TIF1 γ expression in CRC. Correlation with abnormal expression of Smad4, TGF β R II in TGF- β pathway and Kras mutation in CRC has also been investigated.

Innovations and breakthroughs

This is the first study attempting to elucidate the role of TIF1 γ in colorectal carcinogenesis and to determine its interaction with Smad4, a key regulator of TGF- β signaling pathway and Kras mutation in CRC. The findings suggest that TIF1 γ is overexpressed in early stages, independently from the inactivation of Smad4 protein and Kras mutation. This study further demonstrates that overexpression of TIF1 γ is associated with high stage of CRC, indicating that it is a poor prognostic factor.

Applications

The results will open an avenue for further research to evaluate the role of TIF1 γ in colorectal carcinogenesis, its interaction with other factors in TGF β /bone morphogenetic proteins pathways, and to elucidate its utility as prognostic marker for CRC.

Terminology

The TGF- β signaling pathway is involved in regulating cell proliferation, apoptosis, and angiogenesis. TIF1 γ (also termed TIF1 γ /TRIM33/RF7/PTC7/Ectodermin) functions as a cofactor of the TGF- β signaling pathway, proposed to have functions both dependent and independent from receptor-regulated Smad proteins. Understanding the pathways involved in carcinogenesis provides potential prognostic value and facilitates novel therapeutic molecular targets.

Peer review

This is a new insight into colorectal carcinogenesis, which deserves publishing. One would like to see the results confirmed with alternate techniques e.g., other expression studies. The English is good. The number of samples is adequate.

Abstract

AIM: To investigate the rates of polyp detection in a mixed risk population using standard definition (SDC) vs high definition colonoscopes (HDC).

METHODS: This was a retrospective cohort comparative study of 3 colonoscopists who each consecutively performed 150 SDC (307, 200 pixel) and 150 HDC (792, 576 pixels) in a community teaching hospital.

RESULTS: A total of 900 colonoscopies were evaluated (mean age 56, 46.8% men), 450 with each resolution. Polyps of any type were detected in 46.0% of patients using SDC and 43.3% with HDC ($P = 0.42$). There was no significant difference between the overall number of polyps, HDC (397) and SDC (410), detected among

all patients examined, ($P = 0.73$). One or more adenomatous polyps were detected in 24.2% of patients with HDC and 24.9% of patients with SDC colonoscopy ($P = 0.82$). There was no significant difference between HDC (M = 0.41) and SDC (M = 0.42) regarding adenomatous polyp ($P = 0.88$) or advanced adenoma ($P = 0.56$) detection rate among all patients examined.

CONCLUSION: HDC did not improve yield of adenomatous polyp, advanced adenoma or overall polyp detection in a population of individuals with mixed risk for colorectal cancer.

INTRODUCTION

It is estimated that up to 15 million colonoscopies are performed annually in the United States^[1,2]. Colonoscopy and polypectomy have been estimated to prevent 50%-80% of colorectal cancers^[3-5]. However, recent trials have implied a lower level of protection and even a failure of colonoscopy to prevent right sided colon cancer^[6,7]. With adenoma miss rates of up to 20% demonstrated for moderate sized polyps, the potential of improved polyp detection in preventing colon cancer

deaths could be substantial^[8-10].

A considerable effort is being spent on optimizing the yield of colonoscopy with respect to polyp detection. Several technologies such as wide-angle, cap-fitted, retroflexion colonoscopy and Third Eye Retroscope colonoscopy have been used in an attempt to increase mucosa exposure. Various optical enhancing technologies such as chromoendoscopy, narrow-band (NBI) and multi-band imaging, high definition, and autofluorescence have been studied as well. While some have been found to be effective in expert hands in tertiary care centers, many techniques suffer from issues of practicality. The rising demand of colon cancer screening and the advent of several different modalities for this purpose, such as computerized tomography colonoscopy, have stressed the importance of improved efficiency in colonoscopy.

At present, the only technical developments that are readily available and in use in routine practice settings in the United States are wide angle, high definition and NBI/multi-band imaging. High-definition endoscopes have been touted by manufacturers to show markedly clearer images in hopes that this would translate into higher polyp detection rates. In the current study, we present a comparison of polyp detection rate of endoscopists using standard definition and high definition endoscopy systems.

MATERIALS AND METHODS

Patients

Nine hundred consecutive patients who had colonoscopy between May 2007 and May 2008 by three experienced endoscopists (> 6000 colonoscopies each) were selected for analysis retrospectively. Patients were mixed risk and all colonoscopies were performed at the same endoscopy center of a community teaching hospital in Florida, United States. Colonoscopies performed by gastroenterology fellows were excluded from the study. The study was approved by the Institutional Review Board at Cleveland Clinic Florida.

Endoscopy equipment

The standard definition colonoscopies (SDC) were performed with an EPK-1000 processor (Pentax), EC-3430LK, EC-3830LK, EC-3470LK, and EC-3870LK model colonoscopes (Pentax), a 19-inch CRT monitor at a resolution of 640 × 480 producing a 307, 200 pixel image at distance of approximately 2.8 m from the endoscopists. The high definition colonoscopies (HDC) were performed with an EPX-4400 digital processor (Fujinon), EC-450HL5 and EC-450LS5 model colonoscopes (Fujinon), a 32-inch LCD monitor at a resolution of 1032 × 768 producing a 792, 576 pixel image at a distance of approximately 2.8 m from the endoscopists. Both standard definition and high definition colonoscopes had a 140° field of view.

The Fujinon system has the capability of multi-band imaging that produces images similar to the NBI endo-

scopes, commercially termed Fuji Intelligent Chromo Endoscopy (FICE). The difference lies in that the Fujinon system uses software to construct images based on preset RGB wavelength combinations. The NBI systems use optical filters that restrict the bandwidth of a transmitted light signal. Currently available NBI systems utilize 2 narrow-band filters that provide tissue illumination in the blue (415 nm) and green (540 nm) spectrums of light^[11]. The Fujinon equipment has ten factory-determined wavelength preset combinations.

Endoscopic procedures

Data from one hundred fifty consecutive patients who had colonoscopy with standard definition (SD) equipment were collected for three endoscopists from May - October 2007. Following the installation of the HDC system, all endoscopic procedures in our unit were performed exclusively using the high definition (HD) scopes and data was collected from 150 consecutive patients who had colonoscopy by the same three endoscopists from October 2007 - March 2008. The endoscopists were not aware of the study. Bowel preparation agents used were predominantly sodium phosphate and polyethylene glycol based regimens. The procedures were performed under a nurse administered standard sedation with Meperidine and Midazolam or anesthesiologist administered Propofol. Colonoscopy withdrawal times were recorded by the nursing staff.

Endoscopists were free to use the multi-band feature on the HDC system as needed. The system was initially set on the factory default preset of 0, which produced an image restricted to the following wavelengths: R 500 nm, G 445 nm, and B 415 nm. A push-button on the handle of the colonoscope was programmed to enable switching between conventional white-light image and the preset multi-band image. Endoscopists were also free to change to a different factory preset according to their preferences. The study was designed prior to arrival of the high definition system; however, data collection was started afterwards.

Data collection

The data was collected from electronic medical records, procedure nursing notes, procedure reports, and pathology reports. The numbers of detected polyps recorded on the procedure reports were corroborated with the pathology reports and the nursing notes. The main outcome parameter was the polyp detection rate in the two groups. Secondary outcome measures included: detection rates of adenomatous polyps, advanced adenomas, and cancer. Advanced adenoma was defined as adenomatous polyps having one or more features of: > 1 cm in diameter, high-grade dysplasia, and villous histology. Additional data was collected with regards to patient age, gender, race, indication for colonoscopy, polyp location, procedure time, withdrawal time, type of sedation, and prep quality.

Statistical analysis

The Statistical Package for Social Sciences (SPSS 16.0) was used in order to organize, validate and analyze the collected data. Quantitative data were summarized using mean values (M) and standard deviation; Student's *t* test were performed in order to detect significant differences between colonoscope types; equality of variances was inspected using Levene's tests. We examined associations between categorical variables, performing χ^2 tests or Fisher's exact test when appropriate.

RESULTS

A total of 900 colonoscopies were evaluated, comparing 450 patients each who had colonoscopy with SDC equipment and HDC equipment. Each endoscopist performed 300 colonoscopies equally divided between standard and high definition procedures. The mean age of the study population was 56, and 46.8% were men. There were no statistically significant differences in patient characteristics between the two groups with the exception of a higher number of Hispanic patients and those that had screening colonoscopy in the HDC group (Table 1). However, there was no overall difference in adenomatous polyp detection rate in Hispanics (23.9%) *vs* Non-Hispanics (24.6%) ($P = 0.86$) and the screening (25.7%) and non-screening (21.7%) groups ($P = 0.18$).

Cecal intubation, bowel prep quality and withdrawal times were also not statistically significantly different between the HDC and SDC groups. The cecum was reached in 96.7% of all cases. Average withdrawal time was 11.1 min, which included polypectomy time.

Polyps of any type were detected in 46.0% of patients with SDC and 43.3% of those patients who had HDC ($P = 0.42$). There was no significant difference between the overall number of polyps, HDC (397) and SDC (410), detected among all patients examined ($P = 0.73$). One or more adenomatous polyps were detected in 24.2% of patients with HDC and 24.9% of patients with SDC ($P = 0.82$). There was no significant difference between HDC (M = 0.41) and SDC (M = 0.42) regarding adenomatous polyp detection rate among all patients examined ($P = 0.88$). In addition, there was no significant difference between the study groups regarding advanced adenoma polyp detection rates ($P = 0.60$) or cancer detection rate among all patients examined ($P > 0.05$) (Table 2). There was no difference in polyp detection rates when each individual endoscopist's HDC and SDC detection rates were compared (data not shown).

Polyps detected during the procedures were also analyzed according to size. There was no significant difference between the detected number of polyps of sizes < 6 mm, 6-10 mm, and >10 mm in the HDC and SDC groups.

Gender was shown to be a significant variable as men in this study were found to have a higher incidence of all polyps ($P < 0.01$), adenomatous polyps ($P < 0.01$) and

NBI: Narrow-band imaging; SD: Standard definition; HD: High definition.

advanced adenomas ($P < 0.01$). However, this disparity was consistent in both cohorts with no statistically significant difference between the HDC and SDC groups (Table 3).

We found that the overall polyp and adenoma detection rates did not change significantly between the first, second or third 50 HDC performed by our endoscopists when the three were coned ($P > 0.05$). Therefore, there does not seem to be a learning effect associated with use of HDC with on demand multi-band imaging capability by endoscopists who had not used them before (Figure 1).

DISCUSSION

Our goal in this study was to assess the performance of HDC with regards to polyp detection. Five prior studies have compared adenoma detection rate between standard and high definition white light colonoscopy with conflicting results. There have been methodological and technical differences between the studies (Table 4) with all using Olympus colonoscopes, whereas our study is the first performed using Fujinon HDC with FICE. Among the three prospective studies, Pellisé *et al*^[12] had the largest patient population. It was a prospective randomized controlled trial of 620 patients conducted in

Spain involving seven colonoscopists. Patients were randomized to either HDC with wide angle (170°) field or SDC with 140° view, with the investigators finding no difference in adenoma detection rate between the study groups (HDC 26% vs SDC 25%, $P = 0.85$). The study by East *et al*^[13] was not randomized, consisting of 130 patients who underwent either HDC with 140° view or SC 140° view by a single colonoscopist. Although HDC did not improve the yield of adenomatous polyp detection, there was a trend in this direction (71% vs 60%). The Tribonias *et al*^[14] study randomized 390 patients prospectively into HDC with wide angle vs SDC groups and, although there was a significant difference between the two groups with regards to overall rate of polyp detection, (HDC 63% vs SDC 53%, $P = 0.03$), there was no significant difference demonstrated in the detection of rate of adenomas (HDC 58% vs SDC 50%, $P = 0.16$).

The largest patient population study on this topic, by Buchner *et al*^[15], was retrospective involving 2430 patients in two arms: HDC and SDC. The HRC were 170° wide-angle and NBI was used as needed. The SDC in the study had a 140° view and did not have NBI. The study found that the HDC were able to detect a statistically significant higher number of adenomatous polyps compared with SDC (28.8% vs 24.3%, $P = 0.012$). The most recently

published study was by Burke *et al.*^{16]} and consisted of 426 individuals in each group and found no advantage of HDC in overall polyp detection rate, adenomas or advanced adenomas.

In our study, we found no difference in detection rates of overall polyps, adenomas, advanced adenomas, and cancer between the HD and SD groups. There was no difference in polyp detection rates when each individual endoscopist's HD and SD detection rates were compared despite having used 32-inch LCD high-resolution monitors with the Fujinon system whereas 19-inch CRT monitors were used with the standard definition colonoscopes. Although there are considerable methodological differences between the Pellisé *et al.*^{12]} and our study, both studies show very similar results and conclusions. In fact, their adenomatous polyp detection rates are nearly identical to ours in the SD and HD arms: 0.45 ± 1.07 *vs* our 0.41 ± 1.04 adenomas per patient in SD and 0.43 ± 0.87 *vs* our 0.42 ± 0.94 adenomas per patient in HD. Our polyp detection rates are well in line with several other studies of white light colonoscopy with regards to prevalence of adenomas, advanced adenomas, cancer, and gender differences^[17-19]. We were also able to demonstrate that polyp detection rate did not improve as the endoscopist experience with HDC increased by comparing adenoma detection in consecutive groups of 50 colonoscopies ($P > 0.05$). This lack of learning effect was also demonstrated by Adler *et al.*^{20]} in 2008 in a prospective randomized study of NBI *vs* conventional colonoscopy for adenoma detection. Although prior studies were meant to compare HD and SD, the HD equipment used in these reports also had a wide angle field of view and the study by East is the only one that used 140° scopes in both arms, but it was underpowered for detecting small differences in polyp detection rate. Similar to East, our study design eliminates the confounding factor of the wide angle field of view by using 140° scopes in the HD and SD groups.

There is significant variability amongst endoscopists in adenoma detection rates, making the endoscopist probably the most important variable in adenoma detection rate^[21]. We tried to minimize the impact factor of the endoscopist by assigning an equal number of overall cases per endoscopist (300) and dividing these equally amongst the study groups. Our study has a significant advantage in this.

It can be argued that our study's retrospective design was a limitation, but it may have also served to reduce endoscopist bias. Endoscopist bias is an inherent limitation of nearly all prospective colonoscopy study designs since the equipment cannot be hidden from the performer of the examination. A second limitation is that the population was a mixed-risk sample and there were slight differences with respect to Hispanics and screening patients. However, there was no statistically significant difference in the detection of adenoma, advanced adenoma or cancer between the Hispanic *vs* Non-Hispanic and screening *vs* non-screening groups. In fact, there was a slightly higher prevalence of adenomas in the populations that were overrepresented in the HD group. This would have

worked to bias the results in favor of HDC had it been a significant difference. In summary, the results of our study are relevant to most practices as the majority of the new colonoscopy equipment purchased in the future will have HD and NBI or multi-band imaging capabilities. Until recently, evidence regarding the potential of this new technology in improving yield of polyp detection was lacking. Complementing the results of Pellisé, and Burke, our study concludes that HDC with multi-band imaging capability does not detect more total polyps, adenomas, advanced adenomas or cancer. For now at least, the endoscopist and not the equipment used, continues to be the major factor in polyp detection.

COMMENTS

Background

It is estimated that up to 15 million colonoscopies are performed annually in the United States. Colonoscopy and polypectomy have been estimated to prevent 50%-80% of colorectal cancers. A considerable effort is being spent on optimizing the yield of colonoscopy with respect to polyp detection. At present, high definition colonoscopy (HDC) is being widely adapted but whether or not it impacts detection of colon polyps is debatable.

Research frontiers

HDC is widely touted by manufacturers to improve polyp detection. Yet, several studies have compared detection of polyps with standard definition colonoscopy (SDC) *vs* HDC with variation in results.

Innovations and breakthroughs

A major confounding factor in previous studies on this subject is that the endoscopists are aware of the high definition equipment and this may have led to bias in polyp detection rates. This study uniquely eliminates the issue of endoscopist bias by using a retrospective model of consecutive colonoscopies.

Applications

By providing added evidence of HDC's role in polyp detection, this study may shift opinion further to the side of lack of benefit in improving yield.

Terminology

Standard colonoscopes typically use 640×480 resolution monitors producing a 307, 200 pixel image. The HDC with high resolution monitors can produce a 1032×768 resolution and a 792, 576 pixel image.

Peer review

The authors examined whether or not HDC resulted in detection of more polyps. The results show no significant difference in polyp detection between SDC and HDC. The results complement the conclusion of other recent studies in this field and suggest that high definition by itself may not improve yield of polyp detection.

SPSS 15.0 software was used for statistical analysis.

RESULTS: Ninety-six (44.4%) patients underwent D1 dissection and 120 (55.6%) had D2 dissection. When groups were evaluated, 23 (24.0%) patients in D1 and 21 (17.5%) in D2 had stage migration ($P = 0.001$). When both D1 and D2 groups were evaluated for number of pathological lymph nodes, despite the fact that there was no difference in N ratio between D1 and D2 groups, a statistically significant difference was found between them with regard to pN1 and pN2 groups ($P = 0.047$, $P = 0.044$ respectively). In D1, pN0 had the longest survival while pN3 had the shortest. In D2, pN0 had the longest survival whereas pN3 had the shortest survival.

CONCLUSION: N ratio is an accurate staging system for defining prognosis and treatment plan, thus decreasing methodological errors in gastric cancer staging.

Abstract

AIM: To identify whether there could have been changes in survival if lymph node ratio (N ratio) had been used.

METHODS: We assessed 334 gastric adenocarcinoma cases retrospectively between 2001 and 2009. Two hundred and sixteen patients out of 334 were included in the study. Patients were grouped according to dissection1 (D1) or dissection 2 (D2) dissection. We compared the estimated survival and actual survival determined by Pathologic nodes (pN) class and N ratio, and

Does N ratio affect survival in D1 and D2 lymph node dissection for gastric cancer? *World J Gastroenterol* 2011; 17(35): 4007-4012 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i35/4007.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i35.4007>

INTRODUCTION

Staging in gastric cancer is usually carried out according to

Japanese Research Society for Gastric Cancer (JRS GC) or Union for International Cancer Control (UICC)/American Joint Committee on Cancer (AJCC) systems. In JRS GC, staging depends on anatomical localization of the involved lymph nodes, whereas the UICC/AJCC system uses number of metastatic lymph nodes. The UICC/AJCC system requires removal of at least 15 lymph nodes^[1-3]. One shortcoming of the UICC/AJCC system is presence of less than 15 nodes in the surgical specimen, which might cause inadequate staging and over-optimistic prediction of prognosis. Only 29%-31% of curative gastric resections include ≥ 15 nodes^[4,5]. Low number of lymph node removal increases risk of shift migration.

In the Japanese system, lymph nodes are classified in stations according to their localization. Lymph node dissections performed according to these stations are expressed as D0, D1, D2, D3. Japanese surgeons generally recommend D2 dissection as gold standard. Experts from the USA and Europe state that there is not a survival difference between D1 and D2 dissections and that there is high postoperative morbidity and mortality rate in D2^[6,7]. However, there are some surgeons in the Western world who support D2 dissection^[8,9].

Lymph node ratio (N ratio) is defined as the ratio of positive lymph nodes to total number of lymph nodes examined^[10]. In the latest publications it is shown that N ratio compared to UICC/AJCC pN class is a more independent prognostic factor and predicts survival more accurately^[11,12]. Tumor nodule metastasis (TNM) classification stages gastric cancers 10%-15% lower than they should be, which causes errors in survival expectations and treatment planning^[13-15]. When N ratio is used instead of pN, there is 10% upgrade in staging which results in a 8.14% decrease in 5 year survival^[16]. When nodal staging in TNM classification is changed to N ratio, pN1 in TNM might become N ratio 2. This alters treatment planning as N ratio 2 requires adjuvant chemoradiation while pN1 does not. Accurate staging is necessary for an accurate adjuvant therapy planning, which can increase survival and quality of life.

In this study, we re-staged patients who previously had either D1 or D2 dissection according to N ratio and investigated whether there could have been a change in treatment and survival if N ratio had been used for staging.

MATERIALS AND METHODS

We retrospectively assessed 334 gastric adenocarcinoma cases who underwent either D1 or D2 lymph node dissection between May 2001 and October 2009. Exclusion criteria were distant metastasis (including macroscopically significant paraaortic, superior mesenteric artery and mid-colic artery lymph node metastasis), D3 and D0 dissections, previous history of gastric surgery, postoperative mortality (death within 30 d postoperatively) and palliative surgery. Two hundred and sixteen patients out of 334 were included in the study. Ninety-six (44.4%) of these patients had D1 dissection and 120 (55.6%) had D2

dissection. Forty-seven patients who were lost in follow up, 17 with insufficient pathology reports, 5 with gastric stump recurrence, 12 who died within 30 d postoperatively, 7 who were inoperable, 15 who had palliative surgery, 12 with D0 dissections, and 3 with D3 dissections made up the excluded 118 patients.

In all patients, dissection was carried out according to JRS GC criteria, taking into account the anatomical localization of primary tumor and lymph nodes (n0 = no lymph node metastasis, n1 = metastasis to N1 lymph nodes, n2 = N2 lymph node metastasis, n3 = N3 lymph node metastasis)^[17]. Metastatic lymph nodes were classified according to UICC/AJCC 2002 criteria. According to these criteria: N0 = no metastasis, N1 = 1-6 lymph node metastasis, N2 = 7-15 lymph node metastasis, N3 = more than 15 lymph nodes metastasis. N ratio was classified according to previously published studies as: N ratio 0 = 0%, N ratio 1 = 1%-10%, N ratio 2 = 11%-25%, N ratio 3 $\geq 25\%$. Patients with adjacent organ involvement or lymph node positivity in histopathological examination were referred to the oncology department.

Patients were grouped according to D1 or D2 dissection. Groups were analyzed for the significance of age (< 70, ≥ 70 years), gender, type of resection (total, subtotal), tumor localization (diffuse, upper 1/3, middle 1/3, lower 1/3), number of lymph nodes removed, number of metastatic lymph nodes, depth of invasion, N class, TNM stage, pathological diagnosis, N ratio and Lauren classification.

Statistical analysis

SPSS 15.0 (SPSS Inc. Chicago, IL, United States) was used for statistical analysis. A *P* value < 0.05 was accepted as statistically significant. Independent two sample *t* test was used for quantitative variables (age, number of lymph nodes, number of pathological lymph nodes). χ^2 test was used for categorical variables (type of surgery, gender, anatomical location of tumor, N ratio, TNM stage, pathological diagnosis).

For survival analysis in the D1 and D2 groups, Kaplan-Meier method was used. Log rank test was used to analyze differences between statistical significances. Log rank test was also used to assess each N class and N ratio crossed with D1 and D2 groups for 5 year survival analysis.

RESULTS

The characteristics of D1 and D2 groups are shown in Table 1. Groups were compared with univariate analysis for significant prognostic factors. There were statistically significant differences in age, localization of primary tumor, depth of invasion and TNM stage (*P* = 0.009, 0.007, 0.001, 0.001, respectively). In 72 (33.3%) cases, more than 15 lymph nodes were identified in pathology specimens. There was a statistically significant difference in D1 and D2 groups regarding > 15 lymph node removal [27 (28.1%), 45 (37.5%), respectively] (*P* < 0.001).

The total number of lymph nodes obtained in all cases in the D1 group was 1381 (14.4 \pm 6.1) and in the D2

D1: D1 lymphadenectomy; D2: D2 lymphadenectomy; N: Groups with respect to number of lymph nodes removed.

pared. None of the N ratio subgroups (N ratio 0, 1, 2, 3) demonstrated statistically significant differences in 5 year survival after D1 or D2 dissections (*P* = 0.389, *P* = 0.070, *P* = 0.192, *P* = 0.267, respectively). In the pN0 and pN3 subgroups, D1 or D2 dissection did not cause a statistically significant change in 5 year survival (*P* = 0.172, not available) while pN1 and pN2 did (*P* = 0.047, *P* = 0.044, respectively).

In the D1 group, 20 patients who were deemed pN0 (no metastasis) were found to be N ratio 0. Twenty-one out of 32 cases (65.6%) with 1-6 lymph node metastasis (pN1) were found to be N ratio 1, while the remaining 11 (34.4%) were classed as N ratio 2. Twenty-eight (70%) of pN2 patients (*n* = 40) were classified as N ratio 2; 12 were classified as N ratio 3. Four patients who had ≥ 16 positive nodes were found to be N ratio 3.

In the D2 group, 26 patients who were classified as pN0 were N ratio 0. Thirty-seven (78.7%) out of 47 pN1 patients were N ratio 1, six of them (12.8%) were N ratio 2 and 4 of them (8.5%) were N ratio 3. Thirty-seven cases were pN2; of which 26 (70.3%) were N ratio 2, and 11 were (29.7%) N ratio 3. All pN3 cases (*n* = 10) were found to be N ratio 3 (Table 3).

When both D1 and D2 groups were evaluated, 23 (24.0%) patients in D1 and 21 (17.5%) in D2 had stage migration (*P* = 0.001).

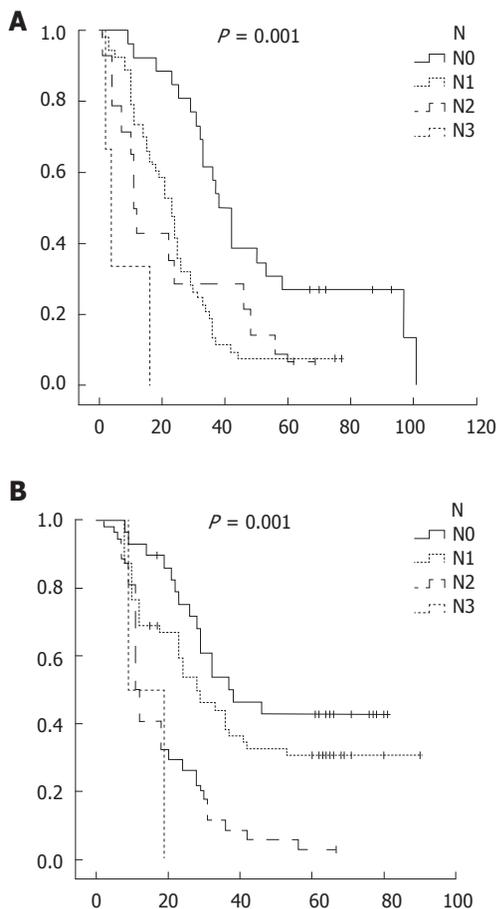

Figure 1 Kaplan meier survival analysis of dissection 1 (A) and dissection 2 (B) group with N class.

In D1, pN0 had the longest survival while pN3 had the shortest. In D2, pN0 had the longest survival whereas pN3 had the shortest survival (Figure 1). In D1, N ratio 0 had the longest survival while N ratio 2 had the shortest (24.3 mo for N ratio 2, 24.8 mo for N ratio 3). In D2, N ratio 1 had the longest survival whereas N ratio 3 had the shortest survival. Overall, 5 year survival was 20.8% ($n = 45$). Survival in the D2 (24.2%) group was longer than in the D1 group (13.3%) ($P < 0.001$) (Figure 2).

DISCUSSION

Staging is of paramount importance in decision making for treatment of cancer. This staging should be universally accepted and standardized. Currently, the most commonly used staging system for gastric cancer is the AJCC/UICC system. For an accurate staging in this system at least 15 nodes are required, thus at least a D2 dissection should be performed (pN3 class requires at least 16 lymph nodes in the specimen). A lesser lymph node dissection is inadequate for predicting survival and making a treatment plan. Sun *et al*^[18], in 2159 curative resections, showed a correlation between total number of lymph nodes and metastatic lymph nodes. In our study, total lymph node number dissected in the D1 group was 1 381 (14.4 ± 6.1) and 2823 (23.5 ± 9.3) in the D2 group. Pathological lymph nodes

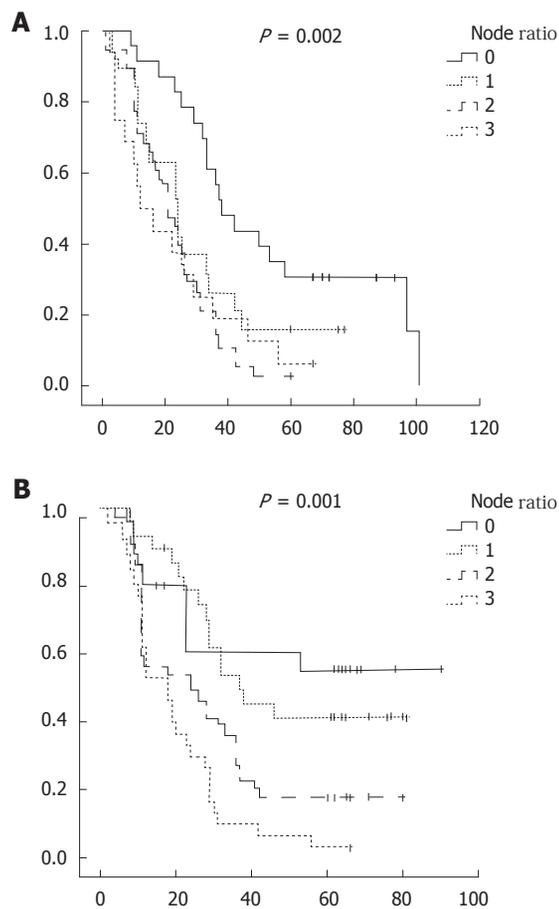

Figure 2 Kaplan meier survival analysis of dissection 1 (A) and dissection 2 (B) group with N ratio.

in the D1 and D2 groups were 374 (3.8 ± 2.2) and 732 (6.1 ± 4.6), respectively. This might mean that in D1 dissection an average of 2.3 lymph nodes are not included in specimens, which could end up in recurrence.

Multivariate analysis shows that N ratio is independent of the number of lymph nodes dissected (even less than 10 lymph nodes is enough for classification)^[11]. Thus, there was no change in N ratio or stage regardless of overall number of dissected lymph nodes. It was Okusa *et al*^[19] who first showed that N ratio in addition to number of positive lymph nodes is a prognostic factor affecting survival in gastric cancer. In contrast to previous study, Bilici *et al*^[20] concluded that in 202 curative gastric resections N ratio and pN were independent prognosticators and did not have superiority over each other. Pedrazzani *et al*^[21], in their study of 526 gastric cancer patients, showed that survival was not different between pN1 and pN2 patients while patients classified as N ratio 1 and 2 had different mortality and survivals.

The aim of lymphadenectomy in gastric adenocarcinoma is to prolong survival. All metastatic lymph nodes should be removed for this purpose. The wider the lymphatic dissection, the higher the chance of removing all metastatic lymph nodes. However, this must be achieved with low mortality and morbidity rates. In their multi-center study, Marchet *et al*^[22] found that in 1853 cases

when D2 dissection was performed, patients who had D1 dissection and were staged as pN1 would turn out to be pN2 or pN3. Bando *et al.*^[15] stated in their study that if their 228 patients with lymph node metastasis (who actually had D2 gastrectomy) had D1 gastrectomy, 103 of them would have been understaged. The authors also stated that using the N ratio would have decreased this shift in staging. Nitti *et al.*^[11] suggested that D2 dissection should be performed to define number of metastatic, reactional or normal lymph nodes and to also decrease stage migration. In our study, in the D1 group, N ratio 0 had the longest survival while N ratio 2 had the shortest. In the D2 group, N ratio 1 had the longest survival despite shortest survival in the N ratio 3 group. There was a statistically significant difference between both N1 and N2 in both the D1 and D2 groups ($P = 0.047$, $P = 0.044$, respectively). N ratio groups did not show any significant difference for either D group.

Another target in gastric cancer treatment is maintaining locoregional control. Wide lymph node dissection is necessary for this. In one study, it was shown that higher number of lymph nodes provides better staging and more accurate prediction of prognosis^[23]. Marchet *et al.*^[22] stated that 15 lymph nodes was the cut off point for statistical significance for survival in corresponding N ratio groups. In 257 patients with D1 gastrectomy, Maduekwe *et al.*^[24] obtained an average of 14 lymph nodes and showed that cases with > 15 lymph node removal had better overall survival than cases with < 15 nodes in pathology specimen. Karpeh *et al.*^[25] showed in 1038 gastric cancer patients that there was an increase in median survival in patients with ≥ 15 lymph node removal. When the same patients were staged with N ratio independent from number of lymph nodes, there was no difference in survival. In our study, we resected ≥ 15 nodes in 27 (28.1%) patients in the D1 group and 45 (32.5%) patients in the D2 group ($P < 0.001$). When each group was analyzed separately, stage migration was less in D2 when compared to D1 (17.5% and 24.0%, respectively).

Curative gastric resections include total gastrectomy or subtotal gastrectomy. Total gastrectomy should be performed for patients with proximal, middle or diffusely located cancers. Prospective, randomized studies have proven that in distally-located tumors, total gastrectomy does not have an advantage over distal subtotal gastrectomy^[26]. The crucial point is achieving tumor-free distal and proximal margins. Extent of gastric resection does not affect the predictive power of N ratio. Huang *et al.*^[10] showed that in 634 distal gastrectomy patients, N ratio was more accurate in predicting survival than pN stage, thus better for treatment planning.

It might not be radical to say that until a reliable staging with less stage migration is proposed, N ratio could be used for staging. Regardless of the lymph node staging used, a wide lymph node dissection should be done to prevent errors in staging. The shortcomings of our study were mainly the number of cases involved and the retrospective design. Prospective, multicenter trials are needed to better define whether N ratio should replace pN stag-

ing in gastric cancer.

In conclusion, N ratio is an accurate and up-to-date staging system for defining prognosis and treatment plan, thus decreasing methodological errors in gastric cancer staging. We believe that, in order to better evaluate prognosis and define a treatment plan, D2 dissection should be the preferred option instead of D1 dissection.

COMMENTS

Background

Staging in gastric cancer is usually carried out according to Japanese Research Society for Gastric Cancer or Union for International Cancer Control /American Joint Committee on Cancer systems. The authors tried to identify whether there could have been change in survival if Node ratio had been used for classification of gastric cancer.

Research frontiers

In this study, the authors re-staged patients who previously had either dissection 1 and dissection 2 according to N ratio and investigated whether there could have been a change in treatment and survival if N ratio had been used for staging.

Innovations and breakthroughs

N ratio is an accurate and up-to-date staging system for defining prognosis and treatment plan, thus decreasing methodological errors in gastric cancer staging. In order to better evaluate prognosis and define a treatment plan, D2 dissection should be the preferred option instead of D1 dissection.

Peer review

This study retrospectively analyzed relationships between n-factors and prognosis among gastric cancer patients who underwent D1 or D2 resection, and concluded that N ratio, which is defined as the ratio of positive lymph nodes to total number of lymph nodes examined, is an accurate staging system for defining prognosis and treatment plan.

Abstract

AIM: To study the outcome of patients undergoing surgical resection of the bowel for sustained radiation-induced damage intractable to conservative management.

METHODS: During a 7-year period we operated on 17 cases (5 male, 12 female) admitted to our surgical department with intestinal radiation injury (IRI). They were originally treated for a pelvic malignancy by surgical resection followed by postoperative radiotherapy. During follow-up, they developed radiation enteritis requiring surgical treatment due to failure of conservative management.

RESULTS: IRI was located in the terminal ileum in 12 patients, in the rectum in 2 patients, in the descending

colon in 2 patients, and in the cecum in one patient. All patients had resection of the affected region(s). There were no postoperative deaths, while 3 cases presented with postoperative complications (17.7%). All patients remained free of symptoms without evidence of recurrence of IRI for a median follow-up period of 42 mo (range, 6-96 mo).

CONCLUSION: We report a favorable outcome without IRI recurrence of 17 patients treated by resection of the diseased bowel segment.

INTRODUCTION

Intestinal radiation injury (IRI) is a common complication of radiation therapy for rectal, gynecologic and urologic malignancies. Despite improvements in radiation

technology, the incidence of IRI is increasing mainly as a consequence of the rapidly expanding application of radiation plus chemotherapy in the management of pelvic malignancies^[1,2]. It usually develops either early as acute radiation enteropathy, during or shortly after radiation therapy and resolving within 2-6 wk, or late, from 6 mo to as long as 30 years post radiotherapy as a chronic injury^[3-9]. Although the true incidence of IRI has not been well defined, it varies from 1.2% to as high as 37% especially in patients with rectal cancer^[5,6,8].

Surgical management of IRI patients adopts either a conservative approach with adhesiolysis, and/or creation of diverting stomas, or a more radical operation with resection of the diseased segment of the bowel. Morbidity, mortality and recurrence rate after these two surgical options in the management of radiation enteropathy have not been well documented.

We report on the clinical presentation, pathology and outcome of 17 consecutive IRI cases managed by surgical removal of the diseased segment.

MATERIALS AND METHODS

Of the 1261 patients irradiated for pelvic malignancies in the radiotherapy department of Metaxa Cancer Memorial Hospital during a 7-year period, 83 were hospitalized for IRI and 17 (5 male, 12 female) required surgery. Their mean age was 69.3 years (range, 46-88). They were irradiated with a mean dose of 48.6 Gy (range, 40-55Gy) for pelvic visceral organ malignancies. Their main presenting symptoms were: intractable abdominal pain in 10 patients, rectal bleeding in 5 patients, intractable diarrhea in 5, constipation in 3 and vomiting in 3. Eleven of the 17 patients had obstructive ileus and malabsorption before surgery. Table 1 provides comprehensive data of the operated patients.

Upon admission, all patients submitted to routine laboratory tests, endoscopic examination with biopsies, barium contrast studies of the small intestine and colon as required and computed tomography scans of the abdomen and pelvis. On admission they were placed on supportive measures to deal with the acute clinical situation and finally surgery was decided for failure of the conservative management approach.

RESULTS

Of the 17 patents, 12 had right hemicolectomy, 3 had sigmoidectomy and 2 underwent low anterior resection. We treated all patients by resection of a variable length of bowel and primary anastomosis and only 2 required an isolated stoma after resection. Figure 1 shows characteristic histological manifestations of the broad range of IRIs observed in our patient group (Figure 1B-D) relative to normal tissue (Figure 1A).

No postoperative death was recorded while morbidity was seen in 3/17 patients. Two patients developed abdominal wound infection and one an enterocutaneous

fistula that was treated conservatively and required prolonged hospital stay (Table 1). No evidence of recurrent IRI disease was observed during a median follow-up period of 42 mo (range, 6-96 mo).

DISCUSSION

IRI symptoms appeared 6 mo to several years after radiation therapy. Their severity was disproportional to the extent of mucosal damage projected from the histology of the resected bowel (Figure 1). The shortened bowel and its mesentery along with marked compromise of the vasculature were common operative findings.

It is well recognized today that radiation-induced intestinal fibrosis seems to be the unifying underlying cause for most symptoms in patients who undergo postoperative radiotherapy for intra-abdominal malignancies. Abdominal pain, the most frequent symptom, is commonly due to intestinal obstruction or colonic loading and spasm, both treatable either by conservative measures or surgery^[10].

The exact incidence of enteropathy lesions from radiotherapy varies considerably^[11]. When a total radiation dose of 45 Gy is delivered, chronic radiation lesions will be observed in 5% of patients. With 65 Gy of radiation, as many as 50% of patients are likely to be affected. Late injuries develop in 2%-8% of patients within 12 to 30 mo after treatment^[12-14]. A decreasing daily radiation dose increases the number of required sessions and minimizes radiation injury to normal tissue^[15]. Certain medical conditions, such as diabetes mellitus, hypertension and cardiovascular disease, that affect blood supply and compromise the splanchnic circulation are associated with a higher incidence of bowel injury^[16].

In our series no postoperative death occurred and the patient morbidity was 17.7% (Table 1). Reappraisal of the surgical treatment on 48 IRI patients reported 21.7% morbidity and 4.1% mortality following small bowel resection of the radiation-damaged bowel and restorative proctectomy for rectal disease^[17]. Similar findings of 4.5% mortality and 30.2% morbidity after bowel resection on 109 operated patients with radiation enteritis and good life expectancy without recurrence of previous neoplastic disease have previously been reported^[18].

The total dose of radiation therapy delivered to our patients never exceeded 55 Gy. In all patients adhesiolysis was performed before the definitive surgical procedure. All patients were followed for a median time of 42 mo and showed no evidence of IRI recurrence.

It is well known that acute infections secondary to mucositis of the oral cavity appear as complications after systemic chemotherapy and local radiation therapy for head and neck cancers^[19]. Potential causes of increased incidence of infections are vascular damage impairing oxygen delivery and immunologic function, lymphatic vascular injury leading to lymphedema and soft tissue necrosis. Similarly, the radiation-induced bowel injury in patients who have also received chemotherapy renders them susceptible

Table 1 Clinical presentation and surgical management of radiation enteritis patients

Sex/age (yr)	Primary site of tumor	Radiation dose/period delivered (Gy/wk)	Dominant symptoms	Localization of radiation lesions	Procedure	Morbidity/mortality	Follow-up (mo)

M: Male; F: Female; SML: Spinal metastasis from lung cancer; PR: Per rectum; RC: Right colectomy; LC: Left colectomy; LAR: Low anterior resection; SWI: Surgical wound infection.

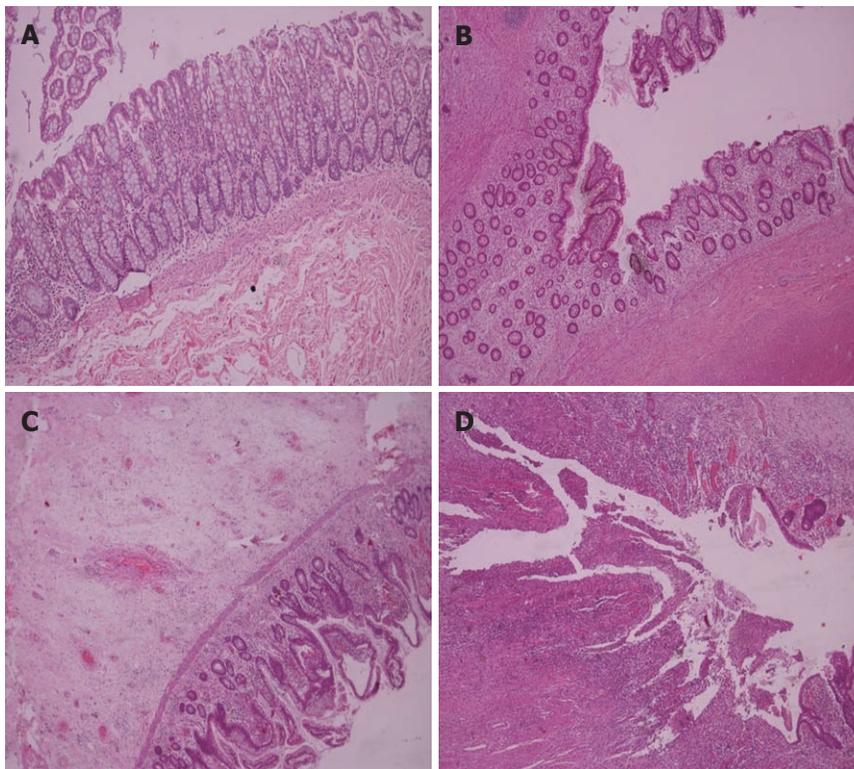

Figure 1 Representative histologic findings of normal (A) and radiation enteritis associated (B-D) intestinal mucosa. A: Normal; B: Mild lesions with edema and increased number of fibroblasts; C: Moderate lesions with sub-mucosal edema and disturbed mucosal architecture; D: Severe lesions with mucosal ulceration. Tissue sections were stained with standard hematoxylin-eosin (40 x magnification).

to septic complications. Thus, when surgery is mandatory and resection is feasible, it should be performed, since removal of the diseased bowel segment acting as a possible source of sepsis diminishes the risk of recurrence of IRI and improves patient outcome.

Use of preventive surgical measures to avoid the harmful consequences of IRI is the most preferable choice^[20]. The 2 most common techniques utilized for IRI preven-

tion have been the omental flap used as a sling across the pelvis^[21] and an absorbable mesh to suspend the small intestine up out of the true pelvis. Another surgical technique involves peritoneal reconstruction using the posterior rectus sheath to form a tissue shelf just at the level of the umbilicus, suturing this to the sacral promontory^[22,23]. Although the long-term efficacy of the above techniques is unproven, the poly-glycolic acid mesh sling appears to

be the most reliable and reasonable method of keeping the small intestine out of the pelvis when postoperative pelvic radiation therapy is contemplated^[24,25].

In conclusion, functional staging of IRI^[26-28] may reveal either acute radiation enteritis or chronic radiation injury that should be managed conservatively. If that fails and resection of the diseased bowel is feasible^[29], it should be adopted in all cases without exception.

COMMENTS

Background

Surgical resection of the radiation damaged bowel segment and primary anastomosis whenever possible is accompanied by a better outcome in patients who failed to respond to the original conservative management due probably to the removal of a septic area following surgical resection of the original pelvic malignancy and postoperative radiotherapy.

Research frontiers

The reasoning of this study is the development of an area in the radiation-damaged bowel that serves as a potential cause of sepsis not responding to conservative management and requiring radical measures for effective treatment.

Innovations and breakthroughs

Surgical removal of a sepsis inside the abdomen is always more effective resulting in a better outcome.

Applications

It is always desirable to be able to treat patients suffering from serious complications of radiation enteritis with radical resection if they fail conservative management.

Peer review

The article is an important topic. The problem of radiation-induced intestinal injury causes important morbidity. The number of patients in this series is small. However, the results are impressive.

Abstract

AIM: To study the production and secretion of corticotropin-releasing factor (CRF) by dendritic cells and the influence of commensal bacteria.

METHODS: JAWSII cells (ATCC CRL-11904), a mouse dendritic cell line, were seeded into 24-well culture plates and grown for 3 d. Commensal bacterial strains of *Clostridium clostridioforme* (JCM1291), *Bacteroides vulgatus* (*B. vulgatus*) (JCM5856), *Escherichia coli* (JCM1649), or *Fusobacterium varium* (*F. varium*) (ATCC8501) were added to the cells except for the control well, and incubated for 2 h. After incubation, we performed enzyme-linked immunosorbent assay for the cultured medium and reverse transcription polymerase chain reaction for the dendritic cells, and compared these values with controls.

RESULTS: The level of CRF secretion by control dendritic cells was 40.4 ± 6.2 pg/mL. The CRF levels for cells incubated with *F. varium* and *B. vulgatus* were significantly higher than that of the control ($P < 0.0001$). CRF mRNA was present in the control sample without bacteria, and CRF mRNA levels in all samples treated with bacteria were above that of the control sample. *F. varium* caused the greatest increase in CRF mRNA expression.

CONCLUSION: Our results suggest that dendritic cells produce CRF, a process augmented by commensal bacteria.

Key words: Commensal bacteria; Corticotrophin-releasing factor; Dendritic cell; *Fusobacterium varium*; Irritable bowel syndrome

INTRODUCTION

Corticotropin-releasing factor (CRF), a 41-amino acid peptide, is produced mainly in the paraventricular nucleus of the hypothalamus. CRF is a key regulator of the hypothalamic-pituitary adrenal axis. Release of CRF leads to pituitary production of adrenocorticotrophic hormone,

followed by glucocorticoid secretion by the adrenal cortex^[1-5]. Stress induces the release of CRF by the hypothalamus^[6]. Stress is known to delay gastric emptying, accelerate colonic transit and evoke colonic motility^[7-9], and to decrease the visceral threshold^[10] resulting in the development of abdominal symptoms. These events can be triggered by intracerebroventricular or intravenous administration of CRF^[18,9,11-13], while stress-induced gastrointestinal dysmotility and visceral hypersensitivity can be improved by central or peripheral administration of a non-selective CRF receptor antagonist^[14-16]. Accordingly, stress can induce changes in gastrointestinal motility and visceral perception through CRF. Stressful events are more common in irritable bowel syndrome (IBS) patients^[17]. Gastrointestinal dysmotility and visceral hypersensitivity, which are often observed in IBS patients, play an important role in the pathogenesis of IBS^[18,19]. Therefore, it appears that CRF is involved in the pathogenesis of IBS.

The risk of developing IBS is increased after an episode of bacterial gastroenteritis. Rodríguez *et al.*^[20] reported that the risk of developing IBS after bacterial gastroenteritis increased by 14.4-fold compared to the general population. Three months after development of bacterial gastroenteritis, patients with IBS symptoms and those without IBS symptoms appeared to be negative for macroscopic colitis, but only patients with IBS symptoms showed increases in the number of chronic inflammatory cells^[21]. Moreover, intraepithelial lymphocytosis is observed in some IBS patients without history of bacterial gastroenteritis^[22]. Accordingly, inflammation is also involved in the pathogenesis of IBS. The colitis that develops spontaneously in animal models^[23-26] requires the presence of intestinal flora, since the disease fails to develop under germ-free conditions. Thus, it appears that commensal bacteria affect the intestinal mucosa and may be required for chronic intestinal inflammation. Dendritic cells (DCs) recognize luminal antigens (such as bacteria or viruses) through toll-like receptors (TLRs), activate natural immunity, and act as antigen-presenting cells resulting in the activation of acquired immunity. Consequently, it is possible that DCs react to common intestinal microbes.

CRF is present not only in the brain but also in several other human tissues, such as the spinal cord, adrenal medulla, lung, liver, pancreas, placenta, and gastrointestinal tract^[27-31], and in arthritic joints of patients with rheumatoid arthritis^[32]; however, other tissues may also serve as a source of CRF. Lymphocytes appear to be an important source of immunoreactive CRF^[33-35], and normal human colonic mucosal enterochromaffin cells have also been reported to produce CRF^[36]. Moreover, CRF receptor expression in DCs was recently reported^[37]; however, the possibility that CRF is present in DCs has not yet been investigated.

We hypothesize that (1) DCs produce and secrete CRF; (2) that some commensal bacteria augment these processes; and (3) that secreted CRF influences gut motor function and visceral perception prior to the development of IBS. In the present study, we examined whether CRF

is produced or secreted by DCs, and whether production or secretion of CRF from DCs is augmented by commensal bacteria.

MATERIALS AND METHODS

Dendritic cell cultures

Mouse dendritic cells (JAWS II; ATCC CRL-11904) were obtained from the American Type Culture Collection (ATCC; Manassas, VA, United States). JAWS II cells were grown in alpha minimum essential medium with ribonucleosides + deoxyribonucleosides (Gibco, Invitrogen Co., NY, United States) containing 20% fetal bovine serum (Thermo Electron Corp. Melbourne, AU) and 5 ng/mL murine GM-CSF (PeproTech EC, London, United Kingdom). 1×10^5 JAW II cells per well were added to 24-well culture plates (Corning Inc., Corning, NY, United States) and incubated for 72 h under 5% CO₂ at 37 °C in a humidified incubator.

Bacterial strains and culture conditions

We used 4 type strains: *Clostridium clostridioforme* (*C. clostridioforme*) (JCM1219; Japan Collection of Microorganisms, RIKEN, Wako, Japan), *Bacteroides vulgatus* (*B. vulgatus*) (JCM5826), *Escherichia coli* (*E. coli*) (JCM1649), and *Fusobacterium varium* (*F. varium*) (ATCC8501; ATCC, Rockville, MD, United States). These strains have been reported to be pathogens for inflammatory diseases such as ulcerative colitis^[38-40]. The bacterial strains were harvested in GAM agar plates (Nissui Pharmaceutical Co. Ltd., Tokyo, Japan) at 37 °C for 72 h. Aerobic bacteria (*E. coli*) were incubated under 5% CO₂ in a humidified incubator. Anaerobic bacteria (*C. clostridioforme*, *B. vulgatus*, and *F. varium*) were incubated in an anaerobic chamber (Forma Scientific, Marietta, Ohio) containing 10% CO₂, 10% H₂, and 80% N₂. After collection of colonies with a disposable plastic loop, they were suspended at 1×10^5 cells/mL in the same medium as used for dendritic cell culture and used immediately.

Sample preparation

JAWS II cells were grown to near confluence before infection with bacteria. Bacteria were added into each well, except the control well, at a cell to bacteria ratio of 1:1000 and incubated for 2 h under 5% CO₂ at 37 °C. Following incubation, conditioned medium and floating cells were collected using a pipette and attached cells were removed from the wells using a cell scraper. All cells with medium were pooled and centrifuged at $125 \times g$ for 7 min according to the manufacturer's instructions. The pelleted cells were resuspended in 200 µL of Isogen (Nippon Gene, Inc., Japan) and frozen at -80 °C. Conditioned medium was also stored at -80 °C.

