Abstract

AIM: To detect the effects of plasma DNA methylation of Wnt antagonists/inhibitors on recurrence of esophageal squamous cell carcinoma (ESCC).

METHODS: We used methylation-specific polymerase chain reaction to detect hypermethylation of the promoter of four Wnt antagonists/inhibitors (*SFRP-1*, *WIF-1*, *DKK-3* and *RUNX3*) using DNA from the plasma of ESCC patients (n = 81) and analyzed the association between promoter hypermethylation of Wnt pathway modulator genes and the two-year recurrence of ESCC.

RESULTS: Hypermethylation of *SFRP-1*, *DKK-3* and *RUNX-3* was significantly associated with an increased risk of ESCC recurrence (P = 0.001, 0.003 and 0.001 for *SFRP-1*, *DKK-3* and *RUNX3*, respectively). Patients carrying two to three methylated genes had a significantly elevated risk of recurrence compared with those not carrying methylated genes (odds ratio = 15.69, 95% confidential interval: 2.97-83). The area under the receiver operating characteristic curve (AUC) was 77.1 for ESCC recurrence prediction (sensitivity = 66.67 and specificity = 83.3). When combining methylated genes and the clinical stage, the AUC was 83.69, with a sensitivity of 76.19 and a specificity of 83.3.

CONCLUSION: The status of promoter hypermethylation of Wnt antagonists/inhibitors in plasma may serve as a non-invasive prognostic biomarker for ESCC.

INTRODUCTION

Esophageal cancer, predominantly esophageal squamous cell carcinoma (ESCC), is one of the most common malignancies in the world, with 482 300 incident cases and

406 800 deaths estimated in 2008[1]. Most patients with ESCC are diagnosed at an advanced stage. Although therapeutic advances have been designed to improve treatment outcome, the prognosis of patients with ESCC is still poor, with long-term survival rates between 5% and 20%[2]. The poor prognosis is partially due to the high rate of recurrence, which occurs in approximately half of patients after curative surgical resection. Therefore, development of accurate prognostic biomarkers for ESCC is imperative and crucial for improving ESCC prognosis and for guiding treatment.

DNA methylation is one of the most common epigenetic modifications[3]. One of the major changes caused by DNA methylation is transcriptional silencing of tumor suppressor genes resulting from hypermethylation of CpG islands in promoter regions[4]. This change occurs frequently during tumor pathogenesis and progression and has become widely recognized as a mechanism of gene inactivation in cancer[5-7]. The methylation profile may also help predict the response to a chemo-/radio-therapeutic agent and thus the prognosis of cancer[8,9]. In addition, detection of promoter CpG methylation in body fluid DNA is feasible and nearly non-invasive[10].

Wnt signaling operates across cell boundaries *via* secretion by cells of one tissue type, which results in activation of surface receptors on neighboring cells and tissues, leading to activation of transcription factors that regulate cell proliferation, survival, and differentiation[11]. Dysregulation of these processes in cancer results in aberrant activation of the Wnt pathway[11,12]. Several antagonists of Wnt signaling have been identified, including the secreted frizzled-related protein-1 (SFRP-1) and Wnt inhibitory factor-1 (WIF-1), which bind directly to Wnt proteins, and Dickkopf-3 (DKK-3), which binds to the LDL-receptor-related protein5 (LRP5)/LRP6 component of the Wnt receptor complex[13]. In addition, another Wnt inhibitor, runt-related transcription factor-3 (RUNX3), reportedly forms a ternary complex with β-catenin/transcription factor-4 (TCF4) to attenuate Wnt signaling, which regulates cell proliferation, apoptosis, and invasion[14,15]. Given the important roles of Wnt antagonists/inhibitors in cancer progression and prognosis, we evaluated the association between methylation of promoter CpG islands of the four tumor suppressor genes, *SFRP-1*, *WIF-1*, *DKK-3* and *RUNX3*, in the Wnt signaling pathway and ESCC recurrence using plasma DNA from 81 Chinese patients with ESCC.

MATERIALS AND METHODS

Study population

This study was approved by the institutional reviewer board of Nantong Cancer Hospital, and written informed consent was obtained from each patient or from the patient's representative. Briefly, patients with histopathologically diagnosed incident ESCC were recruited from Nantong Cancer Hospital from June to December 2008. Exclusion criteria included self-reported previous cancer history, metastasis from other organs, and surgical section, radiotherapy, or chemotherapy before blood collection. Patients were followed up at the 24th month after recruitment by personal or family contacts. All patients were genetically unrelated, ethnic Han Chinese, and each patient donated 5 mL of venous blood at their first admission to the hospital. As a result, 81 ESCC patients who had complete clinical information, adequate DNA samples, and successful follow-up were included.

DNA extraction and methylation-specific polymerase chain reaction

DNA was extracted from 200 μL plasma from each patient using an SG Spin Column Clinical Sample Genomic DNA MiniPreps kit (Shanghai ShineGene Molecular Biotech, Inc., Shanghai, China). The plasma DNA was modified with sodium bisulfite using the EZ DNA methylation™ kit (Zymo Research, Orange, CA, United States). The methylation status of CpG islands in the promoter region of *SFRP-1*, *WIF-1*, *DKK-3* and *RUNX-3* was determined by methylation-specific polymerase chain reaction (PCR)[16]. In brief, the first universal primer set covered no CpG sites in either the forward or the reverse primer but amplified a DNA fragment of the promoter region containing several sites. Then, a second round of nested methylation-specific PCR or unmethylation-specific PCR was performed using the universal PCR products as templates. Primer sequences are shown in Table 1.

Statistical analysis

Differences in demographic and clinical characteristics were evaluated with χ^2 tests (or the Fisher's exact test). The association between methylation and ESCC recurrence was

estimated by computing odds ratios (ORs) and 95% confidence intervals (CIs) from logistic regression analyses for adjusted ORs and crude ORs, with or without adjustments for age, gender, smoking, drinking, clinical stage, surgical operation and chemo-/radio-therapy status. Receiver operating characteristic (ROC) curve analysis was conducted by using the "pROC" package in R. All the statistical analyses were performed with R software (version 2.11.1; The R Foundation for Statistical Computing).

RESULTS

Characteristics of patients

The clinicopathologic features of the patients are summarized in Table 2. A total of 81 ESCC patients were included in our current study. The mean age was 63 years (range, 46-80 years), and 61 patients were male (75.3%). Sixty-five (80.2%) patients underwent chemo-/radio-therapy, and 31 (38.3%) patients underwent surgical operation after blood collection. Among the 81 patients, there were 21 recurrences (26%) at the 24th month after recruitment. As expected, advanced stage was a risk factor for ESCC recurrence ($P < 0.001$). However, there were no significant differences in the recurrence rates among the subgroups of age, gender, smoking status, drinking status, with or without surgical operation, and/or chemo-/radio-therapy.

Single-gene analysis

The percentage of promoter methylation in the genes we analyzed was as follows: 29.6% for *SFRP-1*, 35.8% for *WIF-1*, 37.4% for *DKK-3*, and 35.8% for *RUNX-3*. Three genes showed significant associations with ESCC recurrence after adjusting for age, gender, smoking, drinking, stage, surgical operation, and chemo-/radio-therapy. As shown in Table 3, patients with methylated *SFRP-1* had a 10.8-fold increased risk of recurrence compared with those with unmethylated *SFRP-1* (95% CI: 2.54-46, $P < 0.001$). Similarly, methylated *DKK-3* was associated with a 6.07-fold increased risk of recurrence (95% CI: 1.73-21.28, $P = 0.003$), and methylated *RUNX-3* was associated with a 7.81-fold increased recurrence risk (95% CI: 2.30-47, $P = 0.001$). Methylation of *WIF-1*, however, was not significantly associated with an increased risk of recurrence ($P = 0.107$).

Combined analysis

We then performed combined analysis to assess the effect of methylation of the three genes (*SFRP-1*, *DKK-3* and *RUNX-3*) on ESCC recurrence. As shown in Table 4, compared with patients without methylated genes, those with two to three methylated genes had a significantly increased risk of recurrence (OR = 15.69, 95% CI: 2.97-83).

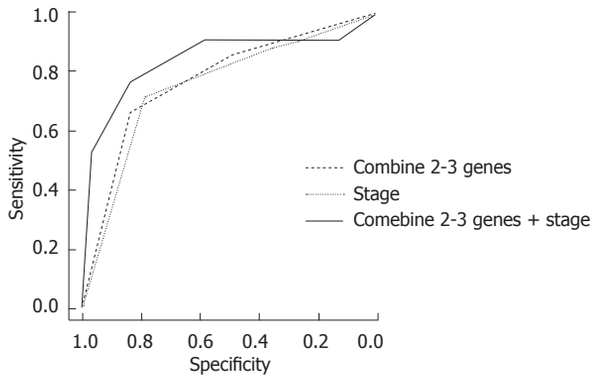

Figure 1 Receiver operating characteristic curve analysis to assess the sensitivity and specificity of the status of methylated genes in combination with the stage for predicting esophageal squamous cell carcinoma recurrence using the "pROC" package in R. Combination of 2-3 genes, area under curve (AUC) = 77.1, sensitivity = 66.67, specificity = 83.3, stage, AUC = 75.24, sensitivity = 71.43, specificity = 78.3, combination of 2-3 genes + stage, AUC = 83.69, sensitivity = 76.19, specificity = 83.3.

Furthermore, there was a dose-response effect between plasma DNA methylation status and ESCC recurrence (OR = 4.1, 95% CI: 1.73-9.72, *P* for trend: 0.001).

AUC analysis

We also conducted a ROC curve analysis and area under curve (AUC) analyses to assess the sensitivity and specificity of the status of methylated genes individually and in combination for predicting ESCC recurrence. For single genes, the AUC were 71.79 (*SFRP-1*), 70 (*DKK-3*) and 70.83 (*RUNX3*). When we considered two to three methylated genes, the AUC increased to 77.1, with a sensitivity of 66.67 and a specificity of 83.3. As a risk factor for ESCC recurrence, the AUC for stage was 75.24 (sensitivity = 71.43, specificity = 78.3). For the combination of methylated genes and clinical stage, the AUC was 83.69 (sensitivity = 76.19, specificity = 83.3) (Figure 1).

DISCUSSION

Wnt antagonists/inhibitors function as tumor suppressors, and thus hypermethylation of their promoters and subsequent silencing of these genes may be implicated in the pathogenesis or progression of a broad spectrum of human malignancies[17-19]. In our current study, we found that the methylation status of *SFRP-1*, *DKK-3* and *RUNX-3* promoters in plasma DNA can individually and jointly predict ESCC recurrence.

Most published studies on the association between hypermethylation of Wnt antagonist/inhibitor gene promoters and cancer development have focused on tumor tissues. Yu *et al*[17] found that epigenetic silencing of *DKK-3* is a common event in gastric cancer and is associated with a poor disease outcome. Urakami *et al*[18] used a methylation score to analyze the combined effects of hypermethylated Wnt antagonist family genes on bladder cancer detection, and they found that the score was significantly higher in bladder tumors than in bladder mucosa. Hamilton *et al*[9] assessed the methylation status of nine genes, including *RUNX-3*, in esophageal cancer patients and found that increased methylation of this gene correlated with poor responsiveness to therapy, suggesting potential clinical application of these biomarkers in guiding prognosis and management. A growing body of evidence suggests that the methylation signature is consistent between DNA derived from tissue and DNA derived from serum/plasma[19,20]. However, serum/plasma DNA has obvious advantages compared with DNA derived from tissue samples, i.e., with respect to the ease to obtain, non-invasiveness, and relative reproducibility. Therefore, serum/plasma DNA may be an excellent source of samples for assessing biomarkers, especially for patients who have not undergone surgery.

Previous studies have shown that methylation of various genes in serum/plasma can be a highly specific biomarker for human cancers[19,21-26]. Herbst *et al*[24] reported that *NEUROG1* is frequently methylated in sera of patients with colorectal cancers independent of the tumor stage and is a suitable non-invasive screening approach for detecting asymptomatic colorectal cancer. Göbel *et al*[25] found that methylated *PITX2* and *RASSF1A* in plasma are therapy-independent prognostic factors in breast cancer patients. Salazar *et al*[26] showed that the methylation status of *CHFR* in serum can influence the outcome of chemotherapy in stage Ⅳ non-small-cell lung cancer patients and that unmethylated *CHFR* predicts increased survival to EGFR TKIs. Urakami *et al*[19] reported that hypermethylation of Wnt antagonists can serve as an excellent epigenetic biomarker panel for detection, staging and prognosis of renal cell carcinoma using serum DNA. These studies all indicate the available and feasibility of using plasma DNA to establish the methylation status of gene promoters as a biomarker for cancer.

Given that ESCC is one of the most aggressive cancers in the world and that no non-invasive test is available, our preliminary study yielded a promising result. Limitations of our study include the lack of detection of DNA methylation in tissue and the unpredictability of the link between methylation status and gene expression. Nevertheless, the methylation status of Wnt antagonists/inhibitors may serve as a valuable biomarker for predicting ESCC recurrence.

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is one of the most common malignancies in the world. The prognosis of patients with ESCC is poor, which is partially due to the high rate of recurrence. Therefore, development of accurate prognostic biomarkers for ESCC is imperative and crucial for improving ESCC prognosis and for guiding treatment.

Research frontiers

Wnt antagonist/inhibitor genes function as tumor suppressors, and hypermethylation of their promoters and subsequent silencing of the genes, which can be detected in plasma DNA, may serve as a valuable non-invasive biomarker for predicting ESCC recurrence.

Innovations and breakthroughs

The association between methylation of promoter CpG islands of four tumor suppressor genes (*SFRP-1*, *WIF-1*, *DKK-3* and *RUNX3*) in the Wnt signaling pathway and ESCC recurrence was evaluated using plasma DNA from ESCC patients.

Applications

This result offers great potential for using plasma DNA to analyze methylation as a non-invasive biomarker for predicting ESCC recurrence.

Terminology

Epigenetic changes: Heritable changes in the gene structure that do not change the gene sequence. CpG islands: CpG-rich areas located in the promoter regions of many genes. CpG island methylation: The addition of a methyl group to a cytosine residue that is next to guanine.

Peer review

The study aimed to verify the promoter hypermethylation status of four Wnt [antagonist genes odds ratio (OR) antagonists] (using methylation-specific polymerase chain reaction with OR with the methylation-specific polymerase chain reaction technique using) DNA from plasma of 81 ESCC patients. The article reports interesting results that are important to the field.

Abstract

AIM: To confirm the role of sex-determining region Y-box 7 (Sox7) in aspirin-mediated growth inhibition of COX-independent human colorectal cancer cells.

METHODS: The cell survival percentage was examined by MTT (Moto-nuclear cell direc cytotoxicity) assay. SOX7 expression was assessed by using reverse transcription-polymerase chain reaction and Western blotting. SB203580 was used to inhibit the p38MAPK signal pathway. SOX7 promoter activity was detected by Luciferase reporter assay.

RESULTS: SOX7 was upregulated by aspirin and was involved in aspirin-mediated growth inhibition of SW480 human colorectal cancer cells. The p38MAPK pathway played a role in aspirin-induced SOX7 expression, during which the AP1 transcription factors c-Jun and c-Fos upregulated SOX7 promoter activities.

RESULTS: SOX7 is upregulated by aspirin and is involved in aspirin-mediated growth inhibition of human colorectal cancer SW480 cells.

Key words: SOX7; Aspirin; p38MAPK; Colorectal cancer; SB203580

INTRODUCTION

In Western Europe and the United States, colorectal cancer is the second most common fatal cancer next to lung cancer. Aspirin is believed to have a chemopreventive role in colorectal cancer based on considerable observational data, which show that the rates of colorectal cancers and adenomas are 40%-50% lower in aspirin users[1,2]. Aspirin is a nonsteroidal anti-inflammatory drug (NSAID). There have been indications that use of NSAIDs can lead to the regression of colorectal adenomas[3]. In several rodent models of colorectal cancer, the NSAIDs indomethacin, aspirin, sulindac and piroxicam were shown to be able to reduce tumor growth[4]. However, the molecular mechanisms underlying the cancer preventive effects of NSAIDs are not well understood, and this has been an active issue of research interest.

Commonly, prevention of cancer may be implemented

through several means, including cell cycle arrest, induction of apoptosis and inhibition of angiogenesis. One most widely accepted mechanism for the anticancer effect of NSAIDs is the reduction of prostaglandin synthesis by inhibiting COX activity[5-7]. However, the importance of COX inhibition for the anti-proliferative effects of NSAIDs is controversial at the present time, since NSAIDs also manifest growth inhibitory effects against colon cancer cell lines that do not express COX-1 or COX-2 enzymes[8-11]. A common mechanism of NSAID action appears to be the induction of apoptosis, although several *in vitro* studies in CRC cells have proposed that different molecular pathways may be affected by distinct types of NSAIDs[9,12-14]. To date, little is known about the COX-independent molecular targets of NSAID action in cancer cells.

The mitogen-activated protein kinase (MAPK) superfamily, including the extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 MAPK, is involved in mediating the processes of cell growth and death[15,16]. JNK and p38 MAPK pathways are activated in response to chemicals and environmental stress[17], while the ERK cascade, activated by mitogenic stimuli, is critical for proliferation and survival[18]. Recent evidence indicates that the MAPK family proteins are important mediators of apoptosis induced by stressful stimuli[18,19]. JNK and p38 MAPK are collectively termed stress-activated protein kinases because they are activated by a variety of stress-related stimuli and also activated by chemotherapy drugs[20,21]. Activation of p38 MAPK distorts mitochondrial function *via* an increase in the ratio of Bax and anti-apoptotic (Bcl-2) members leading to an increased mitochondrial membrane permeability, the release of cytochrome c, and the activation of caspases[22]. Once activated, p38 regulates multiple cellular processes, including transcription, translation, cell cycle progression, and apoptosis. Schwenger *et al*[23] previously showed that sodium salicylate, the active component of aspirin, activated p38 to induce apoptosis. Also, aspirin activates the p38MAPK pathway, leading to the degradation of cyclin D1, nucleolar translocation of RelA, and apoptosis[24].

Sox genes encode transcription factors that possess strong homology to the high-mobility group (HMG box), which are homologous to sex-determining region of Y-chromosome in the HMG box. There are at least 30 Sox members expressed in many different cell types and tissues, and at multiple stages during development[25]. Sex-determining region Y-box 7 (Sox7), together with Sox17 and Sox18, belongs to the Sox group F subfamily. Sox7 encodes an HMG box transcription factor and has been implicated in parietal endoderm differentiation[26]. Our previous study demonstrated that the expression of SOX7 mRNA was frequently down-regulated in human colorectal cancer cell lines and in primary colorectal tumor tissues, and restoration of SOX7 induced colorectal cancer cell apoptosis, inhibited cell proliferation and colony formation[27].

Despite these available data, the mechanistic function of aspirin in inhibiting COX2 negative colorectal cancer cells awaits further investigation. In this study, we have examined the role of SOX7 in aspirin-mediated growth inhibition of COX2 negative SW480 cells, and we found that SOX7 is regulated by aspirin and the p38 MAPK pathway in SW480 cells. Our study has disclosed the involvement of SOX7 in aspirin-mediated growth inhibition of COX2 negative cancer cells, providing a new insight into the mechanism by which aspirin inhibits COX2 negative colorectal cancer.

MATERIALS AND METHODS

Cell lines and reagents

Human colorectal cancer cell line SW480 and human embryonic kidney HEK-293T cells were cultured in appropriate media with 10% FBS (fetal bovine serum), 100 U/mL penicillin and 100 μg/mL streptomycin, and kept in a humidified atmosphere of 20 mL/L CO_2. Genomic DNA was extracted using the standard Proteinase-K method. Total RNA was extracted by using the Trizol reagent (TAKARA).

Drug treatment

Aspirin (Sigma, St. Louis, MO) was dissolved in 1 mol/L Tris-HCl (pH 7.5) to a stock concentration of 1 mol/L and the pH adjusted to 7.2 with 4 mol/L HCl. SW480 cells were treated for 24, 48 and 72 h by adding various volumes of stock to obtain final concentrations of 1, 2 and 5 mmol/L of aspirin. Control cells were treated with an equivalent volume of Tris-HCl (pH 7.2).

The p38 inhibitor SB203580 (Sigma, St. Louis, MO) was dissolved in dimethyl sulfoxide (DMSO) to a stock concentration of 10 mmol/L. SW480 cells were treated with 10 μmol/L SB203580 for 30 h. Control cells were treated with an equivalent volume of DMSO.

MTT assay

Cell proliferation was assessed by the MTT (Moto-nuclear cell direc cytotoxicity assay) [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazoliumbromide] assay. SW480 cells were plated at 1×10^3 cells/well on 96-well plates. After treatment with aspirin or transfection, 20 μL of MTT (5 mg/mL) was added to each well; the samples were incubated for 4 h at 37 ℃ and then subcultured in the medium with 100 μL DMSO. The absorbance of each well was determined at 492 nm. Survival percentage (%) was calculated relative to the control.

Plasmid constructs and transfection

SOX7 gene promoter (GenBank accession NM_031439) was cloned by PCR from the genome derived from normal human colorectal tissue using the following primers: 5'-CCCAAGCTTCTGCCGACTTTCATTCAGTAGGTG-3' (sense) and 5'-CCGCTCGAGGTAGGCTCCCAGCAGCGAAG-3' (antisense). To generate SOX7 promoter-luciferase (pGL3-SOX7-luc) construct, the PCR production was subcloned into the pGL3 enhancer vector *via* *Hin*dⅢ and *Xho*l Ⅰ sites. Short interfering RNA (siRNA) targeting SOX7 sequence (ACGCCGAGCTGTCGGATGG) was synthesized[27]. An oligonucleotide that represents the siRNA was cloned into the pSliencer4.1-CMV neo-vector (Ambion) between *Bam*H Ⅰ and *Hin*d Ⅲ sites following the manufacturer's instructions. c-Fos

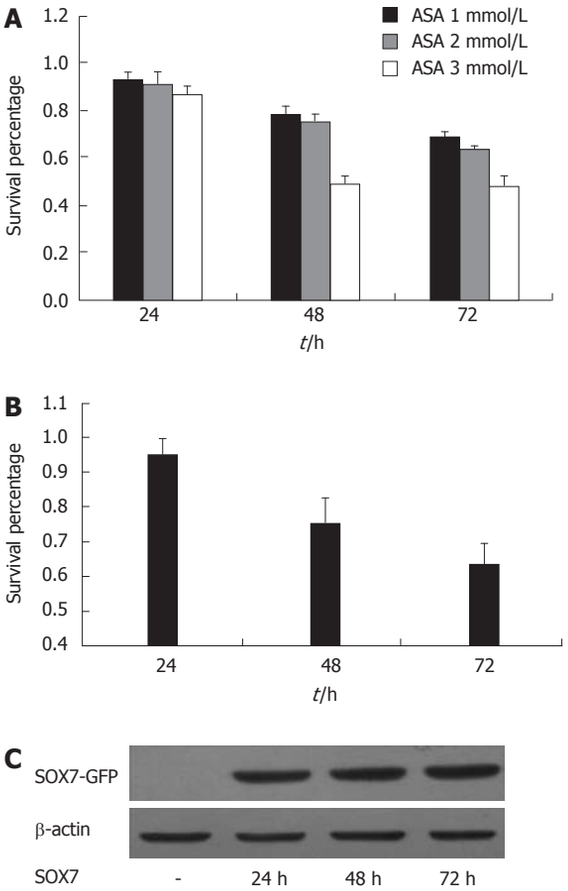

Figure 1 Aspirin and SOX7 inhibit the growth of SW480 cells. A: Dose- and time-dependent effects of aspirin on the growth rates of SW480 human colon cancer cells. SW480 cells were treated for 24, 48 or 72 h in aspirin-containing culture medium; 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay was used to estimate the survival percentage compared with untreated cells; B: Effect of SOX7 expression on cell proliferation. MTT assay was used to estimate the proliferation at different time points after transfection of SOX7 expression vector; C: Western blotting was used to verify the expression of SOX7 after transfection of SOX7 expression vector at indicated time points. MTT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide. ASA: Aspirin.

and c-Jun were gifts from Dr. Shizuo Akira (Osaka University, Japan); p38α was a gift from Dr. Roger David (University of Mass. Medical School); and SOX7 expression plasmid was previously constructed in this laboratory[27]. Plasmids were transfected using Lipofectamine™ 2000 (Invitrogen) follow the manufacturer's instructions.

Luciferase reporter assay

Reporter gene assays were done as previously described[27]. Briefly, 5×10^4 cells were seeded in 24-well tissue culture plates 24 h before transfection. The pGL3-SOX7-luc reporter vector was transfected at 500 ng/well and the *Renilla* luciferase control plasmid pREP7-RLuc was cotransfected at 50 ng/well as an internal control reporter. After treatment with indicated doses of aspirin or cotransfection with c-Fos and c-Jun expression vectors for 24 h, cells were washed and lysed in passive lysis buffer (Promega) and the transfection efficiency was normalized to the paired *Renilla* luciferase activity by using the Dual Luciferase Reporter Assay System (Promega) according to the manufacturer's instructions.

Reverse transcription-polymerase chain reaction

For cDNA synthesis, 1 μg of total RNA was reverse transcribed using the RT-Systems supplied by Promega. Quantitative real-time reverse transcription-polymerase chain reaction (RT-PCR) was carried out on an ABI Prism 7000 Sequence Detection System (Applied Biosystems), and SYBR Green (TOYOBO) was used as a double-stranded DNA-specific fluorescent dye. The PCR primer sequences were as follows: SOX7: 5'-ACCAACGGGTCCCACAGA-3'(sense) and 5'-CCACTCAAGGCACAAGAAGG-3' (antisense)[27]; β-actin: 5'-TCGTGCGTGACATTAAGGAG-3' (sense) and 5'-ATGCCAGGGTACATGGTGGT-3' (antisense)[28].

Western blotting assay

Western blotting was performed as described previously[29]. The primary antibodies used were the mouse anti-SOX7 (1:1 000, R&D system) and mouse anti-β-actin (1:10 000, Sigma).

RESULTS

Aspirin and SOX7 inhibit the growth of SW480 human colorectal cancer cells

We first demonstrated that aspirin treatment results in a profound concentration- and time-dependent reduction in the proliferation rate of SW480 cells (Figure 1A). Our previous experiments showed that SOX7 was frequently down-regulated in human colorectal cancer cell lines including SW480[27]. In order to investigate the relationship between SOX7 and aspirin, we tested the effect of SOX7 on the growth of SW480 cells, and we found that restoration of SOX7 inhibits SW480 cell proliferation (Figure 1B and C).

SOX7 is induced by aspirin in SW480 colorectal cancer cells

Since both aspirin and SOX7 were able to inhibit the growth of SW480 cells, we sought to examine whether SOX7 can be induced by aspirin in SW480 cells. Our reporter gene experiments demonstrated that aspirin upregulated the activities of SOX7 promoter, and a dose of 1 mmol/L aspirin was sufficient to induce SOX7 promoter activity (Figure 2A). This dose was then used in the later experiments throughout the study. RT-PCR and Western blot assays showed that the mRNA (Figure 2B) and protein (Figure 2C) levels of SOX7 were both upregulated by 1 mmol/L aspirin. These data indicate that the SOX7 expression is induced by aspirin in SW480 cells.

SOX7 is involved in aspirin-mediated growth inhibition of human colorectal cancer cells

The above data indicate that both aspirin and SOX7 inhibit the growth of SW480 cells, and aspirin upregulates the expression of SOX7 in SW480 cells. We next intended to determine whether SOX7 played a role in aspirin-inhibited growth of SW480 cells. First, we constructed a SOX7 siRNA plasmid and tested the interference efficiency of this plasmid. As shown in Figure 3A, transfection of SW480 cells with SOX7 siRNA plasmid resulted

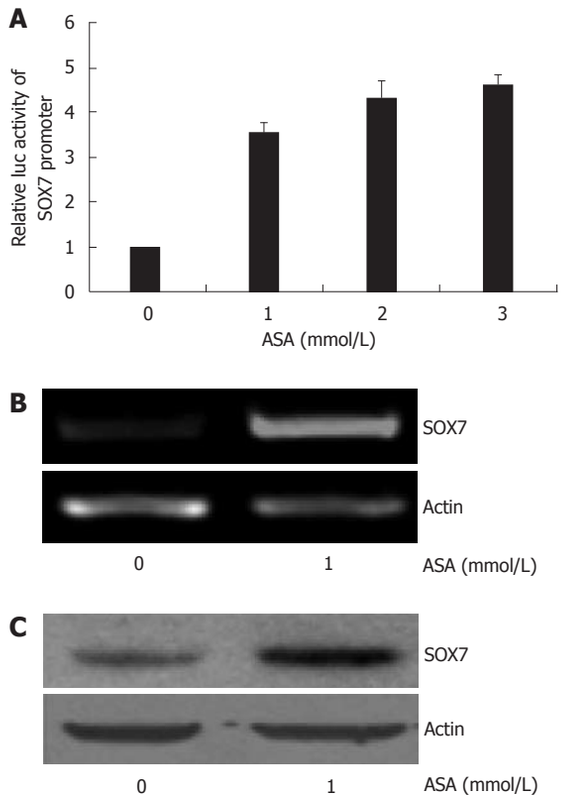

Figure 2 Aspirin upregulates SOX7 expression in SW480 cells. A: SW480 cells were transfected with pGL3-SOX7-luc plasmid, and relative luciferase activity was determined after treatment with different doses of aspirin for 24 h; B and C: Reverse transcription-polymerase chain reaction (B) and Western blotting (C) detected the expression of SOX7 after treatment with aspirin for 30 h; β-actin was used as the internal reference. ASA: Aspirin.

in a significant reduction in the SOX7 protein expression induced by aspirin, confirming the effective interference of this SOX7-siRNA. We then transfected SOX7 siRNA plasmid into SW480 cells, and we found that interference of SOX7 expression restored the growth rate of the aspirin-inhibited SW480 cells (Figure 3B). This indicated that SOX7 is involved in aspirin-mediated growth inhibition of human colorectal cancer SW480 cells.

Aspirin induces SOX7 expression through the p38MAPK pathway in SW480 colorectal cancer cells

We and others have shown that the p38 MAPK pathway can be activated by aspirin (data not shown)[24]. We thus sought to examine whether the p38 MAPK pathway is involved in aspirin-induced SOX7 expression. We demonstrated that SOX7 mRNA is significantly upregulated upon the overexpression of p38α in SW480 cells (Figure 4A). In contrast, in HEK-293T cells that express relatively high levels of SOX7, inhibition of p38 by SB203580 reduced the mRNA level of SOX7 (Figure 4B). We further examined the effects of the p38 inhibitor SB203580 on aspirin-induced SOX7 expression, and we discovered that chemical inhibition of p38 substantially abrogates the aspirin-induced upregulation of SOX7. We also found that upon the inhibition of the p38 MAPK pathway by SB203580, the upregulation of SOX7 by aspirin is counteracted at

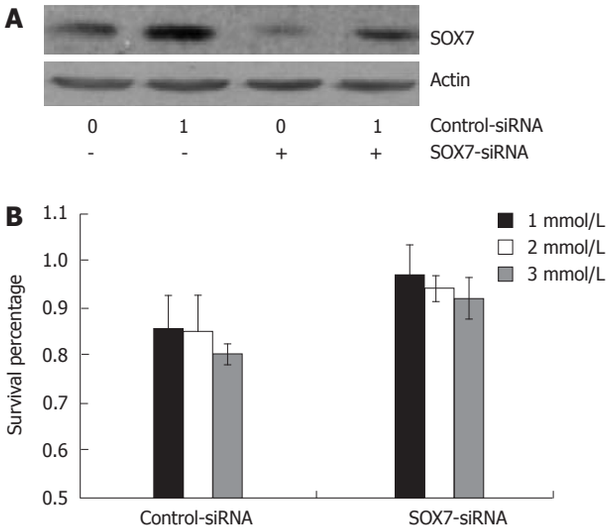

Figure 3 Knockdown of SOX7 counteracts the growth inhibitory effect of aspirin in SW480 cells. A: Western blotting verification of the interfering efficiency of SOX7 Short interfering RNA in aspirin-treated SW480 cells. β-actin was used as the internal reference; B: Effect of SOX7 knockdown on SW480 cell proliferation after treatment with different doses of aspirin for 48 h by moto-nuclear cell direc cytotoxicity assay assay. MTT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide.

both mRNA and protein levels (Figure 4C and D). In addition, our data show that the AP1 transcription factors c-Jun and c-Fos upregulate SOX7 promoter activities in SW480 cells (Figure 4E).

DISCUSSION

The primary purpose of this study was to shed insights into the complex mechanistic action of aspirin in colorectal cancer inhibition and prevention. The results of the study show that SOX7 is upregulated by aspirin, and that SOX7 is involved in aspirin-mediated growth inhibition of human colorectal cancer SW480 cells. Moreover, we provided evidence that aspirin induces SOX7 expression through the p38 MAPK pathway.

Recently, aspirin and related NSAIDs have attracted considerable research attention as the compounds that might be of potential benefit in the chemoprevention of cancer[2]. However, the molecular mechanisms by which aspirin and related NSAIDs inhibit tumor formation and growth have largely remained unsolved; and hence the utilization of these compounds in cancer therapeutics is still a substantially disputed issue. One potential mechanism underlying the action of NSAIDs involves the inhibition of COX activity[5]; but there is evidence that in COX negative colorectal cancer SW480 cells, aspirin is also able to inhibit the growth of the cells[8]. Goel *et al*[30] reported that aspirin could act through COX-independent mechanisms that resulted in an increased expression of DNA mismatch repair proteins and subsequent apoptosis in SW480 cells. Our previous data suggested that the *SOX7* gene may play a crucial role in colorectal cancer development as a tumor suppressor[27]. The data from the present study show that SOX7 is upregulated by aspirin in SW480

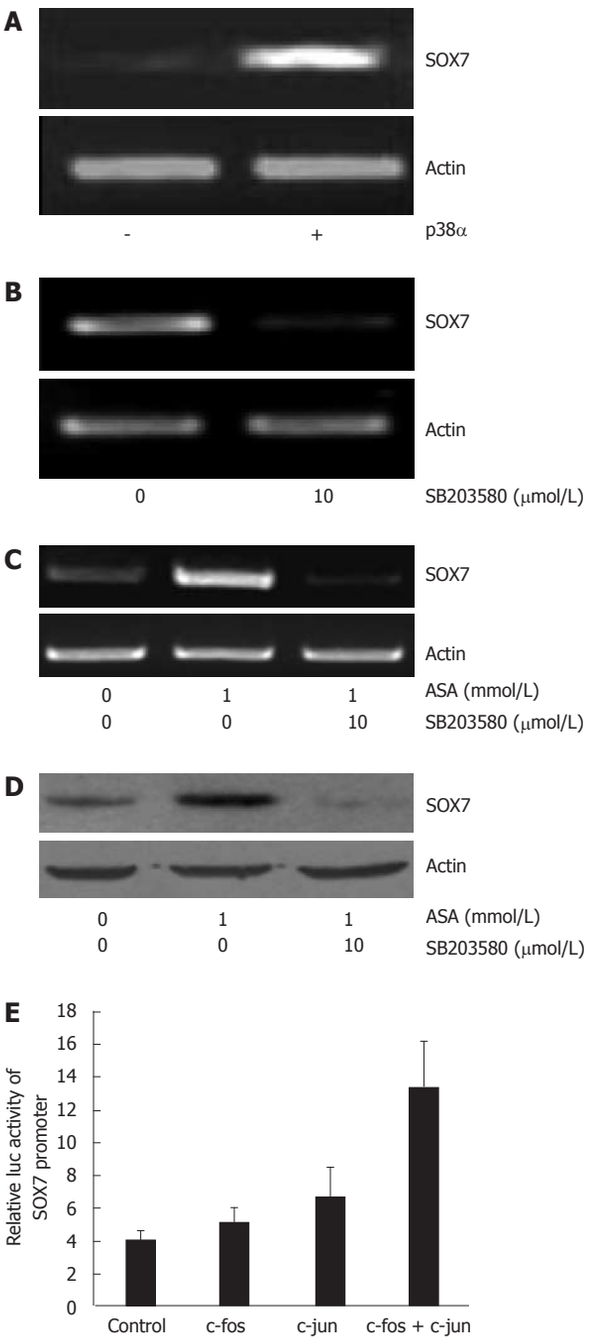

Figure 4 Role of the p38MAPK pathway in aspirin-induced SOX7 expression. A: HEK 293T cells were transfected with p38α expression vector; reverse transcription-polymerase chain reaction (RT-PCR) was used to detect SOX7 mRNA level 30 h after transfection; B: SW480 cells were treated with 10 μmol/L SB203580 for 30 h and SOX7 mRNA level was measured by RT-PCR; C: SW480 cells were treated with aspirin or aspirin combined with SB203580 for 30 h and SOX7 mRNA level was measured by RT-PCR; D: Cells were treated as in Figure 4 and SOX7 protein level was detected by Western blot; E: SW480 cells were transfected with pGL3-SOX7-luc plasmid and various expression vectors as indicated for 24 h and relative luciferase activity was examined. ASA: Aspirin.

cells and that it is involved in aspirin-mediated growth inhibition of SW480 cells (Figures 2 and 3), implying that SOX7 may be a target for aspirin in COX-independent cancer cells.

The p38 MAPK pathway plays pivotal roles in regulation of inflammation, proliferation, and cell death. Activation of the p38 pathway is generally mediated by conditions of cell stress and culminates in phosphorylation of p38 on a conserved regulatory domain by the upstream kinases MKK3 and MKK6[31]. In COX negative colorectal cancer SW480 cells, aspirin can activate the p38 MAPK pathway[24]. However, the mechanisms that are involved in this process need to be future investigated. Moreover, in the process of mouse preimplantation development, inhibition of the p38 MAP kinase pathway resulted in the suppression of SOX7 expression, implying that SOX7 may be a target gene of the p38 MAPK pathway[32]. Our experiments in this study indeed prove that the chemical inhibition of p38 substantially abrogates the upregulation of SOX7 upon aspirin treatment (Figure 4). These results indicate that SOX7 is regulated by aspirin and the p38 MAPK pathway in COX negative colorectal cancer cells.

The AP1 transcription complex consists of homodimers and heterodimers of the members from the fos (c-fos, fosB, fra-1 and fra-2) and jun (c-jun, junB and junD) families, and the complex activates target genes by binding with high affinity to particular DNA cis-elements, i.e., the 12-O-tetradecanoylphorbol-13-acetate (TPA) response elements (TRE)[33]. The AP1 activity is regulated at the transcriptional and post-translational levels by several external stimuli, mainly involving MAPK cascades[34]. Our Luciferase reporter assays showed that SOX7 promoter activity was moderately upregulated upon the overexpression of c-fos or c-jun, but markedly upregulated upon the simultaneous overexpression of both c-fos and c-jun (Figure 4E), indicating that c-fos and c-jun may form a dimer to regulate SOX7 promoter, though the details need to be further studied.

In summary, the experimental data presented in this report demonstrate that SOX7 is upregulated by aspirin and is involved in aspirin-mediated growth inhibition of human colorectal cancer SW480 cells. The regulation of SOX7 by aspirin is implemented through the p38MAPK pathway. Overall, this study will help to advance our understanding of the mechanisms of action of aspirin in inhibiting COX-independent colorectal cancer cells.

COMMENTS

Background

Colorectal cancer (CRC) is one of the most prevalent cancers worldwide. Aspirin has been implicated to prevent CRC. The p38MAPK pathway is activated in aspirin-mediated apoptosis in a number of cancer cells. The sex-determining region Y-box 7 (Sox7) is a member of the high mobility group (HMG) transcription factor family, essential for embryonic development and endoderm differentiation.

Research frontiers

Aspirin is a nonsteroidal anti-inflammatory drug (NSAID), which has been implicated in preventing human colorectal cancer (CRC). However, the molecular mechanisms underlying the cancer preventive effects of NSAIDs are not well understood, and this has been an active issue of research interest. One most widely accepted mechanism for the anticancer effect of NSAIDs is the reduction of prostaglandin synthesis by inhibiting COX activity. To date, little is known about the COX-independent molecular targets of NSAID action in cancer cells.

Innovations and breakthroughs

The experimental data presented in this report demonstrate that SOX7 is upregulated by aspirin and is involved in aspirin-mediated growth inhibition of COX-independent human colorectal cancer SW480 cells. The regulation of SOX7 by aspirin is implemented through the p38MAPK pathway. Overall, this study will help to advance our understanding towards the mechanisms of action of aspirin in inhibiting COX-independent colorectal cancer cells.

Applications

By understanding how SOX7 is involved in aspirin-mediated growth inhibition of COX-independent human colorectal cancer cells, this study may represent a future gene target strategy for patients with COX-independent colorectal cancer.

Terminology

SOX7 is an HMG box transcription factor and has been implicated in parietal endoderm differentiation; recent reports have referred to the role of SOX7 in tumor suppression. mitogen-activated protein kinase (MAPK) is the mitogen-activated protein kinase superfamily, which includes the extracellular signal-regulated kinase, c-Jun N-terminal kinase, and p38 MAPK, and is involved in mediating the processes of cell growth and death. Recent evidence indicates that the MAPK family proteins are important mediators of apoptosis induced by stressful stimuli.

Peer review

The authors examined the role of SOX7 in aspirin-mediated growth inhibition of COX2 negative SW480 cells, and found that SOX7 was regulated by aspirin and the p38 MAPK pathway in SW480 cells. The present results disclose the involvement of SOX7 in aspirin-mediated growth inhibition of COX2 negative cancer cells, providing a new insight to the mechanism as to how aspirin inhibits COX2 negative colorectal cancer.

Abstract

Drug-induced hypersensitivity syndrome (DIHS) is a severe reaction usually characterized by fever, rash, and multiorgan failure, occurring 2-6 wk after drug introduction. It is an immune-mediated reaction involving macrophage and T-lymphocyte activation and cytokine release. A 54-year-old woman was diagnosed with rheumatic arthritis and initiated salazosulfapyridine by mouth. About 10 d later, she had a high fever, skin rash and liver dysfunction. She was admitted to hospital and diagnosed with a drug eruption. She was treated with oral prednisolone 30 mg/d; however, she developed high fever again and her blood tests showed acute liver failure and cytopenia associated with hyperferritinemia. She was diagnosed with acute liver failure and hemophagocytosis caused by DIHS. She was transferred to the Department of Medicine and Bioregulatory Science, Kyushu University, where she was treated with arterial steroid injection therapy. Following this treatment, her liver function improved and serum ferritin immediately decreased. We hypothesized that an immune-mediated reaction in DIHS may have generated over-activation of macrophages and T-lymphocytes, followed by a cytokine storm that affected various organs. The measurement of serum ferritin might be a useful marker of the severity of DIHS.

INTRODUCTION

Drug-induced hypersensitivity syndrome (DIHS) is one of the most severe drug eruptions, and is similar to toxic epidermal necrolysis and Stevens-Johnson syndrome[1]. It is characterized by maculopapular rash, high fever (≥ 38 ℃), hepatic dysfunction, leukocytosis with eosinophilia, and an increased number of atypical lymphocytes usually appearing 2-6 wk after exposure to certain drugs[2]. Although the pathology of DIHS remains unknown, in-

volvement of human herpes virus 6 (HHV-6) has recently been suggested[3,4]. DIHS is an immune-mediated reaction involving macrophage and T-lymphocyte activation and cytokine release associated with HHV-6 reactivation. However, there is no consensus on its etiology[5,6]. On the other hand, overactivation of macrophages is crucial for the development of other diseases, including hemophagocytic syndrome[7]. In patients with hemophagocytic syndrome, increased serum ferritin levels are thought to be secreted by activated macrophages[8]. However, to our knowledge, there are few reports that examine the correlation between the severity of DIHS and serum ferritin levels. In this report, we describe a case of acute liver failure (ALF) caused by DIHS associated with hyperferritinemia.

CASE REPORT

In January 2009, a 54-year-old woman presented to a clinic with morning stiffness in her hands. She was diagnosed with rheumatic arthritis and started treatment with oral salazosulfapyridine at 1 g/d on January 21. She developed a rash on her upper and lower extremities on February 2, with a fever of 37.6 ℃ on February 5. She presented to the clinic and discontinued salazosulfapyridine. Her blood test showed liver enzyme elevation [aspartate aminotransferase (AST), 50 U/L; alanine aminotransferase (ALT), 65 U/L]. However, her skin rash worsened. She was admitted to the Department of Dermatology, Kyushu Medical Center, National Hospital Organization on February 13. On admission, she had multiple areas of exudative erythema on her trunk and limbs. Laboratory data showed a white blood cell count of 14 700/μL with 9.0% eosinophils. AST and ALT levels were 59 U/L and 112 U/L, respectively.

She was diagnosed with drug eruption on the basis of clinical symptoms and the results of laboratory data, and treated with oral prednisolone 30 mg/d. After treatment, her liver function and rash improved gradually. However, she developed a high fever again on February 17. Her blood test showed ALF and cytopenia. Laboratory data on February 20 were as follows: white blood cell count of 6200/μL with 2.0% eosinophils; hemoglobin, 10.8 g/dL; platelet counts, 63 000/mm^3; AST, 1849 IU/L; ALT, 1623 IU/L; PT-INR, 1.79. Ultrasonography showed moderate ascites. A bone marrow aspiration demonstrated an increased number of macrophages with hemophagocytosis. The patient was diagnosed with ALF and hemophagocytosis caused by DIHS. She was transferred to the Department of Medicine and Bioregulatory Science, Kyushu University, for treatment of ALF.

Laboratory data on admission were as follows: total bilirubin, 5.8 mg/dL; AST, 2121 IU/L; ALT, 2231 IU/L; alkaline phosphatase, 1283 IU/L; γ-glutamyl transpeptidase, 736 IU/L; ferritin, 14 270 ng/mL; PT-INR, 1.79. Viral markers were negative for hepatitis A-C, Epstein-Barr virus, and cytomegalovirus. Serum anti-HHV-6 immunoglobulin G (IgG) titer was normal, but HHV-6 DNA was positive. She had multiple areas of exudative erythema on her trunk and limbs (Figure 1) and swelling of cervical lymph nodes. Abdominal computed tomography showed edematous change of the portal vein and moderate ascites (Figure 2).

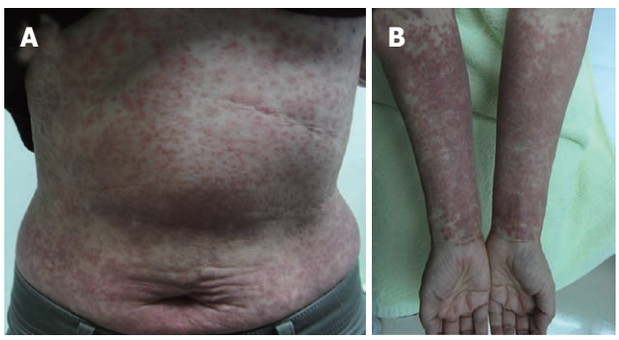

Figure 1 Multiple areas of exudative erythema were seen on admission. A: Body trunk; B: Forearm.

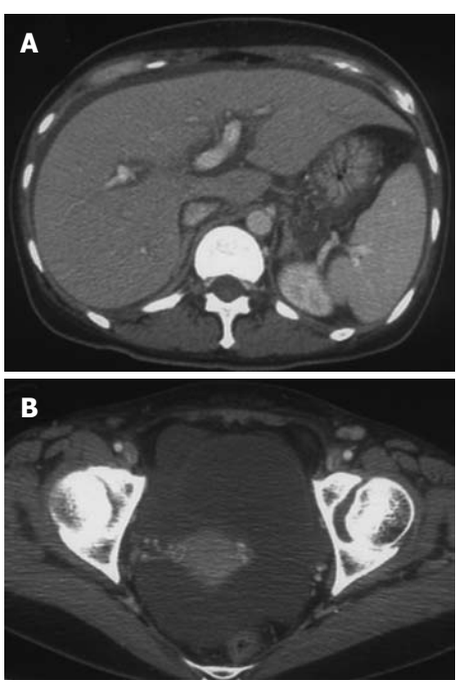

Figure 2 Abdominal computed tomography. A: Edema of portal vein; B: Moderate ascites.

Our diagnosis was DIHS based on high fever, rash, liver dysfunction, swelling of cervical lymph nodes, and eosinophilia. Hyperferritinemia in her blood samples led us to think that activated macrophages in the liver might play a key role in ALF. Therefore, we decided to use arterial steroid injection therapy to suppress macrophage activation seen in ALF[9].

A 5-frame catheter was inserted from the right femoral artery to the common hepatic artery and the tip of the catheter was set in the proper hepatic artery. After insertion of the catheter, 1000 mg of methylprednisolone was infused for 2 h per day. We also performed plasma exchange therapy on the first day of admission, because

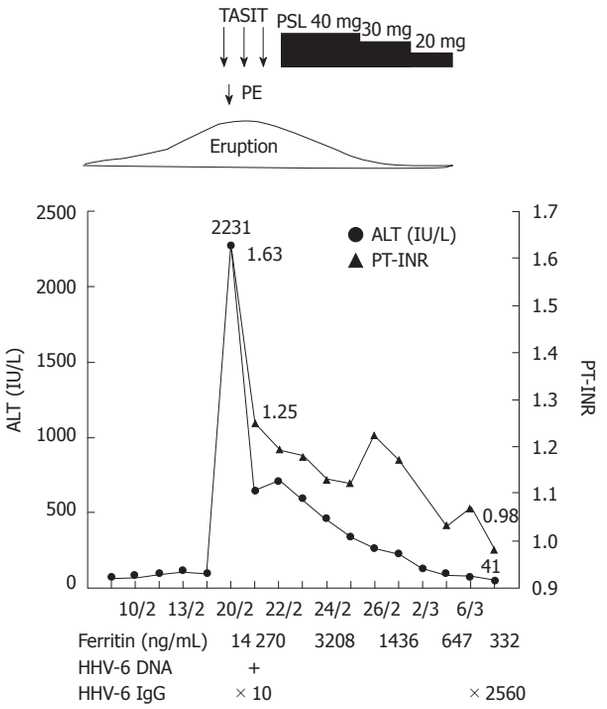

Figure 3 Clinical course of the patient. PE: Plasma exchange, TASIT: Transarterial steroid injection therapy.

the level of PT-INR was decreased. The arterial steroid injections were continued for 3 d, and the catheter was removed just after injection on the third day. Following arterial steroid injection therapy, her liver function improved immediately (Figure 3). Laboratory data on the fourth day of admission were as follows: AST 180 IU/L; ALT 597 IU/L; PT-INR, 1.18. After arterial steroid injection therapy, we started treatment with oral prednisolone at 40 mg/d and gradually decreased the dose. When liver dysfunction resolved, she was discharged from hospital (on March 3). In a serum sample taken 2 wk after hospitalization, anti-HHV-6 IgG titer had increased from 1:10 to 1:2560. She was diagnosed with typical DIHS according to criteria proposed by the Japanese Consensus Group; the patient had 7 items.

DISCUSSION

It is well-known that many patients with DIHS suffer liver injury and some progress to fatal liver failure. Until now, however, there has been no explanation of what causes ALF in some patients. Recently, it has been widely accepted that reactivation of herpes viruses such as HHV-6 and Epstein-Barr virus play a key role in the development of DIHS[3,4]. The question then becomes whether the reactivation of these viruses also contributes to the progression to ALF.

Hashimoto *et al*[10] evaluated clinical symptoms in 100 patients with DIHS and found that those with increasing serum anti-HHV-6 IgG titers suffered from severe organ involvement and a prolonged course of illness. In addition, they noted that flaring of symptoms, such as fever and hepatitis, was closely related to HHV-6 reactivation. However, none of the subjects in the study had ALF. In an investigation of case reports on the progression to ALF from DIHS, none indicated a correlation between viral reactivation and the development of ALF.

Since DIHS is triggered by some drugs, we should evaluate the possibility of drug-induced reactions that might directly harm hepatocytes and cause ALF. To our knowledge, there is no evidence that ALF is easily caused by specific drugs or in a dose-dependent manner. Therefore, we believe that the drugs causing DIHS do not directly injure numerous hepatocytes.

Some authors, speculating on the mechanism of progression to ALF, have indicated that DIHS develops through an immune-mediated reaction involving macrophages and T-lymphocytes[11]. In the last decade, several studies have suggested that activated intrahepatic macrophages play a key role in the development of ALF[12,13]. We also observed over-activation of intrahepatic macrophages in most of the patients with ALF in Japan[14]. One of the findings supporting this hypothesis is the markedly elevated serum ferritin concentration in those patients.

The patient presented in this report also had a markedly elevated serum ferritin concentration of over 20 000 ng/mL. One hypothesis is that intrahepatic over-activation of macrophages contributes to the development of ALF from DIHS as well as other etiologies. However, none of the past reports describing ALF from DIHS have referred to the elevation of serum ferritin concentration. To evaluate this hypothesis, cohort studies have focused on the correlation between the clinical course of patients with ALF from DIHS and the factors reflecting immune-mediated reactions.

Patients with DIHS can suffer not only from liver failure, but also various patterns of multiple organ failure, however, it remains unclear what induces these complications. We have hypothesized that an immune-mediated reaction in DIHS might generate over-activation of macrophages and T-lymphocytes, followed by a cytokine storm that affects various organs. In fact, this patient had elevated serum cytokines on admission (IL-6 10.8 pg/mL; IL-10 21 pg/mL). Such an immune reaction in bone marrow would result in pancytopenia, and liver involvement would cause liver failure. Both of these were seen in our patient.

It is well known that corticosteroids can suppress the activity of macrophages[15,16]. Therefore, it seems appropriate to use high-dose corticosteroids for DIHS. However, past reports show that corticosteroids are not always effective for ALF from DIHS. We speculate that intravenous injection of corticosteroids could be ineffective because the disturbance of hepatic microcirculation would prevent the drug from diffusing to the whole liver. Even in such a situation, injection *via* hepatic artery might be a useful option.

In this case report, we described a patient with ALF caused by DIHS associated with hyperferritinemia. In conclusion, we speculate that activated macrophages and

a cytokine storm were associated with DIHS. The measurement of serum ferritin might be a useful marker of the severity of DIHS.

Abstract

Pneumatosis cystoides intestinalis (PCI) is a rare condition that may be associated with a variety of diseases. The presenting clinical picture may be very heterogeneous and represent a challenge for the clinician. In the present paper we describe both a common and an uncommon clinical presentation of PCI and review the pertaining literature. Our cases confirm that, apart from asymptomatic cases, the clinical presentation of PCI may be widely different and suggest that a new onset of stipsis might be the presenting symptom. Diagnosis might be suggested by a simple X-ray of the digestive tract showing a change in the characteristics of the intestinal wall in two-thirds of these patients. However, one third of the patients do not have a suggestive X-ray and require a computed tomography (CT) scan/nuclear magnetic resonance that may reveal a thickened bowel wall containing gas to confirm the diagnosis and distinguish PCI from intraluminal air or submucosal fat. CT also allows the detection of additional findings that may suggest an underlying, potentially worrisome cause of PCI such as bowel wall thickening, altered contrast mucosal enhancement, dilated bowel, soft tissue stranding, ascites and the presence of portal air. Our results also point out that clinicians and endoscopists should be aware of the possible presentations of PCI in order to correctly manage the patients affected with this disease and avoid unnecessary surgeries. The increasing number of colonoscopies performed for colon cancer screening makes PCI more frequently casually encountered and/or provoked, therefore the possible endoscopic appearances of this disease should be well known by endoscopists.

INTRODUCTION

Pneumatosis cystoides intestinalis (PCI) is a rare disease characterized by the presence of gaseous cysts containing nitrogen, hydrogen and carbon dioxide[1] in the intestinal wall that may be iatrogenic[2-5] or associated with a wide variety of conditions[6-9].

In particular, the cysts are located beneath the serosa and mucosa of the intestine with an increase, in recent years, of cases of colonic localization due to an increase in the number of examinations with barium and colonoscopies[10].

Jamart[11] in a study of 919 cases in 1979 found a prevalence of 42% for ileal localization, and 36% for the colon, in the remaining 22% of cases both the small and the large intestine were involved.

The exact etiology of the disease is still unknown. PCI may appear in association with ileal surgery[12], colonoscopies[5], chronic pulmonary disease[13], connective tissue disorders[14] and ingestion of sorbitol[15] or lactulose[16].

Various theories have been proposed: mechanical, bacterial and pulmonary. According to the mechanical theory, the bowel gas is pushed through a mucosal defect into lymphatic channels and is then distributed distally by peristalsis[17]. This may happen secondarily to a bowel obstruction that may be caused by trauma, surgery and colonoscopy leading to increased intraluminal pressure[18] and this could explain the association between these maneuvers and PCI. However this theory does not explain the high content of hydrogen present in the cysts[19].

The bacterial theory proposes that submucosal localization of fermenting *Clostridia* and *Escherichia Coli* leads to the production of gas which is retained by the submucosa and lymphatic channels. In fact, in animal experiments the introduction of bacteria in the gut wall by injection causes the pneumatosis and these cysts have a high content of hydrogen[13]. This theory is also supported by the resolution of pneumatosis with the use of metronidazole for bacterial overgrowth[20].

The pulmonary theory is demonstrated in patients with asthma and chronic bronchitis and argues that the gas freed by the rupture of the alveoli, travels through the mediastinum into the retroperitoneal space and then comes through the perivascular spaces in the intestinal wall[21].

Some recent reports[22] show an association between PCI and treatment with alpha-glucosidase inhibitor. The explanation would be the fermentation of carbohydrates by the intestinal bacterial flora with production of intestinal gas. The absorption of these carbohydrates is inhibited by αGI. Here we describe two cases of pneumatosis cystoides intestinalis.

CASE REPORT

Case 1

A 49 years old male (S.A.) presented to the gastroenterology outpatient clinic for abdominal pain. The pain was crampy and diffuse with no clear localization in the abdomen and had no clear relationship with meals or evacuation. Bowel habit was characterized by chronic constipation; the abdomen showed no relevant physical findings, in particular there was no palpable mass. The patient also suffered from a chronic obstructive pulmonary disease and had finger clubbing. Routine biochemical examinations were within normal values as well as inflammation indices. The physician prescribed a colonoscopy revealing melanosis coli, a sessile polyp 2 cm in diameter and two sessile formations with a large base and a reddened but regular overlying mucosa (Figure 1). The formations appeared soft when touched with a closed biopsy forceps and collapsed when biopsied suggesting the presence of air. The endoscopist performed multiple biopsies along the colon. The pathologist described the presence of optically empty spaces in the biopsies confirming the hypothesis of pneumatosis cystoides intestinalis. The patient was then referred to the pneumologist for oxygen therapy. At a subsequent colonoscopy the air cysts appeared reduced in volume and the patient referred pain reduction to the endoscopist. The patient did not present to subsequent control visits.

Case 2

N.F. 44 years old presented to the GI Unit for the re-evaluation of a known celiac disease. Despite adequate gluten free diet the patient complained of a worsening of his symptoms dominated by stipsis and abdominal distension. The patient suffered from recurrent subocclusive episodes and referred recent tetanic crisis from hypocalcemia on treatment with calcium and vitamin D. Biochemical analysis on admission revealed a megaloblastic anemia related to a Vitamin B12 deficiency and hypomagnesemia. Physical examination was consistent with abdominal distension and revealed hyperreflexia of the extremities. The patient had no fever nor any other remarkable finding.

The first postulated hypothesis, based on patient history was the complication of a celiac disease with intestinal lymphoma. A plain X ray of the abdomen revealed distension caused by dilatation of colonic loops leading to diaphragm elevation. The patient was then prescribed an upper GI endoscopy and an abdomen computed tomography (CT). The esophagogastroduodenoscopy revealed a normal endoscopic appearance of the mucosa and orientated biopsies were done in the distal duodenal mucosa. Histological examination revealed normal villi with a mild, non significant, lymphocytic infiltrate (below 25%) consistent with a celiac disease in remission responding to gluten free diet. The abdomen CT scan showed a complex picture including fecal stasis in the colon, severe distension of the large bowel with the presence of free air under the diaphragm (Figure 2A), and small air bubbles in the rectum wall (Figure 2B). Despite the radiologic picture, the patient was feeling well, with distended but tractable abdomen and no Blumberg sign. Therefore, the patient was kept fasting and received liquids and antibiotics iv. Subsequent radiologic evaluation of the small and large bowel, using gastrografin as contrast media, revealed no perforation suggesting that the free air might have come from the rupture of a subserosal air cyst. The patient then started hyperbaric therapy (5 treatments of 90 min: 2.5 atmospheres, 75 min of oxygen respiration divided in 3 cycles) with prompt amelioration of bowel movements and subjective feeling. The patient became asymptomatic and apyretic with normal bowel movements and was dismissed with antibiotic therapy.

DISCUSSION

There is no characteristic clinical presentation of pneumatosis. Patients may be asymptomatic or complain of

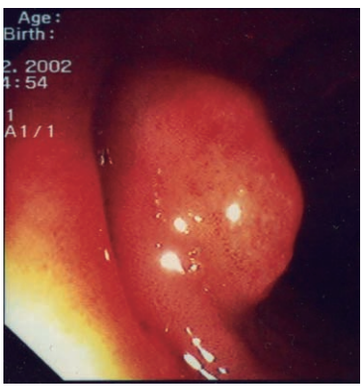

Figure 1 This photograph shows a typical endoscopic appearance of a larger cysts with a reddened overlying mucosa.

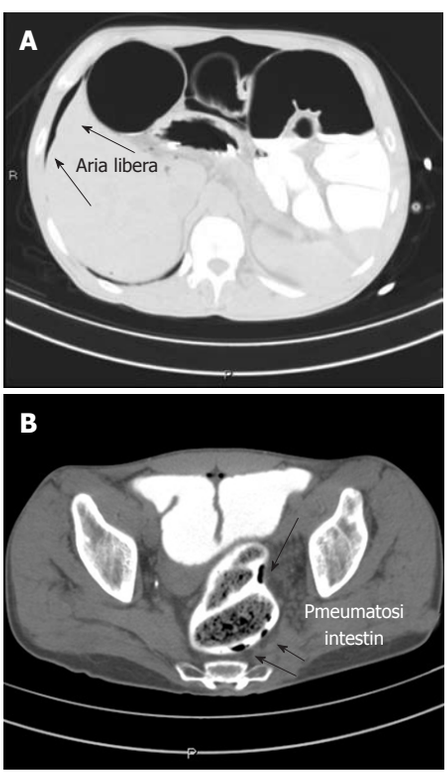

Figure 2 Computed tomography scan image. A: Presence of free air (arrows) in the abdomen; B: Presence of air in the bowel wall (arrows).

pain and abdominal distension, diarrhea and rectal blood loss with a mortality rate that may reach 75%[23]. Apart from the cases associated with chronic intestinal pseudo-obstruction[20,24,25], the majority of cases reported in the literature present with diarrhea; in the present manuscript we described two cases of PCI that presented with stipsis. The first was diagnosed after a colonoscopy that put the suspect of PCI, while the second required a CT scan because of the atypical presentation and the misleading anamnesis. In fact, the history of celiac disease lead the clinicians to hypothesize a complication of the pre-existent disease more than the onset of a new pathology. It is difficult to say whether the motility defects are a cause or a result of the pathologic condition and we are not aware of any longitudinal study evaluating such a question. However, on a purely hypothetical basis, it seems more reasonable to think that motility defects are secondary to PCI or to underlying pathological process that may have lead to PCI (i.e., ischemia, diverticular disease, *etc.*).