Detection of CRF by ELISA

To examine whether dendritic cells secrete CRF, enzyme-linked immunosorbent assays (ELISAs) were conducted for the conditioned medium using commercial assay kits

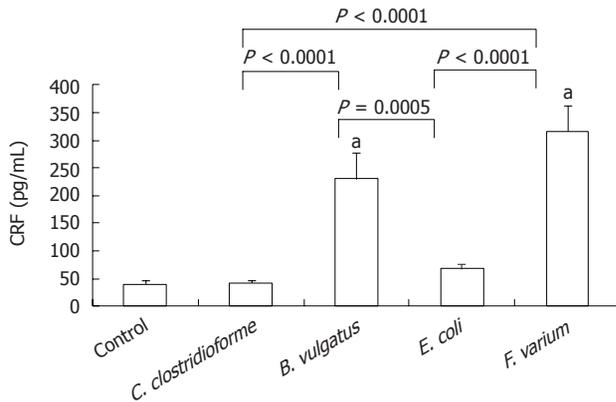

Figure 1 Detection of corticotropin-releasing factor by enzyme-linked immunosorbent assay. JAWS II cells were treated with indicated bacteria for 2 h and conditioned medium was examined by enzyme-linked immunosorbent assay. Data represent the mean \pm SEM of 8 independent experiments. Statistical analysis was carried out using analysis of variance and Fisher's protected least significant difference. ^a $P < 0.0001$ vs control. CRF: Corticotropin-releasing factor; *C. clostridioforme*: *Clostridium clostridioforme*; *B. vulgatus*: *Bacteroides vulgatus*; *E. coli*: *Escherichia coli*; *F. varium*: *Fusobacterium varium*.

(CRF EIA kit; Phoenix Pharmaceuticals Inc., CA, United States). Data represent the averages of 8 independent experiments.

Detection of CRF mRNA by real-time reverse transcription polymerase chain reaction

Total RNA was isolated from cells using an RNeasy Mini Kit (QIAGEN, Inc., Chatsworth, CA), and treated with an RNase-free DNase Set (QIAGEN) following the manufacturer's instructions. RT for synthesizing the first-strand cDNAs was carried out using SuperScript II RT (Invitrogen) according to the manufacturer's instructions. The resultant cDNA corresponding to 10-100 ng of total RNA in a 25 μ L final volume was examined by real time PCR using the ABI PRISM 7700 sequence detection system (Applied Biosystems, CA, United States) with Taqman Universal PCR Master Mix together with TaqMan gene expression assay products (Assay ID Mm01293920-s1; Applied Biosystems). Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene expression was examined as an internal reference and CRF gene expression was examined by means of the comparative C_T method. C_T values reflect the PCR cycle number for which the amount of amplified target reaches a fixed threshold. The C_T for the target gene and reference gene was calculated for each sample. ΔC_T is the difference in C_T between the target and reference genes. $\Delta\Delta C_T$ is the difference between the ΔC_T of the sample and the ΔC_T of the calibrator (the control sample). CRF mRNA expression normalized to an internal reference and expressed relative to the control sample treated without bacteria is given by $2^{-\Delta\Delta C_T}$. Data represent the averages of 4 independent experiments.

Statistical analysis

All the data were expressed as mean values \pm SEM. Sta-

tistical analysis was carried out with analysis of variance and Fisher's protected least significant difference. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Secretion of CRF and augmentation of secretion upon infection with commensal bacteria

The level of CRF secretion by DCs was 40.4 ± 6.2 pg/mL [95% confidence interval (CI), 25.7-55.2]. When commensal bacteria of the strains *C. clostridioforme* JCM1291, *B. vulgatus* JCM5826, *E. coli* JCM1649 and *F. varium* ATCC8501 were added, the level of CRF secretion by DCs was 41.9 ± 4.9 pg/mL (95% CI, 30.4-53.4), 230.7 ± 46.7 pg/mL (95% CI, 120.3-341.1), 67.9 ± 8.0 pg/mL (95% CI, 49.0-86.7) and 316.9 ± 46.4 pg/mL (95% CI, 207.1-426.6), respectively (Figure 1). The CRF levels for both *F. varium* and *B. vulgatus* were significantly higher than that of the control ($P < 0.0001$). When CRF levels for different bacterial strains were compared, the levels for both *F. varium* and *B. vulgatus* were significantly higher than for *E. coli* ($P < 0.0001$, $P = 0.0005$) and *C. clostridioforme* ($P < 0.0001$, $P < 0.0001$), respectively.

Induction of CRF mRNA upon infection with commensal bacteria

CRF mRNA was present in all samples. Mean C_T values were as follows: control, 27.44; *C. clostridioforme*, 25.70; *B. vulgatus*, 25.96; *E. coli*, 26.27; *F. varium*, 24.63. *F. varium* caused the greatest increase in CRF mRNA expression (3.7 ± 0.2 fold increase; 95% CI, 3.1-4.3 fold), followed by *E. coli* (2.4 ± 0.4 ; 1.3-3.6), *B. vulgatus* (2.2 ± 0.3 ; 1.2-3.2), and *C. clostridioforme* (1.6 ± 0.1 ; 1.1-1.2). The 95% CI for CRF mRNA levels in all samples treated with the indicated bacteria were above that of the control sample without bacteria, indicating that the bacteria significantly stimulated CRF mRNA expression (Figure 2). A comparison of CRF mRNA levels in different bacterial strains showed that levels were significantly higher with *F. varium* than with the other bacteria ($P < 0.0001$ vs *C. clostridioforme*, $P < 0.0018$ vs *B. vulgatus*, $P < 0.006$ vs *E. coli*). The CRF mRNA level for *E. coli* was significantly higher than for *C. clostridioforme* ($P = 0.0398$).

DISCUSSION

The results from this study demonstrate that DCs can secrete CRF protein. Moreover, secretion of the CRF protein and expression of CRF mRNA were stimulated after challenge with commensal bacteria.

The term "commensal" generally refers to living in a relationship in which one organism derives food or other benefits from another organism without hurting or helping it; therefore, intestinal microorganisms have been referred to as commensal bacteria. Studies with animal models of mucosal inflammation, such as the interleukin-10 knockout mouse model^[24,26] and the T cell receptor alpha-chain-deficient mouse model^[25], suggested that

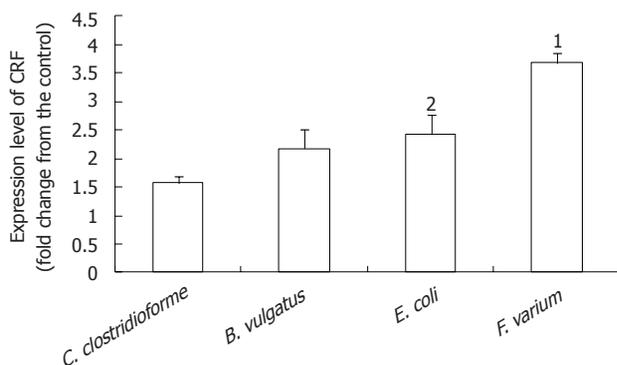

Figure 2 Corticotropin-releasing factor expression determined by comparative Ct method. JAWS II cells were treated with the indicated bacteria for 2 h. After treatment, total RNA was isolated from cells. Ct value reflects the polymerase chain reaction cycle number for which the amount of amplified target reached a fixed threshold. Data represent the mean \pm SEM of 4 independent experiments. Statistical analysis was carried out using analysis of variance and Fisher's protected least significant difference. ¹Significantly higher than other indicated bacteria [$P < 0.0001$ vs *Clostridium clostridioforme* (*C. clostridioforme*), $P < 0.0018$ vs *Bacteroides vulgatus*, $P < 0.006$ vs *Escherichia coli*]. ²significantly higher than *C. clostridioforme* ($P = 0.0398$). CRF: Corticotropin-releasing factor; *C. clostridioforme*: *Clostridium clostridioforme*; *B. vulgatus*: *Bacteroides vulgatus*; *E. coli*: *Escherichia coli*; *F. varium*: *Fusobacterium varium*.

the presence of intestinal flora was required in order for colitis to develop spontaneously, since the disease failed to develop under germ-free conditions. Bacterial overgrowth in the small intestine is associated with the severity of symptoms of IBS associated with increased intestinal gas and immune responses, and antibiotic therapy has been shown to attenuate IBS symptoms in human patients^[41]. Thus, intestinal flora that have been described as commensal flora may actually have several harmful effects on the intestinal mucosa.

DCs recognize luminal antigens, and consequently trigger mucosal inflammation. In such instances, DCs may react to common intestinal microbes and may increase the output of CRF. In the present study, the commensal bacteria *F. varium* and *B. vulgatus* resulted in a significant increase in CRF protein levels as compared with control samples that were not exposed to bacteria. All 4 bacterial strains caused an increase in the expression of CRF mRNA as compared with control samples. Thus, all of the bacterial strains examined in this study appear to have the ability to increase the output of CRF from DCs. *F. varium* appeared to have the strongest effect, since CRF mRNA levels in the presence of *F. varium* were significantly higher than in the presence of the other bacteria. *C. clostridioforme* had the lowest ability to increase both CRF protein and CRF mRNA from DCs. *C. clostridioforme* are the only gram-positive bacteria of the 4 strains examined in this study. Gram-negative bacteria activate immune cells through TLR4 of DCs, while gram-positive bacteria initiate their effect through TLR2^[42]. Differences in such pathways may lead to different results. In further work, another intestinal microbe such as probiotic bacteria should be examined. As probiotic bacteria should have a potentially beneficial effect for the host^[43], it would be of great interest to similarly examine the response of DCs

with regard to CRF levels.

JAWS II cells, a type of DC, are derived from the bone marrow. In the murine Peyer's patch, myeloid DCs are present in the subepithelial dome region. While little is known about the phenotype of colonic DCs, it was recently reported that myeloid DCs made up the largest population^[44]. Thus, JAWS II cells are thought to have the character of colonic DCs. Additional studies with human colonic DCs would be valuable, as would further studies to delineate the processes by which commensal bacteria increase the amount of CRF from DCs.

In conclusion, DCs produce and secrete CRF, and commensal bacteria augment production or secretion of CRF from DCs. The results of the present study suggest that the secretion of CRF from DCs is stimulated by commensal bacteria in the gut, and that CRF derived from DCs may play a role in the pathogenesis of IBS.

COMMENTS

Background

Corticotropin-releasing factor (CRF) influencing gut motor function and visceral perception appears to be involved in the pathogenesis of irritable bowel syndrome (IBS). Intestinal inflammation is associated with post-infectious IBS, and also observed in some IBS patients without history of bacterial gastroenteritis. Intestinal inflammation may be triggered by dendritic cell-mediated immune responses to commensal bacteria, which may involve CRF generation by dendritic cells (DCs).

Research frontiers

Spontaneously developing colitis requires intestinal flora, since colitis fails to develop under germ-free conditions. DCs recognize luminal exogenous antigens and activate natural and acquired immunity. It is possible that DCs react to common intestinal microbes. CRF is present in several human tissues, and CRF receptor expression in DCs was recently reported. There has been no report on the production and secretion of CRF from DCs.

Innovation and breakthroughs

This is the first report that DCs produce and secrete CRF and that commensal bacteria augment production or secretion of CRF from DCs.

Applications

DCs produce and secrete CRF and some commensal bacteria augment these processes. Secreted CRF may influence gut motor function and visceral perception prior to the development of IBS. Accordingly, the results of this study may shed light on the pathogenesis of irritable bowel syndrome.

Terminology

CRF is produced mainly in the paraventricular nucleus of the hypothalamus, but recently has been reported to be present not only in the brain but also in several other human tissues. CRF is a key regulator of the hypothalamic-pituitary-adrenal axis, and it appears that CRF is involved in the pathogenesis of IBS.

Peer review

The manuscript reports the effect on CRF secretion in short term cultures (3 d) by a murine dendritic cell line following incubation with three different commensal bacterial strains. The methodology appears generally well conceived and the manuscript is well written. The conclusions that dendritic cells produce and secrete CRF and that commensal bacteria augment production or secretion of CRF from dendritic cells are straightforward and justified by the results obtained, although the biological significance of the observations remains obscure.

Abstract

AIM: To investigate the role and clinicopathological significance of aberrant expression of Notch receptors and Delta-like ligand-4 (DLL4) in extrahepatic cholangiocarcinoma and gallbladder carcinoma.

METHODS: One hundred and ten patients had surgically resected extrahepatic cholangiocarcinoma (CC) and gallbladder carcinoma specimens examined by immunohistochemistry of available paraffin blocks. Immunohistochemistry was performed using anti-Notch receptors 1-4 and anti-DLL4 antibodies. We scored the immunopositivity of Notch receptors and DLL4 expres-

sion by percentage of positive tumor cells with cytoplasmic expression and intensity of immunostaining. Coexistent nuclear localization was evaluated. Clinicopathological parameters and survival data were compared with the expression of Notch receptors 1-4 and DLL4.

RESULTS: Notch receptor proteins showed in the cytoplasm with or without nuclear expression in cancer cells, as well as showing weak cytoplasmic expression in non-neoplastic cells. By semiquantitative evaluation, positive immunostaining of Notch receptor 1 was detected in 96 cases (87.3%), Notch receptor 2 in 97 (88.2%), Notch receptor 3 in 97 (88.2%), Notch receptor 4 in 103 (93.6), and DLL4 in 84 (76.4%). In addition, coexistent nuclear localization was noted [Notch receptor 1; 18 cases (18.8%), Notch receptor 2; 40 (41.2%), Notch receptor 3; 32 (33.0%), Notch receptor 4; 99 (96.1%), DLL4; 48 (57.1%)]. Notch receptor 1 expression was correlated with advanced tumor, node, metastasis (TNM) stage ($P = 0.043$), Notch receptor 3 with advanced T stage ($P = 0.017$), tendency to express in cases with nodal metastasis ($P = 0.065$) and advanced TNM stage ($P = 0.052$). DLL4 expression tended to be related to less histological differentiation ($P = 0.095$). Coexistent nuclear localization of Notch receptor 3 was related to no nodal metastasis ($P = 0.027$) and Notch receptor 4 with less histological differentiation ($P = 0.036$), while DLL4 tended to be related inversely with T stage ($P = 0.053$). Coexistent nuclear localization of DLL4 was related to poor survival ($P = 0.002$).

CONCLUSION: Aberrant expression of Notch receptors 1 and 3 play a role during cancer progression, and cytoplasmic nuclear coexistence of DLL4 expression correlates with poor survival in extrahepatic CC and gallbladder carcinoma.

INTRODUCTION

Cholangiocarcinoma (CC) is a highly malignant neoplasm that generally is diagnosed at advanced stage and is associated with a fatal outcome^[1]. CC includes cancers originating by malignant transformation of biliary epithelial cells, histologically occurring in the intrahepatic and extrahepatic biliary trees with gallbladder. The extrahepatic CC accounts for 80% to 90% of CC and intrahepatic CC comprises the remainder^[1]. The incidence of intrahepatic CC is increasing, in comparison with the stagnant incidence of extrahepatic CC, especially in Western countries^[2], although the cause of rising incidence of intrahepatic CC has not been clarified. Intrahepatic and extrahepatic CCs differ in biologic and clinical variables, including not only histopathologic distinction and clinical characteristics, but also carcinogenesis and molecular profiling, even management. In order to define the carcinogenesis of CC, dysregulated genes and pathways involved in proliferation, evasion from apoptosis and senescence, cell cycle dysregulation, invasion, metastasis and angiogenesis, have all been investigated, suggesting a complex network of variable factors and pathways^[3,4]. The development of new therapeutic modalities for molecular targeting resulting from defining of the molecular carcinogenesis of CC has been growing recently, mainly as a consequence of preclinical *in vitro* studies. Till now, complete surgical resection has been regarded as the only curative therapy.

Since the Notch gene was originally discovered in *Drosophila*, Notch signaling has been investigated in varied organisms from *C. elegans* to humans. Thus, Notch signaling has been noted to be an evolutionally conserved pathway which regulates physiological processes and is involved in pathological conditions^[5]. There are four Notch receptors (Notch 1-4) and five ligands [Jagged 1, Jagged 2, Delta-like ligand-1, -3 and -4 (DLL1, DLL3, DLL4)] in mammals. Ligand-receptor interaction between two neighboring cells activates two sequential proteolytic cleavages of Notch receptor, mediated by the metalloprotease tumor necrosis factor- α -converting enzyme, and by γ -secretase^[6]. The liberated Notch intracellular domain translocates into the nucleus, activating target genes, such as *Hex*, *Hey*, etc. Physiologically, Notch signaling regulates cellular differentiation, proliferation, apoptosis and stem cell maintenance, and participates in cell-fate specification during development of multicellular organisms^[7]. Also, Notch signaling regulates biological events in adult tissue. Recently, the disruption of Notch gene was reported to

be implicated in hematological malignancies^[8,9]. In addition, aberrant Notch signaling has been reported in a variety of solid cancers, including breast, kidney, pancreas, prostate, cervix, endometrium, brain, lung, liver and skin^[10-12]. According to the type of cancer, Notch receptors may have a role as an oncogene or a tumor suppressor gene, though the majority of studies reveal that Notch signaling promotes tumorigenesis^[13]. In both physiological and pathological angiogenesis including tumor angiogenesis, the role of Notch signaling has been recognized^[8].

DLL4 is an endothelial-specific ligand of the Notch signaling pathway, expressed at areas of vasculogenesis and angiogenesis^[14,15]. DLL4 is induced by vascular endothelial growth factor (VEGF) and acts to the downstream of VEGF, as an autoregulatory negative feedback network for inactivation of VEGF, resulting in maturation and stabilization of microvessels^[14]. Recently, in addition to endothelium, DLL4 has been shown to be expressed in epithelium, stromal cells of inflammatory cells in normal or reactive tissues, and in tumor cells of solid cancers in humans^[16], raising possibilities for a role in tumorigenesis.

In this study, we investigated the role of Notch receptors and DLL4 in progression of human extrahepatic CC and gallbladder carcinoma by analysis of expression with immunohistochemistry (IHC), during carcinogenesis. Furthermore, we investigated the correlations between aberrant expression of Notch receptors and DLL4, and clinicopathological parameters with survival.

MATERIALS AND METHODS

Patient selection and specimens

One hundred and ten patients with surgically resected extrahepatic CC and gallbladder carcinoma were included in this study, from January 1999 till December 2008 at Dong-A University Hospital, Busan, South Korea. None of the patients recruited in this study received chemotherapy or radiotherapy before surgery. After review of pathological information and medical records, available cases for IHC with paraffin blocks were collected. The pathologic reviews were performed by two pathologists who are experienced in biliary cancer pathology. Outcomes were determined from the date of surgery until death or 31 December 2008, which resulted in a follow-up period of from 1 to 88 mo (mean, 28 mo). Cases lost to follow-up or who died from problems other than extrahepatic CC and gallbladder carcinoma were censored during the survival analysis. The sites of extrahepatic biliary tract consisted of common bile duct and gallbladder. All cases were adenocarcinomas. Clinicopathological parameters such as age, gender, site, tumor differentiation and tumor, node, metastasis (TNM) with staging according to American Joint Committee on Cancer classification were evaluated by reviewing medical and pathological records. The study was approved by the Institutional Review Board of Dong-A University Hospital, Busan, South Korea (10-10-6).

Preparation of tissue array

Core tissue biopsy specimens (diameter 2 mm) were obtained from individual paraffin-embedded extrahe-

patic CC and gallbladder carcinoma (donor blocks) and arranged in new recipient paraffin blocks (tissue array blocks) using a trephine apparatus (Superbiochips Laboratories, Seoul, South Korea). Non-neoplastic biliary mucosa specimens were included in each of the array blocks. Each tissue array block contained up to 60 cores.

Immunohistochemistry

Immunohistochemistry was performed using tissue array paraffin blocks. Utilized antibodies are summarized in Table 1. With antibodies to Notch receptors 1-4, avidin-biotin-peroxidase complex (ABC) method was applied and with anti-DLL4, Ventana Autostainer System was used. Four to six micron thick sections from array blocks were dewaxed in xylene, rehydrated using a graded alcohol series and placed in an endogenous peroxidase blocker for 15 min and washed with buffer. The slides were then placed in citrate buffer (10% citrate buffer stock in distilled water, pH 6.0) and microwaved for 10 min for antigen retrieval. Non-reactive staining was blocked using 1% horse serum in Tris buffered saline (pH 6.0) for 3 min. Primary antibodies to Notch receptors 1-4 were applied and antibody binding was detected using avidin-biotin-peroxidase complex (Universal Elite ABC kit PK-6200; Vectastain, Burlingame, CA, United States) for 10 min and diaminobenzidine tetrahydrochloride solution (Kit HK153-5K; Biogenex, San Ramon, CA, United States). For DLL4, antigen retrieval was performed using CC1 antigen retrieval buffer (Ventana Medical Systems, Tucson, AZ, United States). Next, the sections were incubated with anti-DLL4, and stained on the Ventana automated slide stainer (NEXES) using the Ventana diaminobenzidine detection kit (Ventana Medical Systems, Tucson, AZ, United States).

Interpretation after IHC

There are few analysis criteria for the immunopositivity of Notch receptors and DLL4 expression. The scoring was based on distribution and intensity according to a previous report^[12]. Briefly, the percentage of positive tumor cells with cytoplasmic expression was determined semi-quantitatively and each sample was scored on a scale of 0-4, in which 0: negative, 1: positive staining in 1%-25% of cells, 2: in 26%-50%, 3: 51%-75%, and 4: 76%-100%. The intensity of immunostaining was determined as 0: negative staining, 1: weakly positive staining, 2: moderately positive staining, and 3: strongly positive staining. The immunoreactive score of each section was calculated by the sum of these two parameters. The total sum score was transformed into a three tier system and graded as negative (sum: 0), low (sum: 2-4) and high (sum: 5-7).

Statistical analysis

The two-tailed χ^2 test was performed to determine the significance of the difference between the covariates. Survival durations were calculated using the Kaplan-Meier method. The log-rank test was used to compare cumulative survival in the patient groups. The SPSS software program (version 12.0; SPSS Inc., Chicago, IL) was used in the analyses.

RESULTS

Clinicopathologic characteristics of patients

One hundred and ten patients comprised 47 males (42.7%) and 63 females (57.3%), with a range from 37 to 81 years. The mean patient age was 63 years. Carcinomas from the extrahepatic common bile duct were 47 cases (42.7%) and from the gallbladder, 63 cases (57.3%). Well differentiated adenocarcinomas were 53 cases (48.2%); moderately differentiated, 46 cases (41.8%); and poorly differentiated, 11 cases (10.0%). Seventeen cases were T1 (15.5%), T2: 55 cases (50.0%), T3: 32 cases (29.1%), and T4: 6 cases (5.4%). Seventy-eight patients showed no evidence of lymph node metastasis (70.9%) and 32 patients (29.1%) showed lymph node metastasis. Seven patients (6.4%) showed distant metastasis. Fifty-one cases were stage I (46.4%), stage II: 45 cases (40.9%), stage III: 6 cases (5.4%), and stage IV: 8 cases (7.3%).

Results of IHC

Expression of Notch receptors: Notch receptors 1, 2, 3 and 4 were expressed in non-neoplastic biliary epithe-

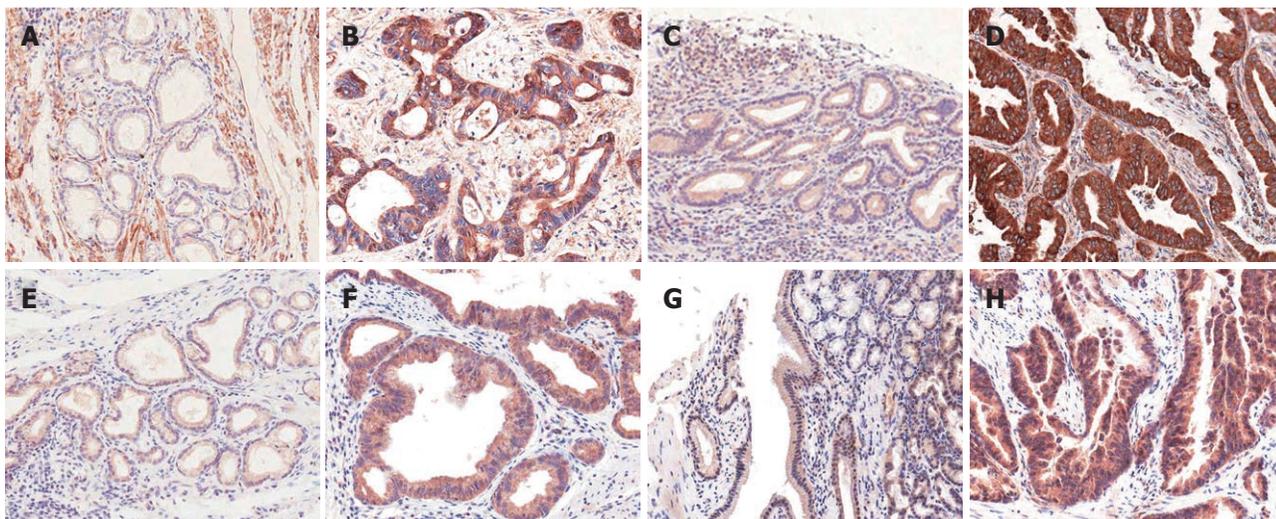

Figure 1 Notch receptor expression in cholangiocarcinomas (Immunohistochemistry). A, E: Notch receptor 1; B, F: Notch receptor 2; C, G: Notch receptor 3; D, H: Notch receptor 4; A-D: Non-neoplastic tissue (x 40); E-H: Cholangiocarcinomas (CCS) (x 100). Non-neoplastic biliary glandular or surface epithelial cells show weak cytoplasmic staining. High grade expression of Notch receptors is detected in cytoplasm of cancer cells of CCs.

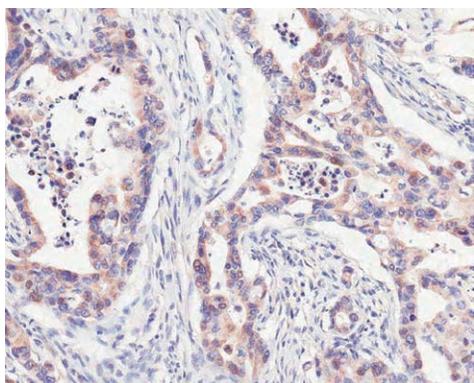

Figure 2 Cytoplasmic and nuclear localization of Notch receptor 3 in moderately differentiated cholangiocarcinoma (immunohistochemistry, × 200). Brown-colored positive immunostaining of cholangiocarcinoma cells in both cytoplasm and nuclei is frequently observed.

lial cells, mesenchymal cells and sometimes inflammatory cells with variable intensities, as well as in micro-vessels (Figure 1A, C, E and G). They were mainly expressed in the cytoplasm of CC cells (Figure 1B, D, F and H) and were evaluated semiquantitatively (Table 2). Notch receptor 1 showed 55 cases (50.0%) of low grade immunoreactivity and 41 cases (37.3%) of high grade immunoreactivity, Notch receptor 2: 60 cases (54.6%) of low grade and 37 cases (33.6%) of high grade, Notch receptor 3: 56 cases (50.9%) of low grade and 41 cases (37.3%) of high grade, and Notch receptor 4: 61 cases (55.4%) of low grade and 42 cases (38.2%) of high grade immunoreactivity.

In some cases with cytoplasmic positive immunoreaction, coexistent distinct nuclear staining was observed (Figure 2). The number of coexistent cytoplasmic and nuclear staining in Notch receptor 1 (+) carcinomas were 18 cases (18.8%), Notch receptor 2: 40 cases (41.2%) and Notch receptor 3: 32 cases (32.7%), and most of the Notch receptor 4 cases (95.2%) showed cytoplasmic and nuclear staining

except 5 cases (Table 3). In addition to cytoplasm and nucleus, occasionally incomplete membranous staining along with staining of luminal borders of neoplastic glands was noted.

Expression of DLL4: DLL4 was expressed in endothelial cells and non-neoplastic biliary epithelial cells, mesenchymal cells and sometimes inflammatory cells with variable intensities (Figure 3A). The cancer cells expressed DLL4 mainly in cytoplasm (Figure 3B), showing low grade: 63 cases (57.3%) and high grade: 21 cases (19.1%) (Table 2). As with Notch receptor protein expression, 48 cases (57.1%) out of DLL4 (+) 84 cases showed cytoplasmic and nuclear coexistent immunostaining (Figure 3C, Table 4). Occasionally, luminal borders of neoplastic glands showed distinct membranous immunostaining (Figure 3D).

Correlation between expression of Notch receptors 1-4 and DLL4, and clinicopathological factors with survival

Table 4 summarizes the correlations between expression of Notch receptors and DLL4, and clinicopathological parameters, including statistical analyses. Notch receptor 1 was expressed at advanced TNM stage, representing a statistically significant correlation ($P = 0.043$). Notch receptor 2 expression was positively correlated with female gender ($P = 0.005$). Notch receptor 3 was expressed at advanced T stage ($P = 0.017$) and tended to express in cases with lymph node metastasis ($P = 0.065$) and at advanced TNM stage ($P = 0.052$). The expression of Notch receptor 4 was not correlated with clinicopathological parameters. High DLL4 expression tended to be related to less histological differentiation ($P = 0.095$). The median survival of 110 extrahepatic CC and gallbladder carcinoma patients was 34.1 mo (Figure 4). There was no significant correlation between the expression of Notch receptors 1-4 and DLL4, and survival (Notch receptor 1;

Correlation between cytoplasmic/nuclear coexistent localization of Notch receptors 1-4 and DLL4, and clinicopathological factors with survival

Cytoplasmic/nuclear coexistent localization of Notch receptor 3 was correlated with no lymph node metastasis ($P = 0.027$), Notch receptor 4 correlated with less histological differentiation ($P = 0.036$), and DLL 4 tended to be

inversely related to advanced T stage ($P = 0.053$) (Table 4). The other clinicopathological parameters were not correlated with cytoplasmic/nuclear coexistent localization of Notch receptors 1-4 and DLL4 expression.

There was no significant correlation between the cytoplasmic/nuclear coexistent localization of Notch receptor 1-4 expression and survival (Notch receptor 1: $P = 0.280$, Notch receptor 2: $P = 0.204$, Notch receptor 3: $P = 0.768$, Notch receptor 4: $P = 0.425$). Cytoplasmic/nuclear coexistent localization of DLL4 expression was related to poor

survival in a statistically significant manner ($P = 0.002$, Figure 5).

DISCUSSION

The Notch signaling pathway has been shown to be expressed in a variety of adult tissues in mammals, and furthermore is involved in tumorigenesis with neoangiogenesis of many malignant tumors. In addition, it participates in the development of multicellular organisms by its self renewal potential and induction of differentiation^[10]. Few studies in the field of Notch signaling involving biliary epithelial cells have been reported with regard to developmental biology and neoplastic transformation. Notch receptor 2 signaling has been reported to be related to

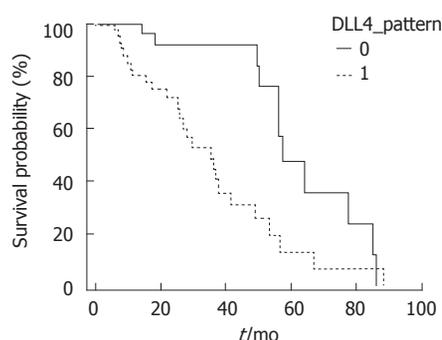

Figure 5 Survival curves of Cholangiocarcinomas with Delta-like ligand-4 expression with or without coexistent cytoplasmic and nuclear localization using the Kaplan-Meier method by log rank test. 0: Without nuclear localization; 1: With coexistent cytoplasmic and nuclear localization. Cases of coexistent cytoplasmic and nuclear localization of Delta-like ligand-4 expression show poor survival ($P = 0.002$).

the regulation of biliary epithelial cell differentiation, induction of tubulogenesis during early intrahepatic bile duct development in mice, and mutations of Jagged 1 and Notch receptor 2 resulting in Alagille syndrome, a rare hereditary multi-organ disorder involving impaired intrahepatic bile ducts^[5,17]. Ishimura *et al*^[18] reported that Notch receptor 1, but not other Notch receptors, was up-regulated in cholangiocytes when induced by inflammatory mediator nitric oxide synthase, and associated with malignant transformation. However, controversies about the role of Notch receptors in tumorigenesis as an oncogene or a tumor suppressor have arisen; Notch receptors

are reported generally as an oncogene in most human cancers^[10]. As a well-studied example, Notch receptor 1 functioned as an oncogene in T-cell leukemia through t(7; 9) chromosomal translocation of Notch receptor 1 and T-cell receptor J β locus^[8,9]. Activation of Notch signaling is reported in human non-hematopoietic solid tumors originating from mammary duct, colon, kidney, pancreas, and liver, etc^[16]. Others have shown Notch signaling as tumor suppressor in skin cancer and small cell lung cancer, and two faces of Notch as oncogene or tumor suppressor in cervical cancer^[10].

In this study, aberrantly high expression of Notch receptors 1-4 in extrahepatic CC and gallbladder carcinoma was observed by immunohistochemical study. In human breast cancer, the high expression of Notch receptor 1, Notch receptor 3 and Jagged 1 was reported to be correlated with poor predicted mortality, and the high-level co-expression of Notch receptor 1 and Jagged 1 was associated with poor overall survival^[19]. We found that the high expression of Notch receptor 1 related to advanced TNM stage ($P = 0.043$), and the high expression of Notch receptor 3 related to advanced T stage ($P = 0.017$) and tended to be related to nodal metastasis ($P = 0.065$) and advanced TNM stage ($P = 0.052$) in extrahepatic CC and gallbladder carcinoma. These results suggest that the up-regulation of Notch receptors 1 and 3 has a possible role in tumor progression of extrahepatic CC and gallbladder carcinoma, reflecting its role as an oncogene. However, there were inherent limitations in the number of studied cases for this study. One further limitation we must point out is that the studied cases were mostly surgically removed cancers, thus this study did not include late advanced or early cancers. In addition, there was no relation between high expression of Notch receptors and the overall survival.

Regarding the biologic roles of Notch signaling, liberated Notch intracellular domain after two sequential proteolytic cleavages translocates into the nucleus, and then activates transcription of target genes^[3]. In addition, the nuclear translocation of Notch receptor proteins is required for target gene activation, especially in malignant transformation^[20]. For the evaluation of gene expression in tissue, *in situ* IHC is valuable in morphologic identification of individual cell and intracellular localization of specific proteins. The reason why IHC should be applied in cases of human cancer tissue composed of neoplastic and non-neoplastic cells is because generally microvasculature cells, stromal cells and inflammatory cells express Notch signaling proteins, thus extracted samples contain non-neoplastic cells as well as cancer cells. We found that Notch receptors 1-4 were expressed in the cytoplasm of cancer cells, some of which were associated with nuclear co-localization. In hepatocellular carcinoma, the nuclear localization of Notch receptor 1 and Notch receptor 4 expression was reported to be involved in carcinoma development, representing target gene activation through translocated Notch receptor protein components^[12]. However, although coexistent cytoplasmic and nuclear localization of Notch receptors 1-4-expressing CC cells was found

with variable ratios, only the coexistent cytoplasmic and nuclear localization of Notch receptor 3 correlated with no nodal metastasis ($P = 0.027$) and Notch receptor 4 with less histologic differentiation ($P = 0.036$). Not many studies in human cancers have dealt with the cytoplasmic and/or nuclear expression of Notch receptor proteins, especially not in biliary epithelial carcinomas. Study of the mechanism of action regarding cytoplasmic high-expression of Notch receptors 1 and 3 in tumor progression during cholangiocarcinogenesis is needed through collection of more cases and application of biological tools.

As one of the five known Notch receptor ligands, the up-regulation of DLL4 expression was found to be involved in vasculogenesis and vessel maturation in human cancers^[21,22]. Recently, the expression of DLL4 was reported in human cancer cells as well as in normal epithelial cells, stromal cells, and endothelial cells of neo-angiogenesis^[16], thus interest was focused on possible roles in the development and progression of tumors, due to the nuclear or membranous localization. This study demonstrated that DLL4 is highly expressed in cancer cells, mainly in cytoplasm similar to Notch receptors, and that the up-regulation of DLL4 tended to be related to less histologic differentiation ($P = 0.095$) of extrahepatic CC and gallbladder carcinoma. Furthermore, the coexistent cytoplasmic and nuclear localization of DLL4 expression was observed and indicated poor survival ($P = 0.002$). Similar to Notch receptors, there are few reports concerning clinicopathological impact of DLL4 expression with intracellular localization. The up-regulation and cytoplasmic and nuclear localization of DLL4 expression is suggested to be involved in progression of cholangiocarcinogenesis, and has a probable role as a poor prognosticator. Overall, more cases should be studied for the identification of biological roles, according to intracellular compartmentalization in the expression of Notch receptors and DLL4.

In conclusion, these results imply that the up-regulation of Notch receptors 1 and 3 correlates with cancer progression, and that the coexistent cytoplasmic and nuclear localization of DLL4 expression correlates with poor survival in extrahepatic CC and gallbladder carcinoma. Further investigation on a large scale should be performed in order to understand the contribution of the involvement of Notch signaling in extrahepatic CC and gallbladder carcinoma.

COMMENTS

Background

Cholangiocarcinoma (CC) is the second most frequent primary liver cancer and the incidence is increasing. It has a poorer prognosis than hepatocellular carcinoma. Recently, in mammals, it was reported that the Notch signaling pathway is engaged in not only embryonic development, differentiation and specification of cell fate, but also in tumorigenesis with consequent possibilities of anti-cancer therapy targets. Basically, in human extrahepatic CC, including gallbladder cancer, the expression patterns of the Notch receptors and the representative ligand, Delta-like ligand-4, in cancer cells should be clarified.

Research frontiers

There are four Notch receptors (Notch 1-4) and five ligands [Jagged 1, Jagged 2, Delta-like ligand-1, -3 and -4 (DLL1, DLL3, DLL4)] in mammals. Recently, they have been reported to be involved in tumorigenesis as oncogenes or as tumor

suppressors, and proposed as prognostic factors or anti-cancer targets in aggressive or advanced cancers. In particular, antibodies to Notch receptor 4 and DLL4 have the possibility to be coupled with chemotherapeutic drugs as targeted therapy.

Innovations and breakthroughs

Abnormal Notch signaling has been reported in many human solid tumors, especially in breast cancer. With regard to cholangiocarcinoma, only its high expression has been reported with little study of the clinical impact. As with other solid tumors, the expression of Notch receptors in CC shows a possible role in cancer progression. The study of DLL4 expression in cancer cells has hardly been looked at. The coexistent cytoplasmic/nuclear localization of DLL4 expression has a novel value as a poor survival indicator.

Applications

The up-regulation and nuclear translocation of DLL4 has a probable role in the evaluation of survival as a poor prognosticator. These results of altered Notch signaling in CC can provide fundamentals for further investigation on an expanded scale of human extrahepatic CC and gallbladder carcinoma, mechanism of action through cross-talk of Notch receptors and their ligands, and other signaling networks.

Terminology

Four Notch receptors (Notch 1-4) and five ligands (Jagged 1, Jagged 2, DLL1, DLL3, DLL4) are found in mammals. Ligand-receptor interaction between two neighboring cells is involved in developmental, physiologic and pathologic processes.

Peer review

The paper is reasonably important and includes data on a large cohort of patient's with extrahepatic cholangiocarcinoma and gallbladder cancer.

Abstract

AIM: To investigate relationships between colorectal adenoma incidence, metabolic syndrome (MS) components and lifestyle factors.

METHODS: We conducted a retrospective cohort study using data from individuals who had multiple sigmoidoscopies for colon cancer at the Health Promotion Center of Ulsan University Hospital in Korea from 1998 to 2007.

RESULTS: By multivariate analysis, the incidence of distal colon adenoma was increased by more than 1.76 times in individuals with at least one component of MS compared to those without a component of MS. After adjustment for age, gender, smoking, drinking, and physical exercise, only high body mass index (BMI)

INTRODUCTION

Colorectal cancer is a major cause of cancer death in developed Western countries such as the United States and nations of Europe^[1]. However, the incidence of colorectal cancer has been increasing rapidly over the past two decades in Korea, which was previously known as a low-risk area. According to a report from the Ministry of Health and Welfare of Korea, colorectal cancer was the third most commonly diagnosed malignancy after stomach and lung cancer in 2005. From 1999 to 2005, the incidence of colorectal cancer rose from 26.2 to 39.6 cases per 100 000 population for men and from 16.4 to 22.2 per 100 000 for women^[2].

As colorectal adenomas are recognized as precursors

of colorectal cancer, identification of their risk factors would seem to be helpful in the prevention of colorectal cancer^[3]. One of the main explanations given for the increasing incidence of colorectal cancer in Korea is the growing adoption of the westernized diet consisting of high fat and sugar. The western diet is also known to increase the risk of metabolic syndrome (MS)^[4].

In several previously reported studies, MS or its individual components such as obesity, impaired glucose tolerance, hypertension, low high-density lipoprotein cholesterol, and hypertriglyceridemia were found to be associated with colorectal adenomas^[5-13]. In addition, lifestyle factors such as alcohol drinking, cigarette smoking, and lack of physical exercise also have been shown to be associated with the incidence of colorectal adenoma^[14-17]. However, most previous studies showed only a weak temporal relationship between exposure and disease occurrence.

To date, no cohort study has examined the association between the individual components of MS or lifestyle factors and the incidence of colorectal adenoma in Korea. In this study, we investigated the relationships between the incidence of distal colon adenoma and MS components and also lifestyle factors in a Korean population-based cohort.

MATERIALS AND METHODS

Study population

We conducted a retrospective cohort study using data from individuals who had multiple sigmoidoscopies at the Health Promotion Center of Ulsan University Hospital in Korea from 1998 to 2007. We recommend screening flexible sigmoidoscopy (SFS) to our patients according to guidelines for colorectal cancer screening issued by the American College of Gastroenterology^[18]. Nevertheless, some patients within our study population had undergone two or more surveillance SFS examinations at short intervals. Perhaps some of these study participants had misunderstood the recommended guidelines or had lower gastrointestinal tract symptoms or risk factors for colorectal cancer such as family history; or there may be other reasons for the multiple examinations at short intervals.

A total of 15 353 asymptomatic adults underwent a flexible sigmoidoscopy. Of these, 13 566 were excluded because they had undergone only one sigmoidoscopy or data were missing from their records. Among the remaining 1787 individuals who had had at least two sigmoidoscopies during a period of two years, 225 individuals who were specific for tubular adenoma ($n = 109$ adults) or hyperplastic polyps ($n = 116$ adults) at the first sigmoidoscopic examination were excluded. Thus, a cohort of 1562 individuals was included in this study (Figure 1).

The following parameters were collected from medical records and from self-administered questionnaires: height, body weight, systolic and diastolic blood pressures, serum biochemistry, flexible sigmoidoscopy re-

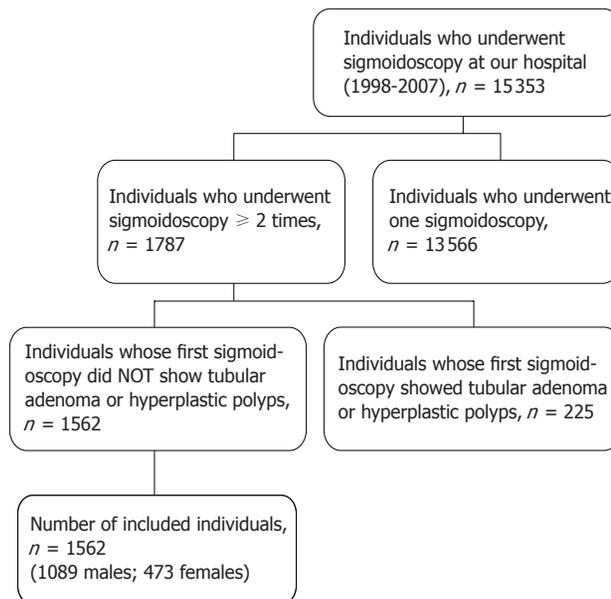

Figure 1 Case selection.

sults, and past medical history. The study protocol was approved by the Institutional Review Board of Ulsan University Hospital.

Questionnaire information

Using a structured, self-administered questionnaire, patients were asked about their smoking and drinking habits, physical activity, medical history and socioeconomic status.

Smoking was categorized as never, ex-smoker and current smoker. An individual who reported smoking within the past 30 d was classified as a current smoker. An ex-smoker was defined as an individual who had smoked at least one pack-year and was distinguished from someone who had never smoked. Current drinkers were defined as individuals who had consumed alcohol at least once per week over a period of at least 1 year. For alcohol consumption, individuals were classified as never or current drinkers.

Physical activity was classified as regular, irregular, and none based on the regularity, regardless of the type of exercise or intensity level. Individuals who reported having exercised regularly within the past year were classified into the regular exercise group. The irregular exercise group comprised individuals who had exercised irregularly within the past year, and were distinguished from those who had never exercised in the past year. The regular and irregular exercise groups were classified as the exercise “yes” group in the analysis.

Anthropometric and laboratory measurements

Anthropometric measurements were made by well-trained examiners in individuals wearing light clothing and without shoes. Height was measured to the nearest 0.1 cm and weight to the nearest 0.1 kg using Inbody 2.0 (Biospace, Seoul, Korea). Body mass index (BMI) values

BMI: Body mass index (kg/m²); FBS: Fasting blood sugar (mg/dL); HBP: High blood pressure (systolic blood pressure ≥ 130 mmHg or diastolic blood pressure ≥ 85 mmHg); TG: Triglyceride (mg/dL); HDL: High density lipoprotein (mg/dL); MS: Metabolic syndrome.

were calculated by dividing weight (kg) by height squared (m²). Blood pressure was measured by well-trained nurses using a mercury sphygmomanometer in the sitting position after at least a 10-min rest period. Following an overnight fasting, blood samples were obtained and analyzed on a Hitachi Modular DPE system (Roche Diagnostics, Germany). The fasting plasma glucose (FPG) level was measured using a hexokinase UV method. Triglycerides (TG) were measured by an enzymatic calorimetric method. HDL-cholesterol (HDL-C) level was determined by the homogeneous enzymatic colorimetric method.

Diagnosis of distal colon adenoma

The sigmoidoscopies were performed by gastroenterologists who observed the entire procedure on a video monitor. The procedure was intended to screen the distal colon, including the descending and sigmoid colon, and the rectum. When fully inserted, the 60-cm sigmoidoscope reached to the mid-descending colon. Endoscopic findings were recorded in a computer database. All visualized lesions were biopsied and histologically assessed by an experienced pathologist. The size of each polyp was estimated by the use of 8-mm-diameter open-biopsy forceps. Histological assessment of the polyps was performed by a single pathologist blinded to each patient's status. In this study, the adenomas were classified as tubular, serrated, villo-tubular, high-grade dysplasia, and adenocarcinoma types according to the World Health Organization classification^[19]. For multiple primary adenomas in the distal colon at different times, the earliest diagnosis was applied, and for those occurring simultaneously, the most advanced and most invasive diagnosis was applied.

Definition of MS

MS was defined according to the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) criteria, with BMI used in place of waist circumference^[20]. BMI was calculated as described above (kg/m²). The definition of obesity was BMI ≥ 25 , as recommended by the Korean Ministry of Health and Welfare in 2006^[21]. The diagnosis of MS in this study was made when at least 3 of the following 5 characteristics were present: (1) BMI ≥ 25 kg/m²; (2) TG

≥ 150 mg/dL, or on drug treatment for elevated TG; (3) HDL-C < 40 mg/dL in males and < 50 mg/dL in females, or on drug treatment for reduced HDL-C; (4) blood pressure (BP) $\geq 130/85$ mmHg, or on drug treatment for hypertension; and (5) FPG ≥ 110 mg/dL, or on drug treatment for elevated glucose.

Statistical analysis

Multivariate Cox proportional hazards analysis was applied to assess the effect of prognostic variables in MS and non-MS individuals. Results of the Cox proportional hazards model were presented as the hazard ratio (HR) and the 95% confidence interval (95% CI). All *P* values were two-sided, and all statistical analyses were performed using SPSS version 14.0.

RESULTS

A total of 1562 individuals (1089 men and 473 women) were included in the study. Of these, 229 (14.7%) subjects (197 men and 32 women) were found to have distal colon adenomas.

Table 1 shows the age- and gender-specific prevalence of MS in the study population. The prevalence of MS in males was slightly higher than in females (18% and 14%, respectively). Hypertension was the most common metabolic abnormality in both sexes.

The associations between the incidence of distal colon adenomas and the number of MS components are shown in Table 2. In our cohorts, 263 (16.8%) of the individuals were diagnosed with MS according to NCEP-ATP III criteria. Among the MS subjects, 182 (69.2%) had three components, 64 (24.3%) had four components, and 17 (6.5%) had all five. After adjusting for age and gender, the presence of any component of MS showed a positive association with the incidence of distal colon adenoma. According to multivariate analysis, the risk of distal colon adenoma was increased in patients with even one component of MS compared to patients without any component of MS, but this result was not statistically significant.

Among the MS components, diastolic blood pressure, systolic blood pressure, BMI, HDL and FBS were posi-

tively associated with the risk of distal colon adenoma; however, only the association with BMI was statistically significant (Table 3). Among the lifestyle factors examined in our study, smoking and drinking were positively associated with the risk of distal colon adenoma whereas exercise showed a negative correlation, but these results were not statistically significant.

DISCUSSION

In this study, we confirmed a positive association between MS and distal colon adenoma in a Korean population. We found that, compared to persons without any

component of MS, the risk of distal colon adenoma positively increased with the presence of even one component of MS. These results are consistent with those of Lee *et al*^[8]. Moreover, we found only BMI to be an independent risk factor of distal colon adenoma among the five components of MS examined.

Although NCEP-ATP III requires waist circumference for diagnosis of MS, we used BMI as an indicator of obesity because the cut-off points of waist circumference in Koreans differ from those currently recommended by the NCEP-ATP III. The cut-off points of waist circumference for central obesity in Koreans are 90 cm for men and 85 cm for women^[22]. Moreover,

currently there is no equivalent method for the measurement of waist circumference, whereas BMI is an easy and accurate index. Waist circumference measurements show strong between-observer differences, and should, where possible, be carried out by one observer. Weight and height are the most precisely measured variables, and it is entirely appropriate that they continue to be the predominant measure of choice in the vast majority of nutritional anthropometric studies^[23]. Therefore, most medical institutions in Korea use BMI as an indicator of obesity, defined by The Korean Ministry of Health and Welfare as $\text{BMI} \geq 25$ ^[21].

Several studies have reported that MS is associated with colorectal adenoma and that obesity is a risk factor for the lesion, but the relationship between BMI and the prevalence of colorectal adenoma has remained controversial^[5-9,16,24,25]. Recently, a retrospective study of the effect of body weight changes on the development of new colorectal adenomas was reported by Yamaji *et al.*^[24]. In their cross-sectional study, they found that the prevalence of colorectal adenoma increased proportionally with increasing BMI. According to their results, the prevalence of colorectal adenoma was 15.4%, 20.6%, 22.7%, and 24.2%, respectively, in the first ($\text{BMI} < 21.350 \text{ kg/m}^2$), second ($\text{BMI} 21.350 \leq \text{BMI} < 23.199 \text{ kg/m}^2$), third ($\text{BMI} 23.199 \leq \text{BMI} < 25.156 \text{ kg/m}^2$), and fourth ($\text{BMI} \geq 25.156 \text{ kg/m}^2$) quartiles. Compared with the first quartile, the adjusted odds ratios (ORs) were 1.15 (95% CI, 0.97-1.37; $P = 0.10$) for the second quartile, 1.19 (95% CI, 1.01-1.41; $P = 0.04$) for the third quartile, and 1.32 (95% CI, 1.12-1.56; $P = 0.001$) for the fourth quartile. Their result is similar to our finding of a positive relationship between BMI and the prevalence of distal colon adenoma. In our study we confirmed that persons with high BMI (≥ 25) had a 66% higher incidence of distal colon adenoma compared to persons with $\text{BMI} < 25$. The study by Lee *et al.*^[8] also revealed that the occurrence of adenomatous colonic polyps was significantly associated with increased BMI levels. In contrast, Willett and colleagues found no significant association between BMI and colorectal adenoma^[16,25].

Another controversy remains regarding whether gender differences exist in the relationship between BMI and colorectal adenoma. Some authors reported that BMI was associated with a higher risk of colorectal adenomas among men but not among women^[26,27]. However, others reported an increased risk and prevalence for significant colorectal neoplasia in women as BMI increased, but not in men^[17,28].

In the present study, current and past smoking and current drinking behaviors all showed a positive association with the occurrence of distal colon adenoma, whereas physical activity showed a negative association. Our results are similar to those of other studies, but none of the associations in any of the studies achieved statistical significance^[29-32]. Prior to this study, we hypothesized that individuals with unhealthy lifestyle behaviors, such as cigarette smoking, alcohol drinking, and physical

inactivity, would be at greater risk of distal colon adenoma. The lack of statistical significance in the current study could be due to the short observation period and the interaction between MS components.

The strengths of our study include the cohort design and the relatively large sample size. Furthermore, we investigated the association of each component of MS, which provided the opportunity to examine the difference in incidence rate of distal colon adenoma between MS and non-MS individuals. Additionally, lifestyle factors related to MS, including cigarette smoking, alcohol consumption, and physical exercise, were examined. One other advantage of our study is that actual measurements of height and weight were made by trained individuals. This is preferred over self-reported data, which have been used frequently in a number of well-known, large-scale cohort studies, because heavier individuals tend to under-report their weight. Furthermore, our study simultaneously measured anthropometrics, FBS, TG, HDL-C, blood pressure, and adenoma incidence in a population of individuals at average adenoma risk undergoing sigmoidoscopy. Moreover, subjects in both the adenoma and normal groups were confirmed as having or not having the lesion through the same diagnostic procedure of sigmoidoscopy. Therefore, it is highly unlikely that the study results might be affected by misclassification bias, and this hospital-based retrospective study is internally valid because the normal and recurrent adenoma groups were selected from the same source population.

There were several limitations in our study which need to be addressed. Firstly, the information on cigarette smoking, alcohol drinking and physical activity was self-reported, thus allowing for recall bias. This may explain why a sedentary lifestyle and cigarette smoking were not associated with an increased risk of distal colon adenoma. Secondly, the study population may not be representative of the general population because the subjects were not randomly selected. Also, there may have been some heterogeneity in fasting status and the time of day that blood was collected. Finally, only the adenomas of the distal colon, not the entire colon, were screened using sigmoidoscopy. For the detection of colon adenoma, colonoscopy may be more accurate than sigmoidoscopy.

In conclusion, only BMI, but no other individual component of MS, was positively associated with distal colon adenoma risk. In contrast with previous cross-sectional studies, we found that other MS components did not have a synergistic effect on development of distal colon adenoma^[3,4]. However, this may be attributable to the limitations mentioned above. One possible explanation for our findings is that each component of MS may promote or prevent adenoma development *via* different mechanisms that do not act in an additive or synergistic manner. Further molecular biological research and epidemiological studies are needed to explore this topic.

To our knowledge, the present study is the first cohort study supporting a relationship between BMI and

new development of distal colon adenoma in a Korean population. BMI appears to be a better predictor than the MS cluster, and therefore BMI may be the only component needed.

COMMENTS

Background

In Korea, as in the developed countries, the incidence of colorectal cancer has been increasing rapidly over the past two decades with the adoption of westernized lifestyles. Because the western diet increases the risk of metabolic syndrome (MS) and colorectal adenomas are precursors of colorectal cancer, some researchers have investigated the relationships between the incidence of colorectal adenoma and MS components and lifestyle factors.

Research frontiers

Several studies have reported that MS is associated with colorectal adenoma and that obesity is a risk factor for the lesion. However the relationship between body mass index (BMI) as a diagnostic tool of obesity and the prevalence of colorectal adenoma has remained controversial. Moreover, to date, no cohort study has examined the association between the individual components of MS or lifestyle factors and the incidence of colorectal adenoma in Korea.

Innovations and breakthroughs

In our study, we found that the incidence of distal colon adenoma was increased by more than 1.76 times in individuals with at least one component of MS compared to those without a component of MS. Among the five components of MS examined, only BMI was the independent risk factor of distal colon adenoma. Persons with high BMI (> 25) had a 66% higher incidence of distal colon adenoma compared to persons with BMI < 25. These results suggest that high BMI may increase the risk of colorectal adenoma in Korean adults. To our knowledge, this is the first cohort study with a relatively large sample size.

Applications

Reducing the BMI can be one of the best ways to prevent colorectal cancer in Korean.

Peer Review

This is the first cohort study to demonstrate an association between the individual components of metabolic syndrome and the incidence of colorectal adenoma in Korean. It revealed that only a high BMI was associated with a high risk of colorectal adenoma. The results are interesting and may contribute to reduce the risk of developing colorectal cancer.

Abstract

AIM: To assess the diagnostic value of computed tomography (CT) imaging in screening for abdominal nonhematogenous disseminated tuberculous lymphadenopathy (TL).

METHODS: The CT scans of 12 patients with abdominal nonhematogenous disseminated TL suggestive of neoplasm were retrospectively analyzed in this review. The final diagnoses were confirmed by lymph node pathology for seven patients and by laparoscopic surgery for five patients. All of the patients were treated at our institution between April 1995 and August 2009.

RESULTS: The sites of involvement were the periportal ($n = 6$), peripancreatic ($n = 3$), periaortic ($n = 3$), and mesenteric ($n = 2$) regions. On the plain CT scan, the lymphadenopathy showed a heterogeneous isodensity or hypodensity in 11 patients and a low density in one

patient. Peripheral enhancement was observed on the dynamic contrast-enhanced CT scans for all patients. In two cases, scans were more revealing during the portal venous and delayed phases.

CONCLUSION: Abdominal lymphadenopathy with predominant peripheral rim-like enhancement on the dynamic contrast-enhanced CT scan may suggest a diagnosis of TL.

INTRODUCTION

The global health burden of tuberculosis (TB) has risen in recent years. In 2009, an estimated 9.4 million cases and 1.7 million deaths globally could be attributed to TB. More than one-third of these cases were found in South-east Asia^[1]. Although the respiratory system remains the primary disease site, TB also increasingly affects the gastrointestinal tract, peritoneum, lymph nodes, kidneys,

and other solid viscera. Intra-abdominal TB (1%-3%) constitutes up to 12% of extra-pulmonary TB, particularly in immunocompromised individuals^[2,5]. Tuberculous lymphadenopathy (TL) is one of the most common findings in patients with abdominal TB. The presence of active pulmonary tuberculosis may indicate the possibility of abdominal TB involvement; however, only 15% of patients with abdominal TB have any evidence of pulmonary involvement^[4]. Clinically, patients with abdominal nonhematogenous disseminated TL typically present with an isolated mass or a mass adhering to the surrounding organs. When abdominal neoplasm is suspected, computed tomography (CT) is used to examine the abdomen. With the widespread use of CT, physicians should be familiar with the features of CT images seen in these patients and be able to make differential diagnoses using CT findings. In this article, we present 12 patients with abdominal nonhematogenous disseminated TL and discuss the features observed on their CT scans.

MATERIALS AND METHODS

We collected and retrospectively reviewed the CT scans of 12 patients who were diagnosed with abdominal non-hematogenous disseminated TL and who were admitted and treated at our institution between April 1995 and August 2009. The patients included 9 women and 3 men, and their ages ranged from 24 to 56 years (median age 43 years). The mean duration of their symptoms was 46 d (range 29-65 d).

Clinical signs and symptoms among these patients included fever (ardent fever, $n = 2$) and weight loss, epigastric pain ($n = 8$), and night sweats ($n = 1$). An elevated blood sedimentation rate and positive tuberculin test were present in only two patients. The initial diagnostic sonography identified an intra-abdominal mass in all of the patients; three patients presented with pancreatic masses and one patient with a hepatic mass. The chest radiographic examinations found evidence of healed TB in 3 of the 12 patients. None of our patients had any evidence or history of opportunistic infection, drug abuse, or previously treated lung TB.

Neoplasms of the pancreas, liver, or periaortic area were pre-operatively diagnosed in seven patients and were removed surgically. The final histopathological examination of the resected masses showed caseous or liquefactive substances in the center of the enlarged lymph nodes surrounded by inflammatory lymphatic tissues and no evidence of malignant cells. TL was suspected in the other 5 patients based on CT findings and clinical presentations. A diagnostic laparoscopy to biopsy the mass was performed to rule out malignancy. The subsequent anti-TB therapy confirmed the diagnosis of TL.

We used the 9800 Quick CT Scanner (General Electric Medical Systems, Milwaukee, WI; $n = 5$), the Picker PQ 6000 CT Scanner (Picker International, Cleveland, Ohio; $n = 6$), and the Brilliance 64 CT Scanner (Philips Medical Systems, Best, Netherlands; $n = 1$). The scans were performed with conventional techniques. Diatrizoate solu-

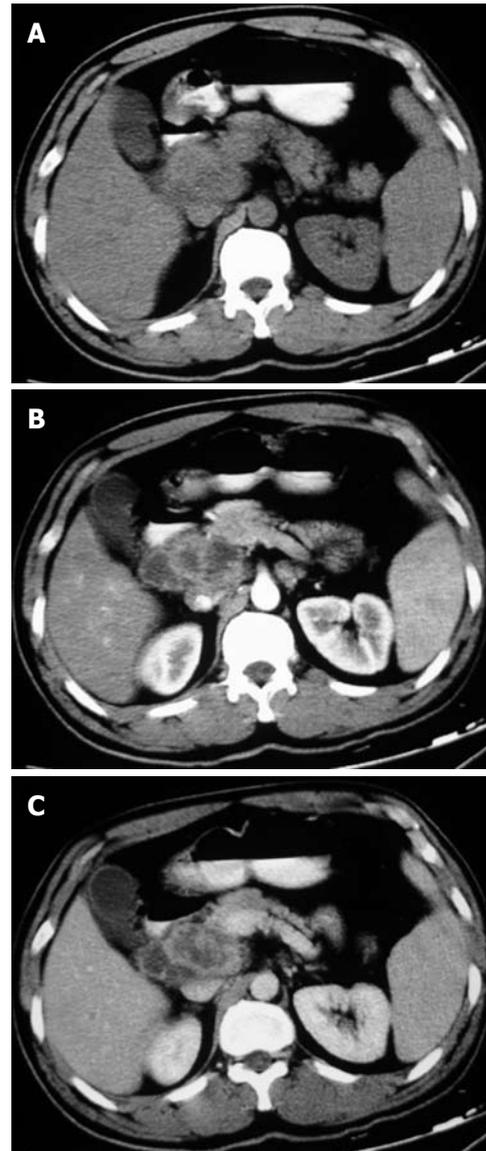

Figure 1 Peripancreatic tuberculous lymphadenopathy. A: Plain computed tomography (CT) showing peripancreatic, lobular, and slightly uneven density mass; B, C: Contrast-enhanced CT of the arterial phase (B) and portal venous phase (C) showing the mass with irregular peripheral enhancement.

tion (500-750 mL of 1.5%) or water was given orally to patients one hour prior to examination. Intravenous contrast medium (Omnipaque 300 mgI/mL, GE Healthcare) was administered at 1.0-1.2 mL/kg body weight with a flow rate of 3 mL/s. For enhanced scans, images were recorded for 25 s (arterial phase) and repeated for 60 s (portal venous phase) following the administration of the intravenous contrast using the single-slice spiral CT. The images of the delay phase (300 s after contrast administration) were recorded using the multi-slice spiral CT. Contiguous axial images of 7.5 mm or 10 mm sections were obtained from the epigastrium or from the dome of the diaphragm to the pubic symphysis.

RESULTS

The sites of lymph node adenopathy included the peri-

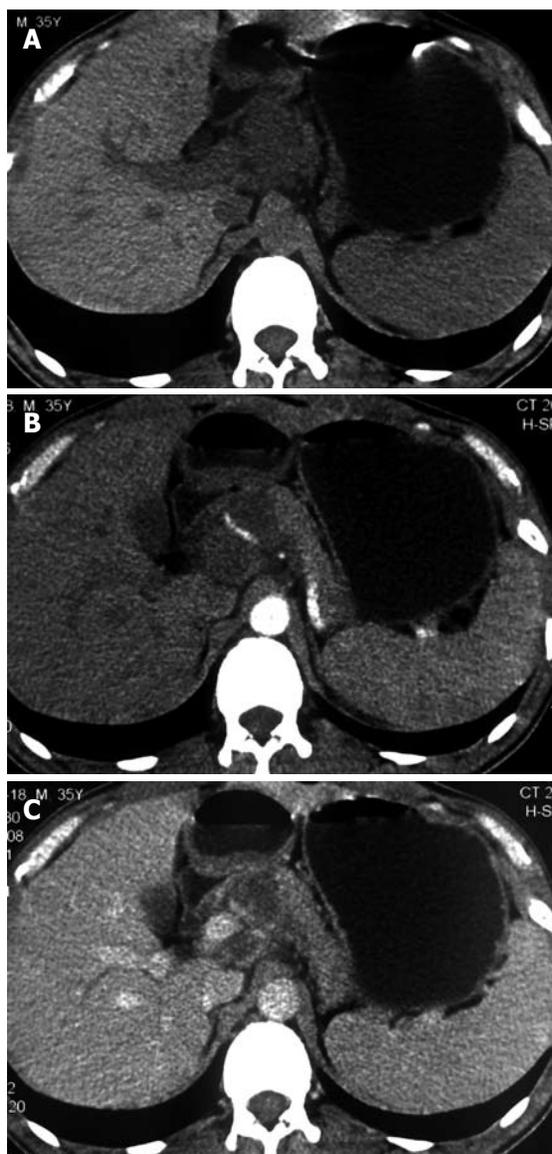

Figure 2 Peripancreatic tuberculous lymphadenopathy. A: Plain computed tomography (CT) showing peripancreatic, lobular, and low density mass; B, C: Contrast-enhanced CT of the arterial phase (B) and portal venous phase (C) showing the mass with slight peripheral enhancement and the encased common hepatic artery.

portal ($n = 6$), peripancreatic ($n = 3$), periaortic ($n = 3$), and small bowel mesenteric ($n = 2$) areas. The enlarged lymph nodes were 1.7-4.2 cm (mean 3.4 cm) in diameter. There was no calcification identified within the lesions. On the plain CT scans, the enlarged lymph nodes were of mostly heterogeneous isodensity or hypodensity, although one patient had lymph nodes of uniform low density. The margins of the involved lymph nodes were poorly defined. The lymph nodes could not be distinguished from the mass of the pancreas in three patients. After the administration of the contrast material, the lesions showed peripheral or ring-like enhancement with an expanded low-density central area in all the cases (Figures 1-4). Some ($n = 5$) had a conglomerated and multilocular appearance instead of single node involvement (Figures 1-3). The peripheral enhancement of the nodes was low in the

ded in the enlarged lymph nodes (Figures 2 and 3) in two patients. None of the patients displayed clinical signs of ascites and/or peritoneum thickening.

One patient had hepatic TB and retroperitoneal lymphadenopathy. The large liver lesion showed irregular rim enhancement with enlarged lymph nodes (Figure 4).

DISCUSSION

The incidence of abdominal TL is low. The disease is thought to result from one of three major routes of transmission of TB. The most common route is through the ingestion of contaminated materials containing the tubercle bacilli. The second source is the hematogenous spread of the bacteria from a distant site of infection (commonly the lungs). The third route is the direct spread from the serosa of the adjacent infected organs or structures^[5]. Our case series identified three patients with X-ray evidence of healed lung TB; none of the patients had an active infection or had been previously treated. Therefore, hematogenous infection was impossible. This finding suggests that the only possible route of these infections was the ingestion of TB bacteria into the gastrointestinal tract. The tubercle bacilli are absorbed into the intestinal submucosal layer and then carried to the draining lymph nodes of the jejunum, ileum and ascending colon. The lymphatic drainage pattern supports our observation that the affected areas included the periportal, peripancreatic, upper periaortic, and mesenteric regions^[6]. Because the tubercle bacilli are hardly absorbed from the left side of the colon, the lower periaortic nodes are rarely involved in cases of nonhematogenous disseminated TL^[7].

The diagnosis of abdominal hematogenous disseminated TL can be made clinically when a patient has active pulmonary miliary TB^[7]. The signs and symptoms of abdominal nonhematogenous disseminated TL in patients include epigastric pain, fever, weight loss, fatigue, and abdominal mass. Other indicative symptoms include the presence of TB at other sites, positive skin TB tests, and night sweats, although these are uncommon in patients with nonhematogenous disseminated TL^[8]. In our review, only two patients had a positive skin TB test and

one patient had night sweats. Obstructive jaundice is a rare complication and may also be caused by periportal lymphadenopathy^[9,10], portal vein thrombosis, or portal hypertension^[11]. Although the clinical presentation of abdominal nonhematogenous disseminated TL has been well characterized, clinical diagnosis is limited because the signs and symptoms are nonspecific.

The CT scan is a useful tool in detecting lesions and making presumptive diagnoses in the abdomen. Lymphadenopathy is the most common manifestation of abdominal TB found on the CT^[12,13]. Plain CT findings are nonspecific in patients with abdominal nonhematogenous disseminated TL. The enlarged lymph nodes display low or soft tissue attenuation values and cannot be used to differentiate TL from neoplasm^[14,15]. On the other hand, contrast-enhanced CT scans can detect the peripheral or rim-like enhancement with a low-attenuation center that was seen in all of our patients. This radiographic feature corresponds histologically to the peripheral inflammatory reaction and neovascularity around central liquefaction or caseous necrosis. Homogeneous enhancement on the CT scan^[6] may reflect an earlier pathologic stage of the disease (i.e., the non caseating epithelioid and giant cell granulomas that precede necrosis) in which the size of the enlarged lymph nodes is often less than 1 cm in diameter. Non-enhancement on the CT scan is presumably due to the diminished inflammatory reaction associated with AIDS or with other immunocompromising diseases in patients. The individuals in this study were selected based upon the following criteria: (1) enlarged lymph nodes greater than 1 cm in diameter and (2) negative HIV infection status and a non-immunocompromised state. These parameters excluded the possibility of the confounding variables discussed above.

Other imaging modalities used for the detection of abdominal nonhematogenous disseminated TL have been described in other studies. Sonography shows TL as a hypoechoic^[16] and homogeneous mass. These features are nonspecific and cannot be used to differentiate TL from a neoplasm^[17]. Limited literature addresses the application of magnetic resonance imaging (MRI) in the diagnosis of abdominal TL. Kim *et al.*^[18] described MRI findings

of abdominal TL in a series of 11 patients who were all diagnosed correctly as having TL. The lesions may show a variety of signal intensities depending on the stage of evolution and are frequently hypointense on the T1-weighted images and hyperintense on the T2-weighted images. The enhancement pattern is similar to that of the CT scans, which show predominant peripheral rim-like enhancement^[18,19]. Furthermore, the MRI seems to be useful in differentiating the enlarged lymph nodes around the pancreas from a cystic neoplasm. Limited evidence suggests that the MRI scan has a valuable role in the diagnosis of abdominal TL. However, MRI scanners are not always available in developing countries. ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) CT imaging is increasingly used as a tool for detecting malignancies. The accumulation of FDG in tuberculous lymph nodes prevents its use as a diagnostic tool for TL^[20].

Intra-abdominal lymphoma can be confused with abdominal nonhematogenous disseminated TL both clinically and on CT scans. Lymphoma often involves the abdominal lymph nodes in the entire periaortic region, including above and below the third lumbar areas^[6,21]. The enlarged lymph nodes in lymphoma can grow to be as large as 4.0 cm in diameter and appear homogeneous on CT scans in most patients^[6,21,22]. Yu *et al.*^[21] considered embedded vessels to be a unique finding of lymphoma. Nonhematogenous disseminated TL involves the mesentery lymph nodes, the lesser omentum, and the upper periaortic regions in most cases and is rarely found in the lower periaortic region. In general, the size of the lymph nodes is less than 4 cm in diameter. The CT scan shows the peripheral enhancement in TL. On rare occasions, the peripheral enhancement may, however, be seen in untreated lymphoma and lymphoma following radiotherapy. Two of our cases even had embedded vessels that could be seen on a CT scan, and our initial misinterpretation led to a diagnosis of neoplasm. Therefore, the distribution characteristics of the anatomic regions, morphological patterns including size, and enhancement features on the CT scans are all helpful in distinguishing TL from lymphoma, although the results may not be conclusive in some cases.

Another important goal in the development of CT imaging as a screening tool for abdominal nonhematogenous disseminated TL is to differentiate this disease from metastatic lymphadenopathy. Most of the metastases are easily diagnosed because of the presence of a primary tumor, and they generally show homogeneous enhancement on the contrast-enhanced CT scans. Some malignant adenopathies, especially testicular tumors, can result in abdominal metastatic lymphadenopathy with peripheral rim enhancement^[12]. Diagnosis aims to locate the primary tumors first. The anatomic distribution characteristics can sometimes provide clues to the differential diagnosis. For testicular tumors, the metastases may be located in the renal perihilar, paralumbar, and aortic bifurcation regions^[12]. Moreover, other infectious diseases, such as Whipple's disease, can also appear on contrast-enhanced CT scans and may look similar to TL. Although these diseases are

rare, they should be considered in the differential diagnosis.

Three patients received an initial diagnosis of pancreatic tumor following sonography and CT scans. The retrospective review of the CT scans found the clear boundary of lymphadenopathy presented on contrast-enhanced images and could be easily distinguished from the pancreas. This misdiagnosis was likely the result of unfamiliarity with identifying the features of non-malignant lymphadenopathies using CT imaging.

CT or ultrasound-guided needle aspiration cytology has been used to confirm diagnoses^[23,24]. These methods are quicker and less invasive than surgery; moreover, these methods can offer high diagnostic accuracy. In a study by Suri *et al.*^[25], ultrasound-guided needle aspiration cytology yielded a positive diagnosis in 78.6% of 14 cases of abdominal TL and a false negative result in only one patient. However, this technique is heavily operator dependent, particularly when not enough tissues are harvested and when the nodes are situated in close proximity to major blood vessels or important viscera, posing a risk to the patient. In cases where this technique is inconvenient or its result is ambiguous, diagnostic laparoscopy could be scheduled to collect sufficient tissues for histological and microbiological examinations, except in those patients with significant risk of perforation^[26,27].

In conclusion, the characteristics of anatomic distribution, morphological pattern, and enhancement features on contrast-enhanced CT scans will help to differentiate between abdominal nonhematogenous disseminated TL and lymph node neoplasms. Ultrasound-guided needle aspiration cytology performed by an experienced operator should be the first method of diagnosis, although diagnostic laparoscopy is a more reliable method for selected patients.

COMMENTS

Background

Tuberculous lymphadenopathy (TL) is the most common manifestation of abdominal tuberculosis. The diagnosis of abdominal hematogenous disseminated TL can be made clinically in patients with active pulmonary miliary tuberculosis. Patients with abdominal nonhematogenous disseminated TL typically present with an isolated mass or a mass adhering to the surrounding organs, and these masses may easily be confused with neoplasm. With the widespread use of computed tomography (CT), physicians should be familiar with the features of CT images for these patients and be able to make differential diagnoses based upon such findings.

Research frontiers

CT is a useful method in the diagnosis and differential diagnosis of abdominal lesions. This study reports on CT findings from 12 patients with abdominal non-hematogenous disseminated TL.

Innovations and breakthroughs

Abdominal nonhematogenous disseminated TL still presents a diagnostic dilemma. The authors reviewed 12 patients with this condition and also reviewed the related literature to develop a diagnostic algorithm.

Applications

The recognition of relatively specific CT findings of abdominal nonhematogenous disseminated TL may help avoid misdiagnosis and unnecessary invasive procedures, allowing for the prompt consideration of antituberculosis therapy.

Peer review

The authors describe typical CT features of abdominal nonhematogenous disseminated tuberculous lymphadenopathy in 12 patients. The paper is well organised and informative.

Abstract

Pancreatic fistula is a common complication of distal pancreatectomy; although various surgical procedures have been proposed, no clear advantage is evident for a single technique. We herein report the case of a 38-year-old patient affected by an advanced gastric carcinoma infiltrating the pancreas body, with extensive nodal metastases involving the celiac trunk, who underwent total gastrectomy with lymphadenectomy, distal pancreatectomy and resection *en bloc* of the celiac trunk (Appleby operation). At the end of the demolitive phase, the pancreatic stump and the aorta at the level of the celiac ligature were covered with a layer of Tachosil[®], a horse collagen sponge made with human coagulation factors (fibrinogen and thrombin). Presenting this case, we wish to highlight the possible sealing effect of this product and hypothesize a role in preventing pancreatic fistula and postoperative lymphorrhagia from extensive nodal dissection.

INTRODUCTION

Even though several technical solutions have been proposed, pancreatic fistula remains a frequent complication after distal pancreatectomy, ranging in incidence from 15% to 40%^[1,2]. Almost all serious postoperative sequelae can be ascribed to this complication, and hospitalization times are significantly longer. In the cases in which distal pancreatic resection is only a part of a more complicated, usually oncological, surgical operation, the occurrence of a fistula containing large amounts of proteolytic enzymes can endanger the integrity of visceral sutures and lead to the contamination of prosthetic material, if present. The performance of extensive lymphadenectomy represents an additional risk factor for possible infection of fluids coming from lymphorrhagia. In these cases, achieving a completely dry pancreatic stump and an optimal lymphostasis is a very important goal. No clear evidence is given in the literature with regard to both aspects: there is no indication of a technique or a method guaranteeing a higher level of success.

We would like to report a clinical case during which we successfully experimented with a collagen-based biological glue which had originally been proposed as a hemostatic means. We applied it as a sealer on the pancre-

atic stump after distal resection and on the aorta after a periaortic lymphadenectomy removing the celiac trunk in a young patient affected by advanced gastric carcinoma.

CASE REPORT

A 38-year-old male patient was affected by an averagely differentiated intestinal adenocarcinoma of the esophago-gastric junction recently complicated by a digestive hemorrhage. Multiphase computed tomography (CT) scan showed that the neoplasm had extended to the pancreatic body with an extensive lymph nodal involvement along the left gastric artery which was completely encompassed as far as the celiac trunk. The contact between the celiac trunk and the larger node (3.5 cm) corresponded to 180 degrees (Figure 1). Neoadjuvant chemotherapy with epirubicin, cisplatin, fluorouracil (ECF) cycles was undergone according to the formerly validated protocol^[3]. The restaging CT scan showed a stability of the radiological picture, with no evident regression of the adenopathies along the small curvature and the celiac trunk. We decided therefore to proceed with a demolition surgery. The surgical exploration revealed neither peritoneal carcinosis nor hepatic metastases and confirmed the extensive nodal involvement of the proper hepatic artery and the celiac tripod, the origin of which from the aorta was free (Figure 2). We performed a temporary clamping test of the common hepatic artery and kept the hepatic arterial perfusion under control by inverting the flow of the gastroduodenal artery. We then proceeded to a total gastrectomy and to a distal spleno-pancreatectomy (the pancreas was sectioned by green stitches and a 60 mm GIA stapler), to left adrenalectomy and to *en bloc* removal of perigastric nodes and of the celiac artery (Appleby operation)^[4]. The intervention was then completed by performing a lymphadenectomy of the hepatic pedicle, of the rear-pancreatic and of the interaorto-caval basins. Gastroenteric continuity was restored by mechanical termino-lateral esophago-digiunostomy using a defunctionalized Roux-en-Y loop. The pancreatic stump was then covered with a layer of Tachosil®; a further layer of the same material was then applied to the aorta at the level of the celiac ligature (Figure 3).

The postoperative course was uneventful and the patient left the hospital on the 15th day after surgery. Daily monitoring of the hepatic function did not reveal functional insufficiencies and the increase in cytolysis values was low (AST 92 U/dL, ALT 89 U/dL; normal values < 50 U/dL) and transitory. The outcome of the 3 abdominal drains was always lower than 50 mL/d; the enzymatic dosage in the drained liquid showed a pathological value only on the 1st postoperative day (1500 U/dL; normal value < 286 U/dL), which, according to recent publications^[5], does not indicate the presence of pancreatic fistula. It then dropped to normal values (< 35 U/dL starting from the 4th day). Serum lipases were always normal.

The final pathological report indicated an intestinal type gastric adenocarcinoma of the cardias, infiltrating the whole thickness of the wall and extending to the peri-

Figure 1 Contrast-enhanced computed tomography scan. A cardia tumor is evident (A), associated with multiple enlarged nodes infiltrating the celiac trunk origin (B) and the pancreatic body (C).

Figure 2 Intraoperative findings. Celiac trunk origin from the aorta is free from tumor infiltration.

gastric adipose tissue, directly infiltrating the pancreatic body, the hepatic artery and the left adrenal gland. Lymph node metastases were present in 19 out of 51 removed

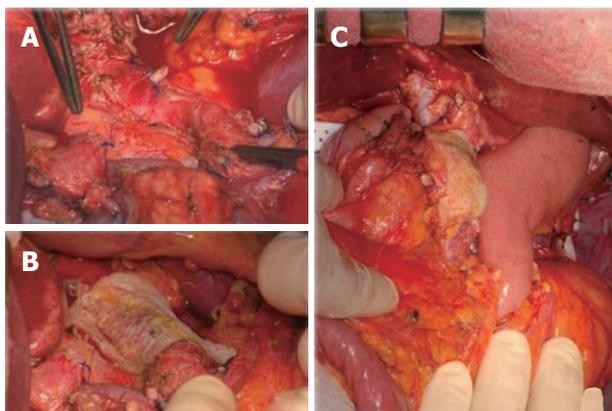

Figure 3 Intraoperative findings after the demolitive phase. A: From the left, the distal hepatic artery stump, the celiac stump and the superior mesenteric artery; B, C: Tachosil® is then applied over the aorta (B) and over the pancreas stump (C).

nodes (pT4N3M0, stage IV). The patient therefore underwent 3 further adjuvant chemotherapy cycles using EFC. After 17 mo the patient developed multiple hepatic metastases treated with a further chemotherapy cycle and died 23 mo after surgery.

DISCUSSION

Distal pancreatectomy involves a higher risk of pancreatic fistulas than duodeno-pancreatectomy. Even though these are “pure” pancreatic fistulas, subsequent complications have a significant effect on the patient postoperative course. It is commonly believed that, along with the clear role played by the structure and consistency of the pancreas, the main risk factors for fistula are the technique used for sectioning the pancreas neck and the treatment of the residual stump. Up to the present, no standardized procedure has been defined^[6]. Several technical proposals have been presented, often employed in an insufficient number of cases; furthermore, patient selection bias and a non-homogeneous definition of the primary end-point (clinical or biochemical pancreatic fistula with different cut-offs in terms of enzymatic values on different postoperative days)^[7] are quite evident. Also, the potentially influential effect of the experience of the surgeon, which, in itself, seems to produce great divergence in results even when the same technique is being used, must be taken into consideration.

The reported clinical case presents some interesting elements; the neoplasm affected the stomach and involved the pancreas as a direct infiltration, with an extensive lymph node involvement mainly along the vascular axes. The clear infiltration of the proper hepatic artery, of the celiac trunk and of the left adrenal gland made an ample periaortic dissection, including the celiac nodes, necessary. The presence of two sutures at risk, the duodenal stump and the origin of the celiac trunk which had been removed *en bloc*, made it particularly important to find a treatment which would reduce the risk

of complications to a minimum. The pancreatic body was sectioned with a mechanical stapler. From a recent review, it seems that this technique presents a lower risk of failure, even though no statistical significance levels have been reached. However, even using this treatment, the fistula rate is higher than 20%^[8]. Among the elements to explain this non-satisfactory result we can consider the compression exerted by the stapler, which can lacerate the parenchyma, especially if it is fragile, and the fact that the Wirsung duct is not identified and individually secured. In the case we are describing, the choice of this method, which we do not routinely use, was justified by the reduced thickness of the pancreas at the point chosen for sectioning. Thus, we deviated from the procedure we generally use for the treatment of distal tumors; specifically, the sectioning of the pancreas with a cutter, the application of 5/0 monofilament fine hemostatic stitches and the meticulous search for the Wirsung duct. This latter phase is particularly important to reduce the risk of fistula; it requires careful preparation of the duct and subsequently the application of a double loop suture or an anchoring stitch before sectioning.

If, as in the described case, a selective treatment of the Wirsung is not possible, we believe that it is useful to perfect the treatment of the residual stump using Tachosil®, a horse collagen sponge on which human coagulation factors (fibrinogen and thrombin) are applied. From a first analysis of the components, it transpires that this product combines the hemostatic characteristics of biological glue with the adhesive/reparatory properties of collagen. On the basis of these characteristics, the product was initially used for hemostasis and, as a logical consequence, it is now being used more and more in the field of hepatic resection surgery, in emergency trauma surgery and in every situation in which one wishes to perfect a hemostasis “which is already sufficiently completed”^[9,10]. However, in the application we are presenting, we wish to highlight the sealing effect of this product resulting from the rapid adhesion of collagen, helped by means of the rapidly activated coagulation process on the pancreatic stump. This consolidates the obliteration of the excretory duct and reduces to a minimum the effect of small, accessory pancreatic ducts left open. The sealing effect is practically immediate; moderate pressure, which we recommend applying for some minutes, mainly aims at letting the product adhere. After wetting it, the product can be modeled onto the section surface, including its margins and also the ventral and dorsal surface, at a depth of at least one centimeter. Although the product does not require a completely dry surface for the best adhesion to the section surface, it is recommended to have a moderately anfractuous plane. The absorption of the product takes a few weeks and therefore the product cannot favor septic complications in the case of fistula.

The present report simply suggests a possible application of Tachosil®; there is no direct evidence of its ability to prevent the pancreatic fistula, so more cases of distal pancreatectomy should be collected, as it is actually ongoing in a multicenter, randomized, prospective Italian trial.

This sealing effect of Tachosil® was also used to reduce the risk of lymphorrhagia after the extensive lymphadenectomy performed in this case because of the metastatic involvement of lymph nodes in the celiac area, as far as the area adjacent to the aorta. In a case such as this, lengthy draining is commonly used to successfully treat lymphatic losses if the quantity exceeds 1 liter a day, if they persist for a few days and if they show a further increase as soon as free feeding is re-introduced. The application of Tachosil® to refreshed areas at higher risk can contribute to sealing open lymphatic channels and to facilitate the healing process, thus making the early removal of drainage possible and reducing the risk of bacterial contamination. This indication has also not been verified in controlled trials and it represents at this time a simple hypothesis for further studies.

Abstract

Dual antiplatelet therapy consisting of low-dose aspirin (LDA) and other antiplatelet medications is recommended in patients with coronary heart disease, but it may increase the risk of esophageal lesion and bleeding. We describe a case of esophageal mucosal lesion that was difficult to distinguish from malignancy in a patient with a history of ingesting LDA and prasugrel after implantation of a drug-eluting stent. Multiple auxiliary examinations were performed to make a definite diagnosis. The patient recovered completely after concomitant acid-suppressive therapy. Based on these findings, we strongly argue for the evaluation of the risk of gastrointestinal mucosal injury and hemorrhage if LDA therapy is required, and we stress the paramount importance of using drug combinations in individual patients.

INTRODUCTION

Low-dose aspirin (LDA) is used widely as an antiplatelet therapy for the prevention of cardiovascular and cerebrovascular events^[1]. Dual antiplatelet therapy is more effective than aspirin alone^[2]. However, the risk of severe bleeding, including life-threatening hemorrhaging, increases with the use of aspirin therapy^[3]. The most vulnerable organs are the stomach and duodenum, although recent reports indicate an increased risk of esophageal lesions with LDA use^[4,5]. The US Preventive Services Task Force recommends the use of aspirin for men aged 45 to 79 years when the potential benefit due to a reduction in myocardial infarction outweighs the potential harm due to an increase in gastrointestinal hemorrhage^[6].

Prasugrel, a third-generation thienopyridine, specifically inhibits platelet clotting by binding the adenosine diphosphate receptor. Prasugrel is approved by the Food and Drug Administration (FDA) for acute coronary syndrome (ACS) in patients undergoing percutaneous coronary intervention (PCI). Its recommended loading dose is 60 mg x1, followed by a maintenance dose (10 mg once daily), and combined with concomitant aspirin (81-325 mg, once daily)^[7]. Compared to clopidogrel, prasugrel has been shown to reduce thrombotic cardiovascular events significantly, including stent thrombosis, in patients with ACS who are managed with PCI. However, prasugrel

can cause significant and fatal bleeding, and it has a FDA black-box warning regarding bleeding risk^[7]. Thus, patient selection is important.

Here, we present a case with esophageal lesion mimicking malignancy related to aspirin and prasugrel treatment after drug-eluting stent (DES) implantation.

CASE REPORT

A 58-year-old male was admitted in August 2010 because of melena and hematemesis. About 1.5 mo before admission, the patient underwent PCI and received a DES due to chest pain. Low-dose aspirin (100 mg, once per day) and prasugrel (Effient, 10 mg, once per day) were administered.

One month later, the patient felt epigastric discomfort accompanied by severe chest pain. Coronary arteriography was repeated without positive findings. Gastroendoscopy was then performed, which showed edematous esophageal mucosa with blood clots, a column of violaceous and nontortuous lesions with minimal whitish exudates that occupied more than half of the lumen from the 26 cm to the 42 cm level (Figure 1A). Esophageal candidiasis was suspected. Biopsy indicated that there were necrotic tissues with partly degenerated atypical fusiform to epithelioid cells of undetermined significance.

At 7 d before admission, the patient passed a dark pasty stool of about 250 g after taking some cathartics. Three days later, gastroendoscopy was performed in Shanghai Cancer Center, which revealed a slim ulcer from the 26 cm down to the 40 cm level. Pathology suggested inflammation and granuloma gangraenescens. Chest contrast computed tomography demonstrated thickening of the middle-lower segment of the esophageal wall and a few of the small lymph nodes at the mediastinum (Figure 1B and C) with some pleural effusion. An upper gastrointestinal series (barium X-ray) showed an irregular esophageal wall with stiff movement, and the possibility of malignant tumor could not be excluded (Figure 1D).

One day after the examination, the patient felt nauseous and vomited dark blood clots. He was sent urgently to our emergency room. After treatment with proton pump inhibitors (PPIs), he had no signs of active bleeding. He was transferred to the gastroenterology department for further diagnosis. Another gastroendoscopy was performed after intravenous PPI therapy for 1 wk. Endoscopy by white light imaging (WLI) and narrow band imaging (NBI) showed that the esophageal mucosa was peeled off (Figure 1E and F). Endoscopic ultrasonography suggested that the layers of the esophagus were clear and identifiable; the lesion took on a minimal higher echo (Figure 1G). Tumor markers were normal. Antiplatelet drugs were discontinued after admission, and symptoms improved within 7 d. Clopidogrel and oral PPI were administered afterwards. He was discharged on the 7th day. Two months later, endoscopy showed that the esophageal lesion had completely healed.

DISCUSSION

It was very difficult to identify the esophageal lesion in this patient. After the first gastroendoscopy showed edematous mucosa with blood clots, it was risky to perform a biopsy and difficult to recognize the lesion. It seemed to be a malignant tumor on the basis of the previous auxiliary examinations. Moreover, the accuracy of the biopsy was affected by the focal position and depth; such a situation could easily mislead medical providers.

If discrete erosions had occurred in areas away from the Z line, then drug-induced injury would have been strongly considered^[8]. The occurrence of esophageal mucosal injury by LDA is related closely to the intragastric pH value, especially at night^[9]. A multicenter randomized controlled trial documented that use of the NBI mode could improve the diagnostic accuracy of endoscopy, compared to the WLI mode^[10]. When the auxiliary examination is not consistent with clinical symptoms, further diagnostic modalities are required. If all of the tests are inconclusive, then repeat examinations are needed to confirm or rule out the prior diagnosis after diagnostic treatment. The appropriate use of diverse and repeatable examinations to improve the accuracy of an uncertain disease is of great value.

Esophageal cancer develops rapidly and has a fatal prognosis. It has displayed an increasing incidence in the past decade, with the highest incidence in the age group of 50-70 years. The disease is diagnosed more frequently in males than in females, with an approximate ratio of 3-5^[11]. Whether aspirin has implications for cancer prevention is debatable. Kawai *et al*^[5] investigated 101 consecutive outpatients with cardiovascular diseases who had been on LDA therapy. They found that the incidence of esophageal lesions was 8.9%, whereas the rate of esophageal and gastric cancers was up to 5.9%. Abnet *et al*^[12] found no correlation between the self-reported use of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) and esophageal adenocarcinomas in a prospective cohort followed for 7 years. However, their meta-analysis manifested that aspirin use was inversely associated with esophageal adenocarcinomas, with a summary odds ratios for esophageal adenocarcinomas of 0.64. Considering these previous findings, we speculate that regular endoscopic surveillance might benefit patients on dual antiplatelet therapy.

Upper gastrointestinal hemorrhage is an urgent life-threatening event that is commonly incited by a peptic ulcer or varices. However, evidence indicates that aspirin or other NSAIDs are another potential cause, especially in elderly patients with cardiac or cerebral events. A meta-analysis of 24 randomized controlled trials documented gastrointestinal hemorrhage in 2.47% of patients taking aspirin, compared with 1.42% taking placebo [Odds ratio (OR): 1.68], and no relationship was observed between gastrointestinal hemorrhage and dose^[13]. Among 674 patients with upper gastrointestinal bleeds, the odds ratio for the presence of erosive esophagitis in aspirin users

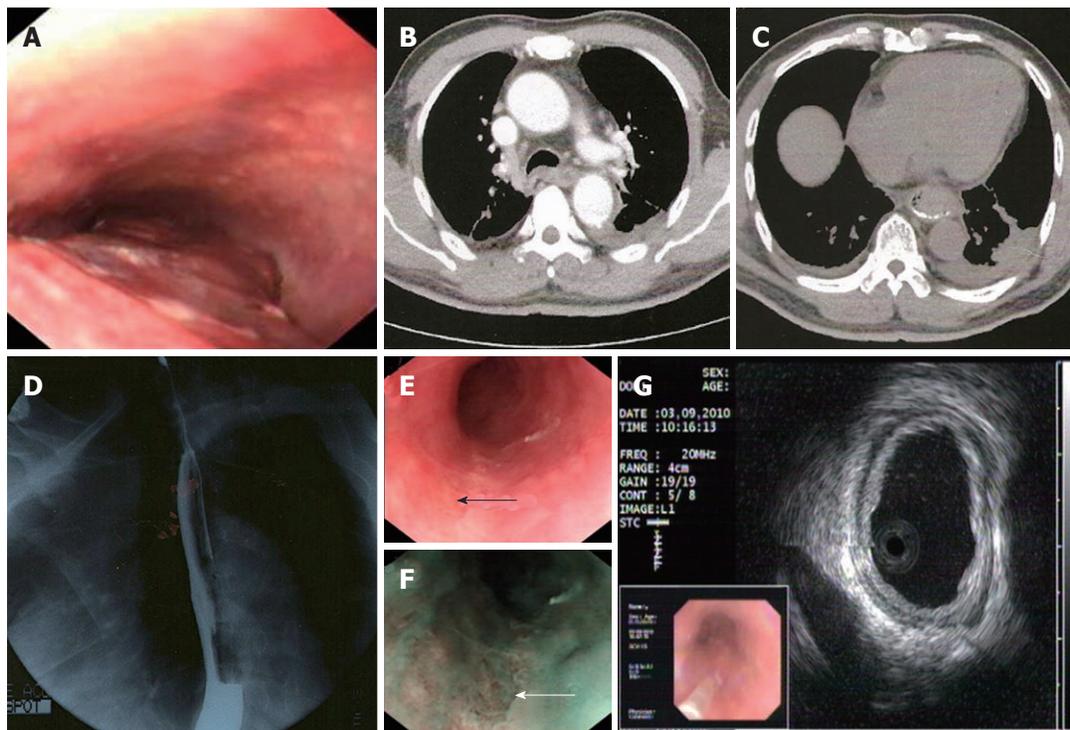

Figure 1 Auxiliary examination. A: Gastroendoscopy showing edematous mucosa with blood clots; B and C: Obstructive esophageal lumen and lymph nodes with some pleural effusion shown by chest contrast computed tomography; D: Barium X-ray displaying irregular esophageal wall; E and F: The mucosal lesion evaluated by white light imaging (black arrow) or narrow band imaging (white arrow) mode of endoscopy; G: Endoscopic ultrasonography showing focal minimal higher echo.

was 2 [95% confidence interval (CI): 1-3], and 3 (95% CI: 2-5) in patients taking other antithrombotic agents, including warfarin, clopidogrel, and dipyridamole. In 41 patients with esophagitis who were taking these drugs, 36 (88%) had cardiovascular disease and only 4 (10%) had peptic symptoms^[14]. These findings suggest that the gastrointestinal risk should be determined, even if LDA is required.

The appropriate use of aspirin is complicated. It is difficult to determine how to balance the prevention of stent thrombosis with the potential injury of the gastrointestinal mucosa. The use of enteric-coated aspirin decreases mucosal damage in the short term, but does not decrease the risk of hemorrhagic gastrointestinal events compared with noncoated aspirin^[15]. Yeomans *et al*^[16] investigated 991 patients who were randomized to take esomeprazole (20 mg, once per day) or placebo for 26 wk. They found that the cumulative proportion of patients with erosive esophagitis was significantly lower for esomeprazole *vs* placebo (4.4% *vs* 18.3%). Esomeprazole-treated patients were more likely to experience resolution of heartburn, acid regurgitation, and epigastric pain.

On the other hand, insufficient antithrombotic drugs might cause stent thrombosis. In November 2009, the FDA warned that the effectiveness of clopidogrel was reduced when clopidogrel and omeprazole were taken together. Warner *et al*^[17] reported that the use of aspirin in the presence of prasugrel could increase the clinical risk of residual ischemic events and bleeding complications. Whether dual antiplatelet therapy should be prescribed routinely to high-risk patients requires a complete un-

derstanding of its long-term consequences. In particular, for an individual patient, this decision must consider the trade-off between the potential benefits of preventing ischemic events weighed against the risk of bleeding complications.

Drug combinations must be prudently selected for individual patients. Compared with the second-generation clopidogrel (Plavix), prasugrel is more potent, faster in onset, and more consistent in inhibiting platelets, but bleeding complications are more frequent^[18]. From the aspect of clinical and cost effectiveness, prasugrel in combination with aspirin could be an option for preventing atherothrombotic events in people having ACS with PCI only when immediate primary PCI for ST-segment-elevation myocardial infarction is necessary, stent thrombosis has occurred during clopidogrel treatment, or in cases of diabetes mellitus. Prasugrel should be used with caution in patients at an increased risk of bleeding, especially in patients who are ≥ 75 years old with a tendency to bleed or with body weight of < 60 kg^[19]. A guideline has recommended that clopidogrel should be continued for at least 12 mo for patients who receive a DES^[7,19]. A randomized controlled trial found no apparent cardiovascular interaction between clopidogrel and omeprazole, and prophylactic use of a PPI reduced the rate of upper gastrointestinal bleeding^[20]. Thus, for such patients with a high risk of bleeding, clopidogrel plus PPI might be a better recommendation to decrease the risk of gastrointestinal bleeding.

In conclusion, this case report of a patient developing an esophageal mucosal lesion mimicking malignancy

while under LDA and prasugrel treatment highlights the need to evaluate the gastrointestinal risk if LDA therapy is required. The findings also stress the importance of the rational selection of drug combinations in individual patients.

Abstract

Carcinoid tumors are the most common neuroendocrine tumors. Gastric carcinoids represent 2% of all carcinoids and 1% of all gastric masses. Due to the widespread use of Esophagogastroduodenoscopy for evaluating a variety of upper gastrointestinal symptoms, the detection of early gastric carcinoids has increased. We highlight an alternative management of a young patient with recurrent type 1 gastric carcinoids with greater than 5 lesions, as well as lesions intermittently greater than 1 cm. Gastric carcinoids have a variable presentation and clinical course that is highly dependent on type. Type 1 gastric carcinoids are usually indolent and have a metastasis rate of less than 2%, even with tumors larger than 2 cm. There are a number of experts as well as organizations that recommend endoscopic resection for all type 1 gastric carcinoid lesions less than 1 cm, with a follow-up every 6-12 mo. They also recommend antrectomy for type 1 gastric carcinoids with greater than 5 lesions, lesions 1 cm or greater, or

refractory anemia. However, the American Society of Gastrointestinal Endoscopy guidelines state that type 1 gastric carcinoid surveillance is controversial based on the evidence and could not make an evidence-based position statement on the best treatment modality. Our report illustrates a rare cause of iron deficiency anemia in a young male (without any medical history) due to multiple recurrent gastric carcinoid type 1 lesions in the setting of atrophic gastritis causing hypergastrinemia, and in the absence of a vitamin B12 deficiency. Gastric carcinoid type 1 can present in young males without an autoimmune history, despite the known predilection for women aged 50 to 70 years. Type 1 gastric carcinoids can be managed by endoscopic resection in patients with greater than 5 lesions, even with lesions larger than 1 cm. This course of treatment enabled the avoidance of early antrectomy in our patient, who expressed a preference against more invasive measures at his young age.

gastric carcinoid^[1]. Carcinoid tumors are the most common neuroendocrine tumors^[2] and gastric carcinoids represent 2% of all carcinoids and 1% of all gastric masses^[1]. Due to the widespread use of Esophagogastroduodenoscopy (EGD) to evaluate a variety of upper gastrointestinal symptoms, the detection of early gastric carcinoids has increased. We highlight an alternative management of a young patient with recurrent type 1 gastric carcinoids with greater than 5 lesions as well as lesions intermittently greater than 1 cm.

A 28-year-old Indian male with no significant medical history presented with fatigue. He was found to have severe iron deficiency anemia (hemoglobin of 68 gm/L) with a mean corpuscular volume of 77 fL, and an iron level of 370 mcg/L. Endoscopic evaluation for anemia revealed nine sessile polyps in the body and fundus of the stomach ranging from 5 mm to 9 mm, which were all resected. An Endoscopic Ultrasound showed the lesions to be within the mucosa and there was no evidence of gastrinoma or metastatic disease to the liver or pancreas. The serum gastrin level was 1534 ng/L and other causes of hypergastrinemia were considered (Table 1)^[3-6]. Histopathological examination of the polyps confirmed carcinoid tumors with positive synaptophysin and chromogranin. The body of the stomach revealed autoimmune atrophic gastritis without oxyntic mucosa, helicobacter pylori, or evidence of parietal cell hyperplasia. Capsule endoscopy and colonoscopy did not reveal any other sources of blood loss or further carcinoid tumors. Octreotide scans, vitamin B12 levels, as well as Computed Tomography

scans of the thorax, abdomen, and pelvis were normal. Surveillance EGD 6 mo later showed recurrence with 5 polyps, with the largest measuring 1.1 cm, which was resected. Since resection, the patient has experienced a resolution of his anemia along with normal gastrin levels. The patient has not had more than 5 lesions or a lesion greater than 1 cm for over two years.

Gastric carcinoids have a variable presentation and clinical course that is highly dependent on type (Table 2)^[7]. Type 1 gastric carcinoids are usually indolent and have a metastasis rate of less than 2%, even with tumors larger than 2 cm^[8]. Kadikoylu *et al*^[1] recommend endoscopic resection for all type 1 gastric carcinoid lesions less than 1 cm with follow-up every 6-12 mo and antrectomy for type 1 gastric carcinoids with greater than 5 lesions, lesions 1 cm or greater, or refractory anemia. However, the American Society of Gastrointestinal Endoscopy guidelines state that type 1 gastric carcinoid surveillance is controversial based on the evidence and could not make an evidence-based position statement on the best treatment modality^[9].