Colonoscopy is frequently requested to exclude colonic lesions. The endoscopic appearance of PCI is typically dual: multiple white small cysts coupled to a sub-atrophic mucosa or larger cysts (up to 3 cm) with a reddened overlying mucosa[26]. The cysts usually collapse when biopsied. Nowadays, given the increasing number of colonoscopies performed because of the colon cancer screening programs, the endoscopists should be aware of the endoscopic appearance of this rare pathology. In fact, some patients may be asymptomatic and in such cases the clinical suspect may rely on the endoscopist performing the procedure. In our case 1, the endoscopist cautiously biopsied the cyst because of his unusual appearance that was not suggestive of a typical polyp. This allowed a confirmation of the suspect and avoided an unnecessary snare polypectomy with the related costs and complications.

A simple X-ray of the digestive tract may show a change in the characteristics of the intestinal wall in two-thirds of these patients leading to further investigations. However, one third of the patients do not have a suggestive X-ray and require a CT scan/magnetic resonance imaging, showing a thickened bowel wall containing gas to confirm the diagnosis[27]. Suggestive images on plain radiography comprise different pattern of radiolucency: linear, small bubbles or collection of larger cysts[27]. CT is more sensitive than plain radiography in distinguishing PCI from intraluminal air or submucosal fat. In fact, CT more easily visualizes the presence of air in the bowel wall. Furthermore, CT allows the detection of additional findings that may suggest an underlying, potentially worrisome cause of PCI, i.e., bowel wall thickening, altered contrast mucosal enhancement, dilated bowel, soft tissue stranding, ascites, and the presence of portal air[28].

The intestinal pneumatosis may experience various complications, in particular, Goel *et al*[29] described the complications of pneumatosis of the small intestine which may be intestinal or extra-intestinal. Intestinal complications are obstruction caused by the cysts (i.e., fecal impaction) and perforation from stercoral ulceration. The extra-intestinal complications are adhesions or compression of adjacent structures by large masses of cysts.

For the resolution of these complications surgical treatment is often required because sometimes we have a picture of pneumoperitoneum due to rupture of cysts.

To determine the need for surgical therapy Knechtle *et al*[23] found a correlation between the clinical presentation, the need for surgery and the final outcome. It is necessary to evaluate six physical parameters, like pain, diarrhea, fever, tenderness, rectal blood loss and hypotension, and their severity coupled to clinical laboratory tests including white blood cell count, aspartate aminotransferases, alanine aminotransferases, alkaline phosphatase, pH, bicarbonate, lactic acid and amylase.

Surgical therapy is still a second-line therapy, chosen especially for complications, the first approach is oxygen therapy. It is also our opinion that the clinical decisions should not rely only on the radiologic picture of pneumoperitoneum, but should be coupled to the clinical symptoms (i.e., the positivity of the Blumberg sign). In fact, when the mucosa is intact surgery may be avoidable as in our case 2.

The rationale of oxygen treatment is based on increasing partial pressure of oxygen in blood and thus increasing the pressure gradient of the gas in the cysts. Cysts release gases contained within them and refills with oxygen which is then metabolized leading to resolution[26].

Oxygen therapy can be made through humidified oxygen administered by Venturi mask (6 L/min) or nasal cannula (4 L/min). However, treatment with oxygen at high doses can be toxic. The patient may experience a narcotic effect and therefore lung function should be monitored closely (during therapy) by measuring the vital capacity, daily blood gas estimations and chest radiography. A decrease in lung vital capacity can be a early parameter of oxygen toxicity[30].

To reduce the duration of oxygen administration hyperbaric oxygen can be used at a pressure of 2.5 atmosphere for up to 2 h a day [31]. To decrease the recurrence rate oxygen therapy should be continued until two days after the disappearance of cysts[32].

In conclusion, our cases confirm that the clinical presentation of PCI may be very heterogeneous and suggest that a new onset of stipsis might be the presenting symptom. Furthermore, it should be taken into account that the patients may also be totally asymptomatic. The clinicians and the endoscopist should be aware of the possible presentations of PCI in order to correctly manage the patients affected with this disease and avoid unnecessary surgeries. It is possible that with the increasing number of colonoscopies performed for colon cancer screening PCI is casually encountered and/or provoked, therefore the possible endoscopic appearances of this disease should be known.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Events Calendar 2011

January 14-15, 2011
AGA Clinical Congress of Gastroenterology and Hepatology: Best Practices in 2011 Miami, FL 33101, United States

January 20-22, 2011
Gastrointestinal Cancers Symposium 2011, San Francisco, CA 94143, United States

January 27-28, 2011
Falk Workshop, Liver and Immunology, Medical University, Franz-Josef-Strauss-Allee 11, 93053 Regensburg, Germany

January 28-29, 2011
9. Gastro Forum München, Munich, Germany

February 4-5, 2011
13th Duesseldorf International Endoscopy Symposium, Duesseldorf, Germany

February 13-27, 2011
Gastroenterology: New Zealand CME Cruise Conference, Sydney, NSW, Australia

February 17-20, 2011
APASL 2011-The 21st Conference of the Asian Pacific Association for the Study of the Liver
Bangkok, Thailand

February 22, 2011-March 04, 2011
Canadian Digestive Diseases Week 2011, Vancouver, BC, Canada

February 24-26, 2011
Inflammatory Bowel Diseases 2011-6th Congress of the European Crohn's and Colitis Organisation, Dublin, Ireland

February 24-26, 2011
2nd International Congress on Abdominal Obesity, Buenos Aires, Brazil

February 24-26, 2011
International Colorectal Disease Symposium 2011, Hong Kong, China

February 26-March 1, 2011
Canadian Digestive Diseases Week, Westin Bayshore, Vancouver, British Columbia, Canada

February 28-March 1, 2011
Childhood & Adolescent Obesity: A whole-system strategic approach, Abu Dhabi, United Arab Emirates

March 3-5, 2011
42nd Annual Topics in Internal Medicine, Gainesville, FL 32614, United States

March 7-11, 2011
Infectious Diseases: Adult Issues in the Outpatient and Inpatient Settings, Sarasota, FL 34234, United States

March 14-17, 2011
British Society of Gastroenterology Annual Meeting 2011, Birmingham, England, United Kingdom

March 17-19, 2011
41. Kongress der Deutschen Gesellschaft für Endoskopie und Bildgebende Verfahren e.V., Munich, Germany

March 17-20, 2011
Mayo Clinic Gastroenterology & Hepatology 2011, Jacksonville, FL 34234, United States

March 18, 2011
UC Davis Health Informatics: Change Management and Health Informatics, The Keys to Health Reform, Sacramento, CA 94143, United States

March 25-27, 2011
MedicReS IC 2011 Good Medical Research, Istanbul, Turkey

March 26-27, 2011
26th Annual New Treatments in Chronic Liver Disease, San Diego, CA 94143, United States

April 6-7, 2011
IBS-A Global Perspective, Pfister Hotel, 424 East Wisconsin Avenue, Milwaukee, WI 53202, United States

April 7-9, 2011
International and Interdisciplinary Conference Excellence in Female Surgery, Florence, Italy

April 15-16, 2011
Falk Symposium 177, Endoscopy Live Berlin 2011 Intestinal Disease Meeting, Stauffenbergstr. 26, 10785 Berlin, Germany

April 18-22, 2011

ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Hirschsprung's disease is a congenital disorder that occurs in 1:5000 live births. It is characterised by an absence of enteric neurons along a variable region of the gastrointestinal tract. Hirschsprung's disease is classified as a multigenic disorder, because the same phenotype is associated with mutations in multiple distinct genes. Furthermore, the genetics of Hirschsprung's disease are highly complex and not strictly Mendelian. The phenotypic variability and incomplete penetrance observed in Hirschsprung's disease also suggests the involvement of modifier genes. Here, we summarise the current knowledge of the genetics underlying Hirschsprung's disease based on human and animal studies, focusing on the principal causative genes, their interactions, and the role of modifier genes.

Key words: Neural crest; Enteric nervous system; Hirschsprung's disease; Aganglionosis; Modifier genes

INTRODUCTION

The enteric nervous system (ENS) comprises neurons and glial cells within the wall of the gastrointestinal tract. It is responsible for regulating intestinal motility, immune function, luminal secretions, and blood flow[1]. During development, the ENS arises from a highly migratory population of cells, called the neural crest[2-4]. The neural crest arises as a result of an epithelial to mesenchymal transition during the formation of the neural tube. Two separate populations of neural crest, arising from different axial levels, contribute to the ENS - the vagal level (defined as the post-otic hindbrain adjacent to somites 1-7) and the sacral level (caudal to somite 24 in mice and humans)[5,6]. Vagal neural crest cells migrate ventrally to the presumptive foregut, and then into and along the entire length of the gastrointestinal tract, a process that takes five days in mice (embryonic day E9.5-E14.5)[7] and three weeks in humans (during 4th-7th wk of gestation)[8].

The formation of a functional ENS requires the coordination of many processes, including survival, migration, proliferation, and differentiation of precursor cells within the gastrointestinal tract. Failure of neural crest cells to fully colonise the entire length of the gastrointestinal tract results in a region of gut that lacks enteric neurons, called an "aganglionic zone", which affects a variable length of the distal most bowel. As enteric neurons are essential for motility, the aganglionic zone remains

tonically constricted, preventing the passage of faecal material. In humans, this condition is known as Hirschsprung's disease (HSCR) and occurs in approximately 1:5000 live births[9]. HSCR can either be familial or sporadic, and is subdivided into short or long segment HSCR (S-HSCR and L-HSCR), which refers to the extent of the aganglionic zone[10]. The less severe S-HSCR (about 80% of cases) is more common than L-HSCR (about 20% of cases) and displays a more pronounced gender bias (4:1 male:female in S-HSCR compared to 1.2:1 male:female in L-HSCR)[11]. HSCR may present as an isolated condition (about 70% of cases) or as part of a syndrome, such as Mowatt-Wilson or Waardenburg Shah type 4 (Table 1). Although HSCR is normally detected soon after birth, there have been reports of HSCR being identified in patients after childhood[12]. Failure to treat HSCR is often fatal because of malnutrition or sepsis following rupture of the bowel. Present treatment involves surgery to remove the affected portion of bowel and re-anastomosis of the remaining gut to the anus. Although refinements to surgical techniques have improved patient outcome, post-operative complications persist in a large number of patients[13,14].

In the majority of cases, the genetics of HSCR are complex and non-Mendelian in nature[15]. To date, more than a dozen genes have been identified as being associated with HSCR[9,16]. However, mutations in these genes account for only about 50% of all HSCR cases[17]. The phenotypic variability and incomplete penetrance observed in HSCR also suggests the involvement of modifier genes. The aim of this review is to summarise the current knowledge of the genetics underlying HSCR. We first discuss the principal causative genes and detail the interactions between these genes that alter the severity or incidence of HSCR. Finally, we discuss the accumulating evidence for the role of modifier genes in the development of HSCR.

GENES INVOLVED IN ENS DEVELOPMENT

Many of the genes associated with HSCR encode members of the Glial cell line-derived neurotrophic factor (GDNF)/RET- and ET-3/EDNRB-signalling pathways or transcription factors, such as *SOX10, PHOX2B* or *ZFHX1B*. Mutations in these genes have been shown to result in Hirschsprung's disease in humans (Table 1) or aganglionosis in mice (Table 2).

GDNF/RET-GFRα1

GDNF is a secreted protein and a distant member of the TGF-β superfamily[18]. GDNF binds to the glycosylphosphatidylinsoitol-linked receptor, GFRα1. The GDNF-GFRα1 complex then binds to and activates the transmembrane receptor tyrosine kinase, RET[19]. Mutations in genes encoding members of the GDNF/RET-GFRα1 signalling pathway account for about 50% of familial cases and around 30% of sporadic cases of HSCR[17]. Non-coding mutations in RET have also been proposed to increase susceptibility to HSCR[20-23]. In mice, *Gdnf* is expressed by the gut mesenchyme prior to the entry of neural crest cells[24]. *Ret* is expressed exclusively by neural crest-derived cells and *Gfrα1* is expressed by both crest-derived cells and the gut mesenchyme[25]. *Gdnf*-, *Gfrα1*- or *Ret*-null mice die within 24 hours of birth, and lack enteric neurons along the entire length of the gastrointestinal tract caudal to the stomach[25-27]. $Gdnf^{+/-}$ and $Ret^{+/-}$ mice are viable and do not exhibit aganglionosis[28].

RET is subject to alternative splicing and translated into two functional isoforms, RET51 and RET9, which differ in the number of amino acids at their C terminal end[29]. These isoforms are highly conserved between human and mouse[30]. Mice lacking the Ret51 isoform ($Ret^{9/9}$ mice) have enteric neurons along the entire length of the gastrointestinal tract, while mice lacking the Ret9 isoform ($Ret^{51/51}$ mice) suffer colonic aganglionosis and kidney hypodysplasia[31]. The phenotype of the $Ret^{51/51}$ mice is highly reminiscent of the colonic aganglionosis observed in patients with HSCR. Interestingly, the developing ENS in humans appears to be more sensitive to reduced RET signalling than that of the ENS in mice. *RET* mutations in humans act dominantly to give rise to HSCR, whereas ENS development is normal in *Ret* heterozygous mice[28]. In fact, it has recently been shown that a loss of around 60%-70% of *Ret* expression in mice is required to mimic the aganglionic phenotype observed in humans[32].

Targeted mutations in RET have identified signalling sites that are required for ENS development. Mutation of a putative protein kinase A phosphorylation site, which changes serine to alanine (Ret^{S697A}), results in aganglionosis of the distal colon[33]. Mutation of an intracellular docking site, which converts tyrosine to phenylalanine (Ret^{Y1062F}), induces total intestinal aganglionosis[34]. The mutation of cysteine to arginine (Ret^{C620R}), which is observed in some MEN2A/HSCR patients, has also been shown to result in total intestinal aganglionosis[35].

ENDOTHELIN SIGNALLING PATHWAY

Endothelin 3 (ET-3) is a secreted peptide, which is expressed by the gut mesenchyme[36]. ET-3 is initially expressed in an immature form before being processed to an active peptide by the enzyme, endothelin converting enzyme 1 (ECE1)[37,38]. ET-3 signals through the receptor Endothelin receptor B (EDNRB), which is expressed on migrating enteric neural crest cells[39].

Mutations in *ET3* and *EDNRB* account for around 5% of HSCR cases, whilst only a single case of *ECE1*-associated HSCR has been reported[40]. *ET3*- and *EDNRB*-associated HSCR can present as both syndromic (such as Wardenburg-Shah syndrome) and non-syndromic forms of HSCR. In mice, *lethal spotted* (*ls*) and *piebald lethal* (*sl*) are naturally occurring mutants of *Et-3* and *Ednrb* respectively, and lack enteric neurons in the distal bowel[37,41]. Although enteric neurons are absent only from the distal colon of *Et-3* and *Ednrb*-null mice, the migra-

Table 1 Genes associated with Hirschsprung's disease

Locus	Gene	Associated syndrome	Incidence	Penetrance	Inheritance	Ref.
10q11	*RET*	Non-syndromic HSCR	50% familial 30% sporadic	70% male 50% female	Dominant	82-84
5p13	*GDNF*	Non-syndromic HSCR	5 cases	Low	Dominant	85-89

Et3	ls/+	ls/ls $Et3^{tm1Ywa}/Et3^{tm1Ywa}$		
Sox10	Dom/+ (~80%) LacZ/+ (~80%)	Dom/+ (~20%) LacZ/+ (~20%)	Dom/Dom LacZ/LacZ	
Interactions		$Ret^{+/-}$; $Ednrb^{s/s}$ $Ret^{51/+}$; $Et3l^{s/ls}$	$Ret^{51/51}$; $Et3l^{s/ls}$ $Sox10^{Dom/+}$; $Et3l^{s/ls}$ $Sox10^{Dom/+}$; $Edrnb^{sl/sl}$	
Other genotypes		$Sall4^{-/-}$ B1Intergrin$^{-/-}$ $Ece1^{-/-}$	$Gdnf^{-/-}$ $Gfra1^{-/-}$ $Phox2b^{-/-}$ $Pax3^{-/-}$	$Gdnf^{+/-}$ $Hlx1^{-/-}$

tion of neural crest cells through the small intestine is also delayed[42,43]. As with *RET*, the human ENS appears to be more sensitive to reduced *EDNRB* signalling than that in mice. Around 21% of patients heterozygous for the W276C mutation in *EDNRB* develop HSCR[44], while heterozygous *piebald lethal* (*sl*) mice do not develop any form of aganglionosis[45].

SOX10

SRY (*Sex determining region Y*)-*box 10* (*SOX10*) is a high mobility group transcription factor of the SRY (sex determining factor) family. Mutations in *SOX10* account for around 5% of HSCR cases[46-48], and comprise both syndromic [Waardenburg-Shah types 4 (WS4)] and non-syndromic forms[49]. Some WS4 patients with *SOX10* mutations also suffer dysmyelination of the central and peripheral nervous systems[47]. *Sox10* is expressed by migrating enteric neural crest cells[50]. *Dom* is a naturally occurring mouse mutant of *Sox10*, which carries a single base insertion in the *Sox10* locus that prematurely truncates the transcription factor downstream of the DNA binding domain, producing a dominant negative form of the protein[50]. Mice lacking *Sox10* are devoid of enteric neurons throughout the entire gastrointestinal tract[50,51]. Around 20% of $Sox10^{+/-}$ mice suffer colonic aganglionо-

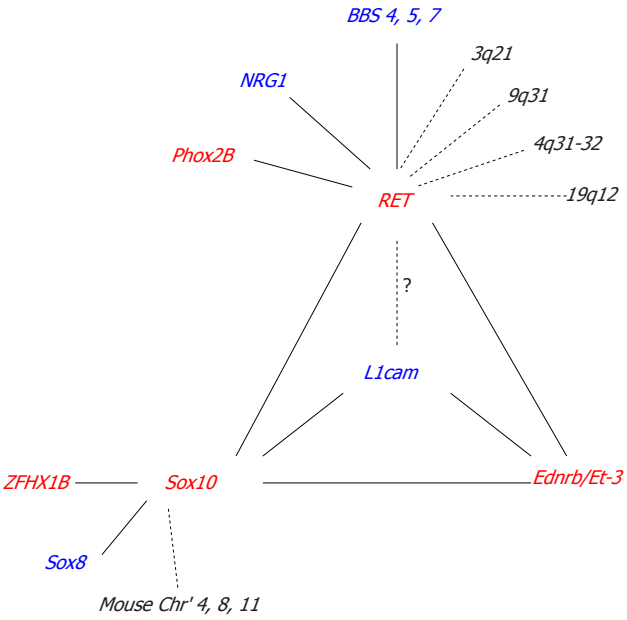

Figure 1 Interactions between known Hirschsprung's disease associated genes and their modifiers. Confirmed and putative interactions are shown by the solid and dotted lines, respectively. Red: HSCR associated gene; Blue: Known HSCR modifier gene; Black: Modifier loci with unknown gene. The question mark represents a disparity in the existing data obtained from human clinical and animal studies. HSCR: Hirschsprung's disease; BBS: Bardet-Biedel syndrome.

sis, although the incidence varies depending on the background strain[45,50,52,53]. These mice also exhibit coat colour defects analogous to the pigmentation defects seen in WS4 patients. *Sox10* has been shown to regulate the expression of both *Ret* and *Ednrb*[54-56].

ADDITIONAL TRANSCRIPTION FACTORS ASSOCIATED WITH HSCR

PHOX2B

Paired-like homeobox 2b (*PHOX2B*) is a transcription factor that is expressed by enteric neural crest cells[57]. Human studies have linked mutations in *PHOX2B* with HSCR associated with congenital central hypoventilation syndrome (CCHS)/Ondines curse in two thirds of patients[58]. The causative mutations in these patients are most commonly polyalanine expansions[59]. *Phox2b* null mice lack enteric neurons along the entire length of the gastrointestinal tract[60]. *Phox2b* has been shown to regulate the expression of *Ret*[60-61].

ZFHX1B

ZFHX1B, also known as SMAD interacting protein 1 (*SMADIP1*/*SIP1*), is a zinc finger homeodomain transcription factor. Mutations in *ZFHX1B* are associated with Mowat-Wilson syndrome, and have been shown to result in HSCR with a varying degree of penetrance[62]. In mice, *Zfhx1b* is expressed by vagal neural crest cells, which are absent in *Zfhx1b* null mutant mice[63].

INTERACTIONS BETWEEN KNOWN HSCR ASSOCIATED GENES

Interactions between known HSCR associated genes significantly influence the incidence and severity of intestinal aganglionosis (Table 2) (Figure 1).

Gdnf/Ret and Et-3/Ednrb signalling pathways

Genetic interactions were first proposed based on a human study of the genetically isolated Mennonite population, suggesting that the *RET* and *EDNRB* loci may interact to govern the susceptibility to Hirschsprung's disease[64]. Studies in mice, using a two-locus complementation approach, confirmed a genetic interaction between the *Ret* and *Ednrb* loci by showing that the generation of $Ret^{+/-}$; $Ednrb^{s/s}$ mice resulted in colonic aganglionosis; a phenotype not observed in $Ret^{+/-}$ or $Ednrb^{s/s}$ mice alone[64,65]. A similar genetic interaction was also reported using Ret^{51} and $Et\text{-}3^{ls}$ mice[42]. A significant increase in aganglionosis, extending all the way to the stomach, was observed in $Ret^{51/51}$; $Et\text{-}3^{ls/ls}$ mice compared to the colonic aganglionosis normally observed in $Ret^{51/51}$ or $Et\text{-}3^{ls/ls}$ mice alone[42]. The mechanism underlying these interactions is not yet known; however, it has been proposed that *Ret* and *Ednrb* may interact by activating common downstream signalling molecules, such as PKA[42].

Gdnf/Ret signalling pathway and the transcription factors Sox10 and Phox2b

Although genome-wide linkage studies failed to detect any genetic interaction between the *Sox10* and *Ret* loci[66], *Sox10* has been shown to form a transcriptional complex with the transcription factor, *Pax3*, to directly regulate the expression of RET[67]. In addition to *Sox10*, *Phox2B* has also been shown to bind the *RET* promoter and regulate transcription[61]. Although no genetic interactions were observed in double heterozygotic mice ($Ret^{+/-}$; $Phox2b^{+/-}$ mice), human clinical studies have reported interactions between *RET* and *PHOX2B* in CCHS patients[68].

Sox10 and Zfhx1b

Sox10 has been shown to interact with the transcription factor, *Zfhx1b*, in mice[69]. The generation of double heterozygotic progeny ($Sox10^{LacZ/+}$; $Zfhx1b^{\lrcorner/+}$ mice) resulted in a significant increase in the severity of aganglionosis compared to a mutation in $Sox10^{LacZ/+}$ or $Zfhx1b^{\lrcorner/+}$ mice alone[69]. The mechanism underlying this interaction is not known, but is likely to be mediated by the modulation of *Bmp* expression[69].

Et-3/Ednrb signalling pathway and Sox10

In mice, interactions between *Sox10* and members of the endothelin signalling pathway (*Et-3* and *Ednrb*) have been reported[45,52]. Using a two-locus complementation approach, mice carrying mutations in *Sox10* and *Et-3* ($Sox10^{Dom/+}$; $Et\text{-}3^{ls/ls}$) or *Ednrb* ($Sox10^{Dom/+}$;$Ednrb^{s/s}$ and *Sox-*

10$^{Dom/+}$; *Ednrb*$^{sl/sl}$) exhibited a significant increase in the severity of intestinal aganglionosis compared to mutations in *Sox10*, *Et-3*, or *Ednrb* alone[45,52]. In addition, the expression of Ednrb has been shown to be significantly reduced in *Sox10*$^{Dom/+}$ mice[50]. The mechanism underlying this interaction can be explained, at least in part, by the presence of SOX10 binding sites within a conserved enhancer region of the *Ednrb* promoter, which are required for the spatiotemporal expression of Ednrb in the ENS[56].

MODIFIER GENES

The incomplete penetrance and interfamilial variation commonly observed in HSCR strongly suggests the involvement of modifier genes. We define a modifier gene as a gene that, when mutated, is insufficient on its own to produce an effect, but, when coupled with another genetic mutation, it produces or enhances an effect[70]. To date, only a handful of modifier genes have been identified for HSCR (Figure 1).

Modifiers for RET

Linkage studies and genome-wide screens have identified a number of putative modifying loci for *RET*, such as 3q21, 4q31-32, 8p12, 9q31, and 19q12[71,72]. However, many of the genes responsible for interacting with *RET* at these loci are yet to be identified. One gene that has been identified is neuregulin 1 (*NRG1*)[72]. Association studies have shown that individuals that possess a specific *NRG1* haplotype have an increased risk of HSCR conferred by *RET*[72]. *NRG1* signals through ErbB2 and ErbB3 receptors to regulate neural crest cell development and in turn, *ErbB3* is regulated by the HSCR associated gene *Sox10*[73].

Although not detected in any of the genome-wide screens, three further modifier genes for *RET* were identified through the Bardet-Biedel syndrome (BBS). Subsets of patients with BBS, a genetically heterogeneous disorder with 14 identified causative loci, also present with HSCR. BBS patients with HSCR are more frequent carriers of a common *RET* intronic hypomorphic allele than the general population[74]. In zebrafish, suppression of *Ret* in conjunction with a loss of either *Bbs 4*, *5*, or *7* has been shown to significantly increase the severity of ENS defects compared to loss of these genes independently[75].

Human clinical studies have also suggested that the X-linked gene *L1CAM*, may act as a modifier gene for *RET*. Some individuals with *L1CAM* mutations who have HSCR, also possess a common *RET* polymorphism that is over-represented in HSCR populations[76]. However, animal model studies using a two-locus complementation approach failed to detect any genetic interaction between *L1cam* and *Ret*[70]. One reason for this discrepancy could be that humans are more sensitive to a reduction in RET levels than mice[28,32]. It is not yet known whether interactions with *L1cam* can be detected in *Ret*$^{51/51}$ and *Ret*$^{S697A/S697A}$ mice that exhibit colonic aganglionosis and more closely resemble human HSCR[31,33].

Modifiers for Sox10

A genome-wide screen in mice has identified five putative modifying loci for *Sox10* on chromosomes 3, 5, 8, 11, and 14[66]. Two of these loci have been identified as Ednrb and Phox2b[66], while the other three loci, on chromosomes 3, 8, and 11, are yet to be determined.

Although not identified in the *Sox10* genome-wide screen, one modifier gene that has been shown to significantly increase the penetrance and extent of aganglionosis in *Sox10* heterozygous mice, is *Sox8*[53]. *Sox8* is a transcription factor that is closely related to *Sox10*, and is expressed by all enteric neural crest cells[53]. *Sox8*$^{-/-}$ mice are viable and fertile and show no ENS phenotype[53]. Using a two-locus complementation approach, double heterozygotic progeny (*Sox8*$^{+/-}$; *Sox10*$^{+/-}$ mice) were shown to have a significant increase in the incidence and severity of aganglionosis compared to a mutation in *Sox8* or *Sox10* alone[53]. The most likely mechanism underlying this interaction is genetic redundancy, as Sox8 has been shown to have DNA binding and subcellular redistribution properties similar to that of Sox10[77-80] and is capable of activating Sox10 target genes[78].

The X-linked gene, *L1cam*, can also act as a modifier gene for *Sox10* in mice[70]. Loss or haploinsufficiency of *L1cam* in conjunction with a heterozygous loss of *Sox10* significantly increases the incidence of intestinal aganglionosis compared to a mutation in *Sox10* alone[70]. *Sox10* has been shown to directly regulate the expression of endogenous *L1cam*[70].

Modifiers of Et3/Ednrb

To date, only one modifier gene has been identified for members of the endothelin signalling pathway. Loss or haploinsufficiency of *L1cam* in conjunction with a null mutation in *Et-3* or *Ednrb* significantly increases the severity of intestinal aganglionosis compared to a loss of *Et-3* or *Ednrb* alone[81]. Although the mechanism underlying these interactions is not yet known, it is most likely mediated through the activation of common downstream targets, such as PI3K[81].

CONCLUSION

HSCR research has now entered a second phase. Having identified many of the key genes capable of independently inducing HSCR, we are now undertaking the difficult task of identifying the interactions that modulate the severity and penetrance of this disease. By combining human genetic data from patients, family pedigrees, and genome wide association screens with animal studies, we are beginning to assemble the pieces of the HSCR puzzle into a coherent picture of multigenetic inheritance and interactions. To further aid this goal, as the cost of genome sequencing becomes more affordable, the potential to sequence the entire genome of individual HSCR patients becomes viable, which is likely to provide significant advances into our understanding of the genetic basis of HSCR.

Abstract

Gallbladder diseases are very common in developed countries. Complicated gallstone disease represents the most frequent of biliary disorders for which surgery is regularly advocated. As regards, cholecystectomy represents a common abdominal surgical intervention; it can be performed as either an elective intervention or emergency surgery, in the case of gangrene, perforation, peritonitis or sepsis. Nowadays, the laparoscopic approach is preferred over open laparotomy. Globally, numerous cholecystectomies are performed daily; however, little evidence exists regarding assessment of post-surgical quality of life (QOL) following these interventions. To assess post-cholecystectomy QOL, in fact, documentation of high quality care has been subject to extended discussions, and the use of patient-reported outcome satisfaction for quality improvement has been advocated for several years. However, there has been little research published regarding QOL outcomes following cholecystectomy; in addition, much of the current literature lacks systematic data on patient-centered outcomes. Then, although several tools have been used to measure QOL after cholecystectomy, difficulty remains in selecting meaningful parameters in order to obtain reproducible data to reflect postoperative QOL. The aim of this study was to review the impact of surgery for gallbladder diseases on QOL. This review includes Medline searches of current literature on QOL following cholecystectomy. Most studies demonstrated that symptomatic patients profited more from surgery than patients receiving an elective intervention. Thus, the gain in QOL depends on the general conditions before surgery, and patients without symptoms profit less or may even have a reduction in QOL.

Key words: Gallbladder disease; Gallstones; Quality of life; Laparoscopy

INTRODUCTION

Gallbladder diseases are very common in developed countries. They comprise a large spectrum of disorders caused by alterations in bile composition and biliary function, placing a substantial burden on inpatient and outpatient resources. Clinical manifestation of gall-

stone disease varies from attacks of intense biliary colic, prompting surgical intervention, to an absence of symptoms. Biliary colic is usually secondary to temporary obstruction of the cystic duct by a gallstone. When obstruction holds over, the gallbladder becomes inflamed and the patient may develop cholecystitis or other, potentially serious complications, such as cholangitis, gangrene, perforation, peritonitis, sepsis or pancreatitis. Complicated gallstone disease (e.g., symptomatic cholelithiasis) represents the most frequent of biliary disorders for which surgery is regularly advocated. In fact, patients with cholelithiasis account for about 10% to 15% of the total adult western population[1-4]; among them around 30% have surgery, and only 2% develop symptoms[4,5]. Today, cholecystectomy is a standard practice for cholelithiasis, and surgery for complicated gallstone diseases has a significant impact on quality of life (QOL) in developed countries[4]. QOL assessments are increasingly being recognized as an integral factor in surgical decision-making. However, considering the enormous number of cholecystectomies performed daily worldwide, surprisingly little data has been collected about QOL after biliary surgery. Laparoscopic cholecystectomy (LC) has become a very frequent surgical procedure, with over 500 000 operations annually in Western countries[5]. The laparoscopic technique, introduced in the 1990s, resulted in a significant reduction in the number of open cholecystectomies. As a consequence of this movement towards minimally invasive procedures, over the past 15 years the number of cholecystectomies increased, which may reflect a change in the threshold to perform surgery. This shift has also significantly impacted postoperative QOL. Today, estimates are that 86% of cholecystectomies are performed laparoscopically. This number continues to increase, especially in the treatment of acute cholecystitis and biliary colic; therefore, in recent years, the accumulating surgical experience and advances in technology have extended the indications for LC to include patients with complicated gallbladder disease[6,7]. On this basis, there is suggestive evidence that immediate postoperative health-related QOL (HRQOL) may be better after laparoscopic procedures. That being said, the introduction of LC has also increased the incidence of injuries to the biliary tree, along with an increasing number of serious vascular lesions[8-10]. In fact, 15%-20% of patients require conversion to open cholecystectomy for the safe completion of the procedure, countering the potential benefit of the laparoscopic approach[11].

To assess QOL, documentation of high quality care in cholecystectomy has been subject to extended discussions, and the use of patient-reported outcome satisfaction for quality improvement has been advocated for several years[12]. It would be ideal to consider the entire spectrum of gallbladder diseases that indicate surgery. Among them, for example, acalculous cholecystitis represents a controversial clinical indication for surgery, yet it accounts for 5%-20% of all cholecystectomies[13]. Furthermore, debate continues regarding the decision for elective surgery in patients following an acute episode of gallstone disease. Although several tools have been used to measure QOL after cholecystectomy, difficulty remains in selecting meaningful parameters in order to obtain reproducible data to reflect postoperative QOL. Classically, evaluations of surgical procedure outcomes have focused on perioperative complications, morbidity, recurrence rate, and long-term survival. However, much of the current literature lacks systematic data on patient-centered outcomes. Endpoints such as symptom resolution or duration of convalescence represent QOL measures that are at least as important as the classical outcomes. There has been little research done regarding QOL outcomes following cholecystectomy. Furthermore, laparoscopic surgery is usually perceived by patients as a routine procedure. Thus, the impact of LC on QOL, as well as the identification of predictors of subjective patients outcomes, remains undetermined in these patients[14].

Usually, the principal criterion guiding patients' acceptance of a treatment modality is their subjective condition prior to surgery. Additionally, those subjective reports become important criteria in a surgeon's decision-making process[15]. Thus, the aim of this review is to evaluate and summarize the published data on QOL after cholecystectomy in adults. A text word literature search was performed using the Medline databases. Although this was not a systematic review, the search terms used were as follows: gallstones, cholecystitis, surgery, gallbladder disease, and quality of life. The reference lists of identified articles were searched for further relevant publications. The databases were consulted from January 1993 to July 2010. The authors independently selected the studies, particularly those comparing different surgical approaches. Whenever there was discordance regarding study inclusion the authors negotiated an agreement.

GLOBAL QOL MEASURES FOR CHOLECYSTECTOMY: A LACK OF STANDARDIZED AND UNIVERSALLY VALIDATED INSTRUMENTS

HRQOL measures have been shown to be useful in predicting health care expenditure; different QOL indices exist and have been validated to determine the general subjective perceptions and expectations of individuals; in surgery in general, and in particular in the case of cholecystectomy, there is no clear, validated and standardized instrument for assessing QOL postoperatively. The development of well-validated and sensitive non-disease-specific questionnaires is useful for comparing different surgical approaches and techniques. Although specific, HRQOL instruments have been proposed for cholelithiasis and cholecystectomy, they have appeared

with only limited reproducibility, restricted psychometric aspects and with linguistic gaps when translated into different languages[16-18].

The most frequently used tool to assess QOL is the short form (SF)-36 questionnaire and the Gastrointestinal Quality-of-Life Index (GIQLI), each instrument having its own advantages and limitations. The generic SF-36 is a widely used instrument that allows comparison between different studies. However, it has a low discriminative ability and low specificity for identifying determinant changes related to a specific clinical factor. The GIQLI is an established tool for assessing QOL outcomes for patients with various gastrointestinal symptoms including domains of general health, but it is not specific for gallbladder disease.

Some studies used both SF-36 and GIQLI, combining a questionnaire for general well-being and another for more specific postoperative QOL. Quintana *et al*[19] used, for example, the SF-36 to validate the explicit appropriateness criteria in subjects after cholecystectomy. Their results indicated similar improvements in SF-36 QOL measures compared with GIQLI, indicating that both tools were adequate QOL measures and thus confirmed their validity. Recently Fledman *et al*[20] proposed a physical activity questionnaire (Community Health Activities Model Program for Seniors) as an indicator of postoperative recovery. Their aim was to specifically correlate physical activity caloric expenditure as an estimation of postoperative recovery after LC in older patients; evidence has been provided for the validity of this questionnaire as a measure of surgical recovery.

However, the most appropriate measures for identifying relevant changes in QOL after biliary surgery remain to be determined.

An important proposed concept of a questionnaire' s appropriateness is the accuracy of a measure over time in the same patient, assessing prospective changes in the patient's health status. In fact, a highly responsive QOL instrument has been considered able to detect significant treatment effects in a small sample size: an outstanding proposed tool is the "minimal clinically important difference" (MCID) that potentially can examine all significant differences at the individual patient level[21,22]. The MCID is one of the most effective and widely used methods of HRQOL assessment, and can be used to provide an indication of the minimal change that is of clinical relevance. An interesting work by Shi *et al*[23] aimed to estimate MCIDs for the GIQLI score of patients after cholecystectomy; they showed that this instrument can play a role in interpretation of scores and useful application in clinical practice. Thereafter, the same group clinically compared the responsiveness derived by the SF-36 and the GIQLI before and after cholecystectomy; correlation analyses revealed significant correlation between the SF-36 and GIQLI in the preoperative and 3-mo postoperative period[24].

In conclusion, there is an overall propensity to use both generic instruments, SF-36 and GIQLI, to assess the QOL after cholecystectomy; however in the case of limited time and resources, the GIQLI index may be used alone since it incorporates all domains of a QOL. The main issue is the choice of disease-specific outcome measures, adjusted for potential variables, that may act as confounders to identify the effective relevant changes after cholecystectomy.

IMPACT ON QOL OF LAPAROSCOPIC *VS* OPEN CHOLECYSTECTOMY

The literature offers positive and encouraging results in several reports comparing laparoscopic *vs* open surgery in the clinical setting. The development of the laparoscopic technique has drastically changed the protocols for treatment of gallstone disease and cholecystitis, and has been accompanied by evident clinical benefit for patients. Over the years since its introduction, reduced morbidity and mortality rates have confirmed LC as a safe and standard procedure in the treatment of some gallbladder diseases[25]. These results reinforce the feasibility of laparoscopy as a treatment modality for the biliary tract itself, and have provided reliable scientific material in support of an expanded role for laparoscopy in hepatobiliary surgery. Collected data seems to confirm a positive post-laparoscopic subjective satisfaction and perceived QOL[20,26]. Indeed, Harju *et al*[27] compared minilaparotomy with LC, demonstrating that the minilaparotomy procedure represents a good alternative to the LC procedure, when QOL is measured.

Although the rate of increase of QOL following LC is greater than that after open surgery, long-term overall QOL has proven to be only slightly better or show no difference when compared with open surgery. Therefore, the only significant long-term advantage of laparoscopic surgery, as compared with open surgery, seems to be the higher satisfaction rate regarding the cosmesis of the surgical scar. There remains no clear explanation regarding the similarity of this comparative data between the two surgical techniques; feasible hypotheses are that indications for LC might be more easily proposed than those for open surgery. This could impact patient selection as well as patient expectation regarding laparoscopy[28]. Furthermore, patients selected for open surgery more frequently have a lower perception of QOL and more co-morbidities than matched laparoscopic patients prior to surgical intervention. These factors likely influenced outcomes and potentially introduced bias in the above-mentioned studies.

ADULT PATIENTS WITH CHOLELITHIASIS: IMPACT OF QOL FOLLOWING LC

The use of objective outcome measures after surgical procedures, even though non-disease specific, is helpful

for laparoscopic surgery such as cholecystectomy. Quintana *et al*[29] aimed to determine clinical variables that predicted changes in HRQOL using both instruments, GIQLI and SF-36. Patients were grouped according to diagnosis (complicated symptomatic cholelithiasis, including acute cholecystitis, choledocholithiasis, pancreatitis or cholangitis; uncomplicated symptomatic cholelithiasis; asymptomatic cholelithiasis) and surgical risk categories; patients were asked to complete a questionnaire before and 3 mo after cholecystectomy. The study concluded that cholecystectomy is the suitable treatment especially for patients with symptomatic cholelithiasis and low surgical risk since they experienced the highest QOL gains; whereas patients with asymptomatic cholelithiasis or high surgical risk experienced least improvement. Conversely, Mentes *et al*[30] observed significant GIQLI score improvements in both symptomatic and asymptomatic gallstone groups. However, the gallstone-related QOL improvements were particularly marked in symptomatic patients, indicating that gallstone patients with lower baseline GIQLI scores are more likely to benefit from LC. Thus, LC seems to be the appropriate intervention for patients with symptomatic gallstone and low surgical risk.

Alternatively, Vetrhus *et al*[31] evaluated gallstone-related acute cholecystitis *vs* symptomatic but non-complicated disease. They used QOL and pain surveys to compare chronic gallbladder disease outcomes between conservative observational treatment and cholecystectomy. The patients in this study answered standardized questions at baseline (before surgery), and at 6, 12 and 60 mo post-cholecystectomy. The observation group (no intervention) had a higher rate (36% *vs* 19%) of gallstone-related events, but the difference was not significant. When patients were grouped according to randomization or actual operative outcome (+/- cholecystectomy), the authors did not find any significant differences in pain or QOL measurements. The authors concluded that conservative treatment in acute cholecystitis did not significantly increase the risk of subsequent gallstone events, and importantly this did not influence the QOL outcome and pain measurements. Thus, conservative (non-operative) treatment and observation of acute cholecystitis would be an acceptable option and should at least be considered in high risk patients[27].

Another longitudinal QOL study from Taiwan provided data using the SF-36 questionnaire and GIQLI scores[32]. The preoperative SF-36 scores from gallstone patients were significantly inferior to an age- and sex-matched control population; LC effectively reduced gastrointestinal symptoms, confirmed by the improvement in GIQLI total, physical well-being, mental well-being, gastrointestinal digestion, and defecation subscale scores. Yet, certain authors' evidence indicates that some patients did not regain full GIQLI scores after surgery, deducing that some residual gastrointestinal discomfort remained. Indeed, some investigators described a persistent decrement in many of the SF-36 health dimensions at 12 mo following surgery; thus they identified different markers to evaluate QOL outcomes after surgery; they found that QOL improvements can be partially predicted by the preoperative direct bilirubin level and by the placement of a drainage tube intra-operatively. This aspect confirms data indicating that patients with worse preoperative health conditions may have greater gains in QOL improvement following LC surgery; moreover, QOL measures should consider potential variables that may act as confounding events. In fact, although there is no doubt that cholelithiasis may decrease the QOL during its acute symptomatic phase, the postoperative course after cholecystectomy, independent of the operative technique, might be potentially altered by other factors (bloating, slow digestion, *etc*.) that were not sufficiently controlled or distinguished by researchers, and could determine cholecystectomy as an overused procedure.

Finan *et al*[33] designed a study to determine gastrointestinal symptoms and QOL after cholecystectomy for better measurement of the change in QOL after surgery. In this study, SF-36 was employed along with a symptom survey that was designed to include both classic symptoms of biliary disease as well as other benign gastrointestinal (GI) diseases. Their results showed that LC significantly improved GI symptoms as well as QOL in subjects with symptomatic gallstone disease; the quantitative evaluation of GI symptoms allowed for analysis of symptom improvement by including patient perceived severity and distress. These results permitted the development of clear indications for operative management, supporting the effectiveness of cholecystectomy for elective biliary disease. In conclusion, in adult patients operated for cholelithiasis, QOL improved most in patients with symptomatic disease and average surgical risk; particular attention must be paid in regard to appropriate selection of patients, especially in terms of discrimination between biliary disease-related symptoms and other GI disorders.

IMPACT ON QOL OF LC FOR ACALCULOUS CHOLECYSTITIS

One of the most controversial and frequent dilemmas for surgeons in clinical practice is recurrent acalculous biliary pain. Surgical treatment of this disease represents a controversial issue, especially considering the similarities between its clinical presentation and that of other GI conditions. Therefore, clinical resolution cannot be guaranteed with surgical interventions and there is significant risk for decreased QOL following this procedure. Planells Roig *et al*[13] evaluated the QOL in patients with chronic acalculous cholecystitis in comparison to a control group of patients who underwent cholecystectomy for chronic calculous cholecystitis. They concluded that the prevalence of associated gastrointestinal symptoms

was similar for both groups, and QOL was similarly affected by both chronic diseases. The limitation of this work was primarily a disparity between the numbers of subjects (34 patients with chronic acalculous cholecystitis *vs* 297 with chronic calculous cholecystitis); moreover, the study population was a highly selected, though heterogeneous group of patients. A comprehensive and reproducible preoperative investigation for proper diagnosis of biliary disease has constituted an essential prerequisite for the appropriate selection of patients for surgery, and the appropriate exclusion for other GI disorders. Thus, the frustration due to the lack of understanding this disease consequently implies an impact in terms of post-surgical QOL for these patients. An accurate clinical selection seems to remain the most important criterion for surgical and healthcare expenditures in primary hepatobiliary centers.

CHANGES IN QOL FOLLOWING IATROGENIC INJURIES AFTER CHOLECYSTECTOMY

Unfortunately, with the introduction of LC, an increase in potentially dangerous injuries to the biliary tree has been observed, along with an increasing number of serious vascular lesions. Nowadays iatrogenic bile duct-related injuries (BDI) occur in less than 0.3% of all cholecystectomy procedures[34]. BDI are not always identified immediately during the surgical procedure and sometimes appear only in the postoperative course, mostly between days 1 and 5[35]. The clinical manifestations start with early biliary obstruction, biliary abdominal collection or biliary peritonitis, whereas late presentations include obstructive jaundice and ascending cholangitis. On this basis the optimal management of complications often advocates interventional procedures such as percutaneous drain placement or, sometimes, second-look surgery. The literature includes numerous studies confirming satisfactory technical and clinical approaches, demonstrating acceptable clinical outcomes, even in tertiary hepatobiliary centers. However, data is lacking regarding QOL. Only poor documentation of high quality care after bile-duct injuries exists. Results vary significantly between studies, and most recorded true BDI rather than simple cystic duct leaks.

Hogan *et al*[36] has recently published an interesting study, which compared an iatrogenic BDI study group with an age- and sex-matched control group, which underwent uncomplicated cholecystectomy. The SF-36 form was administered to the patients at a median postoperative time of 12 years (range, 2 mo to 20 years). The authors finally concluded that QOL of the surviving patients following BDI seems to be favorable to that after uncomplicated LC. Other studies showed different results; in particular, Sarmiento *et al*[37] and Melton *et al*[40] showed favorable comparisons between BDI and a control group whereas Boerma *et al*[39] and Moore *et al*[38] found that the BDI group had lower QOL scores. However, Boerma's work has been criticized, although they had the largest series[37,39]: for example, patient enrollment included those with cystic duct as well as peripheral hepatic injuries (e.g., leakage, 30%), which technically do not represent BDI. Furthermore, different QOL instruments were used for measuring health-related impact, invalidating any potential comparison between groups. Sarmiento *et al*[37] assessed QOL with the SF-36 questionnaire with a minimum follow-up of 5 years; the QOL after surgical biliary reconstruction compared favorably with that of patients undergoing uneventful LC. Melton *et al*[40] assessed QOL of patients after surgical reconstruction of major bile duct injury from LC with a median follow-up of 59 mo. Although using different survey instruments, the conclusions of the studies are quite similar, and all found that major BDI should be managed surgically, which constitutes a definitive therapy (although more invasive), and is not punctuated by repetitive interventions; in fact, patients with BDI managed endoscopically often require repeat intervention resulting in a worse QOL. In any case, an equivalence of QOL in BDI and uncomplicated LC is quite surprising and points to a possible bias. Patients with the most severe BDI may die, thus QOL cannot be assessed. Moreover, the numbers of patients included were small and in general, the instruments employed were nonspecific.

CONCLUSION

Many studies in the literature lack systematic data regarding QOL outcomes after cholecystectomy. Reported works have conflicting data and sometimes several limitations (i.e., small sample size, single-institution experience), and thus may not be generalizable. A general agreement is that postoperative QOL depends on preoperative clinical status; moreover the first essential criterion for an improvement in subjective change in QOL is accurate preoperative diagnosis. In fact, appropriate patient selection for surgery represents the most important criteria guiding the patients' subjective feeling after cholecystectomy, independent of the selected surgical technique. On the other hand, an effective way to investigate the factors that may influence subjective QOL outcomes would be to measure the satisfaction rate pre- and post-surgery, and repeatedly after surgical treatment; a QOL assessment is generally suggested at 1 and 6 mo postoperatively. On this basis, symptomatic patients usually gain more QOL from a surgical intervention (open or laparoscopic) in terms of long-term well-being. Even though LC improves QOL faster than open surgery, long-term results are only slightly better or show no difference compared with those of open surgery; at the same time, these data should be considered as a mean, and might be limited by study design (e.g., small sample size, biased and confounding variables). The only certain and significant long-term advantage of laparoscopic surgery might be the higher satisfaction rate in regard to

scar cosmesis, in the absence of complications.

In conclusion, although sensitive and responsive instruments for the measurement of post-cholecystectomy QOL exist, more research is needed to identify modifications that could lead to significant improvements.

REVIEW

Review of dynamic contrast-enhanced ultrasound guidance in ablation therapy for hepatocellular carcinoma

Yasunori Minami, Masatoshi Kudo

Abstract

Local ablative techniques-percutaneous ethanol injection, microwave coagulation therapy and radiofrequency ablation (RFA)-have been developed to treat unresectable hepatocellular carcinoma (HCC). The success rate of percutaneous ablation therapy for HCC depends on correct targeting of the tumor *via* an imaging technique. However, probe insertion often is not completely accurate for small HCC nodules, which are poorly defined on conventional B-mode ultrasound (US) alone. Thus, multiple sessions of ablation therapy are frequently required in difficult cases. By means of two breakthroughs in US technology, harmonic imaging and the development of second-generation contrast agents, dynamic contrast-enhanced harmonic US imaging with an intravenous contrast agent can depict tumor vascularity sensitively and accurately, and is able to evaluate small hypervascular HCCs even when B-mode US cannot adequately characterize the tumors. Therefore, dynamic contrast-enhanced US can facilitate RFA electrode placement in hypervascular HCC, which is poorly depicted by B-mode US. The use of dynamic contrast-enhanced US guidance in ablation therapy for liver cancer is an efficient approach. Here, we present an overview of the current status of dynamic contrast-enhanced US-guided ablation therapy, and summarize the current indications and outcomes of reported clinical use in comparison with that of other modalities.

Key words: Dynamic contrast-enhanced ultrasound; Hepatocellular carcinoma; Percutaneous ethanol injection; Radiofrequency ablation

INTRODUCTION

Hepatic resection forms part of the conventional treatment for patients with primary liver cancers; however, the majority of hepatocellular carcinomas (HCCs) are not suitable for curative resection at the time of diagnosis. Difficulties of surgical resection may be related to size, site, and number of tumors, vascular and extrahepatic involvement as well as liver function of the patient[1-4]. There is a need to develop a simple and effective technique for treatment of unresectable HCCs; therefore, local ablative techniques [percutaneous ethanol injection (PEI), microwave coagulation therapy (MCT) and radiofrequency ablation (RFA)] have emerged in clinical practice to expand the pool of patients considered for

liver-directed therapies[5-8]. In particular, RFA is not associated with some of the side-effects of other ablative techniques[9]. Thus, RFA is currently more widely accepted due to the ease of use, safety, reasonable cost and applicability to minimally invasive techniques[10].

Percutaneous ablation therapy for HCC is widely performed under real-time sonographic guidance. The success rate of percutaneous RF ablation depends on correct targeting *via* an imaging technique. However, multiple sessions of ablation therapy are often required for small HCCs, which are poorly defined on conventional B-mode ultrasound (US) alone[11]. There are two particular situations in which B-mode US cannot adequately characterize the tumors[12]. The first is the presence of residual HCC nodules after ablation, because B-mode US findings cannot adequately differentiate between treated and viable residual tumor tissue. The second is the presence of naïve HCC nodules among many large regenerated nodules in cirrhotic liver. Color Doppler and power Doppler have increased the sensitivity of hepatic lesion detection compared to that using gray-scale US, but these modalities do not provide levels of sensitivity comparable to those of contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI)[13-16]. However, two breakthroughs in US technology, harmonic imaging and the development of second-generation contrast agents, have demonstrated the potential to dramatically broaden the scope of US diagnosis of hepatic tumors[14-16]. Dynamic contrast harmonic US can depict tumor vascularity sensitively and accurately, and is able to evaluate small hypervascular HCCs even when B-mode US cannot adequately characterize the tumors[17-21]. Therefore, contrast-enhanced harmonic US is expected to improve the detectability of HCC nodules, and decrease the number of sessions required for ablation of HCC in difficult cases[22,23].

This paper reviews the evidence for the use of dynamic contrast-enhanced US guidance in ablation of HCC, and illustrates the potential of the techniques for improving the targeting in percutaneous ablation therapy.

DIAGNOSIS AND TREATMENT OF HEPATOCELLULAR CARCINOMA

HCC can be diagnosed radiologically, without the need for biopsy if the typical imaging features are present[20,24,25]. This requires a contrast-enhanced study (dynamic CT or MRI). HCC enhances more intensely than the surrounding liver in the arterial phase, whereas the presence of 'washout' persists in the delayed phase. Tumor markers including alpha-fetoprotein and descarboxyprothrombin have been used for the diagnosis of HCC.

The management of HCC involves multiple disciplines including hepatology, surgery, diagnostic and interventional radiology, oncology, and pathology[20,25-27]. One has to consider several patient and tumor factors including the severity of underlying liver disease, tumor bulk, and associated comorbidities, as well as several practice-setting factors including availability and expertise in surgical resection, transplantation, and ablative therapies. RFA is basically recommended for HCC nodules with a maximum diameter of 3 cm in patients with not more than three tumors who are contraindicated for surgery.

DYNAMIC CONTRAST-ENHANCED ULTRASOUND

Contrast agents

Levovist (Schering, Berlin, Germany) is a first-generation US agent made of galactose[28]. A trace of palmitic acid is added as a surfactant to stabilize the resultant microbubbles. These bubbles have a weak encapsulating shell and are easily destroyed by US exposure. The contrast effect of Levovist is based on the destruction of microbubbles by high mechanical index (MI) pulses. In addition, Kupffer cells phagocytose Levovist microbubbles; therefore, liver parenchymal findings are obtained as Kupffer imaging in the postvascular phase at least 10 min after administration.

Sulfur hexafluoride microbubbles (SonoVue; Bracco SpA, Milan, Italy), perflutren lipid microbubbles (Definity; Bristol-Myers Squibb, North Billerica, MA), perflutren protein microbubbles (Optison; GE Healthcare, Buckinghamshire, United Kingdom), and perfluorocarbon microbubbles (Sonazoid; Daiichi-Sankyo, Tokyo, Japan) are second-generation contrast agents[29-33]. These microbubbles provide stable nonlinear oscillation in a low power acoustic field because of the hard shell of these bubbles, producing great detail in the harmonic signals in real-time. The only second-generation contrast agent that can be taken up by Kupffer cells in the liver is Sonazoid. Sonazoid microbubbles accumulate in the liver parenchyma over time[34,35].

Generally, few drug toxicities have been reported; these being pain at the point of injection, sense of heat and sense of cold. The incidence of complications was shown not to differ from historical controls (1.7%, P = 0.867 by Fisher's exact probability test)[36].

Imaging and procedure

In point of fact, there is a clinical need for high resolution and real-time imaging for dynamic contrast-enhanced US guidance in ablation therapy.

Using Levovist, real-time images of tumor enhancement by the simultaneous collapse of microbubbles caused by high mechanical index pulses can be obtained in the early vascular phase only[28]. The collapse of microbubbles in viable HCC lesions is seen as white flashes on the screen[12]. However, maintaining real-time US imaging for guidance reduces the enhancement period to approximately one minute after injection because Levovist microbubbles are easily disrupted (Figure 1). Therefore, great skill is required because the procedure time is too short to search for enhanced HCC nodules and insert the probe.

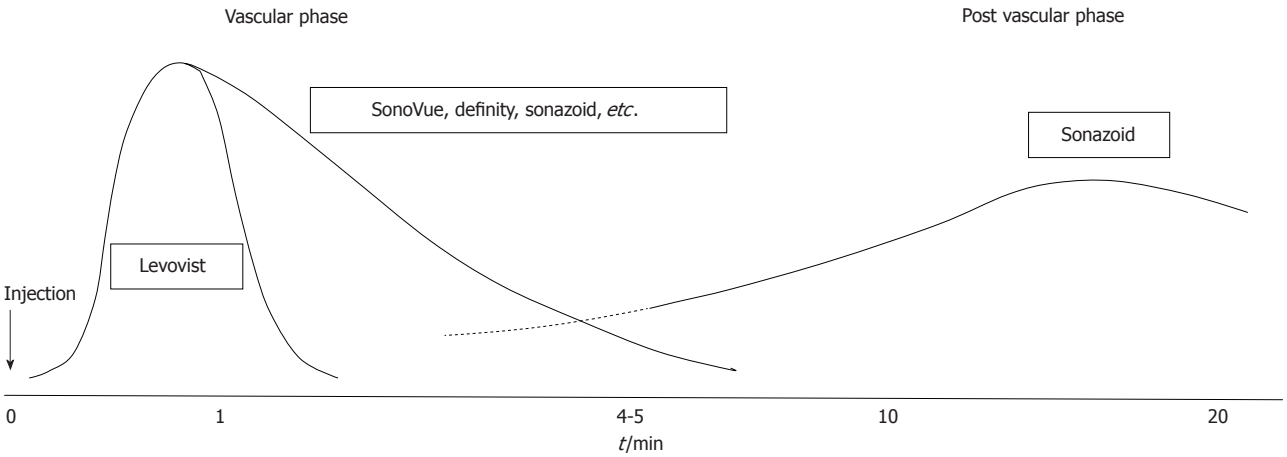

Figure 1 ***In vivo*** **kinetics of intravenous contrast ultrasound agents in the liver.**

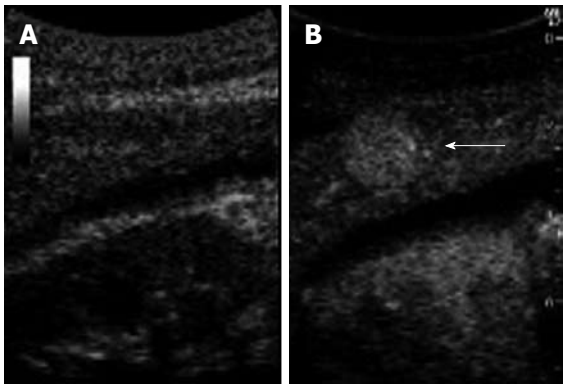

Figure 2 A 67-year-old man with a 1.5-cm hepatocellular carcinoma nodule located in segment 3 of the liver. A: B-mode ultrasound (US) cannot clearly depict the hepatocellular carcinoma (HCC) nodule; B: Contrast-enhanced US shows enhancement of HCC focus (arrow) in early vascular phase after administration of sonazoid.

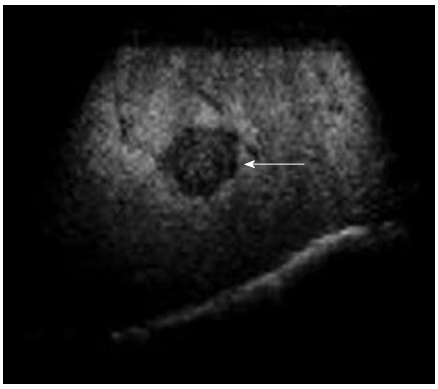

Figure 3 A 70-year-old man with a 2.0-cm hepatocellular carcinoma nodule located in segment 6 of the liver. Contrast-enhanced ultrasound using sonazoid shows the defect (arrow) imaging in post-vascular phase. The defect lesion can be targeted for insertion of a single needle by extending the time limitation.

Using second-generation contrast agents, real-time findings are better than those reported with Levovist[37] (Figure 1). Hypervascular HCC shows a short early arterial flushlike enhancement for less than 20 s, followed by homogeneous enhancement of the lesion in the late phase under low MI imaging (Figure 2). Needle insertion can be performed between the early arterial phase to late vascular phase in which maximum lesion conspicuity is observed[38]. In particular, HCCs have been visualized as defects in the liver parenchyma in the post-vascular phase only with Sonazoid use (Figure 1)[39-43]. Therefore, we can use these defect lesions as a target for insertion of a single needle (Figure 3). In patients who had previously undergone ablation for HCC, demonstration of viable nodules among all nodules detected in the post-vascular phase was achieved by injecting an additional new dose of Sonazoid in order to confirm tumor vascularity before needle insertion[44]. This defect-reperfusion US imaging is extremely useful in the depiction and confirmation of HCCs that are otherwise undetectable on US.

CLINICAL OUTCOMES

Treatment sessions and local tumor progression

Table 1 shows the treatment sessions of percutaneous ablation guided by contrast-enhanced US for HCC in published papers[12,36,45-49]. Numata *et al*[45] first reported that nine HCC nodules were successfully treated with percutaneous ablation therapy guided by intravenous contrast-enhanced US. These nine lesions were not detected on conventional US but were depicted on real-time contrast-enhanced harmonic gray-scale US with Levovist (incomplete local treatment, $n = 4$; small new lesion, $n = 5$). Since 2004, second-generation contrast agents of US have been used in percutaneous ablation guided by contrast-enhanced US. Particularly with Sonazoid use, complete tumor necrosis has been achieved in 94% with a single session of RF ablation[49]. In cases of HCC that are not clearly demarcated by B-mode US, dynamic contrast-enhanced sonography-guided RFA and are efficient approaches for guiding ablation.

Table 1 Treatment sessions of percutaneous ablation guided by contrast-enhanced ultrasound for hepatocellular carcinoma

Author[Ref.]	Year	Procedure	*n*	Contrast agent	Tumor size (mean, cm)	Treatment sessions (mean)
Numata *et al*[45]	2003	PEI, RFA	9	Levovist	1.4	ND
Minami *et al*[12]	2004	RFA	21	Levovist	1.7	1.05
Solbiati *et al*[46]	2004	RFA	51	SonoVue	ND	ND
Numata *et al*[47]	2008	RFA	15	Sonazoid	ND	1.04
Maruyama *et al*[48]	2009	PEI, RFA	42	Sonazoid	1.3	ND
Miyamoto *et al*[49]	2009	RFA	52	Sonazoid	ND	1.04
Minami *et al*[50]	2010	RFA	108	Sonazoid	1.7	1.1
Masuzaki *et al*[36]	2010	RFA	291	Sonazoid	1.6	1.33

HCC: Hepatocellular carcinoma; ND: Not described; PEI: Percutaneous ethanol injection; RFA: Radiofrequency ablation.