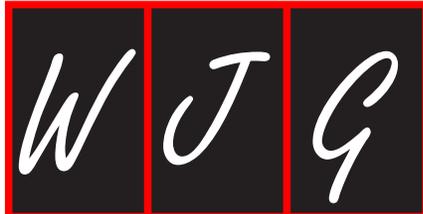

This report illustrates a rare cause of iron deficiency anemia in a young male (without any medical history) due to multiple recurrent gastric carcinoid type 1 lesions in the setting of atrophic gastritis causing hypergastrinemia and in the absence of a vitamin B12 deficiency. Gastric carcinoid type 1 can present in young males without an autoimmune history, despite the known predilection for women aged 50 to 70 years. Type 1 gastric carcinoids can be managed by endoscopic resection in patients with

greater than 5 lesions, even with lesions larger than 1 cm. This course of treatment enabled the avoidance of early antrectomy in our patient, who expressed a preference against more invasive measures at his young age.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copyright” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under

study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be

Instructions to authors

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Plased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published

by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D, Ocean International Center, No. 62 Dongsihuan Zhonglu,

Instructions to authors

Chaoyang District, Beijing 100025, China

Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekaAlert/AAAS (<http://www.eurekaalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Chronic hepatitis due to any cause leads to cirrhosis and end-stage liver disease. A growing body of literature has also shown that fatty liver due to overweight or obesity is a leading cause of cirrhosis. Due to the obesity epidemic, fatty liver is now a significant problem in clinical practice. Steatosis has an impact on the acceleration of liver damage in patients with chronic hepatitis due to other causes. An association between hepatitis C virus (HCV) infection, steatosis and the onset of insulin resistance has been reported. Insulin resistance is one of the leading factors for severe fibrosis in chronic HCV infections. Moreover, hyperinsulinemia has a deleterious effect on the management of chronic HCV. Response to therapy is increased by decreasing insulin resistance by weight loss or the use of thiazolidinediones or metformin. The underlying mechanisms of this complex interaction are not fully understood. A direct cytopathic effect of HCV has been suggested. The genomic structure of HCV (suggesting that some viral sequences are involved in the intracellular accumulation of triglycerides), lipid metabolism, the molecular links between the HCV core protein and lipid droplets (the core protein of HCV and its transcriptional

regulatory function which induce a triglyceride accumulation in hepatocytes) and increased neolipogenesis and inhibited fatty acid degradation in mitochondria have been investigated.

INTRODUCTION

Chronic hepatitis due to any cause leads to cirrhosis and end-stage liver disease. A growing body of literature has also shown that fatty liver due to overweight or obesity is a leading cause of cirrhosis^[1-3]. Due to the obesity epidemic, fatty liver is now a significant problem in clinical practice. An association between hepatitis C virus (HCV) infection, steatosis and the onset of insulin resistance has been reported^[4-6]. Moreover, steatosis has an impact on the acceleration of liver damage in patients with chronic hepatitis due to other causes. The underlying mechanisms of this complex interaction are not fully understood. A direct cytopathic effect of HCV has been suggested. The genomic structure of HCV (suggesting

that some viral sequences are involved in the intracellular accumulation of triglycerides, lipid metabolism, and the molecular links between the HCV core protein and lipid droplets (the core protein of HCV and its transcriptional regulatory function which induce a triglyceride accumulation in hepatocytes) and increased neolipogenesis and inhibited fatty acid degradation in mitochondria have been investigated (Figure 1).

BACKGROUND OF FATTY LIVER

Excessive accumulation of triglycerides in hepatocytes in the absence of significant alcohol consumption, defined as > 5% fat by weight, occurs in about 20%-30% of adults^[1-3]. Excessive fat in the liver predisposes to the development of steatohepatitis which is a significant risk factor for developing cirrhosis and its complications, including hepatocellular carcinoma.

Background of insulin resistance in patients with HCV

The frequency of type 2 diabetes is more common in patients with chronic HCV infection than in hepatitis B infection (21% *vs* 12%, respectively) which is evidence of a link between HCV infection and diabetes mellitus (DM)^[4-6]. This relationship is independent of the existence of cirrhosis. A large cross-sectional United States study which included over 9000 individuals showed that the frequency of type 2 DM is 3-fold more common in hepatitis C patients. Both older age and higher body mass index (BMI) are more common among patients with both hepatitis C and type 2 diabetes.

Insulin resistance (IR) is a specific feature of chronic HCV, associated with genotypes 1 and 4 and high serum HCV RNA level^[7]. Chronically HCV infected subjects present a 3-fold increased risk of IR and glucose metabolism impairment, with IR occurring in the very early stages of hepatic lesions (fibrosis stage 0 or 1), with a worsening tendency as hepatic fibrosis progresses^[8-10]. There is also an association between IR severity and DM, with higher viral load and an improvement in IR after a sustained viral response.

A recently published study which investigated 600 patients [chronic hepatitis C (CHC) in 500 and chronic hepatitis B (CHB) in 100] reported that IR was present in 32.4% of the 462 nondiabetic CHC patients and was associated with the metabolic syndrome, genotypes 1 and 4, significant fibrosis, and severe steatosis^[7]. IR was diagnosed in 15% of 145 CHC patients without metabolic syndrome or significant fibrosis, and was associated with genotypes 1 and 4, high serum HCV RNA level, and moderate-to-severe necroinflammation. IR was less frequent in CHB patients than in matched CHC patients (5% *vs* 35%, respectively, $P < 0.001$).

In our clinic, we investigated 76 patients. Of these 76, 12 had hepatitis B, 19 had hepatitis C, 34 had simple steatosis and 11 were control subjects. We found that IR was only significant and associated with severe fibrosis in patients with HCV^[11].

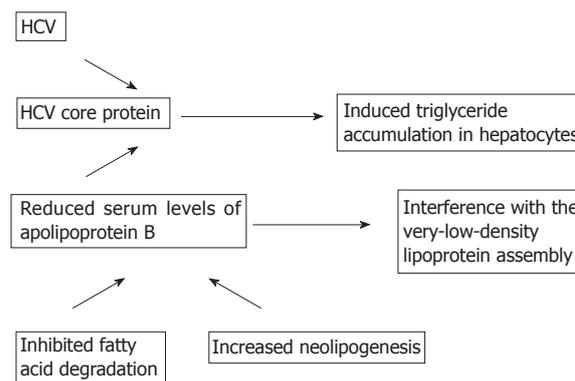

Figure 1 Underlying mechanisms of the complex interaction resulting in steatosis in patients with hepatitis C virus. HCV: Hepatitis C virus.

Whether fat in the liver is an important determinant of IR is debatable. The study showed that insulin secretion assessed by intravenous glucose injection was not impaired in CHC patients compared to the controls^[12]. When they studied the IR of 29 people with hepatitis C (14 with genotype 1 and 15 with genotype 3) and confirmed they had high IR, nearly all the IR was found to be in the muscle and hardly any in the liver. Of the 29 patients, 15 had very high levels of fat in the liver and had the same degree of IR as the 14 patients who did not have fatty livers.

IR is one of the leading factors for severe fibrosis in CHC infections independent of steatosis, as compensatory hyperinsulinemia is fibrogenic^[12]. Moreover, a relationship between exogenous hyperinsulinemia and hepatocellular carcinoma has been reported. Hyperinsulinemia decreases therapy response and has a deleterious effect on the management of chronic HCV infection. Response to therapy is increased by decreasing insulin resistance by weight loss or the use of thiazolidinediones and metformin. Metformin improved virologic response when added to hepatitis C interferon-ribavirin therapy in those with IR^[13].

A relationship between type 1 diabetes and hepatitis C, and type 2 diabetes and hepatitis B has not so far been reported^[14].

Background of steatosis in patients with HCV infection

The prevalence of steatosis is 20%-30% in the general population and is 50%-80% in patients with HCV infection. HCV itself has the ability to directly promote steatosis and IR^[15-18]. If all steatogenic co-factors are excluded, the prevalence of steatosis remains at 50% resulting in a 2.5-fold increased prevalence as compared with the general population and other forms of chronic liver disease. The prevalence of steatosis is 18% in hepatitis B virus infection^[19].

There are 2 types of liver steatosis: metabolic steatosis which is related to high BMI in patients with genotype 1, and viral steatosis which is related to hepatitis C genotype 3. Steatosis is more frequent in association with genotype 3a as compared to other genotypes such

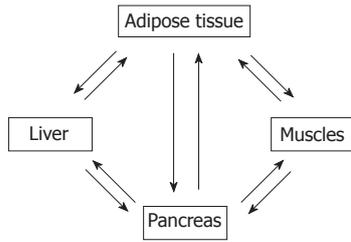

Figure 2 Cross-talk among the insulin sensitive organs.

as genotype 1, 2 and 4 (74% vs 50%), which suggests that some sequences of the viral genome may be involved in intracellular lipid accumulation^[16]. Additionally, steatosis correlates with viral load and can revert after effective treatment and reoccurs with re-infection in genotype 3 infection.

The localization of steatosis, particularly in genotype 3 infected patients, is predominantly in the periportal zone (acinar 1) and not in the centrilobular zone (acinar 3) and is more typical of metabolic associated steatohepatitis^[20-23]. All genotypes are steatogenic, however, genotype 3 is three times more potent. Transgenic mouse models showed that the core protein can induce the appearance of lipid droplets. One possible molecular explanation for the greater steatogenic property of genotype 3, could be a phenylalanine residue at position 164 in core protein domain II, instead of tyrosine as in other genotypes, which results in a higher affinity to lipids.

Hyperinsulinism, IR related, directly activates stellate cells and, in association with hyperglycemia, increases connective tissue growth factor, a key cytokine in hepatic fibrogenesis^[24,25]. Steatosis also relates to more advanced fibrosis and to accelerated fibrosis progression. Thus, treating HCV infected patients with evidence of hepatic steatosis, even if they only present mild inflammatory activity, has been suggested. How? Steatosis may sensitize the liver to inflammation and apoptosis, and subsequently enhance fibrosis. A recent study showed that hepatic steatosis is associated with higher programmed cell death by apoptosis with stellate cell activation^[26].

Background of insulin resistance

A balance exists between energy demand and intake in the human body. Obesity and its consequences such as IR and the metabolic syndrome, is a growing threat to the health of people in developed nations. While insulin receptor defects cause severe IR, most patients with IR have impaired post-receptor intracellular insulin signaling^[27].

INSULIN SIGNALING PATHWAY AND GLUCOSE HOMEOSTASIS

There is cross-talk among insulin sensitive tissues such as skeletal muscle, adipose tissue, and liver (Figure 2). Insulin binds α -subunits of its receptor which is a cell surface receptor on insulin sensitive cells such as skeletal

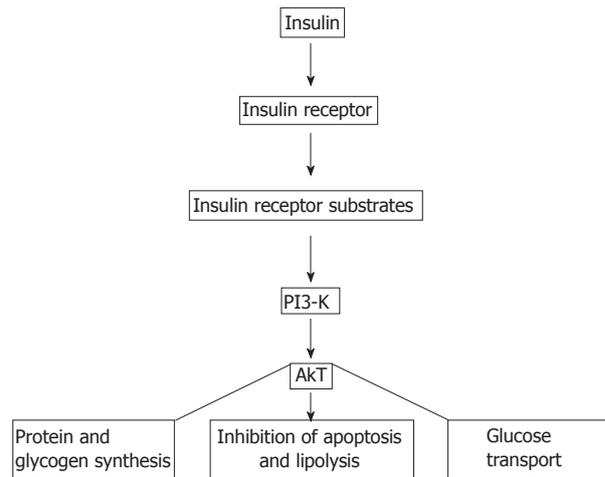

Figure 3 Insulin signaling pathways. PI3-K: Phosphatidylinositol 3-kinase; Akt: A serine/threonine protein kinase.

muscle, adipocytes, and hepatocytes leading to autophosphorylation of the cytoplasmic domains (β -subunits) of the receptor^[25-40]. The insulin receptor has intrinsic tyrosine kinase activity activated by insulin binding and the autophosphorylated receptor activates its substrates that include insulin receptor substrate (IRS)-1, IRS-2, Src homology collagen (Shc), and an adaptor protein with a pleckstrin homology (PH) and Src homology (SH) 2 domain by tyrosine phosphorylation (Figure 3). These phosphorylated docking proteins bind and activate several downstream components of the insulin signaling pathways. Activated IRS-1 associates with phosphatidylinositol 3-kinase (PI3-K), which then activates Akt. Akt substrate of 160 kDa (AS160), a serine/threonine kinase, was identified in 3T3-L1 adipocytes. In both skeletal muscle and adipose tissue, these insulin-mediated phosphorylation-dephosphorylation signaling cascades induce the translocation of glucose transporters (GLUT), predominantly GLUT4-containing vesicles, from intracellular storage sites to the plasma membrane, increasing glucose uptake to prevent abnormal glucose and insulin elevations in the plasma (insulin-stimulated glucose transport). These events and insulin-dependent inhibition of hepatic glucose output maintain glucose homeostasis. Insulin also affects glucose homeostasis indirectly by its regulatory effect on lipid metabolism. Any interference in this insulin signaling pathway causes glucotoxicity, insulin resistance and, when islet β cells are capable of responding, compensatory hyperinsulinemia. Hepatitis C virus Genotype 1b diminishes IRS-1 levels and causes IR.

Hepatic expression of insulin receptor protein was decreased in chronic hyperinsulinemic states. IRS-1 was more closely linked to glucose homeostasis with the regulation of glucokinase expression, while IRS-2 was more closely linked to lipogenesis with the regulation of lipogenic enzymes sterol regulatory element-binding protein-1c (SREBP-1c) and fatty acid synthase. Moreover, insulin activates synthesis and inhibits catabolism

of lipids, while shutting off the synthesis of glucose in the liver.

Adipose tissue is one of the major insulin sensitive organs in the human body and the process of differentiation of preadipocytes to adipocytes, induced by insulin, is called adipogenesis. Within the adipose tissue, insulin stimulates triglyceride synthesis (lipogenesis) and inhibits lipolysis by upregulating lipoprotein lipase activity which is the most sensitive pathway in insulin action, facilitating free fatty acid uptake and glucose transport, inhibiting hormone sensitive lipase, and increasing gene expression of lipogenic enzymes. Insulin also induces the degradation of apolipoprotein B100 (apo B100), a key component of very-low-density lipoprotein, in the liver^[41].

Insulin resistance

Insulin resistance can be defined as the failure of insulin sensitive cells to respond to insulin normally. It is characterized by elevated plasma glucose and, before attrition of pancreatic β -cells develops, elevated insulin levels. Chronic hyperinsulinemia is a major contributor to glucose and lipid metabolism abnormalities. Insulin resistance also inappropriately activates peripheral lipolysis and stimulates free fatty acid mobilization from adipocytes in the fed state. Increased circulating free fatty acids contribute to fat accumulation in the liver and muscle, further causing these tissues to be insulin resistant by disturbing their downstream insulin signaling cascades.

Mechanisms of insulin resistance (role of tumor necrosis factor- α and plasma free fatty acids)

The most common mechanism of IR is disturbed post-receptor insulin signaling (Figure 4)^[42-48]. Whereas most

insulin signaling is propagated by tyrosine phosphorylation, serine (Ser) phosphorylation is often inhibitory. Ser phosphorylation of IRS-1 decreases both insulin stimulated tyrosine phosphorylation of IRS-1 (phosphorylated Ser residues of IRS-1 become poor substrates for insulin receptor) and PI3-K activation. This diminishes the downstream insulin signaling and insulin sensitivity of insulin target tissues. IRS-1 has several Ser residues including Ser 307, Ser 612 and Ser 632 which can be phosphorylated. Insulin and tumor necrosis factor- α (TNF- α) can phosphorylate the same Ser residues of IRS-1. IR occurs very early in HCV infection, in parallel with an elevation in TNF- α levels. HCV also directly promotes IR through the proteasomal degradation of IRS-1.

TNF- α and plasma free fatty acids have been shown to be major stimuli of Ser 307 phosphorylation of IRS-1. Inhibition of IRS-1 due to the phosphorylation of its Ser 307 residues also requires the activation of both c-Jun N-terminal kinase (JNK) and inhibitor κ B kinase (IKK) β . Both TNF- α and free fatty acids induce JNK and IKK- β activation.

TNF- α stimulates phosphorylation of Ser residues of both IRS-1 and IRS-2 in hepatocytes^[48-50]. It was recently reported that monocyte-derived macrophages increasingly accumulated within the adipose tissue of obese patients. In addition to the dysregulated production of adipocytokines by adipocytes, adipose tissue macrophages also produce proinflammatory cytokines such as TNF- α , interleukin-6, and C-reactive protein. Both adipose tissue and its macrophages contribute to the TNF- α burden. Indeed, its circulating concentrations are very low, commonly undetectable even in obese mice or humans.

Elevated free fatty acids in the circulation are also major contributors to IR in both humans and mice by stimulating Ser 307 phosphorylation of IRS-1. Adipose tissue triglycerides are the main source of circulating free fatty acids in obesity. One mechanism of elevated free fatty acid-induced IR in muscle is the impaired activation of protein kinase C lamda (PKC λ) and protein kinase C XI (PKC ξ)^[50-52]. PKC θ can also activate IKK- β which phosphorylates Ser 307 residues of IRS-1. Additionally, increased acyl CoAs or ceramide which is a derivative of acyl CoAs, promote IR by diminishing Akt1 activation. Increased ceramide activates a phosphatase (protein phosphatase 2A) that reverses tyrosine phosphorylation of Akt/protein kinase B (PKB). Inactivated PKB inhibits the insulin downstream signaling cascade leading to IR in muscles [Le]. Several oxidative stress mediators might also induce IR by affecting insulin downstream signaling. Phosphatases such as phosphatase and tensin homolog, small heterodimer partner 2, and protein tyrosine phosphatase 1B are now recognized to be major mediators involved in IR. Another possible mechanism for IR is defective glucose transport such as down-regulation of GLUT4.

JNK is one of the stress-related kinases and plays an important role in the development of IR^[48,52]. The

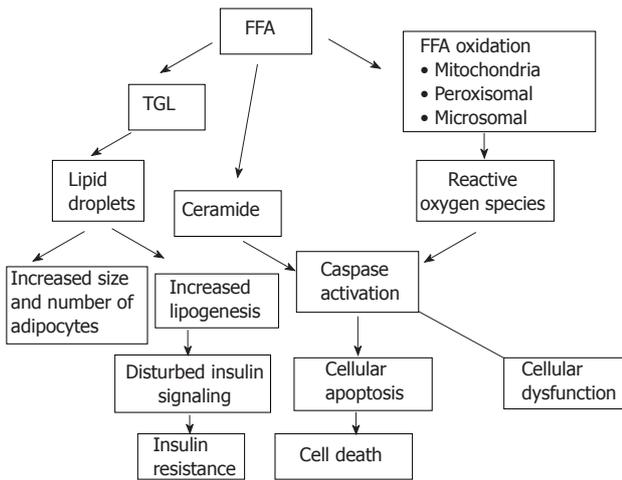

Figure 5 Insulin resistance and cell death. FFA: Free fatty acids; TGL: Tryg-lycerides.

three members of the JNK group of serine/threonine kinases, namely JNK-1, -2, and -3 are activated by proinflammatory cytokines such as TNF- α as well as free fatty acids and endoplasmic reticulum stress due to metabolic overload, which is an intracellular abnormality found in obesity. Activated JNK induces Ser 307 phosphorylation of IRS-1, disturbs insulin downstream signaling, and subsequently causes insulin resistance. JNK activity has been found to be elevated in liver, muscle, and adipose tissue of experimental obese models. Additionally, the loss of JNK-1 activity such as in JNK-1 knockout mice has been shown to prevent the development of IR in leptin-deficient *ob/ob* mice or mice with high-fat induced dietary obesity.

PKC θ and IKK- β are two proinflammatory kinases involved in insulin downstream signaling. They are activated by lipid metabolites such as high plasma free fatty acid concentrations and there is a positive relationship between the activation of PKC θ and the concentration of intermediate fatty acid products. PKC θ activates both IKK- β and JNK, leading to increased Ser 307 phosphorylation of IRS-1 and IR. IKK- β is a mediator of IR and one of the other stress-related kinases^[53,54]. Activation or overexpression of IKK- β diminishes insulin signaling and causes IR, whereas inhibition of IKK- β improves insulin sensitivity. IKK- β phosphorylates the inhibitor of nuclear factor (NF)- κ B leading to the activation of NF- κ B by the translocation of NF- κ B to the nucleus. NF- κ B is an inducible transcription factor and promotes specific gene expression in the nucleus. NF- κ B has both apoptotic and anti-apoptotic effects. The finding that NF- κ B deficient mice were protected from high-fat diet-induced IR suggests that NF- κ B directly participates in processes that impair insulin signaling.

Suppressors of cytokine signaling (SOCS) and inducible nitric oxide synthase (iNOS) are two inflammatory mediators recently recognized to play a role in insulin signaling^[54-61]. Induction of SOCS proteins [SOCS 1-7 and cytokine-inducible src homology 2 domain-contain-

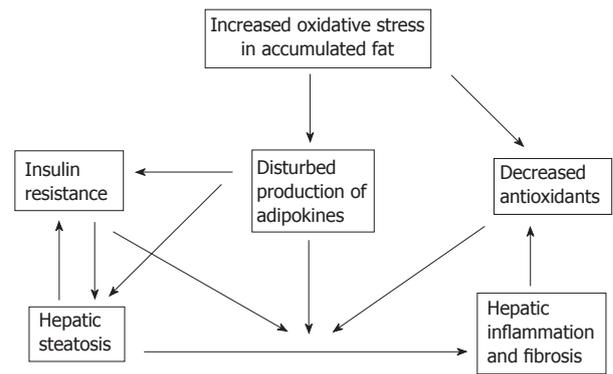

Figure 6 Fate of accumulated fat within hepatocytes.

ing protein [CIS]) by proinflammatory cytokines might contribute to the cytokine-mediated IR in obese subjects. SOCS-3 might also regulate central leptin action and play a role in the leptin resistance of obese human subjects. SOCS-1 knockout mice showed low glucose concentrations and increased insulin sensitivity. In animal studies, inactivation of SOCS-3 or SOCS-1 or both in the livers of *db/db* mice partially improved insulin sensitivity and decreased hyperinsulinemia, whereas overexpression of SOCS-1 and SOCS-3 in obese animals caused IR and also increased activation of SREBP-1c^[62]. SREBP-1c is one of the key mediators of lipid synthesis from glucose and other precursors (*de novo* lipogenesis) in the liver. Indeed, SOCS proteins markedly induce *de novo* fatty acid synthesis in the liver by both the up-regulation of SREBP-1c and persistent IR with hyperinsulinemia which stimulates SREBP-1c-mediated gene expression.

The molecular mechanism that leads to IRS-1 degradation varies according to genotype in patients with hepatitis C virus infection. Genotype 1 promotes the expression of SOCS-3 as genotype 3 promotes SOCS 7 expression, with a mechanism of IRS-1 degradation similar to that induced by SOCS 3; it also inhibits PPAR- γ , further worsening IR. One of the steatogenic mechanisms is the promotion of *de novo* fatty acids synthesis by induced expression of SREBP-1c by HCV infection.

Nitric oxide synthase-2 (NOS2) or iNOS production are also induced by proinflammatory cytokines^[63,64]. High-fat diet in rats causes up-regulation of iNOS mRNA expression and increases iNOS protein activity. Increased production of NOS2 might reduce insulin action in both muscle and pancreas and decreased iNOS activity protects muscles from high-fat diet-induced IR.

HCV induces protein phosphatase 2A expression, through an endoplasmic reticulum stress response pathway, which dephosphorylates protein kinase B (Pkb)/Akt (a main enzyme in the insulin signaling pathway), and thereby lowers its kinase activity^[65].

THE PATHOGENESIS OF HEPATOCELLULAR INJURY IN STEATOSIS

The accumulation of fat within the hepatocytes sensitizes

the liver to injury from a variety of causes and the regenerative capacity of a fatty liver is impaired (Figures 5 and 6)^[66-68]. An interacting network of cytokines and adipokines that regulate inflammation is disrupted. **p53 is involved in the mechanisms of hepatocellular injury accompanied by steatosis**^[69].

CONCLUSION

Steatosis is one of the characteristic histopathologic features of HCV caused by chronic liver disease, and is also closely related to IR. Insulin resistance is one of the leading factors for severe fibrosis in chronic HCV infections. Moreover, hyperinsulinemia has a deleterious effect on the management of chronic HCV. The underlying mechanisms of this complex interaction are not fully understood. A direct cytopathic effect of HCV has been suggested. The genomic structure of HCV, lipid metabolism, the molecular links between the HCV core protein and lipid droplets and increased neolipogenesis and inhibited fatty acid degradation in mitochondria have been investigated.

ACKNOWLEDGMENTS

This article is dedicated to my mentors Professor Stephen H Caldwell from the University of Virginia Health System and Professor Brent A Neuschwander-Tetri from the St. Louis University Hospital in gratitude for having guided me into Basic and Clinical Hepatology.

Abstract

The parathyroid glands are the main regulator of plasma calcium and have a direct influence on the digestive tract. Parathyroid disturbances often result in unknown long-standing symptoms. The main manifestation of hypoparathyroidism is steatorrhea due to a deficit in exocrine pancreas secretion. The association with celiac sprue may contribute to malabsorption. Hyperparathyroidism causes smooth-muscle atony, with upper and lower gastrointestinal symptoms such as nausea, heartburn and constipation. Hyperparathyroidism and peptic ulcer were strongly linked before the advent of proton pump inhibitors. Nowadays, this association remains likely only in the particular context of multiple endocrine neoplasia type 1/Zollinger-Ellison syndrome. In contrast to chronic pancreatitis, acute pancreatitis due to primary hyperparathyroidism is one of the most studied topics. The causative effect of high calcium level is confirmed and the distinction from secondary hyperparathyroidism is mandatory. The digestive manifestations of parathyroid malfunction are often overlooked and serum calcium level must be included in the routine workup for abdominal symptoms.

INTRODUCTION

The parathyroid glands play a major role in calcium homeostasis, and ultimately have an effect on all organs because of the complexity of intracellular calcium physiology. The gut and accessory organs are not spared. However, digestive manifestations of dysparathyroidism are not well known and typically rely on old articles and theories. This paper summarizes the digestive consequences of parathyroid disorders and highlights recent theories based on older studies.

DIGESTIVE MANIFESTATIONS OF HYPOPARATHYROIDISM

Hypoparathyroidism may be transient, genetically inherited, or acquired due to an autoimmune process. It may also be secondary to surgery or neck irradiation^[1]. Digestive manifestations of hypoparathyroidism are few and consist mainly of steatorrhea.

Steatorrhea related to hypoparathyroidism is a consequence of bilio-pancreatic exocrine deficit due to insufficient meal-stimulated cholecystokinin secretion by the

duodenal mucosa^[2]. The treatment of fat malabsorption in idiopathic hypoparathyroidism comprises: medium-chain triglycerides diet^[3], correction of hypoparathyroidism, administration of vitamin D^[4], and normalization of hypocalcemia^[5]. In contrast, secondary hyperparathyroidism, as a consequence of malabsorption and steatorrhea, is accompanied by normal or sub-normal serum calcium level.

Idiopathic hypoparathyroidism can be associated with other digestive autoimmune diseases that may cause diarrhea. Few reports have been published on the coexistence of primary hypoparathyroidism and celiac disease^[6-8]. Kumar *et al*^[9] have explored this association in a cross-reactive immunological pathway. If suspected by resistance to vitamin D supplementation^[10], the coexistence of celiac sprue must be ruled out by duodenal biopsy. In such cases, gluten-free diet should be included in the treatment regimen^[11,12]. Moreover, in the specific context of celiac sprue, Parathyroid hormone (PTH) level might not be elevated because of parathyroid atrophy, and secondary hyperparathyroidism might not appear^[13]. Finally, since its description by Reisner *et al*^[14] more than 50 years ago, the coexistence of idiopathic hypoparathyroidism and pernicious anemia has not been further reported.

DIGESTIVE MANIFESTATIONS OF HYPERPARATHYROIDISM

The gastrointestinal manifestations of primary hyperparathyroidism (PHPT) have been described many decades ago^[15]. Truly asymptomatic hyperparathyroidism is rare when thorough anamnesis looks for subtle symptoms. Most frequent digestive manifestations are constipation, heartburn, nausea and appetite loss that occur in 33%, 30%, 24% and 15% of cases, respectively^[16]. Significant reduction in symptom rates is found after parathyroidectomy. Vague abdominal pain can be as frequent as 29%^[17]. The exact pathophysiological mechanism is not fully understood. Alterations in gene expression secondary to sustained stimulation of PTH receptors may help explain the symptoms^[18]. As a result, gut atony occurs and leads to constipation in the colon and dyspepsia in the stomach^[17]. Finally, PHPT has been associated with increased incidence of malignancies, especially of the colon^[19].

The association between PHPT and peptic ulcer disease is a yet-to-be-resolved issue. Most studies about this subject date were performed several decades ago^[18,20,23], did not include prospective large-scale studies, and led to controversial results. Compared to 30% in adults with hyperparathyroidism^[18], peptic ulcer was found in 5% of autopsies in the general population before the advent of the proton pump inhibitors^[20]. Other studies have reported results between these two extremes^[21]. On the other hand, among patients with duodenal ulcer, Frame *et al*^[22] have shown a 10-fold increase in the incidence of PHPT. As reported in old studies, complete correlation between hyperparathyroidism and increased gastric acid secretion could not be found, and normalization of the latter was

not systematic after parathyroidectomy^[21,23-28]. Again, the correlation between hypergastrinemia and hyperparathyroidism was not constant throughout previous studies^[28,29], although Reeder *et al*^[30] have found a direct calcium-to-gastric hypersecretion relationship in hypergastrinemia. The only prospective study conducted by Corleto *et al*^[31] failed to confirm these findings. Zollinger-Ellison syndrome (ZES) may coexist with PHPT in the context of multiple endocrine neoplasia type 1. In a prospective study, Norton *et al*^[32] reported a significant biochemical improvement of ZES in 20% of patients who underwent resection of more than three parathyroid glands. Finally, pancreatic polypeptide was once correlated with hyperparathyroidism^[33].

Acute pancreatitis caused by PHPT was first described by Cope *et al*^[34] in 1957. Since that date, the exact relationship between these two entities has been questioned, until PHPT was accepted as an etiology for pancreatitis^[35]. Incidence of acute pancreatitis in patients with PHPT has varied from 1%^[36] to 12%^[37] in retrospective series, with intermediate values^[38,39]. Jacob *et al*^[40] have shown a 28-fold increased risk of pancreatitis in hyperparathyroid patients compared to the general population. After eliminating all other causes, mean plasma calcium level seems to be the only predictive factor for pancreatitis development^[37,40,41]. Its dosage must be included in the etiological work-up, although hyperparathyroidism is found in < 1% of patients who present with acute pancreatitis^[42]. Carnaille *et al*^[37] have shown that most patients had single adenoma, which suggested that pancreatitis was a consequence (and not the cause) of hyperparathyroidism. Additionally, acute pancreatitis may be the presenting form of PHPT^[38,43,44], even in its ectopic localization^[45,46]. In contrast, Felderbauer *et al*^[39] have stressed that genetic mutations constitute a greater risk factor for pancreatitis than serum calcium.

The pathophysiological mechanism that leads to pancreatitis seems more related to hypercalcemia than to PHPT. It has been shown that hypercalcemia from any cause can lead to pancreatitis^[47-49]. As confirmed by experimental studies, calcium ions cause calculus deposition within the pancreatic ductules, with consequent obstruction and inflammation^[50]. Moreover, calcium can trigger the pancreatitis cascade by promoting conversion of trypsinogen to trypsin^[51,52].

Interrelation between acute pancreatitis and parathyroid function can be summarized as follows: (1) acute pancreatitis results in a tendency to hypocalcemia and secondary hyperparathyroidism^[53,54]. **Compensation need** is correlated to pancreatitis severity as shown by PTH level^[55]; (2) **severe and/or complicated pancreatitis** can lead to overt hypocalcemia through relative deficiency in PTH secretion^[54], because exogenous administration of PTH normalizes calcium level^[56]; (3) **in severe pancreatitis**, resistance to PTH action in bones and kidneys may occur because of fluid sequestration and reduction in efficient arterial blood volume^[53]; (4) **once the diagnosis** of PHPT-induced acute pancreatitis is established, parathyroidectomy is mandatory because it prevents recurrence^[37,42].

Bhadada *et al*^[57] have studied PHPT-induced chronic pancreatitis and compared it to pancreatitis of other causes. PTH and calcium levels are significantly more elevated in PHPT, while in others, elevated PTH level is secondary to maintain normocalcemia. With regard to complications, it seems that chronic pancreatitis secondary to PHPT does not differ from chronic pancreatitis of other causes. This entity needs to be studied by larger studies for further understanding.

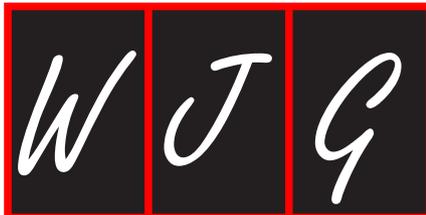

In conclusion, serum calcium level must be considered among the usual tests in patients with rare and/or non-specific abdominal symptoms. Hypoparathyroidism mainly manifests in the gut as malabsorptive diarrhea. Laboratory tests are essential for the diagnosis of secondary hypocalcemia when treatment is medical. PHPT causes non-specific digestive symptoms that are consequent to smooth-muscle atony. Association of peptic ulcer with PHPT is not as clear as described by old literature except for ZES in MEN 1. In contrast, PHPT is a confirmed risk factor for acute pancreatitis that can be its presenting form. Finally, PHPT-induced chronic pancreatitis needs further study for confirmation.

Abstract

Surgical resection offers the best opportunity for survival in patients with colorectal cancer metastatic to the liver, with five-year survival rates up to 58% in selected cases. However, only a minority are resectable at the time of diagnosis. Continuous research in this field aims at increasing the percentage of patients eligible for resection, refining the indications and contraindications for surgery, and improving overall survival. The use of surgical innovations, such as staged resection, portal vein embolization, and repeat resection has allowed higher resection rates in patients with bilobar disease. The use of neoadjuvant chemotherapy allows up to 38% of patients previously considered unresectable to be significantly downstaged and eligible for hepatic resection. Ablative techniques have gained wide acceptance as an adjunct to surgical resection and in the management of patients who are not surgical candidates. Current management of colorectal liver metastases requires a multidisciplinary approach, which should be individualized in each case.

INTRODUCTION

Colorectal cancer (CRC) is the fourth most common cancer in the West and the second most common cause of cancer related mortality after lung cancer in Europe and North America^[1,2]. More than 50% of patients with CRC will develop liver metastases during their lifespan^[2,3]. A quarter of patients with primary CRC are found to have synchronous hepatic secondaries^[4]. Almost half of patients undergoing resection for primary CRC eventually develop metachronous liver secondaries^[5]. Despite improvements in chemotherapies and biological agents, survival is rarely longer than three years^[6,7].

Evidence based on numerous retrospective and comparative studies indicates that hepatic resection is the only available treatment that allows long-term survival^[8]. Experiences with liver resection is associated with a 25% to 51% 5-year survival^[9,10]. By contrast, five-year survivors with chemotherapy alone are anecdotal. Historically, only 5%-10% of patients with colorectal liver metastases were resectable; currently, with the advances in diagnostic methods and new therapies, resectability rates have increased to 20%-25%^[11].

Emerging strategies designed to increase the proportion of patients who are candidates for complete surgical resection have been introduced in clinical practice. Neoadjuvant chemotherapy^[11], preoperative portal vein embolization^[12], and the two-stage resection approach^[13]

contribute to this aim. However, even with these new strategies, the majority of patients with colorectal liver metastases are not candidates for a curative resection.

In this review, the current data supporting the use of liver resection in the management of colorectal liver metastases are analyzed. For this purpose, the role of new imaging techniques for the preoperative evaluation and new staging systems to stratify the patients are extensively reported. Moreover, the most recently introduced chemotherapies and biological therapies to prevent recurrence after surgery or to downstage unresectable tumors are analyzed.

NATURAL HISTORY

Liver metastases from colorectal cancer carry a median survival of 5 to 20 mo if left untreated; two-year survival is unusual, and five-year survival is extremely rare^[4,14]. Factors associated with a significant disadvantage in the unresected group include extent of liver disease, presence of extrahepatic disease, age of the patient, and carcinoembryonic antigen (CEA) level^[14]. Prognosis is closely related to the extent of liver replacement by the tumor^[4,15]. Indeed, Wood *et al*^[15] in a retrospective study of 113 patients undertaken in the Glasgow Royal Infirmary, reported a one-year survival rate of 5.7% for patients with widespread liver disease, 27% for patients with metastases localized to one hepatic lobe, and 60% for patients with solitary metastases.

Even when hepatic resection is performed with curative intent^[16], 60% to 70% of patients will develop local or distant recurrence^[17]. Recurrence occurs equally at intrahepatic and extrahepatic sites; 80% of all recurrences occur within two years. The median survival of patients with recurrent disease is 8 to 10 mo without any treatment^[14]. Repeat resection is feasible in 10% to 15% of these cases and may achieve a five-year overall survival rate of 15% to 40% in selected patients. Cure is considered after the achievement of 10-year disease-free survival^[18].

Chemotherapy alone, whether administered systemically or regionally, has a palliative role and rarely results in prolonged survival. Several retrospective studies have reviewed the clinical outcome of patients with potentially resectable liver metastases treated with chemotherapy alone. An obvious survival advantage for patients undergoing curative resection compared to those treated with chemotherapy was noted^[19]. Scheele *et al*^[19] compared 183 patients with resected hepatic metastases with 62 patients with resectable lesions who did not undergo surgery and 920 patients with unresectable disease. The median survival for the three groups was 30 mo, 14.2 mo and 6.9 mo, respectively. Although the patients of the second group lived longer than those of the third group, no patient in either group survived more than five years.

These poor results in untreated hepatic metastases from colorectal cancer and the continuous improvements in hepatic surgery provided the rationale for increasingly aggressive hepatic resections for the treatment of this condition^[20].

CURRENT CRITERIA OF HEPATIC RESECTION

During the past two decades the five-year survival rates for hepatic colorectal metastases patients have almost doubled, from 30% to 60%^[14]. The introduction of new chemotherapeutic agents and the shift in the criteria of surgical resection were the main factors in this progress^[21]. Previous absolute or relative contraindications to resection included the presence of extrahepatic disease^[8], involvement of hepatic pedicle lymph nodes^[22], and an inadequate resection margin of < 1 cm^[23]. All above contraindications for hepatic resection have been challenged and have already lost their importance in patient selection for hepatectomy^[24,25].

The current criteria focus on what should be left after hepatic resection. Previous criteria for resection, such as the size, location, number of intrahepatic metastases, and the presence of bilobar or extrahepatic disease have been largely abandoned^[14,26,27]. Nowadays, the definition of resectability includes a complete resection with tumor-free surgical margins (R0 resection), sparing at least two liver segments having an independent inflow, outflow, and biliary drainage. The amount of the liver remnant after resection should not be less than 20% and 30% of the total liver volume in normal and cirrhotic patients, respectively. This can be accurately predicted by computed tomography (CT) or magnetic resonance imaging (MRI) during preoperative evaluation.

PREOPERATIVE EVALUATION

Preoperative investigations before resection of colorectal liver metastases are focused on: (1) determining the diagnosis; (2) anatomically defining the lesion in the liver parenchyma for surgical planning; and (3) meticulous staging to rule out extrahepatic disease^[28].

Preoperative biopsy

Fine needle aspiration (FNA) cytology is a well established approach for diagnosis. The potential benefit of FNA in suspect cases is the cytological confirmation of diagnosis, although this can be effectively obtained by other examinations, together with the patient's history. However, there is a potential for false negative results. Nevertheless, the benefit of this examination may be outweighed by the serious risk of needle tract seeding^[29,30]. For these reasons, FNA cytology has been virtually abandoned in the preoperative evaluation of colorectal liver metastases.

Preoperative investigation

Metastatic liver tumors can usually be differentiated by imaging modalities, including ultrasound, CT, MRI and positron emission tomography (PET). CT plays a pivotal role in selecting patients for hepatic resection. The use of multidetector helical CT scans has improved resolution and increased the previously low sensitivity (53%) of detecting colorectal liver metastases to 70%-90%^[14,31,32]. Liv-

er metastases can be distinguished as hypodense lesions in the portal phase. A CT scan may provide information regarding the anatomical characteristics of the metastatic lesions and their relation to lobar architecture and major vascular structures. However, a CT scan cannot detect subcentimeter lesions^[14]. Colorectal liver metastases usually respect the liver capsule and the intersegmental planes and push these structures away. Even large lesions that appear to involve the inferior vena cava or the diaphragm on a CT scan, often do not do so and such appearances should not preclude surgical exploration^[28].

MRI is more useful than CT in detecting small metastatic lesions in a fatty liver, and in defining the relationship of the lesions to the hepatic vasculature and the biliary tree with MR cholangiopancreatography^[28]. However, it has a sensitivity of 70% to 80% and it does not offer any significant advantage over a CT scan^[14]. Furthermore, MRI angiography and CT angiography have gradually replaced the more invasive direct hepatic angiography.

Ultrasonography is an inexpensive test that may identify small metastatic lesions within the hepatic parenchyma. It can give information regarding the size of the metastatic tumor and the extent of liver involvement. Moreover, Duplex ultrasound can define the relation of the tumor to the hilar structures, the hepatic veins, and the inferior vena cava. Ultrasound may be used as a first-line modality in the diagnostic evaluation of hepatic metastases^[28].

A new modality in the diagnosis of colorectal liver metastases is whole body PET. The most common tracer in PET scanning is fluoro-18-deoxyglucose (FDG)-PET, a glucose analog, which can proceed down the glycolytic pathway, and accumulate within the glucose-avid cancer cells. A recent meta-analysis reported a sensitivity and specificity for FDG-PET of 88% and 96%, respectively, for the detection of hepatic metastases, and 90% to 95% for the detection of extrahepatic disease^[33]. The combination of CT and FDG-PET increases sensitivity and allows the selection of surgical therapy for patients likely to gain the most benefit^[34]. The main limitation of a PET scan is the reduced sensitivity in detecting subcentimeter lesions, mucinous lesions, and lesions that have been treated with neoadjuvant chemotherapy^[35].

During the last two decades, laparoscopy has emerged as a new diagnostic modality for patients with liver malignancies. When laparoscopy is employed, unnecessary laparotomy can be avoided in 78% of patients with unresectable disease^[35]. In these cases, laparoscopy can decrease the morbidity of surgery, and shorten the delay to systemic therapy^[36]. Laparoscopy is indicated in cases in which the results of imaging studies are suspicious, but not diagnostic for extrahepatic tumor, such as enlarged lymph nodes or possible peritoneal dissemination.

PREOPERATIVE TREATMENT

Chemotherapy

Current chemotherapy regimens including oxaliplatin

and irinotecan in addition to 5-fluorouracil (5-FU), and leucovorin (LV) have achieved improved response rates in colorectal liver metastases, with significant reduction in disease bulk in almost 50% of patients and a median survival approaching two years^[37]. New biological agents, such as those targeting epithelial and vascular endothelial growth factor pathways (bevacizumab, cetuximab) have added a significant survival benefit in these patients^[38,39].

The successful use of combination chemotherapy in colorectal liver metastases has led to the concept that these agents could also be used before hepatic resection. In fact, the use of neoadjuvant chemotherapy has the benefit of downstaging the tumor, rendering a previously unresectable tumor resectable. This approach may assess the responsiveness of the tumor to chemotherapy, as the initial response to chemotherapy is strongly predictive of a favorable long-term outcome^[40,41]. The development of steatohepatitis is a complication of preoperative chemotherapy, which results in a significantly increased 90-d postoperative mortality^[42].

Neoadjuvant chemotherapy

The use of preoperative chemotherapy may exert a downsizing effect on the metastatic tumors, so one may perform surgery as soon as resectability is technically feasible. According to the Paul Brousse experience^[43], modern chemotherapeutic regimens allow 12.5% of patients with unresectable colorectal liver metastases to be rescued by hepatic resection. This strategy may offer a possibility of long-term survival (33% at five years and 22% at 10 years) with a low operative risk. It is noteworthy that this strategy involves the wide use of repeat hepatectomies and extrahepatic resections in an effort to eradicate all tumors. Currently most reports suggest that infusional FU/LV with oxaliplatin and/or irinotecan are the most effective protocols for this purpose^[31,44]. However, although the response rates are very high when used as first-line therapy, the response rates for second-line therapy are very low^[31,45]. Therefore, tumors that progress while on chemotherapy usually have a low likelihood of becoming resectable with second-line chemotherapy.

Neo-adjuvant chemotherapy can also be used *via* hepatic arterial infusion (HAI) with high response rates, as first or second-line therapies^[46]. Patients with metastatic lesions confined to the liver, without severe ascites or jaundice, are ideal candidates^[47]. Preliminary data from several clinical trials with oxaliplatin or irinotecan *via* HAI have been promising^[48]. However, HAI is rarely used outside specialized treatment centers, because of limited expertise, high cost of infusion pumps, and ongoing concerns regarding the considerable morbidity due to catheter-related complications, particularly sclerosing cholangitis^[49].

Portal vein embolization

Portal vein embolization (PVE) is another modality used preoperatively for patients where the extent of liver

resection is expected to result in less than the optimal functional liver volume of 25% to 40%, necessary to prevent postoperative liver failure^[21,50]. This technique, which induces ipsilateral atrophy and contralateral hypertrophy, is used to expand the number of patients undergoing curative hepatectomy for colorectal liver metastases. The most commonly used agents for embolization include gelatin sponge particles (Gelfoam) with iodized oil (Lipiodol), cyanoacrylate, alcohol, fibrin glue, or gelatin sponge, and they are usually administered percutaneously^[14,51]. The amount of liver tissue gained is about 15% of the total liver volume, and the time for maximum regeneration ranges from three to nine weeks^[52].

Azoulay *et al*^[51] have reported on a group of 30 patients who were deemed ineligible for liver resection because the estimated remnant liver was considered too small. These patients underwent PVE with minimal morbidity and no mortality. PVE substantially increased the remnant liver volume, rendering liver resection feasible in 19 patients (63%), with low morbidity and mortality rates and survival rates similar to the patients who did not undergo PVE. In conclusion, PVE followed by hepatic resection represents a two-stage hepatectomy: progressive atrophy of the embolized area, which triggers compensatory hypertrophy of the future remaining parenchyma, followed by liver resection. Therefore, PVE increases the resectability of colorectal liver metastases with a survival benefit comparable to that obtained with primary liver resection.

Several disadvantages of PVE have emerged as more experience is collected. Thrombosis, and/or migration of the emboli to the contralateral hepatic lobe, hemobilia, hemoperitoneum, and transient liver insufficiency, are complications occurring in 10% of cases and can be easily managed^[50]. Another adverse side effect is the possibility that PVE may stimulate the growth of tumors in the contralateral liver lobe, although this has yet to be clarified^[53]. A way of counteracting this effect is the administration of concurrent chemotherapy soon after PVE, the so-called “interterm chemotherapy”^[14].

LIVER RESECTION

Over the last two to three decades, an aggressive surgical approach has been followed for the treatment of colorectal hepatic metastases, based on the fact that the liver is the first isolated site of metastases for colorectal cancer. This direct treatment of hepatic metastases prevents dissemination of the disease from the liver to other sites^[54].

The role of hepatic resection as an effective treatment for colorectal liver metastases was established in 1988 from the registry of hepatic metastases^[9]. In a retrospective review on 859 patients with colorectal liver metastases who were surgically treated between 1948 and 1985, the five-year actuarial survival rate and the disease-free survival rate were 33% and 21%, respectively. Along with the gradual improvement in imaging techniques,

better understanding of liver anatomy, recent refinements of surgical techniques, and the continuous progress in pre- and postoperative care, the postoperative mortality rate after hepatectomy has been reduced to < 3% and the five-year survival rate after resection of colorectal liver metastases has reached 26%-58%^[10,25].

Initially, liver resection was based on the anatomic system described in the early 1950s by Couinaud^[55], who defined the intrahepatic divisions of blood vessels and bile ducts. However, there was significant confusion regarding the description of liver anatomy and hepatic resections until the first universally accepted terminology system was introduced. The “Brisbane 2000 terminology of liver anatomy and resections”^[56] was based on the internal anatomy and described the several levels of division of the liver segments; today, it has gained wide acceptance among liver specialists.

The main purpose of liver resection is to resect the tumor with a sufficient tumor-free margin, while preserving as much normal parenchyma as possible. Hepatic resections have regularly been along the liver segmental anatomy planes^[51]. An alternative approach is a non-anatomical or wedge resection, removing a smaller volume of liver with reduced postoperative morbidity and mortality. However, this carries a higher risk of positive resection margins^[41]. However, in a recent series where wedge resections were performed for single rather than multiple lesions, the incidence of positive resection margins was equivalent for both wedge resection and segmental resection (8.3%), and the five-year survival was equivalent in both groups^[57].

Intraoperative ultrasound can delineate the interior anatomy of the liver, including intrahepatic vessels, and allows hepatic resection to be performed more safely and anatomically. Moreover, intraoperative ultrasound may identify extrahepatic sites of the disease, such as infiltrated lymph nodes in the celiac axis and the liver hilum, or deposits in the peritoneal cavity^[58]. Extrahepatic disease sites in the peritoneal cavity impart a significant disadvantage in prognosis, whereas an excellent five-year survival (20% to 48%) can be achieved with pulmonary metastases with an R0 resection^[59].

There is a variety of techniques and devices used for hepatic resection, including the clamp crushing technique, Cavitron Ultrasonic Surgical Aspirator (CUSA, Covidien, Mansfield, MA, United States), Hydrojet (Hydro-Jet, Erbe, Tübingen, Germany), and bipolar sealing devices. Among these, the clamp crushing technique remains the most efficient in terms of reduced operation time, blood loss and total costs^[60].

Synchronous disease

Synchronous hepatic metastases occur in about 20%-30% of newly diagnosed colorectal cancers, and they present a challenging problem in the management of these patients^[9]. Consensus has not been reached as to the timing of surgical resection of the hepatic secondaries and the primary colorectal tumor. Traditionally, these patients

were managed by a second laparotomy 12-16 wk after the resection of the primary tumors^[61]. The advantage of this approach is that it provides less surgical insult to the patient as the incision used in the two operations is different^[14]. However, with advances in perioperative care and the continuous improvements regarding the postoperative morbidity and mortality rates after liver resection, most researchers today support simultaneous resection^[62,63]. In fact, very few reports in the last decade still strongly oppose the simultaneous procedure.

Today, a simultaneous resection is preferred when there is a right colon primary, or when a single hepatic lesion is contemplated, whereas a staged resection is often done in case of rectal primaries, or multiple liver secondaries^[31]. However, no real indications or contraindications exist for simultaneous resection of hepatic metastases, and it seems that the final decision depends on the surgeon's experience and the patient's physical status. In general, the results of simultaneous resection are comparable to staged resection in terms of morbidity, and mortality rates; additionally simultaneous resection offers the advantage of completing the local control of the disease in a single procedure, allowing the use of adjuvant chemotherapy for systemic micrometastases^[64].

Locally ablative modalities in combination with liver resection

Locally ablative modalities, such as radiofrequency ablation (RFA)^[65], cryotherapy^[66], or high intensity focused ultrasound^[67], can be used in combination to hepatic resection, to offer curative treatment in patients with unresectable tumors. RFA is the most widely used modality. The goal of the combined approach is to resect the bulk of the metastatic load and to ablate the residual smaller lesions, to achieve a R0 status, preserving at the same time adequate liver parenchyma to avoid postoperative hepatic failure^[68]. According to the MD Anderson Cancer Center's experience^[65] in the combined approach for advanced hepatic malignancies (72% were hepatic colorectal metastases), the perioperative mortality and morbidity rates were 2.3% and 19.8%, respectively. In addition, patients with colorectal secondaries had a median actuarial survival of 37.3 mo. The authors point out that the functional residual hepatic volume has to be accurately estimated to avoid fatal hepatic failure postoperatively, which is quite common in this combined approach.

The use of RFA in combination with surgical resection allows the hepatic surgeon to ablate small lesions while removing the large ones. RFA combined with hepatectomy is well tolerated by the patients and adds minimal complexity and morbidity to the operation. However, RFA is inferior for local control of metastatic lesions, systemic spread, and long-term survival. Indeed, there is a higher local recurrence rate associated with RFA than with resection, resulting in inferior disease-free survival rate^[21]. Therefore, for the treatment of solitary hepatic metastases, the application of RFA cannot be primarily recommended^[69]. On the other hand, RFA can be used

as palliative treatment for unresectable metastases, as it achieves better survival than chemotherapy^[21]. The only limitations in the use of RFA and other locally ablative modalities are the size of the lesion and its location close to major biliary or vascular structures^[31].

Bilobar metastases

The management of bilobar liver metastases demonstrates the advantages of a multidisciplinary approach with a step-by-step strategy and restaging at regular intervals, to achieve a complete resection in most of these patients. The prognostic significance of bilobar distribution of multiple metastases is controversial. Some researchers report bilobar distribution as a poor prognostic factor^[9], whereas others support the view that bilobar distribution does not affect overall patient survival^[8,10]. In fact, the total tumor volume of liver metastases seems to have a stronger influence on survival than the number or location of metastatic lesions^[70].

Surgical resection should be performed only if all the metastatic load of the liver can be removed (R0 resection). In case of involvement of lymph nodes in the hepatic pedicle, with frozen section confirmation, an extensive lymphadenectomy should be performed from the liver hilum to the celiac axis. Moreover, in patients who have more than three poorly differentiated metastatic lesions in segments IV and V, a routine extended lymphadenectomy of the hepatic pedicle seems justified^[71,72].

In general, hepatic lymph node involvement is a poor prognostic factor affecting survival of these patients^[9], but according to a multi-center study by the Association Francaise de Chirurgie, the five-year survival rate of patients with hepatic pedicle lymph node involvement who underwent lymphadenectomy was 12%, compared to the expected 0% to 2% without resection^[10].

The presence of extrahepatic disease is no longer a contraindication to hepatic resection. Recently, encouraging results have been reported in patients treated for liver metastases and peritoneal carcinomatosis^[73]. However, this approach is suitable only for expert teams with experience in liver surgery and intraperitoneal chemotherapy^[72].

Two-stage hepatectomy

The aim of this approach is to achieve in two steps a complete resection of the metastases in cases initially considered unresectable. In these cases, a single hepatectomy would have left too small a remnant liver after surgery, with a high risk of liver insufficiency after surgery^[72]. In two-stage hepatectomy the highest possible number of tumors are resected first, and the remaining tumors are resected in a second procedure after a period of liver regeneration^[13].

The aim of the first hepatectomy is to make the second hepatectomy potentially curative. Mapping permits the surgeon to achieve this by resecting the highest possible number of liver tumors or by clearing the metastatic load from the less invaded hepatic lobe, leaving

the other to be resected after regeneration. Neoadjuvant chemotherapy is given after the first operation, beginning three weeks postoperatively, so it does not interfere with initial liver regeneration. The usual interval between the two stages should be usually around 4 mo, (from 2 to 14 mo), depending on the progress of liver regeneration^[13]. Patients with multiple bilobar liver metastases and too small a future remnant liver could be treated with a two-stage procedure with the use of portal vein embolization^[72].

This approach can also be used at the time of colectomy when multiple synchronous hepatic lesions preclude a single curative hepatectomy. In such cases, a limited resection of the metastatic load of one hemiliver could be done at the same time as the colectomy, leaving the second major hepatectomy to be done in a second stage^[72].

FOLLOW UP AFTER RESECTION

Patients who have undergone hepatic resection of colorectal metastases are monitored to identify early recurrence that may be amenable to repeat resection for cure. Most patients undergo serial physical examination, serum CEA level, chest X-ray, and CT of the upper and lower abdomen every 3 to 4 mo for the first two years and then every 6 mo for the following five years^[28]. Most patients surviving after liver resection present with recurrent disease at the liver or lung. The liver is the site of recurrence in 45% to 75% of cases after liver resection^[5], and this explains the fact that most chemotherapeutic regimens address mainly the liver.

ADJUVANT CHEMOTHERAPY

Postoperative chemotherapy following complete resection of metastatic disease may lead to improvement in long-term prognosis. The past decade has been marked with significant changes in the options available for this group of patients. In addition to 5-FU, which has been used since 1996, several new drugs have been introduced on the market for the treatment of metastatic colorectal cancer (2006): irinotecan, oxaliplatin, capecitabine, bevacizumab, and cetuximab. Therefore the efficacy of treatment regimens has substantially increased^[28].

Adjuvant chemotherapy is used to increase survival and decrease the rate of recurrence. Recently, the first randomized clinical trial by Portier *et al*^[74], which compared surgery alone to surgery plus adjuvant chemotherapy, provided clear evidence that adjuvant chemotherapy is beneficial for patients with colorectal liver metastases. In this study, 173 patients were randomly assigned to surgery and observation or surgery plus 6 mo of systemic adjuvant chemotherapy. The results showed a significantly improved five-year disease-free survival in the surgery plus chemotherapy group compared to surgery alone (33.5% *vs* 26.7%), with a trend towards improved overall five-year survival.

Adjuvant chemotherapy does not decrease the meta-

static recurrence rate in the remnant liver after resection^[75]. Indeed, according to another study^[76], in patients with complete clinical response to chemotherapy according to CT imaging, in situ recurrence was observed in 78% one year after surgery, because of non-visible but viable tumor cells or microscopic disease.

REPEAT RESECTION

As mentioned in the natural history section, the majority of patients with colorectal liver metastases (55%-60%) will develop recurrent disease in the liver within the first two years after surgery, despite any mode of treatment that they have received^[17]. For these patients, the only chance to prolong life would be a repeat resection, usually combined with a locally ablative therapy (RFA). The results of repeat curative resection are comparable to the first one^[14].

The only problem with a second or third hepatectomy on the same patient is increased technical difficulty. Repeat resection carries perioperative morbidity and mortality rates of 5%-7% and 20%-39%, respectively^[27,77]. Therefore, repeat hepatectomy provides similar long-term survival to primary hepatectomy, without increasing perioperative morbidity and mortality^[78]. Indeed, Pessaux *et al*^[79] showed that overall five-year survival rates after the first, second and third hepatectomy are similar: 33%, 21% and 36%, respectively.

There are a number of prognostic factors determining patient eligibility and probable success after a third hepatectomy. These factors are: the curative nature of the first two hepatectomies, an interval of more than one year between the two procedures, the number of recurrent tumors, serum carcinoembryonic antigen levels, and the presence of extrahepatic disease^[80,81]. The best candidates for repeat resection are patients with a low tumor load, no extrahepatic disease, and removal of all visible metastatic load during the second hepatectomy^[69]. However, the role of repeat liver resection in patients with intrahepatic recurrence still remains controversial, because of the disputable survival benefit and the additional risks of repeat surgery.

CONCLUSION

There is an ongoing progress in the diagnostic imaging, chemotherapeutic regimens, and surgical techniques in the management of hepatic colorectal metastases. Hepatic resection has been recognized as the only treatment that could offer long-term survival. Traditional risk factors, indications, and contraindications have been abandoned. The present principle as to resectability is that resection should be performed if all metastases could be removed, while leaving a sufficient remaining liver parenchyma, regardless of their size, number, location and distribution.

Proper use of modern chemotherapy, PVE and/or two-stage hepatectomy and locally ablative modalities

might improve the resectability and prognosis in these patients. This review emphasizes the importance of a multidisciplinary approach for the optimal management of this disease. Moreover, decision making and patient care requires careful assessment of the risks and benefits for each individual, as well as balancing the technical feasibility and oncological options for each case.

ACKNOWLEDGMENTS

We would like to thank Professor Gregory Kouraklis for his constant support throughout the design and preparation of this review.

Abstract

AIM: To determine the effect of non-selective cyclooxygenase (COX) inhibitors, selective COX-2 inhibitors and nitric oxide (NO)-releasing aspirin in the healing of ulcerative colitis.

METHODS: Rats with 2,4,6 trinitrobenzenesulfonic acid (TNBS)-induced colitis received intragastric

(ig) treatment with vehicle, aspirin (ASA) (a non-selective COX inhibitor), celecoxib (a selective COX-2 inhibitor) or NO-releasing ASA for a period of ten days. The area of colonic lesions, colonic blood flow (CBF), myeloperoxidase (MPO) activity and expression of proinflammatory markers COX-2, inducible form of nitric oxide synthase (iNOS), IL-1 β and tumor necrosis factor (TNF)- α were assessed. The effects of glyceryl trinitrate (GTN), a NO donor, and 2-(4-carboxyphenyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazolyl-1-oxy-3-oxide, onopotassium salt (carboxy-PTIO), a NO scavenger, administered without and with ASA or NO-ASA, and the involvement of capsaicin-sensitive afferent nerves in the mechanism of healing the experimental colitis was also determined.

RESULTS: Rats with colitis developed macroscopic and microscopic colonic lesions accompanied by a significant decrease in the CBF, a significant rise in colonic weight, MPO activity and plasma IL-1 β and TNF- α levels. These effects were aggravated by ASA and 5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole (SC-560), but not celecoxib and counteracted by concurrent treatment with a synthetic prostaglandin E₂ (PGE₂) analog. Treatment with NO-ASA dose-dependently accelerated colonic healing followed by a rise in plasma NO_x content and CBF, suppression of MPO and downregulation of COX-2, iNOS, IL-1 β and TNF- α mRNAs. Treatment with GTN, the NO donor, significantly inhibited the ASA-induced colonic lesions and increased CBF, while carboxy-PTIO or capsaicin-denervation counteracted the NO-ASA-induced improvement of colonic healing and the accompanying increase in the CBF. These effects were restored by co-treatment with calcitonin gene related peptide (CGRP) and NO-ASA in capsaicin-denervated animals.

CONCLUSION: NO-releasing ASA, in contrast to ASA,

COX-1 inhibitors, and SC-560, accelerated the healing of colitis *via* a mechanism involving NO mediated improvement of microcirculation and activation of sensory nerves releasing CGRP.

INTRODUCTION

In humans inflammatory bowel disease (IBD) includes ulcerative colitis (UC) and Crohn's disease, considered as chronically relapsing disorders. The pathogenesis of IBD is complex, with individuals displaying a genetic predisposition, specific immunological properties of the gastrointestinal (GI) mucosa and the type of GI microflora all being involved^[1-4]. The features of animal models of colitis do not necessary mimic the human scenario of UC with the use of chemical stimuli and the magnitude of inflammatory changes. However, it is believed that an increase in mucosal prostaglandin (PG) synthesis, mainly cyclooxygenase (COX)-2 derived, correlates with the disease activity of human IBD and experimental colitis in rats^[5]. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in the treatment of pain and inflammation, but are also recommended prophylactically and used as therapeutic strategies against both neurological and cardiologic disorders. The therapeutic effects and side effects of NSAIDs in the gut are the consequence of the inhibition of COX activity, which is the key enzyme in the biosynthesis of prostanoids from arachidonate^[6]. It was reported that COX-2 is undetectable or expressed at very low levels in the healthy GI mucosa of humans and animals but is upregulated in the GI tract of individuals with inflammatory conditions^[7]. Thus, it has been suggested that the anti-inflammatory action of NSAIDs depend on the inhibition of COX-2 activity, whereas side effects, such as gastrointestinal damage and renal toxicity, is a consequence of COX-1 inhibition^[8,9]. It is believed that COX-2 derived PG play an important role in the healing

process of colitis, which is similar to that observed for the mechanisms of gastric ulcers^[10,11]. Results of studies on the influence of COX-2 inhibitors in experimental colitis and human IBD thus far have provided conflicting evidence for the exacerbation of colitis, and the attenuation of inflammation by COX-2 inhibitors^[12,13].

The mechanism of ulcerogenic activity of NSAIDs on the healing of the intestinal and colonic lesions has not been fully explained. Reuter *et al*^[12] reported that NSAIDs can exacerbate colitis by a mechanism attributable to the suppression of COX-2 derived PG synthesis. Tanaka *et al*^[14] showed that the non-selective COX inhibitor indomethacin, suppressed the mucosal prostaglandin E₂ (PGE₂) level, which in turn caused intestinal damage that was accompanied by the upregulation of COX-2 expression. It should be emphasized that neither a selective COX-1 inhibitor [5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole (SC-560)], nor a COX-2 selective inhibitor (rofecoxib) when applied alone caused intestinal damage^[8,15,16]. Recent evidence indicates that incorporation of a nitric oxide (NO) generating moiety into the basic structure of NSAIDs, such as aspirin, attenuates the ulcerogenic activity of native NSAID^[17]. Under basal conditions, NO derived from the activity of constitutive NO synthase (cNOS) contributes to the maintenance of intestinal integrity and the control of intestinal motility^[2,18].

In human IBD and experimental colitis, the inducible form of nitric oxide synthase (iNOS), excessive production of NO derived from iNOS and abundant amounts of toxic peroxynitrite are observed^[2]. On the other hand, NO was shown to possess anti-inflammatory properties and contributes to the resolution of intestinal inflammation^[18]. Moreover, iNOS deficient mice with colitis were more susceptible to inflammation as compared to animals with normal iNOS expression^[3]. The role of NO released from NO-NSAIDs in the mechanism of gastroprotection has been well documented^[19-21], but the efficacy of NO-aspirin (ASA) in the healing of experimental colitis has yet to be determined.

In this study, we focused mainly on the mechanism of healing of colitis by NO-ASA and therefore we compared the effect of vehicle, conventional NSAIDs such as ASA and indomethacin, SC-560 (a selective COX-1 inhibitor), celecoxib (a selective COX-2 inhibitor) with the new derivative of ASA, NO-releasing ASA, on the intensity of inflammation and the accompanying alterations in the colonic blood flow (CBF), myeloperoxidase (MPO) activity and expression of mRNA for COX-2, IL-1 β , tumor necrosis factor (TNF)- α and iNOS and their activities in rats with trinitrobenzenesulfonic acid (TNBS)-induced colitis. An attempt was made to determine the involvement of NO in the mechanism of healing of colitis by using NO-ASA and ASA-treated rats with 2-(4-carboxyphenyl)-4, 5-dihydro-4, 4, 5, 5-tetramethyl-1H-imidazolyl-1-oxy-3-oxide, onopotasium salt (carboxy-PTIO), which is a NO scavenger and glyceryl trinitrate (GTN), an NO donor, respectively.

Also, the importance of sensory nerve neurotransmitters in the healing of colitis were determined in rats by the functional ablation of sensory nerves by capsaicin, in the absence and the presence of NO-derivative of ASA.

MATERIALS AND METHODS

Animal studies were carried out on male Wistar rats weighing 180-220 g. The animals had free access to water and food and were adapted to laboratory conditions and 12 h day/night cycles for 10 d after TNBS administration. The study was approved by the local Ethical Committee at the Jagiellonian University Medical College in Cracow, Poland and run in accordance with the Helsinki declaration.

Colitis in rats was induced by rectal administration of TNBS (Sigma, Slough, United Kingdom) at a dose of 10 mg/kg, dissolved in 50% solution of ethanol as reported in our previous study^[22]. Briefly, the animals were anaesthetized with phenobarbital (60 mg/kg ip) and TNBS was administered into the colon in a volume of 0.25 mL per rat at a depth of 8 cm from the rectum with the use of a soft polyethylene catheter. Until the moment of awakening the rats were positioned in the Trendelenburg position so as to avoid loss of the TNBS solution *via* the rectum. Animals in the control group were given 0.9% saline or in some cases 50% ethanol in the same volume, corresponding to the rats that were administered TNBS.

Animals with TNBS-induced colitis were randomized into 8 experimental groups (A-H), consisting of 6-10 rats per group. Rats received ig the following daily treatments: A: vehicle (saline); B: ASA (80 mg/kg) or indomethacin (5 mg/kg) suspended in 0.25% carboxy methylcellulose (CMC); C: SC-560 (5 mg/kg); D: celecoxib (10 mg/kg); E: NO-ASA (80 mg/kg; NicOx SA, Sophia Antipolis, France); F: PGE₂ (5 µg/kg) combined with non-selective COX-1 (ASA) and selective COX-2 (celecoxib) inhibitors; G: GTN (10 mg/kg ig), a NO donor combined with ASA and carboxy-PTIO (5 mg/kg ig) combined with NO-ASA, both NSAID administered in a dose of 80 mg/kg. In series H consisting of 30 rats, capsaicin was administered in a large neurotoxic dose of 125 mg/kg applied in three doses of 25, 50 and 50 mg/kg 14 d prior to TNBS administration to induce the functional ablation of sensory nerves as described previously^[23]. On day 15, capsaicin-denervated rats received TNBS and were subsequently given NO-ASA (80 mg/kg ig) with or without calcitonin gene related peptide (CGRP) (10 µg/kg sc), and administration was similar to those treated with vehicle (saline). The doses of NO-ASA and selective COX-1 and COX-2 inhibitors were selected on the basis of our group and others published evidence^[14,15,19-21]. In the doses used in this study, the COX-1 and COX-2 selective inhibitors failed to produce gastrointestinal lesions after single or prolonged administration. The dose of 80 mg/kg of ASA was selected based on our preliminary determination of the dose-dependency of this

conventional ASA applied in graded doses starting from 10 mg/kg up to 160 mg/kg on healing of TNBS colitis. ASA given in a dose of 10 mg/kg failed to significantly affect the healing of colitis but when this NSAID was administered ig in graded doses of 40 mg/kg, 80 mg/kg and 160 mg/kg, the area of colonic damage was significantly increased by 23%, 42% and 74%, respectively, at day 10 upon TNBS administration (data not shown). We have previously published that 80 mg/kg of ASA is equimolar to 128 mg/kg of NO-ASA and this dose of NO-ASA by itself does not influence the gastrointestinal integrity but markedly increases organ blood flow^[21].

After 1, 3, 10 and 14 d from induction of colonic lesions with TNBS, the animals were weighed and anaesthetized to determine CBF using the H₂-gas clearance technique^[22,23]. The abdominal cavity was opened and after separation of the colon, the CBF in the areas of the mucosa not affected by inflammatory lesions was measured. CBF was expressed as a percentage of the CBF in the vehicle-control rats without TNBS administration.

At the termination of the experiment, the entire colon was removed, isolated from surrounding tissues, opened along the antimesenteric border, rinsed, weighed, and processed for gross and histology determinations. The areas of colonic damage were evaluated planimetrically (Morphomat, Carl Zeiss, Berlin, Germany) by two independent researchers. Subsequently, fragments of the colon (2 mm × 10 mm) with colonic lesions were sampled, fixed with formaldehyde, embedded in paraffin and routinely stained with haematoxylin and eosin for histological assessment.

The presence and intensity of histological changes was evaluated for the following criteria: presence, area and depth of ulceration, presence and intensity of inflammatory infiltrations, ulcerations and fibrosis^[24].

Determination of plasma IL-1 β and TNF- α levels, NO concentration the mucosal generation of prostaglandin E₂ and gastric mucosal MPO activity

Immediately after CBF measurements, a venous blood sample was drawn from the vena cava and placed into EDTA-containing vials and used for the determination of plasma IL-1 β and TNF- α . Blood was collected and placed into sterile, plastic syringes, kept in ice till centrifugation. The blood samples were centrifuged at a speed of 1000 g for 10 min at a temperature of 15 °C temperature and the sera were stored at -80 °C. The serum levels of proinflammatory cytokines IL-1 β and TNF- α were evaluated with high sensitive enzyme-linked immunosorbent assay (ELISA) (Quantikine HS, R and D Systems, Minneapolis, Minn., United States) according to manufacturer's instructions. Intensity of the color reaction was estimated in the spectrophotometer Stat Fax 2100 (Awareness Technology Inc., Pal City, FL, United States) at 490 nm. The intra- and inter-assay coefficients of variation were 8.5% and 10.6%, respectively, for TNF- α , and 10.2% and 10.4%, respectively, for IL-1 β . The plasma NO concentration was quantified indi-

rectly as nitrate (NO₃⁻) and nitrite (NO₂⁻) levels using the nitrate/nitrite kit purchased from Cayman Lab, Michigan, United States as described before^{125,26}. This method is based on the Griess reaction and the generation of a chromophore absorbing at 595 nm, according to the original procedure reported previously¹²⁶. Since NO in the colonic mucosa is quickly transformed into NO₃⁻ and NO₂⁻¹²⁵, the total nitrate and nitrite concentration (NO_x) is routinely used as an index of NO production. In order to determine NO_x, the blood was withdrawn and centrifuged for 10 min at 3000 r/min, the samples were mixed with Griess reagent from the commercially available kit.

In rats with colitis treated with or without concurrent COX-1 and COX-2 inhibitors, the mucosal samples were taken by biopsy (about 200 mg) from unchanged colon mucosa without mucosal lesions to determine PGE₂ generation by radioimmunoassay (RIA) as described previously^{119,211}. Briefly, the mucosal samples were placed in preweighed Eppendorf vial with 1 mL of Tris buffer (50 mmol/L, at pH 9.5) added to each vial. The samples were finally minced (15 s) with scissors, washed and centrifuged for 10 s, with the pellet being resuspended again in 1 mL of Tris. Then, each sample was incubated on a vortex mixer for 1 min and centrifuged for 15 s. The pellets were weighed and the supernatant was transferred to a second Eppendorf vial containing indomethacin (10 mmol/L) and kept at -20 °C until the time for RIA. The capability of the mucosa to generate PGE₂ was expressed in nanograms of wet tissue weight.

Fragments of colonic tissue weighing about 200 mg were collected and frozen in -70 °C for the determination of MPO activity by ELISA as reported before¹²².

Expression of COX-2, IL-1β, TNF-α and iNOS transcripts in the rat colonic mucosa determined by reverse transcriptase-polymerase chain reaction

The mRNA expression for COX-2, IL-1β, TNF-α and iNOS were determined by reverse transcriptase-polymerase chain reaction (RT-PCR) in the unchanged colon mucosa of intact rats or those with TNBS colitis given vehicle, ASA and NO-ASA. Samples of the colon

mucosa (about 200 mg) were scrapped off into ice using glass slides and then immediately snapped frozen in liquid nitrogen and stored at -80 °C. The total RNA was isolated from the colon mucosa according to the technique using Trizol Reagent (Invitrogen, Carlsbad, United States) and the manufacturer's protocol¹²⁷. The first strand of cDNA was synthesized from total cellular RNA (2 μg) using a Reverse Transcription System (Promega, Madison, United States). The PCR was carried out in an automatic DNA thermal cycler, using 1 μg of cDNA and Promega PCR reagents. For amplification of β-actin, COX-2, TNF-α, IL-1β and iNOS cDNA, and gene-specific primers (SIGMA-Aldrich St. Louis, United States) were used. The sequences for primers used in this study are presented in Table 1. Primer annealing was carried out as follows: at 56 °C, 60 °C, 60 °C and 58 °C for COX-2, IL-1β, TNF-α and iNOS, respectively. Amplification of the control rat β-actin was performed on the same samples to verify the RNA integrity. PCR products were separated by electrophoresis in 2% agarose gel containing 0.5 μg/mL ethidium bromide and then visualized under UV light. Location of the predicted PCR product was confirmed by using O'Gene Ruler 50 bp DNA ladder (Fermentas, Life Sciences, San Francisco, United States) as a standard marker. Comparison between different treatment groups was made by determination of COX-2, IL-1β, TNF-α and the iNOS/β-actin ratio of the immunoreactive area by densitometry (Gel-Pro Analyzer, Fotodyne Incorporated, Hartland, WI, United States).

Statistical analysis

Results are expressed as mean ± SE. Statistical analysis was done using Student *t* test or analysis of variance and two-way ANOVA test with Tukey *post hoc* test where appropriate. Differences of *P* < 0.05 were considered significant.

RESULTS

Effect of vehicle, non-selective and selective COX-1 and COX-2 inhibitors on TNBS-induced colitis and accompanying changes in CBF and MPO activity

Intrarectal administration of TNBS caused severe damage to the colonic mucosa manifested by inflammatory changes in the colon with extensive ulcerations of the mucosa. The area of these lesions was at a maximum at 24 h, it was not significantly decreased on day 3 but then it significantly declined at day 10 and day 14 (Figure 1). The CBF was decreased by about 46% and 43% on day 1 and 3, respectively, but it was significantly increased on day 10 and 14 (Figure 1). The 10 d administration of NO-ASA applied ig in gradual concentrations ranging from 20 mg/kg up to 120 mg/kg produced a dose-dependent decrease in the area of colonic lesions and this effect was accompanied by a significant rise in plasma NO_x concentrations and CBF (Figure 2). In contrast, after 10 d of ASA, indomethacin and SC-560 administration, a significant aggravation of the area of colonic lesions and a significant fall in CBF when

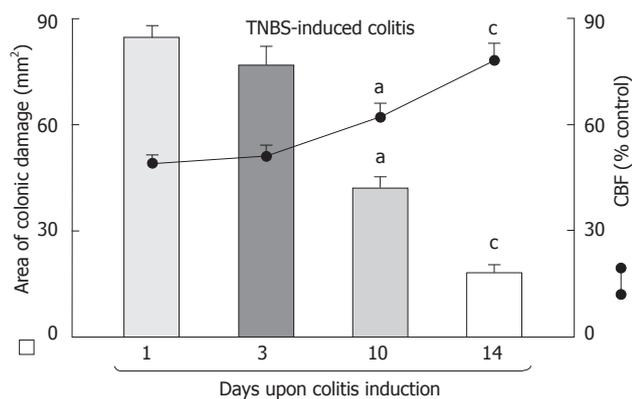

Figure 1 Time-sequence of the healing of trinitrobenzenesulfonic acid-induced colonic lesions, and accompanying changes in the colonic blood flow following day 1, 3, 10 and 14 upon induction of colitis. The area of trinitrobenzenesulfonic acid-induced lesions was maximal on day 1 and then it significantly declined on day 10 and day 14, respectively. Mean \pm SE of 6-8 rats. ^a*P* < 0.05 vs values obtained on day 3; ^c*P* < 0.05 vs values on day 3 and day 10. TNBS: Trinitrobenzenesulfonic acid; CBF: Colonic blood flow.

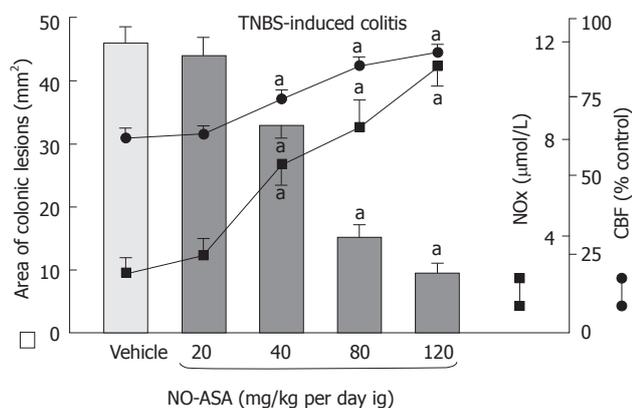

Figure 2 The effect of 10 d administration of nitric oxide-aspirin, applied ig in gradual concentrations ranging from 20 mg/kg up to 120 mg/kg on the area of colonic lesions, alterations in colonic blood flow and plasma NOx concentrations in rats with trinitrobenzenesulfonic acid-induced colitis on day 10. Mean \pm SE of 6-8 rats. ^a*P* < 0.05 vs vehicle (control) and animals treated with a dose of 20 mg/kg nitric oxide-aspirin (NO-ASA). TNBS: Trinitrobenzenesulfonic acid; CBF: Colonic blood flow.

compared with vehicle was observed (Figure 3). Similarly as shown in Figure 2, the treatment with NO-ASA applied in a dose of 80 mg/kg ig produced a significant decrease in the area of colonic damage and significantly increased the CBF comparing to vehicle-control (Figure 3). Treatment with celecoxib also significantly decreased the area of colonic damage and produced a significant increase in CBF; however, these changes were significantly less pronounced as compared to those achieved with NO-releasing ASA (Figure 3). Ten days after colitis induced by TNBS treatment all animals had a significant reduction in body weight compared with the control rats without TNBS administration and this loss of body weight was counteracted by treatment with NO-ASA. In contrast, treatment with ASA and indomethacin failed to attenuate the loss of weight induced by TNBS administration (data not shown). As shown in Figure 4A, the intact colonic mucosa

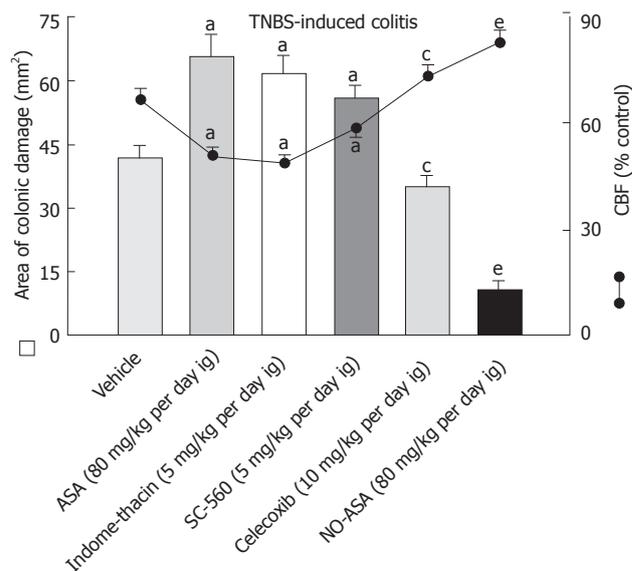

Figure 3 Effect of administration of vehicle, aspirin or indomethacin, non-selective cyclooxygenase inhibitors, a selective cyclooxygenase-1 inhibitor 5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole, a selective cyclooxygenase-2 inhibitor (celecoxib) and nitric oxide releasing aspirin, on the area of colonic lesions and alterations in colonic blood flow on day 10 after colitis induction. Mean \pm SE of 6-8 rats. ^a*P* < 0.02 vs vehicle (control); ^c*P* < 0.05 vs aspirin (ASA), indomethacin- and 5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole (SC-560) groups; ^e*P* < 0.02 vs vehicle, ASA, indomethacin, SC-560 and celecoxib groups. CBF: Colonic blood flow; NO-ASA: Nitric oxide-ASA; TNBS: Trinitrobenzenesulfonic acid.

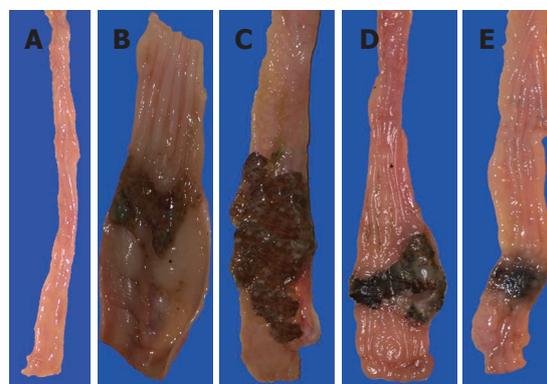

Figure 4 Gross appearance of the intact colon (A), and that of trinitrobenzenesulfonic acid-induced colitis rats treated with vehicle (B), aspirin (C), celecoxib (D) and nitric oxide-aspirin (E) at day 10 of colitis induction. In aspirin-treated rats (C) the area of colonic damage was larger than in the control trinitrobenzenesulfonic acid rats, which were treated with vehicle (B). In the celecoxib group (D), the area of colonic damage was significantly smaller when compared to the aspirin (ASA) and vehicle groups. The healing of colonic lesions was significantly improved in nitric oxide-ASA treated rats as documented by the small ulceration area and scar formation.

showed a normal macroscopic appearance. At day 10 after TNBS administration, colonic damage was still observed in vehicle-control animals (Figure 4B). This gross damage, as reflected by the area of ulceration, was exacerbated by treatment with ASA but significantly reduced by treatment with celecoxib. The area of TNBS-induced damage was significantly smaller in NO-ASA-treated animals as compared to that in rats treated with vehicle or celecoxib

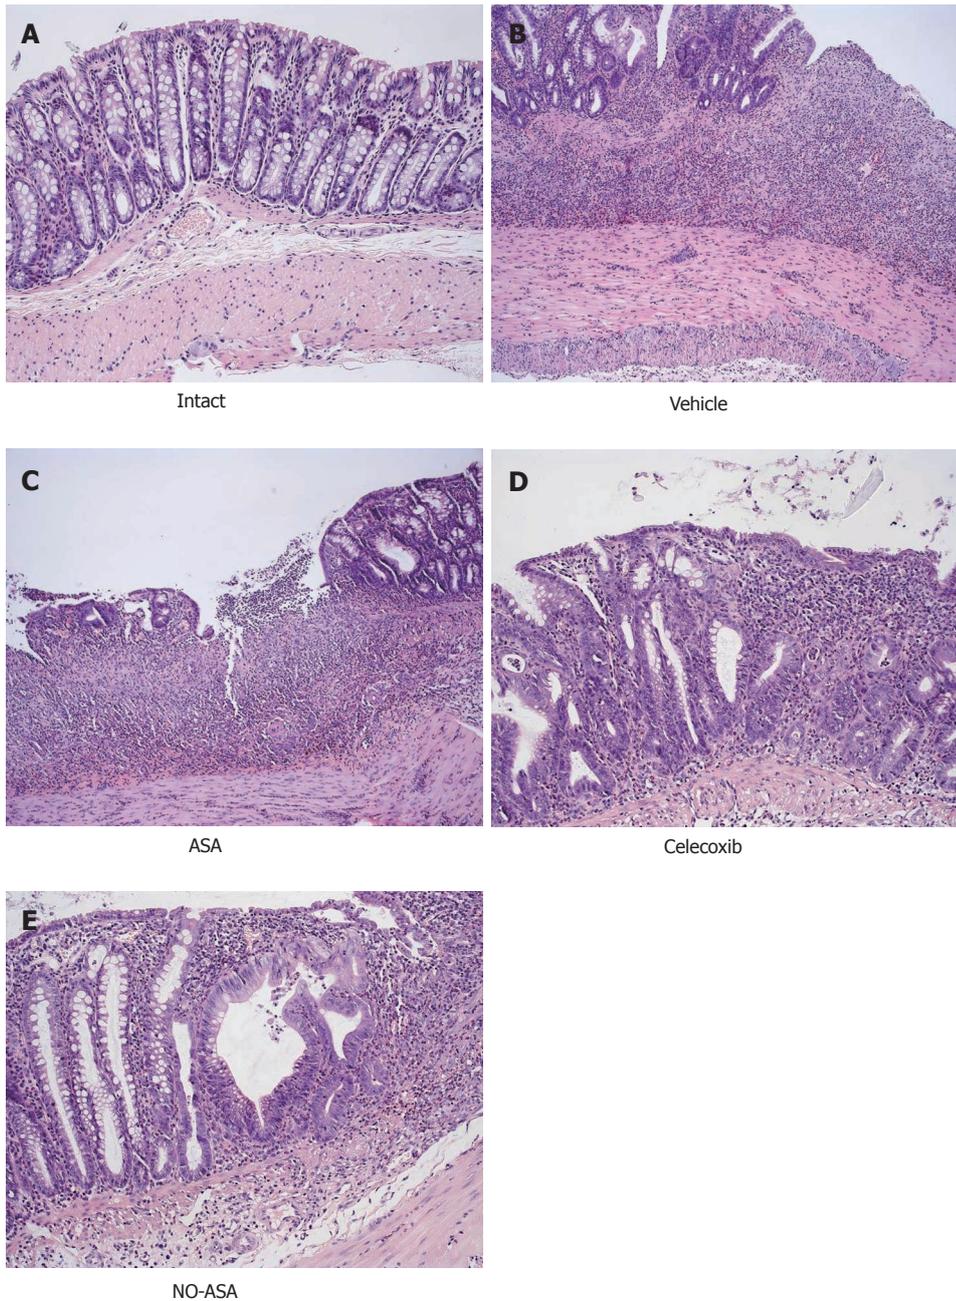

Figure 5 Histological appearance of the intact colonic mucosa (A) and that treated with vehicle (B), aspirin (C), celecoxib (D) and nitric oxide releasing aspirin on day 10 in rats with trinitrobenzenesulfonic acid-induced colitis. Intact rat colon shows regular colonic architecture and normal colonic mucosa continuity with no signs of inflammation (A). In trinitrobenzenesulfonic acid rats treated with vehicle, deep ulceration and an intense neutrophil infiltration with the presence of numerous neutrophils penetrating the muscularis mucosa and submucosa were observed. The features of regeneration adjacent to the ulcer margin are clearly visible. In aspirin (ASA)-treated rats with colitis (C), there is deep ulceration with necrosis and an intense inflammation followed by severe neutrophil infiltration and the formation of granulation tissue penetrating the muscle layer of the *muscularis propria*. Less regeneration is observed with ASA (C) than vehicle (control) animals (B). The partially healed epithelium and abnormal crypt architecture with much more pronounced regeneration was observed in the colonic mucosa of rats with colitis treated with celecoxib (D) as compared with other cyclooxygenase inhibitors. In nitric oxide (NO)-ASA treated rats with colitis (E), the most advanced healing process of colonic ulcers as reflected by scar formation, epithelial regeneration and significantly smaller neutrophil infiltration was observed. Part of the colonic crypts distant to the scar already shows a normal appearance.

(Figure 4E). By histology, intact colonic mucosa showed regular colonic architecture and continuity with no signs of inflammation (Figure 5A). In vehicle-treated TNBS rats on day 10 deep ulcerations and an intense infiltrate with the presence of numerous neutrophils penetrating the *muscularis mucosa* and submucosa were observed. In addition, features of regeneration, adjacent to the ulcer margin were

clearly visible (Figure 5B). In ASA-treated rats with colitis (Figure 5C) there was a deep ulceration with necrosis and an intense inflammation followed by severe neutrophil infiltration and formation of granulation tissue penetrating the muscle layer of the *muscularis propria*. Less regeneration was observed with ASA (Figure 5C) than in vehicle (control) colonic mucosa (Figure 5B). The area of colonic damage

Table 2 Evaluation of related markers in trinitrobenzenesulfonic acid rats treated ig with non-selective and selective cyclooxygenase-1 and cyclooxygenase-2 inhibitors or nitric oxide-aspirin throughout the period of 10 d in 6-10 rats per group (mean \pm SE)

Treatment	Weight (mg)	MPO (ng/mL)	IL-1 β (pg/mL)	TNF- α (pg/mL)
Vehicle	1150 \pm 23.1	51 \pm 8.1	42 \pm 3.4	4.8 \pm 0.6
ASA (80 mg/kg)	1580 \pm 41.4 ^a	78 \pm 9.3 ^a	65 \pm 5.1 ^a	8.5 \pm 0.95 ^a
Indomethacin (5 mg/kg)	1450 \pm 45.8 ^a	65 \pm 5.2 ^a	58 \pm 4.1 ^a	7.8 \pm 0.62 ^a
SC-560 (5 mg/kg)	1310 \pm 32.4 ^a	52 \pm 6.8 ^a	53 \pm 3.9 ^a	7.5 \pm 0.46 ^a
Celecoxib (10 mg/kg)	1082 \pm 14.9 ^c	44 \pm 4.3 ^c	36 \pm 2.2 ^c	3.8 \pm 0.33 ^c
NO-ASA (80 mg/kg)	710 \pm 12.3 ^c	35 \pm 3.2 ^c	18 \pm 1.5 ^c	2.4 \pm 0.21 ^c

MPO: Myeloperoxidase; TNF: Tumor necrosis factor; ASA: Aspirin; SC-560: 5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole; NO: Nitric oxide. ^a*P* < 0.05 vs vehicle; ^c*P* < 0.05 vs vehicle, ASA, indomethacin or SC-560 groups; ^e*P* < 0.05 vs groups treated with non-selective and selective COX-1 or COX-2 inhibitors.

was significantly smaller in celecoxib-treated animals and in those treated with ASA and vehicle (Figure 5B and D). Partially healed epithelium and abnormal crypt architecture possessing a more pronounced regeneration were observed in colonic mucosa of the rat with colitis treated with celecoxib (Figure 5D) when compared to those receiving ASA. By histology, the area of colonic damage was significantly decreased in NO-ASA treated colitis rats as compared to all other COX inhibitors and vehicle-treated rats (Figure 5E). NO-ASA treated rats showed the most advanced healing of colitis, as reflected by the degree of epithelial regeneration and the significantly smaller infiltration of neutrophils. Part of the crypts, which were distant to the scar, displayed a more normal appearance (Figure 5E). In the indomethacin-group, similar to the ASA-group, the massive hemorrhagic lesions and transmural necrosis coexisting with acute inflammatory infiltrate were observed (data not shown).

As shown in Table 2, treatments with ASA, indomethacin and SC-560 were accompanied by a greater increase in the weight of colonic tissue and a significant rise in MPO activity in TNBS-treated animals as compared to vehicle control. In contrast, treatment with celecoxib decreased the weight of colonic tissue and MPO activity below those in the vehicle group; however, these changes were significantly smaller than those caused by NO-ASA (Table 2). In contrast, treatment with NO-ASA resulted in a significant decrease in the area of colonic lesions and colonic tissue weight, accompanied by a significant rise in CBF and a fall in MPO activity compared to the respective values in rats treated with vehicle or those treated with non-selective and selective COX-1 and COX-2 inhibitors (Table 2, Figure 3).

Effect of non-selective and selective COX-1 and COX-2 inhibitors on plasma proinflammatory cytokine levels and PGE₂ generation

Plasma levels of proinflammatory cytokines IL-1 β and TNF- α , which were negligible in intact rats (data not shown), were markedly elevated in animals administered

Table 3 The generation of prostaglandin E₂ in intact rats and those treated rats (mean \pm SE)

Group	PGE ₂ generation in the colonic mucosa (pg/mg tissue weight)
Intact	182 \pm 15.4
Vehicle	409 \pm 23.2 ^a
ASA (80 mg/kg per day)	130 \pm 11.7 ^c
Indomethacin (5 mg/kg per day)	124 \pm 17.8 ^c
SC-560 (5 mg/kg per day)	145 \pm 15.6 ^c
Celecoxib (10 mg/kg per day)	191 \pm 18.3 ^c
NO-ASA (80 mg/kg per day)	175 \pm 17.3 ^c

PGE₂: Prostaglandin E₂; ASA: Aspirin; SC-560: 5-(4-chlorophenyl)-1-(4-methoxyphenyl)-3-(trifluoromethyl)-1H-pyrazole; NO: Nitric oxide. ^a*P* < 0.05 vs intact colonic mucosa; ^c*P* < 0.05 vs vehicle (control); ^e*P* < 0.05 vs ASA, indomethacin and SC-560 groups.

with ASA, indomethacin and SC-560, when compared to those treated with vehicle (Table 2). Plasma IL-1 β and TNF- α levels were significantly attenuated by treatment with the COX-2 inhibitor (celecoxib) when compared to the levels of those cytokines achieved in animals treated with non-selective COX inhibitors (ASA and indomethacin). NO-ASA was administered at a similar dose to that of native ASA, which accelerated the healing of colonic damage, and significantly attenuated plasma IL-1 β and TNF- α levels as compared to those achieved with non-selective COX inhibitors (Table 2).

As shown in Table 3, the intestinal level of PGE₂ increased in the colonic mucosa of animals with TNBS colitis as compared to that measured in vehicle-controls that did not receive TNBS. Administration of ASA and indomethacin significantly reduced the colonic PGE₂ content when compared to the respective value in vehicle-treated control animals. Treatment with ASA and SC-560, the selective COX-1 inhibitor, also significantly reduced PGE₂ generation; however this inhibition was less potent than in the case of ASA and indomethacin (Table 3). Administration of the selective COX-2 inhibitor celecoxib, and NO-ASA significantly inhibited the colonic PGE₂ generation when compared to the value measured in vehicle-control rats (Table 3).

Effect of NO donor, GTN and NO scavenger carboxy PTIO on area of colonic damage and alteration in CBF in rats with TNBS colitis

As shown in Figure 6, the area of colonic damage was significantly increased in animals treated for 10 d with ASA and this effect was accompanied by a significant fall in CBF as compared with the respective values observed in vehicle-control animals. Concurrent treatment with GTN, which by itself significantly attenuated the area of colonic damage markedly decreased these lesions and significantly improved the CBF.

Figure 7 shows the effect of 10 d administration of NO-ASA applied ig at a dose of 80 mg/kg on the area of colonic damage and accompanying alterations in CBF. Treatment with NO-ASA caused a similar decrease in

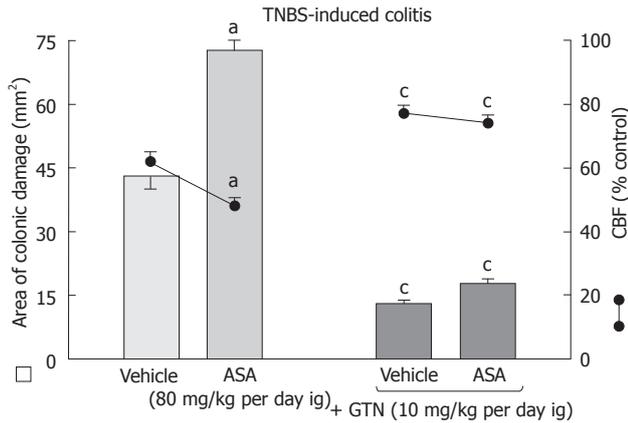

Figure 6 The effect of concurrent administration of nitric oxide donor glyceryl trinitrate on the area of colonic damage and alterations in colonic blood flow in rats with trinitrobenzenesulfonic acid-induced colitis, treated with vehicle or aspirin, on day 10. Mean ± SE of 6-8 rats. ^a*P* < 0.02 vs vehicle (control); ^c*P* < 0.02 vs vehicle or aspirin alone. TNBS: Trinitrobenzenesulfonic acid; ASA: Aspirin; GTN: Glyceryl trinitrate; CBF: Colonic blood flow.

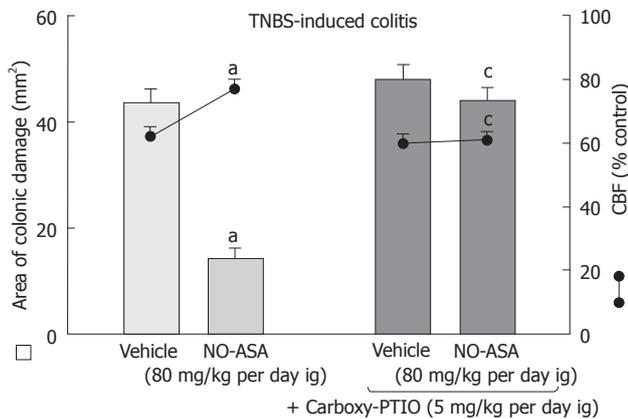

Figure 7 The effect of concurrent administration of nitric oxide scavenger 2-(4-carboxyphenyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazolyl-1-oxo-3-oxide, monopotassium salt on the area of colonic damage and alterations in colonic blood flow in rats with trinitrobenzenesulfonic acid-induced colitis, treated with vehicle or nitric oxide-aspirin (80 mg/kg per day ig) on day 10. Mean ± SE of 6-8 rats. ^a*P* < 0.05 vs vehicle group (control); ^c*P* < 0.05 vs vehicle or nitric oxide-aspirin (NO-ASA) without 2-(4-carboxyphenyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazolyl-1-oxo-3-oxide, monopotassium salt. TNBS: Trinitrobenzenesulfonic acid; CBF: Colonic blood flow.

area of colonic damage and a significant rise in CBF as presented in Figure 2. The concomitant treatment of carboxy-PTIO, the NO scavenger, which by itself had no influence on the CBF, completely abolished the beneficial effect of NO-ASA on healing of TNBS-induced colonic lesions and reversed an increase in CBF induced by this agent (Figure 7).

Effect of replacement therapy with exogenous PGE₂ on TNBS-induced colonic damage and changes in the weight of colonic tissue, CBF, plasma IL-1 β and TNF- α levels in rats treated with COX inhibitors

The role of PGE₂ in the process of healing of colonic lesions in TNBS-induced colitis animals given ASA and celecoxib was determined using rats exogenously admin-

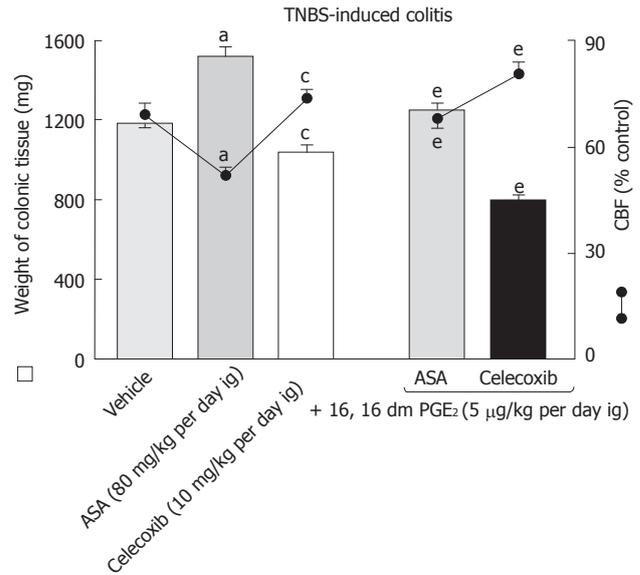

Figure 8 The weight of colonic tissue and alterations in colonic blood flow on day 10 after induction of trinitrobenzenesulfonic acid colitis in rats treated with aspirin or celecoxib with or without 16, 16 dm prostaglandin E₂ (5 µg/kg per day ig). Mean ± SE of 6-8 rats. ^a*P* < 0.02 vs vehicle (control); ^c*P* < 0.05 vs vehicle (control) and aspirin (ASA) groups; ^e*P* < 0.05 vs ASA and celecoxib groups without concurrent prostaglandin E₂ (PGE₂) administration. TNBS: Trinitrobenzenesulfonic acid; CBF: Colonic blood flow.

istered with PGE₂ in doses of 5 µg/kg added to both COX-1 and COX-2 inhibitors. An increase in both the area of colonic lesions and colonic weight as well as a significant fall in CBF induced by ASA and celecoxib were counteracted by concomitant treatment with exogenous PGE₂ (Figures 8 and 9). Moreover, the administration of this synthetic analogue of PGE₂ not only reduced the area of colonic damage but also significantly suppressed the rise in plasma IL-1 β and TNF- α compared to those in ASA- or celecoxib-treated rats without PGE₂ administration (Figure 8).

Effect of NO-ASA on TNBS-induced colonic damage and alterations in CBF in rats with capsaicin induced sensory denervation

Capsaicin-deactivation of sensory nerves, which by itself increased the area of colonic lesions and produced a significant fall in CBF when compared to those in vehicle-controlled rats, significantly attenuated the NO-ASA induced acceleration of healing of these colonic lesions and the accompanying increase in CBF (Figure 10). Concurrent administration of CGRP (10 µg/kg sc) with NO-ASA restored the healing of colonic damage as reflected by the significant decrease in colonic damage and the increase in CBF induced by this NO-derivative of ASA in rats with capsaicin denervation.

Effect of vehicle, ASA and NO-ASA treatments on the mucosal expression of COX-2, IL-1 β , TNF- α and iNOS in rats with colitis

As shown in Figure 11 (left panel), the signal for the expression of COX-2, IL-1 β , TNF- α and iNOS was significantly increased in vehicle-treated colonic mucosa (lane 2) in rats

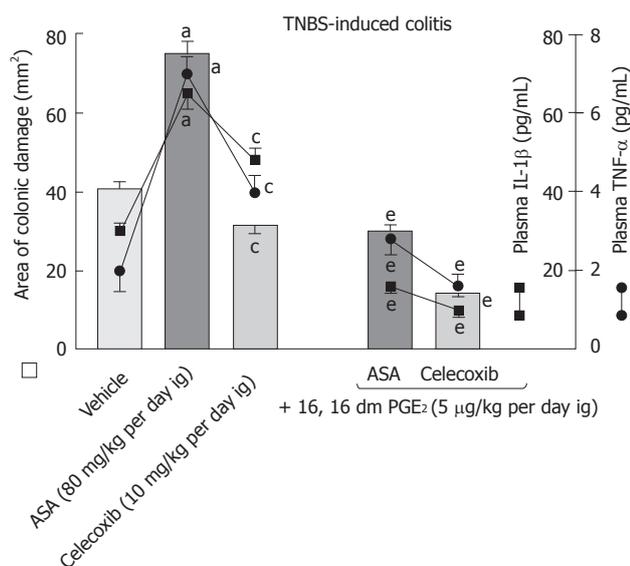

Figure 9 The area of colonic lesions and plasma levels of proinflammatory cytokines IL-1 β and tumor necrosis factor- α on day 10 after induction of colitis in rats treated with aspirin or celecoxib with or without 16, 16 dm prostaglandin E $_2$ (5 μ g/kg per day ig). Mean \pm SE of 6-8 rats. ^a*P* < 0.02 vs vehicle (control); ^b*P* < 0.02 vs vehicle-treated and aspirin (ASA)-treated groups; ^c*P* < 0.02 vs ASA and celecoxib groups without concurrent prostaglandin E $_2$ (PGE $_2$) administration. TNBS: Trinitrobenzenesulfonic acid; TNF: Tumor necrosis factor.