Table 2 Local tumor progression rates of percutaneous ablation guided by contrast-enhanced ultrasound for hepatocellular carcinoma

Author[Ref.]	Year	Procedure	*n*	Tumor size (mean, cm)	Follow-up (mean, mo)	Local tumor progression (%)
Maruyama *et al*[48]	2009	PEI, RFA	42	1.3	8.6	0
Minami *et al*[50]	2010	RFA	108	1.7	4.3	0
Masuzaki *et al*[36]	2010	RFA	291	1.6	ND	2.1
Miyamoto *et al*[51]	2010	RFA	17	1.6	11	12

HCC: Hepatocellular carcinoma; ND: Not described; PEI: Percutaneous ethanol injection; RFA: Radiofrequency ablation.

The local tumor progression rates after RFA have ranged from 0% to 12% during the follow-up period[47,36,49,50] (Table 2). The risk of local tumor progression increases with size, but the local tumor progression rates of small HCCs were markedly dependent on whether or not the center of the HCC nodule was penetrated by the RF needle.

Dynamic contrast-enhanced US guidance vs conventional B-mode US guidance

The effectiveness of contrast harmonic sonographic guidance for RFA of HCC was evaluated in comparison with conventional B-mode US guidance[12,36,51] (Table 3) (Level of evidence: grade B, level 2b). Dynamic contrast-enhanced US significantly helps in the placement of RFA electrodes in hypervascular HCCs that cannot be adequately depicted by B-mode sonography. In a randomized controlled study, the number of treatment sessions was significantly lower in the contrast harmonic US group (mean, 1.1 ± 0.2 *vs* 1.4 ± 0.6, $P = 0.037$)[51]. Treatment analysis showed that the complete ablation rate after a single treatment session was significantly higher in the contrast harmonic US group than in the B-mode US group (94.7% *vs* 65.0%, $P = 0.043$). Moreover, Masuzaki *et al*[36] reported in a large-scale study that the detectability of tumor nodules was 83.5% in conventional US and 93.2% in contrast-enhanced US ($P = 0.04$). The number of RFA sessions was 1.33 ± 0.45 with contrast-enhanced US as compared to 1.49 ± 0.76 in the historical controls ($P = 0.0019$). The number of RFA sessions required for complete ablation could be decreased in contrast-enhanced US-assisted RFA.

Few toxicities using US contrast agents have been reported, therefore the incidence of complications did not differ from that reported in patients treated by RFA alone[12,51].

Advances in techniques: Tumors abutting the diaphragm

HCC nodules abutting the diaphragm are difficult to depict because of ultrasound scatter due to pulmonary air. However, contrast-enhanced US through artificial pleural effusion can depict tumor vascularity in HCC. Thus, percutaneous RFA guided by contrast-enhanced US with artificial pleural effusion is an efficient approach[36,52]. Thirteen tumors were treated by contrast-enhanced US-guided RFA with artificial pleural effusion, and complete tumor necrosis was achieved in a single session in 12 lesions (92.3%)[52]. It took approximately 1 wk for pleural effusions to spontaneously resolve.

OTHER MODALITIES

Computed tomography guidance and computed tomography fluoroscopy

CT has high spatial resolution, good contrast, wide field of view, good reproducibility, and applicability to bony and air-filled structures. Potential advantages of CT guidance include confirmation of probe placement in relation to the tumor, improved visualization of the extent of ablation, and good correlation with actual lesion size[53-56] (grade C, level 3b). The use of a CT-guided method can be expected to reduce the rate of local tumor progression associated with percutaneous RFA. Laspas *et al*[53] reported that the ablation success rate was 87.3% (281/322 HCC nodules), and the survival rates at 1 year, 3 years and 5 years were 94.8%, 73.1% and 51.1%, respectively. Another merit is that the efficacy of treatment can be evaluated using contrast-enhanced CT immediately after treatment. Despite the advantages of CT, there are several limitations such as the increased time that is necessary for the procedure and exposure of the patient to ionizing radiation.

CT fluoroscopy guidance combines the high spatial resolution and good contrast resolution inherent in contrast-enhanced CT with the immediacy of fluoroscopic monitoring. Under CT fluoroscopy using either CT arteriography or iodized oil injection, we can target and puncture hepatic malignancies using a percutaneous ethanol injection needle. Real-time CT fluoroscopy is useful to guide the needle puncture and to monitor ethanol injection in small hepatic malignancies (grade C, level 3b). Takayasu *et al*[57] reported that the overall success rate in puncturing the lesions was 94.4% (17/18 sessions), the average number of punctures was 3.3, and this significantly decreased after the introduction of a puncture guide compared with freehand puncture ($P < 0.01$). However, the operator's hands are directly exposed to the beam of CT fluoroscopy, posing a potentially serious problem.

Magnetic resonance imaging guidance

MRI with its high soft tissue contrast can be advanta-

Table 3 Treatment sessions of radiofrequency ablation: Dynamic contrast-enhanced ultrasound guidance *vs* conventional B-mode ultrasound guidance

Author[Ref.]	Year	Study type	*n* (CEUS/B-mode)	Tumor size, (mean, cm) (CEUS/B-mode)	Mean treatment sessions (CEUS *vs* B-mode)	*P* value
Minami *et al*[12]	2004	Case control study	21/25	1.7/1.7	1.05 *vs* 2.0	0.002
Minami *et al*[53]	2007	RCT	19/20	1.2/1.3	1.1 *vs* 1.4	0.043
Masuzaki *et al*[36]	2010	Case control study	291/291	1.9/1.9	1.33 *vs* 1.49	0.0019

CEUS: Contrast-enhanced ultrasound; HCC: Hepatocellular carcinoma; RCT: Randomized controlled trial.

geous, and the capability of MRI for multiplanar imaging can be of value for needle placement and surveillance of the ablation procedure. Most of the current open MR scanners operate between 0.2 and 0.5 T, while clinical MR systems with a closed cylindrical design allow for significantly higher field strengths of up to 3.0 T or even more. While open MR systems allow for online monitoring of the puncture and easy replacement of the RF needle within a wide range, closed-bore MR systems improve lesion conspicuity and tumor delineation[58-63] (grade C, level 3b). Wu *et al*[59] reported that MRI and optical navigation system-guided ablation procedures were successfully performed on all 32 patients (36 tumor sites), and the 6- and 12-mo overall survival rates were 96.8% and 90.6%, respectively. Although MRI can be used to obtain reference images in ablation therapy, RF needle puncture is actually performed under sonographic guidance. Therefore, an MR-guided system can be used for ablation monitoring, but not for puncture guidance.

CO_2-enhanced ultrasound (ultrasound angiography)

CO_2-enhanced sonography is a sensitive means of detecting small HCC lesions. Kudo *et al*[64] reported that the detection rate of tumor hypervascularity on CO_2-enhanced sonography (86%) showed that it was more sensitive than digital subtraction arteriography (70%) and CT with iodized oil (82%). Imari *et al*[65] reported that CO_2-enhanced sonography is useful for the detection of hypervascular HCC and PEI treatment of lesions not detectable by conventional US. After direct intra-arterial injection of CO_2, enhancement of the tumor lasts approximately 10-60 min. This enhancement provides sufficient time to perform percutaneous ablation therapy (grade C, level 3b). Chen *et al*[66] reported that thirty-four (64.2%) of the 53 tumors showed complete necrosis after treatment, and the cumulative 1-, 2- and 3-year survival rates of patients who underwent CO_2-enhanced sonographically-guided percutaneous ethanol injection were 81%, 71% and 44%, respectively. However, nodules may become unclear because bubbles become trapped and accumulated in sinusoids with repeated injections of CO_2 microbubbles[67,68]. In addition, this method involves angiographic procedures that are invasive.

Virtual computed tomography sonography

Cross-sectional multiplanar reconstruction images from almost isovoxel volume data can be used for virtual sonographic visualization. This technique is available for patients with HCCs that became enhanced in the arterial phase of dynamic CT but were not well visualized with conventional B-mode US. Virtual CT sonography using magnetic navigation [real-time virtual sonography (RVS); HITACHI Medico, Tokyo, Japan] provides cross-sectional images of CT volume data corresponding to the angle of the transducer in the magnetic field in real-time[69-70]. RVS displays a real-time synchronized multiplanar CT image in precisely the same slice of the US plane. Thus, RVS can be used for real-time needle insertion guidance, especially for nodules demonstrated on CT, but not on US (grade C, level 3b). It has been reported that the technical success rate after a single treatment session was significantly higher in the virtual CT sonography group ($P = 0.017$)[71]. However, RVS has a weakness in that imaging gaps might be attributable to variations in the depth of breath-holding on CT and US examinations, as well as in the fact that the distance error between the magnetic sensor attached to the ultrasonic transducer and the magnetic generator becomes greater on intercostal US examination.

CONCLUSION

Percutaneous ablation therapy guided by dynamic contrast-enhanced US is an efficient approach for HCCs that are not clearly demarcated by B-mode US in both untreated and locally recurrent HCC cases. Moreover, second-generation microbubbles could facilitate dynamic contrast-enhanced US guidance of ablation therapy by extending the time limitation, simplifying the procedure, and improving detectability. RF ablation guided by second generation microbubble-enhanced US could become easier and be an efficient approach for hepatic malignancies that are not clearly depicted on B-mode US.

Abstract

AIM: To investigate the effects of moxibustion on down-regulation of the colonic epithelial cell apoptosis and repair of the tight junctions in rats with Crohn's disease (CD).

METHODS: Sixty male Sprague-Dawley rats were randomly divided into a normal control (NC) group, a model control (MC) group, an herbs-partitioned moxibustion (HPM) group, a mild-warm moxibustion (MWM) group and a salicylazosulphapyridine (SASP) group, with 12 rats in each group. The CD model rats were treated with trinitrobenzene sulphonic acid to induce intestinal inflammation. The rats in the HPM and MWM groups were treated at the Tianshu (ST25) and Qihai (CV6) acupoints once daily for 14 d, and the SASP group was fed SASP twice daily for 14 d. No additional treatment was given to the MC and NC groups. The microstructure of the colonic epithelium was observed under a transmission electron microscope, the transepithelial resistance was measured using a short-circuit current, colonic epithelial cell apoptosis was determined by terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labelling assay, and the expression of occludin, claudin-1 and zonula occludens-l (ZO-1) in the colonic epithelial junction was determined by Western blotting and immunofluorescence staining.

RESULTS: Compared with the MC group, the microstructure of the colonic epithelial barrier was significantly improved in rats treated with HPM, MWM or SASP, meanwhile, the current flow was reduced significantly, with values of 168.20 ± 6.14 *vs* 99.70 ± 3.13, 99.10 ± 4.28 and 120.30 ± 3.65 mA, respectively (P = 0.001). However, the HPM and MWM groups had higher current flow rates than the SASP group (99.70 ± 3.13, 99.10 ± 4.28 *vs* 120.30 ± 3.65 mA, P = 0.001). The number of the apoptotic colonic epithelial cells in HPM, MWM and SASP groups was largely reduced (61.5 ± 16.91 *vs* 15.5 ± 8.89, 14.8 ± 6.27 and 24.7 ± 9.68, respectively (P = 0.001); and the expression of occludin, claudin-1 and ZO-1 in the MWM and HPM groups was significantly enhanced (0.48 ± 0.10, 0.64 ± 0.09 *vs* 0.18 ± 0.05 for occludin, 0.12 ± 0.02, 0.17 ± 0.03 *vs* 0.05 ± 0.01 for claudin-1, and 0.08 ± 0.01, 0.11 ± 0.01 *vs* 0.02 ± 0.01 for ZO-1). And in SASP group, the expression of occludin and ZO-1 was also significantly increased (0.27 ± 0.04 *vs* 0.18 ± 0.05 for occludin and 0.05 ± 0.01 *vs* 0.02 ± 0.01 for ZO-1), but there was no significant difference for claudin-1. The HPM and MWM groups had higher expression of occludin, claudin-1 and ZO-1 than the SASP group.

CONCLUSION: HPM and MWM treatment can down-regulate apoptosis of colonic epithelial cells, repair tight junctions and enhance colonic epithelial barrier function in rats with CD.

INTRODUCTION

Crohn's disease (CD) is a chronic and non-specific inflammatory disease that may affect any part of the gastrointestinal tract from the mouth to the anus, thereby causing a wide variety of symptoms. CD has been mostly seen in Western industrialized countries. However, in recent years, the number of individuals affected by CD in China has significantly increased[1]. The exact cause of Crohn's disease is still unknown. In Western medical practices, treatment options include steroids, immunosuppressants and 5-aminosalicylic acid. However, these treatments are restricted to controlling symptoms, maintaining remission, and preventing relapse. Currently, there is no known pharmaceutical or surgical cure for Crohn's disease[2]. Although biologic therapies provide hope for CD patients, the financial cost and the significant side effects limit their application[2].

Moxibustion has been used in China for more than 4000 years to treat various diseases, including gastrointestinal diseases, such as Crohn's[3], ulcerative colitis[4] and irritable bowel syndrome[5]. Mild-warm moxibustion (MWM) and herbs-partitioned moxibustion (HPM) are critical components of moxibustion therapy. MWM is a type of moxa stick moxibustion that is performed by holding an ignited moxa stick a certain distance above the patient's skin, keeping the spot warm and making it reddened, but not burnt. HPM is performed by placing an herbal cake (traditional Chinese medicinal formula dispensing) on the patient's acupoints, followed by the placement and ignition of moxa cones, composed of refined mugwort floss, on the herbal cake to treat diseases. Previously, our group has used moxibustion in the clinic to treat mild or moderate CD, and the efficacy of this treatment can reach nearly 75%[6]. However, the underlying mechanisms of moxibustion treatment of CD remain elusive. Therefore, in this study, we used a rat model with trinitrobenzene sulfonic acid (TNBS)-induced CD and studied the role of moxibustion, as HPM and MWM, in repairing the colonic epithelial barrier using histomorphology, molecular biology, proteinology and electrophysiology.

Several factors have also been shown to contribute to the incidence of CD. For example, defective epithelial barrier function, which can be measured as increased intestinal permeability, has been implicated in CD[7] and can predict relapse during clinical remission[8,9]. However, increased permeability is also present in a subset of unaffected first-degree relatives of patients with CD[10-13] or other functional bowel diseases[14]. It has been demonstrated that damage of the colonic epithelial barrier, as in colonic epithelial death and the connective tissue damage, promotes CD in animal models[15] and humans[16-18]. The mechanisms underlying the loss of barrier function and permeability defects are thought to have a great potential in defining inflammation bowel disease (IBD) pathogenesis and guiding the development of novel treatment for IBD[19].

Therefore, the aim of this study was to investigate whether HPM and MWM can effectively treat CD and to clarify the underlying mechanisms regulating this process. To determine whether HPM and MWM are able to repair the colonic epithelial barrier, we examined the effects of moxibustion on colonic epithelial microstructure and transepithelial resistance, apoptosis of colonic epithelial cells and the expression of the proteins involved in colonic epithelial tight junctions, including occludin, claudin-1 and zonula occludens-l (ZO-1).

MATERIALS AND METHODS

Materials

Sprague-Dawley (SD) rats (male, Specific Pathogen Free, 150 ± 10 g) were purchased from Shanghai University of Traditional Chinese Medicine. All experimental protocols were approved by the Animal Research Ethics Committee of Shanghai University of Traditional Chinese Medicine, No. 09042.

Crohn's disease model establishment

Sixty male SD rats were randomly divided into a normal control (NC) group, a model control (MC) group, an HPM group, an MWM group and an SASP group, with 12 rats in each group. The CD models were established according to Morris' method[20]. Prior to model establishment, the rats were fasted and given water for 24 h. The rats were weighed, and 2% sodium pentobarbital (30 mg/kg) was administered through intraperitoneal injection (ip). The rats were anally injected with a TNBS solution mixed in 50% alcohol at a 1:2 ratio using a rubber tube. All groups of rats received the TNBS injection, with the exception of the normal control group, which received normal saline. The rubber tube was put into the anus 6-8 cm deep. Following the injection, the head of the rat was pushed down for about 1 min to prevent loss of the injected solution. The injection was repeated every 7 d for 4 wk. When the experimental CD rat models were completed, one rat was randomly selected from

each group to ascertain whether the CD models were successful by hematoxylin eosin staining.

Treatment

After the experimental CD rat models were confirmed to be successfully established, the rats were exposed to different treatments. In the HPM group, moxa cones (0.5 cm in diameter and 0.6 cm in length) made of refined mugwort floss were placed on an herbal cake [medicinal formula dispensing (radix) Aconiti praeparata, (cortex) Cinnamomi, *etc.*] at the Tianshu (ST25) and Qihai (CV6) acupoints and ignited. ST25 and CV6 were used to regulate intestinal functions. Two moxa cones were used for each treatment once daily for 14 d. In the MWM group, moxa sticks were ignited 1-2 cm above ST25 and CV6 for 10 min, with the temperature of the local area maintained at 43 ℃ ± 2 ℃. The rats in the SASP group were fed with SASP, which was prepared at the proportion of 1:0.018[21], twice a day for 14 d. The rats in the MC and NC groups did not receive any treatment. After the treatment, five groups of rats were sacrificed simultaneously. The distal colons were dissected at a length of 6 cm.

Transmission electron microscope

Samples (rats colonic mucosa) were cut into 1 mm^3 strips, fixed for 4 h at 4 ℃ in 5% glutaraldehyde, fully washed for 3 times in 0.1 mol/L phosphate buffered saline (PBS), postfixed for 2 h at 4 ℃ in 2% osmium tetroxide, dehydrated in a graded series of ethanols and embedded in Epon 812, cut into ultrathin sections (75 nm) and then stained with uranyl acetate and lead citrate. Sections were viewed in a HITACHI H-600 electron microscope at 80 kV (HITACHI, Tokyo, Japan).

Transepithelial resistance measurement

Colonic epithelial cells were isolated and immediately purified according to Evans *et al*[22]. Transepithelial resistance (Rt) experiments were performed[23] at least 1 wk after seeding the cells on filters, when the Rt of the monolayers reached stable values. The ussing chamber (A and B chamber) (Sigma, United States) used was modified to allow intact inserts to be placed into the chamber. The apical side of the colonic epithelium was directed to the A chamber, and the basolateral side of the colonic epithelium was directed to the B chamber. Both A and B chamber reservoirs contained Krebs-Henseleit solution with 5% oxygenation at 37 ℃. Short-circuit current, open-circuit transepithelial voltage, and transepithelial resistance were recorded by an Axon 2B clamp (Axon, United States). The data were analyzed by p Clamp 8.0 software (Axon, United States).

Western blotting

Western blotting analysis was conducted, as described by Zeissig *et al*[24] We randomly selected six rat colon samples from each group for detection. Rat colon samples were homogenized with a dounce homogeniser in lysis buffer containing 20 mmol/L Tris, pH 7.4, 5 mmol/L magnesium chloride, 1 mmol/L EDTA, 0.3 mmol/L ethyleneglycol tetra-acetic acid, 1 μL/mL aprotinin, 16 μg/mL benzamidine/hydrochloric acid, 10 μg/mL phenanthroline, 10 μg/mL leupeptin, 10 μg/mL pepstatin, 2 mmol/L phenylmethyl-sulphonyl fluoride, 210 μg/mL sodium fluoride, 2.16 mg/mL β-glycerophosphate, 18.4 μg/mL sodium vanadate and 1 μL/mL trypsin inhibitor. The lysates were passed through a needle, and the insoluble material was removed by centrifugation (350 × *g* for 5 min at 4 ℃). The supernatant was centrifuged at 43 000 × *g* for 30 min at 4 ℃, and the pellets were resuspended in lysis buffer. The protein concentrations were determined using a Pierce bicinchoninic acid assay. Aliquots of 5 μg of each sample were separated by polyacrylamide gel electrophoresis and were transferred to a nitrocellulose membrane. The blots were blocked for 2 h in 5% non-fat milk in phosphate-buffered saline and overnight in 5% bovine serum albumin in phosphate-buffered saline (at 4 ℃) before incubation with primary antibodies for 90 min at room temperature. Primary rabbit monoclonal immunoglobulin (Ig)G antibodies directed against occludin (1:200) (BD, United States), claudin-1 (1:200) (Invitrogen, United States) and ZO-1 (1:200) (Santa Cruz, United States) were used. Peroxidase-conjugated goat anti-rabbit IgG (1:1000) (Bioss, Beijing, China) and chemiluminescence fluid A and B (1:1) (Boster, Wuhan, China) were mixed for 1 h and 1 min, respectively. The reactive bands were detected using chemiluminescent reagents (Pierce Company, Minneapolis, United States).

Immunofluorescence staining

Rat colon samples were washed with 4 ℃ normal saline, fixed in 10% formalin for 24 h, embedded in paraffin, cut into sections and heated at 60 ℃ for 20 min. The sections were soaked in dimethyl benzene twice for 10 min, soaked in 100%, 95% and 70% alcohol for 5 min, and washed with water. A total of 2000 mL of 0.01 mol/L natrium citricum buffer solution (pH 6.0) was added to the pressure kettle, and the colon sections were placed on a staining rack in the pressure kettle. The samples were processed for 1-2 min at 0.142 MPa, removed, and quickly washed with water, followed by an additional wash with PBS for 5 min. Goat serum was added to the samples for 20 min at room temperature, and the superfluous fluid was removed. The samples were incubated with primary monoclonal antibody diluted 1:1000 (occludin Ab, claudin-1 Ab, ZO-1 Ab) in blocking buffer overnight at 4 ℃. The samples were incubated at 37 ℃ for 45 min and were washed 3 times for 2 min with PBS. The samples were incubated with secondary antibody diluted 1:10 000 (FITC-conjugated anti-rabbit) (Abcam, United States) in blocking buffer for 20 min at room temperature. Next, the samples were washed 3 times for 2 min with PBS. The samples were incubated with 5-10 mL DAPI staining solution for 10 min and were washed 4 times for 5 min with PBS. One drop of 50% glycerine was added to the sections, and laser confocal microscopy (Nikon, Japan)

was used to detect the expression of occludin, claudin-1 and ZO-1. The protein expression was evaluated in the 5 fields of vision.

Terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling assay

Transferase-mediated dUTP-biotin nick end labeling assay (TUNEL) staining was performed using the Dead-End™ Fluorometric TUNEL System (Promega, Madison, WI). A total of 5×10^7/mL cells were fixed with a 4% formaldehyde solution for 10 min and washed twice for 5 min with PBS. The slides were equilibrated with equilibration buffer and were incubated for 30 min at 37 ℃ with recombinant terminal deoxynucleotidyl transferase (rTdT) incubation buffer. The negative control sections were incubated with control incubation buffer without the rTdT enzyme. The slides were analyzed using a Leica TCS SP5 confocal microscope (Germany).

Statistical analysis

Results were expressed as mean ± SD. Statistical analyses were performed using SPSS 13.0 (SPSS Inc. Chicago, Illinois). Differences in mean were compared by one way analysis of variance. Differences were considered statistically significant if $P < 0.05$.

RESULTS

Microstructure of rat colonic epithelial tissue in different groups

In the NC group (Figure 1A and B), the morphology of the colonic epithelia, the cell membrane and the nuclear membrane were integral. The nucleolus could be seen clearly. In the cytoplasm, both the endoplasmic reticulum and mitochondria could be seen clearly. The junction of the epithelial cells was tight. The junctions among the cells were not broadened. We also observed abundant secretion by the cells, and there were villi present on the cell surfaces.

In the MC group (Figure 1C and D), the colonic epithelial cells were reduced in size, the integrity of the epithelial membrane and the nuclear membrane was compromised, the nuclei were absent, and most of the organelles inside the cytoplasm were absent. The MC group colonic epithelial cells contained bubbles inside the cytoplasm, and the number of mitochondria was significantly reduced. The junctions between the epithelial cells were loose, and a significant broadening of the colonic cells was observed. No villi could be detected on the cell surface.

In the colonic epithelial cells of the SASP group (Figure 1E and F), the integrity of the cell and nuclear membranes were disrupted, the nuclei of the cells were absent, the structure of the organelles inside the cytoplasm could not be seen clearly, and the number of mitochondria was relatively normal. In addition, the size of the colonic epithelial cells was significantly reduced, and bubbles of different sizes were present in the cytoplasm. The junctions between the epithelial cells were not tight, and the intracellular space was enlarged. No villi could be seen on the cell surfaces.

In the colonic epithelial cells of the HPM group (Figure 1G and H), the integrity of the nuclear membranes were almost normal. The nuclei of the cells were clear, the number of the organelles was reduced and the cell membranes were injured. Many mitochondria could be observed, the junctions between the epithelial cells were relatively tight, the intracellular spaces were increased, and some villi could be seen on the cell surfaces.

In the colonic epithelial cells of the MWM group (Figure 1I and J), the integrity of the nuclear membrane was relatively normal. The nuclei of the cells were present, a few bubbles appeared in the cytoplasm, and many mitochondria could be detected. The junctions between the epithelial cells were tight, while some intracellular spaces were tight and some intracellular spaces were broadened. Particle secretion was detected in the intracellular space. There were a few villi on the cell surfaces.

Table 1 Comparison of current value and current flow of rat colonic epithelium in different groups (n = 10, mean ± SD)

Group	Ω/cm^2	mA
NC	0.8603 ± 0.08396	58.60 ± 5.5217
MC	0.2976 ± 0.01099[a]	168.20 ± 6.1427[a]
SASP	0.4160 ± 0.01275[a,c]	120.30 ± 3.6530[a,c]
MWM	0.5054 ± 0.0223[a,c,e]	99.10 ± 4.2804[a,c,e]
HPM	0.5020 ± 0.01581[a,c,e]	99.70 ± 3.1287[a,c,e]

[a]$P < 0.01$ *vs* normal group; [c]$P < 0.01$ *vs* model group; [e]$P < 0.01$ *vs* SASP group. NC: Normal control; MC: Model control; SASP: Salicylazosulphapyridine group; MWM: Mild-warm moxibustion group; HPM: Herbs-partitioned moxibustion group.

Function of rat colonic epithelial barrier in response to moxibustion treatment

Compared with normal rats, the current flow of the colonic epithelial cells was significantly reduced in the MC group (168.20 ± 6.14 *vs* 58.60 ± 5.52 mA, respectively, $P = 0.001$), but the transepithelial resistance was increased (0.30 ± 0.01 *vs* 0.86 ± 0.08, respectively, $P = 0.001$) (Table 1). Following the HPM, MWM or SASP treatment, the transepithelial resistance was increased, and the current flow was decreased compared with normal rats. Compared with the MC group, the transepithelial resistance was significantly increased in rats treated with HPM, MWM or SASP, with values of 0.30 ± 0.01 *vs* 0.50 ± 0.02, 0.51 ± 0.02, 0.42 ± 0.01, respectively ($P = 0.001$). Meanwhile, the current flow was reduced, with values of 168.20 ± 6.14 *vs* 99.70 ± 3.13, 99.10 ± 4.28, 120.30 ± 3.65 mA, respectively ($P = 0.001$). However, we found that the current flow in the HPM and SASP groups was enhanced compared with the SASP group, with values of 0.50 ± 0.02, 0.51 ± 0.02 *vs* 0.42 ± 0.01 and 99.70 ± 3.13, 99.10 ± 4.28 *vs* 120.30 ± 3.65 mA, respectively ($P = 0.001$), but was lower than the flow rate of the normal group. These data suggest

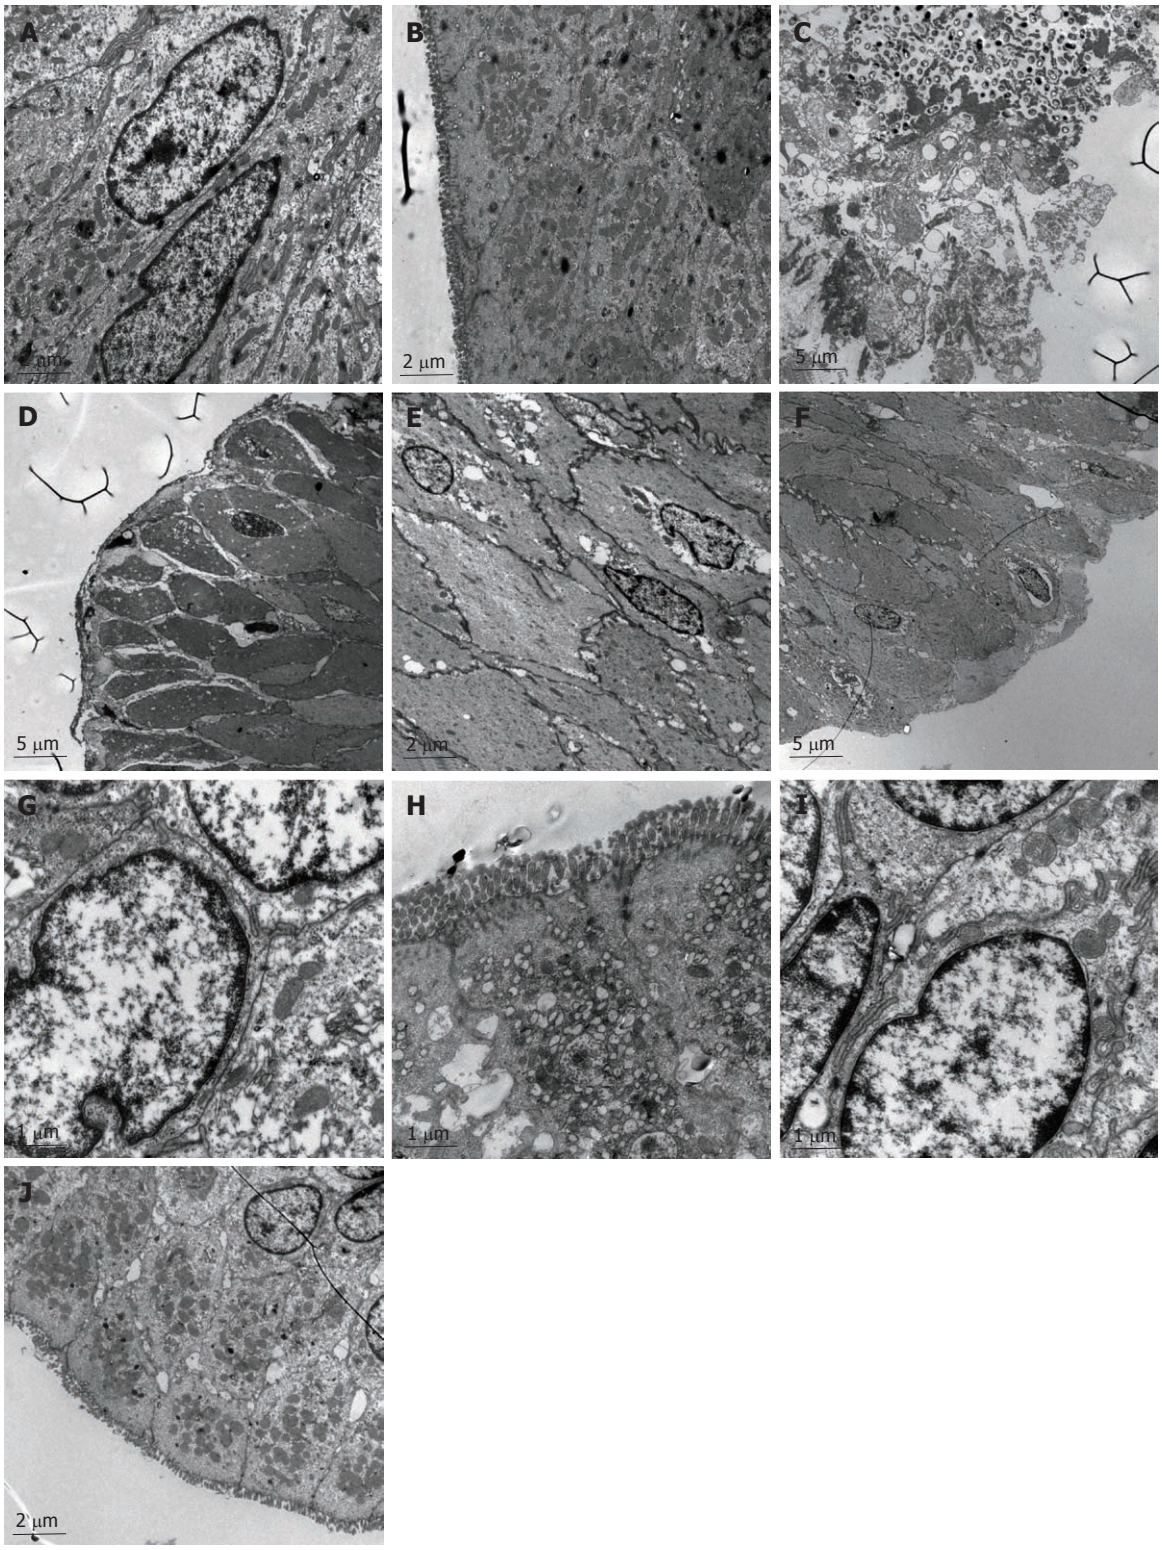

Figure 1 Microstructure of rat colonic epithelial tissues in different groups. A, B: Normal group (6000 ×, 6000 ×); C, D: Model group (2500 ×, 2500 ×); E, F: Salicylazosulphapyridine group (6000 ×, 2500 ×); G, H: Mild-warm moxibustion group (12 000 ×, 12 000 ×); I, J: Herbs-partitioned moxibustion group (12 000 ×, 4000 ×).

that the CD rats treated with HPW, MWM or SASP had colonic epithelial cells with significantly increased transepithelial resistance, which may further cause enhanced repair and/or protection of the colonic epithelial barrier (Figure 2A and B).

Reduced apoptosis of rat colonic epithelial cells in response to moxibustion treatment

Compared with the NC group, the number of apoptotic colonic epithelial cells was significantly increased in the MC group (61.5 ± 16.91 *vs* 11.5 ± 4.48, respectively, *P*

Table 2 Comparison of number and rate of apoptosis of rat colonic epithelial cells in different groups (n = 10, mean ± SD)

Group	Number	Rate (%)
NC	11.5 ± 4.48	0.0220 ± 0.0085
MC	61.5 ± 16.91[a]	0.0996 ± 0.0257[a]
SASP	24.7 ± 9.68[a,c]	0.0454 ± 0.0210[a,c]
MWM	14.8 ± 6.27[c,f]	0.0271 ± 0.0132[f]
HPM	15.5 ± 8.89[c,f]	0.0269 ± 0.0139[f]

Table 3 Expressions of occludin, claudin-1 and zonula occludens-1 in rat colonic epithelium in different groups (n = 10, mean ± SD)

Group	Occludin	Claudin-1	ZO-1
NC	1.26 ± 0.12	0.25 ± 0.04	0.28 ± 0.02
MC	0.18 ± 0.05[b]	0.05 ± 0.01[b]	0.02 ± 0.01[b]
SASP	0.27 ± 0.04[b,c]	0.08 ± 0.02[b]	0.05 ± 0.01[b,d]
MWM	0.48 ± 0.10[b,d,e]	0.12 ± 0.02[b,d,e]	0.08 ± 0.01[b,d,f]
HPM	0.64 ± 0.09[b,d,f]	0.17 ± 0.03[a,d,f]	0.11 ± 0.01[b,d,f,g]

[a]P < 0.05, [b]P < 0.01 *vs* normal group; [c]P < 0.05, [d]P < 0.01 *vs* model group; [e]P < 0.05, [f]P < 0.01 *vs* SASP group; [g]P < 0.01 *vs* MWM group. ZO-1: Zonula occludens-l; NC: Normal control; MC: Model control; SASP: Salicylazosulphapyridine group; MWM: Mild-warm moxibustion group; HPM: Herbs-partitioned moxibustion group.

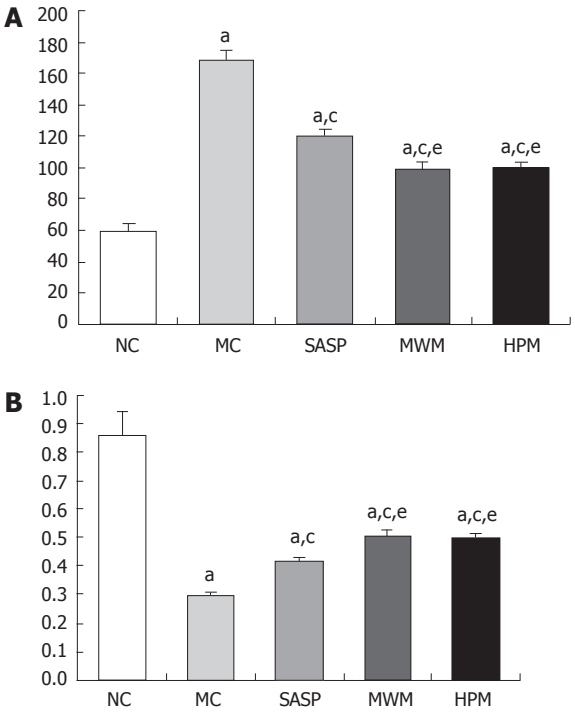

Figure 2 Current flow of rat colonic epithelial cells in different groups. A: The current flow of the rat colonic epithelium; B: The electric resistance of the rat colonic epithelium. NC: Normal control; MC: Model control; SASP: Salicylazosulphapyridine group; MWM: Mild-warm moxibustion group; HPM: Herbs-partitioned moxibustion group. [a]P < 0.01 *vs* normal group; [c]P < 0.01 *vs* model group; [e]P < 0.01 *vs* SASP group.

= 0.001) (Table 2). However, the number of colonic epithelial cells undergoing apoptosis decreased in the MWM, HPM and SASP groups (61.5 ± 16.91 *vs* 15.5 ± 8.89, 14.8 ± 6.27, 24.7 ± 9.68, respectively, P = 0.001). However, no significant differences in colonic epithelial cell apoptosis were found among the HPM, MWM and SASP groups. In addition, compared with the NC group, the differences in the number of apoptotic colonic epithelial cells were not statistically significant between the MWM and HPM groups; however, there was a difference in apoptosis between the SASP and NC groups (24.7 ± 9.68 *vs* 11.5 ± 4.48, respectively, P = 0.017). Moreover, the number of apoptotic colonic epithelial cells in the MC group was significantly increased compared with the NC group (0.10 ± 0.03 *vs* 0.02 ± 0.09, respectively, P = 0.001), and compared with the MC group, the number of apoptotic colonic epithelial cells in the HPM, MWM and SASP groups was also largely reduced (0.03 ± 0.01, 0.03 ± 0.01, 0.05 ± 0.02 *vs* 0.10 ± 0.03, respectively, P = 0.001). There was a larger number of apoptotic cells in the colonic epithelium in the SASP group than in the MWM or HPM groups (0.05 ± 0.02 *vs* 0.03 ± 0.01, 0.03 ± 0.01, respectively, P = 0.024 and P = 0.025). These data suggested that the MWM and HPM were able to down-regulate the apoptosis of colonic epithelial cells in rats with CD (Figure 3).

Expression of occludin, claudin-1 and zonula occludens-l in rat colonic epithelium by Western blotting

Compared with the NC group, the expressions of occludin, claudin-1 and ZO-1 were significantly reduced in the MC, SASP, MWM and HPM groups (Table 3). Compared with the MC group, the expressions of occludin, claudin-1 and ZO-1 in the MWM and HPM groups were significantly increased (0.48 ± 0.10, 0.64 ± 0.09 *vs* 0.18 ± 0.05, P = 0.002 and P = 0.001, respectively, for occluding; 0.12 ± 0.02, 0.17 ± 0.03 *vs* 0.05 ± 0.01, P = 0.001 for claudin-1; and 0.08 ± 0.01, 0.11 ± 0.01 *vs* 0.02 ± 0.01, P = 0.001 for ZO-1). And in SASP group, the expressions of occludin and ZO-1 were significantly increased (0.27 ± 0.04 *vs* 0.18 ± 0.05, P = 0.043 for occludin and 0.05 ± 0.01 *vs* 0.02 ± 0.01, P = 0.001 for ZO-1), but there was no significant difference for claudin-1. Moreover, the HPM and MWM groups had higher expression of occludin, claudin-1 and ZO-1 than the SASP group (0.48 ± 0.10, 0.64 ± 0.09 *vs* 0.27 ± 0.04, respectively, P = 0.015 and P = 0.001 for occluding; 0.12 ± 0.02, 0.17 ± 0.03 *vs* 0.08 ± 0.02, P = 0.021 and P = 0.001 for claudin-1; and 0.08 ± 0.01, 0.11 ± 0.01 *vs* 0.05 ± 0.01, P = 0.002 and P = 0.001 for ZO-1). The expression of ZO-1 between MWM and HPM groups was significantly different (0.08 ± 0.01 *vs* 0.11 ± 0.01, P = 0.001), but there was no significant difference for occludin and claudin-1 (Figure 4).

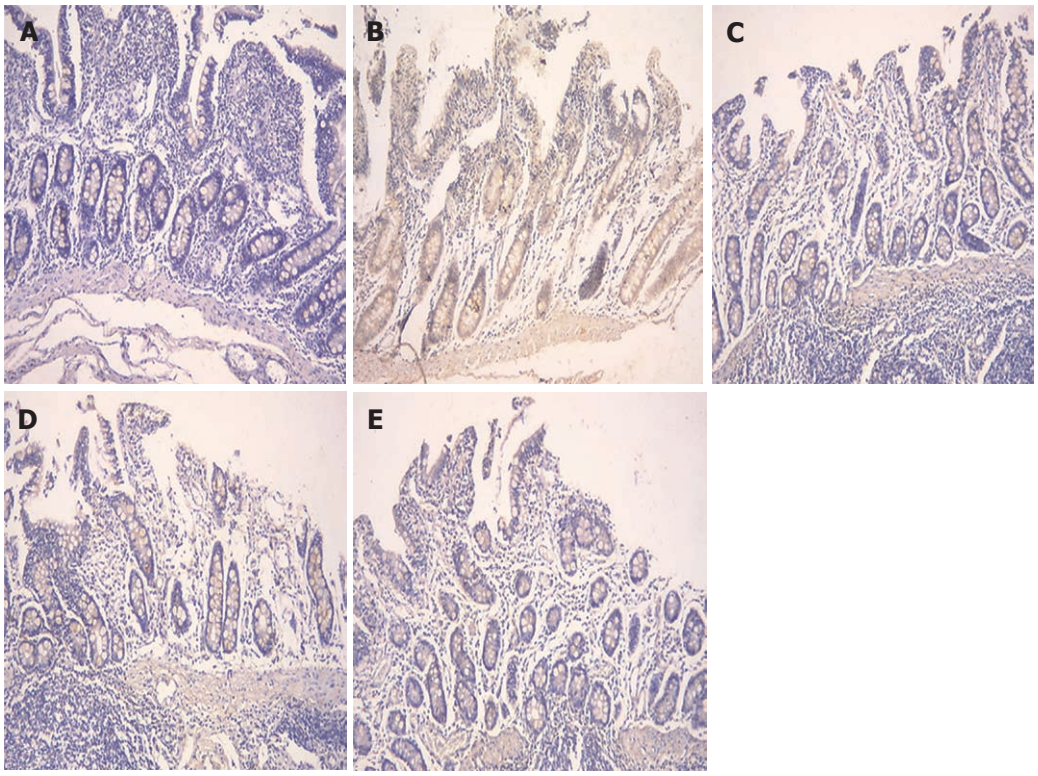

Figure 3 Apoptosis of colonic epithelial cells. A: Normal group (100 ×); B: Model group (100 ×); C: Salicylazosulphapyridine group (100 ×); D: Mild-warm moxibustion group (100 ×); E: Herbs-partitioned moxibustion group (100 ×).

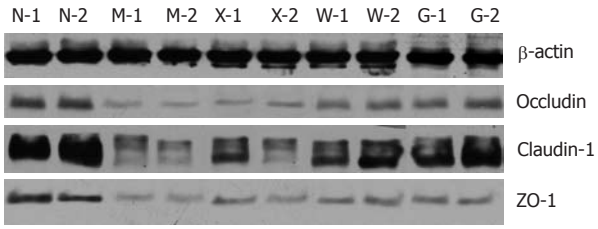

Figure 4 Expression of occludin, claudin-1 and zonula occludens-l in rat colonic epithelium. N: Normal group; M: Model group; X: Salicylazosulphapyridine group; W: Mild-warm moxibustion group; G: Herbs-partitioned moxibustion group.

Expressions of occludin, claudin-1 and zonula occludens-l in rat colonic epithelium by immunofluorescence staining

The expression of occludin (Figure 5), claudin-1 (Figure 6) and ZO-1 (Figure 7) was detected in the tight junctions and subjunctional lateral membranes of surface and crypt enterocytes under confocal immunofluorescence microscope, and the strength of the immunofluorescence signals was significantly reduced in these sites in the MC group. However, in the HPM, MWM or SASP groups, the signal significantly increased as HPM > MWM > SASP, which was consistent with the results obtained using Western blotting.

DISCUSSION

CD is a chronic, recurrent and refractory disease. It primarily causes abdominal pain, diarrhoea with abdominal mass, fistulisation and intestinal obstruction. Patients with CD usually have symptoms, including loss of appetite, sallow complexion, spontaneous perspiration, night sweat, insomnia and loss of energy and weight. The cause of this disease still remains unclear. Although the current pharmaceutical treatments are helpful in temporarily controlling the primary symptoms, they are unable to cure the disease.

Moxibustion has been used to treat various diseases in China and in other countries. Joos *et al*[3] found that Crohn's Disease Activity Index can be decreased from 250 ± 51 to 163 ± 56 (P = 0.003) in patients treated with acupuncture and moxibustion. Furthermore, the researchers observed that the general conditions of the patients that received acupuncture and moxibustion were also improved compared with the controls. We have used HPM and MWM to treat patients with mild and moderate CD. We observed that HPM and MWM alleviates abdominal pain and diarrhoea and improves sallow complexion, loss of energy and insomnia in CD patients[6]. So far, no side effects have been observed. However, the mechanisms underlying moxibustion-induced CD alleviation are undefined.

In this study, we observed under transmission electron microscope that there were reduced apoptosis, clearer cell structures and greater numbers of mitochondria in the colonic epithelial cells of rats treated with HPM or MWM compared with the rats in the MC or SASP groups. In addition, compared with the MC group, we also found that apoptosis of rat colonic epi-

thelial cells was significantly reduced in the HPM, MWM and SASP groups. Previously, we found that HPM and MWM could reduce the apoptosis of the colonic epithelial cells in rats with ulcerative colitis, which was medi-

ated by the Bcl-2/Bax and Fas/FasL pathways[25].

The balance between epithelial cell apoptosis and proliferation is pivotal for the maintenance of mucosal integrity in the intestine[26]; Di Sabatino *et al*[27] found that dysregulation of this balance is caused by an increase in apoptosis, which leads to cellular loss and tissue atrophy and is likely to be involved in the pathogenesis of CD. This increase was not mediated by a Fas-Fas ligand or by abnormal E-cadherin distribution. Increased matrix metalloproteinase-1 release from lamina propria mononuclear cells may be one of the possible mechanisms responsible for the increased apoptosis of enterocytes in CD. Another study showed that an increase of tumor necrosis factor-alpha mucosal release may promote enterocyte apoptosis in CD[28]. Whether similar mechanisms are used by moxibustion to reduce apoptosis in colonic epithelia needs further investigation.

In addition, we investigated the effect of HPM or MWM on the tight junctions of colonic epithelial cells. We observed that the epithelial cell junction was tighter, the intracellular space was relatively broadened and the expression of occludin, claudin-1 and ZO-1 involved in the tight junctions was significantly enhanced in the HPM and MWM groups as compared with the MC and the SASP groups. In addition, we found that the electric current of the cells in the MC group was significantly higher than in the other groups, and the electric current of the epithelial cells in the HPM or MWM groups was lower than in the SASP group.

The tight junction seals the space between adjacent epithelial cells, and in intact gastrointestinal epithelia, tight junction permeability is the rate-limiting step that defines the overall epithelial permeability[14]. Increased permeability of the tight junctions is thought to contribute to CD[24,29]. Occludin, the claudins and ZO-1 are key proteins in the tight junctions[30]. Patients with active or inactive CD have increased intestinal permeability and differential expression of these tight junction proteins[31,32], which may be associated with abnormal expression of the proinflammatory cytokines TNF-α, IFN-γ and IL-13[33-36]; whether moxibustion increases the expression of the proteins involved in tight junctions through similar mechanisms or *via* other mechanisms requires further investigation.

Overall, we found that HPM or MWM administration of the Tianshu (ST25) and Qihai (CV6) acupoints can reduce colonic epithelial cell apoptosis and repair the intracellular tight junctions in rats with CD, which results in a significant improvement of their barrier function and a decrease in epithelial permeability. Our findings provide the novel mechanisms by which moxibustion can significantly improve CD symptoms. These findings suggest that the moxibustion therapy can be used as an effective treatment for Crohn's disease.

ACKNOWLEDGMENTS

We want to thank Dr. Xiao-Ping Zhang for his help and technical support in this study.

COMMENTS

Background

Crohn's disease (CD) is a chronic, recurrent and refractory disease. The pathophysiology of CD has not been completely elucidated, making its treatment difficult. Previously, the authors used moxibustion in the clinic to treat mild and moderate CD, and the efficacy of moxibustion has reached nearly 75%. However, the regulatory effect of moxibustion on CD is still unknown.

Research frontiers

Defective epithelial barrier function is considered to be a critical factor that promotes CD. In this study, the authors investigated the effect of moxibustion on the colonic epithelial barrier.

Innovations and breakthroughs

Moxibustion at ST25 and CV6 has been found to be effective against CD. Both HPM and MWM are able to prevent the apoptosis of colonic epithelial cells, repair tight junctions, and enhance the function and integrity of the colonic epithelial barrier in rats with CD.

Applications

The experimental data can be used in further studies on moxibustion therapy in treatment of CD.

Peer review

This is an interesting study reporting how moxibustion can repair the colonic epithelial barrier in rats with Crohn's disease.

Abstract

AIM: To estimate the burden of undiagnosed celiac disease (CD) in the Mediterranean area in terms of morbidity, mortality and health cost.

METHODS: For statistics regarding the population of each country in the Mediterranean area, we accessed authoritative international sources (World Bank, World Health Organization and United Nations). The prevalence of CD was obtained for most countries from published reports. An overall prevalence rate of 1% cases/total population was finally estimated to represent the frequency of the disease in the area, since none of the available confidence intervals of the reported rates significantly excluded this rate. The distribution of symptoms and complications was obtained from reliable reports in the same cohort. A standardized mortality rate of 1.8 was obtained from recent reports. Crude health cost was estimated for the years between symptoms and diagnosis for adults and children, and was standardized for purchasing power parity to account for the different economic profiles amongst Mediterranean countries.

RESULTS: In the next 10 years, the Mediterranean area will have about half a billion inhabitants, of which 120 million will be children. The projected number of CD diagnoses in 2020 is 5 million cases (1 million celiac children), with a relative increase of 11% compared to 2010. Based on the 2010 rate, there will be about 550 000 symptomatic adults and about 240 000 sick children: 85% of the symptomatic patients will suffer from gastrointestinal complaints, 40% are likely to have anemia, 30% will likely have osteopenia, 20% of children will have short stature, and 10% will have abnormal liver enzymes. The estimated standardized medical costs for symptomatic celiac patients during the delay between symptom onset and diagnosis (mean 6 years for adults, 2 years for children) will be about €4 billion (€387 million for children) over the next 10 years. A delay in diagnosis is expected to increase mortal-

ity: about 600 000 celiac patients will die in the next 10 years, with an excess of 44.4% *vs* age- and sex-matched controls.

CONCLUSION: In the near future, the burden of CD will increase tremendously. Few Mediterranean countries are able to face this expanding epidemic alone.

INTRODUCTION

Recent epidemiological studies show that the prevalence of celiac disease (CD) is underestimated not only in Europe, but also among the populations of Mediterranean regions such as the Middle East and North Africa[1-3], where its prevalence is similar to that recently observed in Western countries[4]. Indeed, in these two regions, a very high prevalence of CD has recently been reported both in the general population and in at-risk groups[2]. These high frequencies are associated with the widespread consumption of wheat and barley[1,5] and the high frequency of the DR3-DQ2 CD-predisposing haplotypes in these populations[6,7]. But these factors alone do not satisfactorily account for the spread of the CD epidemic in recent years[8,9]. The prevalence of CD among the general population varies from 0.14% to 1.17%[10-20]: 1%-1.3% in Turkey[10-12], 0.6%-0.96% in Iran[13,14], 0.5% in Egypt[15], 0.6% in Tunisia and Israel[16-19], and < 0.5% in Jordan, Lebanon and Kuwait[5,20]. Among high-risk groups [including patients with a positive family history, insulin-dependent diabetes mellitus (IDDM), thyroiditis] the prevalence of CD ranges from 2.4% to 44%, assessed by serological markers and biopsy[21-24].

Egypt, and indeed all North African countries, were significant producers of wheat, and largely used barley for beer brewing; they were considered the "granary" of Romans for over 4 centuries. Bread, mostly made of wheat flour and called "the survival" in some local languages[1], has been a staple food for thousands of years. Similarly, the widespread use of couscous [from grossly milled durum wheat (*Triticum durum*)] dates back over 2000 years. But the use of wheat and other gluten-containing cereals is also increasing in the countries where it has been a staple for centuries[25,26].

The diffusion of pasta across all the Mediterranean countries is relatively recent and stems from the industrial development of grain processing. Unfortunately, a side effect of this positive dispersal may be the enormous increase in gluten intolerance, which is at a truly epidemic level. CD is now a widespread public health problem that also involves the populations of developing countries, as well as China and India[27,28]. However, this epidemic is not fully recognized since a sizeable number of cases are neither diagnosed nor cared for. In many Mediterranean countries, few cases are diagnosed because of the low level of awareness, knowledge and skill to deal with the problem, the lack of diagnostic resources and the attribution of CD symptoms to other, similar, illnesses[5,20]. The low awareness of CD often leads to a delay in diagnosis, which contributes to an excess of medical costs (CD includes growth failure, infant malnutrition, gastrointestinal diseases, anemia and more than 20 associated symptoms and conditions) and mortality.

All partners taking part in this study agreed that, to date, the best available estimation of CD-associated medical cost was that reported by Long *et al*[29], and supported by Hershcovici *et al*[31]. The annual medical cost in the year preceding the diagnosis of CD, excluding diagnostic costs, was estimated to be $5023/patient, $1764 more than the cost of the same patients in the year after diagnosis[29]. In the four years preceding the diagnosis of symptomatic CD, the direct medical cost was estimated to be $11 037/patient. For a symptom- and age-matched control individual, not affected by CD, the cost after 4 years was estimated at $7073, with a difference of $3964 (about $1000/patient per year). This difference is due to increased in-patients admissions, out-patient cost, laboratory tests, radiology, and office visits[29]. The diagnosis of CD resulted in a 30% reduction in direct medical expenditure. A similar 30% reduction in direct medical costs after diagnosis of CD was reported by Green *et al*[30]; the mean medical expenditure decreased from $8502 per capita to $7133 for the 2 years after diagnosis of CD.

The CD epidemic is the largest epidemic of food-induced permanent disease in the Euro-Mediterranean region. Very few countries of this region are able to face this expanding problem. The aim of this study was to estimate what the burden of CD will be in the near future, and how the CD epidemic will affect morbidity, mortality and health costs. We aim to provide stakeholders with a reliable prediction of the incoming picture of CD in the Mediterranean area, and so enable them to take action to face this epidemic.

MATERIALS AND METHODS

Population statistics

For statistics regarding each country in the Mediterra-

nean area, we accessed authoritative international sources (World Bank, World Health Organization and United Nations). Population size, median age, number of children (0-14 years), population growth rate, birth rate, death rate, infant mortality rate and literacy were retrieved and validated across multiple sources. The projected population from 2010 to 2020 was computed by adopting the 2008 growth rate as a constant over the following decade because the predicted rate of change of the growth rate would have not significantly affected our estimate. The number of children was incremented yearly by the birth rate and corrected for the infant mortality rate although mortality from 1 to 14 years is minimal in all the countries included in this evaluation.

Celiac disease

The prevalence of CD among the populations of Mediterranean countries, such as the Middle East and North Africa[1-3], is similar to that recently observed in Western countries[4]. The prevalence of CD among the general population varies from 0.14% to 1.17%[10-20]: 1%-1.3% in Turkey[10-12], 0.6%-0.96% in Iran[13,14], 0.5% in Egypt[15], 0.6% in Tunisia and Israel[16-19], and < 0.5% in Jordan, Lebanon and Kuwait[5,20]. An overall prevalence rate of 1% cases/total population was finally estimated to better represent the frequency of the disease in the area, since none of the available confidence intervals of the reported rates significantly excluded this 1% rate. The rate of symptomatic *vs* asymptomatic patients was obtained from several reliable reports from the area[3,9,10,17]. In summary, 85% of symptomatic patients are likely to suffer from gastrointestinal symptoms, which include diarrhea, abdominal pain, vomiting, irritable bowel, and gastritis[5,13,20,32-37]. Among the non-gastrointestinal complaints, the available estimates suggest 20% of children are affected by short stature[5,20,33-35,37], 40% of all cases are affected by anemia[5,20,32,36,37], 30% are afflicted by osteopenia[32,33,35,37], and 10% by abnormal liver enzymes[37,38].

Mortality has been reported in excess of 1.8 compared to age- and sex-matched controls[31,39,40]. The risk of cancer in undiagnosed adults is significantly increased and the mortality is almost doubled in the total cohort of affected persons compared with the general population[41,44].

Crude medical costs

Crude health costs were estimated for the years between symptoms and diagnosis only for symptomatic adults and children, and were standardized for purchasing power parity (PPP) to account for the different economic profile among Mediterranean countries. Since gross national product is different across countries, the PPP is based on the law of one price; in the absence of transaction costs, identical goods will have the same price in different markets. The PPP equalizes the purchasing power of different currencies for a given basket of goods, thereby providing a standardized estimate of cost across countries.

We assume that the cohort of CD without symptoms does not increase the average medical cost compared to non CD individuals (but this should also be revised, since a significant number of patients identified by screening had a posteriori clinical symptoms). Therefore, medical costs are estimated only for 1:7 adults and 1:5 children with CD symptoms.

Table 1 Excess need of health resources before the diagnosis of celiac disease

	n	Adult cost (€)	*n*	Child cost (€)
In-patient admission	2	9818	1	2254
Out-patient admission	1	879	1	586
Medical consultations	3	100	3	150
Specialist consultations	2	150	1	50
Lab test	4	446	2	297
Total per patient		11 393		3337

For each individual adult we assigned (on the basis of the reports cited and the clinical experience of the study partners), a minimal period of 6 years of delay between symptom onset and diagnosis of the disease[45,46], while this delay was two years for each assigned child with CD[9,20]. During that period an adult with CD required, in excess of age- and sex-matched controls, at least: 2 in-patient admissions, 1 out-patient admission, 3 primary medical consultations, 2 specialized consultations, and 4 laboratory tests. Similarly, children needed at least: 1 in-patient admission and 1 out-patient admission, 3 medical consultations, 1 specialized consultation and 2 laboratory tests (Table 1).

Estimated medical costs

The costs of health services were estimated based on the 2007 costs of the Italian National Health Service (NHS) which is similar to that of several European countries. We summed the total costs of the medical services required for each child or adult patient to obtain a standardized cost/per patient before the diagnosis of CD was made (Table 1). In this way, we obtained an estimation of the financial load (only for medical expenses) of symptomatic patients. The estimated cost according to the Italian NHS was then standardized for each country according to its PPP index. The total load of medical expenses for each country was calculated by multiplying the individual cost by the number of symptomatic patients estimated (adults and children).

Summary of reference data

(1) CD prevalence = 1%; incidence: new cases/year estimated at 1% of the live births, corrected for infant mortality rate; (2) symptomatic adults: 1 of every 7 cases, children 1:5 cases; (3) mortality of the total CD cohort: standardized mortality rate 1.8 compared to age- and sex-matched population; (4) delay between symptoms and diagnosis: adults 6 years, children 2 years; (5) associated conditions: 10%-15% of the total cohort - autoimmune disorders 30% (Turkey 1.9%, Iran 33%) and IDDM 10% (6.7%-18.5%); (6) complications: 16% of symptomatic CD patients; and (7) non gastrointestinal

symptoms: short stature 20% (only children), anemia 40% (20%-80%), osteopenia 30% (30%-50%), abnormal liver function 10% (Turkey 38%, Iran 25%)

RESULTS

Table 2 shows the population growth, number of children aged 0-14 years and the predicted figures for the year 2020, calculated based on a constant growth rate. The Mediterranean area will have about half a billion individuals by the year 2020, more than 100 million of which will be children aged 0-14 years. This estimate is likely to be in the low range, since some countries with a large population are likely to grow at a higher rate than this estimate before the year 2010.

Table 3 shows the prevalence of CD in each country in 2010 and the predicted prevalence in 2020. Within 10 years, the Mediterranean area will have to face more than 5 million cases of CD, one million of which will be in children. The large majority will not have clear symptoms and their diagnosis and care will be significantly delayed. Among the adult CD population, about 550 000 will present symptoms, while only 240 000 out of the 1 million estimated celiac children will be symptomatic. Table 4 shows the estimated number of clinical complaints associated with the CD epidemic. It is likely that more than 48 000 children will be affected by growth failure, there will be 317 000 cases of anemia and 238 000 individuals will be afflicted with osteopenia. Table 5 shows the estimated financial burden of the CD epidemic. There is no scope for a detailed calculation of costs, which will be related more to the availability of and access to medical services than to the actual cost of the service, but these figures help to understand the financial burden of the undiagnosed disease. European countries may not be impressed by these estimates but, for several other Mediterranean countries, these predicted costs might be a consistent load to the gross national product. More than €4 billion is a prudent estimate; only crude medical costs are included, not individual or social cost.

Table 6 shows the estimated number of deaths in the celiac disease cohort and the excess of deaths compared to age- and sex-matched controls. At the present rate, there will be more than 250 000 CD-related deaths in the Mediterranean area in 2020.

DISCUSSION

Celiac disease is a very common chronic disease that

affects adults and children in all wheat-consuming countries. It has also recently been reported in countries where its prevalence was previously unknown, such as China[27]. For more than two decades, we have been discussing the difference in the prevalence of CD among countries in Europe, North America and South America, and the conclusion is that there is no country where CD prevalence is significantly different from the overall prevalence of about 1%. Interestingly, the prevalence, at a global level, is not related either to the amount of wheat consumed by each country or to the prevalence of the human leukocyte antigen (HLA) DR3-DQ2 and DR4-DQ8 haplotype worldwide[47].

An excess prevalence of CD has been reported in an isolated population in North Africa and in a large population in Sweden, but again it is plausible that this excess prevalence reflects a bias related to the cohort rather than a true excess. The prevalence of CD is increasing worldwide, including in Europe[4], China[27] and India[28]. The only region where it has not yet been described is Central Africa, and this may be explained by the absence in this region of HLA predisposing haplotypes, and of polymorphisms of the major non-HLA genes, namely *SH2B3, IL12A, SCHIP, IL18RAP,* and *IL1RL1*, among others[47,48]. Recently, Barada *et al*[2] from Lebanon produced a comprehensive report of the situation in the

[2]Undiagnosed celiac patients have 1.8 standard mortality rate[39]. CD: Celiac disease.

countries that face the Mediterranean Sea, thereby increasing the awareness of CD in the area.

The EUROMED program supports several health-promoting activities across the Mediterranean, such as the surveillance of infectious diseases program and the Program for Transplants and Oncology EuroMed (Cancer Registries Network, Cancer screening and early diagnosis program, Mediterranean Transplant Network). Italy has requested that the CD epidemic be included in these programs (www.eeas.europa.eu/euromed/index_en.htm). The first step in facing this epidemic is to estimate the burden of CD in the area. Here we provide a reliable and simple picture of the present situation and a prediction of the development of the CD epidemic in the next 10 years, up to 2021.

The prediction obtained by simple straightforward calculations is impressive. Mediterranean countries will have to be prepared to deal with a considerable number of CD patients in the near future. There will be more than 5 million cases, one million of which will be children. But, more than the overall figures, each country will be especially concerned about the national figures. Our estimates are conservative figures, since we estimated a constant population growth over the next ten years, whereas the faster growing countries may have a more rapid growth rate than slower growing countries. Data on symptoms and common clinical problems are available only for symptomatic individuals, while a considerable percentage of so-called "asymptomatic" subjects notoriously report significant complaints a posteriori[49]. A limitation of this study is related to the uncertainties inherent in any prediction given the wide confidence intervals of rates. However, the starting 1% prevalence rate is not only very robust, because of innumerable replications, but it also probably underestimates rather than overestimates the problem[4,28,50]. The rate of symptomatic versus asymptomatic individuals is also fairly conservative.

The financial burden estimate is not aimed to acquire more precision; we provide a gross figure for the spectrum of resources needed in each country for the services required by symptomatic patients. The priority issue is the availability of services; in many African countries, services are mostly only available in large cities and specialized health institutions. In the rural areas, the availability of services can be far less than that required. Hence, the cost of these services should, sadly, be subtracted from the total financial burden. This impending cohort of CD patients does require, and moreover will require, access to health services as inpatients or outpatients, for medical consultations, laboratory tests and, after diagnosis, financial support for a lifelong gluten-free diet. There is universal concern and many countries demand the expertise and support for dissemination of know how and capacity building for the management of CD.

The EuroMed - MEDICEL project (www.medicel.unina.it) offers a platform to analyze the problem and develop strategies, but active national plans are required to face the burgeoning epidemic, and the heavy burden that it will place on the health and the finances of the population.

COMMENTS

Background

The incidence of celiac disease (CD) (i.e., permanent gluten intolerance), is

increasing in all countries in which there is awareness of this intolerance. In all Western countries, including the United States and South America, the observed prevalence of the disease went from 1:1000 individuals to more than 1:100 individuals in two decades. However, large series of cases have recently been reported from "new" countries like India, China, North Africa and the Middle East. Celiac disease is expanding over and above any predicted trend, and has taken on the semblance of a real epidemic.

Research frontiers

This expanding "epidemic" raises a series of unanswered research questions related to the following hot topics: **(1) the weight of environmental factors in the** increase of CD; **(2) the genetic profile associated with predisposition to CD; (3)** population differences in terms of genetic and environmental factors; **and (4)** the development of "sensitivity" to gluten.

Innovations and breakthroughs

In next 10 years, the Mediterranean area will have about half a billion inhabitants, 120 million of whom will be children. The projected number of CD cases in 2020 will be 5 million cases (1 million celiac children), with a relative increase of 11% compared to 2010. At a 2010 constant rate, there will be about 550 000 symptomatic adults and 240 000 sick children: 85% of patients will suffer from gastrointestinal complaints, 40% are likely to have anemia, 30% will be afflicted with osteopenia, 20% of children will have short stature and 10% will have abnormal liver enzymes. The estimated standardized medical costs for symptomatic celiac disease during the years of delay between onset of symptoms and diagnosis (mean: 6 years for adults, 2 years for children) will be about €4 billion (€387 million for the children) over the next 10 years. A delay in diagnosis is expected to increase mortality; about 600 000 deaths will occur among individuals affected by CD in the next 10 years, with an excess of 44.4% compared to age- and sex-matched controls.

Applications

The data produced in this study provide a picture of the cohort of patients affected by CD that will develop over the next 10 years in each country of the Mediterranean Basin. Stakeholders and health professionals in each country now have the figures with which it is possible to base adequate plans to face this epidemic. The diagnostic protocol must be simplified and made available not only in specialized centers, usually in large cities, but it should be especially important in rural districts.

Terminology

CD: Celiac disease is a permanent intolerance to gluten based on a genetic predisposition; **Projected prevalence: The number of celiac cases that are** expected to be present over the next 10 years; **Excess mortality: Undiagnosed** celiac cases have twice the risk of death compared to age- and sex-matched controls. If the expected cases are not diagnosed, there will be more than 200 000 excess deaths in the Mediterranean area; **Growth failure: 20% of children** (about 50 000) with undiagnosed CD are affected by weight loss and short stature, due to a growth failure.

Peer review

The paper is well written and deals with an important problem people are continuously facing.

Abstract

AIM: To find the most reproducible quantitative parameter of a standard ^{13}C-methacetin breath test (^{13}C-MBT).

METHODS: Twenty healthy volunteers (10 female, 10 male) underwent the ^{13}C-MBT after intake of 75 mg ^{13}C-methacetin p.o. on three occasions. Short- and medium-term reproducibility was assessed with paired examinations taken at an interval of 2 and 18 d (medians), respectively.

RESULTS: The reproducibility of the 1-h cumulative ^{13}C recovery (AUC_{0-60}), characterized by a coefficient of variation of 10%, appeared to be considerably better than the reproducibility of the maximum momentary ^{13}C recovery or the time of reaching it. Remarkably, as opposed to the short gap between consecutive examinations, the capacity of the liver to handle ^{13}C-methacetin increased slightly but statistically significantly when a repeat dose was administered after two to three weeks. Regarding the AUC_{0-60}, the magnitude of this fixed bias amounted to 7.5%. Neither the time gap between the repeat examinations nor the gender of the subjects affected the ^{13}C-MBT reproducibility.

CONCLUSION: ^{13}C-MBT is most reproducibly quantified by the cumulative ^{13}C recovery, but the exactitude thereof may be modestly affected by persistent stimulation of CYP1A2 on repeat examinations.

Key words: ^{13}C-Methacetin; Breath test; Isotope application in medicine; Liver; Reproducibility

INTRODUCTION

There is no surprise that non-invasive diagnostic procedures in medicine attract much attention from either side participating in the search of any cause of malfunctioning of the organism-patients would definitely prefer methods sparing them the necessity of encroaching the body integrity, like for example a liver biopsy, whereas physicians too would prefer to avoid inflicting pain on their patients. A brilliant idea of per oral administration of ^{13}C-enriched substrates in order to get information on the metabolic efficiency or functional mass of the liver is a

practical answer to the requirement outlined above. Continuous research work has brought about considerable progress and nowadays it is possible to assess by means of ^{13}C breath tests the microsomal, the cytosolic, and the mitochondrial function of the liver[1-4]. A look at pertinent literature shows that during the past decade, from among the compounds applied for microsomal ^{13}C breath tests, ^{13}C-methacetin has steadily been making its way to be recognized as the most frequently used substrate. A number of features support its usefulness as a functional liver probe: a fast metabolism to acetaminophen and $^{13}CO_2$ by cytochrome P450 1A2 (CYP 1A2), safety at low doses applied for a breath test, and a low cost[1-4]. Accordingly very promising results on its diagnostic usefulness were obtained in patients with chronic hepatitis C virus infection[5,6], primary biliary cirrhosis[7,8], non-alcoholic steatohepatitis[9], and various stages of liver cirrhosis[10-14], including those awaiting a liver transplantation[15].

A vital asset of any measurement or diagnostic method used in medical practice is an ability to provide reproducible results. Quite surprisingly a search of data on the reproducibility of the ^{13}C-methacetin breath test (^{13}C-MBT) revealed this item as being almost a completely blank research area. We decided therefore to search in this prospective study for a quantitative parameter which would offer the best reproducibility for a standard ^{13}C-MBT.

MATERIALS AND METHODS

Subjects

Twenty healthy non-obese subjects, 10 female and 10 male were invited to enter the study; their mean age was 25 years (range 21-31 years), and their average body mass index was 22.38 ± 0.64 kg/m^2. During a screening interview the participants declared themselves as being in full health according to the World Health Organisation criteria[16]. Among the participants three (1 male and 2 female) were habitual cigarette smokers. All the subjects categorically denied a systematic use of significant amounts of alcoholic beverages. None of the volunteers did take any medication except for oral hormonal contraception which was used by 4 female. Exclusion criteria to attend the study comprised a history of surgery affecting the digestive tract anatomy, with the exception of appendectomy, current use of any drugs which might affect gastrointestinal motility, and pregnancy. In every subject the normal structure and size of the liver was confirmed by means of an ultrasonographic examination performed by a qualified investigator.

The study was conducted in accordance with the Helsinki Declaration, and every volunteer gave written consent to participate after getting information as to the aim, protocol and methodology of the project. During the introductory interview the subjects were instructed not to eat any food with a naturally increased ^{13}C content, such as products made of maize, cane sugar, pineapple, or kiwi fruit for 48 h preceding the examination[17-19].

Experimental protocol

Every subject underwent three examination sessions, held on separate days. In half of the volunteers the two first sessions were taken 2-4 d apart, and the third one was pursued 2-3 wk later. In the other half of the subjects the schedule was inversed, i.e. the first two examination measurements were taken 2-3 wk apart, followed by a third one 2-4 d after the second one. The assignment of the order of intervals separating the sessions (short-long or long-short) was randomized. Accordingly, the assessment of the short-term reproducibility involved 20 pairs of examinations separated by a median 2 d break (range 2-4 d), whereas the medium-term reproducibility was evaluated on 20 pairs of the most distant examinations, i.e. taken at a median interval of 18 d (range 17-23 d).

The volunteers came to the laboratory in the morning, after a 12-h overnight fast and abstaining from cigarette smoking (if applicable). In the female volunteers the examinations were taken always within the same phase of their menstrual cycle. After a 15-min rest in a sitting position, necessary for stabilization of the metabolism, a basal sample of the exhaled air was collected. At the time point designated "0" the subjects took 75 mg ^{13}C-methacetin (code INC590P, Euriso-Top SA, Saint-Aubin, France; according to the certificate of analysis, the manufacturer guarantees ⩾ 99% isotopic ^{13}C atom enrichment determined by proton NMR) orally dissolved in 200 mL unsweetened black tea. Samples of expiratory air for $^{13}CO_2$ measurement were collected at 3, 6, 9, 12, 15, 18, 21, 24, 27, 30, 40, 50, 60, 75, 90, 105, 120, 150 and 180 min[20]. The procedure of collecting the breath air was standardized: the subjects took in breath and held it for 10 s, then steadily blew the air into a special aluminium covered plastic bag of 1.1 L capacity (Fischer Analysen Instrumente GmbH, Leipzig, Germany) equipped with a mouthpiece and an unidirectional valve[21,22]. The bag was closed with a plastic cork immediately at the end of the exhalation and stored for analysis. The subjects remained seated quietly and fasted throughout the whole period of the collection of the samples.

Measurement of $^{13}CO_2$ and derivation of the breath test parameters

Concentrations of $^{13}CO_2$ in the probes of the exhaled air were measured with the use of a non-dispersive isotope-selective infrared spectrometry apparatus (IRIS, manufactured by Wagner Analysen Technik Vertriebs GmbH, Hamburg, Germany; a model equipped with 16 ports for simultaneous mounting of bags with air samples was used). Following the procedures described previously[20,23,24], curves of the momentary and cumulative recovery of ^{13}C in the exhaled air relative to the administered oral dose of ^{13}C-methacetin were constructed within the time domain of 0 to 180 min. Subsequently the following parameters were derived: D_{max} - the maximum momentary ^{13}C recovery in expiratory air, T_{max} - the time elapsing from the intake of the substrate until the occurrence of the D_{max}, and AUC_i - the cumulative ^{13}C recovery within

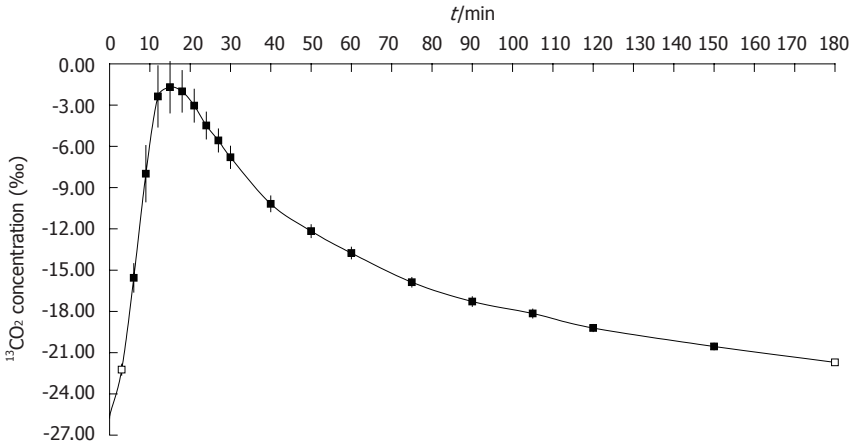

Figure 1 Time course of the $^{13}CO_2$ content within the total pool of exhaled CO_2 after peroral administration of 75 mg ^{13}C-methacetin in 20 healthy volunteers who each underwent three breath tests on separate days. Filled rectangles represent the time points at which the rise in $^{13}CO_2$ concentration was statistically significantly different from the baseline measurement, open rectangles stand for values not statistically different from the baseline. The values shown are mean ± SE.

Table 1 Reproducibility of the ^{13}C-methacetin breath test

	D_{max}		T_{max}		$AUC_{0\text{-}60}$	
	S_term	M_term	S_term	M_term	S_term	M_term
CVp	16.23%	16.46%	30.57%	32.49%	10.00%	10.00%
RC	15.55% dose/h	16.80% dose/h	16.86 min	16.73 min	5.84% dose	5.86% dose
Bias proportional	N	N	N	Y	N	N
Bias fixed	N	Y	N	N	N	Y
$Delta_{0.05}$	3.80% dose/h	3.51% dose/h	4.0 min	3.8 min	1.43% dose	1.26% dose

T_{max}: Time to reach the maximum momentary ^{13}C elimination; D_{max}: Maximum momentary ^{13}C elimination; $AUC_{0\text{-}60}$: 60-min cumulative ^{13}C elimination in expiratory air, respectively; S_term: Short term reproducibility assessment on the basis of 20 pairs of ^{13}C-methacetin breath tests separated by a median 2-d break; M_term: Medium-term reproducibility evaluation involved 20 pairs of examinations accomplished at a median interval of 18 d. CV_P: Coefficient of variation for paired examinations; RC: Repeatability coefficient. $Delta_{0.05}$: The least difference detectable at $P = 0.05$ level, two-tailed in the case of 20 paired examinations.

a time span i, which was calculated by integration of the respective part of the momentary ^{13}C recovery curve.

Statistical analysis

The data were subjected to the Bland and Altman statistic for calculation of repeatability coefficients and check for a proportional or fixed bias[25,26]. In addition the reproducibility of breath test parameters was expressed in terms of the coefficient of variation for paired examinations, CV_p[27,28]. Sets of absolute values of individual differences in paired measurements were compared with the use of the paired or unpaired *t* test (where appropriate) in order to check if factors such as the time gap between the examinations, or the gender of the subjects affected the reproducibility. Other statistical methods comprised the use of a repeated measures analysis of variance (R_ANOVA) followed by a *post hoc* check on the significance of differences between means, which was accomplished with the Tukey's honest significant difference test[29]. Statistical significance was set at the $P < 0.05$ level, two-tailed. The results are presented as mean ± SE. All statistical analyses were performed with the use of Statistical 6.0 software[30].

RESULTS

Similar basal concentrations of $^{13}CO_2$ in the expiratory air were observed on the three study days, amounting to -25.79‰ ± 0.25‰, -25.44‰ ± 0.21‰ and -25.59‰ ± 0.22‰. After oral intake of the ^{13}C-methacetin solution an expected biphasic course of $^{13}CO_2$ content within the exhaled air was observed, characterized by a rapid rise followed by a less steep decline. R_ANOVA indicated that when referred to the basal situation, the rise in breath $^{13}CO_2$ was statistically significant between the 6th and the 150th minute (Figure 1).

Basic reproducibility assessment

As shown in Table 1, the T_{max} exhibited rather an unsatisfactory reproducibility, whereas the D_{max} displayed a fair reproducibility, supposedly sufficient from the point of view of diagnostic applications of the breath test. The reproducibility of the cumulative ^{13}C recovery relative to the administered substrate dose was strongly dependent on the time span included for the calculation of this parameter, and improved rapidly with inclusion of the subsequent measurement points (Figure 2). The $AUC_{0\text{-}60}$ attained a CV_p of 10%-identical in both the case of the

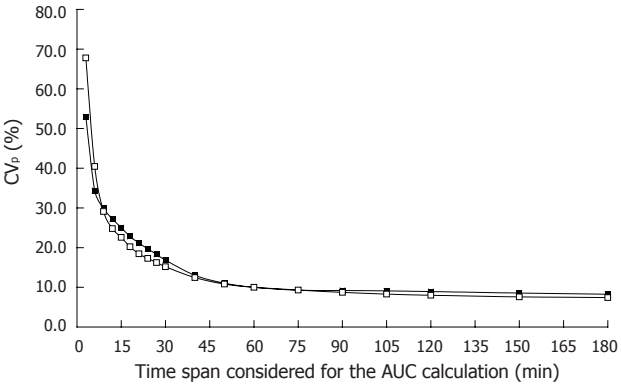

Figure 2 Relationship of the reproducibility of the cumulative ^{13}C recovery, expressed in terms of the coefficient of variation for paired examinations (CV_P), on the time span taken for the calculation of the area under the curve. The short-term reproducibility (open rectangles) assessment involved performance of 20 pairs of ^{13}C-methacetin breath tests separated by a median 2-d break, whereas 20 pairs of examinations accomplished at a median interval of 18 d were considered for the evaluation of the medium-term reproducibility (filled rectangles). AUC: Area under the curve.

short- or the medium-term reproducibility. The inclusion of data from beyond the 60 min did not bring about much refinement of the reproducibility of the AUC.

No statistically significant difference between the short- and medium-term reproducibility of the breath test parameters was found. Moreover, none of the parameters considered had a different short- or medium-term reproducibility in men and women.

Bland and Altman statistics of reproducibility

Bland and Altman plots pertaining to representative parameters of the ^{13}C-MBT are provided in Figure 3. Bland and Altman statistics revealed no proportional bias in either D_{max} or $AUC_{0\text{-}60}$ (Table 1). The same applied to the short-term reproducibility of T_{max}, whereas analysis of its medium-term reproducibility showed that the slope of the linear regression of the between-day differences on the corresponding means of the paired measurements was statistically significantly different from zero (Table 1).

The Bland and Altman statistic disclosed a fixed bias in the case of the medium-term reproducibility of either the D_{max} or the $AUC_{0\text{-}60}$. It means that the mean differences between the paired measurements taken a median of 18 d apart differed statistically significantly from zero. A closer look at the pertinent differences indicated that the ability of the liver to handle ^{13}C-methacetin increased when a repeat dose was administered after two to three weeks (D_{max}: 34.60% ± 2.75% dose/h on the first administration *vs* 39.08% ± 2.77% dose/h on the second administration, $P = 0.015$; $AUC_{0\text{-}60}$: 20.80% ± 0.99% dose on the first administration *vs* 22.27% ± 0.98% dose on the second administration, $P = 0.017$). No such effect was observed if two doses of ^{13}C-methacetin were administered in close sequence [D_{max}: 34.26% ± 2.41% dose/h on the first administration *vs* 34.91% ± 2.68% dose/h on the second administration, not significant (NS); $AUC_{0\text{-}60}$: 21.16% ± 0.96% dose on the first administration *vs* 21.03% ± 1.07% dose on the second administration, NS]. A graphical representation of the phenomenon observed is provided in Figure 4.

DISCUSSION

Without any doubt provision of reproducible measurement results is a feature of paramount importance, expected to be assured by methods designed for research and/or clinical applications in medicine[28,31-33]. Breath tests performed with the use of stable isotopes, such as ^{13}C, cannot be considered an exception in this respect, especially because during the past decade their clinical use has been constantly growing[24,34,35]. An increase in the number of relevant scientific papers indicates that, from among the tests dedicated to assess the activity of cytochrome P450, known as the microsomal breath tests, the ^{13}C-MBT has lately taken the lead. Accordingly, Yaron Ilan in his very recent review[36] provides evidence-based arguments that the ^{13}C-MBT is a powerful tool to aid hepatologists in bedside decision making.

While searching the literature we came across only one study which was aimed at the evaluation of the reproducibility of the ^{13}C-MBT. Petrolati *et al*[15] performed repeat measurements separated by an interval of 12 wk in 10 healthy volunteers. This scarcity of data encouraged us to undertake a systematic, prospective study on the reproducibility of the quantitative measures of a standard ^{13}C-MBT. Much effort was given in order to assure comparable conditions while performing the ^{13}C-MBT. Accordingly, all the examinations were started at the same time in the morning, a 15-min rest always preceded the collection of the basal samples of expiratory air, the procedure of taking the breath samples was standardized, and comfortable surroundings were provided to the volunteers so that they could stay relaxed while maintaining a sitting position throughout the examination. Moreover, the female participants were always examined in the same phase of the menstrual cycle. While designing the study protocol we decided to adopt the currently accepted mode of administration of ^{13}C-methacetin, namely a fixed oral dose of 75 mg[5,6,8,13,15,20,37,38]. It should be noted, however, that formerly other body mass adjusted dosage regimens were applied, encompassing 5 mg/kg in the pioneer work by Krumbiegel *et al*[39], then 2 mg/kg[7,11,12,40], as well as 1 mg/kg[10,41], and finally Iikura *et al*[42] applied in infants 0.5 mg/kg ^{13}C-methacetin.

Taking into account the investigative nature of our research, we generously took as many as 19 samples of breath air throughout 3 h. This approach appears to be precedential in nature, because for routine clinical use just a few measurement points are usually considered[15,42]. Nine samples were collected in the study by Zipprich *et al*[13] (at 10, 20, 30, 40, 50, 60, 80, 100 and 120 min after application of the substrate), and twelve samples of the expiratory air-every 15 min for 3 h of observation – were taken by Ciccocioppo *et al*[41]. A team of German researchers from Bochum collected thirteen samples-at 5, 10, 15, 20,

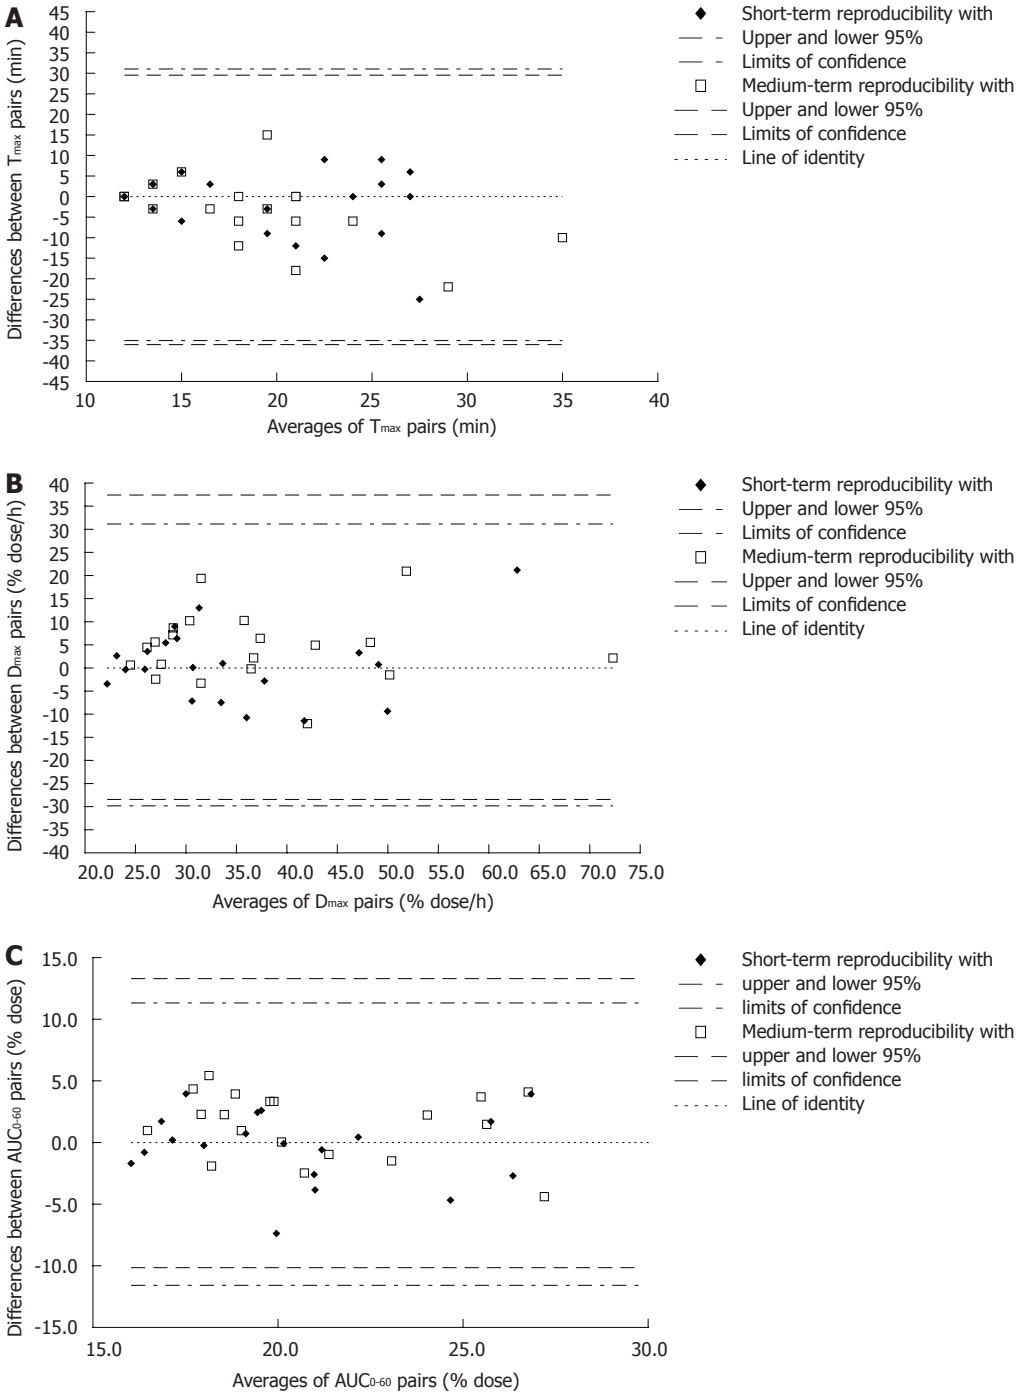

Figure 3 Bland and Altman statistics (plot of differences between pairs *vs* their means) of the short- (filled diamonds) and medium-term (open rectangles) reproducibility of the ^{13}C-methacetin breath test. T_{max}: Time to reach the maximum momentary ^{13}C elimination (panel A); D_{max}: Maximum momentary ^{13}C elimination (panel B); $AUC_{0\text{-}60}$: 60-min cumulative ^{13}C elimination in expiratory air (panel C). On each panel the respective borders of the 95% confidence intervals are plotted.

30, 40, 50, 60, 80, 100, 120, 150 and 180 min after administration of ^{13}C-methacetin[12]. One should mention that our frequent sampling of breath air (an aliquot was taken every 3 min during the first half hour) is similar to the new approach recently proposed by Lalazar *et al*[6,38] who introduced a "continuous" ^{13}C-MBT wherein samples of breath air are taken every 2-3 min and analysed with a laser-based device.

Our intention was to determine the length of the T_{max} with the greatest exactitude possible. Nevertheless, with the CV_p between 30.6% and 32.5%, the reproducibility of this parameter appeared to be a bit disappointing. Apparently the T_{max} may therefore not be the most useful parameter for the purposes of clinical decision making. On the other hand, we established on the basis of the within-subject study protocol that the repeatability of the T_{max} was sufficient to discern a difference in its length as small as 4 min ($P = 0.05$ level, two-tailed, $n = 20$).

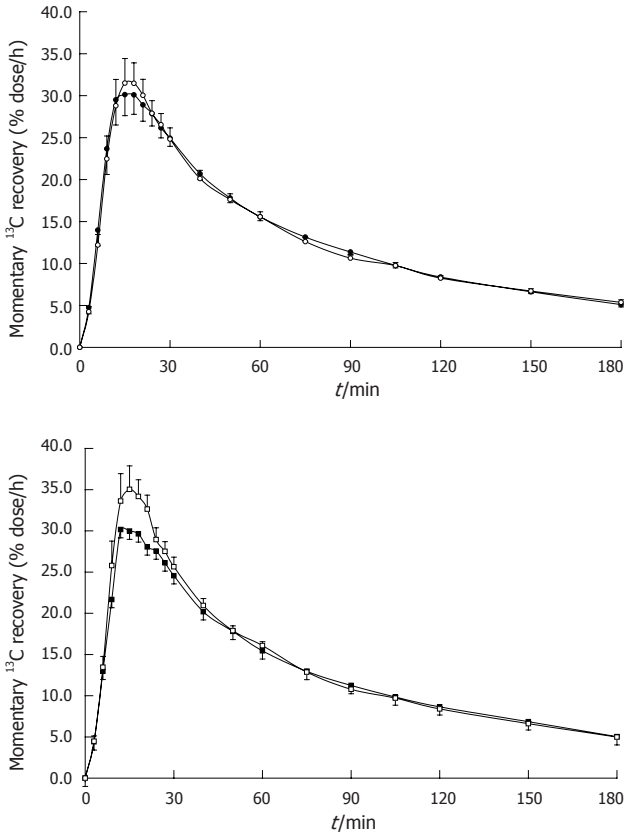

Figure 4 Corresponding curves of the momentary ^{13}C recovery in breath air after peroral administration of 75 mg ^{13}C-methacetin in 20 healthy volunteers if two examinations were taken at a median of 2 d apart (panel A) or if the examinations were separated by a median 18 d gap (panel B). Open symbols, the first administration, filled symbols, the second administration, the values shown are mean ± SE. See the text for the results of the statistical comparison of the matching D_{max} and $AUC_{0\text{-}60}$ values.

D_{max} (CV_p of 16%) showed better reproducibility, whereas the most reliable with regard to its repeatability appeared to be cumulative ^{13}C recovery in expiratory air. At this point it is important to emphasize that the reproducibility of the cumulative ^{13}C recovery was dependent on the time span considered for its calculation. Hence the CV_p improved rapidly with inclusion of the subsequent measurement points, achieving a reasonable value of 10% for the period comprising the first 60 min following the administration of the substrate. Consideration of later measurement points offered only a small further improvement in the reproducibility of the AUC. Our finding provides an argument in support of limiting the time for sample collection to 1 h when performing the ^{13}C-MBT-which is a standpoint coherent with the procedure proposed lately by the research group headed by Yaron Ilan from Israel[6,38].

Of great importance is the finding that in the case of each of the considered parameters, characterizing quantitatively the result of the ^{13}C-MBT, the reproducibility depended neither on the time gap between the repeat examinations nor on the gender of the subjects. Thus a convincing proof of reliability of this test has been obtained. Quite unexpectedly a thorough analysis of reproducibility, involving the application of the Bland and Altman statistic, disclosed the existence of a fixed bias in the case of the medium-term reproducibility of the D_{max} and the AUC_{60}. It was found that those two parameters increased statistically significantly if the repeat examinations were separated by a two- to three-week gap, which was not the case when the results of examinations taken at a close sequence were compared. A similar trend can, however, be discerned when looking at the results obtained by Petrolati *et al*[15] in their attempt to evaluate the reproducibility of the ^{13}C-MBT. They found that the 45-min cumulative ^{13}C recovery ($AUC_{0\text{-}45}$) in breath air after peroral intake of 75 mg ^{13}C-methacetin amounted to 17.5% ± 2.8% dose and to 18.8% ± 4.3% dose on the first and the second occasion, respectively. Although the two means did not differ statistically significantly (P = 0.30), it is evident that the $AUC_{0\text{-}45}$ determined on the second occasion increased by 7.4%. Quite a similar magnitude of increment was determined in our study-the $AUC_{0\text{-}60}$ rose by 7.5% on the repeat measurement taken after two to three weeks (P = 0.017), whereas it remained unchanged with an average difference of -0.6% (NS) between measurements performed a median of 2 d apart. A delayed and persisting stimulation of a minor, but statistically significant, magnitude of the CYP1A2 capacity to metabolize methacetin would therefore be inferred. It remains unclear if the phenomenon disclosed would have a clinically relevant impact. It is rather obvious that not all patients with liver disease require performance of a series of ^{13}C-MBTs, which most likely may pertain to those awaiting liver transplantations[15]. At present one cannot predict whether a stimulation of CYP1A2 observed on repeated ^{13}C-MBT in healthy volunteers will occur also in patients with major impairment of the liver functional reserve. Nevertheless the error in estimating the cumulative ^{13}C recovery in breath air caused by a stimulation of CYP1A2 by ^{13}C-methacetin seems to be quite small, not exceeding 8% according to our results, as well as those obtained by Petrolati *et al*[15].

Summing up, the study renders evidence that the ^{13}C-MBT provides satisfactorily reproducible results. Remarkably, the cumulative ^{13}C recovery appear to be the most reproducible quantitative index of the test, the computation of which over the first hour following administration of the substrate offers a reasonable 10% coefficient of variation, regardless of the time span separating the repeat measurements. One should be aware that the exactitude of this parameter may be modestly affected by a persistent stimulation of CYP1A2 on repeat examinations.

COMMENTS

Background

Great progress has been made during the past two decades with respect to the diagnostic use of stable isotopes in hepatology - it is now possible to assess by means of ^{13}C breath tests the microsomal, the cytosolic, or the mitochondrial function of the liver. From the point of view of a patient those tests are particularly attractive as in many instances they may result in avoidance of the inconvenience of a repeat liver biopsy.

Research frontiers

A crucial asset of any measurement or diagnostic method used in medical practice is provision of reproducible results. Stable isotope breath tests cannot be exempted from this scrutiny. Quite surprisingly, the reproducibility of one of the most popular among the ^{13}C breath tests applied in hepatology, the ^{13}C-methacetin breath test (^{13}C-MBT) has not been sufficiently examined before.

Innovations and breakthroughs

This prospective study is the first one dedicated to thorough evaluation of the repeatability of the ^{13}C-MBT. According to the study results, cumulative ^{13}C recovery is the most reproducible quantitative index of the ^{13}C-MBT, the computation of which over the first hour following administration of the substrate offers a 10% coefficient of variation, regardless of the time span separating the repeat measurements. An additional finding is that in the case of repeat examinations the exactitude of this parameter may be modestly affected by a persistent stimulation of CYP1A2 responsible for a fixed bias which amounted to 7.5%.

Applications

Promising results on the usefulness of the ^{13}C-MBT to evaluate reliably and accurately the metabolic liver functional reserve were documented in patients with various stages of liver cirrhosis, including those awaiting a liver transplantation, as well as those with chronic hepatitis C virus infection, primary biliary cirrhosis, or non-alcoholic steatohepatitis.

Terminology

The breath tests dedicated to get information on the metabolic efficiency of the liver are based on an elegant but simple idea of monitoring the elimination of $^{13}CO_2$ in expiratory air after per oral administration of ^{13}C-enriched substrates. Depending on the chemical structure of such substrates, the microsomal, the cytosolic, or the mitochondrial function of the liver may be evaluated noninvasively.

Peer review

The study was conducted carefully and the paper is well written.

Abstract

AIM: To determine the distribution of viral genotypes for primary or acquired lamivudine resistance.

METHODS: A total of 283 patients with chronic hepatitis B virus (HBV) infection (245 patients with chronic hepatitis B and 38 inactive hepatitis B surface antigen carriers) were included in the study. The HBV genotype was determined by using quantitative real-time polymerase chain reaction and sequence analysis, and tyrosine-methionine-aspartate-aspartate (YMDD) motif mutations were determined using the reverse transcriptase hybridization method.

RESULTS: Lamivudine resistance was determined in a total of 25 (10.7%) chronic hepatitis B patients. Eight subjects (4%) had primary resistance to lamivudine, and 17 (53.1%) had secondary resistance to lamivudine. Genotype D, which was isolated from 267 of the patients with chronic HBV infection, was the dominant genotype in Turkey.

CONCLUSION: Identification of YMDD motif mutations should have a positive impact on the selection of proper antiviral medication for patients, even for those who are nucleoside naïve.

Key words: Hepatitis B virus; Genotype; Resistance; Lamivudine; Tyrosine-methionine-aspartate-aspartate mutation

INTRODUCTION

Chronic infection with hepatitis B virus (HBV) is an

important cause of morbidity and mortality worldwide[1]. The objective in the treatment of this disease is to cease viral replication and provide improvement in liver histopathology; thereby preventing complications such as cirrhosis and hepatocellular carcinoma and the associated mortality[2].

Lamivudine is a synthetic nucleoside analogue that suppresses viral replication by inhibiting viral polymerase activity[3]. Although lamivudine is an effective and well-tolerated medication, duration of treatment is quite long, and resistance is an important issue[4]. Resistance to lamivudine is associated with mutations in the HBV polymerase gene. The most frequent mutation that develops with lamivudine is the tyrosine-methionine-aspartate-aspartate (YMDD) mutation of the HBV polymerase gene. It has been shown that all lamivudine resistant patients had a HBV YMDD mutation[5]. Among them, 41.3% of the patients had the rtL180M/M204V mutation, 25.7% had the rtL180M/M204I mutation and 33% had the rtM204I mutation. The frequency of mutation increases proportionally with the duration of lamivudine treatment, and the five-year post-treatment frequency is about 65%-70%[6,7]. On the other hand, resistance to lamivudine might also be seen in nucleoside naïve chronic hepatitis B patients or inactive HBsAg carriers. This resistance is associated with structural changes in the DNA polymerase enzyme gene[8,9]. The recommended methods of treatment aimed at preventing resistance include the use of more potent agents, changing the treatment in patients in whom the disease progressed during treatment, and the use of combined antiviral agents.

There are eight HBV genotypes (A-H), and the distribution of these genotypes varies by geographic region. Genotype A and C are prevalent in the American continent, whereas the prevalent genotypes are B and C in Asian countries, D in Europe, and E in Africa[10-13].

The aims of the present study were to determine the dominant viral genotype in chronic HBV infection in Turkey, and determine the prevalence of primary or acquired lamivudine resistance by genotype.

MATERIALS AND METHODS

This is a multi-center study including 17 centers from Turkey between January and September 2007. Patients between the ages of 18 and 65 years who were inactive HBsAg carriers or who had chronic hepatitis B (regardless of antiviral treatment status) were included in this study. Patients with co-infections with hepatitis C virus, hepatitis D virus or human immunodeficiency virus, along with patients with primary or secondary causes of liver disease other than hepatitis B (e.g., autoimmune hepatitis, steatohepatitis, hemochromatosis, Wilson's disease, alpha-1 antitrypsin deficiency, and severe cardiopulmonary disease) were excluded from the study. This study was approved by the Local Ethics Committee of the Department of Medicine at the Erciyes University in Turkey. A written informed consent was obtained from all participants before laboratory tests were performed.

Laboratory tests

The complete blood count was determined using an automated cell counter (Coulter LH750). Liver alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were measured in serum using standard commercial kits (Boehringer, Mannheim, Germany). All samples were screened to detect HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HBc (total), and anti-HBc IgM, by using third-generation microparticle enzyme immunoassays (Abbott Laboratories, Chicago, IL). HBV DNA was investigated by real-time polymerase chain reaction (PCR) (COBAS TaqMan 48 analyzer, Roche Diagnostics) according to manufacturer's instructions.

HBV genotypes were determined by DNA sequencing. HBV DNA was extracted from serum samples. HBV DNA polymerase gene region was amplified by nested-PCR using specific primers. PCR products were analyzed on UV transilluminator and purified from agarose gel. The purified products were sequenced by the Visible Genetics OpenGene system (Visible Genetics, Toronto, Ontario, Canada) and the Cy5.5 dye terminator cycle sequencing kit (Amersham, Pharmacia Biotech, Piscataway, NJ, United States). YMDD mutation in the HBV DNA polymerase gene was determined with RT hybridization (INNO-LiPA HBV DR-Innogenetics, Ghent-Belgium), according to manufacturer's instructions. A part of HBV domains B and C of the pol gene was amplified. The biotinylated PCR fragments were reverse hybridized using typing-membrane-based INNO-LIPA HBV DR strips. After hybridization, streptavidin labeled with alkaline phosphatase were added and bound to the previously formed biotinylated hybrids. Incubation with the substrate 5-bromo-4-chloro-3-indolylphosphate (BCIP)-nitro blue tetrazolium chromogen resulted in a purple- brown color development.

A percutaneous liver biopsy was performed at each center under local anesthesia (optional). A biopsy specimen of more than 1 cm in length with five to six portal tracts was collected. Chronic hepatic disease activity was classified according to the Knodell histological activity index (HAI)[14].

Diagnostic criteria

Chronic hepatitis B: (1) HBsAg positive for at least 6 mo; (2) serum HBV DNA > 20.000 IU/mL (> 10^5 copies/mL), often ranges between 2.000-20.000 IU/mL in HBeAg-negative patients; (3) persistent or intermittent elevation of ALT/AST levels; and (4) moderate or severe necro-inflammation.

Inactive HBsAg carriers: (1) HBsAg positive for at least 6 mo; (2) HBeAg-negative, anti-HBe-positive; (3) serum HBV DNA < 2.000 IU/mL (< 10^4 copies/mL); (4) persistently normal ALT/AST; and (5) no signs of hepatitis in liver biopsy.

Demographic features of the patients, possible routes of transmission of HBV, and the antiviral treatments

Table 1 Demographic features of study patients

	Chronic hepatitis B	Inactive HBsAg carriers	*P* value
No. of patients, *n* (%)	245 (86.6)	38 (13.4)	
Sex (male/female)	166/79	11/27	0.852

ALT: Alanine aminotransferase; HBV: Hepatitis B virus.

administered and their durations were all recorded. The decision to start antiviral therapy was based on the serum HBV DNA and aminotransferase levels, histological grade and stage at each center[15,16]. Lamivudine (100 mg/d) was administered orally in all eligible chronic hepatitis B patients. Resistance status was determined for patients receiving and not receiving lamivudine. The relationship between resistance and sex, body mass index, genotype, HBV DNA levels, ALT/AST levels, HBeAg positivity or negativity, and necro-inflammation and fibrosis in the liver were investigated in subjects with primary resistance.

Statistical analysis

"SPSS 12.0 for Windows" was used for statistical analyses. For continuous variables, descriptive statistics (mean, median, standard deviation, minimum and maximum) were calculated. For comparisons of categorized variables, the Chi-square test was used, and for continuous variables, the Student's *t* test and Mann-Whitney *U* test were used. $P < 0.05$ was considered statistically significant.

RESULTS

A total of 283 patients with chronic HBV infection composed of 245 patients with chronic hepatitis B and 38 inactive HBsAg carriers were included in the study; 193 were males, and 90 were females. No differences were observed between the two groups except for the levels of HBV DNA and ALT/AST (Table 1). The histopathological findings of chronic hepatitis B patients who underwent optional liver biopsy are presented in Table 1. The median Knodell fibrosis score was 2 (0-4), and the median HAI was 7 (1-18).

Genotype determination with sequence analysis revealed that the HBV isolated from 267 patients were all of genotype D. Comparison of subgroups of chronic hepatitis B patients in terms of the "e" antigen revealed that the levels of ALT were higher in patients who are positive for HBeAg compared to those who were negative (121.6 U/L and 81.9 U/L, respectively, $P = 0.012$). However, there was no statistically significant difference between the levels of HBV DNA (1.7×10^9 copies/mL and 1×10^8 copies/mL, respectively, $P = 0.150$, Table 2).

HBV drug resistance

HBV was isolated from a total of 267 patients with chronic HBV infection and analyzed for YMDD resistance using INNO-LiPA HBV DR. Of these patients, 104 (39%) had a history of previous treatment with an antiviral, and 32 (30.8%) of these patients had received lamivudine. The mean duration of lamivudine treatment was 18.5 ± 14.5 mo in these subjects, and 17 of these (53.1%) developed secondary resistance. Primary resistance to lamivudine was determined in 8 (4%) out of 202 lamivudine naïve patients. The frequency of YMDD

Table 3 Rates of tyrosine-methionine-aspartate-aspartate mutation in patients with chronic hepatitis B virus infection *n* (%)

	Chronic hepatitis B			Inactive HBsAg carriers	Total
	Previous lamivudine treatment		Total		
	Yes[1]	No			
YVDD + YIDD positive	17 (53.1)	8 (4)	25 (10.7)	1 (3)	26 (9.7)
YMDD negative	15 (46.9)	194 (96)	209 (89.3)	32 (97)	241 (90.3)
Total	32	202	234	33	267

[1]Patients who are receiving or received lamivudine previously. YMDD: Tyrosine-methionine-aspartate-aspartate; YIDD: Tyrosine-isoleucine-aspartate-aspartate; YVDD: Tyrosine-valine-aspartate-aspartate.

mutation in patients with chronic hepatitis B is shown in Table 3. Wild-type HBV was determined in 241 (90.3%) patients. YMDD mutation was determined in 26 (9.7%) patients, and only one of these subjects (1/33, 3%) was an inactive HBsAg carrier.

No relationship was established between YMDD motif mutation and viral load, body mass index, liver function tests, HBeAg positivity and liver histopathology. Similarly, there was no difference in those same parameters between chronic hepatitis B patients with primary and secondary resistance to lamivudine.

DISCUSSION

Lamivudine is the first nucleoside analogue approved for the treatment of chronic hepatitis B infection. It has been used successfully for years in the treatment of chronic hepatitis B patients due to its rapid suppression of HBV DNA levels and perfect side effects profile. It is often received as a single daily 100 mg dosage and is generally well-tolerated[17]. Although lamivudine is a potent medication against HBV, the duration of the treatment is quite long, and resistance is an important issue [4]. It has been shown that YMDD mutations increase with the duration of lamivudine treatment in chronic hepatitis B patients treated with lamivudine for long periods of time[5-7].

In the study by Alvarado-Esquivel *et al*[18], the prevalence of wild-type HBV was found to be 94.9%, and the prevalence of genotypic resistance to lamivudine was reported as 2.6%. Sun *et al*[19], on the other hand, observed the YMDD mutation in 17% (42/247) of patients treated with lamivudine. These patients had used lamivudine for a mean duration of 533 d, and the cumulative incidence of YMDD mutation was 41.3%. The YMDD motif mutation has been investigated in the polymerase gene in 267 of 283 chronic hepatitis B patients. Among the subjects, 90.3% were infected with wild-type HBV. The frequency of the YMDD mutation was 10.7%, and the majority of these were chronic hepatitis B patients. However, the prevalence of YMDD mutation was lower in inactive HBsAg carriers (3%). This patient group was infected with viruses that replicate less compared to wild-type viruses. The cause of YMDD mutations and the effects of these mutant serotypes on hepatic activation are not known. The findings of the present study are in line with the literature, as mutations were observed in 53.1% of the total 32 patients whose lamivudine therapy duration was 18.5 mo (secondary resistance).

Sensitive diagnostic tests allow for the identification of rtM552I/V mutant HBV in patients receiving lamivudine at the third month of treatment. The wild-type virus re-emerges upon termination of treatment with lamivudine, and resistant serotypes emerge immediately upon re-initiation of treatment. However, lamivudine resistance has also been reported in chronic hepatitis B patients with no history of lamivudine use, and inactive HBsAg carriers (primary resistance). The frequency of primary resistance, which is associated with structural changes in the DNA polymerase enzyme gene, ranges between 0% and 27.7%[9,20-23]. Five (27.7%) out of 18 nucleoside naïve patients, and 4 out of 36 (11.1%) patients were found to have the YMDD mutation in studies by Kobayashi *et al*[20] and Kirishima *et al*[21], respectively. Both studies revealed that all patients who were positive for mutation were also anti-HBe positive. Heo *et al*[22] observed mutations in 3 (7.5%) out of 40 lamivudine naïve patients and reported HBeAg positivity in one of these subjects. However, no YMDD mutation was observed in the first study by Matsuda *et al*[9,23] performed on nucleoside naïve chronic hepatitis B patients, whereas 2 (2.8%) out of 71 subjects were found to have the mutation in their second study.

Akarsu *et al*[24] reported from Turkey that 13 (18.3%) out of 71 asymptomatic carriers of hepatitis B with no history of antiviral treatment were infected with lamivudine-resistant HBV. In another study from Turkey, 6 (7.8%) of 77 nucleoside naïve patients were reported to have the YMDD motif mutation[25]. In the present study, YMDD motif mutations were found in 8 (4%) out of 202 patients with no history of antiviral treatment. The reason for the marked difference between these studies might be due to differences in geographical location, mean age, age at infection, HBeAg positivity, HBV genotype and levels of viral load.

Some studies have shown that YMDD mutation is a feature of patients with low viral load[20,21]. However, no relationship was demonstrated in other studies between viral load and mutation[22-24]. In this study, no relationship was found between YMDD motif mutation and viral load, body mass index, liver function tests, HBeAg positivity and liver histopathology.

Studies from Turkey performed by Tuncbilek *et al*[25], Senturker *et al*[26] and Bozdayi *et al*[27] have reported that all examined patients (77, 23 and 41 patients, respectively) were infected with HBV genotype D. However, the results from the previous studies may not be generalizable to the larger population of Turkey due to the inadequate number of patients and limited geographic locations from which the data in these studies were obtained.

In the present study, all 267 Turkish chronic hepatitis B patients were infected with HBV genotype D according to the genotype analysis performed with the sequence analysis method. This multi-center and comprehensive study was the first to show the dominance of the genotype D in Turkey.

In conclusion, lamivudine therapy has been associated consistently with secondary resistance in chronic hepatitis B patients. The assessment of genotypic resistance prior to re-treatment of chronic hepatitis B patients with lamivudine or a different antiviral agent might increase the efficacy of treatment and prevent complications. In this study, the frequency of primary resistance to lamivudine was found to be 4% in nucleoside naïve patients with chronic hepatitis B. In addition, the identification of YMDD motif mutations prior to nucleoside treatment should have a positive impact on the selection of proper antiviral medication for patients, even for those who are nucleoside naïve.

COMMENTS

Background

Hepatitis B virus (HBV) infection is a worldwide problem, with potentially 400 million individuals with active HBV infection. HBV is a significant cause of morbidity and mortality from cirrhosis, liver failure, and hepatocellular carcinoma in these populations. Lamivudine is still used widely to treat HBV infection in Turkey. However, lamivudine resistance is a major concern.

Research frontiers

Eight genotypes of HBV (A-H) have been identified, and increasing evidence suggests that certain genotypes may have a significant impact on both the choice of treatment and clinical outcome, and is also affected by the patterns of resistance manifested by local strains. The authors studied the genotype profiles and lamivudine resistance patterns of HBV isolates among Turkish patients.

Innovations and breakthroughs

The tyrosine-methionine-aspartate-aspartate (YMDD) motif mutation has been investigated in the polymerase gene in chronic hepatitis B patients. The findings of the present study are in line with the literature. A significant proportion of patients with lamivudine resistance would not be able to receive proper antiviral medication and may run the risk of disease progression in Asia. Although it is expected that HBV genotype D to be dominant in Turkey, it was surprising that no other genotypes were detected.

Applications

Identification of YMDD motif mutations prior to nucleoside treatment might help in decisions regarding selection of antiviral therapy, and expected responses to treatment.

Peer review

In this manuscript, the authors have reported that the HBV genotype is prevalent in Turkey. The frequency of YMDD mutants was also determined. The methodology employed in this study was very much standard. The results are of significant local importance.

Abstract

AIM: Prospective evaluation of repeat endoscopic retrograde cholangiopancreatography (ERCP) for failed Schutz grade 1 biliary cannulation in a high-volume center.

METHODS: Prospective intention-to-treat analysis of patients referred for biliary cannulation following recent unsuccessful ERCP.

RESULTS: Fifty-one patients (35 female; mean age: 62.5 years; age range: 40-87 years) with previous failed biliary cannulation were referred for repeat ERCP. The indication for ERCP was primarily choledocholithiasis (45%) or pancreatic malignancy (18%). Successful biliary cannulation was 100%. The precut needle knife sphincterotomy (NKS) rate was 27.4%. Complications occurred in 3.9% (post-ERCP pancreatitis). An identifiable reason for initial unsuccessful biliary cannulation was present in 55% of cases. Compared to a cohort of 940 naïve papilla patients (female 61%; mean age: 59.9 years; age range: 18-94 years) who required sphincterotomy over the same time period, there was no statistical difference in the cannulation success rate (100% *vs* 98%) or post-ERCP pancreatitis (3.1% *vs* 3.9%). Precut NKS use was more frequent (27.4% *vs* 12.7%) (P = 0.017).

CONCLUSION: Referral to a high-volume center following unsuccessful ERCP is associated with high technical success, with a favorable complication rate, compared to routine ERCP procedures.

Key words: Failed endoscopic retrograde cholangiopancreatography; Failed biliary cannulation; Unsuccessful biliary cannulation; Tertiary referral endoscopic retrograde cholangiopancreatography; Needle knife sphincterotomy; Biliary cannulation; Precut sphincterotomy; Post endoscopic retrograde cholangiopancreatography pancreatitis

INTRODUCTION

Despite technical innovations, structured training programs and improved endoscopic imaging, failed biliary

cannulation during endoscopic retrograde cholangiopancreatography (ERCP) occurs in 5%-20% of all cases[1]. Achieving biliary cannulation during ERCP remains an important and transparent determinant of a successful procedure for biliary endoscopists and patients alike. The American Society for Gastrointestinal Endoscopy recommendations suggest a biliary cannulation rate of > 85% should be the goal for all endoscopists engaged in ERCP[2]. Differing rates of successful biliary cannulations have been reported from community and tertiary institutions[1,3,4], with higher rates (up to 98%) achieved in specialized tertiary institutions[5,6,7], which reflects higher workload and experience, greater expertise, and more frequent use of more advanced cannulation techniques.

The therapeutic options following failed biliary cannulation may include: (1) repeat endoscopic attempt; (2) percutaneous cholangiography; (3) endoscopic ultrasound (EUS)-guided bile duct puncture and drainage; and (4) surgical management. This study was undertaken to assess the clinical impact of a tertiary referral ERCP service for prior unsuccessful biliary cannulation.

MATERIALS AND METHODS

Over a 34-mo period to September 2009, patients referred for a repeat ERCP following a previous failed biliary cannulation were enrolled prospectively on an intention-to-treat basis. A number of different hospitals and endoscopists referred patients to our center following an unsuccessful unsuccessful biliary cannulation at ERCP. All the referring endoscopists were accredited specialist biliary endoscopists[8]. The indication for ERCP was evaluated and deemed appropriate to require a further attempt at biliary cannulation by both the referring specialist and our center. The referring specialist was asked to provide a reason (if any) as to the possible cause for the failed cannulation.

Procedures were performed under propofol-based sedation provided by an anesthetist. An Olympus Exera TJF-160R duodenoscope (Olympus Optical, Japan, Tokyo) was used.

The cannulation technique and algorithm has been previously described in detail elsewhere[7]. A wire-guided technique utilizing a triple-lumen sphincterotome (CleverCut3™; Olympus Medical) and a 400-mm long hydrophilic wire (Jagwire™, Boston Scientific, Spencer, IN, United States) was used initially in all cases. In the event that a precut needle knife sphincterotomy was needed, all procedures used the conventional (freehand papillotomy/deroofing) needle knife sphincterotomy (NKS) method (Figure 1).

As is standard practice at our center[7,9], all cannulation parameters were recorded at the time of the procedure, including time to cannulation, number of attempts on papilla, number of pancreatic cannulations, and cannulation techniques performed. All procedures were performed by or under the direct supervision of two experienced high-volume biliary endoscopists (MJB, SJW). Clinical follow-up was obtained at 24 h and 30 d post-procedure.

Table 1 Schutz grade for endoscopic retrograde cholangiopancreatography degree of difficulty for biliary procedures[11]

	Biliary procedures
Grade 1	Diagnostic cholangiogram
	Biliary cytology
	Standard sphincterotomy ± removal of stones < 10 mm
	Stricture dilatation/stent for extra-hepatic stricture or bile leak
Grade 2	Diagnostic cholangiogram with Billroth Ⅱ anatomy
	Removal of CBD stones > 10 mm
	Stricture dilatation/stent for hilar tumors or benign intrahepatic strictures
Grade 3	SOD manometry
	Cholangioscopy
	Any therapy with Billroth Ⅱ anatomy
	Removal of intrahepatic stones or any stones with lithotripsy

CBD: Common bile duct; SOD: Sphincter of Oddi dysfunction.

Patients referred after prior failed cannulation were compared with a cohort of naïve papilla patients undergoing ERCP for a biliary indication performed at our center during the same time period.

Failed biliary cannulation was defined as the inability to gain deep and free access to the bile duct. Cholangiography alone without deep instrumentation of the bile duct was not recorded as being successful. Complications were defined and recorded according to established consensus criteria[10]. The indication and complexity of the ERCP procedure was graded according to the modified Schutz criteria (Table 1)[11]. Only Schutz grade 1 cases were included in this study. Exclusion criteria were patient age < 18 years old, surgically altered anatomy (Roux-en-Y, Billroth Ⅱ partial gastrectomy), and duodenal obstruction. As a referral center, Schutz grade 2 and 3 cases were received and managed by our group but were not included in this study.

Primary endpoints were success of biliary cannulation and post-ERCP complications.

Statistical analysis was performed using StatPlus:mac LE, (AnalystSoft, Vancouver, BC, Canada). Student's *t* test was used to detect differences between the two groups. Statistical significance was accepted on the basis of a *P* value < 0.05.

RESULTS

Fifty-one patients [35 female (69%); mean age: 62.5 years; age range: 40-87 years] with previously unsuccessful biliary cannulation at previous ERCP were referred and prospectively enrolled. The main indications for biliary cannulation and therapeutic intervention (Table 2) in the tertiary referral group were choledocholithiasis (45.1%), pancreatic malignancy (17.7%) and benign biliary disease [i.e., primary sclerosing cholangitis (PSC), chronic pancreatitis related biliary stricture] (12%).

All referred ERCP procedures were assessed as grade 1 difficulty, indicating that they were applicable to be

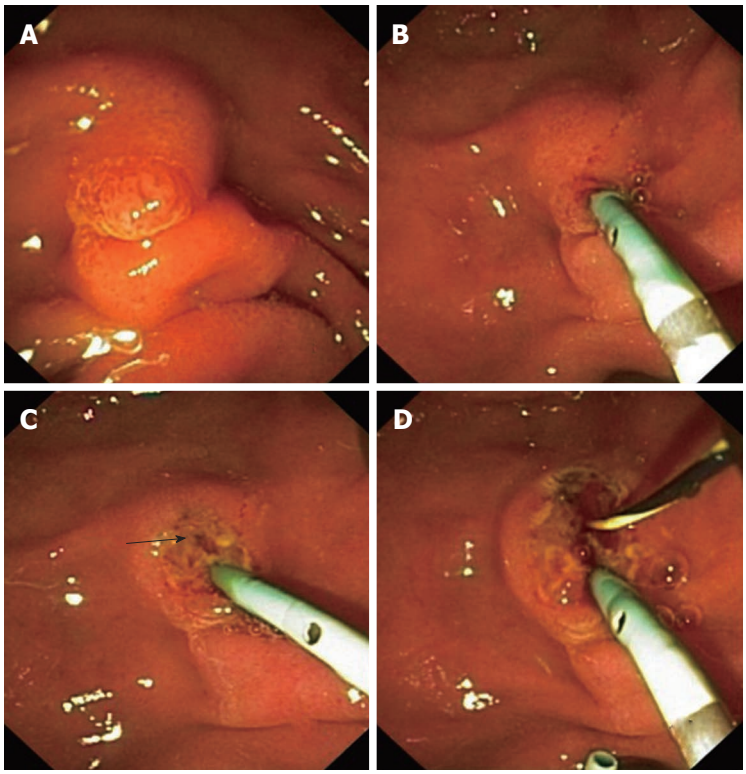

Figure 1 Technique of conventional/freehand/deroofing precut needle knife sphincterotomy. Case of previously failed biliary cannulation without an identifiable cause. A: Normal papillary appearance; B: After we were unable to cannulate selectively the biliary orifice after several pancreatic duct wire cannulations, a pancreatic stent was inserted; C: Precut needle knife sphincterotomy was performed with a cut directed from the ampullary orifice towards the 12 o'clock position. Biliary epithelium and bile noted (arrowpoint) at apex of the cut; D: Bile duct selectively cannulated with wire and sphincterotomy performed.

Table 2 Clinical indication for procedures *n* (%)

Indication	Tertiary referral cohort (*n* = 51)	Naïve papilla cohort (*n* = 940)	*P* value
Choledocholithiasis	23 (45.1)	446 (47.4)	0.78
Pancreatic malignancy	9 (17.7)	194 (20.6)	0.72
Benign biliary stricture/PSC	6 (11.8)	41 (4.4)	0.03
Bile leak	5 (9.8)	59 (6.3)	0.37
Cholangitis	4 (7.8)	57 (6.1)	0.48
Other (acute pancreatitis, suspected sphincter dysfunction)	4 (7.8)	143 (15.2)	0.22

PSC: Primary sclerosing cholangitis.

ERCP: Endoscopic retrograde cholangiopancreatography; NKS: Needle knife sphincterotomy; PEP: Post-ERCP pancreatitis; NS: Not significant.

performed by all competent biliary endoscopists. Eleven (21.6%) patients had had a previously attempted precut NKS. Two patients (5%) had post-ERCP pancreatitis (PEP) following their initial unsuccessful biliary cannulation.

Biliary cannulation was successful in all 51 referred patients in a single procedure. A mean of 2.96 attempts (range: 1-8) was required to gain biliary access, with a mean time to successful cannulation of 4.4 min (range: 0.8-13.5 min). Fourteen patients (27.4%) required precut NKS. Eleven patients (21.6%) had had a previous precut NKS attempt before referral, of which 7 seven (64%) required a further NKS to gain biliary access. Two patients (3.9%, both choledocholithiasis indication) developed moderate severity PEP (requiring uncomplicated 5 d and 4 d inpatient stays, respectively). Definitive organic findings (choledocholithiasis, biliary sludge, stricture, malignancy) were identified in 42/51 patients (82%), with the remainder having non-specific features such as biliary duct dilatation only.