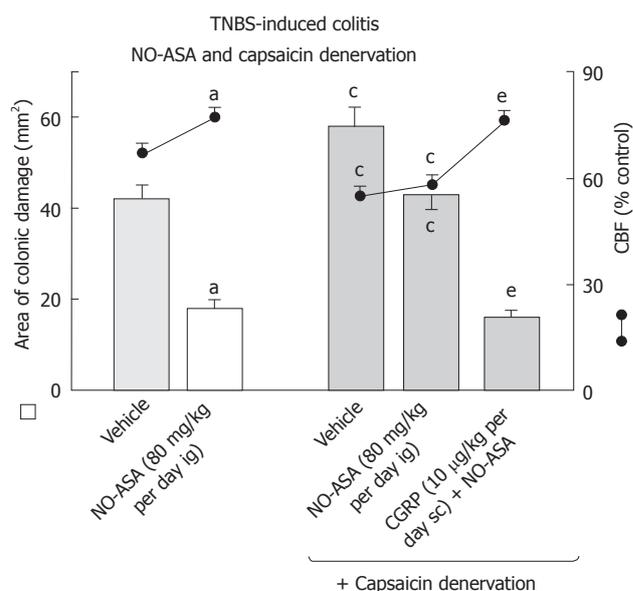

Figure 10 The area of colonic damage and changes in colonic blood flow on day 10 after colitis induction in rats with intact sensory nerves and in those with capsaicin-sensory denervation treated with vehicle (saline) or nitric oxide-aspirin (80 mg/kg per day ig) with or without administration of calcitonin gene related peptide (10 μ g/kg per day sc). Mean \pm SE of 6-8 rats. ^a*P* < 0.05 vs vehicle (control); ^b*P* < 0.05 vs trinitrobenzenesulfonic acid (TNBS) rats without capsaicin denervation; ^c*P* < 0.02 vs rats with TNBS colitis treated with nitric oxide-aspirin (NO-ASA). CGRP: Calcitonin gene related peptide; CBF: Colonic blood flow.

with colitis when compared to that in the intact mucosa (lane 1). The ratio of COX-2, IL-1 β , TNF- α and iNOS mRNA over β -actin mRNA, confirmed that expression of COX-2, IL-1 β , TNF- α and iNOS mRNAs were significantly elevated in TNBS-treated animals (Figure 11, right panel). Treatment with ASA resulted in a strong signal of mRNAs for COX-2, IL-1 β , TNF- α and iNOS. The semi-quantitative ratio of COX-2, IL-1 β , TNF- α and iNOS (lane 3) confirmed that the expression of these inflammatory markers was significantly increased in the colonic mucosa of rats treated with ASA (Figure 11, right panel). In NO-ASA-treated animals the signal for COX-2, IL-1 β , TNF- α and iNOS mRNAs was less pronounced (lane 4) and the determination of the ratio of COX-2, IL-1 β , TNF- α and iNOS confirmed that expression of mRNAs for these inflammatory factors was significantly inhibited as compared to those recorded in ASA-treated animals (Figure 11, right panel).

DISCUSSION

Worldwide, NSAIDs are among the most widely prescribed medications, and are often the drugs of choice for the treatment of various inflammatory conditions. Currently, NSAIDs, including ASA, are recommended as a prophylactic therapy against neurological and cardiologic disorders including strokes and heart infarcts^[28]. In humans, UC is a chronic relapsing disorder, characterized by colon mucosa inflammation, ulcerations, diarrhea, bloody stools and abdominal pain^[1,3]. The inflamed mucosa of the lower GI tract produces a high amount of PG derived from COX-2 expression and activity in response to stimulation by proinflammatory cytokines and growth

factors, also co-expressed at a site of inflammation^[14]. Although the NSAIDs effect on the upper GI tract is well documented, the mechanisms by which NSAIDs and their new NO-releasing derivatives affect the course and the healing of colitis in humans and experimental animals has not been fully explored. In the present study, using a rodent model of colitis we determined the effect of the new ASA derivative NO-ASA, and selective and non-selective COX-1 and COX-2 inhibitors on the healing process of this colonic damage, and the effects on weight of colonic tissue, the CBF and MPO activity. Moreover, we assessed the colonic expression of COX-2 which in contrast to COX-1 expression is negligible in normal GI mucosa, but has been shown to be significantly upregulated in most GI-related disorders such as gastritis, gastric mucosal damage, ulcers and ulcerative colitis^[3,11,14,29].

Interestingly, the inhibition of COX-2 activity by selective COX-2 inhibitors enhances gastric damage induced by stress and ischemia-reperfusion and delays the healing process of gastric ulcers in the GI tract^[29,30]. Moreover, a single application of either COX-1 or COX-2 inhibitors does not cause GI damage, but concurrent treatment with inhibitors of COX-1 and COX-2 activity, resulted in both gastric and intestinal damage. For instance, administration of celecoxib alone or SC-560 alone failed to cause gastric damage, but administration of both selective COX-1 together with COX-2 inhibitors resulted in the formation of gastric mucosal injury. It was concluded that both COX-1 and COX-2 are essential for the maintenance of the integrity of the

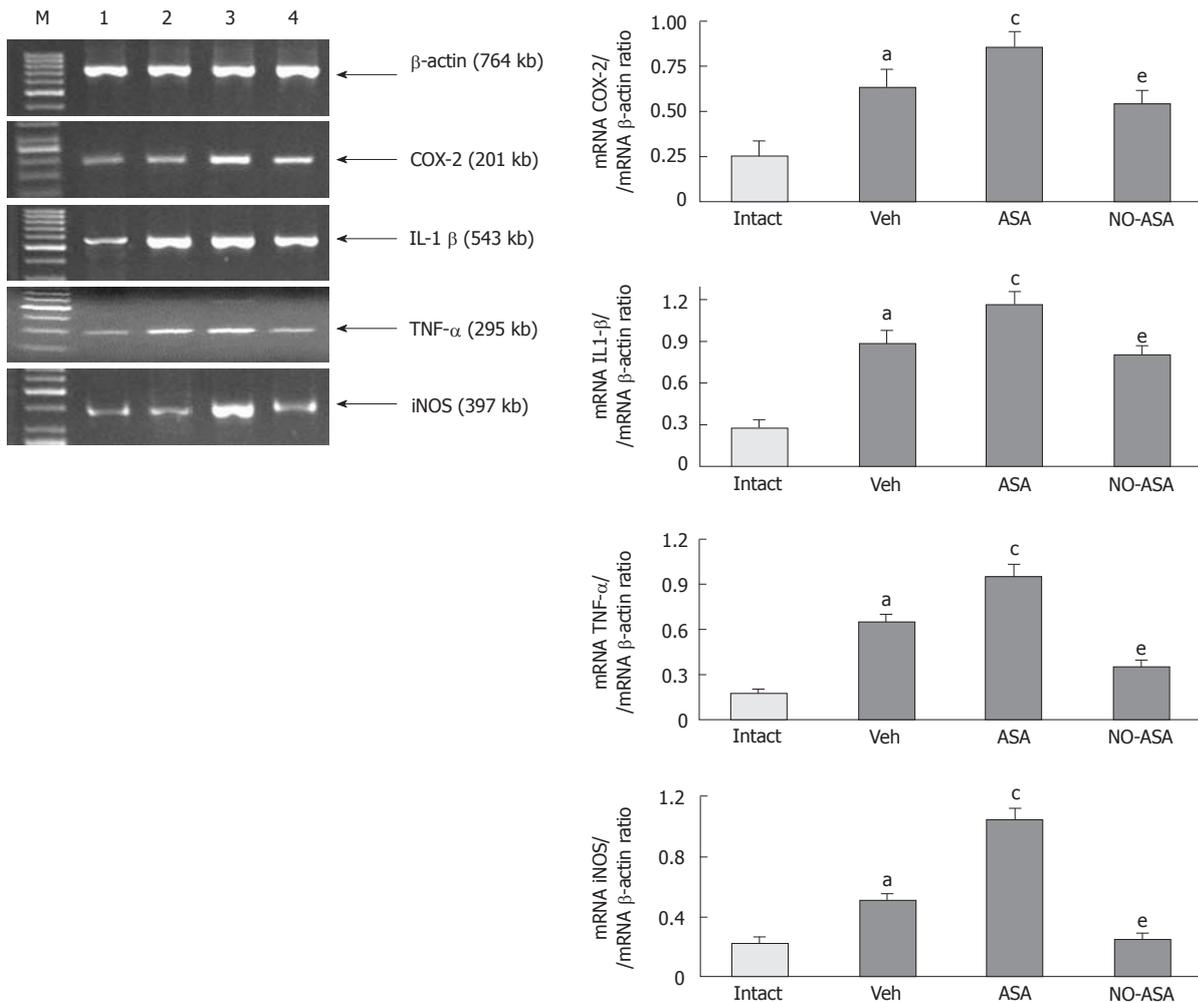

Figure 11 The expression of mRNA for cyclooxygenase-2, IL-1 β , tumor necrosis factor- α and inducible form of nitric oxide synthase in colonic mucosa of intact rats (lane 1) those treated with vehicle (lane 2), aspirin (lane 3) and nitric oxide-aspirin (lane 4) at day 10 after induction of colitis. Mean \pm SE of 4 determinations in 4 rats. ^a $P < 0.05$ vs intact colonic mucosa; ^c $P < 0.05$ vs rats with trinitrobenzenesulfonic acid colitis administered with vehicle (Veh); ^e $P < 0.05$ vs vehicle and aspirin (ASA) groups. upper GI-tract^[7,31]. Tanaka *et al.*^[31] have shown that only TNF- α was influenced by the administration of SC-560 or celecoxib but other cytokines were not affected in mice models of dextran sulphate (DSS)-induced colitis. In their model of colitis produced by adding 3% DSS to drinking water, the inhibition of both COX-1 and COX-2 resulted in exacerbation by these NSAIDs of a widespread intestinal inflammation in mice. This model has, however, different histological appearance characteristics and time course of pathology^[31] from that used in our present study^[31]. We have utilized a colitis model with TNBS which rather mimics some features of human UC and Crohn's disease (CD) which do not readily apply to the DSS model.

Expression of TNF- α is considered an important pathogenic feature of human IBD, especially CD^[13]. Another cytokine, IL-1 β , plays an immunoregulatory role in amplifying the inflammatory response by inducing the cascade activation of immune cells. In high doses, IL-1 β is responsible for the formation of epithelial cell necrosis, edema and neutrophil infiltration^[24]. In our

study TNBS-induced colonic damage was accompanied by a prominent increase in colon tissue weight as well as the rise in the MPO, the gene expression and the plasma levels of both IL-1 β and TNF- α . This data is in keeping with previous observations^[12] that pathogenesis of colitis is associated with an increase in expression and activity of TNF- α and IL-1 β . Furthermore, treatment with the non-selective COX-1 and COX-2 inhibitors such as ASA or indomethacin in our study produced a further rise in plasma IL-1 β and TNF- α levels. In contrast, the administration of celecoxib moderately improved the healing of colitis followed by a minor increase in plasma IL-1 β and TNF- α levels, while a significant improvement of this healing, accompanied by the suppression of these proinflammatory cytokines, was observed in NO-ASA-treated animals. We have also found significant differences not only in macroscopic and microscopic appearance of the colonic mucosa treated with the selective COX-2 inhibitor and NO-releasing ASA *vs* the conventional NSAID (aspirin) on healing of colonic lesions but also in functional alterations such as CBF and MPO activity.

We documented that an increase in plasma levels of IL-1 β and TNF- α in colitis was reduced to a greater extent by treatment with NO-ASA and to a lesser extent by a COX-2 inhibitor, which was not the case with the non-selective COX inhibitor, ASA. In ASA-treated rats, the expression and activity of these cytokines were both enhanced. The involvement of PG in healing of colitis is supported by our finding that an exogenously administered synthetic analog of PGE₂ reversed the delay in this healing, the increase in colonic weight and the rise in plasma levels of both IL-1 β and TNF- α induced by ASA and celecoxib. It is concluded that the lack of intestinal PGE₂ plays a crucial role in the pathomechanism of exacerbation of inflammatory colonic lesions and the perturbations in CBF in animals administered non-selective COX inhibitors but not to the same extent as in the case of selective COX-2 inhibitors. This is in keeping with the observation that PGE₂ is essential to the process of regeneration of epithelial crypts during the time course of DSS-induced colitis^[32]. In another report, PGE₂ was shown to inhibit production of proinflammatory cytokines, particularly that of TNF- α ^[33]. We found an apparent increase in MPO activity, which is considered to be an indicator of neutrophil-induced inflammatory infiltration, which was significantly elevated in colitis. The colonic MPO activity was further enhanced by non-selective COX inhibitors and selective COX-1 inhibitors such as ASA, indomethacin and SC-560, respectively, while both celecoxib and especially NO-ASA attenuated MPO activity in colitis rats treated with vehicle. This deleterious effect of non-selective COX-inhibitors, ASA and indomethacin, observed in our study could not be attributed to GI toxicity of these NSAIDs, since e.g. indomethacin was used in our study in a dose which by itself failed to induce gastric mucosal lesions but as shown before, prolonged the healing of acute and chronic gastric ulcers, mostly due to inhibition of protective PG^[19,21]. Indomethacin was previously reported to induce experimental colitis at doses up to 10 mg/kg^[34] that was higher than that in our present study.

We were particularly interested in exploring the mechanism of accelerated colonic healing of the new class of so-called “safer NSAID” such as NO-ASA. In our study the TNBS-induced colitis was associated with a fall in CBF, but this impairment in the colonic microcirculation was worsened by native ASA and indomethacin. Celecoxib moderately enhanced colonic healing and slightly increased CBF, suggesting that this COX-2 inhibitor exerts the opposite effect on colonic microcirculation than non-selective COX inhibitors. In clear contrast, NO-ASA greatly improved CBF and reduced both MPO activity and the expression of mRNAs and reduced plasma IL-1 β and TNF- α levels thus contributing to the process of healing of inflammatory lesions. We conclude that these healing and anti-inflammatory effects could be attributed to NO being released from NO-ASA, which ultimately was responsible for the improvement of CBF observed in our study. This is supported by the fact that

GTN which is an NO donor, when co-administered with ASA, significantly reduced colonic damage and counteracted the fall in CBF induced by this NSAID. Moreover, the mechanism of the acceleration of colonic healing involves the release of NO from NO-ASA. This notion is supported by the observation that NO-ASA dose-dependently accelerated healing of these lesions followed by an increase in plasma NO_x levels. Second, carboxy-PTIO, an NO-scavenger, abolished the healing efficacy of this NO-derivative of ASA and the accompanying increase in CBF. In addition, NO released from NO-ASA could contribute to the intestinal elimination of bacteria, protozoa and fungi as reported previously^[35]. In other studies, the addition of a NO-releasing moiety to mesalamine exerted an immunomodulatory effect and suppressed intestinal inflammation by inhibiting T-helper cells while stimulating the activity of the anti-inflammatory cytokine IL-10, TGF β and mucosal Treg pathway whereas standard mesalamine was less effective^[36].

It is known that the maintenance of GI mucosal integrity depends on different protective mechanisms against injury, which involves the stimulation of two populations of afferent nerves, vagal and spinal. As shown previously, these sensory neurons are involved in GI protection *via* activation of vasodilatory and anti-inflammatory reflexes^[37]. It was reported that the afferent neurons from the dorsal root ganglia play a role in the local regulation of GI circulation, secretion, motility and the process of mucosal repair and healing after injury^[37]. CGRP, a neurotransmitter, is released from the peripheral fibers of sensory neurons and plays an important role in GI mucosal defense^[37]. Capsaicin, an active ingredient of red pepper has been found to act on the capsaicin sensitive afferent nerves releasing CGRP^[38]. When applied in small doses, capsaicin induces a protective response, but a large dose of this neurotoxin renders the gastric mucosa more susceptible to damage induced by indomethacin, ischemia and reperfusion and cold stress^[23,26]. This has also been shown to result in a delay in the process of gastric ulcer healing, an event associated with decreased tissue levels of gastric CGRP^[37].

In our study, capsaicin-induced functional ablation of sensory nerves with capsaicin, which by itself markedly prolonged the healing process of colonic lesions, attenuated the increase in the healing of these lesions and the accompanying rise in CBF induced by NO-ASA. The impaired healing and evident fall in CBF were restored by concurrent administration of CGRP with NO-ASA in capsaicin-denervated rats. These findings suggest that sensory nerve neuropeptides such as CGRP may contribute to the healing effect and hyperemia induced by NO-ASA. Both CGRP and NO contribute to hyperemia in the GI tract mucosa and facilitate other mechanisms of defense, such as bicarbonate secretion^[21,23]. Existing evidence in the lower GI tract revealed an increased inflammatory reaction in experimental colitis of transient receptor potential vanilloid-1 (TRPV-1) knockout mice^[37,38]. TRPV-1 is expressed by many afferent nerves and its activation results

in the release of vasodilatory peptides such as CGRP^[38,39].

In summary, conventional NSAIDs, such as ASA and indomethacin or selective COX-1 inhibitors such as SC-560^[40], delay the healing of experimental colitis and this effect is accompanied by a fall in CBF and an enhancement in gene expression and release of proinflammatory cytokines IL-1 β and TNF- α . These deleterious effects are less pronounced with the use of the selective COX-2 inhibitor, celecoxib, which differs with respect to colonic healing with that of conventional ASA. NO-ASA exerts the opposite effects to those of native ASA and selective COX-1 inhibitors on the delay in healing of TNBS colitis and accompanying fall in colonic microcirculation induced by these agents. The beneficial healing action of NO-ASA, involves the NO mediated suppression of proinflammatory cytokines and the activation of sensory nerves resulting in a local release of sensory vasodilatory neuropeptides such as CGRP.

COMMENTS

Background

Nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, are among the most prescribed drugs because of their anti-inflammatory, antipyretic, analgesic effects. Inhibition of prostaglandin synthesis seems to be the major mechanism implicated in both the beneficial and adverse effects of NSAIDs. Aside from the systemic activity of NSAIDs, resulting from the inhibition of mainly cyclooxygenase (COX)-1 activity, the NSAIDs exert a deleterious influence on the upper and lower gastrointestinal (GI) mucosal integrity by affecting the local inflammatory mechanisms, such as neutrophil recruitment, the activation of proinflammatory cytokines, impairment of microcirculation and the release of free oxygen metabolites. A new class of nitric oxide (NO)-releasing NSAIDs was developed to limit the serious adverse effects associated with NSAIDs ingestion, but their effect in lower GI healing with respect to colitis in animal models has not been carefully investigated. Sensory neurons releasing neuropeptides such as calcitonin gene related peptide (CGRP) are involved in the mechanism of GI protection and ulcer healing due to activation of vasodilatory mediators such as CGRP. Currently, it is unknown whether these sensory neuropeptides could influence the healing of ulcerative colitis (UC) in animals treated with NO-releasing aspirin (ASA).

Research frontiers

Both UC and Crohn's disease belong to the category of inflammatory bowel diseases (IBD). It is believed that three major factors influence the pathogenesis of these two diseases: an individual's susceptibility, microflora of the gastrointestinal tract and immunological properties of the gastrointestinal mucosa. UC is a disease of the colon which is characterized in humans by chronic inflammation in both the mucosal and submucosal layer with a cellular and humoral immunological response. Patients suffering from UC frequently require anti-inflammatory analgesics such as NSAIDs because of inflammatory conditions

such as arthritis, sacroiliitis or osteoporosis-related fractures. On the other hand conventional NSAIDs may either induce development of colitis in the healthy colon or exacerbate preexisting colitis. Previous studies revealed that COX exists in the following two isoforms: the inducible COX-2, which is detected at the site of inflammation, and COX-1, which functions in a housekeeping fashion, is present in the majority of human tissues and organs, and is responsible for homeostasis and GI tract integrity. PGs induced by COX-2 are involved in maintaining the intestinal mucosa integrity, in the healing of gastrointestinal ulcers and the modulation of IBD. But the inhibition of both COX-1 and COX-2 isoforms seems to be necessary to induce significant intestinal damage. The new class of NSAIDs containing the NO moiety, such as NO-releasing ASA, could be an alternative strategy in the attenuation of GI side effects of conventional NSAIDs such as ASA. This is due to the fact that NO released from ASA possesses anti-inflammatory properties and contributes to the resolution of intestinal inflammation.

Innovations and breakthroughs

The authors attempted to determine the involvement of NO released from NO-ASA and its role in the mechanism of the healing of colitis. This was accomplished by using NO-ASA and glyceryl trinitrate (GTN), an NO donor, added to classic ASA to mimic the protective action of NO-ASA. Treatment with NO-ASA improved the healing of colitis, with these effects as well as the anti-inflammatory properties of NO-ASA being attributed to the NO released from NO-ASA, which was ultimately responsible for the improvement of colonic blood flow (CBF) observed in this study. Furthermore, the authors found that both NO and the activation of sensory nerve neuropeptides such as CGRP may contribute to the healing effects and the hyperemia induced by NO-ASA. This could be responsible for the attenuation of the expression and the release of pro-inflammatory cytokines such as IL-1 β and tumor necrosis factor (TNF)- α . This is supported by the fact that GTN, which is an NO donor, when co-administered with ASA, significantly decreased colonic damage and counteracted the decrease in CBF induced by this NSAID. The study demonstrates that NO-ASA is beneficial when compared to its parent drug ASA in the healing of experimental colitis. Furthermore, celecoxib, the selective COX-2 inhibitor, showed greater efficacy in healing colitis than was observed with non-selective COX-1 and COX-2 inhibitors (conventional ASA, indomethacin). However, the prolonged use of coxibs in clinical practice may be associated with prothrombotic action and increased risk of acute myocardial infarction. This significant finding of the authors with respect to selective COX-2 inhibitors and healing of ulcerative colitis requires further investigation and confirmation in clinical trials.

Applications

(1) Inhibition of both COX-1 and COX-2 isoforms by non-selective and selective COX-1 inhibitors exacerbates colonic damage and leads to functional impairment of the colonic mucosa blood flow during the process of healing of colitis; (2) The importance of PG inhibition by NSAIDs in the pathogenesis of colitis is confirmed by the finding that supplementation with exogenous PGs of animals concurrently treated with COX-1 or COX-2 inhibitors attenuated the colonic damage and the decrease of CBF induced by these agents; and (3) The NO released from ASA may be an alternative option to native ASA in patients with lower GI tract disorders such as UC.

Terminology

Incorporation of NO generating moiety into the basic structure of NSAIDs, such as aspirin (NO-ASA) attenuates the ulcerogenic activity of native NSAID. Under basal conditions, NO derived from the activity of constitutive NO synthase (cNOS) contributes to the maintenance of intestinal integrity and the control of intestinal motility. NO and CGRP exhibit a protective action against NSAIDs induced impairment of colonic healing. GTN, an NO donor, and 2-(4-carboxyphenyl)-4,5-dihydro-4,4,5,5-tetramethyl-1H-imidazolyl-1-oxy-3-oxide, monopotassium salt, an NO scavenger were used for the evaluation of the involvement of NO in the process of colonic healing in rats with colitis. CGRP is a sensory neurotransmitter released from the peripheral endings of afferent sensory neurons implicated in the defense mechanism of the GI mucosa. Capsaicin, an active ingredient of red pepper, has been found to induce a functional ablation of the capsaicin-sensitive afferent nerves releasing CGRP. Previous studies revealed that when applied in small doses capsaicin exerts a protective action, but large doses of this neurotoxin render the GI mucosa more susceptible to damage induced by various ulcerogens and stressors.

Abstract

AIM: To explore the role of high-mobility group box 1 (HMGB1) protein during liver fibrogenesis and investigate the functional effects of *HMGB1* gene silencing in hepatic stellate cells (HSCs) using siRNA.

METHODS: Hepatic fibrosis in rats was induced through serial subcutaneous injections of dimethylnitrosamine, and expression of HMGB1 was detected by immunohistochemistry. HMGB1 siRNAs were developed and transiently transfected into HSC-T6 cells using Lipofectamine 2000. HMGB1 expression was evaluated by real-time polymerase chain reaction (PCR) and Western blotting analysis. Expression of α -smooth muscle actin (α -SMA) and collagen types I and III was evaluated by real-time PCR. Cell proliferation and the cell cycle were determined

using the methyl thiazolyl tetrazolium method. Finally, collagen content in HSC supernatant was evaluated by an enzyme-linked immunosorbent assay.

RESULTS: The results showed that HMGB1 was up-regulated during liver fibrosis and that its expression was closely correlated with the deposition of collagen. siRNA molecules were successfully transfected into HSCs and induced inhibition of HMGB1 expression in a time-dependent manner. Moreover, HMGB1 siRNA treatment inhibited synthesis of α -SMA and collagen types I and III in transfected HSCs.

CONCLUSION: This study suggests a significant functional role for HMGB1 in the development of liver fibrosis. It also demonstrates that downregulation of HMGB1 expression might be a potential strategy to treat liver fibrosis.

INTRODUCTION

Hepatic fibrosis is a major medical problem associated with significant morbidity and mortality. Regardless of

the underlying aetiology^[1], hepatic fibrosis is characterized by the accumulation of excess extracellular matrix (ECM). The amount of matrix deposition depends on the balance between its synthesis and degradation. When synthesis of ECM exceeds its degradation, the pathological accumulation of ECM leads to liver fibrosis. Therefore, a critical balance must be achieved between maintaining the proper amount of ECM for homeostasis, while at the same time, providing a means of ensuring that excess or improper accumulation does not occur.

High-mobility group box 1 (HMGB1) protein was originally identified as a nuclear nonhistone protein with DNA-binding domains, and it has been implicated as an important endogenous danger signaling molecule. In addition, it can be secreted from cells and exert extracellular functions as a proinflammatory cytokine^[2,3]. Increasing evidence now points to multiple functions of HMGB1 in infection, tissue injury, inflammation, apoptosis, and the immune response^[4]. HMGB1 can be released both through active secretion from various cells, including activated monocytes/macrophages, neutrophils, and endothelial cells, and through passive release from necrotic cells^[5-7]. HMGB1 can directly promote the secretion of proinflammatory cytokines [tumor necrosis factor (TNF), interleukin (IL)-1A/B, IL-6 and IL-8] and chemokines (macrophage inflammatory protein-1A/B) by peripheral blood mononuclear cells (PBMCs)^[8,9]. In turn, PBMCs also produce different cytokines that are potentially involved in virus-induced liver damage. HMGB1 acts as a chemoattractant for fibroblasts and endothelial and smooth muscle cells, which are cell types that significantly contribute to wound repair^[9,10]. Consequently, HMGB1 can directly stimulate fibroblast proliferation and participate in fibrogenesis^[4]. Additionally, inhibitors of HMGB1 significantly reduce tissue damage^[5,6]. Moreover, Hamada *et al*^[4] have reported that inhibition of HMGB1 may be beneficial in pulmonary fibrosis. Therefore, we postulated that inhibiting the up-regulation of HMGB1 during liver fibrogenesis could be a potential strategy for treating liver fibrosis.

RNA interference is known as a powerful tool for post-transcriptional gene silencing^[11] and has opened new avenues in gene therapy. In this study, we induced hepatic fibrosis in rats through serial subcutaneous injections of dimethylnitrosamine (DMN) for 4 wk and evaluated the expression of HMGB1 during the process of hepatic fibrogenesis. Additionally, siRNA molecules targeting the sequences within the rat *HMGB1* gene were transfected into hepatic stellate cell (HSC)-T6 cells. The results show that the expression of HMGB1 was correlated with collagen deposition during hepatic fibrosis and that down-regulating HMGB1 expression could prohibit collagen production and enhance collagen degradation.

MATERIALS AND METHODS

Animal models

Thirty-two 6-wk-old male Sprague-Dawley rats (230-260 g)

were purchased from the Shanghai Laboratory Animal Centre of Chinese Academy of Sciences and fed *ad libitum* with standard laboratory chow. All rats received humane care according to the Guide for the Care and Use of Laboratory Animals by the Chinese Academy of Sciences. Hepatic fibrosis was induced by intraperitoneal injections of 1% DMN (1 mL/kg body weight) for three consecutive days per week for up to 4 wk^[11]. Rats were sacrificed at 1, 2 and 3 wk from the first DMN injection. Liver tissues were either snap-frozen in liquid nitrogen or fixed in 10% formalin for histology and immunostaining.

Histological and immunohistochemical examination

Liver tissue sections were stained with hematoxylin-eosin (HE) for histopathological examination. Immunohistochemical examination was performed to detect the expression of HMGB1 and collagen types I and III in liver tissues. Briefly, the paraffin sections of left median hepatic lobes were incubated with 3% H₂O₂ in methanol at 37 °C for 10 min to quench endogenous peroxidase activity. After blocking at room temperature for 20 min, the sections were incubated with antibodies against HMGB1 (R and D Systems, Germany), collagen type I or collagen type III (Boster, Wuhan, China) overnight at 4 °C followed by incubation with horseradish-peroxidase-conjugated secondary antibody (Dako, Kyoto, Japan) at 37 °C for 20 min. Finally, the signals were detected using the Diaminobenzidine Substrate Kit (Vector Laboratories, Burlingame, CA, United States), and a positive outcome was indicated by brown staining in the cytoplasm or nucleus. For the semiquantitative analysis of HMGB1 and collagen expression, the brown-stained tissues in immunohistostaining sections were measured on an image analyzer by a technician blinded to the samples. Five fields were selected randomly from each of two sections, and six rats from each group were examined.

Double immunostaining of HMGB1 and α -smooth muscle actin

Liver sections were blocked with 5% normal goat serum after fixing and then simultaneously incubated with both monoclonal anti-HMGB1 (R and D Systems, Germany) and polyclonal α -smooth muscle actin (α -SMA) (Fremont, CA, United States) antibodies prepared in phosphate-buffered saline (PBS). The sections were incubated overnight at 4 °C or 1 h at room temperature and then washed with PBS. Sections were then simultaneously incubated with fluorescein-isothiocyanate-conjugated secondary antibody and rhodamine-conjugated secondary antibody for 30 min at 37 °C in the dark. Both primary antibodies were produced in different species. Antibody labeling was examined under a Zeiss LSM-510 laser scanning confocal microscope.

Cell culture

The HSC-T6 cell line, an immortalized rat HSC line, which has a stable phenotype and biochemical characteristics, was kindly provided by Dr. SL Friedman (Divi-

sion of Liver Diseases, Mount Sinai School of Medicine, New York, NY, United States). All cells were cultured in RPMI1640 medium supplemented with 10% fetal bovine serum and 5% antibiotics and incubated at 37 °C in a humidified atmosphere of 5% CO₂. Cells were seeded at 2 × 10⁵ per well in six-well plates 24 h before transfection. The amount of siRNA and transfection reagent was calculated according to the manufacturer's instructions.

Immunofluorescence study

HSC-T6 cells were cultured for 24 h on glass coverslips and fixed in 4% formaldehyde for 30 min at room temperature prior to detergent extraction with 0.1% Triton X-100 for 10 min at 4 °C. Coverslips were saturated with PBS containing 2% bovine serum albumin (BSA) for 1 h at room temperature. Next, cells were incubated with the specific primary antibody for HMGB1 (R and D Systems, Germany) in 1% BSA for 1 h, washed, and incubated with secondary antibody (TRITC AffiniPure Goat Anti-Rabbit IgG, EarthOx, LLC, United States). Finally, cells were stained for 30 min at room temperature with 4,6-diamidino-2-phenylindole. Slides were viewed with a Zeiss LSM-510 laser scanning confocal microscope.

Preparation of siRNA, construction of siRNA expression vector and transfection assay

The siRNAs for rat HMGB1 mRNA were designed and synthesised by Invitrogen Life Technologies. We prepared three siRNAs, and the most effective one was selected for construction of the siRNA expression vector. The siRNA sequences used are shown in Table 1. Negative control siRNAs were used to assess non-specific gene silencing effects, and the mock group was the non-transfection group. Cells were transfected with a mixture of plasmid DNA and Lipofectamine 2000 (Invitrogen) in Opti-MEM I medium without serum as recommended by the manufacturer. The medium was then replaced with standard RPMI medium (containing 10% FBS and gentamicin) 24 h post-transfection.

Real-time quantitative polymerase chain reaction

Total RNA was extracted at different time points after siRNA transfection using the Trizol kit (Gibco/Life Technologies) according to the manufacturer's protocol. The mixture of RNA and primers was loaded into the polymerase chain reaction (PCR) amplifier. The PCR protocol was as follows: predenaturate setting at 95 °C for 5 min, 94 °C for 45 s, annealing at 50 °C for 1 min, and extension at 72 °C for 1 min. The PCR was performed for 40 cycles followed by a final extension at 72 °C for 10 min. We then visualized the PCR product by running it on a 1.5% agarose gel and quantitatively analysed it with Lab Works 4.5 analysis software.

Western blotting

The same quantities of cells were collected from the four groups, and the protein was extracted from the cells at the 24, 48 and 72 h after transfection. The pro-

tein content in the supernatant was detected using the bicinchoninic acid method. An equal amount of protein was used for sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred onto a polyvinylidene fluoride (PVDF) membrane. The PVDF membrane was incubated overnight at 4 °C with monoclonal anti-human HMGB1 (1:300) and was then incubated for 2 h with a secondary antibody (1:5000). Finally, after staining and fixing, the film was analyzed using the Image Analysis System.

Enzyme-linked immunosorbent assay

Commercial kits (Sigma, St. Louis, MO, United States) were used to quantitate the amount of collagen types I and III in the culture supernatant of HSCs at different time points after siRNA transfection.

Methyl thiazolyl tetrazolium used for observing cell proliferation

The cell suspension was inoculated into 96-well plates at 1000 cells per well with eight ambi-wells and incubated for 1, 2, 3, 4 and 5 d after transfection. Cells were incubated with 20 μL methyl thiazolyl tetrazolium for 4 h. After centrifugation, 150 μL dimethyl sulfoxide was added to the precipitate, and the absorbance of the enzyme was measured at 490 nm. Cell growth rates (average absorbance of each transfected group/non-transfected group) were then calculated.

Statistical analysis

Continuous data were expressed as the mean ± SD and were analyzed using the Student's *t* test. Correlations among the study variables were tested using Pearson's correlation coefficients. *P* < 0.05 were considered statistically significant. All calculations were performed using SPSS version 13.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Histological and immunohistochemical assessment

To investigate the expression of HMGB1 during liver fibrosis, liver sections were analysed by HE staining and immunohistochemistry. We localized HMGB1 and collagen types I and III in liver specimens by immunohistochemistry. None of these proteins were observed in control rat livers. In fibrotic rat livers, HMGB1 was markedly increased during liver fibrogenesis and was correlated with

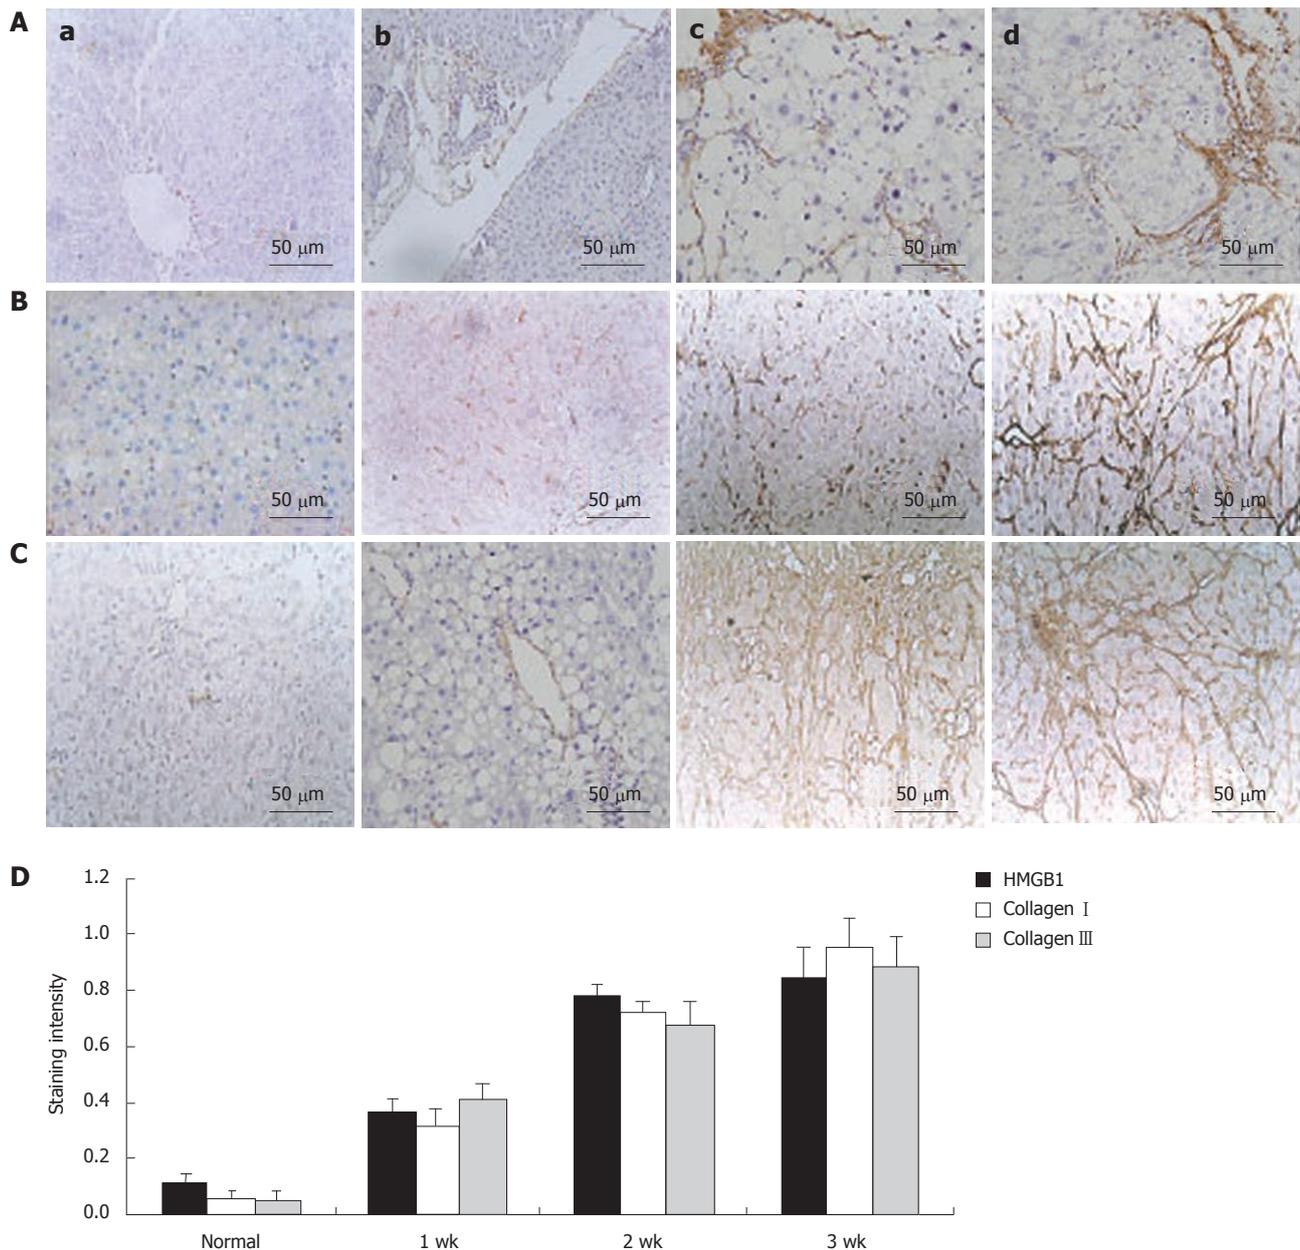

Figure 1 High-mobility group box 1 protein was upregulated after dimethylnitrosamine injection. A: Immunohistochemical study of high-mobility group box 1 (HMGB1) distribution and expression in liver fibrosis specimens (original magnification, $\times 400$). Brown color displays the positive expression. a: There was no immunoreactivity in the normal liver tissue; b: Weak staining in liver fibrosis tissue at 1 wk after the first dimethylnitrosamine (DMN) injection; c: Moderate staining in liver fibrosis tissue at 2 wk after the first DMN injection; d: Strong staining in liver fibrosis tissue at 3 wk after the first DMN injection; B: Immunohistochemical study of collagen type I in liver fibrosis specimens (original magnification, $\times 400$). Brown color displays the positive expression. Collagen type I was markedly increased during liver fibrogenesis; C: Immunohistochemical study of collagen type III in liver fibrosis specimens (original magnification, $\times 400$). Collagen type III was markedly increased during liver fibrogenesis; D: The amount of HMGB1, collagen types I and III staining in liver tissue was measured using an image analyzer during liver fibrosis. HMGB1 was markedly increased during liver fibrogenesis, correlated with the expression of collagen types I and III ($r = 0.90$, $P < 0.05$ and $r = 0.89$, $P < 0.05$).

the expression of collagen types I and III. Immunohistochemistry indicated that the intensity of HMGB1 immunostaining was stronger in the fibrotic samples (DMN week 1) than in the control group. After DMN injection for 2-3 wk, greater HMGB1 staining was found around the portal tracts and fibrotic septa (Figure 1A). With the development of hepatic fibrosis, there was an enhanced expression of HMGB1, correlating with collagen types I and III expression, which was mainly located within

the mesenchymal (Figure 1B and C). Statistical analysis showed that the expression of HMGB1 was completely correlated with the expression of collagen types I and III during the development of hepatic fibrosis (Figure 1D) ($P < 0.05$).

Cellular localization of HMGB1 in DMN-treated rats

α -SMA, a typical marker of activated HSCs, was selected to determine the cellular localization of HMGB1 in hepat-

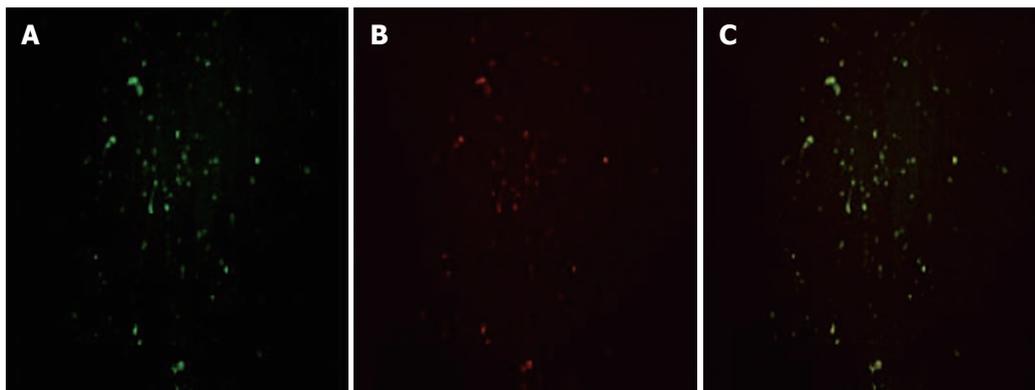

Figure 2 Double immunostaining was used to analyze the cellular localization of high-mobility group box 1 protein and α -smooth muscle actin in hepatic fibrosis tissue (original magnification, $\times 200$). A: α -smooth muscle actin (α -SMA) was stained with polyclonal α -SMA antibody and secondarily by rhodamine-conjugated anti-rabbit antibody (green); B: High-mobility group box 1 (HMGB1) was stained with monoclonal anti-HMGB1 antibody and secondarily by fluorescein isothiocyanate-conjugated anti-rabbit antibody (red); C: The yellow areas on the merged image show co-localization of α -SMA and HMGB1.

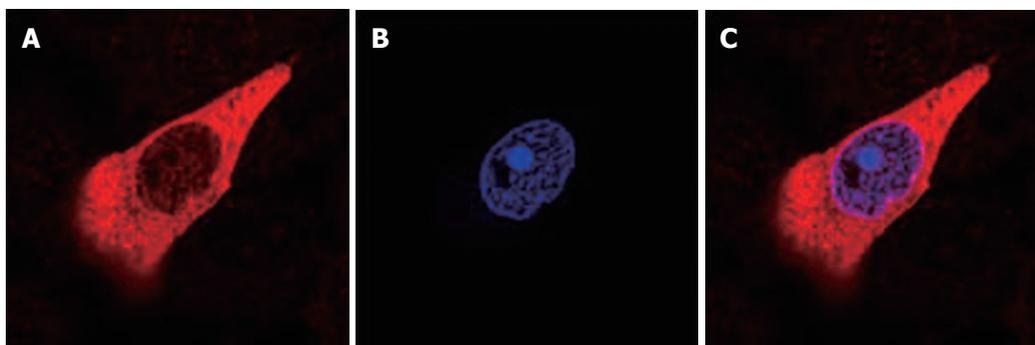

Figure 3 High-mobility group box 1 protein expression in hepatic stellate cell-T6 cells by immunofluorescence staining (original magnification, $\times 200$). A: High-mobility group box 1 (HMGB1) protein was stained with monoclonal anti-HMGB1 antibody and secondarily by fluorescein isothiocyanate-conjugated anti-rabbit antibody (red); B: Nuclei were labeled with 4',6-diamidino-2-phenylindole (blue); C: The merge picture.

ic fibrosis tissue. The localization of HMGB1 and α -SMA was visualized by immunofluorescent double labeling and laser scanning confocal microscopy. The image analysis showed a diffused distribution of HMGB1 throughout the hepatic fibrosis tissue (Figure 2A), and a similar distribution was observed for α -SMA (Figure 2B). When the two images were merged, there was a very high degree of co-localization of HMGB1 with α -SMA throughout the hepatic fibrosis tissue (Figure 2C).

Intracellular localization of HMGB1 in activated HSC-T6 cells

An immunofluorescence study of HSC-T6 cells after 24 h of culture demonstrated the intracellular localization of HMGB1. We evaluated the subcellular localization of HMGB1 by separating bulk nuclei and cytosolic fractions, and HMGB1 was detected primarily within the cytosol of activated HSC-T6 cells (Figure 3).

Selection of HMGB1 mRNA sequence target

As shown in Table 1, a total of three candidate siRNA sequences were chosen to be complementary to various regions of the rat *HMGB1* gene. In a set of preliminary experiments designed to identify the most appropriate sequence for further study, these sequences were transfected

into HSC-T6 using Lipofectamine. Forty-eight hours after transfection, HMGB1 transcript and protein levels were reduced in transfected cells. This *HMGB1* gene-silencing effect was reproducible and was specific in that it failed to knock down the expression of an unrelated protein, β -actin. All three HMGB1 shRNAs tested in this study were able to reduce the HMGB1 expression in HSC-T6 cells compared with the negative control (NC) siRNA transfectants. Although all three HMGB1 shRNA constructs were effective, shRNAH3 was more efficient in reducing the HMGB1 transcript levels than shRNAH2 and shRNAH1 (Figure 4A). Western blotting analysis (Figure 4C) further confirmed the shRNAH3 silencing of the HMGB1 protein in HSC-T6 cells. Semiquantitative analysis of the real-time (RT)-PCR and Western blot results (Figure 4B and D) also showed that HMGB1 shRNAH3 decreased the expression of HMGB1 in HSC-T6 cells more efficiently than shRNAH2 and shRNAH1. Accordingly, we chose shRNAH3 for the subsequent experiments.

HMGB1 siRNA downregulated mRNA expression of α -SMA and types I and III collagen in HSC-T6

To investigate the effect of HMGB1 siRNA on HSCs and its potential molecular mechanisms, we detected the

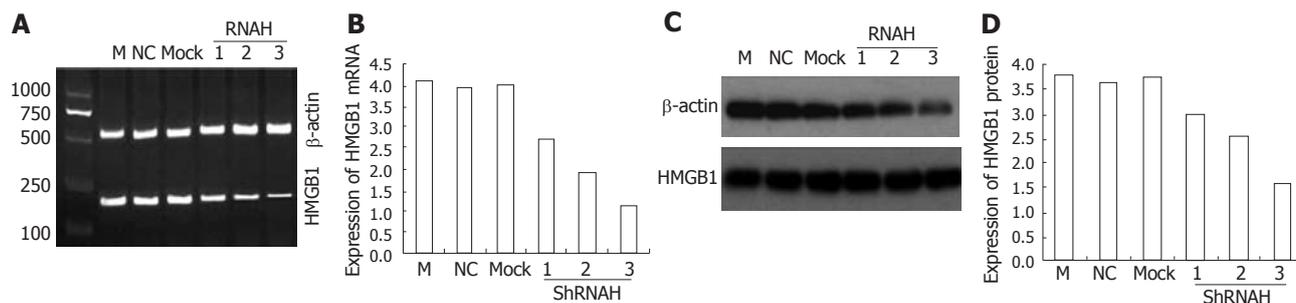

Figure 4 Screening the most effective high-mobility group box 1 siRNA sequence. Total RNA and protein were obtained from hepatic stellate cell-T6 transfected with negative control (NC), mock and three different high-mobility group box 1 (HMGB1) siRNA molecules (shRNAH1, shRNAH2 and shRNAH3). A: Real-time polymerase chain reaction (RT-PCR) for the effect of three different HMGB1 siRNA molecules on HMGB1 mRNA level 48 h after transfection. The expression was normalized against β -actin; B: Semiquantitative analysis of the RT-PCR result; C: Western blotting analyzed HMGB1 protein expression 48 h after transfection; D: Semiquantitative analysis of the western blotting results. Data represent results from one of three similar experiments. Results show that all three HMGB1 shRNA constructs were effective, but shRNAH3 was more efficient in reducing the HMGB1 mRNA and protein levels than shRNAH2 and shRNAH1.

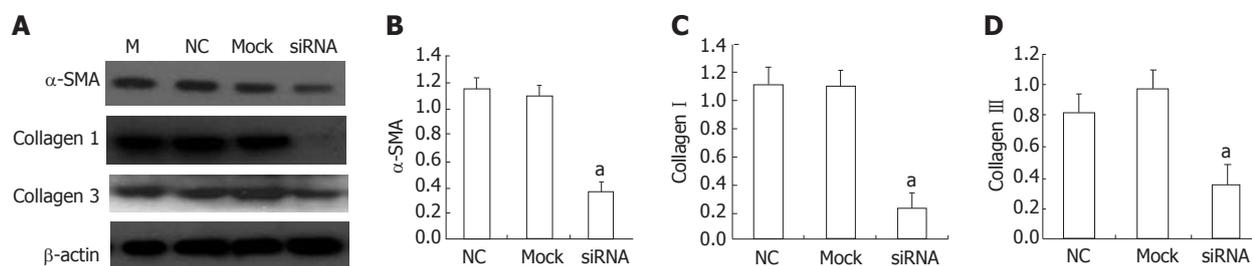

Figure 5 High-mobility group box 1 siRNA inhibited α -smooth muscle actin, collagen types I and III mRNA expression in hepatic stellate cell-T6 cells. A: Real-time polymerase chain reaction (RT-PCR) analysis for α -smooth muscle actin (α -SMA), collagen types I and III mRNA expression in hepatic stellate cell-T6 cells after siRNA high-mobility group box 1 transfection. β -actin was used as the internal loading control; B-D: Semiquantitative analysis of the RT-PCR result. ^a $P < 0.05$ vs negative controls (NC) or mock.

Table 2 Effect of high-mobility group box 1 siRNA on the cell cycle

Cell cycle phases(%)	ShRNAH3 group	NC group
G0/G1 phase	58.31% \pm 0.48% ^a	44.25% \pm 0.63%
S phase	29.12% \pm 1.26% ^a	41.32% \pm 1.58%
G2/M phase	12.57% \pm 1.04%	14.53% \pm 1.28%

^a $P < 0.05$ vs negative controls (NC) group.

mRNA expression of some profibrogenic markers, including α -SMA and collagen types I and III, in transfected HSC-T6. As shown in Figure 5, HMGB1 siRNA reduced the mRNA levels of α -SMA and collagen types I and III.

HMGB1 siRNA reduced the collagen content in the HSC-T6 supernatant

To confirm the effect of HMGB1 siRNA on collagen secretion and degradation, we examined the amount of collagen types I and III in HSCs 48 and 72 h after transfection with shRNAH3 using an ELISA. The results reveal that the content of both collagen types I and III was decreased after transfection with HMGB1 siRNA. Compared with the NC group, the content of collagen types I and III was reduced to 63% and 61%, respectively, 72 h after shRNAH3 transfection (Figure 6).

HMGB1 siRNA inhibited HSC-T6 cells proliferation

The trypan blue dye test showed that there were no sig-

nificant differences in the number of cells in the three-groups 2 d after transfection ($P > 0.05$), but the proliferation in the shRNAH3 group was less than that in the NC group and non-transfection group (Mock group) 3, 4 and 5 d after transfection ($P < 0.05$, Figure 7). A cell cycle study also indicated that cells were arrested in the G0/G1 phase and that the proportion of cells in the S phase was significantly reduced after downregulation of HMGB1 in HSCs (Table 2).