The naïve ERCP cohort comprised 940 patients (female 61%; male 39%; mean age: 59.9 years; age range: 18-96 years) and was not significantly different from the referred failed ERCP cohort (Table 3). Indications were similar to those in the referral cohort (Table 2). The majority of procedures were performed for either choledocholithiasis (47.4%) or pancreatic malignancy (20.6%). Cannulation success was 98% (920/940), and 12.7% required NKS to gain access to the bile duct. A mean 3.2

cannulation attempts (range: 1-14) was required to gain biliary access, with a mean time to successful cannulation of 4.2 min (range: 8 s-41 min). The complication rate was 3.8% overall: 3.1% PEP, 0.5% bleeding, and 0.2% perforation. Two patients had perforation following sphincterotomy and both were managed conservatively in hospital for 9 and 11 d, respectively.

No reason for the initial failed biliary cannulation was identified in 23 (45%) patients. The 28 patients (55%) with an identifiable reason had a wide range of possible explanations for initial failure, including long and mobile (floppy) papilla and intraduodenal segment of the common bile duct (n = 8, 29%), unstable position (n = 9, 32%), small papilla (n = 4, 14%) or periampullary diverticulum (n = 7, 25%). In two of the periampullary diverticular cases, the papilla could not be identified at the initial procedure.

Technical rates, rates of successful biliary cannulation and complications were comparable in both groups (Table 3). Only the use of precut NKS in the tertiary referral cohort was significantly different at 27.4% *vs* 12.7% (P = 0.017). Half of the NKS procedures were performed in patients with a previous NKS attempt. Correcting for this variable, the NKS rate in the referred group was still statistically significantly greater (20%) than in the comparison group ($P < 0.05$).

DISCUSSION

Following a failed cannulation attempt, the endoscopist, in consultation with the patient and family, should carefully consider the next management step. The procedural indication and the definitive need for therapeutic intervention should be re-evaluated. Non-invasive imaging including magnetic resonance cholangiography or EUS should be utilized if they are likely to add value before proceeding. This study demonstrates that following an unsuccessful attempt at biliary cannulation, a further attempt in a tertiary referral center achieves a high success rate with minimal complications. We have specifically examined Schutz grade 1 patients; a cohort typical of cases managed by appropriately trained and competent biliary endoscopists in routine practice. The current study's incidence of complications of 3.9% (which was limited to PEP) is not different from the large and carefully studied comparison group or from other large recently published studies[12,13].

Outcomes for a repeat endoscopic attempt following unsuccessful ERCP in heterogeneous groups of patients have been reported > 10 years previously[14-16]. The past decade has seen many changes in ERCP practice, coupled with enhanced awareness of the risk factors for complications, particularly PEP, and greater utilization of non-invasive imaging. The importance of dedicated training and continuous quality audit has also been more widely recognized. The endoscopes, accessories utilized and cannulation techniques used have also evolved. This contemporary study carefully examined a well-characterized group of Schutz grade 1 cases and confirmed that prior failure by a competent and accredited biliary endoscopist is not an absolute indication to seek an alternative strategy to access the biliary tree, nor is a repeat attempt associated with higher complications. In 1999, Ramirez *et al*[14] reported 47 patients with failed cannulation, of which 24 (51%) underwent repeat ERCP by the same endoscopist. Successful cannulation was achieved in 87.5%, without any complications being noted. Although a significant proportion of cases were Schutz 1 complexity, Billroth Ⅱ anatomy was present in 17% of cases and minor papillary cannulation was required in 2%. Kumar *et al*[16] in 1995 and Choudari *et al*[15] in 2000 documented referral to a tertiary center for a second ERCP attempt in 113 and 562 patients, respectively. Over 50% of cases were Schutz grade 2-3 and represented a high degree of difficulty, including > 20% of cases requiring manometry. Both studies achieved 96% successful cannulation, although complications (mostly pancreatitis) occurred in 10%-11% of patients. Unlike the current study, the higher proportion of more complex cases in these last two retrospective studies reduces the ability to extrapolate the results to more general endoscopic practice. It is quite reasonably argued that Schutz grade 2 and 3 cases should not be attempted outside of high volume, expert tertiary centers. The rate of NKS in the cohort of referred patients (27.4%) was significantly higher than in the naïve papilla group, as well as appreciably higher than the aforementioned studies of repeat ERCP following previously failed cannulation[13-15] and other recent studies[17]. Our unit has recently shown that, in experienced hands, NKS is not a risk for PEP[17]. The use of NKS in a referred group of previous unsuccessful cannulations should be considered a necessary and vital part of the armamentarium of an experienced ERCP endoscopist.

Increasingly compelling data are emerging to confirm that, when the clinical entity or its treatment is complex or attended by high morbidity, then referral to experienced high-volume centers results in superior procedural and patient outcomes and reduced costs[18,19]. Similarly, ERCP procedures in high-volume centers have confirmed benefits including improved cannulation rates, lower complication rates and better patient outcomes[20,21]. Patients who have failed one attempt at cannulation in competent hands self select themselves as a group of "difficult cannulation" patients and are therefore best managed in an experienced tertiary center.

In the event of failed ERCP cannulation, studies indicate that 50%-60% of patients have further therapeutic procedures-radiological, surgical or repeat endoscopic management[22,23]. Percutaneous trans-hepatic cholangiography drainage and stenting is a common interventional radiological procedure utilized in the management of malignant obstructive jaundice, as well as in the treatment of operative bile leaks and benign biliary strictures[24,25].The technical and clinical success of a radiological approach has been reported to be > 90%, however, complications

occur in 20%-30%, including cholangitis, bile leak, hemorrhage, post-procedural pain and stent/tube malfunction[26]. Protracted inpatient management is also usually necessary. The use of surgical management is of limited utility in non-malignant indications due to high morbidity (17%-37%) and high mortality (2%-5%)[27-29]. Recently, EUS-guided biliary drainage, either via rendezvous approach or direct puncture and stenting, has emerged as a viable therapeutic alternative[30,31]. This technique is used mainly in malignant obstructions, with technical and clinical success rates above 90% and 5%-15% complication rates. However, experience is currently limited to enthusiastic proponents of this technique and its durability is not well established.

The technical reasons for unsuccessful Schutz grade 1 biliary cannulation have not been previously documented. Although this study does not have an explanation for unsuccessful biliary cannulation in all cases (only 55% had an identifiable etiology), it does detail situations that intuitively may lead to more difficult cannulation, such as a long and mobile intraduodenal portion of the bile duct, periampullary diverticulum, an unstable position or a small papilla. Peripapillary diverticulum was cited as the cause of 14% of the unsuccessful biliary cannulations, despite two recent studies indicating no effect on cannulation rates[32,33].

The current study is limited by lack of randomization to an alternative therapeutic modality or a comparator group. Selection bias may also have been present because the referred patients were likely to have been considered more appropriate for a repeat ERCP attempt by the referrers than those not referred.

In conclusion, referral to an experienced high-volume center following an initial unsuccessful Schutz grade 1 biliary cannulation attempt is associated with high technical success and a favorable complication profile, compared to other routine naïve papilla ERCP procedures. We believe that a second ERCP procedure in a tertiary referral center should be the next management step following an unsuccessful biliary cannulation in this patient group. This type of clinical pathway should be part of the range of management options available to biliary endoscopists working outside high-volume tertiary centers.

COMMENTS

Background

Endoscopic retrograde cholangiopancreatography (ERCP) is an invaluable endoscopic technique in the management of gallstones and bile duct pathology. The technique is not always successful and it is unclear what the next management step should be following a failed attempt.

Research frontiers

Knowledge in endoscopy continues to evolve on many fronts with an ever-expanding repertoire of indications and techniques. Evidence based justification is addressed with each new advance however more common dilemmas (such as what to do following a failed ERCP procedure) lack clear evidence. Repeat ERCP attempt has been evaluated in three previous studies, but all have involved a higher complexity than that what is seen in routine, everyday practice. Recent publications have addressed alternative therapeutic modalities but either lack widespread availability or inferior safety profiles.

Innovations and breakthroughs

This study demonstrated that in the setting of a low risk, uncomplicated patient a failed ERCP procedure can be successfully and safely managed by a repeat ERCP procedure *via* referral to a specialized, high volume endoscopy unit.

Applications

This type of clinical pathway following a failed ERCP attempt should be part of the range of management options available to biliary endoscopists working outside of high volume tertiary centres.

Terminology

ERCP is an advanced endoscopic technique that is used to access and visualize the bile ducts and pancreas, as well as to perform therapeutic management in the setting of gallstones, malignancy and post surgical complications.

Peer review

This paper deals with a clinical pathway in failed biliary cannulation. Results showed clear data about the high success rate of biliary cannulation in tertiary referral centre. Overall, the study clearly demonstrated a clinical pathway in failed biliary cannulation.

Abstract

AIM: To investigate the endoscopic features of pharyngeal superficial carcinoma and evaluate the utility of narrow-band imaging (NBI) for this disease.

METHODS: In the present prospective study, 335 patients underwent conventional white light (CWL) endoscopy and non-magnified/magnified NBI endoscopy, followed by an endoscopic biopsy, for 445 superficial lesions in the oropharynx and hypopharynx. The macroscopic appearance of superficial lesions was categorized as either elevated (< 5 mm in height), flat, or depressed (not ulcerous). Superficial carcinoma (SC) was defined as a superficial lesion showing high-grade dysplasia or squamous cell carcinoma on histology. The color, delineation, and macroscopic appearances of the lesions were evaluated by CWL endoscopy. The ratio of the brownish area/intervascular brownish epithelium (IBE), as well as microvascular proliferation, dilation, and irregularities, was determined by non-magnified/magnified NBI endoscopy. An experienced pathologist who was unaware of the endoscopic findings made the histological diagnoses. By comparing endoscopic findings with histology, we determined the endoscopic features of SC and evaluated the diagnostic utility of NBI.

RESULTS: The 445 lesions were divided histologically into two groups: a non-SC group, including non-neoplasia and low-grade dysplasia cases, and an SC group. Of the 445 lesions examined, 333 were classified as non-SC and 112 were classified as SC. There were no significant differences in age, gender, or the location of the lesions between the patients in the two groups. The mean diameter of the SC lesions was significantly greater than that of non-SC lesions (11.0 ± 7.6 mm *vs* 4.6 ± 3.6 mm, respectively, $P < 0.001$). Comparisons of CWL endoscopy findings for SC and non-SC lesions by univariate analysis revealed that the incidence of redness (72% *vs* 41%, respectively, $P < 0.001$) and a flat or depressed type of lesion (58% *vs* 44%, respectively, $P = 0.013$) was significantly higher in the SC group. Using non-magnified NBI endoscopy, the incidence of a brownish area was significantly higher for SC lesions (79% *vs* 57%, respectively, $P < 0.001$). On magnified NBI endoscopy, the incidence of IBE (68% *vs* 33%, $P < 0.001$) and microvascular proliferation (82% *vs* 51%, $P < 0.001$), dilation (90% *vs* 76%, $P =$

0.002), and irregularity (82% *vs* 31%, $P < 0.001$) was also significantly higher for the SC compared with the non-SC lesions. Multivariate analysis revealed that the incidence of redness ($P = 0.022$) on CWL endoscopy and IBE ($P < 0.001$) and microvascular irregularities ($P < 0.001$) on magnified NBI endoscopy was significantly higher in SC than non-SC lesions. Redness alone exhibited significantly higher sensitivity and significantly lower specificity for the diagnosis of SC compared with redness plus IBE and microvascular irregularities (72% *vs* 52%, $P = 0.002$; and 59% *vs* 92%, $P < 0.001$, respectively). The accuracy of redness plus IBE and irregularities for the diagnosis of SC was significantly greater than using redness alone (82% *vs* 62%, respectively, $P < 0.001$).

CONCLUSION: Redness, IBE, and microvascular irregularities appear to be closely related to SC lesions. Magnified NBI endoscopy may increase the diagnostic accuracy of CWL endoscopy for SC.

INTRODUCTION

Most epithelial malignancies of the head and neck are squamous cell carcinomas (SCCs)[1]. The most important known risk factors for these carcinomas are tobacco use and alcohol consumption, direct exposure to which may result in the synchronous or metachronous development of SCC and dysplasia (a precancerous lesion) in the upper aerodigestive tract, especially in the oropharynx and hypopharynx, and the esophagus[1,2]. This was reported more than 50 years ago as part of the concept of "field cancerization"[2].

In the esophagus, the clinical utility of Lugol chromoendoscopy for the early detection of superficial neoplasms has been established, and this technique is now widely used[3]. Consequently, the rate of detection of early stage esophageal SCC (ESCC) is increasing. Endoscopic treatment of tumors at the earliest stages, particularly mucosal carcinomas, has resulted in considerable improvements in prognosis[4]. However, although early treatment increases the long-term survival of patients with ESCC, in accordance with the concept of field cancerization, the incidence of secondary head and neck SCCs in patients with ESCC has also increased[5]. Among the secondary head and neck SCCs associated with ESCC, oropharyngeal and hypopharyngeal SCCs (OHSCCs) are the most common and adversely affect the improved prognosis of ESCC[5].

Despite its usefulness in screening for superficial neoplasms in the esophagus, Lugol chromoendoscopy cannot be used to screen for OHSCCs because of the accompanying irritation due to iodine and the risk of aspiration. Early stage OHSCCs show an obscure appearance and most affected patients have few symptoms, making the early detection of OHSCCs difficult. Most such lesions are detected at advanced stages, thereby resulting in an extremely poor prognosis[6]. Furthermore, even if the advanced lesions can be removed, dysphagia or aphonia following surgery for advanced OHSCCs causes a marked deterioration in the patients' quality of life[5,6]. Accordingly, a new approach that facilitates the detection and diagnosis of early stage OHSCCs is needed.

The narrow-band imaging (NBI) system is a revolutionary optical image-enhanced technology that uses narrow bandwidth NBI filters. Magnifying endoscopy combined with NBI clearly visualizes the surface microvascular structures in different organs because NBI illumination consists of two limited wavelength ranges that are well absorbed by hemoglobin[7]. Recent studies have reported the usefulness of NBI for the early detection and diagnosis of OHSCCs using gastrointestinal endoscopy or rhinolaryngoscopy[8-10]. However, to the best of our knowledge, there have been no studies to date that have investigated the relationships between detailed findings of conventional white light (CWL) endoscopy, magnified NBI endoscopy, and histology in superficial pharyngeal lesions. There is also scant information currently available in the literature regarding the differential diagnosis of non-neoplasia, dysplasia, and carcinoma using endoscopy.

The process underlying the carcinogenesis of OHSCCs has been proposed to be a dysplasia-carcinoma sequence similar to that seen in ESCC, proceeding from mild or moderate dysplasia (low-grade dysplasia) to severe dysplasia [high-grade dysplasia (HGD)] and SCC[11]. Previous epidemiological follow-up studies of esophageal squamous neoplasms have suggested that the relative risk of HGD developing into invasive SCC is comparable to that of SCC *in situ*[11,12]. In contrast, a low-grade dysplasia indicates a significantly lower risk of malignant transformation[11]. Among squamous neoplasias, HGD appears to be a good candidate for intervention, as with SCC[13].

The aim of our present study was to investigate the relationships between the endoscopic and histologic findings of superficial lesions in the oropharynx and hypopharynx, and to evaluate the diagnostic utility of NBI for superficial squamous neoplasms showing HGD or SCC.

MATERIALS AND METHODS

The macroscopic appearance of superficial lesions was evaluated and lesions were classified as either elevated (< 5 mm in height), flat, or depressed (not ulcerous). Between March 2005 and April 2009, CWL and non-magnified/magnified NBI endoscopies were performed in 1010 consecutive patients for the evaluation of the oropharyngeal and hypopharyngeal region. The endoscopic findings for 455 superficial lesions in the oropharynx and hypopharynx in 342 patients were evaluated prospectively in our present study. Biopsy samples were obtained for all 455 superficial lesions, although 10 lesions from seven patients were excluded from analysis because insufficient material was obtained by biopsy to enable a histological diagnosis to be made. The findings for 445 superficial oropharyngeal and hypopharyngeal lesions in 335 patients were therefore analyzed in the present study.

Superficial lesions that demonstrated HGD or SCC histologically were defined as superficial carcinomas (SC). Endoscopic findings of SC lesions were compared with those of non-SC lesions in the oropharynx and hypopharynx to reveal the endoscopic features of SC lesions. Moreover, we investigated the diagnostic utility of NBI for SC lesions. The present analyses were performed with local ethics committee approval and all patients provided informed consent prior to their inclusion in the study.

Endoscopic procedures

All patients were orally administered 20 000 U pronase (Pronase MS; Kaken Pharmaceutical Products Inc., Tokyo, Japan) prior to pharyngeal anesthesia to eliminate saliva and mucus. Pharyngeal anesthesia was achieved using four to five pump-spray applications of lidocaine (Xylocaine; AstraZeneca, Osaka, Japan). All endoscopic inspections were performed in conscious, sedated patients after the administration of pethidine hydrochloride (35-70 mg; Opystan; Mitsubishi Tanabe Pharma, Osaka, Japan) and flunitrazepam (0.2-0.8 mg; Rohypnol; Chugai Pharmaceutical, Tokyo, Japan).

Endoscopic examinations were performed using a high-resolution and zoom gastrointestinal endoscope (GIF-Q240Z or GIF-H260Z; Olympus Medical Systems, Tokyo, Japan) with a maximum magnification of × 90 on a 19 inch (48.3 cm) monitor. The light source unit (Olympus Medical Systems) has two rotary filters in front of a xenon bulb, one for CWL and the other for NBI. Thus, it is easy to switch from the CWL to NBI mode by simply pushing the control knob on the endoscope. A black rubber attachment (Olympus Medical Systems) was mounted on the tip of the scope to enable the endoscopist to adjust the focus easily and to maintain the focal distance between the tip of the scope and the lesion surface at 2 mm during magnified observation.

Three endoscopic techniques, namely CWL and non-magnified and magnified NBI, were performed for each patient by one of three endoscopists (NY, YY or KG). First, the oropharynx and hypopharynx were inspected thoroughly using CWL endoscopy, after which the endoscope was withdrawn to the oral cavity and a switch made from the CWL to NBI mode. The oropharynx and hypopharynx were then examined using non-magnified NBI endoscopy. For lesions that had not been detected by CWL endoscopy and were first detected using non-magnified NBI endoscopy, the NBI mode was switched back to the CWL mode and the lesions were evaluated using CWL endoscopy. All lesions were then inspected using magnified NBI endoscopy. Finally, tissue samples were obtained endoscopically from the lesions using biopsy forceps (Radial Jaw 3; Boston Scientific, Natick, MA). All endoscopic images were preserved in digital form.

After completion of each endoscopic inspection, each endoscopic finding of CWL, non-magnified NBI, or magnified NBI was recorded immediately on a case report form.

Definitions of endoscopic findings

CWL endoscopy: Endoscopic findings for each superficial lesion were evaluated with regards to color, delineation, and macroscopic appearance. Superficial lesions were determined to be either "redness" or "white or isochromatic" in terms of color, "well-delineated" or "poorly delineated", and either "elevated" or "flat or depressed" macroscopically. Each of these parameters was classified based on the predominant finding.

Non-magnified NBI endoscopy: Superficial lesions exhibiting a well-demarcated brownish area by non-magnified NBI endoscopy were classified as having a "brownish area"[8].

Magnified NBI endoscopy: In a preliminary study[14], we found that the "brownish area" observed by non-magnified NBI endoscopy can comprise any one or a combination of the following observations on magnified NBI endoscopy: (1) an intervascular brownish epithelium (IBE); (2) microvascular dilation; and (3) microvascular proliferation. IBE is the presence of brown-colored epithelium between superficial microvessels in a lesion that differs from the whitish surrounding squamous epithelium. Microvascular dilation is defined as the presence of a group of superficial microvessels, the calibers of which are more than twice the caliber of the surrounding reference microvessels. Microvascular proliferation is defined as the presence of a group of superficial microvessels with a greater density than that of the surrounding reference microvessels. In addition, microvascular irregularities were assessed using magnified NBI endoscopy, where "irregularities" were defined as the presence of a group of superficial microvessels showing marked variations in caliber and/or highly variable forms compared with the surrounding reference microvessels.

Figure 1 schematically summarizes the features of superficial lesions and the surrounding mucosa seen using magnified NBI endoscopy. A representative image

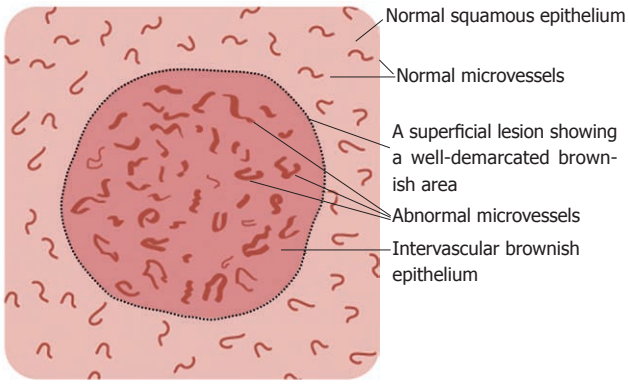

Figure 1 Schema of the magnified endoscopic features of a superficial lesion and its surrounding mucosa as detected by narrow-band imaging. The superficial lesion shows an intervascular brownish epithelium and abnormal microvessels exhibiting dilation, proliferation and irregularities.

of an SC lesion is shown in Figure 2.

Histologic assessment

Endoscopic biopsy specimens of the 445 superficial lesions examined in this study were subjected to histologic assessment. Tissue samples were placed on custom-made black filter paper (Toyo Roshi Kaisha, Tokyo, Japan) and fixed in 40 g/L formaldehyde for 24 h. Black filter paper makes it easier to flatten out the whitish specimens, which makes it easier to prepare vertical microsections and make a more accurate diagnosis of the histological grade of the intraepithelial neoplasm. All specimens were embedded in paraffin, sectioned and stained with hematoxylin and eosin.

Histologic diagnoses were made by a pathologist (MI) specializing in gastrointestinal pathology who was unaware of the endoscopic findings and were based on the revised Vienna classification[13].

Statistical analysis

Continuous variables are expressed as the mean ± SD and were analyzed using the Student's *t* test. The χ^2 test and logistic regression were used to analyze categorical data. $P < 0.05$ was considered significant. All analyses were performed using STATA 10.0 software (STATA, College Station, TX).

RESULTS

Table 1 lists the clinicopathologic features of our current cohort of 335 patients comprising 445 superficial lesions in the oropharynx and hypopharynx. These 445 lesions were divided histologically into two groups, namely non-SC (normal epithelium, inflammation, hyperplasia, papilloma, "other", and low-grade dysplasia) and SC (HGD and SCC). The category of "other" included hyperkeratosis ($n = 2$), regenerative atypia ($n = 1$), atrophy ($n = 1$), xanthoma ($n = 1$), and melanosis ($n = 1$). Most patients in both groups were male and there were no significant differences found in age, male:female ratio, or in the location of the lesions between the two groups. However, the lesion diameter was significantly greater in the SC group ($P < 0.001$).

Table 1 Clinicopathologic features of patients with pharyngeal superficial lesions

	Total (n = 445)	Non-SC (n = 333)	SC (n = 112)	P value
Age (yr)	63 ± 9	63 ± 10	64 ± 8	
Male:female ratio	16:1	14:1	27:1	
Lesion location (n)				
Oropharynx/hypopharynx	269/176	206/127	63/49	
Lesion diameter (mm)	6.2 ± 5.6	4.6 ± 3.6	11.0 ± 7.6	< 0.001[1]
Histology (n)		Normal: 40 Inflammation: 115 Hyperplasia: 50 Papilloma: 33 Other[2]: 6 LGD: 89	HGD: 35 SCC: 77	

Where appropriate, data are given as the mean ± SD. [1]Student's *t* test. [2]"Other" histologic diagnoses included hyperkeratosis ($n = 2$), regenerative atypia ($n = 1$), atrophy ($n = 1$), xanthoma ($n = 1$), and melanosis ($n = 1$). HGD: High-grade dysplasia; LGD: Low-grade dysplasia; SC: Superficial carcinoma; SCC: Squamous-cell carcinoma.

Table 2 lists the results of univariate analysis of the relationships between the endoscopic findings in the two study groups. Univariate analysis of the CWL endoscopy findings identified significant differences in the color and macroscopic appearance of lesions between the SC and non-SC groups. Redness was more commonly seen for lesions in the SC than in the non-SC group (72% *vs* 41%, respectively, $P < 0.001$). In addition, lesions in the SC group were significantly more likely to appear flat or depressed (58% *vs* 44%, respectively, $P = 0.013$). In both groups, approximately three-quarters of the lesions appeared to be well delineated, with no significant difference detected.

On non-magnified NBI endoscopy, the incidence of a brownish area was significantly higher in the SC group than in the non-SC group (79% *vs* 57%, respectively, $P < 0.001$). On magnified NBI endoscopy, the incidence of IBE was also significantly higher in the SC group (68% *vs* 33%, respectively, $P < 0.001$). Furthermore, the incidences of microvascular proliferation (82% *vs* 51%, $P < 0.001$), dilation (90% *vs* 76%, $P < 0.001$), and irregularities (82% *vs* 31%, $P < 0.001$) were again significantly greater in the SC group.

The results of multivariate logistic regression analysis are listed in Table 3. Significant differences between the non-SC and SC groups were identified for redness ($P = 0.022$) on CWL endoscopy, and for IBE ($P < 0.001$) and microvascular irregularities ($P < 0.001$) on magnified NBI. The diagnostic sensitivity, specificity, and accuracy using redness alone and redness plus IBE and microvascular irregularities are indicated in Table 4. The redness of lesions on CWL endoscopy had 72% sensitivity, 59% specificity, and 62% accuracy for a diagnosis of super-

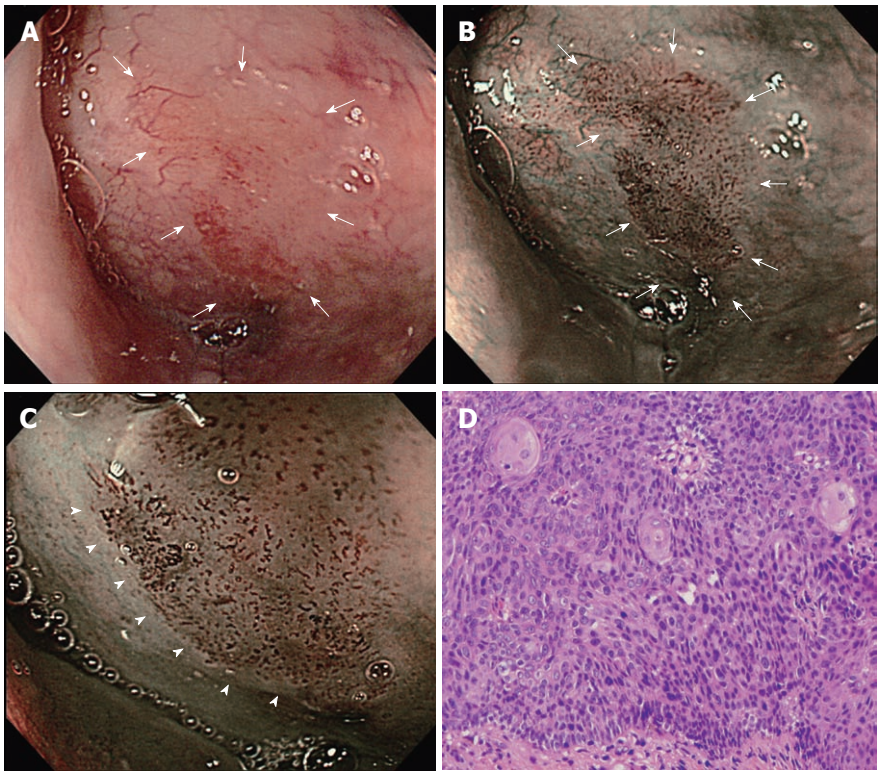

Figure 2 Representative images of a superficial carcinoma. A: Conventional gastrointestinal endoscopy image revealing a flat and poorly delineated lesion with a slight redness at the piriform sinus of the right hypopharynx (arrows); B: The superficial carcinoma lesion is revealed as a well-demarcated brownish area by non-magnified narrow-band imaging (NBI) endoscopy (arrows); C: Magnified NBI endoscopy visualizes the brownish area of the superficial carcinoma and shows it to be comprised of intervascular brownish epithelium and superficial microvessels of a dark brown color exhibiting dilation, proliferation and irregularities. Arrowheads indicate the demarcation line of the lesion; D: Histology of an endoscopically biopsied superficial carcinoma specimen demonstrating squamous cell carcinoma *in situ* with keratinization (hematoxylin and eosin stain; original magnification × 50).

Table 2 Univariate analysis of relationships between endoscopic findings and histology

Endoscopy	Endoscopic findings	Non-SC (n = 333)	SC (n = 112)	OR	95% CI	P value
CWL (Non-magnified)	Color (redness; %)	41	72	3.69	2.31, 5.89	< 0.001[1]
	Delineation (well delineated; %)	66	69	1.13	0.71, 1.79	
	Macroscopic type (flat or depressed; %)	44	58	1.73	1.12, 2.67	0.013[1]
NBI						
(Non-magnified)	Brownish area (%)	57	79	2.79	1.69, 4.61	< 0.001[1]
(Magnified)	IBE (%)	33	68	4.22	2.67, 6.67	< 0.001[1]
	Microvascular					
	Proliferation (%)	51	82	4.41	2.60, 7.49	< 0.001[1]
	Dilation (%)	76	90	2.9	1.48, 5.68	0.002[1]
	Irregularities (%)	31	82	10.27	6.01, 17.56	< 0.001[1]

[1]Univariate logistic regression analysis between superficial carcinoma (SC) and non-SC groups. CWL: Conventional white light endoscopy; NBI: Narrow-band imaging; IBE: Intervascular brownish epithelium; OR: Odds ratio; CI: Confidence interval.

ficial carcinoma in the oropharynx and hypopharynx. If IBE and irregularities on magnified NBI endoscopy were taken into account in addition to the redness of lesions, the diagnostic yield was 52% for sensitivity, 92% for specificity, and 82% for accuracy. The sensitivity for redness alone was significantly higher than that for redness plus IBE and microvascular irregularities (P = 0.002). Specificity and accuracy for redness plus IBE and microvascular irregularities were significantly higher than values for redness alone (P < 0.001 and P < 0.001, respectively).

There were no complications, such as massive hemorrhaging or aspiration, associated with the endoscopic examinations undertaken in the present study cohort.

DISCUSSION

Advances in endoscopic techniques enabling accurate diagnoses to be made in the oropharynx and hypopharynx are crucially needed. At present, endoscopic biopsy in the pharyngeal region may be quite challenging due to the gag reflex and the complicated structure of the region.

Table 3 Multivariate analysis of relationships between endoscopic findings and histology

Endoscopy	Endoscopic findings	Non-SC (n = 333)	SC (n = 112)	OR	95% CI	P value

Indeed, in our present study we failed to obtain sufficient biopsy material for the histologic assessment of 10 lesions. Thus, progress in endoscopic diagnostics in the pharyngeal region will be of greater clinical significance than for other regions of the gastrointestinal tract.

Previous studies have revealed that a brownish area with a proliferation of dilated microvessels on NBI endoscopy facilitates the endoscopic detection of OHSCCs at an early stage[8-10]. However, the differences that are evident on NBI and CWL endoscopy and that can differentiate between non-SC and SC lesions in the oropharynx and hypopharynx remain unclear. The results of the present study suggest that there are several endoscopic features that are closely related to SC lesions that could be used in the differential diagnosis of SC and non-SC lesions. Our univariate analysis revealed that SC lesions are associated with a brownish area and microvascular proliferation and dilation. These results are similar to those of a previous study that reported that all malignant lesions appear as well-demarcated brownish areas with proliferation of dilated microvessels[8].

However, the multivariate analysis performed in the present study revealed that redness, IBE, and microvascular irregularities seem to be independent factors related to SC lesions, rather than a brownish area or microvascular dilation and proliferation. In our non-SC group, most lesions (61%) were found to be inflammatory lesions (n = 115) or low-grade dysplasias (n = 89), which are often found to have a brownish area (80% and 67%, respectively) or to exhibit microvascular proliferation (63% and 62%, respectively) and dilation (89% and 78%, respectively). The relatively high rates of these endoscopic features in inflammatory lesions and low-grade dysplasias may have affected the outcome of the multivariate analysis in the present study.

The sensitivity of redness by CWL endoscopy alone for SC lesions was significantly higher than that combined with IBE and microvascular irregularities by magnified NBI endoscopy. Conversely, the specificity and accuracy of redness plus IBE and microvascular irregularities for SC lesions were significantly higher than redness alone. These results suggest that magnified NBI endoscopy may complement CWL endoscopy in the diagnosis of SC lesions.

Ishihara *et al*[15] have reported that in the esophagus, the criterion of a brownish epithelium (with the same definition used for IBE in the present study) was an independent factor significantly associated with high-grade intraepithelial neoplasia consisting of HGD and intramucosal SCC. IBE seems to be a key finding associated with superficial high-grade neoplasms. Histologically, the appearance of IBE could be attributed to increased intraepithelial cell density or changes in the intraepithelial cells themselves as a result of malignant transformation. Further investigations in the future are needed to identify the mechanisms underlying IBE.

There are some notable limitations to the present study. First, the three endoscopic procedures performed in each patient were performed by the same endoscopist. Thus, the possibility exists that the subsequent assessment of endoscopic images may have been influenced by information bias and a carryover effect from prior endoscopies. Moreover, it remains unclear whether non-magnified or magnified NBI endoscopy provides an additional benefit over CWL endoscopy alone. Second, our histological diagnoses were based on biopsy samples obtained during the endoscopic procedure. The histologic findings for these samples may therefore not be representative of the histology of the entire lesion.

The image resolution of a gastrointestinal endoscope is greater than that of a rhinolaryngoscope. Because of the growing interest in the pharyngeal region by gastroenterologists, the number of cases of OHSCCs detected

and treated by gastrointestinal endoscopy is also increasing[16,17]. However, the field of view obtained using gastrointestinal endoscopy is limited compared with the comprehensive examinations performed by otorhinolaryngologists, using rhinolaryngoscopy as well as direct visual inspection. It thus remains difficult for gastrointestinal endoscopists to detect or treat tumors of the tongue, the floor of the oral cavity, and the nasopharynx. Hence, to improve the prognosis and quality of life of patients with head and neck SCCs and/or esophageal SCCs, gastrointestinal endoscopists and otorhinolaryngologists need to collaborate in the future to further develop endoscopic diagnosis and treatment methods for these conditions.

The endoscopic features of redness, IBE, and microvascular irregularities seem to be significantly associated with SC lesions in the oropharynx and hypopharynx. The diagnostic accuracy of redness plus IBE and microvascular irregularities for SC lesions was found to be greater than the accuracy of redness alone. Therefore, magnified NBI endoscopy may increase the diagnostic accuracy of CWL endoscopy for SC lesions.

COMMENTS

Background

Prolonged tobacco use and alcohol consumption may result in the synchronous or metachronous development of squamous cell carcinoma (SCC), both in the pharynx and the esophagus. The prognosis of patients with esophageal SCC has improved due to the early detection of these lesions as a result of the widespread adoption of an upper gastrointestinal endoscopy with Lugol staining. However, an early detection of oropharyngeal and hypopharyngeal SCCs (OHSCCs) remains difficult because Lugol staining is not possible during a screening endoscopy for OHSCCs. Moreover, OHSCCs at an early stage show an obscure appearance and manifest few symptoms. Hence, most OHSCCs are detected at advanced stages, resulting in an extremely poor prognosis, including that of patients with esophageal SCCs. Identifying the endoscopic features of superficial OHSCCs is thus essential for both early detection and differential diagnosis.

Research frontiers

The narrow-band imaging (NBI) system is a revolutionary optical image-enhanced technology that uses narrow bandwidth NBI filters. Magnifying endoscopy combined with NBI clearly visualizes the surface microvascular structures in different organs as NBI illumination consists of two limited wavelength ranges that are well absorbed by hemoglobin. NBI endoscopy can visualize a hemoglobin rich lesion such as a superficial squamous neoplasia as a brownish area with no use of Lugol staining.

Innovations and breakthroughs

Recent studies have reported the usefulness of NBI for the early detection and diagnosis of superficial OHSCCs using gastrointestinal endoscopy or rhinolaryngoscopy. However, there has been no report to date that has compared the endoscopic features of non-neoplastic lesions and pharyngeal squamous neoplasias using magnified NBI as well as conventional white light (CWL) endoscopy. This is the first report to investigate the relationships between detailed findings of CWL endoscopy, magnified NBI endoscopy, and histology in an analysis of superficial pharyngeal lesions. Moreover, we have for the first time evaluated the diagnostic utility of magnified NBI endoscopy for superficial OHSCCs compared with CWL endoscopy.

Applications

This study may help to reveal endoscopic features of superficial carcinomas in the pharynx and the accuracy of endoscopy with CWL, NBI, or magnified NBI for diagnosing superficial carcinoma. Identifying these endoscopic features will lead to an enhanced detection rate of these lesions and will be useful in making a differential diagnosis.

Terminology

NBI is a revolutionary optical image-enhanced technology that allows people to see an obscure tumor as a brownish area and observe the detailed structure of superficial microvessels when this technology is combined with magnified endoscopy. Superficial carcinoma is histologically defined as a high-grade dysplasia (HGD) as well as an SCC as HGD seems to have the same clinical implications as SCC *in situ*.

Peer review

The topic itself is interesting for otorhinolaryngologists as well as for gastroenterologists. The NBI technique can still be considered as a novel method and therefore is a valuable source of new and interesting studies such as this one. The authors outlined the limitations of this study, because many researchers do not do so. The abstract and key words are appropriate. The abstract gives clear insight into the materials and diagnostic procedures used. The materials and methods section is also appropriately detailed and will enable replication of the methodologies used in this study. The discussion is well organized, systematic and clearly written. The cited references are relevant and appropriate. The figures are nicely incorporated in the text and appropriately presented. The language used is good and clear. It is a well structured article.

Abstract

AIM: To examine whether hepatitis C virus (HCV)-infected patients who carry hypercoagulable mutations suffer from increased rates of liver fibrosis.

METHODS: We analyzed DNA samples of 168 HCV patients for three common hypercoagulable gene mutations: prothrombin 20210 (PT20210), factor V Leiden (FV Leiden) and methylene tetrahydrofolate reductase (MTHFR). The patients were consecutively recruited as part of the prospective "Fibroscore Study" in France. The effect of the various mutations on the rate of fibrosis was analyzed statistically and was correlated with epidemiological, clinical and biochemical data such as grade and stage of liver biopsies, patients' risk factors for liver cirrhosis, and timing of infection.

RESULTS: Fifty two of the patients were categorized as "fast fibrosers" and 116 as "slow fibrosers"; 13% of the "fast fibrosers" carried the PT20210 mutation as compared with 5.5% of the "slow fibrosers", with an odds ratio of 4.76 (P = 0.033; 95% CI: 1.13-19.99) for "fast" liver fibrosis. Carriage of MTHFR or FV Leiden mutations was not associated with enhanced liver fibrosis.

CONCLUSION: Carriage of the PT20210 mutation is related to an increased rate of liver fibrosis in HCV patients.

Key words: Hepatitis C virus; Liver fibrosis; Hypercoagulation; Prothrombin 20210

Increased fibrosis progression rates in hepatitis C patients carrying the prothrombin G20210A mutation. *World J Gastroenterol* 2011; 17(45): 5007-5013 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i45/5007.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i45.5007

INTRODUCTION

Cirrhosis is a major cause of morbidity and mortality in patients who suffer from chronic hepatitis C virus (HCV) infection. Up to 24% of patients will develop cirrhosis during their lifetime[1]. Various characteristics, such as male gender, older age at infection, alcohol consumption, obesity and concurrent hepatitis B or human immunodeficiency virus (HIV) infection enhance the rate of liver fibrosis[2,3]. Unfortunately, it is still largely impossible to predict who is more prone to fibrosis, and, thus, careful follow-up or treatment is required for most patients.

Hypercoagulable states have been hypothesized to play a role in organ fibrosis. In various inflammatory states, such as those of the lung or kidney, thrombosis and fibrin formation result in organ injury. It has been recently proposed that hypercoagulable states may be an additional contributing factor to liver fibrosis through several mechanisms, such as thrombotic events in small venous blood vessels in the liver and stimulation of hepatic stellate cells by thrombin[4]. Moreover, increased fibrin deposition has been demonstrated in animal models of liver fibrosis[5]. These observations have been strengthened by a study conducted by Anstee *et al*[6], which explored a mouse model of liver fibrosis and demonstrated that the extent of fibrosis was much higher in mice carrying the factor V Leiden (FV Leiden) mutation.

Primary hypercoagulable states, such as FV Leiden and prothrombin 20210 (PT20210), result from mutations in genes that encode proteins of the coagulation cascade[7]. FV Leiden results from a G1691A single nucleotide polymorphism gene mutation that leads to an amino acid substitution of arginine for glutamine at position 506 of the protein, which is one of the cleavage sites of activated protein C (APC). The mutated protein is more resistant to APC cleavage, and, as a result, the negative feedback on the coagulation cascade is impaired. Thus, the FV Leiden mutation is responsible for venous thromboembolisms at a high prevalence of 1%-8.5%[8]. Another common mutation involves the elevation of plasma prothrombin levels due to a G→A transition in nucleotide 20210 in the prothrombin gene. The prevalence of heterozygosity for this mutation among Caucasian populations is 1%-6%[9]. A third common mutation that results in hypercoagulation is a genetic variant of the *methylene tetrahydrofolate reductase* (*MTHFR*) gene, which leads to an elevation in homocysteine levels and an increased risk of venous and arterial thrombosis. Epidemiological data from humans have shown that APC resistance resulting from FV Leiden heterozygosity is related to an increased rate of fibrosis in HCV patients[4,10], as opposed to carriage of the PT20210 mutation, which has not been found to be a contributing factor to liver cirrhosis[10]. Hyperhomocysteinemia and MTHFR C677T mutations have been found to play roles in liver steatosis in HCV patients and, thus, indirectly play a role in the progression of liver fibrosis[11].

In this work, we examined whether a mutation in one of these genes contributes to accelerated liver fibrosis in French HCV patients.

MATERIALS AND METHODS

Patients

In this retrospective study, we analyzed data that were collected from HCV-infected patients. The first 168 consecutive patients were included from the "Fibroscore Study", which was a French national, multicenter, prospective, and cross-sectional study of Caucasian patients that was performed by researchers who are well known for their specific expertise in HCV in five centers in the southeast region of France, including Saint-Joseph Hospital and La Conception Hospital (Marseille), Archet Hospital (Nice), Hyeres Hospital and the Arnault Tzanck Institute (St. Laurent du Var). All patients who suffered from chronic HCV infection, as documented by a positive test screen for HCV RNA in serum, were included in this study. Signed informed consent was obtained from all of the patients before their inclusion. Liver biopsy and biochemical markers were performed the same day. Liver biopsy was performed at each center and analyzed by the resident pathologist. For all patients, ultrasound examination was performed before liver biopsy.

Information relating to the patients' demographics, risk factors, virological status, clinical examinations, clinical data [age at exposure to the virus, alcohol consumption and body mass index (BMI)] and biological data (virus genotype) was prospectively recorded at each center on the day of biopsy.

Patients were excluded if they suffered from another proven liver disease, such as autoimmune hepatitis or alcoholic liver disease, or if they had positive serology for hepatitis B or HIV. Patients for whom the date of infection was unknown were excluded as well.

The stored DNA samples from the 168 recruited patients were analyzed for the three mutations that are responsible for hypercoagulable states, that is, FV Leiden, PT20210 and MTHFR.

This study was approved by the local Helsinki ethics committees.

Definitions of slow and fast fibrosis

Fibrosis rates were calculated by dividing the fibrosis stage by the number of years of infection. We employed Poynard's fibrosis progression model in order to define our patients' fibrosis rate status and classified them as "fast fibrosers" or "slow fibrosers"[12]. According to the model,

Table 1 Patient characteristics by fibrosis rates (by Poynard)

	Slow fibrosers (n = 116)	Fast fibrosers (n = 52)	P value
Female (%)	37%	31%	0.43
Age (yr)	49.8 ± 10.5	43.9 ± 7.1	< 0.001
Age at infection (yr)	25.1 ± 10.8	25.2 ± 7.7	0.97
Infection duration (yr)	24.7 ± 8	18.7 ± 8.1	< 0.001
Alcohol intake ⩾ 50 g/d	7.1%	10.4%	0.53
BMI (kg/m^2)	23.8 ± 2.9	23.4 ± 3.1	0.5
Genotype (%)			0.49
1	74.3%	62.8%	
2	2.8%	2.3%	
3	16.5%	23.3%	
4	6.4%	11.6%	
Inflammatory score, grade (units)	1.3 ± 0.68	1.81 ± 0.69	< 0.001
Fibrosis stage (%)			< 0.001
0	14.7%	0%	
1	45.7%	9.6%	
2	29.3%	5.8%	
3	8.6%	48.1%	
4	1.7%	36.5%	

BMI: Body mass index.

the means of the fibrosis progression rates, as predicted by age and infection duration, are as follows: (1) patients who were infected at an age of less than 20 years were expected to develop cirrhosis after 40 years of infection; (2) patients who were infected in their third or fourth decade progress to cirrhosis after 35 years of infection; (3) patients in the fifth decade of life were expected to develop cirrhosis after 20 years of infection; and (4) patients who were older than 50 years were expected to become cirrhotic after 15 years of infection.

Histopathology

Liver biopsy examinations were performed at each center and analyzed by the local pathologist, wherein the fibrosis stage and activity grading were evaluated according to the METAVIR scoring system. Fibrosis was staged on a scale of 0-4: F0, no fibrosis; F1, portal fibrosis without septa; F2, few septa; F3, numerous septa without cirrhosis; and F4, cirrhosis.

The grading of activity that was assessed by the METAVIR system (based on the intensity of necroinflammatory activity, largely on necrosis) was scored as follows: A0, no histological activity; A1, mild activity; A2, moderate activity and A3, severe activity.

In order to assess liver biopsy quality, Regev quality criteria were used (fragment length of 15 mm or more, five or more portal tracts and one fragment). A biopsy that is between 10 and 15 mm in length and has less than five portal tracts or is fragmented is considered to be a fair quality biopsy, whereas a biopsy is considered to be of poor quality when it is less than 10 mm in length.

DNA collection and gene analysis

DNA samples were isolated from the peripheral blood of all patients. DNA extraction was performed using the QIAamp DNA blood kits and silica-membrane-based DNA purification (Qiagen, Germany).

Table 2 Frequency of hypercoagulation mutations (%)

Mutation type	Wild type	Heterozygote	Homozygote
Factor V Leiden (n = 159)	96.2	3.8	0
Prothrombin 20210 (n = 156)	92.3	7.1	0.6
MTHFR (n = 163)	35.6	50.9	13.5

Percentages of patients carrying each of the mutations by genotype. MTHFR: Methylene tetrahydrofolate reductase.

Analyses of gene mutations of FV Leiden, prothrombin G20210A and MTHFR C677T were performed *via* real-time polymerase chain reaction, using fluorescent hybridization probes (Dyn Diagnostics Roche, Israel) in a LightCycler instrument (Roche Diagnostics, Basel, Switzerland), specified as follows: FV Leiden: anchor: '5-LC-Red640-TGT CCT TGA AGT AAC CTT TCA GAA ATT CTG-PH, sensor WT: '5-GGC GAG GAA TAC AGG TAT-FL; PTG20210A: anchor: '5-LC-Red640-TGC TCC CAG TGC TAT TCA TGG AC-PH, sensor WT: '5-GAC TCT CAG CGA GCC TCA-FL; and MTHFR: anchor: '5-LC-Red640-CGC AGC TTT TCT TTG AGG CTG ACA-PH, sensor WT: '5-CGG GAG CCG ATT TCA TCAQ-FL.

Statistical analysis

All statistical analyses were performed using SPSS, version 17 (SPSS Inc., Chicago, Illinois, United States). The rate of fibrosis was calculated as the ratio of the fibrosis score to the duration of infection at the time of biopsy. This value was used for a univariate analysis of variance (ANOVA) in order to calculate whether the factors were significantly associated with the rate of fibrosis, and in a linear regression model to calculate the influence of each variable on the fibrosis rate. Fibrosis rates were subdivided into "slow fibrosers" or "fast fibrosers" for the construction of a multivariate logistic regression model that served to calculate the odds ratio (OR) for fast fibrosis.

Demographic differences between the "fast" and "slow" fibrosers were assessed using independent sample t test and ANOVA, whereas χ^2 test or Fisher's exact test were employed when appropriate, as designated in the tables.

RESULTS

One hundred and sixty-eight consecutive patients with available liver biopsies were recruited in this study. The average fibrosis rate in the entire cohort was 0.11 ± 0.17 fibrosis units per year. Demographic and disease-related data categorized by fibrosis rate are presented in Table 1. Patients who were categorized as "fast fibrosers" were significantly younger, had shorter disease duration, consumed more alcohol, and had a higher disease grade and stage according to histological analyses. HCV genotypes did not statistically differ between the two groups.

The frequencies of the three mutations that were analyzed in this cohort are specified in Table 2.

Table 3 Percentage of hypercoagulation gene mutation carriage by rate of fibrosis (by Poynard)

Gene	Mutation carriage	Percent of slow fibrosers	Percent of fast fibrosers	*P* value
PT20210	Wild type	94.5	86.9	0.18[1]
	Heterozygote	5.5	10.9	
	Homozygote	0	2.2	
Factor V Leiden	Wild type	95.5	98	0.67
	Heterozygote	4.5	2	
	Homozygote	0	0	
MTHFR	Wild type	35.6	36	0.80
	Heterozygote	52	48	
	Homozygote	12.4	16	

[1]Heterozygote and homozygote categories were unified for Fisher's exact test. PT20210: Prothrombin 20210; MTHFR: Methylene tetrahydrofolate reductase.

Table 4 Prothrombin 20210 mutation rates in various "fibrosis rate" models

Rate of fibrosis	PT20210 mutation in slow fibrosers (%)	PT20210 mutation in fast fibrosers (%)	*P* value[3]
Rate of fibrosis by Poynard	5.50	13	0.18
0.13 units/yr[1]	5.10	15.80	0.07
0.133 units/yr[2]	5	16.70	0.03

Various cut-offs of rate of fibrosis were employed on our cohort to differentiate between fast and slow fibrosers. [1]Rate of fibrosis according to Fishman *et al*[22]; [2]Rate of fibrosis according to Wright *et al*[10]; [3]*P* value calculated by Fisher's exact test. PT20210: Prothrombin 20210.

PT20210 carriers

Six patients (5.5% of 110 patients) of the "slow fibrosers" group were carriers of the PT20210 mutation, whereas, in the "fast fibrosers" group, 5 patients (10.9% of 46 patients) and one patient were heterozygous and homozygous, respectively, for the mutation (Table 3).

The occurrence of the PT20210 mutation among the "slow fibrosers" and "fast fibrosers" was not significantly different when the fibrosis rate was calculated according to the Poynard model; however, when we tested other cut-offs that have been used in the literature to differentiate slow and fast fibrosers, the difference became statistically significant (Table 4). Nevertheless, we used the Poynard model to define the slow and fast fibrosis groups in all of our calculations.

In a univariate analysis using the "rate of fibrosis" as the dependent variable and the PT20210 mutation status as the independent variable, while controlling for age, gender, BMI, amount of alcohol consumption, age of infection, and inflammation grade, we found that PT20210 status had a statistically significant association with the fibrosis rate ($P = 0.002$).

In order to explore the influence of PT20210 status, age, gender, age of infection, amount of alcohol consumption, BMI, and inflammation grade, we constructed a linear regression model with the above variables as the predictive variables, and the rate of fibrosis as the dependent variable (Table 5). These variables accounted for 44.8% of the variance in the fibrosis rate ($R^2 = 0.448$). The PT20210 status accounted for 9% of the fibrosis rate ($R^2 = 0.093$, $P = 0.002$).

Table 5 Linear regression analysis of rate of fibrosis

Predictive variable	R^2	*P* value
PT20210 status	0.093	0.002
Age	0.022	0.033
Gender	0.016	0.042
Age of infection	0.167	< 0.001
BMI	Not contributing	
Alcohol consumption	Not contributing	
Inflammation grade	0.121	< 0.001

PT20210: Prothrombin 20210; BMI: Body mass index.

Table 6 Multivariate analysis of the association between rate of liver fibrosis (slow fibrosers *vs* fast fibrosers) predicted by prothrombin 20210 mutation and various known parameters

Parameter	OR (95% CI)	*P*-wald[1]
Age	0.91 (0.86-0.96)	< 0.001
PT20210	4.76 (1.13-19.99)	0.033
Inflammation grade[2]	7.42 (3.07-17.95)	< 0.001

Variables removed from the model: gender, BMI and alcohol consumption. [1]The Wald test was used to assess the significance of each logit; [2]Inflammation was categorized: grades 0 and 1 compared with grades 2 and 3. PT20210: Prothrombin 20210; OR: Odds ratio; CI: Confidence interval.

In order to calculate the adjusted OR of the variables that affected liver fibrosis, we constructed a multivariate logistic regression model in a stepwise method. The variants that were included were PT20210 status, age, gender, BMI, alcohol consumption, and inflammation grade. The age of infection was not included, as it is used to define which patients are "fast fibrosers" in Poynard's model. We found that the presence of the PT20210 mutation corresponded with an OR of 4.76 ($P = 0.033$; 95% CI: 1.13-19.99) for "fast" liver fibrosis (Table 6).

Recent studies[13] have suggested that genotype 3 might be associated with the rate of fibrosis in hepatitis C patients. In order to account for this, we constructed an additional multivariate logistic regression model. This model included all universal variables that are known to affect the HCV fibrosis rate as well as genotype 3 status and the presence of the PT20210 mutation. Genotype 3 status was not a statistically significant predictor ($P = 0.25$), as opposed to PT20210, which remained in the model with an OR of 4.02 ($P = 0.048$; 95% CI: 1.01-16.00) (data not shown).

FV Leiden and MTHFR carriers

No significant association was found between FV Leiden carriage and fibrosis rate. Five patients (4.5% out of 110 patients with available gene analyses) of the "slow fibrosers" group were heterozygous for this mutation, as was only one patient (2% of 49 patients) of the "fast

fibrosers" group (Table 3).

Similarly, MTHFR was not associated with fibrosis rate in HCV patients (Table 3). Of the "slow fibrosers," 59 patients were heterozygous (52% of 113 patients with available gene analyses), whereas 14 (12.4%) patients were homozygous to the mutation. Among the "fast fibrosers", 24 (48% of 50 patients) patients were heterozygous for the mutation and 8 (16%) patients were homozygous for the mutation.

DISCUSSION

We have shown that carriage of the PT20210 mutation is related to an increased incidence rate of fibrosis in hepatitis C patients, whereas MTHFR or Factor V Leiden mutations are non-contributory.

The mean fibrosis rate in the "fast fibrosers" group was 0.23 ± 0.27 fibrosis units/year, which translates to 17 years of disease duration from infection to stage 4 cirrhosis. This rate was substantially faster than that of the "slow fibrosers" group (0.057 ± 0.037 fibrosis units/year), although classic contributing factors, such as BMI or alcohol consumption, did not substantially differ between the two groups.

In theory, enhanced coagulation may be an important factor in liver fibrosis. This hypothesis is supported by animal model studies, and, accordingly, a probable association between FV Leiden carriage and enhanced liver fibrosis in HCV patients was proposed[4,10]. The association of liver fibrosis with MTHFR carriage has not been directly examined, and the carriage of PT20210 has exhibited only an insignificant trend towards increased fibrosis in a single prior study[10].

In order to confirm that our results do not represent a type 1 statistical error, we employed three different cutoffs that have been previously used in the literature to differentiate fast from slow rates of liver fibrosis (Table 4) and eventually used the one that was the most stringent (the Poynard rate of fibrosis) in our calculations. Moreover, when the rate of fibrosis was used as a continuous variable (in the linear regression and univariate analysis models), the carriage of the PT20210 mutation was associated with faster fibrosis and explained up to 9% of the observed fibrosis rates when known factors that may affect fibrosis rate (age, age of infection, gender, alcohol consumption, BMI, and inflammation grade, which is more controversial) were controlled for.

Thus, although our cohort was relatively small, our findings suggest an impact of PT20210 mutation carriage on liver fibrosis in HCV patients. Interestingly, multiple mutations in more than one of the examined genes did not increase the fibrosis rate. We have not found a correlation between fibrosis rate and FV Leiden or MTHFR mutations. The relatively small number of patients who carried the FV Leiden mutation in our cohort may account for the lack of agreement between our findings and previous publications. With regard to MTHFR, one has to take into account folic acid and homocysteine levels, which were not examined in our cohort and may result in a non-hypercoagulation phenotype despite a procoagulation genotype. An additional limitation of our study may be the fact that none of the recruited patients had a clinical history of a hypercoagulable state, such as deep vein thrombosis. This may reflect a non-intentional selection bias and may have resulted in an underestimation of the hypercoagulation mutations in our cohort. Nevertheless, the percentage of patients who carried the PT20210 mutation in our cohort was at the high end of the range that has been reported in European cohorts, where the prevalence of the PT20210 mutation in the control groups is usually between 1%-3%, but may be as high as 6.5%[14]. PT20210 prevalence increases as one shifts from northern to southern Europe, and it is more prevalent in Caucasians as opposed to other ethnicities[15]. These two factors apply to our cohort and may at least partially explain the prevalence of PT20210 mutation carriage. Among the "slow fibrosers" group, 5.5% of patients carried the mutation, and this figure is within the reported prevalence of the PT20210 mutation in southern Europe.

The combined frequency of PT20210 among the entire cohort was above 7%; however, this statistic includes the "fast fibrosers" group, which we found to have a high frequency of PT20210 mutation carriage (13%). This signifies the importance of our findings. The PT20210 mutation was much more common in the "fast fibrosers" group, and, thus, the results of this study strengthen the notion that hypercoagulation causes faster fibrosis in HCV patients. In addition, the high percentage of PT20210 carriage in our cohort may partially explain why our results reached statistical significance, whereas Wright *et al*[10] demonstrated only a trend for a contribution of the PT20210 mutation to the fibrosis rate in HCV patients. In their cohort, although the number of patients was larger (n = 287), the prevalence of PT20210 mutation was only 4.5%.

Consistent with previous studies, we found that the age of infection and gender are related to fibrosis rate, whereas the HCV genotype had no effect on the rate of fibrosis, wherein the latter of these two has been controversial in the literature[2,13]. In contrast, inflammatory grade, which is considered to be a controversial factor regarding fibrosis rate, was determined to be a significant contributor to the fibrosis rate in our study. Because patients who suffered from alcoholic liver disease were excluded, only a small number of patients (< 8%) consumed large amounts of alcohol. This may account for the fact that we did not observe the well-known effect of alcohol consumption on liver fibrosis.

Although HCV patients who carry hypercoagulable gene mutations may account for only 5%-10% of all patients, millions of patients belong to this group around the world. Moreover, apart from the hypercoagulable states that relate to PT2010 and FV Leiden and were discussed here, other disease states may result in hypercoagulablity and perhaps in increased rates of liver fibro-

sis. Among these is the anti-phospholipid syndrome that has long been in debate with respect to its frequency and its effects in HCV patients. Specifically, anti-cardiolipin antibodies have been found in a sizable portion of HCV patients and are considered to be one of several autoimmune phenomena that are associated with this disease[16,17]. The implications of this disease on coagulation in this context are still under debate[18-21].

Ultimately, an analysis of gene mutations for hypercoagulability and the detection of hypercoagulable states in these patients may assist the clinician in the risk stratification of HCV patients according to fibrosis risk. Patients who are at high risk of liver fibrosis may be recommended to receive earlier anti-HCV therapy. With regard to the risk stratification of HCV patients according to the prevalence of the PT20210 mutation, a more specific and accurate method to stratify these patients may be found by assessing their prothrombin plasma levels, which may correlate better with the fibrosis rate.

This study lends additional support to the hypothesis that coagulation processes are involved in the pathogenesis of fibrosis in the liver. These accumulating reports should encourage the design of a larger prospective cohort study that will examine the impact of the various hypercoagulation states on liver fibrosis in HCV patients in particular, and in other fibrosis states of the liver in general. A better understanding of the pathophysiology of liver fibrosis may facilitate the development of novel therapeutic interventions that will help slow the rate of fibrosis.

We would like to thank Ms. Yvette Levy and Sali Usher for their excellent technical support.

COMMENTS

Background

Cirrhosis is a major cause of morbidity and mortality in patients suffering from chronic hepatitis C virus (HCV) infection. Although various factors are known to affect liver fibrosis, it is still impossible to predict who will suffer from an increased rate of liver fibrosis among these patients. Recently, it has been suggested that HCV patients who possess hypercoagulation mutations [such as factor V Leiden (FV Leiden) mutation] may have an increased liver fibrosis rate.

Research frontiers

Hypercoagulable states have been hypothesized to play a role in organ fibrosis. In various inflammatory states, such as those of the lung or kidney, thrombosis and fibrin formation result in organ injury. It has been recently proposed that hypercoagulable states may be an additional contributing factor to liver fibrosis through several mechanisms, such as thrombotic events in small venous blood vessels in the liver, and hepatic stellate cell stimulation by thrombin. Increased fibrin deposition has also been demonstrated in animal models of liver fibrosis. These observations have been strengthened by a mouse model of liver fibrosis that demonstrated that the extent of fibrosis was much higher in mice carrying the FV Leiden mutation.

Innovations and breakthroughs

The study is the first to find a significant impact of an additional common hypercoagulation mutation, namely prothrombin G20210A (PTG20210A), on the rate of liver fibrosis in HCV patients.

Applications

The work strengthens the notion that hypercoagulation states affect the rate of liver fibrosis. If proven true in larger, prospective trials, HCV patients should be assessed for hypercoagulation mutations and should be regarded as a susceptible group for early cirrhosis, and receive early treatment against HCV. Additionally, better understanding of the role of hypercoagulation states in fibrosis may aid in the development of new therapies for organ fibrosis.

Terminology

Cirrhosis is a state of liver fibrosis with major morbidity and mortality in patients who suffer from liver diseases, in general, and particularly from hepatitis C. Hypercoagulation states such as PTG20210A, FV Leiden and methylene tetrahydrofolate reductase, are pathological conditions that cause an enhanced activity of the coagulation system and may expose patients to thrombotic events.

Peer review

The authors reported the association of fibrosis progression in chronic hepatitis C patients with PTG20210A mutation. This paper is interesting and informative.

Abstract

AIM: To discuss the safety, feasibility and regularity of destruction to porcine spleen *in vivo* with congestion and tumescence by microwave ablation (MWA).

METHODS: Ligation of the splenic vein was used to induce congestion and tumescence *in vivo* in five porcine spleens, and microwave ablation was performed 2-4 h later. A total of 56 ablation points were ablated and the ablation powers were 30-100 W. The ablation time (1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 min) was performed at a power of 60 W. After ablation, the ablation size was measured in pigs A, C, D and E and spleen resection. In pig B, the ablation size was measured and 2 ablation points were sent for pathology analysis and all tissues were sutured following ablation. Pig B was killed 1 wk later and the ablation points were sent for pathology analysis. Bleeding, tissue carbonization surrounding electrodes, and pathological changes were observed, and the effect on destruction volume relative to different ablation powers, times and positions was analyzed.

RESULTS: The incidence of bleeding (only small amounts, < 20 mL) in the course of ablation was 5.4% (3/56) and was attributed to tissue carbonization surrounding electrodes, which also exhibited an incidence of 5.4% (3/56). The destruction volume was influenced by different ablation powers, times and points. It showed that the ablation lesion size increased with increased ablation time, from 1 to 10 min, when the ablation power was 60 W. Also, the ablation lesion size increased with the increase of ablation power, ranging from 30 to 100 W when the ablation time was set to 3 min. A direct correlation was seen between the destruction volume and ablation time by the power of 60 W (r = 0.97542, P < 0.0001, and also between the destruction volume and ablation powers at an ablation time of 3 min (r = 0.98258, P < 0.0001). The destruction volume of zone Ⅱ (the extra-2/3 part of the spleen, relative to the first or second class vascular branches), which was near the hilum of the spleen, was noteably larger than the destruction volume of zone Ⅰ (the intra-1/3 part of the spleen) which was distal from the hilum of the spleen (P = 0.0015). Pathological changes of ablation occurring immediately and 1 wk after MWA showed large areas of coagulation. Immediately following ablation, intact spleen tissues were observed in the areas of coagulation necrosis, mainly around arterioles, and there were no obvious signs of hydropsia and inflammation, while 1 wk following the ablation, the coagulation necrosis was well distributed and complete, as many nuclear fragmentations were detected, and there were obvious signs of hydropsia and inflammation.

CONCLUSION: *In vivo* treatment of congestion and tumescence in the spleen using microwave ablation of water-cooled antenna is a safe and feasible method that is minimally invasive.

INTRODUCTION

Minimally invasive methods for treatment of hypersplenism, such as partial splenic embolization (PSE) and radiofrequency ablation (RFA), have been developed in recent years. PSE has been widely used, but is not optimal due to a high recurrence rate and the finding that the embolism volume varies based on the surgeon's experience and the estimation of contrast medium's flow rate, making it difficult to accurately evaluate embolism volume in real time[1]. In recent years, RFA has been used for the treatment of hypersplenism, since it has greater control over the destruction volume of the spleen; however, RFA runs a high risk of bleeding. In this study, we propose microwave ablation (MWA) as an effective method for controlling the destruction volume of the spleen. MWA has the added advantages of higher rate of temperature increase, high thermal efficiency, stable and controllable thermal field, good hemostasis effect, and good blood vessel coagulation[2,3]. This study describes the destruction to porcine spleen *in vivo* using microwave ablation with water-cooled antenna.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. This study was approved ethically by Cancer Center, Sun Yat-sen University.

Materials

Five healthy Tibet pigs (assigned A, B, C, D and E), one female and four males aged 6-8 mo (weighing 32-39 kg) were selected for this study.

Methods

All the pigs were fasted for 12 h before operation and received atropine i.m. (0.5 mg; 30 min before operation), Su Mian Xin i.m. (1 mL/kg; 20 min before operation), and ketamine i.m. (8 mg/kg; 20 min before operation). After successful induction of anesthesia, the animal was fixed on the operation table. After abdominal skin preparation and sterilization, the skin, hypoderma, fat, muscle and peritoneum were cut open for complete exposure of the spleen. Then the hilum of the spleen was separated and the splenic artery and splenic vein were exposed. Next, the splenic vein was ligated using blood vessel forceps. Microwave ablation was performed when congestion and tumescence were seen, which was 2-4 h after ligation of the splenic vein. The ablation size was measured in pigs A, C, D and E after ablation and spleen resection. In pig B, the ablation size was measured and 2 ablation points were sent for pathology analysis and all tissues were sutured following ablation. Pig B was killed 1 wk later and the ablation points were sent for pathology analysis (Figure 1).

Device parameters

Specifications of water-cooled antenna: diameter 1.7 mm, model Ⅲ with high-power (made by Qi Ya Medical Treatment Facility Limited Company, Nanjing, China; batch No. 090226003EX); Emission Facility: made by Qi Ya Medical Treatment Facility Limited Company, Nanjing, China; Frequency: 2450 MHz; Output power: 0-120 W; Precision of temperature control: ± 0.1 ℃; Discharge waveform: continuous wave; operating conditions: main voltage AC 220% ± 10%, environmental temperature 5 ℃-40 ℃.

Ablation points

There were a total of 56 ablation points (8 in pig A, 12 in B, 14 in C, 13 in D and 9 in E). The ablation powers were 30, 40, 50, 60, 70, 80, 90 and 100 W. The ablation time (1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 min) was performed at a power of 60 W. The whole spleen was divided into two sections: zero Ⅰ, which was adjacent to the hilum of the spleen (the intra-1/3 part of the spleen); and zero Ⅱ, which was distal from the hilum of the spleen (the extra-2/3 part of the spleen), relative to the first or second class vascular branches.

Observation index

The incidence of bleeding of the pin hole, tissue carbonization surrounding electrodes, ablation volume (multiplied by long diameter and short diameter), and the pathological changes of ablation points and the surrounding tissues were observed using hemotoxylin and eosin.

Statistical analysis

Statistical analysis was performed using SAS 8.0 (not all the carbonization points were included).

The correlation analysis between the ablation volume (zero Ⅰ and zero Ⅱ) and the ablation time (1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 min) was performed at a power of 60 W.

Figure 1 Procedures of experimental study of destruction to porcine spleen *in vivo* by microwave ablation. A: The appearance of the spleen before ligation of splenic vein; B: Splenomegalia was seen 2 to 4 h after ligation of the splenic vein; C: The ablation size was measured after microwave ablation.

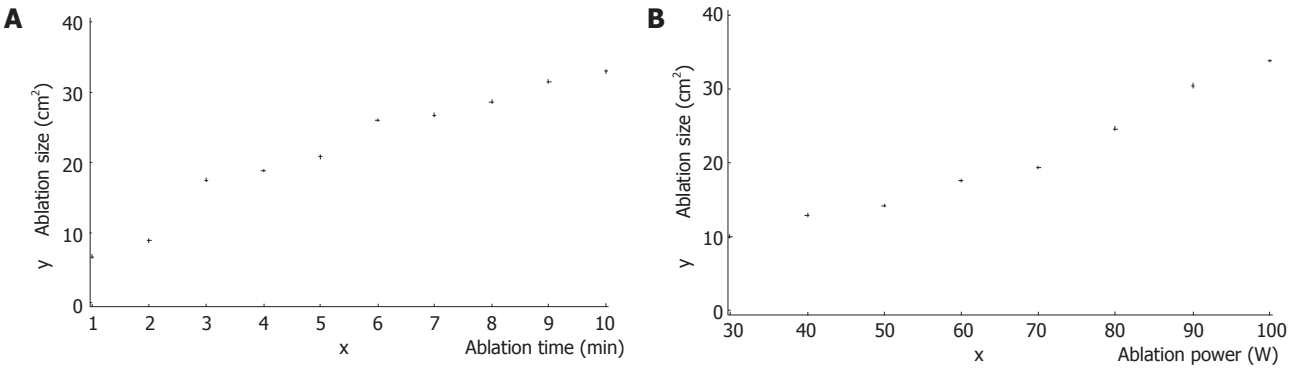

Figure 2 The ablation lesion size was correlated with the ablation time and power. A: $r = 0.97542$, x = 5.5 ± 3.028, y = 23.4 ± 9.023, $P < 0.0001$; B: $r = 0.98258$, x = 65.0 ± 24.495, y = 18.47 ± 8.47, $P < 0.0001$.

The correlation analysis between the ablation volume and the ablation power (30, 40, 50, 60, 70, 80, 90 and 100 W) was performed using an ablation time of 3 min. For each correlation analysis, the data was represented by scatterplot and the value of r was calculated.

The t test of independent samples was performed to compare the ablation range of zero I (9 points of 3 min by 60 W) and that of zero Ⅱ (8 points of 3 min by 60 W).

RESULTS

Incidence of bleeding of the pin hole and tissue carbonization

The incidence of bleeding was 5.4% (3/56), only small amounts (< 20 mL) were caused by tissue carbonization surrounding the electrodes. The carbonization incidence rate was also 5.4% (3/56).

Relationship between ablation lesion size and time

As shown in Figure 2A, the ablation range had a direct correlation with ablation time by the power of 60 W (r = 0.97542, x = 5.5 ± 3.028, y = 23.4 ± 9.023, P = 0.0001). The ablation lesion size increased with increased ablation time, from 1 to 10 min, when the ablation power was 60 W.

Relationship between ablation lesion size and power

As shown in Figure 2B, the ablation range was directly correlated with the power (30-100 W), at an ablation time of 3 min (r = 0.98258, x = 65.0 ± 24.495, y = 18.47 ± 8.47, P = 0.0001). The ablation lesion size increased with the increase of ablation power, ranging from 30 to 100 W when the ablation time was set to 3 min.

Comparison between the ablation lesion size of zone Ⅰ and zone Ⅱ (60 W, 3 min)

The ablation lesion size of zone Ⅱ (the extra-2/3 part of the spleen, relative to the first or second class vascular branches), which was near the hilum of the spleen was significantly larger than that of zone I (the intra-1/3 part of the spleen) which was distal from the hilum of the spleen (10.763 ± 2.001 *vs* 16.569 ± 4.112, P = 0.0015, t = -3.81, P = 0.0015).

Pathological changes of ablation points and the surrounding tissues

As shown in Figure 3, pathological changes occurred immediately and up to 1 wk after the ablation, and were marked by a large area of coagulation necrosis. Immediately following ablation, intact spleen tissues were observed in the areas of coagulation necrosis, mainly around arterioles, and there were no obvious signs of hydropsia and inflammation. One week following the ablation, the coagulation necrosis was well distributed and complete, as many nuclear fragmentations were detected, and there were obvious signs of hydropsia and inflammation.

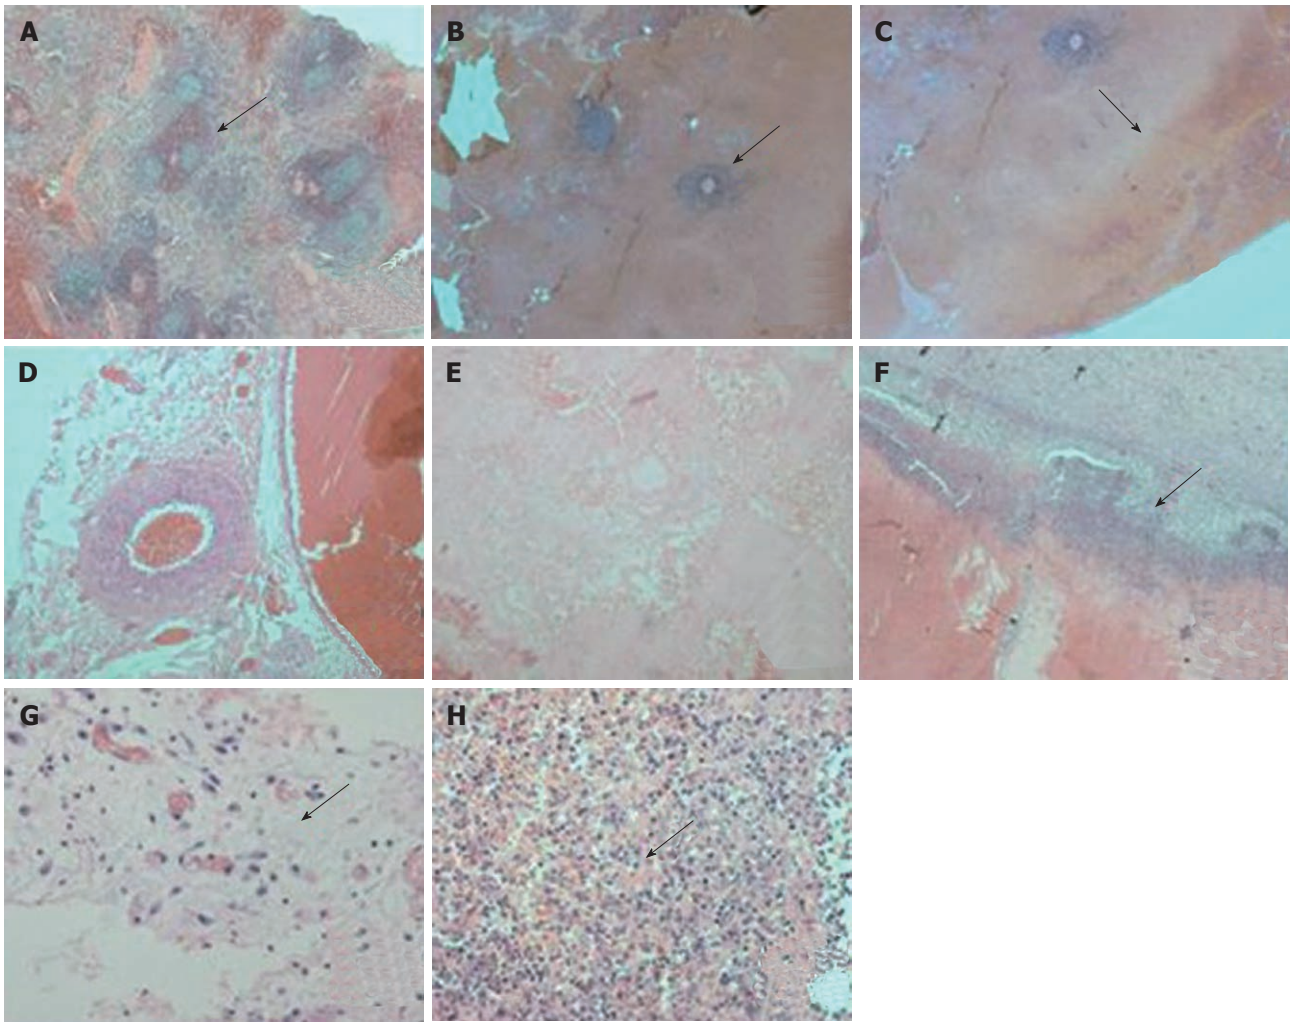

Figure 3 The pathological changes after microwave ablation. A: Normal spleen tissue (the arrow indicates the splenic corpuscle), hemotoxylin and eosin (HE) × 20; B-D: The pathological changes immediately after microwave ablation (MWA); B: There was some remaining spleen tissue around arterioles in the areas of coagulation necrosis (↑), HE × 20; C: The ablation borderline was not very clear (↑), HE × 20; D: There were no obvious signs of hydropsia or inflammatory reaction, HE × 40; E-H: Pathological changes 1 wk after MWA; E: The coagulation necrosis was well-distributed and complete, HE × 20; F: The ablation borderline was clearer 1 wk after ablation (↑), HE × 20; G: There were some signs of hydropsia and inflammation (↑), HE × 40; H: Many nuclear fragmentations could be seen clearly (↑), HE × 40.

DISCUSSION

Advantage of MWA in the treatment of splenomegalia and hypersplenism

With the development of minimally invasive therapy, new methods such as PSE and RFA are being optimized for the treatment of hypersplenism. Many research studies and clinical practices have proved that PSE has good therapeutic effects in the treatment of hypersplenism[4-7]. However, it has a high recurrence rate and the embolism volume varies based on the surgeon's experience and the estimation of the contrast medium's flow rate. For this reason, PSE is usually influenced by subjective factors, making it difficult to accurately evaluate embolism volume in real time[1]. Recently, some studies reported that RFA can effectively control the destruction volume of the spleen and overcome the limitation posed by PSE[8,9]. With RFA, coagulative necrosis, not liquefaction necrosis, occurred in the spleen after thermo-ablation, and the probability of splenic abscess was obviously decreased. Furthermore, the recurrence rate of hypersplenism was obviously decreased because the heat-sink effect can damage the vascular endothelium and lead to thrombogenesis, which can lead to spleen consolidation, interstitial fibrosis and decreased splenic recirculation.

MWA is one method of thermo-ablation and can also control the destruction volume of the spleen. MWA has the added advantages of a rapid rise in temperature, high thermal efficiency, stable and controllable thermal field, good hemostatic effect, and effective blood vessel coagulation[2,3]. Shibata *et al*[10] first compared MWA with RFA in pig liver and found that the temperature of the area surrounding the MWA electrode was significantly higher than the temperature of the area surrounding the RFA electrode; the MWA electrode achieved superior results to the RFA electrode with respect to the diameter of the coagulated area and the temperature of the area in which the electrode was inserted, at the specified times. Yu *et al*[11] also compared the effectiveness of MWA and RFA using a single internally cooled probe

in a hepatic porcine model and the results showed that MWA had higher potential for complete destruction of liver tumors than RFA. Crocetti *et al*[12] designed a study to compare the feasibility, safety, and effectiveness of MWA versus RFA of lung tissue at histopathology in a rabbit model and found the feasibility and safety of MWA and RFA are similar in a lung rabbit model, but MWA produced a greater damage to peripheral small vessels inducing thrombosis. So, MWA has the advantage in the treatment of splenomegalia and hypersplenism and shows good prospects in the treatment of spleen diseases[13]. Some reports have also shown that MWA improves the peripheral blood conditions[13,14]. Further experimental and clinical research should investigate the relationship between the destructive proportion of the spleen and the improvement of the peripheral blood conditions. Regarding the type of cooled antennas, two types, air-cooled and water-cooled, have been used for microwave ablation to create as large ablation patterns as possible[15]. Firstly, cooling water significantly reduces the temperature near the antenna, as confirmed by a previous study[16]. This approach avoids carbonization near the antenna, since the coagulation region is limited by the carbonized tissues. Therefore, a water-cooled antenna makes it possible to create the maximum ablation pattern. Secondly, a water-cooled antenna could effectively reduce the adhesion between antenna and tissue, and reportedly reduces patient pain during treatment and reduces the risk of infection after the operation[16].

Safety of microwave ablation

The main complication of MWA treatment is bleeding of the pin hole, because the spleen tissue is soft and fragile and it has many close-set blood sinuses. In the current study, we report that the incidence of bleeding was 5.4% (3/56), only small amounts (< 20 mL), and that the bleeding was controlled by further ablation of the pin hole, suggesting that MWA is a safe method. Compared to RFA, MWA has higher thermal efficiency and better blood vessel coagulation[17,18]. So, the risk of pin hole errhysis is lower than that occurring with RFA, especially since the pin hole coagulation after MWA further decreases the probability of bleeding. In this study, the risk of pin hole bleeding is likely increased due to splenic congestion and tumescence, and the splenic sinus expanding 2-4 h after splenic vein ligation. In the cases of splenomegalia and hypersplenism caused by long-term portal hypertension, in which there is endangium hyperplasia and arteriole and veinule obstruction, MWA may run a lower risk of bleeding. Animal models of splenomegalia and hypersplenism caused by portal hypertension should be developed to test this hypothesis.

Regarding the relation between the carbonization surrounding electrodes and bleeding, the current study presumes that the crushing and avulsion of carbonization tissues to the spleen tissues without ablation, such as in the course of needle withdrawal, can lead to bleeding, especially since the spleen has an abundant blood supply. So, cutting down the carbonization incidence rate is an effective method for reducing the risk of bleeding, which can be regulated based on ablation power.

In this study, the carbonization incidence rate was 5.4% (3/56). Because the spleen has an abundant blood supply, the tissues of coagulative necrosis are easy to adhere to the pinhead after dehydration, and then carbonization occurs, which decreases the heat conduction and affects the ablation range. Further statistical analysis was not performed because there were few carbonization cases in this study, presumably due to the higher speed of water circulation and ice water circulation, which could decrease the carbonization incidence rate.

Effect of the ablation point on lesion size

Some reports find that thermo-ablation targeted next to blood vessels affects the ablation range, and that the extent of this effect is closely related to the caliber of the blood vessel[19-23], but there are no related reports describing the effect of the point of MWA in spleen ablation. In the current study, it is presumed that the blood vessels adjoining the hilum of the spleen are always branches of the first class, and that the caliber is larger and the blood flow rate is faster, and therefore they can convey the heat acquired by the spleen easily and have a predictable affect on the ablation range. The blood vessels distal from the hilum of spleen are always branches of the second and third class, with a smaller caliber and slower blood flow rates, and therefore they cannot convey the heat acquired by the spleen easily and consequently have little effect on ablation lesion size. In this study, the ablation lesion size of zone I was obviously smaller than that of zone Ⅱ by the power of 60 W in the same time period.

Effect of ablation time and power to the ablation lesion size

This study found that the ablation lesion size increased with increased ablation time, from 1 to 10 min, when the ablation power was 60 W. Also, the ablation lesion size increased with the increase of ablation power, ranging from 30 to 100 W when the ablation time was set to 3 min. So, by adjusting ablation time and power, MWA can accurately control the destruction volume of the spleen in cases of splenomegalia and hypersplenism, and effectively overcome the limitations in existing treatments, such as a reduced therapeutic effect caused by a smaller destruction volume and more complications associated with excess destruction volume.

Some studies that use PSE for the treatment of hypersplenism caused by portal hypertention[1,24] report that 50%-70% is the best embolism proportion. The best destruction proportion of MWA needs further research. Different studies report different results on the best ablation power and time. Hope *et al*[25,26] found that 45 W was the best ablation power and 10 min was the best ablation time for in vivo experimental treatment of porcine kidney using microwave ablation. Hines-Peralta *et al*[27]

found the ablation range increased with the increase in ablation time and power when used for *in vivo* and *ex vivo* experimental treatment of porcine liver using microwave ablation (50-150 W; 2-20 min). The current study is similar to that of Hines-Peralta, and the best ablation power and time should be further studied using more ablation points.

Pathological changes after microwave ablation

Similar to other reports[28,29], in the current study pathology marked by coagulation necrosis of a large area was noted both immediately and 1 wk after MWA. Immediately following MWA, some remaining spleen tissue was observed around arterioles, within areas of coagulation necrosis, and there were no obvious signs of hydropsia and inflammation. However, 1 wk after MWA, coagulation necrosis was well-distributed and complete, with clear detection of many nuclear fragmentations and hydropsia and inflammation. The remaining spleen tissues detected around arterioles immediately following MWA was likely due to the heat conveying. This tissue mainly consisted of lymphocytes which had integrated cytolemma, cell organelles and cell nuclei. Though the current study did not assess pathological changes occurring beyond 1 wk post-ablation, it is possible that there is extended hydropsia and inflammation.

The differences between the pathology changes immediately and 1 wk later in this study were the changes around arterioles in the ablation area and the hydropsia and inflammatory reaction beside which was the normal tissue reaction after thermal ablation. The disaggregation and necrosis noted in this study was probably related to the finding that the remaining cells around the arterioles were surrounded by coagulation necrosis and ischemic necrosis due to a loss of blood supply. The difference between the pathological changes occurring immediately versus 1 wk after MWA is also reflected in the change of the ablation borderline. Specifically, the ablation borderline was clearer 1 wk post-ablation, and included many nuclear fragmentations with surrounding inflammatory cells that were trachychromatic. Here we show an optimized method for treatment of hypersplenism. Results from this study have the potential to enhance therapeutic treatment of hypersplenism.

COMMENTS

Background

The incidence of hypersplenism is currently rising faster in China and current treatments have lots of limitations. Microwave ablation (MWA) of water-cooled antenna is expected to be a safe and feasible method to treat this disease that is also minimally invasive.

Research frontiers

MWA is a good method of thermo-ablation which has more advantages of a rapid rise in temperature, high thermal efficiency, stable and controllable thermal field, good hemostatic effect, and effective blood vessel coagulation than radiofrequency ablation (RFA) in tumor treatment. However, whether MWA can be used in spleen ablation and how to control the destruction volume of the spleen has not been unequivocally addressed. In this study, the authors demonstrate that MWA is a safe and feasible method that is minimally invasive in spleen ablation and the appropriate volume of ablation of spleen can be obtained by controlling the ablation time and power.

Innovations and breakthroughs

Recent reports have highlighted the value of RFA in the treatment of hypersplenism. However, MWA has more advantages, such as a rapid rise in temperature, high thermal efficiency, stable and controllable thermal field, good hemostatic effect, and effective blood vessel coagulation than RFA. This is the first study to report MWA as a safe and feasible method in spleen ablation by animal experiment. Furthermore, this studies would suggest the regularity of the spleen damage *in vivo* using MWA and confirm the efficacy of microwave ablation from the pathological point of view.

Applications

By understanding the regularity of spleen damage *in vivo* using MWA, this study may represent a future strategy for therapeutic intervention in the treatment of patients with hypersplenism.

Peer review

The authors examined the safety, feasibility and regularity of destruction to porcine spleen *in vivo* with congestion and tumescence by microwave ablation. It reveals that MWA is safe in spleen ablation and the destruction volume of the spleen can be easily controlled. The results are interesting and may represent a treatment option for hypersplenism.

Abstract

AIM: To investigate which surgical techniques and perioperative regimens yielded the best survival rates for diabetic rats undergoing gastric bypass.

METHODS: We performed Roux-en-Y gastric bypass with reserved gastric volume, a procedure in which gastrointestinal continuity was reestablished while excluding the entire duodenum and proximal jejunal loop. We observed the procedural success rate, long-term survival, and histopathological sequelae associated with a number of technical modifications. These included: use of anatomical markers to precisely identify Treitz's ligament; careful dissection along surgical planes; careful attention to the choice of regional transection sites; reconstruction using full-thickness anastomoses; use of a minimally invasive procedure with prohemostatic pretreatment and hemorrhage control; prevention of hypothermic damage; reduction in the length of the procedure; and accelerated surgical recovery using fast-track surgical modalities such as perioperative permissive underfeeding and goal-directed volume therapy.

RESULTS: The series of modifications we adopted reduced operation time from 110.02 ± 12.34 min to 78.39 ± 7.26 min ($P < 0.01$), and the procedural success rate increased from 43.3% (13/30) to 90% (18/20) ($P < 0.01$), with a long-term survival of 83.3% (15/18) ($P < 0.01$).

CONCLUSION: Using a number of fast-track and damage control surgical techniques, we have successfully established a stable model of gastric bypass in diabetic rats.

INTRODUCTION

When gastric bypass has been used to treat morbid obesity in patients with concomitant type 2 diabetes mellitus

(T2DM), some of these patients have seen their diabetes resolve even before they have lost weight[1-3]. Available data suggest that reduced caloric intake alone is not sufficient to explain the observed short-term metabolic and endocrine effects[4,5]. Recently, Rubino *et al*[6] demonstrated that a duodenal-jejunal bypass (DJB) procedure that preserved gastric volume could directly benefit T2DM patients, suggesting that duodenal-jejunal exclusion, rather than the restriction or reduction of gastric volume, is the critical factor in surgical treatment of T2DM.

Understanding the mechanisms underlying this surprising phenomenon would enhance our understanding of the pathophysiology of T2DM, and potentially require us to revise our approach to treating this disease[7]. Therefore, as a first step, we chose to apply an existing rat model for DJB in fat-fed/STZ rats. In such a model, a range of surgical, perioperative, and other factors would be expected to influence the effect of bypass surgery on diabetes. However, there are few data regarding the influence of particular surgical modalities or non-surgical aspects of care on diabetic rats. Therefore, in this study, we carefully compared a number of both surgical techniques and perioperative management regimens for their ability to improve the success rate in diabetic rats underlying DJB, including minimally invasive procedural designs and the use of damage control and fast-track surgical modalities.

MATERIALS AND METHODS

Laboratory animals

All animal use was in compliance with the regulations set out by the institutional animal research committee at Harbin Medical University. Male Wistar rats, 8 wk of age and weighing between 200 and 230 g, were purchased from CAAS Harbin Veterinary Research Institute [Approval NO. SCXK (HLJ) 2006-009]. The rats were given a high-fat diet for 8 wk, followed with an intraperitoneal injection of streptozotocin (30 mg/kg). After 72 h of treatment, rats with a non-fasting blood glucose level above 300 mg/dL (16.7 mmol/L), as measured by an electronic glucometer (One Touch Ultra, Lifescan, Johnson and Johnson, Milpitas, CA), were considered diabetic[8,9].

Experimental protocol

Wistar rats (n = 50) were randomly assigned for either conventional DJB (n = 30) or modified DJB (n = 20). The modification consisted of an improved surgical technique and postoperative care regimen, each of which was based on a prior analysis of the histopathological sequelae in failed cases of treatment with conventional DJB. Rats surviving more than 4 wk postoperatively were considered to constitute an operative success. The operative duration was recorded for rats in both groups, as was the mean plasma glucose level (PGL) both preoperatively and 4 wk postoperatively.

Table 1 Postoperative rehydration formula (total volume = 115 mL)

Component	Formula 1	Formula 2
0.9% sodium chloride	50 mL	50 mL
10% potassium chloride	3 mL	3 mL
5% glucose	0 mL	60 mL
10% glucose	30 mL	-
25% glucose	30 mL	-
Regular insulin	2 IU	-
Cimetidine	2 mL (0.2 g)	2 mL (0.2 g)
Cefoperazone sodium/sulbactam sodium	1.0 g	1.0 g

Conventional DJB

After fasting (12 h) and water deprivation (4 h), rats were anesthetized with 0.5% pelltobarbitalum natricum (30 mg/kg). After a median longitudinal incision was made in the upper abdomen, a Roux-en-Y duodenal-jejunal bypass that preserved the gastric volume while excluding the entire duodenum and proximal jejunal loop was constructed. First, after transecting the pylorus, the distal duodenal end was closed. The jejunum was transected 8 cm distal to Treitz's ligament, and the distal jejunal loop was connected *via* an end-to-end anastomosis to the free end of the pylorus[10]. Gastrointestinal continuity was reestablished *via* an end-to-side anastomosis between the proximal end of the jejunum and the distal jejunal loop, 12 cm distal to the gastrojejunal anastomosis. Consecutive sutures were used for the anastomoses, while full-thickness intermittent sutures were used for the closure of abdominal incisions.

Postoperatively, rats were housed separately in metabolic cages that were warmed for 6 h by a 60-watt incandescent lamp. Fluids were administered daily as subcutaneous injections into the back of the neck, providing a daily total of 18.7 kcal/kg, with a 5:1 ratio of glucose to insulin (Table 1, Formula 1). Enteral nutrition with Nutrison® [Nutricia Pharmaceutical (Wuxi) Co., Ltd., Wuxi, China], given three to four times daily, was begun after the first bowel movements (usually 48 h postoperatively), and provided a total daily caloric intake of 120 kcal/kg and a nitrogen content of 0.8 g/kg. Rats were subsequently given free access to water and semisolid food, and were finally graduated to regular rodent chow (the First Affiliated Hospital of Harbin Medical University Animal Center, Harbin, China). Throughout the postoperative period, rats were carefully monitored for general well-being, urine output, the nature and amount of feces, feeding profile, incision healing, and blood glucose.

Modified DJB

Rats were fasted for 12 h, but were given free access to water bottles containing a 50 g/L solution of glucose in normal saline. Before anesthesia, animals received subdermal injections (2 mL into the flexor side of the hindlimbs) of both sodium chloride (0.9%) and glucose (5%). Twenty minutes after subdermal injection of atro-

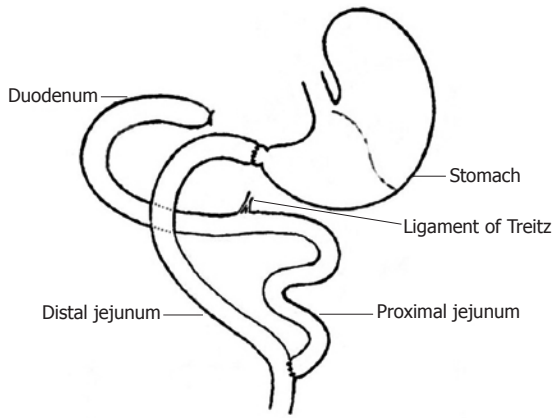

Figure 1 Schematic diagram of Roux-en-Y duodenal-jejunal bypass. The duodenum was transected 2-3 mm distal to the pylorus, and the distal duodenal end was ligated and closed. After the jejunum was transected 8 cm distal to Treitz's ligament, an end-to-end anastomosis was achieved between the distal jejunal loop and the proximal duodenum. The proximal jejunal loop was then anastomosed end-to-side to the distal jejunal loop at 12 cm distal to the gastro-jejunal anastomosis.

pine (0.1 mg/kg), baseline anesthesia was initiated with an intraperitoneal injection of 0.5% pelltobarbitalum natricum (20 mg/kg). Intermittent inhalation of ether was used to maintain anesthetic duration and depth during the operation. Sputum was periodically suctioned throughout anesthesia to maintain airway patency. A median longitudinal incision was begun at the xiphoid and caudally extended approximately 3 cm along the upper abdominal linea alba. The incision was then retracted using a blepharostat. Retraction of the hepatic lobes revealed the gastric pylorus and the initial portion of the duodenum, which was elevated with the notched forceps. The vascular branches running vertically to the pancreatic head, adjacent to the pylorus, were explored to carefully define the transection site. To avoid later damaging the biliary tract, the common bile duct and its point of convergence with the duodenum were also visualized. The first part of the duodenum was retracted caudally to expose the underlying colon, below which Treitz' s ligament was identified. In the Roux-en-Y procedure, the first part of the duodenum was transected 2-3 mm distal to the pylorus and the distal end of the duodenum was closed with a ligature, which both preserved gastric volume and excluded the entire duodenum and proximal jejunal loop. The procedure was otherwise identical to the conventional DJB (Figure 1).

Technical precautions

Although the skin incision was extended to the xiphoid so as to fully expose the surgical field, care was taken to avoid pneumothorax. Prehemostasis of the pyloroduodenal transection was achieved by ligating the major pyloric vascular branches of the gastroduodenal arteries with 7-0 minimally invasive sutures (Warwick Medical Supplies Co., Ltd. Hangzhou China). Treitz's ligament was carefully identified, and the intended site of jejunal transection, 8.0 cm distal to this structure, was marked with 7-0 sutures. To match the caliber of each side of the anastomosis, the jejunal segment to be transected was exteriorized for 3-5 min and subsequently restored. The duodenal segment adjacent to the intended division line was circled with 5-0 minimally invasive sutures (Warwick Medical Supplies Co., Ltd. Hangzhou, China), which were drawn through the vascular branches between the duodenum and the pancreatic head. Before transection of the duodenum, the segment 2-3 mm distal to the pylorus was dissected using a microhemostat. The distal duodenal end was ligated using preplaced 5-0 sutures to close the transection. The jejunum and its mesentery were transected in a similar manner.

Intermittent full-thickness anastomoses were created using 6-0 minimally invasive sutures (Warwick Medical Supplies Co., Ltd. Hangzhou China), with care taken to avoid intestinal distortion. The first stitch of the gastro-jejunal anastomosis was made at the mesenteric margin using varus sutures, with 2-3 cm suture tails retained for marking and traction. The second and third stitches were placed to connect the midpoint of the posterior wall and the contramesenteric margin. The first part of duodenum was reversed, using notched forceps, to expose the posterior wall of the anastomosis, which was anastomosed at a stitch interval of 0.5 mm and a margin interval of 1.0 mm. The anterior wall was anastomosed similarly. The jejunojejunal anastomosis was completed in the reverse sequence.

Closure of the mesenteric hole was achieved using end-to-end stitches in the avascular mesentery, with care taken to avoid ligating vessel arches and thereby compromising the anastomotic blood supply. The surgical field was intermittently rinsed with warm saline to compensate for any fluid loss from the laparotomy, as well as to prevent drying damage to the exposed portion of the intestines. Before closing the abdomen, the blood supply of each anastomosis was routinely inspected, and the intestinal loops were appropriately sequenced. The abdominal incision was closed with full-thickness stitches using 2-0 minimally invasive sutures (Yangzhou Huaxia Medical Devices CO., Ltd. Yangzhou, China). Throughout the procedure, the ambient temperature was maintained at 25 ℃, using an electric blanket if necessary, to keep the rat body surface dry and prevent intraoperative hypothermia.

Postoperative care

Several modifications were made to the standard regimen of postoperative care for DJB in rats[11,12]. First, only half the volume of fluid normally given by infusion was administered on the day of surgery, and it was augmented with insulin-free 5% glucose (12 mL/kg) (Table 1, Formula 2). Routine fluid infusion (50 mL/kg per day) was given on the following day (Table 1, Formula 1). Enteral nutrition using Nutrison® [Nutricia Pharmaceutical (Wuxi) Co., Ltd., Wuxi, China], was begun 48 h postop-

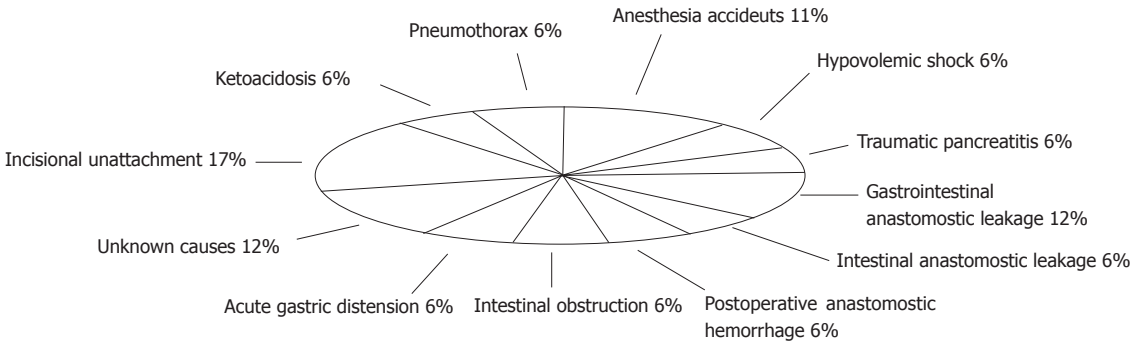

Figure 2 Causes of mortality in the conventional duodenal-jejunal bypass group.

eratively, when the majority of rats had resumed bowel movements.

Statistical analysis

All qualitative data were expressed as percent. Fisher's exact probability test was used to compare the difference in survival rate between rats in the conventional and modified DJB groups. All quantitative data were expressed as mean ± SD. Intragroup PGL values were compared using the paired Student's *t* test, while operative duration and mean PGL were compared between the 2 groups using the independent two-sample Student's *t* test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Procedural success rate and operative duration

The preliminary study allowed us to become familiar with the anatomical structures involved in the procedure and to become proficient in performing the required microsurgical anastomoses. In the conventional DJB group [mean operative duration time (OT) 110.02 ± 12.34 min], 13 rats survived, representing a success rate of 43.3% (13/30). Judging from the histopathological sequelae, the causes of mortality in this group potentially included anesthetic accidents (n = 2, 11%), hypovolemic shock (n = 1, 6%), pneumothorax (n = 1, 6%), traumatic pancreatitis (n = 1, 6%), ketoacidosis (n = 1, 6%), postoperative anastomotic hemorrhage (n = 1, 6%), acute gastric distension (n = 1, 6%), gastrointestinal anastomotic leakage (n = 2, 12%), intestinal anastomotic leakage (n = 1, 6%), intestinal obstruction (n = 1, 6%), and incisional unattachment (n = 3, 17%). Two rats died of unknown causes within 24 h of surgery (Figure 2). In the modified DJB group, the mean OT was reduced to 78.39 ± 7.26 min (P < 0.01). Of the 20 rats in this group, only 2 died, due to anastomotic leakage or intestinal obstruction. The success rate in the modified DJB group (18/20, 90.0%) was significantly higher than that in the conventional DJB group (P < 0.01).

Mean PGL

In the conventional DJB group, the preoperative and 4-wk-postoperative mean PGL levels were 16.69 ± 1.69 mmol/L and 7.46 ± 0.49 mmol/L (P < 0.01), respectively, while the corresponding values in the modified DJB group were 17.02 ± 1.51 mmol/L and 7.23 ± 0.39 mmol/L (P < 0.01). There was no significant difference in mean postoperative PGL between the 2 groups (P > 0.05). However, 4 wk after the operation, the levels of PGL in conventional or modified DJB groups were significantly decreased compared with the preoperative preoperative (P < 0.01).

DISCUSSION

Obese patients with T2DM have been reported to show an improvement in diabetic symptoms after being treated for obesity with DJB. Although the DJB animal model offers a first step toward understanding the mechanism of this phenomenon, it is technically challenging and associated with high procedure-related mortality. In the current study, we modified a number of technical details of both the procedure and the postoperative care regimen that resulted in a reduced operative duration, while yielding a higher success rate, with postoperative PGL levels comparable to those obtained with the standard procedure.

Anesthetic management is an important consideration when performing animal surgery. The anesthetic pelltobarbitalum natricum has potent effects in suppressing breathing and cardiac function. Unfortunately, its pharmacological effects vary greatly from rat to rat, giving it a very narrow safety range. Rats anesthetized with this drug most often die as a consequence of excessive airway secretion. For this reason, we chose to use a combined general anesthetic protocol, beginning with a low-dose of pelltobarbitalum natricum and then controlling the depth and duration of anesthesia using intermittent administration of inhaled ether[13]. Airway management relied on both premedication with atropine, to inhibit airway secretion, and the intraoperative suction of sputum to maintain airway patency.

The success rate in DJB is critically dependent on choosing the correct site of transection and anastomosis. In the modified DJB procedure, the first part of the

duodenum was transected 2-3 mm distal to the pylorus, and the two sides of the prospective gastrojejunostomy were matched in both diameter and layer in order to simplify the anastomotic manipulation and prevent anastomotic stricture. We took care in a number of areas when choosing the jejunal transection site. First, a well-vascularized jejunal loop was transected midway between two main branches of the mesenteric vessel arches, and when necessary, intestinal canals were stitched to reach the major branches of mesenteric vessel arches to ensure that the anastomoses were sufficiently perfused and thus protected from anastomotic leakage or stenosis. In addition, the transected jejunal loop was exteriorized to decrease intestinal tension and allow us to better identify segments that were matched in diameter. The site of anastomosis was chosen based on the mobility of the associated jejunal mesentery, so as to minimize the tension these structures might exert on the subsequent gastrojejunostomy. Although a continuous stitch would have reduced the operative duration, it was also judged likely to increase the risk of postoperative hemorrhage and stenosis at the anastomosis. Supporting this, in the conventional DJB group, hemorrhage from the continuously stitched anastomoses was responsible for one case of postoperative mortality, while intermittent full-thickness sutures had no such sequelae.

We used a number of minimally invasive techniques in an effort to reduce complications from hemorrhage, surgical damage, and infection. First, the anterior pyloric vessels were pre-ligated to provide active hemostasis. Careful identification of anatomical structures and dissection along surgical planes also contributed to preventing excessive hemorrhage and secondary injury[14]. As a relatively constant anatomical marker, Treitz's ligament was carefully identified, to minimize the surgical invasiveness on the intestines. Simple closure of the distal duodenal end with 5-0 ligature significantly decreased the volume of blood lost, and also reduced operative duration without risking duodenal leakage. To reduce the risk of postoperative traumatic pancreatitis, we took care to avoid contact with the pancreas. For the anastomotic reconstruction, the use of 6-0 minimally invasive sutures and notched forceps lessened intestinal contusion, protected the blood supply to the anastomosis, and significantly lessened anastomotic leakage by minimizing mechanical and ischemic injuries. We took particular care to diminish any action, which could contribute to peritoneal contamination.

Damage Control Surgery philosophy is the key to ensure a successful operation[15,16]. Although frequently ignored as a prognostic factor, hypothermia can initiate a lethal triad of complicating factors, as it aggravates metabolic acidosis and compromises coagulation[17,18]. Intraoperative hypothermia can be caused by heat loss from the open peritoneal cavity as well as by anesthesia and fluid infusion[19]. Hypothermic rats are also susceptible to ventricular arrhythmia, infection, and an elevated catabolic rate[20]. Prolonged hypothermia increases the incidence of multiple organ dysfunction syndrome (MODS) and mortality [21]. In the conventional DJB group, the two deaths that occurred within the first postoperative 24 h might have been due to MODS that was itself secondary to hypothermia. Appropriate damage control techniques in the context of the animal duodenal-jejunal model include reducing both the overall procedure time and the period in which the peritoneal cavity lies open, as well as ensuring postoperative active heat preservation. In this study, the techniques used to shorten the OT included the rapid and accurate identification of Treitz's ligament, hemorrhage control by careful dissection along anatomical planes, simple closure of the distal duodenal end, and interrupted closure of the abdominal incision in full-thickness.

Fast-track techniques were used in our modified DJB. Preoperative oral administration of glucose-saline solution to fasted rats prevents hypoglycemia and attenuates postoperative insulin resistance[22,23]. Postoperative stress can be addressed by permissive underfeeding of enteral nutrition, with the low-calorie supply best given in the short term to better meet metabolic requirements and optimize blood glucose[11,24]. Stress hyperglycemia on the operative day should be prevented by strict restriction of glucose intake, with 5% glucose given at a dose of 12 mL/kg to prevent postoperative hypoglycemia. To maintain nitrogen balance in the longer term, the number of calories supplied in enteral nutrition can be progressively increased until a state of balanced enteral nutrition is reached.

Another fast-track surgical measure is the strict restriction of fluid and electrolytes, as overdosing of electrolyte solution will delay the resumption of gastrointestinal activity[25-27]. Marjanovic *et al*[12] reported that restricted rehydration favored the initial healing of intestinal anastomoses, while over-rehydration increased both the severity of peripheral edema and the incidence of complications. In addition to the perioperative use of insulin in T2DM rats, appropriate fluid therapy is also critical to prevent acute metabolic disturbance such as ketosis. Therefore, we suggested using an individualized regimen of goal-directed volume therapy (GDT) to appropriately restrict rehydration[28]. Our results demonstrated that the composition and volume of the fluid infused according to a GDT regimen was able to optimally balance input and output and to effectively decrease the incidence of acute metabolic disturbance. Additionally, in the case of ketoacidosis and hyperosmotic dehydration, adequate rehydration should be given along with insulin, and the animal should be closely monitored.

In conclusion, we successfully established a sound duodenal-jejunal bypass model in diabetic rats that is based on minimally invasive techniques and fast-track surgical management. Our findings suggest that duodenal-jejunal bypass is a potential treatment alternative for diabetic patients who are especially unresponsive to other modalities of medical intervention, provided

that surgical invasiveness is similarly minimized and the principles of fast-track and damage control surgery are observed.

COMMENTS

Background

When gastric bypass is used to treat morbid obesity in patients with concomitant type 2 diabetes mellitus (T2DM), some of these patients have seen their diabetes resolve even before they have lost weight. Available data suggest that reduced caloric intake alone is not sufficient to explain the observed short-term metabolic and endocrine effects. Recently, Rubino *et al* demonstrated that a duodenal-jejunal bypass (DJB) procedure that preserved gastric volume could directly benefit T2DM patients, suggesting that duodenal-jejunal exclusion, rather than the restriction or reduction of gastric volume, is the critical factor in surgical treatment of T2DM. Therefore, as a first step, the authors chose to apply an existing rat model for DJB in animals rendered diabetic by administration of streptozotocin. In such a model, a range of surgical, perioperative, and other factors would be expected to influence the effect of bypass surgery on diabetes. However, there is little data regarding the influence of particular surgical modalities or non-surgical aspects of care on diabetic rats.

Research frontiers

Obese patients with type 2 diabetes mellitus have been reported to show an improvement in diabetic symptoms after being treated for obesity with DJB. Although the DJB animal model offers a first step toward understanding the mechanism of this phenomenon, it is technically challenging and associated with high procedure-related mortality. In the current study, the authors carefully compared a number of both surgical techniques and perioperative management regimens for their ability to improve the success rate in diabetic rats underlying DJB, including minimally invasive procedural designs and the use of damage control and fast-track surgical modalities.

Innovations and breakthroughs

In the current study, the authors modified a number of technical details of both the procedure and the postoperative care regimen (including anesthetic management, the correct site of transection and anastomosis, a number of minimally invasive techniques, hypothermia and fast-track techniques) yielding a higher success rate, and reduced fasting blood glucose levels in diabetic rats. The authors successfully establish a sound duodenal-jejunal bypass model in diabetic rats that is based on minimally invasive techniques and fast-track surgical management.

Applications

In this study the authors successfully establish a sound duodenal-jejunal bypass model in diabetic rats. The findings suggest that duodenal-jejunal bypass is a potential treatment alternative for diabetic patients who are especially unresponsive to other modalities of medical intervention, provided that surgical invasiveness is similarly minimized and the principles of fast-track and damage control surgery are observed.

Terminology

DJB, the operation consists of a stomach-preserving bypass of a short segment of proximal small intestine. DJB may be associated with a sleeve resection of the stomach to reduce potential for marginal ulcerations and increase the weight loss effect if performed in mildly or severely obese patients. Fast-track surgery, a new method of application of preexisting procedures in pre-intra and post surgical phase pre-written and carried out in a multi-disciplinary way in order to obtain a rapid recovery after operation.

Peer review

It is a very well conducted animal model study. The results are interesting and very useful for the study of this subject. Morbidly obese patients undergoing gastric by-pass is lost in T2DM can be more easily treated. In this respect, it is an important study.

Abstract

Crohn's disease is a chronic inflammatory disorder of the gastrointestinal tract that is defined by relapsing and remitting episodes. Tumor necrosis factor alpha (TNF-α) appears to play a central role in the pathophysiology of the disease. Standard therapies for inflammatory bowel disease fail to induce remission in about 30% of patients. Biological therapies have been associated with an increased incidence of infections, especially infection by *Mycobacterium tuberculosis* (*Mtb*). Thalidomide is an oral immunomodulatory agent with anti-TNF-α properties. Recent studies have suggested that thalidomide is effective in refractory luminal and fistulizing Crohn's disease. Thalidomide costimulates T lymphocytes, with greater effect on CD8+ than on CD4+ T cells, which contributes to the protective immune response to *Mtb* infection. We present a case of Crohn's disease with gastric, ileal, colon and rectum involvement as well as steroid dependency, which progressed with loss of response to infliximab after three years of therapy. The thorax computed tomography scan demonstrated a pulmonary nodule suspected to be *Mtb* infection. The patient was started on thalidomide therapy and exhibited an excellent response.

Key words: Anti-tumor necrosis factor alpha; Crohn's disease; Mucosal healing; *Mycobacterium tuberculosis*; Thalidomide

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract that is defined by relapsing and remitting episodes[1]. The inflammatory process is characterized by increased production of proinflammatory cytokines[2]. Tumor necrosis factor alpha (TNF-α) plays a central role in the pathogenesis of the disease[3].

Over the past few decades, medical therapy for CD has progressed significantly with immunomodulating agents such as azathioprine, 6-mercaptopurine, methotrexate, tacrolimus and cyclosporin, and biological agents such as infliximab, adalimumab and certolizumab[1]. Nevertheless, the use of biological therapies has been associated with an increased incidence of infections, especially

infection by *Mycobacterium tuberculosis* (*Mtb*)[4].

Thalidomide is an oral immunomodulatory agent with anti-TNF-α properties[5,6]. Thalidomide increases the IFN-γ level and modulates several other cytokines as well, especially interleukin (IL)-2 and IL-12[2]. Recently, an open-label trial assessing the treatment of refractory CD reported response rates of 64% and 70% after a 12-wk course of thalidomide[7,8].

Thalidomide costimulates T lymphocytes, with greater effect on CD8+ than on CD4+ T cells, which contributes to the protective immune response to *Mtb* infection[9,10]. Results from four case reports, one clinical trial and one placebo-controlled trial suggest the use of thalidomide for central nervous system tuberculosis (TB) not responding to standard therapy is beneficial. Thalidomide should not be used for routine treatment, but it may be useful as a "salvage therapy" in patients with tuberculosis meningitides and tuberculomas that are not responding to anti-TB drugs or to high-dose corticosteroids[11].

We present the case of a 24-year-old CD patient, with gastric, ileal, colon and rectum involvement, as well as steroid dependency, which progressed with diminished response to infliximab after three years of therapy. A thoracic computed tomography scan revealed a pulmonary nodule suspected to be *Mtb* infection. He was started on thalidomide therapy and exhibited an excellent response.

CASE REPORT

A 24-year-old male was first diagnosed with CD at the age of 10 when he presented fever, arthralgia of large joints (knees and ankles), bloody diarrhea (more than 10 bowel movements/d) and a Harvey-Bradshaw Index of 13. Endoscopy showed involvement of gastric corpus, ileum and all segments of the colon and rectum.

Initially, he was prescribed 1 mg/kg per day steroid, 100 mg/d azathioprine and 2.5 g/d sulfasalazine by a pediatric gastroenterologist. After eight years, he presented signs of active inflammatory bowel disease, with imaging revealing CD activity in gastric tissue, ileal tissue, and all segments of the colon and rectum (Harvey-Bradshaw Index 15). He was started on therapy with infliximab 5 mg/kg and continued on 100 mg/d azathioprine. After 2 mo, the patient presented significant clinical improvement with reduced stool frequency of 3 bowel movements/d and remission of joint inflammation. Endoscopic evaluation showed reduction of inflammatory disease activity in all segments of the colon and rectum, as well as healing of gastric lesions. The Harvey-Bradshaw Index was 4 after infliximab treatment.

Six months after the first dose of infliximab, the patient relapsed with bloody diarrhea in 6-8 bowel movements/d and a Harvey-Bradshaw Index of 12. The infliximab dose was increased to 10 mg/kg, which controlled the disease activity and led to a Harvey-Bradshaw index of 2. After 3 years, the patient presented with worsening of disease. Imaging studies revealed inflammatory activity in the gastric body, sigmoid and descending colon (Figure 1A). Infliximab was discontinued, and the azathioprine dose was increased to 150 mg/d in combination with mesalazine 1.2 g/d. We opted not to introduce adalimumab due to the presence of a cavitary pulmonary nodule in the left upper lobe measuring 0.6 × 0.8 cm^2 (Figure 2A). At that time, we suspected infectious pneumonia (fungal/mycobacterial), eosinophilic granuloma or vasculitis. As the lung nodule was not accessible to percutaneous or bronchoscopy biopsy, we opted for a conservative approach. Because we did not have a definitive diagnosis of pulmonary disease and because the patient presented with all the symptoms of inflammatory bowel disease, including diarrhea, abdominal pain, weight loss, arthralgia and a Harvey-Bradshaw Index of 15, we opted to introduce thalidomide.

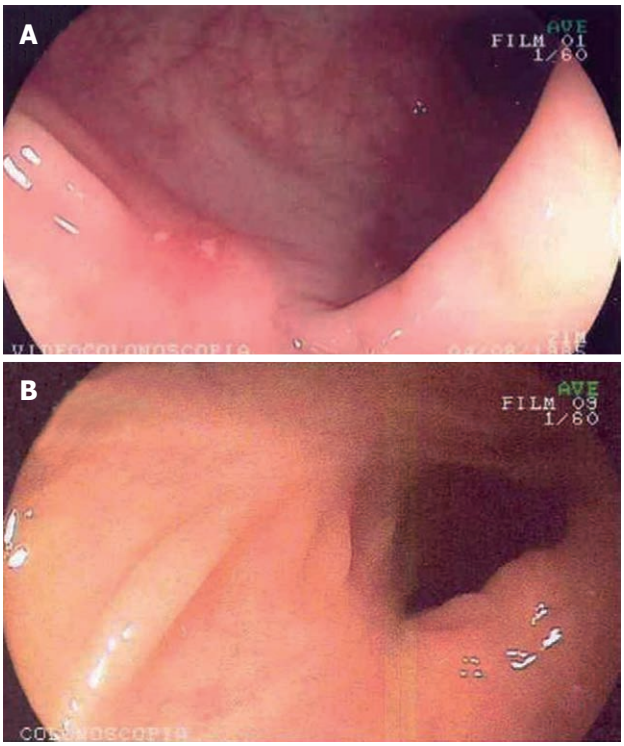

Figure 1 Colonoscopy. A: Colon showing scattered aphthous ulcers, with some confluence; B: Colon showing scar areas.

Thalidomide was started at 100 mg/d, and the patient's symptoms resolved, with initial improvement of abdominal pain and diarrhea between 1 and 4 mo (Harvey-Bradshaw Index 8) and complete remission of symptoms at 6 mo of therapy (Harvey-Bradshaw Index 3). The patient was asymptomatic, presenting 2-3 regular bowel movements/d and pasty stools, without blood or mucus. He denied abdominal pain, nausea and vomiting and complained of neuropathy. His weight increased by 10 kg. Laboratory tests showed normal inflammatory activity (CRP 3; ESR 2). Colonoscopy revealed scar tissue in sigmoid colon, descending, transverse, and ascending colon; and cecum; the ileocecal valve and terminal ileum showed ulceration, with thick fibrin interspersed with normal mucosa (Figure 1B). Control computerized tomography showed small (0.5 cm) calcified pulmonary nodules in the

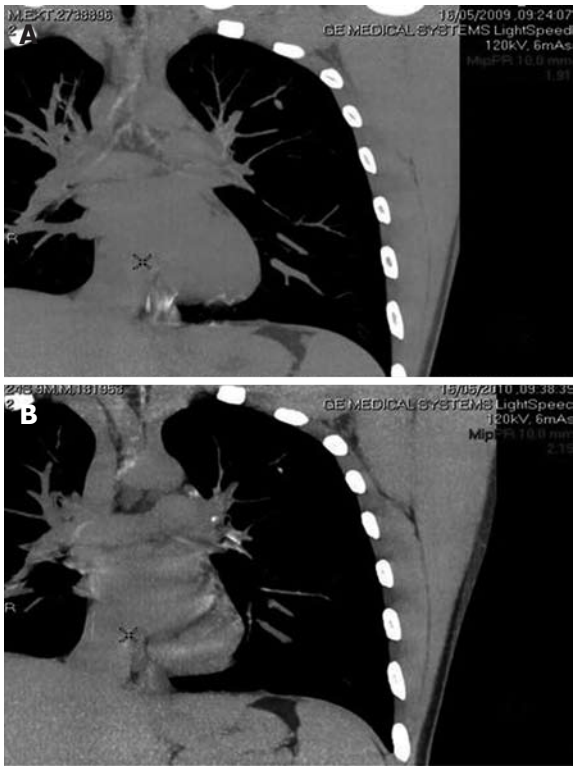

Figure 2 Chest computed tomography. A: Small nodule, measuring 0.8 to 0.6 cm, in the upper lobe of the left lung; B: Small calcified nodule located in the apico-posterior lobe of the left lung, measuring 0.5 cm in diameter.

apico-posterior segment, which were suggestive of primary *Mtb* infection (Figure 2B).

DISCUSSION

Standard therapies for inflammatory bowel disease fail to induce remission in about 30% of patients[12]. Recent studies have suggested that thalidomide at doses varying from 50 to 300 mg/d is effective in refractory luminal and fistulizing CD[10,11]. The response appears to be fairly rapid, and the remission rate is 20%-40% after 12 wk of thalidomide therapy[13].

Considering the present case, a patient with long-standing CD with extensive involvement of the digestive tract who failed to respond to infliximab after 3 years of therapy and had a pulmonary nodule possibly resulting from *Mycobacterium tuberculosis*, it was necessary to offer an effective and safe therapy to avoid infection. New therapies are needed in the context of patients with inflammatory bowel disease and tuberculosis diagnosed or suspected before or after biological treatment. Thalidomide appears to be a good option in this situation, as in selected cases of *Mtb* infection of the central nervous system.

Wettstein and Meagher were the first authors to describe thalidomide therapy in a woman with complicated CD. The patient was treated with all of the current medication at the time, including total parenteral nutrition, metronidazole and cyclosporine, without success. Resolution of the disease was achieved using 300 mg thalidomide per day and maintenance of 100 mg per day until the date of publication of the case[14]. Vasiliauskas *et al*[8] published an open-label trial that evaluated the tolerance and efficacy of low dose thalidomide for the treatment of moderate to severe steroid-dependent CD in 12 males with CDAI $\geqslant$ 250 and $\leqslant$ 500. The patients were treated with thalidomide 50 mg/d during the first 6 mo, increasing to 100 mg/d until the completion of 1 year of treatment. Disease activity (CDAI) improved consistently in all patients during the first 4 wk, with a response rate of 58% and a remission rate of 17%. After 12 mo, 70% of patients had responded, and 20% achieved remission. All patients were able to reduce steroid dosage to less than 50% of the initial dose; 48% of patients discontinued the use of steroids[11]. Our patient also used low doses of thalidomide and is still in remission after 2 years of therapy without adverse events, which demonstrates that low doses of thalidomide appear to be well tolerated and effective over a period exceeding 12 wk.

Ehrenpreis *et al*[7] reported an open-label trial of 22 patients with refractory CD (CDAI > 200 and/or perianal disease) treated with thalidomide 200 mg/d (18 patients) or 300 mg/d (4 patients). Nine patients with luminal disease and 13 with fistulas were included. Sixteen patients completed 4 wk of treatment (12 clinical responses, 4 remissions). Of the patients who completed 12 wk of treatment, 14 met the criteria for clinical response, nine achieved remission. Mean CDAI before and after treatment was 371 (95-468) and 175 (30-468), respectively ($P < 0.001$)[10]. Of note, none of these previous studies described the results of thalidomide usage after a long period of treatment. We describe here the case report of a 24-year-old male maintained on thalidomide therapy for more than 2 years without loss of response.

Bariol *et al*[15] evaluated the safety and efficacy of thalidomide for symptomatic inflammatory bowel disease. Eleven patients (6 with CD, 4 with UC and 1 with indeterminate colitis) were treated with thalidomide 100 mg/d for 12 wk. Two patients were withdrawn from therapy after three weeks because of mood disorders. Of the remaining 9 patients, 8 responded to treatment (5 DC, 2 UC and 1 IC). The frequency of stools fell from 4.3 to 2.3 per day ($P = 0.0012$); stool consistency improved from 2.1 to 1.2 ($P = 0.02$); and mean CDAI decreased from 117 to 48 ($P = 0.0008$). Endoscopic inflammation, histological inflammation, CRP and ESR decreased significantly ($P = 0.011$, $P = 0.03$, $P = 0.023$ and $P = 0.044$, respectively). However, levels of serum TNF-α did not change[15]. Thalidomide acts partly by accelerating the degradation of TNF-α mRNA, resulting in decreased production of this cytokine by activated mononuclear cells. It has also been shown to inhibit NF-κB activation, thus suppressing transcription of other important inflammatory cytokines, such as IL-12 both *in vitro* and *in vivo*[16,17]. Thalidomide increases expression of the Th2-type cytokine IL-4 and decreases the helper to suppress T-cell ratio, effects that are likely to contribute to its efficacy in CD[18]. Furthermore,

it has been shown to interfere with angiogenesis and to downregulate cell adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), thought to be important in lymphocyte homing mechanisms in inflammatory bowel disease[19]. These multiple alternative mechanisms of action may be involved in thalidomide's effectiveness in patients with severe disease refractory to conventional and biological agents, as was the case for the patient presented in this report.