DISCUSSION

Liver fibrosis is highly associated with chronic hepatocellular injury and the subsequent inflammatory response that produces inflammatory cytokines and recruits inflammatory leukocytes to the injured site. This inflammatory circumstance in the liver drives the activation of HSCs through various fibrogenic mediators^[12,13]. Activated HSCs transdifferentiate into myofibroblasts, which then produce excessive amounts of ECM proteins, including collagen types I, III and IV. This leads to irreversible collagen deposition, resulting in liver fibrosis^[12,13]. Many studies have suggested that enhancement of matrix degradation may prove particularly valuable in response to injury caused by matrix deposition^[14-17]. Some studies have shown that HMGB1 can stimulate proinflammatory cytokine synthesis and directly stimulate fibroblast proliferation and participate in fibrogenesis^[8-10].

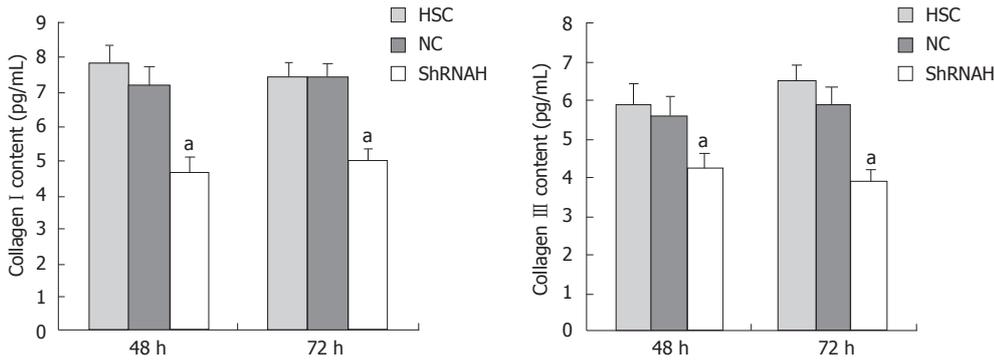

Figure 6 Determination of content of collagen types I and III after shRNAH3 transfection. Enzyme-linked immunosorbent assays were used for quantitative determination of collagen types I and III content hepatic stellate cells (HSCs) culture supernatant at 48 and 72 h after shRNAH3 transfection using Lipofectamine 2000. Values are presented as mean \pm SD. ^a $P < 0.05$ vs negative controls (NC) and HSC group.

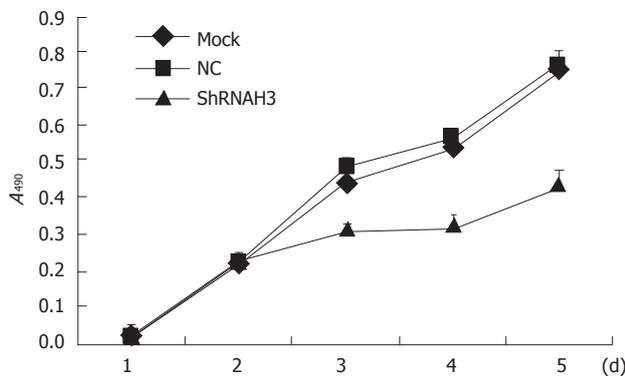

Figure 7 High-mobility group box 1 siRNA suppressed hepatic stellate cell-T6 proliferation. Cell growth curves of hepatic stellate cell-T6 transfected with shRNAH3 were analyzed by methyl thiazolyl tetrazolium conversion. Each sample was tested in triplicate and error bars were included. Compared with negative controls (NC) group and non-transfection group, proliferation of shRNAH3 group was less at the 3-5 d after transfection ($P < 0.05$).

Increased expression of HMGB1 has been reported in several liver diseases, including Con A-induced hepatitis^[18], hepatic ischemia^[2], and orthotopic liver transplantation (OLT)^[19]. In the present study, we evaluated HMGB1 expression in the DMN rat model. We found that the level of HMGB1 was upregulated during DMN injection. Moreover, the expression of HMGB1 was closely correlated with the expression of collagen types I and III and was mainly localized to the nonparenchymal cells, especially HSCs. These results suggest that HMGB1 is involved in hepatic fibrogenesis and may play a critical role in the reversal process of liver fibrosis.

HMGB1 was originally identified as a nuclear non-histone protein with DNA-binding domains and was implicated as an important endogenous danger signaling molecule. Although predominantly located in the nucleus of quiescent cells, HMGB1 can be actively secreted in response to exogenous and endogenous inflammatory stimuli such as endotoxin, TNF- α , IL-1, and interferon- γ ^[20,21]. In addition, extracellular HMGB1 mediates a wide range of inflammatory responses and promotes cell proliferation, migration, and differentiation^[10,22]. The cytoplasmic localization of HMGB1 in our

study may suggest that HMGB1 plays extra nuclear roles in liver fibrosis and that HSC-T6 cells may even secrete HMGB1 to promote extracellular functions. The subcellular location of HMGB1 in monocytic cells is known to be dependent on the acetylation status of the nuclear localization signal (NLS) of the HMGB1 protein^[23]. Inflammatory signals promote acetylation of the NLS, leading to cytoplasmic accumulation of HMGB1 in secretory lysosomes in the monocytic cells^[24]. These secretory lysosomes are subsequently exocytosed when the monocytic cells are triggered by a second inflammatory stimulus. Whether the subcellular location of HMGB1 in HSC-T6 cells is regulated in a similar way remains to be investigated.

It has become apparent in recent years that HMGB1 is instrumental in mediating a response to tissue damage and infection. HMGB1 released from necrotic or damaged cells not only triggers inflammation as a non-specific proinflammatory cytokine but also triggers the adaptive immune response^[25,26]. Extracellular HMGB1 functions as a damage-associated molecular pattern molecule and activates proinflammatory signaling pathways by activating pattern-recognition receptors including toll-like receptor 4 (TLR4) and the receptor for advanced glycation end-products (RAGE)^[27,28]. A previous report showed that RAGE expression in fibrotic livers is restricted to HSCs; its expression is up regulated during cellular activation and transition to myofibroblasts^[29], strongly suggesting that HMGB1 is involved in the pathogenesis of liver fibrosis. TLR4 has been suggested to be a receptor for extracellular HMGB1^[30,31], and previous studies have indicated that the interaction of HMGB1 with TLR4 plays a critical role in hepatic fibrosis^[32]. To date, little has been reported about the pathogenic interactions between HMGB1 and HSCs in terms of profibrogenic propensity. Kao provided evidence that HMGB1 up regulates α -SMA expression and suppresses the activity of the collagen-degrading enzyme matrix metalloproteinase-2^[33]. That study also implied that HMGB1, once it is released during rejection of OLT, activates HSCs and exhibits profibrogenic effects either by increasing the HSC population and ECM deposition

in liver grafts or by transforming HSCs into myofibroblasts. In contrast, neutralization with an anti-HMGB1 antibody may be a therapeutic modality to prevent fibrogenesis in post-OLT liver grafts^[33].

siRNA has become a powerful tool for functional genetic studies and gene therapy in mammals^[34,35]. Although gene knockdown by siRNA is highly effective, the off-target effect of siRNA may represent a major obstacle for therapeutic applications. However, the potential off-target effects could be minimized by choosing an siRNA with maximal sequence divergence from the list of genes with partial sequence identity to the intended mRNA target^[36]. Software was used to choose a maximal sequence identity of HMGB1 siRNA, and three siRNA sequences were designed. In preliminary experiments, we identified the fact that shRNA3 had certain interference effects. Our results show that this sequence was more efficient in reducing the HMGB1 transcript levels.

In the present study, we found that after HMGB1 was downregulated in HSCs by siRNA, there was an inhibitory effect on the mRNA levels of α -SMA and collagen types I and III, suggesting that inhibition of HMGB1 could directly result in suppression of HSC activation and collagen production. We also discovered that HMGB1 siRNA prohibited HSC proliferation, and a cell cycle analysis revealed that downregulation of HMGB1 arrested cells at the G0/G1 phase, which confirmed the effect of HMGB1 on cell proliferation; however, the definitive mechanism responsible is still uncertain because HMGB1 is multifunctional and has multiple molecular interactions.

In conclusion, HMGB1 was upregulated during liver fibrogenesis, and downregulating HMGB1 expression in HSCs by siRNA prohibited the activity of HSCs and collagen synthesis and enhanced collagen degradation. The results of our study indicate a significant functional role for HMGB1 in the development of liver fibrosis, and downregulating HMGB1 expression with siRNA could be an effective way to treat liver fibrosis.

COMMENTS

Background

Hepatic fibrosis is a response to injury in the liver. It is characterized by both a quantitative and qualitative change in the extracellular matrix (ECM). The activated hepatic stellate cell (HSC) is primarily responsible for excessive ECM deposition during liver fibrosis. It has been shown that high-mobility group box 1 (HMGB1) expression is up regulated during myofibroblast cellular activation and involved in the pathogenesis of hepatic fibrosis. This suggests that HMGB1 is a promising molecular target for hepatic fibrosis gene therapy. Inhibition of abnormal expression of HMGB1 may be an effective strategy for biological therapy of hepatic fibrosis.

Research frontiers

HMGB1 is a major component of mammalian chromatin endowed with an architectural function. Increasing evidence now points to multiple functions of HMGB1 in infection, tissue injury, inflammation, apoptosis and the immune response. It has been reported in several liver diseases, including hepatitis, hepatic ischemia, and orthotopic liver transplantation. HMGB1 has been implicated in the pathogenesis of several liver diseases, including Con-A-induced hepatitis, hepatic ischemia, and orthotopic liver transplantation. However, the role of HMGB1 and how to inhibit its expression in hepatic fibrosis has yet to be fully elucidated. In this study, the authors demonstrate that the overexpres-

sion of HMGB1 could be a potential mechanism for mediating collagen expression and downregulating HMGB1 expression might present as a potential strategy to treat liver fibrosis.

Innovations and breakthroughs

Studies of targeting *in vitro* and *in vivo* over expressed genes in hepatic fibrosis by RNA interference, including transforming growth factor- β , connective tissue growth factor and p90RSK, have been reported. However, there has been still no report about targeting HMGB1 by siRNA in hepatic fibrosis. In the present study, the authors used siRNA approach to block HMGB1 expression in HSC-T6 cells, to determine the role of constitutively activated HMGB1 during hepatic fibrosis pathogenesis, and to explore the role and molecular mechanism of targeting HMGB1 in hepatic fibrosis therapy.

Applications

By investigating the effect of silencing HMGB1 expression by siRNA on the collagen synthesis and proliferation of HSC-T6 cells, this study may provides a new strategy for biological therapy of liver fibrosis by targeting HMGB1.

Terminology

HMGB1 was originally identified as a nuclear nonhistone protein with DNA-binding domains and implicated as an important endogenous danger signaling molecule. But it can also be secreted from cells and exert extracellular functions as a proinflammatory cytokine. HSCs are a minor and quiescent cell type in the liver that usually reside in the space of Disse, but which undergo activation after hepatic injury to produce large quantities of fibrillar collagens.

Peer review

The authors demonstrated the increase of HMGB1 expression in fibrotic livers. Then, they investigated the effect of HMGB1 silencing by siRNA on stellate cell activation and proliferation. The results show that siRNA for HMGB1 significantly inhibits collagen expression and stellate cell proliferation.

Abstract

AIM: To evaluate whether combination therapy with anti-tumour necrosis factor α (TNF α) antibody and Zn acetate is beneficial in dextran sodium sulphate (DSS) colitis.

METHODS: Colitis was induced in CD1-Swiss mice with 5% DSS for 7 d. The experimental mice were then randomised into the following subgroups: standard diet + DSS treated (induced colitis group); standard diet + DSS + subcutaneous 25 μ g anti-TNF α treated group; Zn acetate treated group + DSS + subcutaneous 25 μ g anti-TNF α ; standard diet + DSS + subcutaneous 6.25 μ g

anti-TNF α treated group and Zn acetate treated group + DSS + subcutaneous 6.25 μ g anti-TNF α . Each group of mice was matched with a similar group of sham control animals. Macroscopic and histological features were scored blindly. Homogenates of the colonic mucosa were assessed for myeloperoxidase activity as a biochemical marker of inflammation and DNA adducts (8OH-dG) as a measure of oxidative damage.

RESULTS: DSS produced submucosal erosions, ulcers, inflammatory cell infiltration and cryptic abscesses which were reduced in both groups of mice receiving either anti-TNF α alone or combined with zinc. The effect was more pronounced in the latter group (*vs* Zn diet, $P < 0.02$). Myeloperoxidase activity (*vs* controls, $P < 0.02$) and DNA adducts, greatly elevated in the DSS fed colitis group (*vs* controls, $P < 0.05$), were significantly reduced in the treated groups, with a more remarkable effect in the group receiving combined therapy (*vs* standard diet, $P < 0.04$).

CONCLUSION: DSS induces colonic inflammation which is modulated by the administration of anti-TNF α . Combining anti-TNF α with Zn acetate offers marginal benefit in colitis severity.

INTRODUCTION

Ulcerative colitis and Crohn's disease are chronic diseases of the gastrointestinal tract characterized by activation of the immune system with production of several inflammatory cytokines^[1,2]. Altered T cell apoptosis^[3,4] and abnormal production of the pro-inflammatory cytokine tumour necrosis factor α (TNF α) play a central role in intestinal inflammation of inflammatory bowel disease patients^[5].

Novel treatment strategies based on the inhibition of TNF α have shown to be effective both in experimental models of colitis^[6] and in inducing and maintaining remission in humans affected with inflammatory bowel disease^[7]. However, as these therapies are very expensive they may represent an important and unaffordable economic burden in the near future.

Trace element metabolism is altered during inflammatory processes of the gastrointestinal tract. Zinc is essential for intestinal homeostasis, since there are several zinc-dependent antioxidant enzymes such as superoxide dismutase which converts superoxide to hydrogen peroxide and metallothionein which can neutralize free radical production. Moreover, zinc status affects gene expression of the inflammatory cytokines TNF, IL-1B and IL-8. Zinc deficiency causes functional defects in T cells, neutrophils and macrophages, and positive modulatory responses are produced following zinc supplementation^[8]. In the model of acetic acid-induced ulcerations, zinc reduced mucosal damage^[9]. In models of experimental colitis both oral and topical zinc treatment were found to decrease intestinal inflammation, to favour mucosal healing and to improve immune function^[10]. We therefore thought that zinc may be useful if added to conventional anti-TNF α therapy in modulating the symptoms of dextran sodium sulphate (DSS)-induced colitis in mice and in decreasing oxidative stress.

MATERIALS AND METHODS

Animals

Male CD1 Swiss mice, 4 wk old, weighing 20-25 g purchased from Charles River (Calco, Italy) were used in this study. The animals were kept in plastic platform cages in a temperature controlled room (22 °C) under a 12-h light-dark cycle, with free access to water and standard chow containing 125 mg/kg zinc oxide. The experimental protocol was approved by the Veterinary and Health Committee of the University of Padua.

Experimental protocol

Mice were fed 5% DSS (5% dextran sulphate solution purchased from ICN Pharmaceuticals, SRL, Italy) dissolved in drinking water in one single cycle to induce acute colitis. The cycle consisted of administering 5% DSS for 7 d which caused loose stools in all animals and the presence of gross rectal bleeding in about 50% of the animals.

The animals were randomised into the following six groups each with 6 mice: (1) **healthy untreated mice** receiving standard diet; (2) **induced colitis group**, i.e., mice receiving standard diet + 5% DSS for 7 d; (3) **mice** receiving standard diet + 675 mg/kg Zn acetate supplement starting 7 d before induction of colitis; (4) **mice** receiving standard diet + 25 μ g anti-TNF α intraperitoneally after 1 wk of DSS administration; (5) **mice** receiving standard diet + 675 mg/kg Zn acetate supplement + 25 μ g anti-TNF α intraperitoneally after 1 wk of DSS administration; and (6) **mice receiving standard diet + 675 mg/kg Zn acetate supplement + 6.25 μ g anti-TNF α intraperitoneally after 1 wk of DSS administration**. The three groups receiving anti-TNF α treatment were sacrificed 48 h after initiation of treatment. Anti-TNF α monoclonal antibody (rat anti-mouse TNF α) was purchased from Biosource International Inc. (United States) and Zn Acetate 675 mg/kg diet, from Mucedola SRL, (Milano, Italy).

Macroscopic and histologic features of colitis

Damage was assessed macroscopically by scoring the number and extent of ulcers, adhesions, and thickness of the colonic wall^[11] and histologically by scoring cryptitis, crypt abscesses and epithelial injury. Colonic tissue samples were obtained and processed for myeloperoxidase and 8-hydroxydeoxyguanosine (8-OHdG) in order to quantify inflammation and DNA damage.

Colonic samples were immediately fixed in buffered formalin (10%). After fixation, the specimens were routinely processed and embedded in paraffin. Serial histology sections of 4 μ m thickness were obtained from each paraffin block and mounted on poly-L-lysine coated slides. Sections were stained with haematoxylin-eosin and examined blindly.

Cryptitis was defined as the presence of polymorphonuclear cells within crypt epithelium, while crypt abscesses were defined as the presence of polymorphonuclear cells within the crypt lumens. Epithelial injury included changes such as crypt regeneration, mucodepletion, cuboidal shape, nuclear enlargement, loss of surface cells, erosion, and ulceration. Each of the features, defined above, was scored on a 0 to 3+ scale based on the severity and degree of involvement^[12,13].

Mean colonic activity scores for cryptitis, crypt abscesses and epithelial injury were marked for each slide on the following basis: 0 (no activity); 1-2 (mild activity); 3-4 (moderate activity); 5-6 (severe activity).

Assessment of myeloperoxidase activity

Assessment of myeloperoxidase (MPO) activity was as-

Table 1 Biochemical and morphological parameters of colitis severity among the study groups

	Macroscopic score	Colonic activity index	Myeloperoxidase activity (U/g)
Controls	0 (0-0)	0 (0-0)	1.9 (1.34-1.1)
Colitis	1 (1-1) ^b	4 (1-1) ^a	5.69 (0.04-0.21) ^b
Colitis + Zinc	2 (2-2) ^b	5 (0-0) ^a	7.8 (0-0.8) ^e
Colitis + anti-TNF α (25 μ g)	0.5 (0-1)	4 (1-3) ^a	4.85 (1.81-3) ^d
Colitis + Zinc + anti-TNF α (25 μ g)	0 (0-0) ^c	1 (2-0) ^{ad}	3.88 (2.9-2.87)
Colitis + anti-TNF α (6.25 μ g)	1 (0.25-1)	5 (0-2)	5.44 (0.63-0)
Colitis + Zinc + anti-TNF α (6.25 μ g)	0.5 (0-1)	3 (2-0)	4.42 (0.34-0.33)

^a $P < 0.01$ vs controls; ^b $P < 0.03$ vs controls; ^c $P < 0.03$ vs colitis; ^d $P < 0.02$ vs colitis+Zinc; ^e $P < 0.02$ vs controls. TNF: Tumour necrosis factor.

essed according to the method previously described^[14]. Briefly, colonic tissue samples were minced in 1 mL of 50 mmol/L potassium phosphate buffer (pH = 6.0) containing 14 mmol/L hexadecyltrimethylammonium bromide (Fluka), homogenized and sonicated. The lysates were frozen and thawed thrice, then centrifuged for 2 min in cold at 15000 *g*. Aliquots of the supernatants were mixed with potassium phosphate buffer containing *o*-dianisidine-HCl (Sigma-Aldrich, St. Louis, MO, United States) and 0.0005% H₂O₂. MPO activity was expressed as units/g of wet tissue. The enzyme unit was defined as the conversion of 1 mol of H₂O₂ per min at 25.

8-OHdG determination

Oxidative DNA damage was assessed following previously described methods^[15]. Briefly, colonic biopsy specimens were thawed, homogenized in a separation buffer and approximately 20 μ g of purified DNA per sample was injected into the HPLC system (Shimadzu, Kyoto, Japan). The 8-OHdG was detected using an electrochemical detector (ESA Coulochem II 5200A, Bedford, MA, United States). The levels of 8-OHdG were expressed as the number of 8-OHdG adducts per 10⁵ dG bases. The coefficient of variation was < 10%; 100 μ g of DNA were required for the determination.

Statistical analysis

Data are expressed as median (interquartile range). Statistical data were analyzed with Mann-Whitney *U* test for comparison of the groups and Spearman's rank correlation test. *P* values less than 0.05 were considered significant.

RESULTS

Macroscopic evaluation of colitis

The macroscopic score was increased significantly in untreated colitic mice. Groups treated with anti-TNF α or anti-TNF α and zinc acetate showed a decreased macroscopic score which was more evident in the combined diet. Chronic feeding of DSS significantly increased the colonic activity score. The administration of anti-TNF α alone or combined with zinc acetate significantly reduced this index. The effect appeared to be significantly more evident in the group receiving anti-TNF α and zinc acetate than in the group receiving anti-TNF α alone. The

administration of a reduced dose of anti-TNF α (6.25 μ g) was effective only if combined with zinc acetate (Table 1).

Myeloperoxidase activity

Myeloperoxidase activity was increased in all colitic mice. However, there was a significant reduction in this activity in the groups treated with anti-TNF α alone and anti-TNF α + Zn supplementation, with a slightly better effect in the group receiving the combination therapy. A lower dose of anti-TNF α was associated with reduced MPO activity only in the group receiving both zinc and anti-TNF α (Table 1).

Determination of oxidative damage as measured by 8-OHdG mucosal levels

Oxidative damage was significantly increased in colitic mice. Anti-TNF α significantly reduced DNA adducts, OH-dG levels were similar in the group receiving both anti-TNF α and zinc acetate (Figure 1). Anti-TNF α treatment significantly reduced DNA adducts at both doses used. In both groups receiving the combination therapy, DNA adducts were reduced compared to anti-TNF α therapy alone, but no significant effect was demonstrated with respect to the groups receiving anti-TNF α alone (Figure 1).

DISCUSSION

Chemically induced models of intestinal inflammation are widely used as surrogate models of chronic inflammatory bowel disease and oral DSS administration effectively resembles human inflammatory bowel disease with similar clinical features (bloody diarrhoea) and endoscopic/histological findings (**ulcerations and neutrophil infiltration**). DSS is believed to be directly toxic to gut epithelial cells of the basal crypts and affects the integrity of the mucosal barrier.

Zinc metabolism has been reported to be reduced in about 65% of patients with Crohn's disease. In an experimental model of colitis we also reported that zinc supplementation induced metallothionein expression, while having little effect on the short-term course of colitis^[16]. Zinc has several potential mechanisms of action which can benefit the inflammatory process. It regulated tight junction permeability in an experimental model of colitis^[17] and in Crohn disease^[18]. Sturniolo *et al*^[19] reported

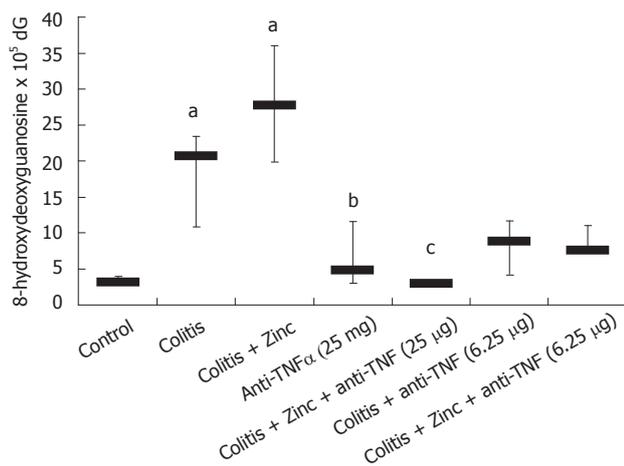

Figure 1 8-hydroxydeoxyguanosine. ^a $P < 0.05$ vs controls; ^b $P < 0.02$ vs colitis; ^c $P < 0.04$ vs colitis. TNF: Tumour necrosis factor.

that zinc sulphate enemas exert an anti-inflammatory action on experimental colitis.

In the last few years, biological therapies have changed the pharmacological armamentarium of inflammatory bowel disease therapy: the first and still most widely used drug is the anti-TNF α monoclonal antibody, infliximab^[20]. Even in experimental models of colitis, the subcutaneous administration of infliximab reduced the inflammatory activity as well as tissue TNF α concentration^[21]. Our experimental approach which added zinc acetate to the diet while administering anti-TNF α monoclonal antibody, aimed to examine the effects on DSS-induced colitis in mice.

The mucosa did not show complete healing probably because the treatment effects were evaluated 48 h after treatment. Nevertheless, therapy with anti-TNF α ameliorated the macroscopic and histological aspects and decreased myeloperoxidase concentration. Similar results were reported by Videla *et al.*^[22] who found that anti-TNF α significantly reduced the release of inflammatory mediators and induced histopathological remission in a model of experimental colitis. Zinc alone had little effect in ameliorating the severity of acute colitis induced by intra-rectal instillation of dinitrobenzene-sulphonic acid in rats, even though Tran *et al.*^[23] and Luk *et al.*^[24] recently reported some therapeutic effects of zinc supplementation in DSS-induced colitis in mice.

Zinc supplementation alone worsened the histopathological and biochemical aspects of colitis compared to colitis alone and this can be explained by the fact that superoxide dismutase by itself is a pro-oxidant enzyme by virtue of its ability to generate hydrogen peroxide^[25,26]. This may explain why a worsening of colitis was recorded when zinc was added alone. However, in our study zinc allowed us to reduce the dose of anti-TNF α maintaining the same biochemical and morphological effects.

Acute colitis is characterised by an increased production of free radicals which contribute to protein, DNA chain and lipid damage. As the antioxidant potential of colonic epithelial cells is quite low, this results in tissue

injury^[27]. The administration of antioxidants thus has the potential to improve the outcome of experimental colitis by scavenging free radicals. In our experimental conditions, the oxidative damage, expressed by DNA adducts was significantly reduced in the groups treated with anti-TNF α confirming the findings of Popivanova *et al.*^[28]. In our study, the effect of anti-TNF α on oxidative stress appeared to be dose-dependent with the highest dose having the strongest effect in reducing oxidative damage, and the combination of anti-TNF α and zinc supplementation added little effect.

Obermeier *et al.*^[29] reported that excess nitric oxide formation occurs in experimental colitis and can be decreased by treatment with rat anti-mouse TNF and interferon gamma monoclonal antibodies. In several studies, zinc supplementation ameliorated antioxidant concentrations thus reducing the production of oxidative species^[27-30]. In the present study, zinc supplementation allowed a reduction in the dose of anti-TNF α antibody, while maintaining the same level of reduced intestinal inflammation observed with a higher dose of anti-TNF α antibody alone, as quantified by the four parameters of tissue inflammation utilized in the study. This effect is in accordance with the described capability of zinc to increase antioxidant concentration and reduce oxidative species.

In conclusion, the combined administration of zinc acetate in the diet along with the systemic administration of anti-TNF α had a positive effect in reducing the severity of DSS-induced colitis in mice, with reduced production of DNA adducts. Moreover, the same effect was demonstrated with the reduced anti-TNF α dose combined with zinc. This experimental approach offers the advantage of reducing the potential side effects of anti-TNF α and costs, while ameliorating oxidative stress and inflammation in patients with inflammatory bowel disease.

COMMENTS

Background

Dextran sodium sulphate (DSS) colitis is a well-known model of inflammatory bowel disease in which the authors tested the effect of the well-known drug anti-tumour necrosis factor α (TNF α) combined with zinc with the aim of evaluating the possibility of lowering the dose of anti-TNF α .

Research frontiers

In this article the authors explore the possibility of a combination therapy in inflammatory bowel disease (IBD) in order to reduce potential side effects and costs.

Innovations and breakthroughs

In this article, zinc was added to a biological therapy in order to evaluate the effects of this combination therapy. **There are no articles in the literature exploring this combination therapy.**

Applications

The potential applications include the possibility of adding zinc to anti-TNF α therapy. Moreover, future perspectives include the application of other combination therapies in inflammatory bowel disease.

Peer review

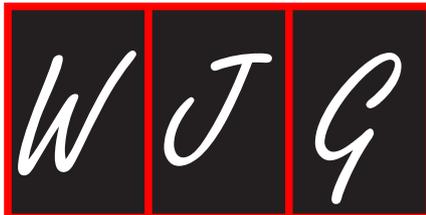

This study considers the investigation of the role of combined administration of Zinc acetate in the diet with systemic administration of anti TNF alpha on the effect of the severity of experimental colitis in mice induced by DSS. The study is set up correctly. The paper is written sufficiently good, the Introduction give a good overview about the study background and the authors raised clearly the hypoth-

esis of the study. The description of methods used is accurate. The results are presented clearly and have been discussed well, the table and figure give good overview about the results.

Abstract

AIM: To analyse the possible association of various *Helicobacter* species and certain common gut bacteria in patients with Meckel's diverticulum and appendicitis.

METHODS: A nested-polymerase chain reaction (PCR), specific to 16S rRNA of the *Helicobacter* genus, was performed on paraffin embedded samples, 50 with acute appendicitis, 50 normal appendixes, and 33 Meckel's diverticulum with gastric heterotopia and/or ulcer. *Helicobacter* genus positive samples were sequenced for species identification. All samples were also analysed for certain gut bacteria by PCR.

RESULTS: *Helicobacter pullorum* DNA was found in one out of 33 cases and *Enterobacteria* in two cases of Meckel's diverticulum. *Helicobacter pylori* (*H. pylori*) was found in three, *Enterobacter* in 18, and *Bacteroides*

in 19 out of 100 appendix samples by PCR. *Enterococcus* was not found in any MD or appendix samples. All *H. pylori* positive cases were from normal appendixes.

CONCLUSION: *Helicobacter* is not an etiological agent in the pathogenesis of symptomatic Meckel's diverticulum or in acute appendicitis.

Key words: Meckel's diverticulum; *Helicobacter*; Appendix; Polymerase chain reaction

INTRODUCTION

Although the stomach is the most frequent site of *Helicobacter pylori* (*H. pylori*) infection, *H. pylori* and enterohepatic *Helicobacter spp.* (*EHS*) have also been associated with extragastric diseases^[1].

Meckel's diverticulum (MD) is the most common developmental anomaly of the gastrointestinal tract and is present in 1%-2% of the general population. It often contains ectopic tissue, notably gastric and pancreatic tissue^[2]. Gastric mucosa is found in 10%-25% of MD and may be associated with inflammation, ulceration, gastrointestinal bleeding, and perforation^[3-5]. *H. pylori*

has been demonstrated in the ectopic gastric epithelium within MD^[6]. *Campylobacter-like* organisms in MD were first reported in 1989^[7-9]. However, conflicting results were reported concerning colonisation by *H. pylori* of such ectopic mucosa^[10,11]. There has been no study that investigated EHS in MD.

Acute appendicitis is the most common abdominal surgical emergency and can be seen in all ages, especially in those younger than 30 years^[12]. However, the aetiology of acute appendicitis is uncertain, and diagnosis is often difficult. There have been some investigations of *H. pylori* in appendix tissue^[13-15], but none that investigated non-*pylori Helicobacters*.

We hypothesized that non-*pylori Helicobacters*, such as enterohepatic *Helicobacters*, might be associated with these diseases. Most studies have investigated only *H. pylori* in MD and the appendix and mostly used non-molecular biological techniques; therefore, we aimed to analyse gastric, EHS and certain common gut bacteria in appendicitis and MD patients by genus specific polymerase chain reaction (PCR) and sequencing.

MATERIALS AND METHODS

Patients and histology

We re-examined all MD patients from 1990-2009 taken from the files of the Department of Pathology, Lund University Hospital. Thirty-three MD patients (two cases of ulcer without heterotopia, 31 cases with gastric heterotopia, of which seven also had an ulcer) (mean age: 11 years; range: 4 wk-73 years; 26 male, 7 female) were included in our study. Abdominal pain was the reason for operation in 16 cases, two of whom had acute appendicitis and one enlarged lymph nodes, nine were operated upon because of gastrointestinal bleeding and six for other abdominal diseases. No indication was given in two of the cases. Histological sections from stored paraffin blocks were stained with Alcian blue-periodic acid Schiff (AB-PAS) pH 2.5, Whartin-Starry silver stain and immunostained with an anti-*H. pylori* antibody (DAKO, Glostrup, Denmark, diluted 1:300).

We also re-examined mucosa from 50 cases of acute appendicitis (26 male, 24 female, median age: 30 years; range: 9-87 years) and 50 cases of normal appendix (16 male, 34 female, median age: 34 years; range: 10 d-80 years) from 2008-2009. Of the latter patients 26 were operated for a suspected appendicitis (8 male, 18 female, median age: 21 years; range: 8-77 years), 12 for intestinal diseases (8 male, 4 female, median age: 59 years; range: 10 d-80 years), and 12 for female genital disorders (median age: 38 years; range: 11-75 years). Histological sections from the *Helicobacter* positive cases were stained as mentioned above.

From the cases of MD, heterotopic mucosa of the gastric as well as the antral type were obtained from the paraffin blocks for PCR-assay with the tip of a scalpel. Ulcers were examined separately. In the case positive for *Helicobacter* DNA, the intestinal type mucosa surrounding

the heterotopia was also studied. Corresponding areas from appendix samples of mucosa, or of necrotic appendicitis were sampled for PCR. It was not possible to avoid including material from the appendical lumen in these samples. In the cases positive for *Helicobacter* DNA, other tissues removed at the same operation were also examined by PCR.

DNA extraction

DNA was extracted from the paraffin-embedded tissue samples by de-embedding, as previously described^[1]. DNA was extracted by a QIAamp DNA Mini Kit Tissue protocol (Qiagen, Hilden, Germany) according to the manufacturer's instructions.

Helicobacter specific PCR

DNA extracts were amplified in a GeneAmp 2700 Thermocycler (Applied Biosystems, Foster City, CA, United States) using a semi-nested PCR assay specific for *Helicobacter spp.* 16S rDNA, as previously described^[1]. *H. pylori* (CCUG 17874) was used as a positive control in all PCR reactions. The 416-bp PCR products were visualized by 1.3% agarose gel electrophoresis.

Amplification of non-Helicobacter bacteria

PCR specific for *Enterobacteriaceae*, the *Bacterioides-Prevotella* group, and *Enterococcus* were performed. The reaction mixture and amplification conditions, except for annealing temperatures, for non-*Helicobacter* PCR assays were the same as in the first step of the semi-nested *Helicobacter* PCR. The annealing temperatures and primers used for detection of *Enterobacteriaceae*, *Bacterioides-Prevotella* group, and *Enterococcus* were as described by Karagin *et al.*^[1] 2010. As positive controls, *Escherichia coli* (CCUG 17620), *Bacterioides fragilis* (CCUG 4856), and *Enterococcus faecalis* (CCUG 9997) were used in all PCR reactions. The 112-bp PCR product of *Enterococcus*, the 418-bp product of *Bacterioides*, and the 195-bp product of *Enterobacteriaceae* were visualized by 1.3% agarose gel electrophoresis.

DNA sequence analysis

Helicobacter specific PCR products were purified from agarose gels using the Montage DNA Gel Extraction Kit (Millipore, Bedford, MA, United States), according to the manufacturer's instructions. DNA sequence reactions were performed using the ABI PRISMTM dRhodamine Terminator Cycle Sequencing Ready Reaction Kit version 3.0 (Applied Biosystems) as described by Tolia *et al.*^[16]. Products of the sequencing reaction were aligned and the closest homologous DNA was identified by BLASTn-analysis.

The study was approved by the Research Ethics Committee at Lund University, permit number 588/2006.

RESULTS

Histology

The most dominant heterotopia seen in MD was of the

corpus type with, in most cases, small areas of antral heterotopia. It was therefore easy to include both types of heterotopia, if present, in the same sample. No *Helicobacter* was found by histological and immunohistological examinations, neither in heterotopia nor in ulcers. In 3/33 of the MD cases, a mild chronic inflammation in the heterotopic area with slightly increased amounts of lymphocytes was seen. The ulcer was infiltrated with polymorphonuclear cells but there was no general, active gastritis. The normal intestinal mucosa in the MD outside the heterotopia did not have an increased amount of lymphatic tissue, in except the *Helicobacter pullorum* (*H. pullorum*) positive case. The nine ulcers and their surrounding mucosa were negative for *Helicobacter* DNA.

One of the heterotopic mucosa specimens was positive for *Helicobacter* DNA, namely that from a 44-year-old male. He was operated on for acute appendicitis. The appendix was not sent for histological analysis. The MD was also removed. Histology displayed a few gastric glands of the corpus type and a small strip of surface epithelium of the gastric type. There were a moderate number of lymphocytes and plasma cells in the heterotopic area. The surrounding mucosa of the intestinal type displayed an unusually well developed lymphatic tissue with germinal centres, a predominance of lymphocytes, and very few polymorphonuclear cells (Figure 1). There was no *Helicobacter* DNA detected by PCR in this sample.

Three normal appendixes were positive for *Helicobacter* DNA: from one an 18-year-old female with suspicion of appendicitis, one from a 63-year-old male with colon adenoma, one from a 55-year-old male with colon diverticulitis. Adenoma, diverticulitis, and normal colon tissue removed from the two latter patients were negative for *Helicobacter*. No tissue other than the appendix was removed from the first patient. All cases revealed *H. pylori* on sequence analysis. There was no gastric metaplasia in any of the appendixes, and no immunopositive *H. pylori* structures in the mucosa of the samples that were PCR-positive for *Helicobacter*.

Helicobacter specific PCR assay and sequencing results

Using the *Helicobacter* specific PCR assay and agarose gel electrophoresis, *Helicobacter spp.* was detected in 1/33 (3%) of specimens from patients with MD by genus specific nested-PCR. The sequenced PCR amplicon showed 98% similarity to *H. pullorum*. There were 3/50 (6%) samples that were positive for *Helicobacter spp.*, among normal appendixes. All of them showed 98%-99% sequence similarity to *H. pylori*. However *Helicobacter spp.* was not found in any samples of acute appendicitis.

PCR detection of bacterial DNA other than Helicobacter

Using the *Enterobacteria* specific PCR assay and agarose gel electrophoresis, *Enterobacteria spp.* was detected in 10/50 (20%) acute appendicitis cases and 8/50 (16%) normal appendixes. There were 7/50 (14%) and 12/50 (24%) samples that were positive for *Bacteroides spp.*,

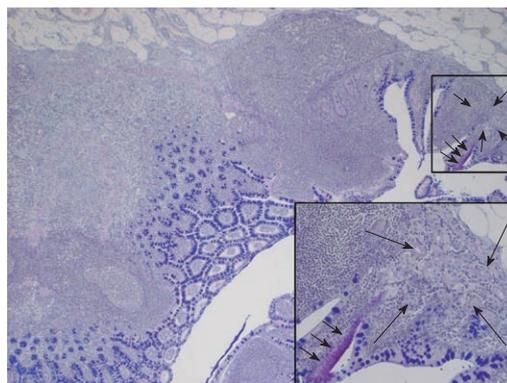

Figure 1 Microscopic analysis of the *Helicobacter pullorum* positive Meckel's diverticulum case. Low power view of a histological section from Meckel's diverticulum, positive for *Helicobacter pullorum* (*H. pullorum*) DNA, in the heterotopic area. There is an unusually well developed lymphatic tissue with germinal centres and a predominance of lymphocytes in the non-heterotopic area. Plasma cells were mainly found in the heterotopic area. The small arrows in the big square, point to a small strip of gastric heterotopia. This area displays at higher magnification in the inset. Large arrows point to gastric glands of corpus type. Blue without arrows in the photo indicates intestinal mucus. Alcian blue-PAS staining pH 2.5.

among the acute appendicitis and normal appendix sample, respectively. However, all MD and appendix samples were negative for *Enterococcus spp.* MD samples were also negative for *Bacteroides*; however, 2/33 (6%) were positive for *Enterobacteria spp.*

DISCUSSION

In this study, we screened for the presence of DNA of *Helicobacter spp.* and certain common intestinal bacteria by PCR in MD with gastric heterotopia and in appendix samples. We detected *H. pullorum* DNA in one out of 33 MD cases (3%) and *Enterobacteria* in two (6%). No *Enterococcus* or *Bacteroides* were found in the MD cases.

The *H. pullorum* case was positive only in the heterotopic area, not in the surrounding diverticulum mucosa of the intestinal type. No luminal contents were seen in these samples. This argues for the interpretation that the *H. pullorum* DNA originated from the heterotopic mucosa and not from the lumen. This assumption is further strengthened by the very low prevalence of other bacterial DNA in the MD samples. *H. pullorum* has, however, been described in stools from cases with gastroenteritis^[17], but our patient did not have such symptoms.

No *Helicobacter* was seen by immunohistochemistry. However, PCR is a more sensitive method and does not require intact bacteria. Our PCR technique is considered to be highly reliable for genus identification of *Helicobacter spp.*^[18,19]. Some authors have found *H. pylori* by immunohistochemistry in MD with active gastritis, implying the presence of polymorphonuclear cells; the prevalence varied between 2 and 28%^[6-8,20-23]. We had no cases with such inflammation and found no *H. pylori* DNA.

Interestingly, there was an increased amount of lymphatic tissue in the intestinal type mucosa of the *H.*

pullorum positive case. However, no conclusions can be drawn from just one case.

EHS are known to cause inflammatory bowel diseases^[24,25]. We have previously found *H. pullorum* DNA in cholecystitis samples with gastric metaplasia^[1]. Perhaps *H. pullorum* has some preference for the gastric epithelium.

We found *H. pylori* DNA in three out of 50 normal appendixes (6%) and none in the 50 cases of acute appendicitis. Other bacterial DNA was found in up to 24% of samples. We could not avoid including some luminal material in the appendix samples and therefore *H. pylori* DNA in the appendixes might be a contamination. Pavlidis et al^[14] found *H. pylori* by PCR in two out of 46 samples (4%) of acute appendicitis. However, most authors have failed to demonstrate the presence of *H. pylori* in the appendix^[13,15,26]. *H. pylori* commonly colonises the gastrointestinal tract. However, our results suggest that *Helicobacter* is without importance in the etiology of acute appendicitis.

In conclusion, *H. pullorum* has, for the first time, been detected by PCR in MD patients with gastric heterotopias. However, there is no association between *H. pullorum* and MD pathogenesis. Moreover, *H. pylori* has no role in the aetiology of acute appendicitis. Its presence might have been that of a passenger.

ACKNOWLEDGMENTS

Hans-Olof Nilsson's expert knowledge on PCR and specimen handling and PCR inhibitor removal and Ingrid Nilsson's valuable expertise on *Helicobacters* are highly appreciated. We also thank Roland Andersson, MD PhD, Department of Surgery, for contributing the case story of the *H. pullorum* positive patient.

COMMENTS

Research frontiers

Helicobacter-like bacteria in Meckel's diverticulum (MD) have been reported by histological methods. However, no study has reported *Helicobacter* DNA in such specimens by polymerase chain reaction (PCR) and there is some doubt as to the presence of *Helicobacter* in patients with appendicitis.

Innovations and breakthroughs

Most studies have analyzed only *Helicobacter pylori* (*H. pylori*) in Meckel's diverticulum and appendix samples. However, enterohepatic *Helicobacter* species might also be important in the etiology of such diseases. The authors demonstrated the presence of *Helicobacter pullorum* in Meckel's diverticulum for the first time and concluded that *Helicobacter* might be a passenger in such patients.

Applications

By understanding the role of *Helicobacters* in the pathology of Meckel's diverticulum and appendicitis, this study could represent a future strategy for further pathological studies.

Terminology

Enterohepatic *Helicobacter* spp. (EHS) are the species of the genus *Helicobacter* that colonize the hepatobiliary tract and can cause extragastric diseases in humans or in animals.

Peer review

This work has been had the objective of seeking any association between *Helicobacter* species other than *H. pylori* with Meckel's diverticulum by very sensitive method, i.e., Nested PCR. Most previous studies were based on conventional methods, such as culture isolation, whereas in this study, the authors have used

molecular techniques. Although they did not find any association between MD and *Helicobacter* species, it does not undermine the importance of the study.

Epinephrine plus argon plasma or heater probe coagulation in ulcer bleeding. *World J Gastroenterol* 2011; 17(36): 4109-4112 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i36/4109.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i36.4109>

Abstract

AIM: To compare the effectiveness of argon plasma coagulation (APC) and heater probe coagulation (HPC) in non-variceal upper gastrointestinal bleeding.

METHODS: Eighty-five (18 female, 67 male) patients admitted for acute gastrointestinal bleeding due to gastric or duodenal ulcer were included in the study. Upper endoscopy was performed and HPC or APC were chosen randomly to stop the bleeding. Initial hemostasis and rebleeding rates were primary and secondary end-points of the study.

RESULTS: Initial hemostasis was achieved in 97.7% (42/43) and 81% (36/42) of the APC and HPC groups, respectively ($P < 0.05$). Rebleeding rates were 2.4% (1/42) and 8.3% (3/36) in the APC and HPC groups, respectively, at 4 wk ($P > 0.05$).

CONCLUSION: APC is an effective hemostatic method in bleeding peptic ulcers. Larger multicenter trials are necessary to confirm these results.

INTRODUCTION

Upper gastrointestinal bleeding (UGIB) is a common and life-threatening medical emergency. UGIB is defined as bleeding proximal to the ligament of Treitz. At least 80% of patients admitted to hospital because of acute bleeding have an excellent prognosis; generally, bleeding stops spontaneously and circulatory supportive therapy is adequate. Endoscopic therapy has been shown to reduce the rate of rebleeding, blood transfusion and surgery^[1]. Endoscopic therapy is indicated in the following situations: (1) bleeding esophageal varices; (2) peptic ulcer with major stigmata of recent hemorrhage (active spurting bleeding, non-bleeding visible vessel or non-adherent blood clot); (3) vascular malformations including actively bleeding arteriovenous malformation, gastric antral vascular ectasia, and Dieulafoy malformation; and (4) active bleeding from a Mallory-Weiss tear.

Endoscopic hemostasis has significantly improved the outcome of patients with gastrointestinal bleeding.

Contact thermal coagulation with heater probe and argon plasma coagulation (APC) are among the hemostatic methods for bleeding peptic ulcers. Devices are applied directly to the bleeding point to cause coagulation and thrombosis in heater probe coagulation (HPC). The heater probe is pushed firmly on to the bleeding lesion to apply tamponade and deliver defined pulses of heat energy. APC is a non-contact method of delivering high-frequency monopolar current through ionized and electrically conductive argon gas^[2].

The aim of this study was to compare these two methods for UGIB due to gastric and duodenal ulcers. The primary outcome measure was initial hemostasis and secondary outcome measure was recurrence of bleeding. This study was approved by Erciyes University Ethical Committee.

MATERIALS AND METHODS

All patients admitted for acute gastrointestinal bleeding due to gastric and duodenal ulcers were included in the study. Gastrointestinal bleeding was diagnosed only if medical staff witnessed hematemesis or melena, or detected black, tarry material on digital examination of the rectum. Patients with actively bleeding peptic ulcers, ulcers with adherent clots, or ulcers with non-bleeding visible vessels were randomly assigned to epinephrine injection plus HPC or epinephrine injection plus APC. Informed consent was obtained before the procedure and this was solely for the procedure itself. Patients with previous malignant ulcers, and unidentifiable ulcers because of torrential bleeding were excluded.

Randomization of patients was carried out by means of sealed numbered envelopes. Informed consent was obtained for therapeutic endoscopic intervention. Patients were blind to the study. All patients underwent endoscopy within 24 h of admission. All procedures were performed by experienced gastroenterologists (experienced endoscopist as a specialist in gastroenterology with a minimum of 3 years of post-training experience) with a Fujinon-2200 endoscope. An Olympus HPU-20 heater probe system with 10 F probes was used with power settings of 30-40 J. The heater probe was pushed firmly on to the bleeding lesion to apply compression and to cause coagulation and thrombosis. We used an Erbe 200 D APC unit, which consists of an argon gas source, a high-frequency electrosurgical unit, an APC probe, and foot switches to activate the argon gas source and current generator. Operative distance between the probe and tissue was adjusted to 2-10 mm by sense of proportion (Technically, APC cannot be activated unless the tip of the probe is at least 2-10 mm distant from the ulcer region. An automated switch-off system has been integrated into the system to avoid damage to the endoscope when this distance increases). Power/gas flow settings were 50 W and 2 L/min. All endoscopists used the same settings on the instrument. Epinephrine injection (5-6 mL, 1/10 000 dilution) was applied around the ulcer

Table 1 Demographic data and randomization of the groups

	APC	HPC	Total	P value
Male	33	34	67	0.418
Female	10	8	18	0.418
Duodenal ulcer	23	25	48	0.366
Gastric ulcer	20	17	37	0.366
Age (yr)	57	52	54	0.19
Forrest				
1a	4	9	13	
1b	39	33	72	0.291

Randomization of the groups was homogeneous (All *P* values > 0.05). APC: Argon plasma coagulation; HPC: Heater probe coagulation.

in all patients, before both of these two methods.

Initial hemostasis was defined as cessation of active bleeding. All the patients were treated with the same protocol after the endoscopic procedure. A policy of early feeding was adopted, and intravenous omeprazole was prescribed at a dose of 40 mg/d. Primary failure was defined as failure to stop bleeding during initial endoscopy. Recurrent bleeding was defined by one of the following: 2 g/dL drop in hemoglobin value compared to that when the patient was discharged from hospital; fresh hematemesis; hypotension (systolic blood pressure < 90 mm Hg) with tachycardia (pulse > 110 beats/min); or melena after endoscopic treatment. Patients who did not have initial hemostasis were excluded during evaluation of rebleeding rates. Patients were followed for the next 4 wk after initial hemostasis to monitor rebleeding. Distribution of bleeding focus and severity of bleeding (by using Forrest Classification) was found to be similar by χ^2 analysis (Table 1).

Analysis of data was performed using SPSS version 16.0 (SPSS, Chicago, IL, United States). *P* < 0.05 was regarded as significant. We calculated the power of the study with PASS 2008 software, with $\alpha = 0.05$, $n = 85$, degrees of freedom = 1, and power of study = 99.9%.

RESULTS

Eighty-five (18 female, 67 male) patients were included in the study between February 2008 and November 2009 in the Gastroenterology Department, Erciyes University School of Medicine. Forty-two patients received HPC and 43 received APC. Forty-eight bleeding duodenal ulcers (25 received HPC therapy and 23 APC) and 37 bleeding gastric ulcers (17 received HPC therapy and 20 APC) were included. A consort flow diagram was designed and is presented in Figure 1.

Initial hemostasis was achieved in 97.7% (42/43) and 81% (36/42) of the APC and HPC groups, respectively (*P* < 0.05). There were significant differences in initial hemostasis rates (*P* = 0.015). One patient died, two had surgery, and three had hemoclips applied in the HPC group; one patient had hemoclips applied in the APC group, who did not have initial hemostasis. Rebleeding rates were 2.4% (1/42) and 8.3% (3/36) in the APC and

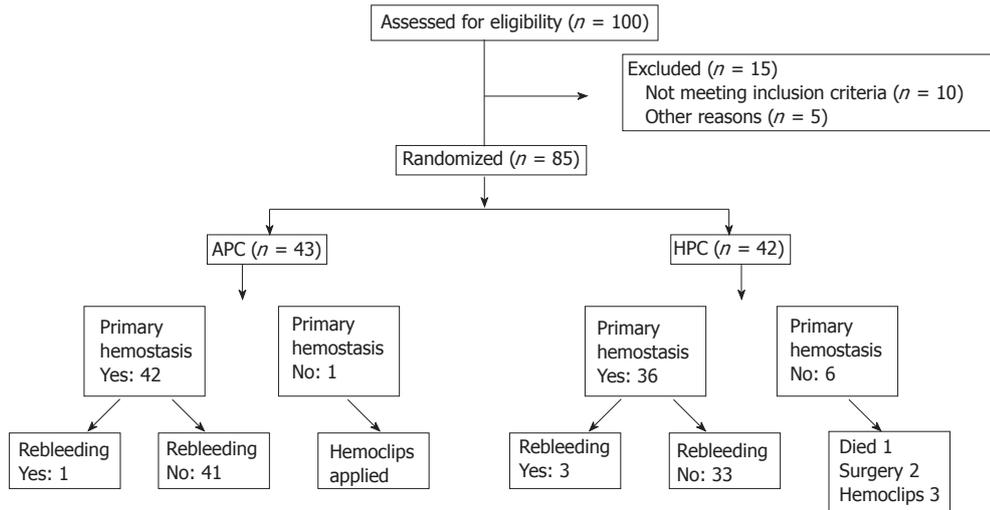

Figure 1 Consort flow diagram of the study. APC: Argon plasma coagulation; HPC: Heater probe coagulation.