Kane *et al*[20] reported a series of cases where thalidomide was a "salvage" therapy for patients with delayed hypersensitivity to infliximab. Four patients (two with active luminal disease and two with fistulous disease) were treated with thalidomide 200 mg/d and were evaluated monthly for 12 wk. One patient with a single perianal fistula had complete closure, and another had improvement in five perianal fistulas in 4 wk and closure in 12 wk. One patient had a CDAI decrease of 250 points in 4 wk. One patient was withdrawn from the study because of sedation after the first week of treatment. Reported side effects were sedation (4/4), hypertension (1/4) and peripheral neuropathy (1/4)[20]. Due to thalidomide's toxicity it is recommended only in selected cases of refractory CD, as in our patient, when the benefits outweigh the risk of peripheral neuropathy, and there is strict and full adherence to the program of birth control, avoiding the risk of teratogenicity.

To our knowledge, this is the first case report of a patient presenting with a pulmonary nodule that could be *M. tuberculosis* infection who was treated with thalidomide to control severe CD after loss of response to biological therapy, with a favorable evolution. Therefore, thalidomide might be considered a therapeutic option in similar clinical situations.

Abstract

A liver-produced hormone, hepcidin, appears to be the key player in iron metabolism. The overexpression of hepcidin is the underlying cause of anemia of inflammation. The identification of compounds inhibiting hepcidin expression could ameliorate anemia associated with inflammation. In the current study, we have demonstrated for the first time that AG490 significantly abolishes hepcidin expression in mice. Our work represents a novel approach to suppress hepcidin expression for treatment of anemia of inflammation and anemias occurring under other conditions.

Key words: AG490; Hepcidin; Anemia; Inflammation

TO THE EDITOR

Hepcidin, mainly secreted by hepatocytes, is the hormone with a central role in regulating iron homeostasis (reviewed in[1]). Hepcidin suppresses iron absorption from the duodenum and iron egress from macrophages by promoting degradation of ferroportin protein (reviewed in[1]). Thus, the hepcidin-ferroportin interaction controls iron content in serum and iron distribution in tissues, and hepcidin level plays a primary role in regulating this interaction. Hepcidin level is predominantly modulated by erythropoietic activity, iron content, and inflammatory stimuli. Both acute and chronic inflammation states lead to anemia of inflammation (AI), which represents a prevalent type of anemia worldwide (reviewed in[2]). The overexpression of hepcidin is the underlying cause of AI. Therefore, identifying selective compounds inhibiting hepcidin expression could ameliorate anemia of inflammation or anemia associated with other chronic conditions (such as tumors).

A recent study has demonstrated that AG490 compound significantly reduced hepcidin expression *in vitro*[3]. This study provided evidence that AG490 suppressed hepcidin transcription by inhibiting the JAK/STAT signaling pathway in mouse hepatocytes[3]. AG490 is a tyrosine kinase inhibitor which has been extensively used for inhibiting JAK2/STAT3. However, no *in vivo* study has been performed to investigate the inhibitory effect of AG490 on hepcidin production. Here, we are the first to show that AG490 significantly inhibits hepcidin expression in mice.

AG490 (from Calbiochem), freshly prepared in 15% ethanol, was injected intraperitoneally into 6-mo-old female BALB/c mice. For an acute treatment, AG490 was given once (15 mg/kg), and mice were then sacrificed

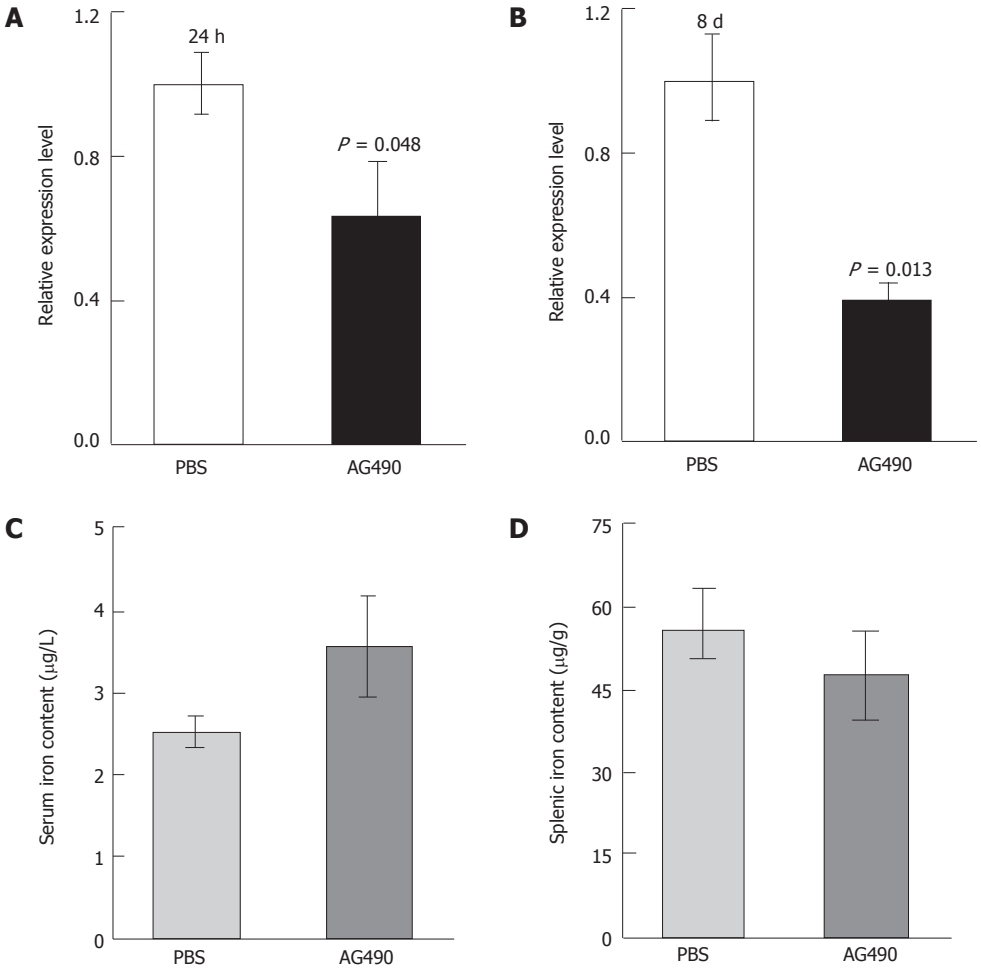

Figure 1 Reduced hepcidin expression upon AG490 treatment. The relative expression level of hepcidin was assessed by quantitative real-time polymerase chain reaction analysis and normalized with β-actin in liver samples from mice treated with AG490 after 24 h (A) and 8 d (B). Hepcidin expression in the phosphate buffer solution (PBS) control mice was defined as 1. Serum and spleen iron content is shown in (C) and (D), respectively, for mice undergoing treatment with AG490 or PBS for 8 d. Results are presented as mean ± SE (n = 9 for A, and n = 3-4 for B, C and D). The SPSS Statistics 17.0 software package was utilized to analyze the data. The difference between two groups was assessed using the independent t test, and $P < 0.05$ was considered statistically significant.

24 h later. For a chronic treatment, AG490 was administered every 4 d for a total of two times at the same dose, and mice were sacrificed on day 8. Control mice received an equal volume of phosphate buffer solution in 15% ethanol. At the end point of the experiments, 50 mg liver and spleen samples from each mouse were collected for tissue iron assay and another batch of 50 mg liver samples were saved for total RNA extraction. A sample of 100 μL serum for each mouse was used for serum iron examination. Iron and hepcidin quantitative real-time polymerase chain reaction assays were carried out as previously described[4,5].

Upon acute and chronic treatment with AG490, we did not observe any abnormality with regard to mouse diet or activities, and no toxicity to various organs was demonstrated through histological examination. After 24 h of treatment with AG490, hepcidin expression from hepatocytes was reduced by 37% compared to control mice ($P < 0.05$, Figure 1A); however, iron content in serum and spleen was not significantly altered (data not shown). Hepcidin expression was further downregulated after two injections over a period of 8 d: the relative expression level in the AG490-treated mice was reduced by 60% compared to control mice ($P < 0.05$, Figure 1B). As a result, serum iron was increased by about 40% in the AG490-treated mice compared to control mice (Figure 1C); there was a corresponding reduction for the splenic iron content in the AG490-treated mice compared to control mice (Figure 1D). These observations together suggested that AG490 efficiently attenuated hepcidin production from the liver to increase intestinal iron absorption and macrophagic iron egress.

Iron acquisition and distribution to tissues in mammals are strictly regulated in order to keep systemic iron homeostasis coordinated[6,7]. Iron level and its homeostasis are closely linked to inflammatory responses. Sequestration of iron presumably limits the uptake of iron by invading microbes and thus enhances resistance to infection; however, infection and inflammation increase hepcidin expression, which consequently leads to AI[8]. Thus, inhibitors such as AG490 might be beneficial to improve anemia caused by inflammation or other chronic diseases by reducing hepatic hepcidin production. Similar to our findings, a recent study indicated that heparin also

has a potent inhibitory effect on hepcidin expression *in vitro* and *in vivo*[9]. Additionally, AG490 or its variants (such as WP1066) have been documented to treat cancers by diminishing active JAK2 signaling[10-12].

To summarize, AG490 represents a prospective approach to attenuate hepcidin-mediated biological actions in order to enhance iron uptake through enterocytes and iron release from macrophages in anemias, and hepcidin repression induced by AG490 *in vivo* reveals a promising and potentially specific therapeutic means to suppress hepcidin expression in AI or other chronic conditions such as cancers.

World J Gastroenterol 2011 December 7; 17(45): I-VI
ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Exciting new features have been described concerning neurogenic bowel dysfunction, including interactions between the central nervous system, the enteric nervous system, axonal injury, neuronal loss, neurotransmission of noxious and non-noxious stimuli, and the fields of gastroenterology and neurology. Patients with spinal cord injury, myelomeningocele, multiple sclerosis and Parkinson's disease present with serious upper and lower bowel dysfunctions characterized by constipation, incontinence, gastrointestinal motor dysfunction and altered visceral sensitivity. Spinal cord injury is associated with severe autonomic dysfunction, and bowel dysfunction is a major physical and psychological burden for these patients. An adult myelomeningocele patient commonly has multiple problems reflecting the multisystemic nature of the disease. Multiple sclerosis is a neurodegenerative disorder in which axonal injury, neuronal loss, and atrophy of the central nervous system can lead to permanent neurological damage and clinical disability. Parkinson's disease is a multisystem disorder involving dopaminergic, noradrenergic, serotoninergic and cholinergic systems, characterized by motor and non-motor symptoms. Parkinson's disease affects several neuronal structures outside the substantia nigra, among which is the enteric nervous system. Recent reports have shown that the lesions in the enteric nervous system occur in very early stages of the disease, even before the involvement of the central nervous system. This has led to the postulation that the enteric nervous system could be critical in the pathophysiology of Parkinson's disease, as it could represent the point of entry for a putative environmental factor to initiate the pathological process. This review covers the data related to the etiology, epidemiology, clinical expression, pathophysiology, genetic aspects, gastrointestinal motor dysfunction, visceral sensitivity, management, prevention and prognosis of neurogenic bowel dysfunction patients with these neurological diseases. Embryological, morphological and experimental studies on animal models and humans are also taken into account.

Key words: Neurogenic bowel dysfunction; Spinal cord injury; Myelomeningocele; Multiple sclerosis; Parkinson's disease; Central nervous system; Enteric nervous system

Awad RA. Neurogenic bowel dysfunction in patients with spinal cord injury, myelomeningocele, multiple sclerosis and Parkinson's disease. *World J Gastroenterol* 2011; 17(46): 5035-5048 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i46/5035.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i46.5035

INTRODUCTION

Exciting new features have been described concerning neurogenic bowel dysfunctions (NBD), including interactions between the central nervous system (CNS), enteric nervous system (ENS), neurotransmission of noxious and non-noxious stimuli, and the fields of gastroenterology and neurology. Patients with spinal cord injury (SCI), myelomeningocele (MMC), multiple sclerosis (MS) and Parkinson's disease (PD) present with autonomic dysreflexia[1], serious upper and lower NBD characterized by constipation[2], incontinence, severe gastrointestinal (GI) motor dysfunction[3] and altered visceral sensitivity[4]. SCI is associated with severe autonomic dysfunction, with bowel dysfunction as a major physical and psychological burden for these patients[5]. The outcome of MMC patients is fraught with multiple problems reflecting the multisystemic nature of the disease[6]. MS is a devastating autoimmune disease[7] with symptoms dependent on the clinical type and the site of lesions[8]. It has been considered a chronic, inflammatory disorder of the central white matter in which demyelination results in the ensuing physical disability. Recently, MS is viewed as a neurodegenerative disorder in which axonal injury, neuronal loss, and atrophy of the CNS can lead to permanent neurological and clinical disability, in which mitochondrial DNA defects are involved[9]. PD is considered as a disorder involving dopaminergic, noradrenergic, serotoninergic, and cholinergic systems, characterized by motor and non-motor symptoms[10]. Interestingly, in recent years it has become evident that PD affects several neuronal structures outside the substantia nigra, between which are the ENS. Recent reports have shown that the lesions in the ENS occur at a very early stage of the disease, even before the involvement of the CNS. This has led to the hypothesis that the ENS could be critical in the pathophysiology of PD, as it could represent a point of entry for a putative environmental factor to initiate the pathological process[11]. This review covers the data related to etiology, epidemiology, clinical aspects, pathophysiology, genetics, gastrointestinal motor dysfunction, visceral sensitivity, management, prevention, and prognosis of NBD patients with these neurological diseases. Embryologic, morphological and experimental studies on animal models and humans are also taken into account.

LITERATURE REVIEW

Search strategy

A Medline search was performed using the following subject headings: spinal cord injury, neural tube defects (NTD), myelomeningocele, multiple sclerosis, Parkinson's disease, animal models, and human. The date of the most recent search was February 28, 2011.

Selection criteria

Clinical, epidemiological, pathophysiological, motor dysfunction, visceral sensitivity and experimental studies on animal models and patients with SCI, MMC, MS, PD, as well as specific therapies for these neurological diseases involving bowel dysfunction were reviewed. Issues related to genetics, embryology, morphology, prevention and prognosis were also taken into account.

Data collection and analysis

A total of 177 articles were included in the analysis.

ETIOLOGY

SCI etiology is generally divided into traumatic and non-traumatic causes[12].

The onset of NTD occurs at 21-28 d of embryonic development[13]. MMC results from lack of closure of the neural tube during this stage[14]. Its etiology is complex, involving both genetic and environmental factors[15]. A maternal effect as well as a gender-influenced effect, have been suggested as part of its etiology[16]. Although there are more than 200 small animal models with NTD, most of them do not replicate the human disease phenotype. The candidate genes studied for risk association with spina bifida include those important in folic acid metabolism, glucose metabolism, retinoid metabolism, apoptosis, and those that regulate transcription in early embryogenesis[17].

MS is an etiologically unknown disease with no cure[7]. It is the leading cause of neurological disability in young adults, affecting over two million people worldwide. MS has been considered a chronic, inflammatory disorder of the CNS white matter in which demyelination results in the ensuing physical disability. Recently, MS has become increasingly viewed as a neurodegenerative disorder in which axonal injury, neuronal loss, and atrophy of the CNS can lead to permanent neurological damage and clinical disability[9].

GI dysmotility in PD has been attributed to the peripheral neurotoxin action[18]. Recently, it has been suggested that sporadic PD has a long prodromal period and several nonmotor features develop during this period. Hawkes *et al*[19] proposed that a neurotropic viral pathogen may enter the brain *via* nasal route with anterograde progression into the temporal lobe or *via* gastric route, secondary to the swallowing of nasal secretions. These might contain the neurotropic pathogen that, after penetration of the epithelial lining, could enter the axons of the Meissner plexus and, through transsynaptic transmission, reach the preganglionic parasympathetic motor neurons of the vagus nerve. This would allow retrograde transport into the medulla and from there into the pons and midbrain until the substantia nigra is reached[19]. A summary of suggested pathogenesis of GI disorders underlying PD is shown in Table 1.

EPIDEMIOLOGY

Traumatic SCI represents a significant public health problem

Table 1 Suggested pathogenesis of gastrointestinal disorders underlying Parkinson's disease

GI pathogenesis	Disorder
Peripheral neurotoxine action	Interstitial cells of Cajal involvement[18]
GI flora? Neurotropic viral pathogen	GI disorders[19]
GI flora? *Helicobacter pylori*	Modified l-dopa pharmacokinetics[102]
GI dysmotility: Early lesions in the enteric nervous system	GI dysfunction[11,163]
GI dysmotility: Disruption in parts of the CNS	Neurogenic dysphagia[54]
GI dysmotility: Lewy bodies in esophageal myenteric plexuses	Manometric abnormalities[97,98]
GI dysmotility: Reduction amplitude of peristaltic contractions	Decreased gastric motility[105]
GI dysmotility: Gastric pacemaker disturbances	Gastric dysrhythmias[106]
GI dysmotility: Loss of enteric dopaminergic neurons	Changes in colon motility[173]
Neurotransmitter dysfunction: Altered enteric nitrergic systems	Disturbed distal gut transit[95]
Neurohormone involvement: Neurotensin	GI disorders[103]
Levodopa	Altered oral phase of deglutition[96]
Monoamine dysfunction	Nonmotor symptoms[176]

GI: Gastrointestinal; CNS: Central nervous system.

worldwide[20]. Each year, 11 000 individuals are estimated to have SCI in the United States[21] with a mortality rate of 27.4 per million people. An annual incidence of 33.6 per million is reported in Greece and 19.5 per million in Sweden[22], while in Denmark the number of SCI patients is about 3000.

NTD is the second most common birth defect, with an incidence of 1/1000. MMC is the most common subtype (66.9%)[16]. NTD is rarely reported in black Americans and Japanese, but is not so rare in Cameroon and sub-Saharan black Africans, with an incidence of 1.9 cases per 1000 births[23]. In Switzerland, the incidence of NTD in children is 0.13 per thousand, corresponding to 9-10 affected newborns each year[15], while in Thailand, the incidence is 0.67 per 1000 births[24]. NTD is reported in adolescents aged 15-18 years[25] and in young adults aged 20-23 years[26].

MS affects young and middle-aged people[27], the mean age at disease onset is 30.7 ± 6.4 years, and it is believed that pregnancy, postpartum status and vaccines[8], as well as infection with Epstein-Barr virus[28], may influence the onset and course of the disease. An increase in females and an almost universal increase in the prevalence and incidence have been reported, challenging the theory of a geographical gradient of incidence in Europe and North America[29]. It affects 100 000 people in the United Kingdom[30], with a prevalence of 30.9/100 000 in Herzegovina[31]. An association between the risk of MS and the season of birth suggested that decreased exposure to the sunshine in the winter leading to low vitamin D levels during pregnancy is an area that needs further research[32].

PD is the second most common neurodegenerative disease after Alzheimer's disease[11], affecting one million people in the United States each year[33], and 20% of the population aged > 65 years in Mexico[34]. It is described in sporadic and familial forms[35] (at least 2 individuals are affected within 2-3 consecutive generations of a family).

DIAGNOSIS, CLINICAL DATA AND SYMPTOMS

Neurophysiologic testing of the sacral reflex is useful in the diagnosis of sacral lower motor neuron lesions, and increased elicitability of the penilo-cavernosus reflex is reported in patients with chronic SCI[36]. Patients with SCI may present[4] with brain anatomical changes of loss of motor control, chronic neuropathic[37] and abdominal pain[38], urinary[39]and sexual dysfunction[40], decubiti[41], neurogenic immune depression syndrome[42], and an increased risk of having a depressive disorder[43]. Spinal cord lesions affect colorectal motility, anorectal sensation, anal sphincter function, and cause neurogenic constipation[44]. Defecation is abnormal in 68% of cases, digital stimulation is required by 20%, suppositories by 10% and enemas by 28% of cases. Time spent in each defecation is more than 30 min in 24% cases. In children aged four years or older, daily fecal incontinence occurred in 14% and weekly incontinence in 14% cases[45]. SCI patients usually do not perceive the normal desire for defecation, rather describing it as abdominal distension, hardened or cool abdomen, hardening of the legs, abdominal pain, chills and dizziness, itching of the head, and a feeling of pain at the sacrum level[4]. Additionally, SCI subjects may develop autonomic dysreflexia in response to noxious stimulus[46]. Cardiovascular dysregulation, characterized by paroxysmal high blood pressure episodes, is the most prominent feature and is precipitated by manual emptying of rectal contents and by gastric and bowel distension[47]. Regarding the gravity of this issue, an NBD score (0-6 very minor, 7-9 minor, 10-13 moderate and 14 severe)[48], an international bowel function basic[49] and extended[50] SCI data set, as well as an international standard to document the remaining autonomic function after SCI[40] have been developed.

Prenatal screening with α-fetoprotein and ultrasonography have allowed the prenatal diagnosis of NTD in current obstetric care[51]. In an animal model with naturally occurring spina bifida (curly tail/loop tail mouse), using standard enzyme linked immunosorbent assay techniques, detection of amniotic fluid levels of the neurofilament heavy chain, glial acidic fibrillary protein and S100B, seems to provide important information for balancing the risks and benefits, both to mother and child, of in utero

surgery for MMC[52]. Colorectal problems are common in children with MMC and their impact on the quality of life becomes more severe as the child grows up.

Diagnosis of MS is made according to the McDonald and the Poser criteria, with the McDonald criteria showing a higher sensitivity for diagnosis[53]. Bowel symptoms are reported to be common in MS, including constipation (29%-43%) and fecal incontinence (over 50%), and 34% of patients spending more than 30 min a day managing their bowel movement[30]. Neurogenic dysphagia is also present[54]. Autonomic dysreflexia may occur in MS[55], characterized by hypertensive attacks, palpitations, difficulty in breathing, headaches and flushing[56]. Autonomic symptoms are disorders of micturition, impotence, sudomotor and GI disturbances, orthostatic intolerance as well as sleep disorders[57]. Neuropsychiatric symptoms include abnormalities in cognition, mood and behavior (major depression, fatigue, bipolar disorder, euphoria, pathological laughing and crying, anxiety, psychosis and personality changes). Major depression is a common neuropsychiatric disorder, with an approximate 50% lifetime prevalence rate[58]. Pediatric MS has been identified as an important childhood acquired neurologic disease[59].

GI diagnosis in PD[60] includes history, clinical examination, barium meal, breath test, stomach scintigraphy and colonic transit time[61]. Oropharyngeal dysphagia is recognized by difficulty in transferring a food bolus from the mouth to the esophagus or by signs and symptoms of aspiration pneumonia or nasal regurgitation[62]. PD is actually considered a neurodegenerative process that affects several neuronal structures outside the substantia nigra. Reports have shown that the lesions in the ENS occurred at a very early stage of the disease, even before CNS involvement[11]. GI symptoms are very important, as GI diseases may also display neurological dysfunction as part of their clinical picture[63]. PD patients have motor and non-motor fluctuations classified into three groups: autonomic, psychiatric, and sensory[64]. GI dysfunction is the most common non-motor symptom which comprises sialorrhea, swallowing disorders[65], dysphagia[66], acid regurgitation, pyrosis[67], early satiety, weight loss, constipation[68], incomplete rectal emptying, the need for assisted defecation and an increased need for oral laxatives[69].

PATHOPHYSIOLOGY

Genetic factors

Data was obtained from 1066 NTD families, 66.9% with MMC, suggesting a maternal effect, as well as a gender-influenced effect in the etiology of NTD[16]. Telomerase, the reverse transcriptase that maintains telomere DNA, is important for neural tube development and bilateral symmetry of the brain. However, it is reported that variants in the telomerase RNA component (TERC) are unlikely to be a major risk factor for the most common form of human NTD, lumbosacral MMC[70].

The association between a polymorphism in the *ABCB1* gene and PD has been observed. The ATP-binding cassette, sub-family B, member 1 (*ABCB1*) gene encoding P-glycoprotein (P-gp), has been implicated in the pathophysiology of PD due to its role in regulating the transport of endogenous molecules and exogenous toxins. ABCB1 polymorphisms thus constitute an example of how genetic predisposition and environmental influences may combine to increase the risk of PD[71]. On the other hand, extensive ENS abnormalities in mice transgenic for PD-associated α-synuclein gene mutations precede CNS changes. Most PD is sporadic and of unknown etiology, but a fraction is familial. Among familial forms of PD, a small portion is caused by missense (A53T, A30P and E46K) and copy number mutations in SNCA, which encodes α-synuclein, a primary protein constituent of Lewy bodies, the pathognomonic protein aggregates found in neurons in PD[72].

Gastrointestinal motor dysfunction and visceral sensitivity

Fecal incontinence in SCI, MMC and MS is mainly due to abnormal rectosigmoid compliance and recto-anal reflexes, loss of recto-anal sensitivity and loss of voluntary control of the external anal sphincter[73]. On the other hand, constipation is probably due to immobilization, abnormal colonic contractility, tone and recto-anal reflexes, or side effects from medication. SCI patients have a higher incidence of esophagitis and esophageal motor abnormalities[74], gastric stasis, paralytic ileus, abdominal distension[75], partial or complete loss of the sensations upon defecation, constipation[75], hemorrhoids[76], and need for assisted digital evacuation than controls[75]. Studies have shown a range of neurological alterations, such as low amplitude, slowly propagating abnormal peristaltic esophageal contraction[74], a decrease in phase Ⅲ of the interdigestive motor complex[77], reduction in gastric emptying[78], delayed GI transit, higher colonic myoelectric activity, reduced emptying of the left colon, and a suboptimal postprandial colonic response[79]. Visceral sensitivity testing according to Wietek *et al*[80] may be a future requirement, in addition to the American Spinal Injury Association (ASIA) criteria, in the assessment of the completeness of cord lesions in patients diagnosed with complete spinal cord transection, as some report the sensation of distension of the rectum. In our laboratory, with barostat methodology, we found that complete supraconal SCI patients preserve rectal sensation, and present with impaired rectal tone and impaired response to food. This data supports the fact that barostat sensitivity studies can complement ASIA criteria to confirm a complete injury. Our results also suggest that intact neural transmission between the spinal cord and higher centers is essential for noxious stimulus, but not for non-noxious stimuli, that patients with supraconal lesions may present PP visceral hypersensitivity, and that incontinence and constipation may not be related solely to continuity of the spinal cord[4,81]. Suttor *et al*[82], using

Table 2 Suggested pathogenesis of gastrointestinal disorders underlying spinal cord injury, myelomeningocele and multiple sclerosis

Disease	GI pathogenesis	Disorder
Spinal cord injury Myelomeningocele Multiple sclerosis	Abnormal rectosigmoid compliance Loss of recto-anal sensitivity Loss of voluntary control of the external anal sphincter	Fecal incontinence[73]
Spinal cord injury Myelomeningocele Multiple sclerosis	Immobilization, abnormal colonic contractility, side effects of medication	Constipation[94]
Multiple sclerosis	Paradoxical puborectalis contraction	Constipation[94]
Multiple sclerosis	Bladder distension	Autonomic dysreflexia[56]
Myelomeningocele	Severe constipation	Ventriculoperitoneal shunt malfunction[87]
Myelomeningocele	Visceral hypersensitivity	Constipation and impaired rectal tone and response to food[88]
Myelomeningocele	Higher spinal level of cord lesion, completeness of cord injury and longer duration of injury	Severe neurogenic bowel dysfunction[20]
Spinal cord injury	Noxious stimulus	Autonomic dysreflexia[46]
Spinal cord injury	Manual emptying of rectal contents and gastric and bowel distension	Cardiovascular dysregulation[47]

a dual barostat in six cervical SCI patients without NBD, reported that intact neural transmission between the spinal cord and higher centres is not essential for normal colorectal motor response from feeding to distension. Lumbosacral neuropathy was demonstrated in 90% of SCI subjects[83] using translumbar and trans-sacral motor-evoked potentials.

In MMC, studies have revealed swallowing disorders characterized by difficulty in bolus formation, nasopharyngeal and gastroesophageal reflux, tracheobronchial aspiration, and vocal cord paralysis[84], as well as a longer mean colonic transit time not related to the level of the spinal lesion[85] and reduction in anal sphincter pressure[86]. Ventriculoperitoneal shunt malfunction may occur in patients with MMC, and severe constipation that increases intra-abdominal pressure resulting in raised intracranial pressure, seems to be one of the causes[87]. Visceral sensitivity studies with the barostat reveal that constipated children with MMC present with impaired rectal tone, impaired response to food and postprandial visceral hypersensitivity[88].

GI dysfunction occurs in MS as in other neurologic diseases[63]. Slow gastric emptying rate[89], increased colonic transit time[90], absent PP colonic motor and myoelectric responses[91], altered maximal contraction pressures and anal inhibitory reflex threshold[92], impaired function of the external anal sphincter, and increased thresholds of conscious rectal sensation[93] have been reported. Paradoxical puborectalis contraction is common in MS patients with constipation[94] and it seems that autonomic dysreflexia occurs due to bladder distension[56]. A summary of suggested pathogenesis of GI disorders underlying spinal cord injury, myelomeningocele, and multiple sclerosis is shown in Table 2.

In PD, dysphagia, impaired gastric emptying and constipation may precede its clinical diagnosis for years[61]. ENS involvement could be critical as it may represent a point of entry for a putative environmental factor to initiate the pathological process[11]. On the other hand, the mechanisms related to enteric autonomic dysfunctions may involve the enteric dopaminergic or nitrergic systems. It has been reported that rats with a unilateral 6-hydroxydopamine lesion of nigrostriatal dopaminergic neurons develop marked inhibition of propulsive activity compared with sham-operated controls. Results suggest that disturbed distal intestinal transit may occur as a consequence of reduced propulsive motility, probably due to an impairment of a nitric oxide-mediated descending inhibition during peristalsis[95]. Neurogenic dysphagia may also appear in PD. It may be caused by a disruption in different parts of the CNS (supranuclear level, level of motor and sensory nuclei taking part in the swallowing process and peripheral nerve level) or a neuromuscular disorder[54]. It is also suggested that levodopa plays a role in the oral phase of deglution in PD[96]. Dysphagia is present in up to 50% of PD cases and seems to be correlated with manometric irregularities[97,98]. Castell *et al*[97] have described esophageal manometric abnormalities in 73% of PD patients characterized by complete aperistalsis or multiple simultaneous contractions (diffuse esophageal spasm) of the distal esophagus. They also reported repetitive proximal esophageal contractions[99], a very interesting finding supporting a previous report of a link between PD, achalasia[100], and scleroderma (e.g., PD and achalasia have Lewy bodies in the esophageal myenteric plexuses and the substantia nigra, as well as evidence of degeneration of the dorsal motor nucleus of the vagus), and esophageal manometric abnormalities were found in these three diseases. A link between PD and *Helicobacter pylori* (*H. pylori*)[101] has also been described, where HP eradication may improve the clinical status of infected patients with PD and motor fluctuations by modifying l-dopa pharmacokinetics[102]. Neurotensin, a 13 amino acid neurohormone located in the synaptic vesicles and released from the neuronal terminals in a calcium-dependent manner, is involved in the pathophysiology of PD and other neurodegenerative conditions[103]. Constipation and gastric atony are important

non-motor symptoms[104]. There is a trend toward a decreased gastric motility in PD patients as compared with healthy controls due mainly to a significant reduction in the amplitude of peristaltic contractions[105]; other authors have found gastric dysrhythmias indicating gastric pacemaker disturbances[106]. Slow transit in the colon has been reported[107], and using ano-rectal manometry, decreased basal anal sphincter pressures, prominent phasic fluctuations on squeeze pressure, and a hyper-contractile external sphincter response to the rectosphincteric reflex have been documented. It has also been suggested that dystonia of the external anal sphincter causes difficult rectal evacuation and the loss of dopaminergic neurons in the ENS may lead to slow-transit constipation[73].

MANAGEMENT

Managing SCI bowel function is complex, time consuming and remains conservative[75]. The use of manual evacuation[108], treatment with oral laxatives[108] and abdominal massage[109] have all been reported. Transanal irrigation is reported safe and can be used in most patients suffering from NBD[110], its results represent a lower total cost than conservative bowel management[111]; however, its rate of success is only 35% after 3 years[110]. Recent approaches include sacral neuromodulation[112] and dorsal penile/clitoral nerve neuromodulation for the treatment of constipation, as well as magnetic stimulation for NBD treatment[113]. Other options include colostomy, ileostomy, malone anterograde continence enema, and sacral anterior root stimulator implantation[114]. However, good quality research data is needed to evaluate the effects of these treatments for this condition.

For MMC patients with constipation, polyethylene glycol[44,115] and the use of transanal irrigation[116] seem to be effective, however, a majority of children found the procedure time consuming and did not help them to achieve independence at the toilet[117]. For incontinence, the approaches included intravesical[118] and transrectal electro-stimulation[119]; nevertheless these procedures lack well-designed controlled trials. For constipation and incontinence, biofeedback is used[120]. Surgical closure of MMC is usually performed in the early postnatal period, however, not all patients benefit from fetal surgery in the same way[121]. The management of cervical MMC is early surgical treatment with microneurosurgical techniques. Surgical excision of the lesions with intradural exploration of the sac to release any potential adhesion bands is safe and effective[122].

The current therapies for MS are few, symptom-related, and experimental[7]. In patients seen due to constipation, incontinence, or a combination of these symptoms a beneficial effect of biofeedback was attributed to some but not to all patients[123]. Other approaches include oral administration of probiotic bacteria, *Lactobacillus casei* and *Bifidobacterium breve*, which do not seem to exacerbate neurological symptoms[124]. An overactive bladder is successfully treated in 51% of cases with anticholinergic medication[125]. The use of agonists or antagonists of prostaglandin-receptors may be considered as a new therapeutic protocol in MS. The reason is that prostaglandins as arachidonic acid-derived autacoids play a role in the modulation of many physiological systems including the CNS, and its production is associated with inflammation, which is a feature in MS[126].

Levodopa, a prodrug of dopamine, is one of the main treatment options in PD[127]. However, in contrast to motor disorders, pelvic autonomic dysfunction is often refractory to levodopa treatment[128]. One point to bear in mind is that treatments should facilitate intestinal absorption of levodopa[128]. Current levodopa products are formulated with aromatic amino acid decarboxylase inhibitors such as carbidopa or benserazide to prevent the metabolism of levodopa in the GI tract and systemic circulation[127]. Food appears to affect the absorption of levodopa, but its effects vary with formulations and studies suggest that a high protein diet may compete with the uptake of levodopa into the brain, thus resulting in reduced levodopa effects[127]. Regarding disturbed motility of the upper GI-tract, hypersalivation is reported to be reduced by anticholinergics or botulinum toxin injections[61] while therapy for dysphagia includes rehabilitative, surgical, and pharmacologic treatments[129]. Regarding constipation, tegaserod improves both bowel movement frequency and stool consistency[130]. Mosapride citrate, a 5-HT4 agonist and partial 5-HT3 antagonist, in contrast to cisapride, does not block K (+) channels or D2 dopaminergic receptors[131]. Other prokinetics agents include metoclopramide, domperidone, trimebutine, cisapride, prucalopride, and itopride[132]. Polyethylene glycol[61], functional magnetic stimulation[133], and psyllium are also used[134]. However, the clinical significance of any of these results is difficult to interpret and it is not possible to draw any recommendation for bowel care from published trials, until well-designed controlled trials with adequate numbers of patients and clinically relevant outcome measures become available[134]. Recently, stem cells have been used as an alternate source of biological material for neural transplantation to treat PD. The potential benefits for this are relief of parkinsonian symptoms and a reduction in the doses of parkinsonian drugs employed. However, the potential risks include tumor formation, inappropriate stem cell migration, immune rejection of transplanted stem cells, hemorrhage during neurosurgery and postoperative infection[135].

PREVENTION AND PREDICTORS

An analysis of predictors of severe NBD in SCI shows that those with a cervical injury or a thoracic injury had a higher risk of severe NBD than those with a lumbar spine injury. Also those classified as ASIA a had a 12.8-fold higher risk of severe NBD than persons with ASIA D. Besides, a longer duration of injury (≥ 10 years) was considered as another risk factor of severe NBD. Moderate-to-severe depression was associated with reduced

bowel function. The results showed that a higher spinal level of cord lesion, completeness of cord injury and a longer duration of injury (≥ 10 years) could predict the severity of NBD in patients with SCI[20]. It is reported that clinical variables are not the best predictors of long-term mortality in SCI. Instead, the significant effect of poor social participation and functional limitations seem to persist after adjustment for other variables[136].

Folic acid supplementation reduced the incidence of NTD in several geographical regions. However, the incidence is still high and associated with a serious morbidity[137]. A study done in newborn babies with NTD and their mothers revealed an association between NTD and decreased hair zinc levels, so large population-based studies are recommended to confirm the association between zinc and NTD[138]. The prevalence of scoliosis in patients with MMC has been reported to be as high as 80%-90%. A study aiming to determine clinical and radiographic predictors of scoliosis in patients with MMC reported that the clinical motor level, ambulatory status, and the level of the last intact laminar arch are predictive factors for the development of scoliosis. It is suggested that in patients with MMC, the term scoliosis should be reserved for curves of > 20 degrees, it is also noteworthy that new curves may continue to develop until the age of fifteen years[139]. Other authors attempting to obtain a spine deformity predictor based on a neurological classification performed at five years of age report that group I (L5 or below) is a predictor for the absence of spinal deformity, group Ⅲ (L1-L2) or Ⅳ (T12 and above) is a predictor for spinal deformity and group Ⅳ is a predictor of kyphosis. This data confirms that future spinal disorders are expected in some patients, while no spinal deformity is expected in others[140]. Other reports indicate that the horizontal sacrum is an indicator of the tethered spinal cord in spina bifida aperta and occulta, as signs and symptoms indicative of a tethered spinal cord appear to correspond to increases in the lumbosacral angle[141]. It is also reported that behavior regulation problems in children with MMC are predicted by parent psychological distress, and that more shunt-related surgeries and a history of seizures predict poorer metacognitive abilities[142]. It seems that adults with MMC and shunted hydrocephalus may be at risk for decreased survival[143].

Inadequate serum vitamin D concentrations are associated with complications of some health problems including MS, which support a possible role for vitamin D supplementation as an adjuvant therapy[144]. In addition, it has been suggested that the favorable effect of sunlight ascribed to an increased synthesis of vitamin D may prevent certain autoimmune diseases, particularly MS. For this reason, limited sunbathing should be publically encouraged[145]. It has also been suggested that altering the composition of the gut flora may affect susceptibility to experimental autoimmune encephalomyelitis, an animal model of MS[146]. This data could have significant implications for the prevention and treatment of autoimmune diseases. In relation to this, an interesting new proposal shows that the GI tract is a vulnerable area through which pathogens (such as *H. pylori*) may influence the brain and induce MS, mainly *via* fast axonal transport by the afferent neurons connecting the GI tract to brain[147].

Symptoms such as dysphagia, impaired gastric emptying and constipation may precede the clinical diagnosis of PD by years and, in the future, these symptoms might serve as useful early indicators of the premotor stage[61]. Motor handicaps, such as rigor and action tremor, are independent predictors of solid gastric emptying[148]. It is currently recommended that the approach to PD should include strategies for detecting the disease earlier in its course and, eventually, intervening when the disease is in its nascent stage. The term Parkinson's associated risk syndrome has been coined to describe patients at risk for developing PD. These patients may have genetic risk factors or may have subtle, early non-motor symptoms including abnormalities in olfaction, GI function, cardiac imaging, vision, behavior, and cognition[149].

EMBRYOLOGICAL, MORPHOLOGICAL AND EXPERIMENTAL STUDIES AND ANIMAL MODELS

Embryology and morphology

Considerable insight into both normal neural tube closure and the factors possibly disrupting this process has been reported in recent years, yet, the mechanisms by which NTD arises as well as its embryogenesis remain elusive[150]. Normal brain development throughout childhood and adolescence is characterized by decreased cortical thickness in the frontal regions and region-specific patterns of increased white matter myelination and volume. Subjects with MMC show reduced white matter and increased neocortical thickness in the frontal regions, suggesting that spina bifida may reflect a long-term disruption of brain development that extends far beyond the NTD in the first week of gestation[151]. These variations in the diffusion metrics in MMC children are suggestive of abnormal white matter development and persistent degeneration with advancing age[152].

In rat fetuses with retinoic acid induced MMC, the normal smooth muscle and myenteric plexus development of the rectum and normal innervations of the anal sphincters and pelvic floor suggest that MMC is not associated with a global neuromuscular alteration in development of lower GI structures[153]. Besides, fetal surgery for repair of MMC allows normal development of anal sphincter muscles in sheep. Histopathologically, in the external sphincter muscles, the muscle fibers were dense, while in the internal sphincter muscles, endomysial spaces were small, myofibrils were numerous, and fascicular units were larger than those in unrepaired fetal sheep[154]. Studies in the development of the pelvic floor muscles of murine embryos with anorectal malformations, demonstrate that the embryos show an impaired

anatomic framework of the pelvis possibly caused by neural anomalous development, whereas muscle development proceeded physiologically. These results support the hypothesis that pelvic floor muscles may function in children with anorectal malformations, in whom neural abnormalities such as MMC have been ruled out, if the surgical correction is appropriately completed[155]. A mouse model was reported about the sharing of the same embryogenic pathway in anorectal malformations and anterior sacral MMC formation[156]. Indeed, some of the brain malformations associated with MMC in human patients are also found in the uncorrected fetal lamb model of MMC[157]. The late stage of gestation is important due to the presence of morphological changes. A study of in-utero topographic analysis of astrocytes and neuronal cells in the spinal cord of mutant mice with MMC revealed that at day 16.5 of gestation there is a deterioration of neural tissue in MMC fetuses, mainly in the posterior region, progressing until the end of gestation with a marked loss of neurons in the entire MMC placode. This study delineated the quantitative changes in astrocytes and neurons associated with MMC development during the late stages of gestation[158]. Data supported by other investigators show, in Curly tail/loop tail mouse fetuses, that around birth the unprotected neural tissue is progressively destroyed[159].

Traditionally, PD is attributed to the loss of mesencephalic dopamine-containing neurons; nonetheless, additional nuclei, such as the dorsal motor nucleus of the vagus nerve and specific central noradrenergic nuclei, are now identified as targets of PD[160]. Early in 1988, Wakabayashi[161] described the presence of Lewy bodies in Auerbach's and Meissner's plexuses of the lower esophagus, indicating that these are also involved in PD. Later on, the presence of α-synuclein immunoreactive inclusions in neurons of the submucosal Meissner plexus, whose axons project into the gastric mucosa and terminate in direct proximity to fundic glands, was reported[162]. The authors propose that these elements could provide the first link in an uninterrupted series of susceptible neurons that extend from the enteric tract to the CNS. The existence of such an unbroken neuronal chain lends support to the hypothesis that a putative environmental pathogen capable of passing the gastric epithelial lining might induce α-synuclein misfolding and aggregation in specific cell types of the submucosal plexus and reach the brain *via* a consecutive series of projection neurons. A recent study aimed at characterizing the neurochemical coding of the ENS in the colon of a monkey model of PD, showed that this element induces major changes in the myenteric plexus and to a lesser extent in the submucosal plexus of monkeys. This data reinforces the observation that lesions of the ENS occur in the course of PD and that this might be related to the GI dysfunction observed in this pathology[163].

Experimental approaches and animal models

Animal models used in MMC include an ovine model constituted by fetal lambs[164], fetal sheep[165], a Macaca mulatta model[166], a mice model[158], and a fetal rabbit model[167]. Several experimental approaches have been used. To study the correction of a MMC-like defect in pregnant rabbits, a spinal defect was surgically created in some of their fetuses at 23 d of gestation. The spinal defect was successfully repaired, and the fetal rabbit model was established for the study of intrauterine correction of an MMC-like defect[167]. A new gasless fetoscopic surgery for the correction of a MMC-like defect in fetal sheep served as an alternative to current techniques used for fetal endoscopic surgery[165]. A Macaca mulatta model was used for replicating MMC and to evaluate options for prenatal management, such as the collocation of an impermeable silicone mesh which protects the spine from amniotic liquid with results similar to skin closure[166]. In-utero analyses of astrocytes and neuronal cells in the spinal cord of mutant mice with MMC using the curly tail/loop-tail mice model have been reported. At day 16.5 of gestation, a deterioration of neural tissue in MMC fetuses was observed mainly in the posterior region, progressing until the end of gestation with a marked loss of neurons in the entire MMC placode. These results support the current concept of placode protection through in-utero surgery for fetuses with MMC[158]. Recently, the notion of prenatal neural stem cell delivery to the spinal cord as an adjuvant to fetal repair of spina bifida has been proposed[164].

The main animal model in MS was developed in mice and is called experimental autoimmune encephalomyelitis[7]. In this experimental model, it was reported that gut flora may influence the development of experimental autoimmune encephalomyelitis[146], and that despite reported blood-brain barrier disruption, CNS penetration for small molecule therapeutics does not increase in MS-related animal models[168]. The migratory potential, the differentiation pattern and long-term survival of neural precursor cells in this experimental autoimmune encephalomyelitis mice model were investigated. The results suggest that inflammation triggers migration whereas the anti-inflammatory component is a prerequisite for neural precursor cells to follow glial differentiation into myelinating oligodendrocytes[169]. A new exciting finding with this model is that a novel regulator of leukocyte transmigration into the CNS, denominated extracellular matrix metalloproteinase inducer (EMMPRIN), indeed regulates leukocyte trafficking through increasing matrix metalloproteinase activity. Amelioration of the clinical signs of experimental autoimmune encephalomyelitis by anti-EMMPRIN antibodies was critically dependent on its administration around the period of onset of clinical signs, which is typically associated with significant influx of leukocytes into the CNS. These results identify EMMPRIN as a novel therapeutic target in MS[170].

Several experimental approaches in PD deal with GI issues using diverse animal models as rats, mice and primates. The advent of transgenic technologies has contributed to the development of several new mouse models, many of which recapitulate some aspects of the

disease; however, no model has been demonstrated to faithfully reproduce the full constellation of symptoms seen in human PD[171]. As GI dysmotility in PD has been attributed in part to peripheral neurotoxin action, rats with salsolinol induced PD were studied to evaluate its effects on intramuscular interstitial cells of Cajal, duodenal myoelectrical activity and vagal afferent activity. The results suggest a direct effect of salsolinol on both interstitial cells of Cajal and the neuronal pathways for gastro-duodenal reflexes[18]. Delayed gastric emptying and ENS dysfunction in the rotenone model of PD suggested that enteric inhibitory neurons may be particularly vulnerable to the effects of mitochondrial inhibition by Parkinsonian neurotoxins and provide evidence that Parkinsonian GI abnormalities can be modeled in rodents[68]. Studies assessing the responses of myenteric neurons to structural and functional damage by neurotoxins *in vitro* reveal that neural responses to toxic factors are initially unique but then converge into robust axonal regeneration, whereas neurotransmitter release is both vulnerable to damage and slow to recover[172]. The prototypical parkinsonian neurotoxin, MPTP, as a selective dopamine neuron toxin in ENS and used in a mouse model, shows loss of enteric dopaminergic neurons and changes in colon motility[173] and its use in a primate animal model reveals changes in the myenteric plexus and, to a lesser extent, in the submucosal plexus. These models further reinforces the observation that lesions of the ENS occur in the course of PD which might be related to GI dysfunction observed in this pathology[163]. In order to determine the changes in the dopaminergic system in the GI tract, two kinds of rodent models were used. In one, 6-hydroxydopamine was microinjected into the bilateral substantia nigra of a rat. In the other, MPTP was injected intraperitoneally into mice. The results suggest that the different alterations of dopaminergic system observed in the GI tract of the two kinds of PD models might underline differences in GI symptoms in PD patients and might be correlated with the disease severity and disease process[174]. In a similar rat model, it is reported that a unilateral 6-hydroxydopamine lesion of nigrostriatal dopaminergic neurons led to a marked inhibition of propulsive activity compared with sham-operated controls, suggesting that disturbed distal gut transit, reminiscent of constipation in the clinical setting, may occur as a consequence of reduced propulsive motility, likely due to an impairment of nitric oxide-mediated descending inhibition during peristalsis[95]. Observations in Parkinsonian primates showed that when the implanted undifferentiated human neural stem cells survived, they had a functional impact as assessed quantitatively by behavioral improvement in this dopamine-deficit model[175]. Nonmotor symptoms of PD studied in an animal model with reduced monoamine storage capacity suggests that monoamine dysfunction may contribute to many of the nonmotor symptoms of PD, and interventions aimed at restoring monoamine function may be beneficial in treating the disease[176]. In a clinical approach, it was demonstrated that delay in gastric emptying did not differ between untreated, early-stage and treated, advanced-stage PD patients, suggesting that delayed gastric emptying may be a marker of the pre-clinical stage of PD[177].

CONCLUSION

This article reviews the current knowledge in all the fields of the neurological diseases with neurogenic bowel dysfunction, and the common issues in need of clarification. The hope is that with a full perspective of the situation, researchers can generate new ideas that can be useful for prevention, cure, or at least for the mean time, a better quality of life for the patient.

Abstract

Adhesions are the most frequent complication of abdominopelvic surgery, yet the extent of the problem, and its serious consequences, has not been adequately recognized. Adhesions evolved as a life-saving mechanism to limit the spread of intraperitoneal inflammatory conditions. Three different pathophysiological mechanisms can independently trigger adhesion formation. Mesothelial cell injury and loss during operations, tissue hypoxia and inflammation each promotes adhesion formation separately, and potentiate the effect of each other. Studies have repeatedly demonstrated that interruption of a single pathway does not completely prevent adhesion formation. This review summarizes the pathogenesis of adhesion formation and the results of single gene therapy interventions. It explores the promising role of combinatorial gene therapy and vector modifications for the prevention of adhesion formation in order to stimulate new ideas and encourage rapid advancements in this field.

INTRODUCTION

Peritoneal adhesions are abnormal deposits of fibrous tissue that occur in the peritoneal cavity as a result of surgery or peritonitis, or their combination. Adhesions occur in more than 90% of patients following abdominal or pelvic surgery[1-3], and are only moderately reduced after laparoscopic surgical procedures compared to open surgery[4-8]. Adhesion reformation occurs postoperatively in 85% of patients, regardless of whether the adhesiolysis is performed *via* laparotomy or laparoscopy[9].

Intraperitoneal adhesions are a major source of morbidity, being the commonest cause of intestinal obstruction[10,11], secondary female infertility, and ectopic gestation[12,13]. They may also cause chronic abdominal and pelvic pain[14,15]. Small bowel obstruction is the most serious consequence of intra-abdominal adhesions. Retrospective studies have shown that 32%-75% of patients who require abdominal re-operation have adhesion-related intestinal obstruction[16,17].

Adhesions result in a large surgical workload and cost to health care systems. An epidemiological study in the United States showed that 282 000 hospital admissions in 1988 were due to adhesion-related disorders, and the cost

of in-patient adhesiolysis was $1.18 billion[18]. In 1994, 1% of all United States admissions involved adhesiolysis treatment, resulting in $1.33 billion in health care expenditure[19].

Adhesions and their associated complications are of rising medico-legal interest. Physicians worldwide need to be aware of the increasing burden of medico-legal claims arising from the complications of intra-abdominal adhesions. Successful medico-legal claims include cases of bowel perforation after laparoscopic division of adhesions, delays in the diagnosis of adhesion obstruction of the small bowel, infertility as a result of adhesions, and pain[20].

Currently, there is no effective method for preventing adhesion formation or reformation[21]. A better understanding of the pathogenesis of adhesion formation at the cellular and molecular level would undoubtedly help to develop more effective treatment strategies[3].

PATHOGENESIS

Vicious triad of trauma, hypoxia, and inflammation

The peritoneum is lined by mesothelial cells loosely attached to the basement membrane, which can readily be detached by the slightest trauma[22]. After injury to the peritoneum, a local inflammatory reaction causes increased vascular permeability in blood vessels supplying the damaged area, followed by an exudation of serosanguinous fluid rich in fibrin and inflammatory cells, ultimately leading to the formation of a fibrin matrix. Normally, the plasminogen activator activity (PAA), which resides in the mesothelial cells and submesothelial fibroblasts, degrades the fibrinous mass, resulting in healing of peritoneal surfaces (within three to five days) without adhesions. However, if the level of PAA is diminished, the fibrinous mass persists and the underlying fibroblasts migrate into the fibrinous mass. The fibroblasts then deposit extracellular matrix, including collagen and fibronectin, leading to adhesion formation. Over time, the adhesion may provide the framework for vascular ingrowth, during the process of angiogenesis[3,23,24].

The pathogenesis of adhesions involves three important trauma-induced processes (Figure 1): (1) trauma induces inhibition of the fibrinolytic and extracellular matrix (ECM) degradation systems[25,26]; (2) trauma, as well as foreign bodies, incites an inflammatory response with the production of cytokines, mainly transforming growth factor-β (TGF-β1), a key regulator of tissue fibrosis[27-29]; and (3) trauma also induces tissue hypoxia as a result of interruption of the blood supply to mesothelial cells and submesothelial fibroblasts, leading to increased expression of hypoxia inducible factor-1 α (HIF-1α)[30,31] and vascular endothelial growth factor (VEGF), responsible for collagen formation and angiogenesis[32].

MOLECULAR CROSSTALK

Sticky connected pathways

Molecular pathways involved in fibrinolysis inhibition, inflammation, and tissue hypoxia crosstalk and potentiate the effect of each. The principal molecular aberrations included in this crosstalk are the reduction of tissue plasminogen activator (tPA) and upregulation of TGF-β1 and HIF-1α.

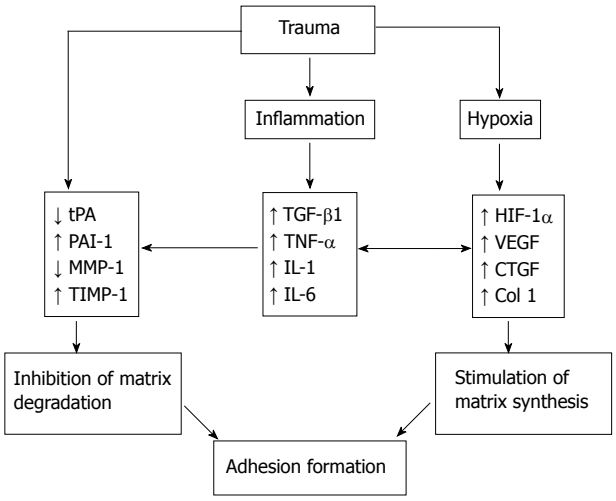

Figure 1 The role of trauma, hypoxia, and inflammation in modulating molecular crosstalk in adhesion formation. tPA: Tissue plasminogen activator; PAI-1: Plasminogen activator inhibitors 1; MMP: Matrix metalloproteinase; TIMP: Tissue inhibitors of MMP; TGF-β1: Transforming growth factor-β; TNF-α: Tumor necrosis factor-α; IL: Interleukin; HIF-1α: Hypoxia inducible factor-1α; VEGF: Vascular endothelial growth factor; CTGF: Connective tissue growth factor.

INHIBITION OF FIBRINOLYSIS AND MATRIX DEGRADATION

The role of fibrinolysis in adhesion formation/reformation is to breakdown the fibrin clots that are formed during the healing process. The inactive proenzyme, plasminogen, is converted to plasmin by the action of tPA. Plasmin degrades fibrin and thus limits adhesion formation. Experimental and clinical studies have identified the presence of PAA in the mesothelium[33,34] and that tPA is the major (95%) physiological mediator of PAA[35,36]. Both mechanical and chemical injury reduce peritoneal PAA, with a progressive reduction in PAA in the first hours following a surgical operation, followed by complete loss of fibrinolytic activity up to 72 h after the operation[37,38]. Laparoscopic surgery also decreases peritoneal tPA[39]. This reduction in PAA is the result of reduced tPA production and increased release of plasminogen activator inhibitors 1 and 2 (PAI-1, PAI-2) by mesothelial, endothelial, and inflammatory cells[3,40]. Extensive human and animal studies confirmed the central role of altered tPA/PAI-1 balance in adhesion formation and demonstrated that this imbalance is more exaggerated in severe adhesions[25,26,34,40].

Plasmin also activates latent matrix metalloproteinases (MMPs) involved in extracellular matrix (ECM) degradation. The proteolytic activity of MMPs is regulated in part by their physiological inhibitors, tissue inhibitors of MMPs (TIMPs). It has been shown that MMPs and TIMPs are ex-

pressed in the human peritoneum, in adhesion fibroblasts, and in serosal layers of several intraperitoneal organs with and without adhesions[3,41,42]. Chegini *et al*[43] demonstrated that serosal tissue of intraperitoneal organs obtained during open surgery expresses more tissue inhibitor metalloproteinase-1 (TIMP-1) than matrix metalloproteinase-1 (MMP-1), and that adhesions express elevated levels of TIMP-1 and a lower ratio of MMP-1 to TIMP-1 compared with intact parietal peritoneum. The association between the imbalance of MMP/TIMP production and adhesion formation has been confirmed in another study in women undergoing laparoscopy[29].

INFLAMMATION AND THE ROLE OF TRANSFORMING GROWTH FACTOR-β-1

Several studies have demonstrated that during the acute phase of the inflammatory response, mesothelial cells and peritoneal macrophages produce a variety of cytokines, including TGF-β1, tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), and IL-6. These pro-inflammatory cytokines, individually and synergistically, stimulate the production of PAI-1 and reduce the synthesis of tPA by human mesothelial cells (Figure 1)[3,44-46]. TGF-β not only interacts with the fibrinolytic system and ECM, but also with many other cellular mediators involved in the process of adhesion formation. TGF-β1 overexpression by the peritoneum, as well as increased concentrations of TGF-β in the peritoneal fluid, has been associated with increased incidence of adhesion formation in both humans and animals[3,27,47,48].

Several studies demonstrated that increased TGF-β1 is associated with a reduction of tPA and an increase of PAI-1 release[27,49,50], an excess of TGF-β1 leads to an increase in the severity of adhesions formed[27,51], whereas an inhibitory antibody to TGF-β1 decreased adhesion formation[52]. TGF-β1 contributes to the synthesis of the ECM by stimulating fibroblastic cell production of collagen and fibronectin[53-55]. TGF-β also antagonizes ECM resorption by decreasing the activity of MMPs through decreasing MMP-1 and increasing TIMP-1 expression from mesothelial cells[3,56,57]. This impairment of MMP activity prevents the ECM deposition that occurs early in wound healing from being adequately remodeled and degraded when necessary, as healing progresses.

THE ROLE OF HYPOXIA IN ADHESION FORMATION

Several lines of evidence have demonstrated that peritoneal tissue hypoxia plays a key role in adhesion formation[58-61]. During laparotomy, tissue injury including trauma, desiccation, and vascular disruption (due to ligatures and other vascular hemostatic methods, including cauterization) reduces oxygen supply to the peritoneum. Laparoscopic surgery was shown to be less adhesiogenic, not only because it is less traumatic, but also due to elevated peritoneal tissue oxygen tension levels compared to those during laparotomy[58]. However, adhesions during laparoscopic surgery increase with duration of pneumoperitoneum and with insufflation pressure. These effects were attributed to desiccation and compression of the capillary flow in the superficial peritoneal layers by the pneumoperitoneum. The addition of oxygen to the insufflation gas decreases adhesion formation[59]. Moreover, supplemental perioperative oxygen was found to increase peritoneal tissue oxygen tension and to reduce the severity of adhesions[61].

Hypoxia negatively modulates all pathways involved in adhesion formation. Hypoxia decreases tPA and increases PAI expression in human peritoneal fibroblasts *in vitro*[62] and in peritoneal tissues *in vivo*[61], thereby decreasing plasmin, inhibiting lysis of fibrin, and increasing adhesion formation. The *PAI-1* gene contains oxygen responsive promoter sequences, namely hypoxia response element (HRE-1 and HRE-2), to which HIF-1α binds and induces gene expression[63]. Hypoxia was found to increase expression of TIMP-1, but not MMP-1, in both peritoneal and adhesion fibroblasts[55], thus decreasing matrix degradation. Hypoxic conditions in cultured human mesothelial cells and peritoneal fibroblasts also increased the expression of TGF-β1[55,64,65]. Hypoxia resulted in increased expression of collagen 1 mRNA in both peritoneal and adhesion fibroblasts[55,66], probably through the production of superoxide[66]. Moreover, hypoxia induces proliferation while inhibiting apoptosis in fibroblasts from adhesion, thus favoring adhesion formation[67]. Finally, hypoxia increases VEGF production through activation of HIF-1α in normal and adhesion fibroblasts *in vitro*[68] and *in vivo* in human adhesion mesothelial cells[69] and in animal adhesion tissues[30,70]. VEGF plays a central role in angiogenesis and its role in adhesion blood vessel development has been established[71]. Furthermore, TGF-β1 stimulates VEGF and connective tissue growth factor (CTGF) expression[72]. CTGF stimulates increased expression of ECM fibronectin, collagen 1, and laminin, while CTGF knockdown inhibits ECM production induced by TGF-β1 in human mesothelial cells[73].

CURRENT PREVENTION THERAPIES

Rules of disengagement

Single therapeutic strategies have failed to completely prevent peritoneal adhesions because of the multifactorial nature of adhesion pathogenesis[74]. As these multifactorial etiologies act independently and synergisctically in adhesion formation, it is imperative to simultaneously address the major molecular aberrations, including reduction of tPA and upregulation of TGF-β1 and HIF-1α, for any therapeutic strategy to be successful. The current preventive approaches of reducing surgical trauma, use of physical barriers or administration of single pharma-

cological agent or gene therapy have all failed to achieve satisfactory results.

Surgical precautions

The general surgical precautions aiming at minimizing surgical trauma include meticulous surgical techniques, delicate purposeful tissue handling, achieving optimal hemostasis, minimizing the risk of infection, and avoiding contaminants (e.g., fecal matter) and the use of foreign materials (e.g., talcum powder) when possible[74,75]. However, these surgical techniques alone are not effective.

Physical barriers

Physical barriers work by separating surgically injured tissues during the initial postoperative time period while remesothelization is occurring, a process that is usually expected to take three to five days[74]. Currently, three barriers, Interceed® (Johnson and Johnson, Gynecare, Somerville, NJ), Seprafilm® (Genzyme, Cambridge, MA), and ADEPT® (Baxter, Deerfield, IL), are approved by the Food and Drug Administration (FDA) for clinical use in the United States[74]. Although barriers have shown some success[74,76], this experience is not universally confirmed[77]. In fact, the FDA warns surgeons that when Interceed is used laparoscopically, patients have more adhesions than patients in the control group[76]. In the United States, ADEPT is only approved for laparoscopic gynecological surgery, and is contraindicated for patients with infection or allergies to cornstarch, as well as procedures involving laparotomy incision, bowel resection, or appendectomy. If used in these contraindicated procedures, patient may experience dehiscence, cutaneous fistula formation, anastomotic failure, ileus, and/or peritonitis. Thus, application and adoption of this product have been very limited[76]. Furthermore, the surgeon must predict the potential sites of adhesion formation in order to determine the placement site and to optimize barrier function[78].