Table 2 Initial hemostasis and rebleeding rates of the groups

	No. of cases (gastric/duodenal ulcer)	Initial hemostasis (%)	Rebleeding (%)
APC	43 (20-23)	42/43 (97.7)	1/42 (2.4)
HPC	42 (17-25)	36/42 (81)	3/36 (8.3)
Total	85 (37-48)	78 (91.7)	4/78 (5.1)

There was a significant difference ($P < 0.05$) in initial hemostasis but not in rebleeding rates between the groups. APC: Argon plasma coagulation; HPC: Heater probe coagulation.

HPC groups, respectively at 4 wk after index bleeding ($P = 0.25$). Although rebleeding rate was greater in the HPC group, there was no significant difference between the groups (Table 2).

DISCUSSION

Acute UGIB is a common medical emergency that carries hospital mortality in excess of 10%^[3]. Bleeding stops spontaneously in about 80% of patients with non-variceal UGIB. Various modalities of endoscopic therapy have been used to reduce recurrent bleeding, surgery, and mortality rates, and therefore, endoscopic intervention is a preferable procedure in acute gastrointestinal (GI) bleeding. In the past few decades, several endoscopic methods have been developed for hemostasis of gastrointestinal bleeding. Some of these are HPC, direct injection of fluids (e.g., diluted epinephrine or distilled water) into the bleeding lesion using disposable needles, mechanical devices such as endoclips, and APC. There have been several studies about the efficiency of these methods in gastrointestinal bleeding. Although APC is used especially for chronic radiation proctitis^[4], watermelon stomach and ablation of Barrett's esophagus, there are no current clinical studies about the application of APC in bleeding ulcers and for other causes of UGIB. APC therapy has various theoretical merits over contact-type thermal coagulation. First, depending on different power/flow

settings, the burn depth can be preset between 0.5 mm and 3 mm, which is a particularly appropriate range for hemostasis in thin-walled duodenum and colon. Second, some bleeding points, such as those in the posterior wall or lesser curvature of the upper gastric body or the posterior wall of the duodenal bulb, may be difficult to approach. The no-touch technique in APC can make the approach easier by the arcing effect^[2,5]. Wang *et al*^[6] have compared APC and distilled water injection in treating high-risk bleeding ulcers, and they have reported that bleeding recurrence was 11% in the APC group and 27% in the distilled water injection group. They have concluded that endoscopic therapy is more effective than distilled water injection for preventing rebleeding in these patients, and no significant differences were observed between the two groups in terms of surgery and mortality. There have been a few studies in which APC and HPC were compared for treatment of peptic ulcer bleeding^[7]. Although HPC is the more commonly used method in active bleeding lesions^[8], APC is not used as much as HPC for stopping gastrointestinal bleeding. In our study, APC appeared to be more effective in initial hemostasis, but rebleeding rates were similar with both techniques. Bleeding recurrence has consistently been identified as the most important prognostic factor for mortality^[9]. Arresting recurrence of bleeding can decrease the rate of morbidity and mortality from UGIB. Cipolletta *et al*^[7] have reported that initial hemostasis rates were 95% and 95.2%, and recurrent bleeding rates were 21% and 15% in HPC and APC group, respectively, and there was no significant difference between the groups in the rate of recurrent bleeding^[2]. Although rebleeding rates were much lower in the APC group, we found no significant difference in the rebleeding rates between the groups. Skok *et al*^[10] have reported that clinically and endoscopically diagnosed bleeding recurred in 14% of patients in the APC group, and 18% of patients in the sclerotherapy group. Although these controlled trials had similar hemostatic efficacy, the patients treated

with APC had noticeably lower rebleeding rates.

The theoretical advantages of APC include its ease of application, speedy treatment of multiple lesions in the case of arteriovenous malformations or wide areas (the base of resected polyps or tumor bleeding), and safety due to reduced depth of penetration^[11]. Superficial ulceration occurs following APC, which typically heals within 2-3 wk. Despite theoretical safety advantages due to reduced depth of penetration, all of the complications that have been reported with other thermal hemostasis techniques may occur. The first series of clinical applications of APC in gastrointestinal endoscopy was published in 1994^[12]. Although no specific data were provided to assess the outcome for GI bleeding, the authors have described the technique as successful^[12]. Several centers have subsequently reported experience with this technique in the management of GI bleeding^[12,12]. However, few randomized studies comparing with APC with other hemostasis techniques have been performed, and our study is believed to be the first comparison of these two techniques in UGIB in recent years. APC application had better rates of initial hemostasis than HPC in our study.

The heater probe has a thermocouple at the tip of the probe that can heat up quickly and achieve tissue coagulation. As a result, deep coagulation is feasible with the heater probe, but this effect may risk perforation. As mentioned above, few studies have directly compared APC to other methods, especially HPC, for achieving hemostasis. In conclusion, APC is one of the effective hemostatic methods in bleeding peptic ulcers. Larger multicenter trials are necessary to confirm these data.

COMMENTS

Background

Contact thermal coagulation with heater probe coagulation (HPC) and argon plasma coagulation (APC) are the hemostatic methods used for the treatment of bleeding peptic ulcers. Few studies have directly compared the use of epinephrine injection plus APC versus epinephrine injection plus HPC for achieving hemostasis.

Research frontiers

Upper gastrointestinal bleeding (UGIB) is a common and life-threatening medical emergency. Contact thermal coagulation with HPC and APC are among the hemostatic methods for treatment of bleeding peptic ulcers. In this study, the authors demonstrate that there is a higher initial hemostasis rate in APC when compared with HPC in ulcer bleeding.

Innovations and breakthroughs

Few randomized studies have compared APC with other hemostasis techniques, and the study is believed to be the first comparison of these two techniques with additional use of epinephrine injections for UGIB in recent years. This study suggests that APC could be used instead of HPC, and that APC could provide clinicians with an effective alternative method to stop bleeding

ulcers, due to its high rate of primary hemostasis and low rate of rebleeding.

Applications

This study may encourage clinicians without experience in APC to use the technique for treatment of ulcer bleeding.

Terminology

APC is a non-contact method of delivering a high-frequency monopolar current through ionized and electrically conductive argon gas. Devices are applied directly to the bleeding point to cause coagulation and thrombosis in HPC. The heater probe is pushed firmly onto the bleeding lesion to apply tamponade and deliver defined pulses of heat energy.

Peer review

The authors have compared the effectiveness of APC and HPC for ulcer bleeding. They have concluded that APC is superior to HPC for initial hemostasis. This was a well-designed study because the patients were assigned to two groups at random.

Abstract

AIM: To evaluate the clinical significance of *-765G/C* and *-1195G/A cyclooxygenase-2 (COX-2)* gene polymorphisms in patients with pancreatic cancer (PC).

METHODS: The study included 201 patients: 85 with PC and 116 healthy controls. *-765G/C* and *-1195G/A COX-2* gene polymorphisms were studied in DNA isolated from blood samples. The associations of the analyzed genotypes and clinical data at diagnosis were evaluated.

RESULTS: We found an increased frequency of the homozygous *-1195AA COX-2* genotype in patients with PC (53.7%) compared with the control group (21%) ($P < 0.01$). In contrast, the distribution of genotype

and allele frequencies of the *-765G/C COX-2* polymorphism in the PC patients were not different from those in control groups. A correlation between presence of homozygous *-1195AA COX-2* genotype and tumor size > 3 cm was observed ($P < 0.05$). Analyzed polymorphisms were unrelated to the patients' sex and age, nor to the presence of regional or distant metastases.

CONCLUSION: These preliminary results indicate that the *-1195G/A COX-2* polymorphism may play an important role in PC prognosis and carcinogenesis.

INTRODUCTION

Cyclooxygenase-2 (COX-2), also known as prostaglandin endoperoxide synthase, is a key enzyme in the arachidonic acid pathway, initiating the synthesis of biologically important prostanoids and eicosanoids. *COX-2* is involved in many biologic processes, such as cell proliferation, invasion, angiogenesis and inhibition of apoptosis, which are all relevant to cancer development and progression^[1].

COX-2 is expressed under certain extracellular or intracellular stimuli, such as mitogens, growth factors, hormones, infectious agents and proinflammatory cytokines^[1,2]. Numerous studies have demonstrated increased expression of *COX-2* in various cancers, including pancreatic tumors^[3-6]. In several studies, the overexpression of *COX-2* in pancreatic cancer (PC) cells has been shown to be an independent prognostic factor and to increase the clinical aggressiveness of this disease^[3,4,7].

The *COX-2* gene was demonstrated to be genetically polymorphic, which may affect the expression or activity of this enzyme and consequently contribute to variation in individual susceptibility to cancer through aberrant arachidonic acid metabolism. Genetic variants represented by single nucleotide polymorphisms (SNPs) of the *COX-2* gene, among them *-765G/C* and *-1195G/A* in the promoter region, have been identified. The functional effects of these SNPs have been recently confirmed^[8,9]. The *-765G* allele is associated with heightened *COX-2* transcription by creating a transcriptional factor c-MYB-binding site and with significantly higher promoter activity compared with *-765C* allele^[8,9]. In the study of Zhang *et al*^[10], the *-1195A*-containing haplotypes also had significantly increased *COX-2* messenger RNA levels in esophageal tissues compared with the *-1195G*-containing counterparts.

COX-2 has been the object of prevention/intervention strategies in many clinical trials, including being a potential therapeutic target for chemoprevention and therapy of PC^[11,12]. Selective inhibition of *COX-2* results in variable responses in individual patients. Information regarding the functional significance of *COX-2* polymorphisms with risk-modulating ability would have significant implications, not only for risk identification, but also for pharmacological management of the disease.

The purpose of this study was to evaluate the clinical significance of *-765G/C* and *-1195G/A* *COX-2* gene polymorphisms in patients with PC.

MATERIALS AND METHODS

The study included 201 Caucasian patients: 85 with PC (41 men and 44 women, aged 44-84 years) and 116 gender- and age-matched healthy volunteers. Analyzed patients were hospitalized in the Department of Digestive Tract Diseases, Medical University of Lodz Hospital or in the Department of Digestive Tract Surgery of Silesian Medical University in Katowice between 2004 and 2009. Only patients with a confirmed pathological diagnosis of ductal pancreatic adenocarcinoma were included in the study. The pathological diagnosis was confirmed after surgical treatment or after pancreatic tissue biopsy in patients who qualified for palliative chemotherapy. Twenty-nine patients (34.1%) with PC underwent Whipple resection or distal pancreatectomy, 33 patients (38.8%) underwent palliative surgery and 23 patients (27.1%) underwent palliative chemotherapy and/or endoscopic treatment. Tumor grade was classified into G1 (well differentiated), G2 (moderately differentiated) and G3 (poorly differentiated).

The study protocol was approved by the ethical committee of Lodz Medical University.

Peripheral venous blood samples were obtained from all analyzed patients at the time of hospital admission. *-765G/C* and *-1195G/A* *COX-2* gene polymorphisms were studied in DNA isolated from blood samples using the QI-Amp DNA Mini Kit (Qiagen). Polymerase chain reaction (PCR) products for the *COX-2* variants were analyzed by the restriction fragment length polymorphism method. The primers used to amplify the *COX-2* promoter region were 5'-TAT TAT GAG GAG AAT TTA CCT TTC GC-3' and 5'-GCT AAG TTG CTT CAA CAG AAG AAT-3' for the *-765G/C* variant; and 5'-CCC TGA GCA CTA CCC ATG AT-3' and 5'-GCC CTT CAT AGG AGA TAC TGG-3' for the *-1195G/A* polymorphism. PCR amplification was performed in a final volume of 25 μ L containing 30-100 ng of DNA, 10 mmol/L Tris-HCl (pH 8.3), 4 μ L of 25 mmol/L MgCl₂, 50 mmol/L KCl, 0.5 μ L dNTP (10 mmol/L), each primer at 1.0 μ mol/L and 1.0 unit of Taq polymerase (BIOKOM, Takara, Japan) in a GeneAmp PCR system 9700 Thermocycler (Applied Biosystems).

Ten microliters of the PCR product were digested with 2 units of restriction enzymes HhaI or Pvu II (BioLabs, New England) using the manufacturer's recommended protocol. PCR products were visualized on 8% polyacrylamide gels with 10% ethidium bromide. *COX-2* genotypes that could be detected were respectively: *-765CC* (100 bp fragment), *-765GC* (100 and 74 and 26 bp fragments), *-765GG* (74 and 26 bp fragments), *-1195AA* (273 bp fragment), *-1195GA* (273 and 220 and 53 bp fragments) and *-1195GG* (220 and 53 bp fragments).

The serum concentrations of CA19-9 were measured by an enzyme-linked immunoassay (DRG International, United States), according to the manufacturer's recommendations. The associations of the analyzed genotypes and patient characteristics at PC diagnosis were evaluated. The following demographic and clinical data were analyzed: age, gender, tumor size, lymph node involvement, histological grade, CA19-9 levels, weight loss and history of smoking. The cut-off point of CA19-9 was set at 37 U/mL.

Statistics analysis

The results were analyzed using StatSoft Statistica for Windows, release 6.0 (StatSoft, Inc., Tulsa, United States). To determine differences between groups, Mann-Whitney *t* tests were used. Clinical significance of analyzed polymorphisms was determined using logistic regression analysis and presented in tables as odds ratios (OR) with their 95% confidence intervals. The deviations from Hardy-Weinberg equilibrium were analyzed using the χ^2 test. Differences with a *P* value less than 0.05 were considered significant.

RESULTS

All patients involved in the study were Caucasians. Mean ages were not significantly different for patients with PC

(mean 66.8 ± 4.1 years) and controls (63.1 ± 4.7 years, $P > 0.05$). In patients with pancreatic adenocarcinoma, the tumor size ranged from 2 cm to 7 cm (mean 3.7 ± 2.3). As for histological differentiation, 19, 29 and 35 patients were classified into G1, G2 and G3 respectively, whereas 2 patients had missing data. Lymph node metastases were observed in 39 patients with PC (45.9%) and liver metastases in 16 of them (18.8%). Serum levels of CA19-9 were higher in patients with PC compared to control group ($P < 0.001$; respectively 101.2 ± 21.4 U/mL *vs* 17.6 ± 3.2 U/mL; data shown in our previously published work^[22]).

The genotype distributions of analyzed -765G/C and -1195G/A COX-2 gene polymorphisms are summarized in Table 1. We found an increased frequency of the homozygous -1195AA COX-2 genotype in patients with PC compared with control group [OR 6.48 (2.93-14.31), $P < 0.01$]. In contrast, the distribution of genotype and allele frequencies of the -765G/C COX-2 polymorphism in the PC patients did not differ from those in control groups (Table 1). Each of the COX-2 polymorphisms in the controls was consistent with Hardy-Weinberg equilibrium.

The potential relationship between COX-2 genotype distribution and clinical data of the PC patients was investigated. COX-2 -1195AA genotype showed a significant association with tumor size > 3 cm in patients with PC ($P < 0.05$, Table 2). This analyzed polymorphism was unrelated to the patients' sex and age, weight loss, history of smoking, CA19-9 levels, nor with the presence of regional or distant metastases. In contrast, the -765G/C COX-2 polymorphism was not associated with any clinical data (Table 3).

DISCUSSION

The overexpression of COX-2 has been shown to induce angiogenesis by increased synthesis of vascular endothelial growth factor and to inhibit apoptosis by activation of proto-oncogene Bcl-2^[2]. It is known that the expression of COX-2 is increased in the majority of PC cells and may represent a target for adjuvant therapy of PC. However, little is known about the role of COX-2 gene polymorphisms in pancreatic carcinogenesis. We investigated the clinical significance of the -765G/C and -1195G/A COX-2 gene polymorphisms, as well as their potential association with the risk of developing PC.

In our study, the presence of the -1195AA genotype was found more frequently in patients with PC compared to the control group. Similarly, Zhao *et al*^[8] observed that subjects carrying the COX-2 -1195A allele had significantly increased risk for developing PC compared with subjects carrying the -1195G allele. In previous studies, the association of the -1195A allele with an increased risk of lung, oral and esophageal cancers was also demonstrated^[12-14]. In the study of Bi *et al*^[13], -1195AA genotype was significantly correlated with worse overall survival (15.7 mo *vs* 20.2 mo, $P = 0.006$) and with shorter

progression-free survival (9.5 mo *vs* 11.9 mo, $P = 0.0034$) in patients with unresectable locally advanced non-small cell lung cancer.

However, others authors observed opposite results. In the study of Kristinsson *et al*^[15], the -1195GG genotype resulted in a higher risk of developing esophageal adenocarcinoma. On the other hand, Pereira *et al*^[16] observed that men carrying the -1195G allele appeared to have a nine-fold increased risk for colorectal cancer. Racial and ethnic differences in the studies' populations may explain these contradictory results, because the distribution of COX-2 polymorphisms may differ considerably between populations.

The published data about clinical significance of the second analyzed polymorphism of COX-2 gene, -765G/C, are also controversial. In the study of Hoff *et al*^[17], the -765GG genotype was present more often in patients with colorectal cancer compared to control group. Similarly, Coskunpinar *et al*^[14] observed increased risk of lung carcinoma in Turkish patients carrying the -765G allele. In contrast, the -765C allele was associated with an increased risk for developing PC and urinary bladder cancer^[8,18]. This is not in line with our findings, since we could not demonstrate a significant difference in -765G/C genotype distribution in patients with PC. Similarly, Dong *et al*^[19] in a meta-analysis of 47 case-control studies did not find a convincing association between -765G/C COX-2 gene polymorphism and the risk of cancer in diverse populations.

Another important aspect of our analysis was to assess the potential association of -765G/C and -1195G/A COX-2 gene polymorphisms with clinical data of patients with PC. In the current study, the homozygous -1195AA was found to be present more frequently in patients with larger tumor size. To the best of our knowledge there are no available data about relationships between -1195G/A COX-2 polymorphism and clinical characteristics of patients with PC. Earlier, Tan *et al*^[20] demonstrated that the COX-2 -1195A allele was associated with the presence of distant metastases in patients with colorectal cancer. They suggested that COX-2 may play a role not only in colorectal tumorigenesis but also in cancer progression by stimulating cell proliferation and spread.

According to our data, the second analyzed COX-2 polymorphism, -765G/C, was not associated with clinical parameters. Similarly, in other studies the -765G/C variant was not correlated with clinical stage of patients with cervical and colorectal cancers^[17,21].

Overexpression of COX-2 may be an important cellular mechanism in smoking-related PC development. Numerous studies have shown that smoking induces COX-2 expression, but the exact signal pathways remain to be elucidated. Zhao *et al*^[8] suggested that COX-2 genetic polymorphisms may determine interindividual variation in the inducibility of COX-2 expression. They observed that smoking remarkably increased COX-2 promoter activity, especially in patients with PC carrying the -765C allele. In contrast, in our study, there was no

association between analyzed polymorphisms and smoking. Similarly, Pandey *et al*^[21] did not find a correlation between smoking and COX-2 polymorphisms in patients with cervical cancer. This lack of association could be due to a relatively small number of subjects and certainly needs further validation.

In summary, we found a significant difference in the -1195G/A COX-2 gene polymorphism distribution between patients with PC and the control group. The presence of -1195AA genotype was associated with an increased PC risk; however, further studies are needed to investigate its possible association with PC prognosis. Our results are consistent with the biological function of the polymorphisms and support the hypothesis that aberrant arachidonic acid metabolism may play an important role in pancreatic carcinogenesis.

COMMENTS

Background

Despite improved diagnostic and therapeutic capabilities, pancreatic cancer (PC) still has a very poor prognosis. Numerous studies suggest a role for cyclooxygenase-2 (COX-2) in pancreatic carcinogenesis. COX-2 is involved in many biologic processes, such as cell proliferation, invasion, angiogenesis and inhibition of apoptosis, which are all relevant to cancer development and progression.

Research frontiers

The COX-2 gene was demonstrated to be genetically polymorphic, which may affect the expression or activity of this enzyme and consequently contribute to variation in individual susceptibility and aggressiveness of PC.

Innovations and breakthroughs

This study analyzed the clinical significance of -765G/C and -1195G/A COX-2 gene polymorphisms in patients with PC. In the study, the presence of the -1195AA genotype was associated with an increased risk of PC; however, further studies are needed to investigate its possible association with PC prognosis.

Applications

The results are consistent with the biological function of the polymorphisms and support the hypothesis that aberrant arachidonic acid metabolism may play an important role in pancreatic carcinogenesis.

Terminology

COX-2 is a key enzyme in the arachidonic acid pathway, initiating the synthesis of biologically important prostaglandin H₂ (the precursor of other prostaglandins), prostacyclin and thromboxanes.

Peer review

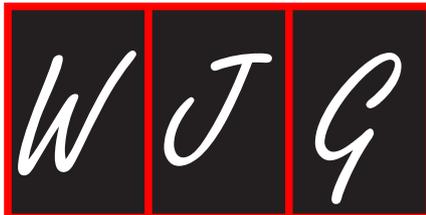

In this manuscript, the authors demonstrate that COX-2 gene polymorphisms might be associated with carcinogenesis of PC. A series of experiments are well-planned and well-performed and this manuscript is well written.

Abstract

AIM: To investigate whether bile duct angulation and T-tube choledochostomy influence the recurrence of choledocholithiasis.

METHODS: We conducted a retrospective study including 259 patients who underwent endoscopic sphincterotomy and cholecystectomy for choledocholithiasis between 2000 and 2007. The imaginary line was drawn along the center of the bile duct and each internal angle was measured at the two angulation sites of

the bile duct respectively. The values of both angles were added together. We then tested our hypothesis by examining whether T-tube choledochostomy was performed and stone recurrence occurred by reviewing each subject's medical records.

RESULTS: The overall recurrence rate was 9.3% (24 of 259 patients). The mean value of sums of angles in the recurrence group was $268.3^\circ \pm 29.6^\circ$, while that in the non-recurrence group was $314.8^\circ \pm 19.9^\circ$ ($P < 0.05$). Recurrence rate of the T-tube group was 15.9% (17 of 107), while that of the non T-tube group was 4.6% (7 of 152) ($P < 0.05$). Mean value of sums of angles after T-tube drainage was $262.5^\circ \pm 24.6^\circ$ and that before T-tube drainage was $298.0^\circ \pm 23.9^\circ$ in 22 patients ($P < 0.05$).

CONCLUSION: The bile duct angulation and T-tube choledochostomy may be risk factors of recurrence of bile duct stones.

INTRODUCTION

Since its introduction in 1974, endoscopic sphincterotomy (EST) has become a well established therapeutic method for the extraction of common bile duct (CBD) stones^[1,2]. In previous studies of EST, 4%-24% of patients experienced recurrent CBD stones during follow-up intervals of up to 15 years^[3-5]. The suggested causes of recurrent bile duct stones after EST are bile duct inflammation, papillary stenosis, dilated common bile duct, peripapillary diverticulum, reflux of the duodenal contents into the bile duct, and foreign bodies within the bile duct^[6,7]. After EST, the biliary sphincter is rendered permanently insufficient^[8]. The loss of this physiologic barrier between duodenum and biliary tract results in duodenocholedochal reflux and bacterial colonization of the biliary tract^[9,10]. The presence of bacteria in the biliary system might lead to late complications after EST. These complications may include recurrence of CBD stones from deconjugation of bilirubin by bacterial enzymes^[11], inflammatory changes of the biliary and/or hepatic system^[12,13], recurrent ascending cholangitis^[14], and even malignant degeneration^[13,15].

Bile stasis may be one of the possible mechanisms of stone recurrence^[16]. If bile flow can be decreased by the bile duct angulation, it may be a risk factor of stone recurrence. In a previous study, it was disclosed that in treatment of CBD stones, a T-tube drainage group had a higher recurrence rate of stones than either a choledochoduodenostomy group or an EST group, although their accurate mechanism was not elucidated^[17]. It was also reported that the angulation of the extrahepatic bile duct—so called “the elbow sign”—occurred as a sequela of T-tube drainage^[18]. Therefore, we investigated whether draining the T-tube changes configuration of the extrahepatic bile duct significantly and then whether bile duct deformity affects recurrence of CBD stones.

MATERIALS AND METHODS

Patient selection

All patients who were treated for choledocholithiasis by means of endoscopic retrograde cholangiopancreatography (ERCP) with EST between January 2000 and December 2007 in our institution were recruited. Their medical records were retrospectively reviewed. Among them, patients who met the following criteria were selected: (1) complete clearance of the bile duct stones was achieved; (2) cholecystectomy performed; (3) absence of bile duct stricture; (4) absence of concurrent hepatolithiasis; (5) absence of coexisting malignant neoplasm; and (6) absence of coexisting severe medical disease. Consequently, in total 259 patients were enrolled in the study.

For all the patients, the following data were collected: gender, age, recurrence, presence of perampullary diverticulum, maximal CBD diameter and presence of T-tube drainage. We divided them into two groups; recurrent and non-recurrent groups, and the sum of extrahepatic bile

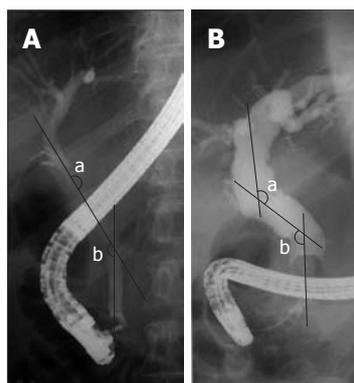

Figure 1 Cholangiographic configuration of (A) usual extrahepatic bile duct and (B) deformed bile duct. The imaginary line was drawn along the center of the bile duct and each internal angle was measured at the angulation of the proximal (a) and distal (b) bile duct level respectively. The values of both angles were added together (a + b).

duct angles and maximal CBD diameter between both groups was compared. EST was performed completely by traction-type or needle-knife sphincterotome and the bile duct stones were extracted with basket and/or stone-retrieval balloon catheters. After extraction of CBD stones, we performed a regular check-up on each patient at the outpatient department base, and considered absence of symptoms of biliary colic or cholangitis episode as absence of recurrence by using telephone interviews in patients who were missed.

Periampullary diverticulum

Periampullary diverticulum was defined as the presence of a diverticulum within a 2-cm radius from ampulla of Vater. We could identify whether periampullary diverticulum was present or not in 231 of the subjects. The information was missing from the medical records of the remaining patients. We divided patients into two groups: non-periampullary diverticulum and periampullary diverticulum groups, and the recurrence rate between the two groups was compared.

Measurement of bile duct angulation

There were films of acceptable quality, taken in the prone position during ERCP. When the extrahepatic bile duct was deformed, the number of its angulation site was one or two in most patients. The angles were measured at the intersection of imaginary lines drawn down the center of the bile duct. Its intersection did not necessarily occur within the lumen of the duct, particularly where angulation took the form of a gentle curve. Each internal angle was measured at the two angulation sites of the proximal and distal bile duct level respectively by one experienced radiologist (Figure 1). **The values of both angles were added together to estimate the grade of angulation.** The smaller sum of angles implies more angulation.

T-tube choledochostomy

T-tube drainage was performed during the cholecystectomy when the bile duct was injured surgically or when a

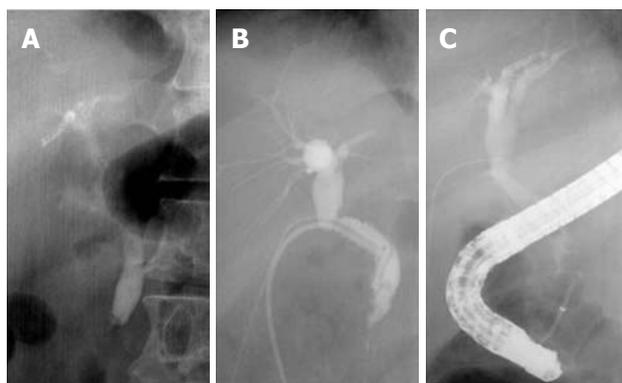

Figure 2 The bile duct angulation caused by T-tube choledochostomy. A: Extrahepatic bile duct configuration before T-tube choledochostomy; B: Bile duct configuration during T-tube drainage; C: Bile duct configuration altered after T-tube drainage. This change of cholangiographic findings showed that T-tube drainage would have induced bile duct angulation.

bile duct stone remained after EST. We divided patients into two groups; T-tube drainage (107 patients) and non-T-tube drainage group (152 patients). The recurrence rate in each group and the sum of angles, especially the sum of the angles before and after T-tube drainages in 22 patients whose films of ERCP before and after T-tube drainage were available among T-tube drainage group, were determined. We compared the recurrence rate and sum of angles between the T-tube drainage group and the non-T-tube drainage group, and evaluated the change of the sum of angles before and after the T-tube drainages in 22 patients to find the influence of T-tube drainage on bile duct configuration (Figure 2).

Maximal transverse common bile duct diameter

We defined transverse diameter of the CBD as a diameter measured in the line which forms a right angle to an imaginary line drawing down along the center of the CBD lumen. We measured the maximal transverse diameter of the CBD in all subjects and corrected for the magnification, with the external diameter of the distal end of the duodenoscope as a reference. We also evaluated the recurrence rate according to the CBD diameter.

Statistical analysis

Categorical variables (gender, presence of periampul-

lary diverticulum and presence of T-tube drainage) were compared by chi-square test or Fisher exact test. Continuous variables (age, CBD diameter, sum of angle) were analyzed using the Student *t* test when the variables were normally distributed or by using the Mann Whitney *U* test for non-normal distribution. Significant predictors for choledocholithiasis recurrence identified by univariate analyses were included in a multiple logistic regression model to determine the most significant risk factors for recurrence of the bile duct stones. For multivariate analysis, we categorized continuous variables into two subgroups: age (< 65 years vs ≥ 65 years), sum of angle (< 270° vs ≥ 270°), and maximal transverse CBD diameter (< 13 mm vs ≥ 13 mm).

Statistical analysis were conducted using SPSS (Statistical Package for the Social Sciences) computer program (version 14.00).

RESULTS

Two hundred and fifty-nine patients were included in the study. Median age was 58 years (range, 17-85 years). There were 132 (50.9%) women and 127 (49.1%) men. Median follow-up period was 47.9 mo (6-101 mo). The results of univariate analyses for recurrence of bile duct stones in relation to each factor were presented in Table 1.

Recurrence rate

The overall recurrence rate of CBD stones was 9.3% (24 of 259 patients). The recurrence rate was 8.7% (11 of 127 patients) in males and 9.9% (13 of 132 patients) in females respectively.

A total of 13.4% (15 of 112) of the patients with periampullary diverticulum developed recurrent stones, while 6.7% (8 of 119) of those without diverticulum showed recurrence. There was no evidence that the periampullary diverticulum exerted a significant influence on the recurrence of bile duct stones statistically (*P* = 0.091). Seventeen of 107 patients (15.9%) who underwent T-tube drainage had a recurrence, compared with 7 of 152 patients (4.6%) without T-tube drainage, and the presence of T-tube drainage was shown to be statistically associated with the recurrence of CBD stones (*P* = 0.002).

Bile duct angulation

The mean value of the sum of angles in the non-recur-

Table 2 Adjusted odds ratio of risk factors for recurrent bile duct stones

Variables	Recurrence of bile duct stones		
	Odds ratio	P value	95% CI ¹
Periampullary diverticulum	2.648	0.107	0.809-8.668
Common bile duct diameter	3.011	0.152	0.564-11.700
T-tube drainage	2.578	0.119	0.785-8.470
Sum of angle (°)	17.897	0.000	5.083-63.015
Age ≥ 65 years	0.372	0.102	0.113-1.219

¹95% CI: Expressed as 95% confidence interval.

recurrence group was $314.9^\circ \pm 20.0^\circ$, while the mean sum of angles in the recurrence group was $268.3^\circ \pm 29.6^\circ$ ($P = 0.001$). These results mean that the more angulation in the extrahepatic bile duct could develop, the greater recurrence of the stone.

common bile duct diameter

The mean maximal transverse CBD diameter in the non-recurrence group was 15.8 ± 6.2 mm while the mean value of CBD in the recurrence group was 20.6 ± 7.6 mm. CBD diameter was a significant risk factor for recurrence on univariate analysis ($P = 0.001$).

T-tube drainage

The mean value of sums of angles at the cholangiogram before T-tube choledochostomy was $311.7^\circ \pm 22.4^\circ$ in T-tube group, while that in the non T-tube group was $314.9^\circ \pm 19.3^\circ$ ($P = 0.232$). On the other hand, the mean value of sums of angles before T-tube drainage was $298.0^\circ \pm 3.9^\circ$, while after T-tube drainage, it was $262.5^\circ \pm 24.6^\circ$ in some patients ($n = 22$) who underwent ERCP after removal of the T-tube among members of the T-tube group ($P = 0.001$). Consequently, these results suggested that T-tube drainage may affect bile duct angulation.

Multivariate analysis

A univariate analysis revealed that CBD diameter, T-tube drainage and sum of angle were significant risk factors for the recurrence of choledocholithiasis ($P < 0.05$). But multivariate analyses of all variables that reached a P value of less than 0.1 in univariate analysis were performed. On multivariate analysis, angulation was the only independent risk factor for the recurrence of choledocholithiasis (Table 2).

DISCUSSION

ERCP with EST is the therapeutic procedure of choice for CBD stones. Early complications of EST include acute pancreatitis, bleeding, duodenal perforation, and acute cholangitis. On the other hand, its late complications include recurrence of stones and papillary stenosis^[19,20]. In long-term follow-up studies after EST, the recurrence rate of CBD stones in patients with cholecystectomy has been in the range of 4% to 24%^[3-5].

However, the theory that loss of sphincter function after EST leads to formation of recurrent CBD stones seems to need validation. Several authors have demonstrated that the biliary tree becomes infected with bacteria after EST^[9,10] and there is substantial evidence that bacteria play an essential role in the formation of brown pigment stones. Some bacterial species, especially *Escherichia coli*^[21], produce enzymes such as β -glucuronidase that are known to precipitate bilirubin and calcium^[11], the main components of brown pigment stone^[22]. Furthermore, electron microscopy studies have demonstrated that bacteria are present in the core of brown pigment stone whereas they are absent in cholesterol and black pigment stone^[14,23,24].

Apart from bacterial infection, biliary stasis is thought to be an important factor in the pathogenesis of recurrent bile duct stones^[6,16,25]. The markedly dilated bile duct is often contaminated with bacteria and also leads to bile stasis, which is thought to be an important factor in the pathogenesis of recurrent stones. The association between dilated CBD and stone recurrence has been reported in previous studies of post-EST patients^[26,27]. In the univariate analysis of our study, in the recurrence group ($n = 21$, mean CBD diameter = 20.6 mm \pm 7.6 mm) there was greater dilation in the extrahepatic bile duct than in the non-recurrence group ($n = 200$, mean CBD diameter = 15.8 mm \pm 6.2 mm) ($P = 0.001$). Therefore dilated bile ducts may be another important risk factor of CBD stone recurrence by causing impaired bile flow.

Previous studies of the peripapillary diverticulum in relation to recurrence of bile duct stone have disclosed inconsistent results^[28-31]. Biliary stasis in patients with diverticulum could be caused by either mechanical factors or the presence of coexisting motility disorders involving the sphincter of Oddi^[28-31]. Theoretically, the effect of the diverticulum on bile flow might not completely disappear after the EST. In our study, the recurrence rate of the diverticulum group ($n = 112$, 13.4%) was higher than that of the non-diverticulum group ($n = 119$, 6.7%), but the result was not statistically significant ($P = 0.91$). Hence further studies on periampullary diverticulum as a risk factor of stone recurrence might be needed.

Bile duct angulation may cause stasis of bile flow. Warren suggested that angulation of CBD is associated with choledocholithiasis^[32]. Mean cholangiographic angulation of CBD differed significantly between patients with cholelithiasis only and those with choledocholithiasis in this previous series. The degree of ductal angulation may be a useful consideration in development of bile duct stones. Recently two reports showed angulation of the CBD contributes to biliary stasis, and hence predisposes to recurrent choledocholithiasis^[33,34]. In the current study, the recurrence group ($n = 24$, mean of sums of angles = $268.3^\circ \pm 29.6^\circ$) was more angulated in the extrahepatic bile duct than the non-recurrence group ($n = 235$, mean of sum of angles = $314.9^\circ \pm 20.0^\circ$) ($P < 0.05$). In multivariate analysis, the sum of angles was the only independent risk factor of CBD stone recurrence (Table 2).

There was a previous study describing long-term results of medical or surgical treatment in patients with choledocholithiasis^[17]. Two hundred and thirteen patients were treated for CBD stones, and then the patients were divided into 3 groups based on the treatment modality: group 1, choledocholithotomy and T-tube choledochostomy; group 2, choledochoduodenostomy; and group 3, endoscopic sphincterotomy. Recurrence of choledocholithiasis was examined for each type of treatment modality. This study suggested that patients treated by T-tube drainage had more recurrent bile duct stones than those in the choledochoduodenostomy or EST groups, but accurate mechanisms were not clearly demonstrated.

Lee and Burhenne suggested that extrahepatic bile duct angulation was caused by T-tube drainage^[18]. They observed lateral distortion in the shape of the bile ducts in a considerable number of patients with an indwelling T-tube such that an angle measured between the proximal and distal parts of the duct, centered at the site of T-tube drainage insertion, decreased to a range of 60 to 158. They have called this finding the “elbow sign”. In the current study, the mean sum of angles before T-tube drainage was $298.0^\circ \pm 23.9^\circ$, while the mean value of angles after T-tube drainage was $262.5^\circ \pm 24.6^\circ$ in the same patients. The sum of the angles in the CBD changed after T-tube drainage by 35.5° and was statistically significant ($P < 0.05$). Furthermore, the extrahepatic bile duct deformity caused by T-tube drainage influenced the recurrence rate of CBD stones. The recurrence rate of the non-T-tube drainage group was 4.6%, while the recurrence rate of the T-tube drainage group was 15.9% ($P < 0.05$). It is presumed that T-tube placement could introduce local adhesion^[33], which, in turn, influences the angulation of the bile duct and then leads to recurrence of bile duct stones as one of the mechanisms.

Our study has some limitations. First, this study is retrospective. Second, we did not prove recurrence with repeat ERCP or cholangiogram in every patient. It may have ascertainment bias. Third, we should estimate the three dimensional image, but we measure bile duct angulation by two-dimensional fluoroscopic imaging. This may show some difference from real angulation. Practically, it is difficult to get three dimensional bile duct images. Fourth, there may be several possible confounders which we did not consider. Medication such as ursodeoxycholic acid and the time of drainage of contrast from the bile duct were not reported in our series. On account of these limitations, it is difficult to be absolutely certain that our specific risk factors were solely responsible for the recurrence of choledocholithiasis.

In conclusion, subsequent to endoscopic biliary sphincterotomy and clearance of bile duct stones, three significant risk factors for the recurrence of the stone were identified on univariate analyses, although bile duct angulation was the only risk factor for recurrence of choledocholithiasis in the multivariate analysis. Patients with a more angulated and dilated bile duct, and a history of T-tube choledochostomy developed stone recurrence more frequently. T-tube choledochostomy performed af-

ter cholecystectomy were prone to recurrence of stones by an influence on bile duct angulation.

COMMENTS

Background

After endoscopic sphincterotomy (EST), 4%-24% of patients might experience recurrent choledocholithiasis. The risk of stone recurrence is an important issue, especially for relatively young patients. Bile duct angulation may be a risk factor of stone recurrence by decreasing bile flow.

Research frontiers

The risk factors for true recurrence of bile duct stones after EST are suboptimally defined. Until now, infection along the bile duct and bile stasis were thought to contribute to the recurrence.

Innovations and breakthroughs

Recent several studies showed the association between bile duct angulation and recurrence of stones. The authors added more information about that. In addition, the authors suggested that T-tube choledochostomy influences the recurrence of choledocholithiasis by angulating the bile duct.

Applications

This article provides important data about the risk factors of choledocholithiasis recurrence. By identifying risk factors for stone recurrence, people can improve outcomes by prophylactic treatments or earlier intervention.

Peer review

This is an interesting study that investigated the risk factors of recurrence of common bile duct stones. This study suggested an association between T-tube drainage and recurrence of choledocholithiasis by analyzing the angulation of the common bile duct before and after T-tube drainage.

Abstract

AIM: To measure the perceived satisfaction with gastric cancer screening as part of the National Cancer Screening Program (NCSP) in South Korea.

METHODS: Data were derived from the participants

in a satisfaction survey of the Quality Evaluation of National Cancer Screening in 2009. This is a population-based nationwide telephone survey of participants who were screened by the NCSP between May and October 2009. This study included 4412 participants who provided full sets of data and who had upper endoscopies for the purpose of gastric cancer screening.

RESULTS: The negative appraisal percentages for each of the seven questions were as follows: explanation in preparation for the upper endoscopy, 12.3%; explanation about the process and procedure of the upper endoscopy, 13.8%; explanation about any pain or discomfort related to the upper endoscopy, 27.5%; level of pain during the procedure, 30.3%; physical environment, 16.2%; manner of the staff, 11.2%, and privacy protection, 8.8%.

CONCLUSION: The critical issues identified by the Pareto analysis include the adequacy of the explanation about any pain or discomfort associated with the upper endoscopy and the level of pain experienced during the procedure.

INTRODUCTION

In recent years, patient satisfaction with endoscopic procedures has become an important outcome measure of gastrointestinal (GI) endoscopies^[1]. Patient satisfaction not only establishes performance standards, but also increases the accountability of physicians and staff, and most importantly, can lead to improvement in the quality of care. Few studies have assessed the factors associated with patient satisfaction with upper endoscopies. Factors that have been significantly and positively associated with patient satisfaction included the adequacy of analgesia during the procedure, low patient anxiety before the endoscopic procedure, respectful personal manner of endoscopists, respectful personal manner of nurses, patient positive perceptions of endoscopists' technical skills, pleasant physical environment in the endoscopy unit, and adequate time spent by physicians explaining the procedure^[1-3].

Understanding the level of satisfaction with upper endoscopies performed for gastric cancer screening may provide information necessary for optimising adherence to screening protocols. The satisfaction or procedure-related discomfort in upper endoscopies has rarely been given priority because the procedure can be done quickly and is associated with few complications. Despite a low rate of medical complications, the procedure is associated with substantial pre-procedural anxiety and procedure-related discomfort. Endoscopists tend to underestimate patient discomfort or dissatisfaction^[4].

Gastric cancer is the second most common type of cancer worldwide. With estimated 934 000 new cases in 2002 (8.6%), gastric cancer fell to the 4th place behind cancers of the lung, breast, and colon and rectum^[5]. However, gastric cancer remains the most frequently diagnosed cancer in South Korea^[6-8]. Gastric cancer screening is an increasingly important activity in the effort to early detect and control gastric cancer^[9,10]. Countries, such as Japan and South Korea, where gastric cancer is highly prevalent, have conducted gastric cancer screenings for people at average risk. Although there is debate over the value and risk of screening asymptomatic individuals, interest has shifted to determining the preferred screening strategy and discerning the most effective ways of implementing screening procedures for the general population^[11].

In South Korea, screening for gastric cancer started in 1999 as a part of the National Cancer Screening Program (NCSP) for low-income groups. Currently, the NCSP provides Medical Aid recipients and National Health Insurance beneficiaries in the 50% of income brackets with free screening services for five common cancers: gastric, liver, colorectal, breast, and cervical. The NCSP recommends a biennial upper gastrointestinal series (UGIS) or an upper endoscopy for men and women over 40 years of age. In recent years, mass screenings using upper endoscopies have replaced upper GI X-rays in several cities in South Korea. In 2002, 75.0% of the participants underwent upper-GI X-rays, and 25.0% received upper

endoscopies. In 2008, 50.9% received upper-GI X-rays, and 49.1% received upper endoscopies^[12].

The objectives of this study were to analyze the data obtained by questionnaires measuring the perceived satisfaction with gastric cancer screening as part of the NCSP and to identify and ameliorate the issues that contribute most to patient dissatisfaction.

MATERIALS AND METHODS

Data source

Quality Evaluation of National Cancer Screening (QENCS) programs to improve the quality of NCSP were established in 2008. QENCS programs in an upper endoscopy evaluate all aspects of cancer screening, including the structure, process and outcome. It also includes the general items, such as the indication for the endoscopic examination, informed consent, patient risk stratification, and sedation practice. Outcome indicators are participant satisfaction and accuracy such as cancer detection rate, false positive rate, and interval cancer.

Based on a previously validated questionnaire^[13], we conducted a population-based nationwide telephone survey among participants who were screened by the NCSP between May and October 2009. A sample of 43 157 participants was randomly chosen and stratified according to age, gender and gastric cancer unit. We evaluated participants' satisfaction with gastric cancer screening performed in hospitals. In total, 12 922 calls were successful, and 9090 participants (70.3%) agreed to complete the survey. Participants who received gastric cancer screening with an upper gastrointestinal series were excluded from the study. Finally, 4412 participants who provided full sets of data and who had upper endoscopies for purposes of gastric cancer screening were included in this study. This research was approved by the Institutional Review Board Committee.

Questionnaire

The questionnaire addressed six specific aspects of participant satisfaction with the screening experience: the adequacy of explanations (questions 1, 2 and 3), the manner adopted by doctors and nurses (question 4), privacy protection (question 5), physical surroundings (question 6), pain or discomfort during the procedure (question 7), and overall satisfaction (question 8). The items and scoring method are presented in Table 1. Participants answered each question, except the question regarding overall satisfaction, with a numerical score on a Likert scale, ranging from 1 (poor) to 4 (excellent). Overall satisfaction was scored on a 10-point scale.

Statistical analysis and graphic representation

We defined the problem rate as the percentage of "fair" or "poor" responses given by all participants to all questions^[14]. The problem rate was calculated by adding all poor or fair responses on all questionnaires, dividing this figure by the total number of questions, and multiplying

Questions	Poor	Fair	Good	Excellent						
I received adequate information/explanations in preparation for the upper endoscopy	1	2	3	4						
I received adequate information/explanations about the process and procedure of the upper endoscopy	1	2	3	4						
I received adequate information/explanations about any pain or discomfort related to the upper endoscopy	1	2	3	4						
I was satisfied with the respectfulness of the staff and the manner of doctors and nurses	1	2	3	4						
I had adequate privacy during the procedure	1	2	3	4						
I was satisfied with the pleasantness of the physical environment	1	2	3	4						
I did not experience too much pain/discomfort during the procedure	1	2	3	4						
	Strongly disagree			Strongly agree						
I am satisfied with my overall experience with gastric cancer screening	1	2	3	4	5	6	7	8	9	10

Variable group	Frequency (%)
Gender	
Male	40.1
Female	59.9
Age	
≥ 40 yr, < 50 yr	49.9

No	52.0

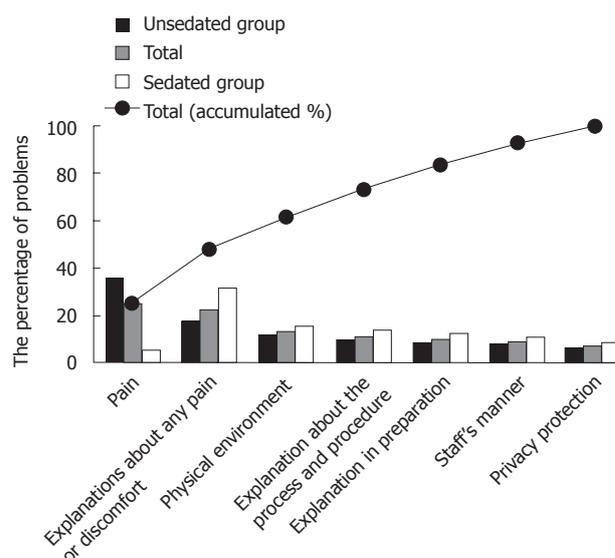

Figure 1 Relative importance of each question for the problem rate among all participants.

this result by 100. This calculation can be expressed by the following formula:

$$\frac{\sum \text{poor and fair answers}}{\sum \text{times each question was evaluated}} \times 100$$

The percentage of poor or fair responses was also calculated for each question.

Quality assessment uses special methods for graphic representation and analysis, and is considered to be as important as the statistical analysis itself. Of the various graphic analysis methods used currently, the Pareto chart was adopted in this study^[14]. This chart presents the relative importance assigned by all participants to each question included in the calculation of the problem rate and produces a bar chart representing the percentage of problems for each question over the total number of problems emerging from the data. Bars are shown from the left to right in order of decreasing level of importance. Figures in the column represent the percentages of poor and fair responses over the total of poor and fair responses. In addition, we drew a line over the bars to represent the accumulated percentage of problems

RESULTS

Of the total 4412 participants in the study population, men accounted for 40.1%, and those aged 40-49 years

accounted for 49.9%. Additionally, 48.0% underwent upper endoscopies while sedated (Table 2). In general, the mean and median satisfaction scores were high (> 3) for all questions, with the exception of the question addressing the level of pain (Table 3). We observed a trend toward higher mean satisfaction scores among the sedated group with respect to seven of the eight questions; the exception was the question addressing the adequacy of the explanation of any pain or discomfort associated with the procedure.

The critical few issues identified by the Pareto analysis included the question about the adequacy of the explanation about any pain or discomfort associated with the procedure and the question regarding the level of pain experienced during the procedure (Table 3, Figure 1). The problem rate was 17.2% (5298 poor or fair responses to a total of 30 884 questions) in the total study population. The critical few with a 30.3% problem rate, included the question about the level of pain experienced during the procedure (Table 3). The problem rate was 12.8% (1900 poor or fair responses to a total of 14 812 questions) in the sedated group and 21.1% (3398 poor or fair responses to a total of 16 072 questions) in the unsedated group.

Table 3 Comparison of satisfaction scores between sedated and unsedated groups

Question label	Total (n = 4412)			Sedated group (n = 2116)			Unsedated group (n = 2296)		
	Mean (SD)	Median (25Q-75Q)	Poor and fair (%)	Mean (SD)	Median (25Q-75Q)	Poor and fair (%)	Mean (SD)	Median (25Q-75Q)	Poor and fair (%)
Adequacy of explanations in preparation for upper endoscopy (%)	3.3 (0.8)	3 (3-4)	12.3	3.4 (0.8)	4 (3-4)	11.4	3.3 (0.8)	3 (3-4)	13.2
Adequacy of explanations about process and procedure of upper endoscopy (%)	3.3 (0.8)	3 (3-4)	13.8	3.3 (0.8)	4 (3-4)	12.6	3.2 (0.8)	3 (3-4)	14.9
Adequacy of explanations about any pain or discomfort related to upper endoscopy (%)	3.0 (1.0)	3 (2-4)	27.5	3.0 (1.0)	3 (2-4)	28.7	3.0 (0.9)	3 (2-4)	26.3
Staff's manner (%)	3.3 (0.7)	3 (3-4)	11.2	3.4 (0.7)	3 (3-4)	10	3.3 (0.7)	3 (3-4)	12.2
Privacy protection (%)	3.4 (0.7)	3 (3-4)	8.8	3.4 (0.7)	4 (3-4)	7.9	3.3 (0.7)	3 (3-4)	9.6
Physical environment (%)	3.2 (0.7)	3 (3-4)	16.2	3.2 (0.7)	3 (3-4)	14	3.1 (0.7)	3 (3-4)	18.3
Level of pain experienced during the procedure (%)	3.0 (1.0)	3 (2-4)	30.3	3.7 (0.6)	4 (4-4)	5.2	2.4 (0.8)	2 (2-3)	53.5
Overall satisfaction	7.8 (1.8)	8 (7-10)		8.0 (1.8)	8 (7-10)		7.6 (1.7)	8 (7-8)	
Problem rate			17.2			12.8			21.1

DISCUSSION

We used the overall score on questions 1-8 as an indicator of participants' satisfaction with the upper endoscopy offered by the NCSP. In general, the mean and median satisfaction scores were high (> 3) for all questions, with the exception of the question concerning the level of pain. We observed a trend toward higher mean satisfaction scores in the sedated group. Our research shows that the level of pain experienced during the procedure and the adequacy of the explanation of any pain or discomfort associated with the procedure constituted the factors that contributed most to the problem rate among participants.