Molecular therapy

A multitude of pharmacological agents, including recombinant proteins and antibodies, have demonstrated moderate success in reducing adhesion formation in different experimental adhesion models. These agents are applied locally into the peritoneal cavity, and work by correcting aberrant molecular pathways operative during adhesion development. One of the most extensively studied pharmacological agents that has demonstrated consistent success is recombinant tPA (reviewed in Ref 92)[79-92]. Experimental studies have reported reduction in adhesion formation and reformation using intraperitoneal recombinant human tPA in a variety of delivery methods and preparations, without impairing the healing of bowel anastomosis and without reduction in wound strength or causing hemorrhagic complications[79,80,92,93]. The action of tPA is localized to fibrin deposits; therefore, fibrinolytic activity is limited to this site, which prevents indiscriminate fibrinolysis[90]. Similar experiences were obtained in studies using neutralizing antibodies for PAI-1[94], TGFβ-1[45,52,95], TNF-α and IL-1[96], IL-6[97], and for VEGF[98,99]. However, these agents have short half-lives (few minutes) limiting their fibrinolytic effect for a sufficient duration of time (three to five days) until complete healing of peritoneal surfaces[92,100].

Gene therapy

Local molecular therapy is inherently limited; therefore, an alternative strategy using gene therapy has been recently employed to correct molecular aberrations induced by surgical trauma in a regulated manner during the period of remesothelialization. Postoperative peritoneal adhesion is an attractive target for gene therapy because of several inherent biological features. The disease is localized to the site of peritoneal trauma and develops over a short period of time, extending for the first few days following surgical trauma. These characteristics lend themselves perfectly to gene therapy using non-integrating vectors. The vector can be applied locally following completion of the operation, and the short duration of gene expression would cover the period of altered molecular aberrations (e.g., depressed tPA, elevated PAI-1, TGF-β1, HIF-1α, *etc.*) following surgery. Nevertheless, gene therapy for peritoneal adhesions is still in its infancy, with very few *in vivo* studies reported in the literature (Table 1).

Using different vectors, the five gene therapy studies reported in the literature were able to express therapeutic nucleic acids (transgenes or small interfering RNA) in the peritoneal tissues after intra-peritoneal administration in a rat adhesion model for at least seven days post-administration[31,101-104]. This duration of expression is enough

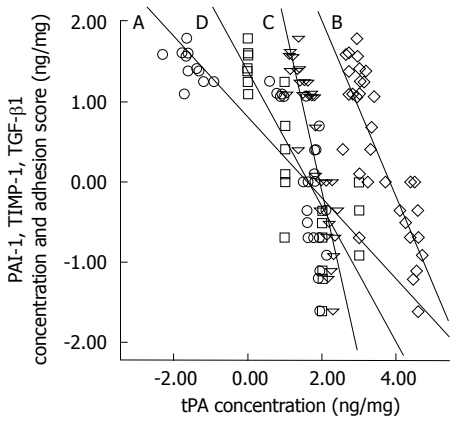

Figure 2 Correlation analysis was performed using two-tailed Spearmen rank correlation test between tPA with respect to PAI-1 (line A, marker ○), TIMP-1 (line B, marker ◇), TGF-β1 (line C, marker ▽) or adhesion score (line D, marker □). Values of tPA, PAI-1, TIMP-1, and TGF-β1 concentration in adhesion tissues were logarithmically transformed to obtain a normal distribution before statistical analysis. There was significant negative correlations ($P < 0.01$) between human tPA and either of PAI-1 (Spearman rank correlation coefficient, $r = -0.89$), TIMP-1 ($r = -0.73$), TGF-β1 ($r = -0.87$), or adhesion score ($r = -0.87$). tPA: Tissue plasminogen activator; PAI-1: Plasminogen activator inhibitors 1; TIMP: Tissue inhibitors of MMP; TGF-β1: Transforming growth factor-β.

to cover the time required for complete healing of the mesothelial cell layer of the peritoneum. The mechanism of adhesion reduction differed among these studies. Two studies showed that an adenovirus encoding the genes of hepatocyte growth factor (HGF) itself or its down-stream signaling molecule sphingosine kinase 1 (SK-1) could achieve adhesion reduction *via* a stimulatory effect on proliferation and migration of mesothelial cells[103,104]. The altered tPA/PAI-1 balance occupies a central role in adhesion formation and two studies tackled this molecular imbalance. Atta *et al*[101] used an adenovirus vector encoding human tPA, while Segura *et al*[31] employed a cationic polymer containing siRNAs to PAI-1 and HIF-1α to downregulate PAI-1, either directly or through its gene inducer, HIF-1α. The expression of TGF-β1 was attenuated by overexpressing its down-stream Smad2/3 natural inhibitor Smad7 using plasmid vector[102].

The moderate success in adhesion reduction in these gene therapy studies supports the concept that the multifactorial nature of molecular aberration during adhesion formation should be collectively and simultaneously addressed for any therapeutic strategy to be effective. This concept does not contradict, but reinforces, the established hypothesis of the central role of tPA reduction following surgical trauma in adhesion formation. In a recent study of adhesion prevention from our laboratory using an adenovirus vector encoding human tPA, we verified that overexpression of human tPA resulted in abrogation of the elevated fibrogenic molecules PAI-1, TIMP-1, and TGF-β1. The study showed that the reduction of these molecules depends on the concentration of the expressed human tPA protein[101]. Further analysis showed that there are significant negative correlations (at 0.01 level, 2-tailed) between human tPA and either of PAI-1 (Spearman's $r = -0.89$), TIMP-1 ($r = -0.73$), TGF-β1 ($r = -0.87$), or adhesion score ($r = -0.87$) (Figure 2).

Prospects

Gene therapy for the prevention of peritoneal adhesions has not been fully explored. Two potential developments for safe and effective gene therapy studies for adhesion prevention include combinatorial gene therapy and vector modifications.

COMBINATORIAL GENE THERAPY

The multifactorial nature of adhesion formation proposes that a combinatorial gene therapy would be more efficacious than a single gene therapy approach. For example, this could include overexpression of the fibrinolytic *tPA* gene together with downregulation of fibrogenic genes, such as TGF-β1 and/or HIF-1α. Overexpression is achieved through delivery of an exogenous gene, while downregulation is accomplished by the delivery of small interfering RNA (siRNA) molecules. Upon delivery, siRNAs complement with specific mRNAs resulting in their degradation, thus enabling the specific silencing of a single gene at the cellular level. As discussed above, single gene overexpression or silencing was moderately successful in reducing experimental adhesions[31,101]. The synergistic effects from the combined fibrinolysis stimulation and fibrogenesis inhibition, however, remain to be confirmed.

SAFE AND EFFICIENT VECTORS

Viral vectors

Delivery of therapeutic nucleic acid molecules to target tissues is accomplished using either viral vectors or non-viral carrier systems. Replication-deficient recombinant adenovirus vectors have become the most widely used viral vectors for *in vivo* gene transfer[101]. Adenovirus vectors have many positive attributes, including their ability to provide efficient *in vivo* gene transfer to both dividing and non-dividing cells, their high *in vivo* stability, and their non integrating nature into the host genome. These merits make adenoviral vectors suitable for proof-of-principle experimental studies. However, the clinical application of virus-mediated gene delivery *in vivo* is hampered by virus-induced acute inflammation, which could be fatal, high immunogenicity, and low tissue specificity. The broad tropism of adenovirus allows the virus to infect many cell types and is responsible for virus dissemination to distant organs. Various modifications of adenoviral vectors are underway to enhance the targeting of adenoviral vectors towards adhesion fibroblasts, which will provide effective and safe methods for localized treatment of postoperative peritoneal adhesions.

Nonviral vectors

Given the unresolved safety limitations of viral vectors, significant research efforts have been directed towards

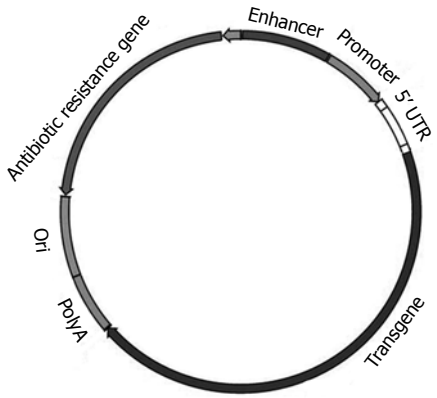

Figure 3 Skeleton of a conventional plasmid. Ori: Origin of replication.

the development of non-viral (plasmid-based) delivery systems. Plasmids are extrachromosomal genetic elements able to replicate autonomously and to be maintained in a host cell. Plasmids, the most basic forms of non-viral gene therapy, carry two main units: a eukaryotic transcription cassette and the bacterial amplification unit (Figure 3). The first bears genetic elements intended for gene expression in mammalian (eukaryotic) cells, such as the enhancer/promoter sequences for gene expression; 5' untranslated region (5' UTR), the gene of interest and polyadenylation (polyA) sequence. The bacterial amplification unit commonly contains an origin for plasmid DNA replication (ori) in bacteria and, generally, an antibiotic resistance selection marker[105]. Plasmids do not enter cells efficiently because of their large size, hydrophilic nature (due to negatively charged phosphate groups), and their susceptibility to nuclease-mediated degradation. Plasmid DNA and siRNA are stable for only 0.5 and 2 h, respectively in human serum[106]. Plasmids can be delivered to cells either naked (carrier-free) by direct injection, electroporation, ultrasound *etc.*, or complexed with cationic lipids (lipoplexes), cationic polymers (polyplexes), peptides or inorganic nanoparticles[107]. Two promising recent modifications of plasmid vectors, minicircles and CpG-depleted vectors, are briefly discussed below. Evaluating the rapid progress in the field of cationic liposomes and polymers is, however, beyond the scope of this brief review, and the reader is referred to excellent recent reviews[107,108].

Minicircle vectors

Limitations of conventional DNA plasmid vectors are related to their size (> 3 kb). Moreover, bacterial sequences contain immunotoxic cytidine-phosphate-guanosine (CpG) dinucleotides motifs, which are approximately four times more prevalent in bacterial than mammalian DNA. Bacterial CpG dinucleotides have been identified to be major contributors to the low and short-lived transgene expression (transgene silencing) in vertebrates after non-viral gene delivery. These bacterial sequences can also interfere with short hairpin RNA (shRNA, precursor of siRNA) expression[106,109]. To overcome these limitations, highly safe and efficient vector systems for gene transfer in eukaryotic cells called minivectors (minicircles) were developed[110]. Minicircles are supercoiled minimal expression cassettes, derived from conventional plasmid DNA by site-specific recombination *in vivo* in Escherichia coli. As a result, two well-defined circular molecules are generated from the parent conventional plasmid, termed minicircle (mammalian expression cassette) and miniplasmid (bacterial backbone elements). Further purification of the minicircle renders it therapeutically applicable[105]. Thus, minicircle DNA lacks the bacterial backbone sequence consisting of an antibiotic resistance gene and an origin of replication. Minicircle DNA is low in immunogenicity due to its lower content of bacterial unmethylated CpG dinucleotides. In addition to their improved safety profile, minicircles have been shown to greatly increase the efficiency of transgene expression in various *in vitro* and *in vivo* studies, compared to the conventional plasmid with the same transgene expression cassette. It has been reported that a minivector incorporating short hairpin RNA efficiently transfected adhesion fibroblasts and was shown to be stable in human serum for > 48 h[107].

CpG-depleted vectors

Bacterial DNA is rich in unmethylated CpG dinucleotides, in contrast to mammalian DNA, which contains a low frequency of CpG dinucleotide, which are mostly methylated. Recognition of unmethylated CpGs present in the bacterial backbone could trigger an innate immune response following detection in the endosome by toll-like receptor 9 (TLR9)[109] and initiate a signaling cascade, leading to the production of proinflammatory cytokines. As plasmids used in *in vivo* gene therapy studies are produced in *Escherichia coli* (*E. coli*), their CpGs are unmethylated and induce immune responses through this host defense mechanism. Recently, plasmids that are completely devoid of CpG dinucleotides have been developed. These plasmids yield high levels of transgene expression both *in vitro* and *in vivo*, and, in contrast to CMV-based plasmids, allow sustained expression *in vivo*[111,112]. In these CpG-free plasmids, all elements required for replication and selection of the plasmid in *E. coli* and for gene expression in mammalian cells (e.g., promoter, polyadenylation signal, reporter gene, *etc.*) either naturally lack CpG dinucleotides, were modified to remove all CpGs, or are entirely synthesized.

CONCLUSION

Gene therapy for the prevention of postoperative peritoneal adhesions is still in its infancy. The potential applications of this strategy have not been fully explored. The recent explosive progress in advanced nonviral gene delivery systems, coupled with the newly developed less immunogenic and more efficient expression plasmids, will undoubtedly accelerate research studies in gene therapy for peritoneal adhesions.

Abstract

The role of whole-body FDG [(^{18}F) 2-fluoro-2-deoxyglucose] positron emission tomography (PET) scanning as an imaging modality in the management of patients with malignancy has evolved enormously over the past two decades. FDG-PET has demonstrated significant efficacy in the staging, prognostication and detection of occult metastatic disease in malignancies of the gastrointestinal tract, in addition to assessment of the response to cytotoxic chemotherapy in a more timely manner than has traditionally been possible by more conventional imaging tools. The sensitivity and specificity of FDG-PET for the detection and staging of malignancy depend not only on the site and size of the primary tumor and metastases, but also on histological cell type, reflecting underlying disparities in glucose metabolism. The metabolic response to neo-adjuvant chemotherapy or to chemo-radiotherapy in cancers of the gastro-esophageal junction or stomach has been demonstrated in several prospective studies to correlate significantly with both the histological tumor response to treatment and with consequent improvements in overall survival. This may offer a future paradigm of personalized treatment based on the PET response to chemotherapy. FDG-PET has been less successful in efforts to screen for and detect recurrent upper gastrointestinal malignancies, and in the detection of low volume metastatic peritoneal disease. Efforts to improve the accuracy of PET include the use of novel radiotracers such as (^{18}F) FLT (3-deoxy-3-fluorothymidine) or ^{11}C-choline, or fusion PET-CT with concurrent high-resolution computed tomography. This review focuses on the role of FDG-PET scanning in staging and response assessment in malignancies of the upper gastrointestinal tract, specifically gastric, esophageal and pancreas carcinoma.

INTRODUCTION

Whole-body positron emission tomography (PET) scanning after the administration of (^{18}F) 2-fluoro-2-deoxyglucose (FDG) has emerged as a promising new imaging modality in the management of patients with malignancy. The role of FDG-PET scanning in upper gastrointestinal (GI) malignancies has evolved tremendously over the past two decades. Like most imaging modalities, FDG-PET initially made its mark in staging for preoperative risk assessment, prognostication, and in evaluation of

distant metastatic disease. FDG-PET scanning has also improved our ability to identify occult metastatic disease in a number of malignancies, including malignancies of the upper GI tract. When considering glucose uptake as a surrogate for metabolic activity, another important application of FDG-PET scanning is therapeutic response assessment. Traditional computed tomography (CT) scanning has been the mainstay for assessment of the effectiveness of cytotoxic therapy in solid tumor oncology; however with the advent of FDG-PET, it has been increasingly apparent that this new modality may also provide an assessment of the therapeutic effectiveness of cytotoxic therapy, and possibly at an earlier time point.

This review focuses on the role of FDG-PET scanning in staging and therapeutic response assessment in malignancies of the upper GI tract, specifically gastric and esophageal carcinoma.

SCIENCE OF FDG-PET AND CHANGES IN FDG UPTAKE

FDG uptake is considered as a surrogate for the metabolic activity of a malignancy, specifically linked to glucose metabolism in malignant cells[1]. The role of FDG-PET imaging, in fact, may be related to the Warburg effect-the observation made by Otto Warburg in 1924 that suggested that cancer cells metabolize glucose differently from normal non-malignant cells[2]. Specifically, cancer cells tend to grow and metabolize nutrients independent of growth factor stimulus, but not in the most efficient manner for ATP generation, but rather in a manner that would support the acquisition of building blocks for continued, uncontrolled cell division and growth[2]. Central to this hypothesis is dysfunction of the phosphoinositide 3-kinase signaling pathway, commonly identified as pathologic in a majority of malignancies, and which is central to both growth control and glucose metabolism. A change in glucose metabolism, as identified by FDG-PET serial imaging, may therefore uniquely predict subsequent cell death[1].

Glucose uptake by malignant cells is largely mediated by the GLUT-1 transporter[3]. In a study of 60 patients with squamous cell carcinoma of the esophagus, Hiyoshi *et al*[4] demonstrated that GLUT-1 expression was correlated with the depth of tumor, lymph node metastasis and pathological stage, in addition to FDG avidity on PET imaging. Mu *et al*[5] correlated the standardized uptake value (SUV) with the expression of GLUT-1 and the Ki-67 proliferative marker, and found that with increasing clinical stage and pathological dedifferentiation, the expression of both markers increased concurrently, indicating an association with tumor aggressiveness. Tohma *et al*[6] demonstrated that FDG uptake may have a more significant association with the intracellular enzyme hexokinase-2 expression than with GLUT-1 expression. In contrast, FDG uptake is not associated with cyclin D1, p53, epidermal growth factor receptor or vascular endothelial growth factor expression in esophageal tumors[7].

ESOPHAGEAL CARCINOMA

Role of PET in staging the depth of disease-esophageal carcinoma

Clinical significance of T stage: Penetration of the primary tumor through successive layers of the walls of the esophagus is described using the T stage of the tumor. Deeper levels of mucosal involvement are associated with a higher risk of nodal and distant metastasis, and diminishing overall survival. The location of the primary tumor within the esophagus has particular relevance to the draining lymph node stations for that area. Nodal metastasis beyond the locoregional nodes may render the patient unresectable as a result. Early cancers (T2 or less) may undergo primary surgical resection. Those tumors with T3 or greater depth of penetration may undergo preoperative chemotherapy or chemoradiotherapy with a view to future resection, or definitive combined modality therapy.

FDG-PET and T stage

In an initial study of FDG-PET in the assessment of esophageal cancer by Flamen *et al*[8], FDG-PET detected 70 out of 74 esophageal lesions. It failed to detect 4 small (< 8 mm) T1 lesions. This study demonstrated no correlation between the SUV and the T stage. A retrospective series from Japan similarly demonstrated superior sensitivity of PET for the detection of T2 or greater disease; 25/25 patients with T2 or greater tumors had FDG uptake, compared to 0/7 with T1 tumors. Significant correlations with increased SUV uptake were seen with both the size of the primary and with the depth of tumor invasion[9].

In a prospective series of 81 patients who underwent surgery with no preoperative treatment, PET detected the primary lesion in 43% of pT1 tumors. Sensitivity was significantly better for pT1b disease at 61%, compared with 18% for pT1a. PET positivity increased with increasing levels of tumor invasion, being 83% at T2, 97% at T3 and 100% at T4[10]. Importantly, in another study examining patients with early stage tumors who underwent primary surgical treatment, PET-CT could not distinguish between those with carcinoma *in situ* (Tis) *vs* those with T1 disease, with FDG uptake in 5/11 (45%) and 26/47 (55%) respectively. The investigators noted a trend towards both increased frequency of FDG uptake and increased SUV with increasing depth of invasion.

It may be concluded from this data that PET, and indeed PET-CT, is an inadequate modality for assessing depth of tumor penetration within the mucosal wall of the esophagus, and also that it cannot distinguish adequately between carcinoma *in situ* and invasive disease. However, with increasing depth of invasion, an FDG-PET scan is increasingly likely to identify the malignancy.

In addition, FDG avidity on FDG-PET scans should be taken in context due to the small but real rate of false positive scans. Specifically, areas of increased FDG uptake within the esophagus may have an alternate cause such as chemotherapy or radiation-induced esophagitis, candida or other benign causes[11-14]. PET lacks the specificity to differentiate between these conditions, under-

scoring the inadequacy of this approach. Due to these factors, endoscopic ultrasound (EUS) is the preferred method for assessment of the depth of invasion of the primary tumor through the wall of the esophagus. This has been demonstrated in a meta-analysis of 49 studies to have a sensitivity of 81%-90% for T staging and a specificity of 99%[15]. EUS is limited by inability to pass through stenotic tumors in these cases, PET or PET-CT based imaging may serve as a useful adjunct.

Role of PET in staging nodal disease-esophageal cancer

Clinical significance of nodal stage: Nodal status in esophageal cancer is determined by the presence or absence of involved locoregional lymph nodes. The regional designation of a lymph node relates to its anatomical relationship to the primary tumor. Tumors of the upper third of the esophagus drain to superior mediastinal and cervical lymph nodes. Tumors of the middle third drain both superiorly and inferiorly to paratracheal, hilar, subcarinal, periesophageal, and pericardial lymph node stations. Tumors of the lower third of the esophagus drain to lymph node basins in the lower mediastinum and celiac areas Patients with non-regional lymph node spread have a worse prognosis than those with locoregional spread only, but better than those with distant metastases.

Initial reports of PET showed promise due to apparent increased sensitivity in the detection of lymph node metastasis when compared to CT[16]. However this may have been due to the use of outdated CT technology and techniques, and this initial promise with respect to increased sensitivity has not been sustained in well designed prospective studies.

In an initial report, Flamen *et al*[8] reported that 74 patients demonstrated a lower sensitivity of PET for the detection of regional lymph node metastasis when compared to EUS (81% *vs* 33%) but with a non-significant trend towards higher specificity (84% *vs* 69%). PET showed a higher specificity than CT and EUS combined when staging both regional and non-regional lymph node metastases for esophageal cancer. In a prospective study of 58 patients comparing CT and PET in the detection of lymph node metastasis within the abdomen by Kneist *et al*[17], the investigators observed a sensitivity of only 24% for PET compared to 73% for CT. Sensitivity of PET was significantly less in the area of the lesser curvature and the celiac trunk. Specificity was 75% and 95%, respectively. Within the thorax, PET demonstrated an improved but still inferior sensitivity (42% *vs* 75%) and again a superior specificity to CT. A prospective evaluation of CT, EUS and PET by Sihvo *et al*[18] demonstrated that EUS had a higher sensitivity for the detection of nodal disease (85%) than CT or PET (42% and 35%). The combination of CT, EUS and PET did not appreciably increase the sensitivity of the assessment. Neither was there any synergy between modalities with respect to specificity. A 2005 study performed by Lowe *et al*[19] comparing CT, PET and EUS for the staging of esophageal cancer showed comparable sensitivities between the three modalities for the detection of nodal disease (82%-86%). Specificity was also not significantly different at 67% for CT and EUS, and 60% for PET.

Progress in the development of both CT and PET imaging may lead to improvements in the diagnostic accuracy of both modalities. A recent study comparing thin slice CT to PET-CT in the detection of subclinical lymph node metastasis in patients with operable squamous cell carcinoma demonstrated the superiority of CT for the detection of disease at all lymph node stations, with the caveat that sensitivity appeared to decrease from the cervical area (100%) to the abdominal area (22%). Specificity was high for both CT and PET in the cervical and abdominal lymph node basins, with superior specificity for PET demonstrated only within the mediastinum[20].

The results of the above studies are described in Table 1. In order to better characterize these heterogenous results, a meta-analysis was performed by van Westreenan *et al*[50]. This included both prospectively and retrospectively obtained data. Pooled sensitivity for the detection of locoregional lymph node metastases was 51% (range, 8%-92%) with pooled specificity of 84% (range, 67%-100%)[21]. The low sensitivity of PET in prospective studies may be due to a selection bias in many cases. These results may be biased by the inclusion only of apparently early stage patients who proceeded immediately to surgery. Those who required preoperative chemotherapy and/or radiation were excluded, leading to an over-representation of solely micrometastatic foci, which are less reliably detected. For reasons of this relatively low sensitivity of PET for locoregional disease, and due to its excellent specificity, FDG-PET is better as an adjunct to conventional

imaging modalities for the detection of lymph node metastases rather than a comprehensive staging investigation in its own right.

Efforts to improve accuracy of PET in the detection of lymph node metastasis

The limited spatial resolution of PET may lead to difficulties due to the fact that uptake within lymph nodes close to the primary tumor may be difficult to distinguish from the tumor itself. Fusion PET-CT and correlation with metabolic and tumor-related parameters may offer superior sensitivity for the detection of nodal disease. A 2009 study by Roedl *et al*[22] compared fusion PET-CT with PET viewed side by side with CT images, in addition to axial tumor area, tumor width diameter and SUV uptake. Fusion PET-CT was more sensitive and more specific for the detection of lymph node metastasis at 70% *vs* 62% and 95% *vs* 91%, respectively. Sensitivity and specificity of 87% and 85% were increased by the addition of tumor diameter measurements. However when qualitative visual analysis was added to quantitative tumor dimension measurement in addition to PET-CT the sensitivity was 96% and the specificity 95%.

Dual time PET may assist in the differentiation between benign and malignant lesions, and may also improve the accuracy of detection of lymph node metastasis in esophageal cancer. Small malignant lesions and malignant lymph nodes show an increase in SUV uptake over time, whereas benign disease does not, and shows an early peak only. An improvement in diagnostic accuracy from 83% to 91% was seen with dual time imaging of squamous cell carcinomas of the thoracic esophagus. In addition, false positive uptake in the lung hilum due to inflammatory processes was distinguished from malignant disease in 19/42 (45%) of patients using this method[23].

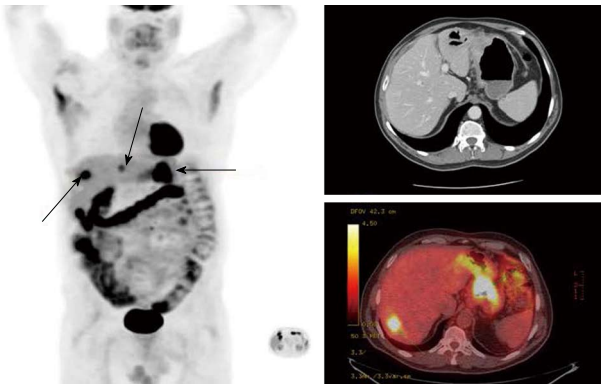

Figure 1 (^{18}F) 2-fluoro-2-deoxyglucose-positron emission tomography/computed tomography image of a patient with a proximal gastric cancer and occult liver metastasis. The liver lesion was not identified on the corresponding staging computed tomography.

DETECTION OF METASTATIC ESOPHAGEAL CANCER USING FDG-PET

PET finds a niche in the detection of metastatic disease, where its performance is superior than in the detection of the depth of the primary lesion or of locoregional lymph node involvement of esophageal carcinoma (Table 2).

An initial prospective study by Luketich *et al*[24] demonstrated a sensitivity of PET for detection of metastatic disease of 69% with a specificity of 93.4% and an overall accuracy of 84%. Following this, Flamen *et al*[8] demonstrated that FDG-PET had a superior accuracy for the detection of metastatic disease compared to combined CT and EUS (82% *vs* 64%), largely driven by the higher sensitivity of PET (74% *vs* 47%). PET correctly upstaged 15% of patients from M0 to M1 disease. The study by Lowe *et al*[19] demonstrated similar sensitivity of PET and CT at 81%, and superior specificity for PET. This may relate to improvements in CT scanning techniques in recent years.

A 2004 study by Heeren *et al*[25] demonstrated that PET upstaged up to 20% of patient to M1 disease. The accuracy of CT was 86% compared to CT/EUS at 69%. All three modalities combined provided an accuracy of 92%. In this study 13% of patients in whom M1 disease was detected on PET were spared an unnecessary surgical procedure, however 87% did require laparoscopy to confirm PET positive findings underscoring the importance of cytological confirmation of metastatic disease. In a combined analysis of 452 patients from 11 studies the pooled sensitivity and specificity for the detection of metastatic disease by PET was 67% (95% confidence interval (CI): 58%-76%) and 97% (90%-100%) respectively. Figures 1 and 2 demonstrate the detection of occult liver (Figure 1) and bone (Figure 2) metastases by FDG-PET/CT not seen on conventional CT imaging.

IS PET PREDICTIVE OF SURVIVAL IN ESOPHAGEAL CANCER?

Many studies have examined the relationship between

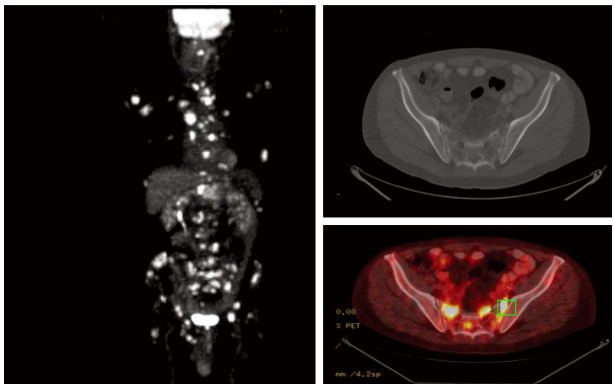

Figure 2 (^{18}F) 2-fluoro-2-deoxyglucose-positron emission tomography/computed tomography detects diffuse bony metastases not seen on staging computed tomography.

SUVmax and survival. In a recent systematic review, all 12 studies selected for inclusion demonstrated that a higher SUVmax of the primary tumor was associated with inferior survival, however only seven of these reached statistical significance. In a meta-analysis of disease-free and overall survival, the hazard ratios for disease recurrence and death were 2.52 and 1.86, respectively, for those with a higher than median SUV[26]. This correlation with peak SUV and survival may hold true even for those with apparently early stage disease[27].

SUVmax is also often significantly correlated with pathological stage, acting as a potential confounder. On multivariate analysis in several smaller studies, peak SUV was significantly associated with survival in univariate but not multivariate analysis, and thus did not emerge as an independent risk factor[28,29]. However in a large retrospective study of 184 patients with operable esophageal cancer, where SUVmax was significantly correlated with the stage of the primary tumor, lymph node status, and presence of metastasis in univariate analysis, on multivariate analysis SUV remained independently and significantly associated with overall survival when correcting for pathological stage of disease. The 5-year overall survival for those with an SUVmax $\geqslant$ 4.5 was 47% compared to 76% in those with an SUV $\leqslant$ 4.5[30]. It should be noted that the majority (91%) of patients in this study had a diagnosis of squamous cell carcinoma, and that these results contrast sharply with those published by Rizk *et al*[31] in a retrospective series of 189 patients with adenocarcinoma of the distal esophagus or gastro-esophageal (GE) junction who underwent chemoradiation as a primary treatment, in which they failed to show any association between survival for those with a high or a low SUVmax. Those with a high SUVmax did however show a superior response to chemoradiation This led the authors to conclude that although high SUVmax was correlated with inferior survival following resection in their earlier study, because high baseline SUVmax was also associated with a superior response to chemoradiation, this acted as an equalizing factor with respect to survival.

Altogether, these data suggest that high SUVmax is most likely to be associated with increased tumor stage and size of lesion. Whether SUVmax is an independent predictor of patient outcome (specifically independent of tumor stage) is not sufficiently validated.

ROLE OF FDG-PET IN RADIOTHERAPY TREATMENT PLANNING FOR ESOPHAGEAL CANCER

The gross tumor volume (GTV) must be accurately delineated in order to successfully treat the area of malignancy. However, conventional CT scanning has a low discriminatory value for this purpose. FDG-PET has been investigated in order to assess whether this improves the accuracy of this delineation. Excellent correlation has been demonstrated between preoperative FDG-PET and EUS measurements of tumor length and measurements of the same resected surgical specimen[32]. The addition of FDG-PET to conventional CT planning may lead to increases or reductions in the GTV of up to 20%, and changes in the planning target volume in over half of patients[33,34]. Modifications of GTV are most often seen in the longitudinal direction[35], however this may also change based on detection of suspicious lymphadenopathy outside the original planned treatment field[36]. Improved accuracy in GTV delineation may lead to changes in radiation dose intensity to critical structures such as the heart and lungs[33,37], whereas utilization of CT alone may lead to undertreatment of FDG-PET avid disease[34]. However, due to a lack of standardization of FDG-PET assessments of GTV and the presence of significant interobserver variation, the use of FDG-PET is not routine in radiotherapy treatment planning, nor has this been validated in terms of improved outcomes such as survival or locoregional tumor control. A prospective trial is ongoing in this regard (NCT01156831)[38].

DOES SUV PREDICT RESPONSE TO CHEMORADIOTHERAPY?

Several studies have examined whether the change in SUV of the primary tumor with chemotherapy or chemoradiotherapy is useful in determining the response to the intervening therapy. A large proportion of studies have been prospective, but were limited in their scope of analysis to some extent by small numbers. Each study evaluated a different treatment regimen. Most studies used pathological response as the gold standard for evaluation of chemotherapy efficacy. This is commonly measured using the Mandard system[39] or a simple modification of this system, where pathological response is classified according to the percentage of viable tumor cells remaining, with non-responders having > 10% tumor cells remaining, partial response 0%-10%, and complete responders 0% viable tumor cells.

A first prospective study in 2001 by Weber *et al*[40] of

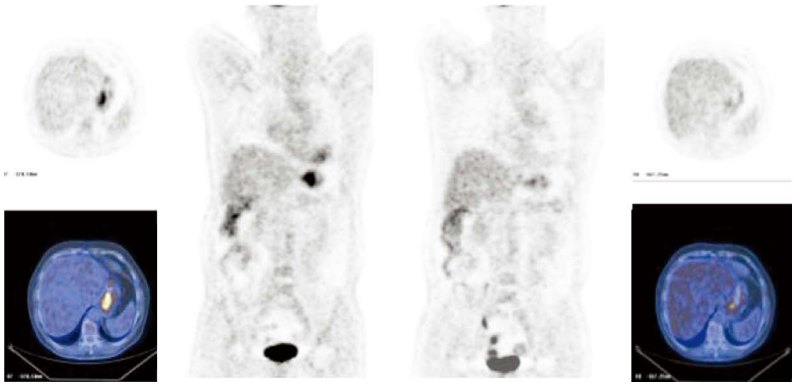

Figure 3 (^{18}F) 2-fluoro-2-deoxyglucose-positron emission tomography response in a patient with a proximal gastric cancer receiving chemotherapy.

40 patients with adenocarcinoma of the GE junction and gastric cardia demonstrated a median reduction in SUV of responders of more than three times that of non-responders and was significantly correlated with pathological response ($P < 0.001$). Response was also significantly associated with survival. Those with no response had a 2-year survival of 37% *vs* 60% in responders. Figure 3 demonstrates a sample FDG-PET/CT response for a patient with a proximal gastric adenocarcinoma.

A prospective trial by Ott *et al*[41] used a predetermined level of reduction in SUV to determine the cut-off point for metabolic responder *vs* non-responder. This had been previously determined to be a reduction of 35% from baseline, which had been demonstrated to have a sensitivity and specificity of 93% and 95%, respectively, for the detection of a pathological response[40]. Sixty five patients with locally advanced GE junction tumors undergoing preoperative chemotherapy were enrolled. Baseline tumor FDG uptake was 8.1 ± 3.4 SUV for assessable patients. SUV uptake significantly decreased to 5.4 ± 2.0 (approximately 33%) in the follow-up scan. Eighteen patients were classified as metabolic responders and 38 as metabolic nonresponders. The pathological response was highly significantly correlated with the metabolic response ($P < 0.001$); 44% of patients with a metabolic response had a pathological response, compared to 5% of metabolic non-responders. Median overall survival for non-responders was 18 mo, significantly shorter than overall survival for the group as a whole at 32 mo. Median survival for metabolic responders had not yet been reached at the time of publication.

A similar study was performed at Memorial Sloan Kettering Cancer Center as a validation study, and reported in abstract form in 2007[42]. In this study, patients with locally advanced but resectable gastric/GE junction adenocarcinoma received preoperative chemotherapy with irinotecan and cisplatin for two cycles. An FDG-PET CT scan was performed at baseline and again at day 15 and day 35. This study confirmed the results initially reported by Weber *et al*, demonstrating that a significant drop in SUV from baseline was associated with the pathologic response to therapy as well as with patient survival[42].

The primary utility of a change in FDG-PET SUV from baseline as a marker for response to chemotherapy and subsequently survival is that this information is available early in the treatment plan, and thus could potentially be used in order to guide future management. This approach was taken by Lordick *et al*[43] in the MUNICON trial. This study recruited 119 patients with locally advanced tumors of the GE junction undergoing preoperative chemotherapy. Patients who did not meet a predefined metabolic response level on FDG-PET of a 35% reduction from baseline SUVmax 2 wk after commencing treatment did not continue with chemotherapy but proceeded directly to surgery. Metabolic responders completed the course of preoperative chemotherapy and then proceeded to surgery; 49% of patients were metabolic responders and 51% were metabolic non-responders. Of the metabolic responders, 58% achieved a major histological response, with 0% in the non-responders. R0 surgical resection was possible in 96% of metabolic responders and in 74% of metabolic non-responders. On pathologic assessment, metabolic responders demonstrated earlier stage tumors than metabolic non-responders. Metabolic non-responders had a median event-free survival of 14.1 mo compared to 29.7 mo in metabolic responders. It was noted that metabolic responders who did not have a pathological response had survival comparable to those who were metabolic non-responders, implying that a metabolic response was necessary but not sufficient for improved survival[43].

In a cross trial comparison between the original study by Ott *et al*, where chemotherapy was continued despite a metabolic non-response, and MUNICON where non-responders proceeded directly to surgery, amongst those patients that went on to complete surgical resection, survival between non-responders in both groups was similar. This suggests that, amongst metabolic non-responding patients, patient survival was unaffected (either adversely or positively) by continuing with ineffective chemotherapy or by stopping ineffective chemotherapy and proceeding early to surgery. These results have led to an ongoing clinical trial in which failure to respond to initial induction chemotherapy with a reduction in SUV on

PET is followed by introduction of a salvage regimen of non-cross resistant chemotherapy in an effort to improve outcome (NCT00737438 on clinicaltrials.gov; Memorial Sloan Kettering study, IRB 08-081).

In contrast, in a study of 32 patients with esophageal/GE junction adenocarcinoma, a FDG-PET scan performed following a week of chemoradiation failed to detect any significant difference between pathologic responders and non-responders with respect to changes of SUVmax on PET[44]. This may in fact be due to the timing of the PET as radiation is known to have a "stunning" effect with respect to FDG uptake, irrespective of further cell kill, which may cause bias in an interpretation performed at an early interval following radiation.

These studies suggest that the utility of FDG-PET in response assessment in esophageal/GE junction adenocarcinoma remains to be verified at this time, but that it is a potentially promising modality to begin "individualized" care for patients with upper GI malignancies (namely esophageal and gastric adenocarcinoma). It should be noted that the response of PET to chemotherapy when compared with that of CT may lead to clinical confusion, such as when a lesion improves by PET criteria, but fails to shrink or may even enlarge slightly by traditional RESIST criteria[45]. Recently proposed guidelines for response assessment in solid tumors suggest that PET progression may be defined as an SUV increase of $\geqslant$ 20% in a region 1 cm or larger in diameter, whereas a response be defined as a decline in SUV of $\geqslant$ 30% in such a region[46]. Such a guideline would seem to be a good starting point for evaluation of the PET response in many solid tumor malignancies, but will need prospective validation.

FDG-PET FOR THE DETECTION OF ESOPHAGEAL CANCER RECURRENCE

The accuracy of CT and magnetic resonance imaging (MRI) for the detection of recurrent disease, particularly within the area of the initial primary tumor may be decreased by post-surgical or post-chemoradiation related changes such as fibrosis, edema, and inflammation. Guo *et al*[47] followed 112 patients with resected squamous cell carcinoma of the esophagus for recurrence with FDG-PET/CT. PET demonstrated excellent sensitivity at local, regional and distant sites of metastases (96.9%, 85.9% and 90.5%, respectively), but lower specificity for local-regional recurrence (50%, 92.2% and 89.9%, respectively). Of note, five out of nine false positive FDG-PET scans were identified in the area of the surgical anastomosis. A French study examined the routine use of FDG-PET in the prospective follow-up of resected esophageal cancer patients[48]. This study demonstrated that for the detection of locoregional recurrence, PET had a higher sensitivity, slightly lower specificity and a superior accuracy than CT (100% *vs* 65%, 85% *vs* 91%% and 91% *vs* 81%, respectively). PET was also superior to CT in the detection of local metastasis. No patient had a negative PET and a recurrence detected by another modality, i.e., there were no false negative PET scans in this study, leading to a 100% negative predictive value. As this recently published study is the first examining the prospective use of PET to detect recurrence in asymptomatic patient, it is too early to comment on whether changes in management based on this strategy will lead to improvements in patient outcomes.

COMPARISON OF FDG-PET AND OTHER PET TRACERS IN THE DIAGNOSIS AND MANAGEMENT OF ESOPHAGEAL CANCER

FDG is not a tumor specific radiotracer, and this leads to the drawback of false positive uptake in areas of inflammation or infection by neutrophils and macrophages, i.e., when there is contamination of the malignancy with other actively dividing or metabolically active cells. An alternative to FDG-PET is (^{18}F) FLT (3-deoxy-3-fluorothymidine) which is trapped intracellularly following phosphorylation by thymidine kinase 1 into (^{18}F) FLT-monophosphate, forming the rationale for the use of FLT as a proliferation tracer[49]. A study by Westreenan *et al*[50] compared the efficacy of FLT *vs* FDG in the detection of esophageal cancer and demonstrated increased uptake for FDG rather than FLT (FLT-PET missed 20% of primary esophageal tumors in this study). FDG-PET also detected a synchronous primary rectal tumor in one patient, which was not detected by FLT-PET. In addition, there was no correlation between uptake of FLT and Ki-67, a marker of proliferation. For this reason, FDG remains the preferred radiotracer for use in the diagnosis and management of patients with esophageal cancer[50].

^{11}C-choline is a small molecule that is integrated into the cell membrane as phosphatidylcholine and serves as a marker of cell membrane metabolism. Because of late urinary excretion, it has been examined in genitourinary tumors such as prostate cancer[51]. ^{11}C-choline has been investigated in two studies of esophageal cancer. Kobori *et al*[52] studied squamous cell carcinoma of the upper esophagus and claimed a superior sensitivity for choline-PET in the detection of primary tumors and nodal metastases in the mediastinum (94% and 88%, respectively). Specificity was not reported. In this study the sensitivity of FDG-PET was 34% and 38% for the primary tumor and nodal involvement, which is somewhat lower than the literature median. These results contrast with those of Jager *et al*[53], who studied a more diverse group of esophageal and GE junction adenocarcinomas in addition to squamous cell carcinoma of the esophagus and GI stromal tumors. They demonstrated the superiority of FDG-PET, with a sensitivity of 100%, 67%, and 100% for the detection of primary tumor, locoregional and lymph node metastases, respectively, compared to 73%, 60%, and 75%, respectively, for choline-PET. Imaging in the abdominal area

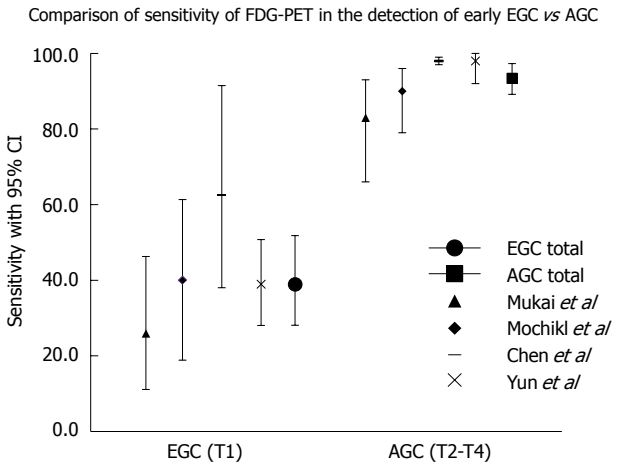

Figure 4 Sensitivity of (^{18}F) 2-fluoro-2-deoxyglucose-positron emission tomography to identify primary early and advanced gastric carcinoma. FDG-PET: (^{18}F) 2-fluoro-2-deoxyglucose-positron emission tomography; EGC: Early gastric cancer; AGC: Advanced gastric cancer; CI: Confidence interval.

using choline-PET is limited by the high background uptake of this agent by the liver.

GASTRIC ADENOCARCINOMA

Gastric cancer remains the most common GI malignancy worldwide, responsible for approximately 934 000 new diagnoses annually (8.6% of new cancer cases) and 700 349 deaths worldwide annually[54]. Gastric cancer may be distinguished anatomically such that proximal tumors (associated with chronic reflux and obesity) have worse prognosis than distal tumors which are more commonly associated with chronic infection by *Helicobacter pylori*[55]. Alternatively, gastric cancer may also be distinguished histopathologically as diffuse, intestinal, or mixed histology which describes the pattern of spread of the primary tumor[56]. Based on these distinctions, an emerging concept in understanding the biology and physiology of gastric cancer is that it likely reflects not one disease, but several[55]. How these distinctions impact on FDG-PET imaging is still evolving.

IMAGING PRIMARY GASTRIC CARCINOMA WITH FDG-PET

Unlike esophageal carcinoma, in which the majority of tumors (particularly T2-T4) are identified on FDG-PET imaging, the primary gastric lesion is less well imaged by FDG-PET. This has been demonstrated in several series with sensitivity for detection of gastric lesions ranging from 21% to 100%[57-65]. Specificity ranged from 78% to 100%. There are several factors that affect the sensitivity and specificity to detect a primary gastric carcinoma. Significantly, there is a variable and occasionally intense uptake of FDG of a physiological nature within the gastric wall[61,63,66]. FDG uptake may also correspond to acute inflammation such as superficial or erosive gastritis[67]. This leads to two disadvantages in the detection of gastric cancer. Firstly, an awareness of this phenomenon must exist in order to avoid a high number of false positive diagnoses. Conversely, over-awareness may lead to failure to detect weakly enhancing and diffuse malignant lesions.

TUMOR SIZE AND DEPTH (T STAGE) AND FDG-PET

Tumor size and T stage may influence the sensitivity of PET imaging in the detection of the primary gastric lesion. In one study, sensitivity was as low as 21% for detecting tumors < 30 mm in size, and increased to 76% for lesions over 30 mm[62]. Gastric cancer limited to the mucosa or submucosa (T1 lesions), are less likely to be detected by PET than more advanced T2-T4 lesions. Sensitivity for detection of early gastric cancers (T1) ranges from 26% to 63%, whereas that for more advanced disease (T2-T4) ranges from 83%-98%[57,61,62,65]. Figure 4 graphically depicts the range of sensitivity in diagnosis of early and advanced gastric cancer.

Histological subtype variants also influence glucose uptake and therefore the ability of PET to detect the primary lesion. The ability of FDG-PET to detect non-intestinal gastric primary tumors can range from 0% for T1 non-intestinal primaries to 77% for advanced non-intestinal disease. For intestinal type tumors, sensitivity ranges from 44% for T1 tumors to 92% for T2 or greater disease[62,63,68]. This may relate to the fact that the GLUT-1 transporter has been shown to be preferentially expressed on the intestinal type gastric carcinoma cell subtype, with decreased expression on mucous-secreting and signet ring type cells[69,70]. GLUT-1 expression has been shown in multivariate analysis to be the most influential factor relating to FDG uptake in gastric carcinoma, although the relationship between histological subtype and SUV uptake and sensitivity of FDG-PET has not been consistent across studies[71,59-61].

TECHNIQUES TO IMPROVE DETECTION OF THE PRIMARY GASTRIC LESION

Simple measures such as distention of the stomach by water or, less commonly, food have been shown to improve the accuracy of detection of gastric lesions both pre-operatively and in the post-operative remnant stomach[72-74]. In an effort to improve detection of gastric cancer by PET, the pyrimidine analog FLT has been used as an alternative radiotracer. One study demonstrated increased sensitivity of FLT-PET for detection of gastric tumors, especially if those tumors which were not FDG avid[58]. This may improve detection of previously difficult-to-detect tumor types such as mucin-producing and signet ring cell tumors. A second smaller study showed comparable efficacy between the two moieties[59]. In both studies, mean SUV uptake was lower for FLT-PET than for FDG-PET. Additional improvements may be made

possible by improving spatial resolution of the imaging equipment[75].

SCREENING FOR GASTRIC CARCINOMA WITH FDG-PET

FDG-PET has not been shown to be an effective screening tool for the diagnosis of gastric cancer. In one study, combined with endoscopy in asymptomatic individuals, PET-CT detected 2/20 cancers from 2861 patients screened giving a sensitivity of only 10% and a positive predictive value of 8.3%; 18/20 cancers were early gastric cancers (T1). There were 22 false positives on this study. There was no significant difference between the SUV values of the false positives and the true positives[76]. A second study of 1336 asymptomatic patients detected two gastric cancers in addition to nine other malignancies. The rate of false positive in this study was three times the rate of true positive findings[77]. Therefore, the screening sensitivity of FDG-PET in an asymptomatic population is less again than that in a diseased population.

FDG-PET AND LYMPH NODE STATUS: GASTRIC ADENOCARCINOMA

Survival in gastric cancer patients decreases with lymph node involvement, and with the number of lymph nodes involved. Knowledge of lymph node status therefore is not only of importance with respect to prognosis, but may also guide surgical treatment planning and which patients may benefit from neoadjuvant chemotherapy.

FDG-PET has been examined both alone, in comparison with CT imaging, and combined as CT-PET, in the preoperative assessment of the nodal status of gastric cancer (see Table 3). The sensitivity of PET is generally low for the detection of lymph node metastases, ranging from 22% to 60% for normal resolution scans[57,60-62,64,65,75,78,79]. It is possible that this may reflect the low spatial resolution of PET at 7 mm-9 mm which leads to difficulty discriminating perigastric lymph nodes from the gastric primary tumor, as sensitivity has been shown to increase to up to 73% with a higher resolution scan[75]. This compares poorly with the sensitivity of CT which ranges from 52% to 77% in the same series. By contrast the specificity of PET is higher than that of CT, ranging from 62%-100%, compared to CT (range, 62%-94%)

The sensitivity and specificity of PET are also influenced by lymph node staging status (i.e., N1, N2, or N3 nodal metastases). In three studies which stratified sensitivity by lymph node status, CT was significantly more sensitive for N1 disease[60,61,65], whereas similar levels of sensitivity and specificity were seen in N3 disease for both imaging modalities; however, this may have reflected the low prevalence of N3 disease in the study groups. Increased SUV of the primary tumor was correlated positively with lymph node metastases in two studies[57,61], possibly indicating increased glucose transport capacity which may in turn correlate with increased aggressiveness of the primary tumor[69].

PERITONEAL DISEASE

A common site of spread for gastric adenocarcinoma is the peritoneum. As many as 25% of patients with locally advanced tumors on EUS will have sub-radiographic occult peritoneal disease that may be identified only at laparoscopy[80]. PET is not a reliable indicator of peritoneal disease, with sensitivity for detection of peritoneal carcinomatosis of between 9% and 30% with normal resolution scans, and increased to 50% sensitivity with the use of a higher resolution 3.9 mm slice. This compares unfavorably with CT which demonstrates a sensitivity of 76%-80% for peritoneal cancer[57,75,81]. Peritoneal lesions are often small and diffuse in nature, which may go some way to explaining the low detection rate. Specificity remains high at 79%-98% in the same series, with less specificity with higher resolution imaging. Due to the need to confirm the absence of metastatic peritoneal spread prior to definitive surgery, staging laparoscopy may still be necessary, as this is the most sensitive modality to evaluate the peritoneum[82,83].

RESPONSE TO TREATMENT

With the introduction of neoadjuvant or perioperative

chemotherapy it is of interest to try to determine those who may respond to such chemotherapy, and those who are likely to fail to respond. This may be crucial in future in order to spare non-responders further potentially toxic chemotherapy, or to switch to another, non cross resistant regimen. The advantage of PET over CT in this regard is that the CT response by RECIST (Response Evaluation Criteria in Solid Tumors) as measured by the change in size may be a late manifestation of a response. PET may demonstrate a decrease in FDG uptake at an earlier stage than could be demonstrated by conventional imaging.

In one study of 44 pure gastric carcinoma patients treated with neoadjuvant cisplatin and 5-fluororuacil, 35 showed FDG uptake at baseline, before the initiation of chemotherapy. The PET response at 14 d post-chemotherapy was correlated with histopathological response at the time of surgery. The PET response was defined as > 35% reduction in the SUV value of the target lesion. A histopathological response was defined as < 10% viable tumor cells remaining in the operative surgical specimen. A metabolic response correctly predicted the histological response after completion of chemotherapy in 10/13 responding and 19/22 non-responding tumors, corresponding with a sensitivity of 77% (95% CI: 46%-95%) and a specificity of 86% (95% CI: 65%-97%)[41]. Metabolic response appeared to correlate significantly with survival. At 2-year follow-up, survival in the metabolic responder group was 90%, compared with 25% in the metabolic non responder group. A second smaller study in the setting of metastatic gastric cancer using chemotherapy and the biologic agent cetuximab demonstrated in this study, PET demonstrated a sensitivity of 83% and a specificity of 75% for the prediction of ultimate best response by RECIST. There was also a significant correlation between metabolic response and progression-free survival in this cohort[84].

FDG-PET AND PREDICTION OF PATIENT SURVIVAL: GASTRIC ADENOCARCINOMA

Data on survival with respect to PET-positive tumors may be confounded by the fact that PET-negative tumors in most studies may represent earlier stage disease. For example, in one study, The 2-year survival rate for patients with PET-positive cancers was 65.9%, and for those with PET-negative cancers was 94.4%, but a significant proportion of PET-negative tumors were T1/T2 *vs* T3/T4 for the tumors visible on PET[61]. One study on recurrent gastric carcinoma with 33 patients showed a higher median survival for those with PET negative recurrence *vs* PET positive recurrence of 18.5 mo *vs* 6.9 mo respectively, however, other studies have failed to corroborate this finding[63,85].

FDG-PET TO DETECT RECURRENCE OF RESECTED DISEASE: GASTRIC ADENOCARCINOMA

When compared to contrast CT, PET showed a non-significant trend towards decreased sensitivity and increased specificity in the detection of recurrent disease. Contrast-enhanced CT was significantly more sensitive for the diagnosis of peritoneal recurrence (87% *vs* 47%)[86]. This concurs with another series demonstrating a high sensitivity of 78% and 67% for liver and lung lesions, respectively, with a lower sensitivity of 30% for bone metastases. Sensitivity for pleural carcinomatosis and ascites were also similarly low[75]. As FDG also demonstrates uptake in acute inflammation and fractures in addition to physiological uptake in the abdomen, this may lead to false positives in the detection of boney disease[87]. Table 4 summarizes these data.

Notably, the utility of FGD-PET in the detection of recurrent gastric cancer is largely dependent on the prevalence of recurrent disease in the screened population. In a population undergoing routine screening examination following definitive primary therapy the sensitivity of screening may be as low as 50%-70%. In contrast, positive predictive value is high in a high prevalence population (i.e., those in whom disease is suspected). This is illustrated when comparing the positive predictive value of 100% in a population with a suspicion of disease based on previous radiological imaging *vs* 25% in a population with no clinical or radiological suspicion of recurrent disease[85,86,88]. If the population undergoing testing has an a priori suspicion of disease based on previous imaging or tumor markers, then sensitivity for detection may reach 94%-100%. Specificity is generally high at 70%-100% for PET in the detection of recurrent disease[89,90].

PANCREAS ADENOCARCINOMA

Pancreatic cancer ranks as one of the most lethal malignancies and only 20% are suitable for resection at presentation. Accurate delineation of tumoral extent and anatomy are crucial prior to surgery in order to avoid potentially futile laparotomy. Conventional work up includes abdominal ultrasound, CT, EUS and MRCP.

PET AND THE DIAGNOSIS AND MANAGEMENT OF PANCREATIC MALIGNANCY

As the normal pancreas exhibits low FDG uptake, and pancreatic tumors have been demonstrated to have high GLUT-1 expression, the expectation is that pancreatic tumors should not be difficult to differentiate from the normal parenchyma by FDG-PET[91]. In an initial study in 1997 by Zimny *et al*[92], 106 patients with pancreatic lesions were examined using FDG-PET; 85% of pancreatic carcinomas were correctly identified, and in 84% of cases of chronic pancreatitis it was possible to exclude malignancy. Ten of 11 false negatives were due to elevated plasma glucose. In patients with normal plasma glucose the sensitivity, specificity, positive and negative predictive values were 98%, 84%, 96% and 93%, respectively. The SUV of carcinoma was significantly higher than that of chronic pancreatitis (6.4 ± 3.6 for pancreatic carcinoma *vs* 3.6 ± 1.7 for chronic pancreatitis ($P < 0.001$). Inokuma *et al*[93] examined the utility of PET in the diagnosis of pancreas cancer in comparison to CT and EUS. In a study of 45 patients PET had a lower sensitivity than EUS, but a higher specificity than all other modalities, and highest positive predictive value and overall accuracy. In a larger study, comparing PET with CT and MRI, the sensitivity of PET was lower than that of CT but higher than that of MRI (91% CT *vs* 82% PET *vs* 78% MRI), and PET had the highest specificity and positive predictive value among the three modalities. There was no correlation between the SUV of the tumor and the degree of differentiation. The ability of PET to detect disease was improved by the correction of SUV for blood glucose[94]. The ability of PET to detect pancreatic cancer may be greater than CT at smaller lesion sizes[95]. In the differentiation of benign *vs* malignant cystic disease of the pancreas, Sperti *et al*[96] showed that PET was superior to CT with respect to sensitivity, specificity, positive and negative predictive value, and diagnostic accuracy at 94%, 94%, 89%, 97%, and 94%, respectively; these figures for CT were 65%, 88%, 73%, 83%, and 80%. A review by Gambhir *et al* suggested a sensitivity of 94% and a specificity of 90% for PET when compared with that of CT (84% and 75%, respectively)[97]

FDG-PET AND STAGING: PANCREAS ADENOCARCINOMA

FDG-PET is not the preferred modality to stage the depth of invasion or invasion of local-regional structures the primary tumor of the pancreas due to its poor spatial resolution. At this time, thin slice CT or EUS are better able to delineate the anatomical boundaries of the primary tumor and thus resectability. Similarly, PET is poorly sensitive for the detection of loco-regional lymph node metastases, which may be due to their proximity to the primary lesion. Sensitivity has ranged from as low as 49% to as high as 76% for the detection of local field lymph node involvement[98,99]. For pancreatic tumors, similar to gastric adenocarcinoma, FDG-PET is sensitive for the detection of metastatic disease to the liver and bone, but less so to the peritoneum. In a series of 168 patients Fröhlich *et al*[100] determined PET had a sensitivity of 97% for hepatic lesions > 1 cm, but only 43% for those < 1 cm, with 95% specificity. Three quarters of false positives were due to intrahepatic cholestasis. A study of 59 patients by Diederichs *et al*[99] confirmed these findings, with an overall sensitivity for the detection of hepatic metastases of 70%, again missing some metastases < 1 cm in diameter. The sensitivity for the detection of peritoneal disease was 25%.

IS SUV UPTAKE PROGNOSTIC IN PANCREATIC CANCER?

An SUV cut-off of ⩾ 4.0 was used by Sperti and colleagues to characterize patients with pancreatic cancer into two groups. Those with an SUV ⩾ 4.0 had an overall survival of only 7 mo, compared to 32 mo in the lower SUV group. This applied also to those who underwent resection. Tumor SUV was confirmed in multivariate analysis to be an independent predictor of survival[96]. This is in agreement with data published by Nakata *et al*[101] for patients with inoperable pancreatic tumors, in which those with a tumor SUV of > 3.0 were shown to have inferior survival to those with SUV uptake of < 3.0. In contrast to many other malignancies, proliferative activity as measured by the Ki67 index did not correlate with FDG uptake in pancreatic tumors[102].

PET AS A PREDICTOR OF RESPONSE TO CHEMOTHERAPY: PANCREAS ADENOCARCINOMA

PET has been used in an attempt to measure the response to neoadjuvant chemoradiotherapy in pancreatic cancer. In a study of 20 patients with locally advanced pancreas adenocarcinoma, of those who had > 50% reduction from the baseline SUV, 10% had a complete surgical resection, compared to 6% of those who had < 50% reduction. Those with a significant response also had a 23.2 mo survival compared to 11.3 mo in those who did not respond[103]. This is in agreement with a study by Bang *et al* which demonstrated the superiority of PET in the detection of a treatment response to chemoradiotherapy, detecting a response in one-third of patients, where conventional

CT failed to detect any response. Those who developed a response on PET also had significantly longer survival than those who did not. The PET and tumor marker response following palliative chemotherapy were also correlated positively with patient survival in a recent Japanese study[104] which contrasts with results of a study by Kobayashi *et al*[105] in which only a fall in tumor markers and not SUV was correlated with survival.

DETECTION OF RECURRENT DISEASE

Ruf *et al*[106], in a study of 31 patients with suspected recurrence after surgery, demonstrated that PET was superior to the combination of CT and MRI in the detection of recurrence (96% *vs* 39%). CT/MRI failed to detect any local recurrence, but did perform well in the detection of small hepatic metastases when compared to PET (92% *vs* 42%). Thus PET may be superior in the detection of recurrence within the tumor bed, but CT/MRI may have better discriminatory power within the hepatic parenchyma. PET may also complement the use of tumor markers or CT for the detection of recurrent disease when CT findings are equivocal, as demonstrated in a small study by Rose *et al*[95], where PET detected 100% of recurrences felt to be equivocal on CT. In a recent study of 45 patients with suspected recurrent disease, PET fused with contrast CT was shown to have a sensitivity of 94.7% for the detection histologically proven metastatic disease. Notably there was also a high sensitivity in this study for the detection of all sites of recurrence, with sensitivity for detection of local recurrence, abdominal lymph node metastasis, and peritoneal dissemination being 83.3%, 87.5%, and 83.3%, respectively[107].

METHODS OF IMPROVING THE ACCURACY OF PET IN PANCREAS CANCER

Although PET is superior to CT for the differentiation of benign *vs* malignant lesions, false positives may occur, most commonly due to pancreatitis, post instrumentation of the biliary tree, due to retroperitoneal fibrosis or hemorrhage or inflammation of a pancreatic pseudocyst. If C-reactive protein serum levels are elevated, the specificity of PET may fall to 50%[108]. Using delayed PET may aid in the differentiation of benign *vs* malignant lesions as evidenced in a prospective series of 47 patients where the diagnostic accuracy for malignant *vs* benign disease was 91.5% using this method[109]. Optimal glycemic control is also an important factor in the accuracy of PET scanning in pancreatic disease as noted in the study by Zimny where 91% of false negative results were due to hyperglycemia reducing the sensitivity of PET from 96% to 63% in those with an abnormally high serum glucose[92].

The fusion of PET-CT may show promise. A retrospective study by Lemke *et al*[110] showed that use of PET-CT improved the sensitivity of either individual imaging modality. Sensitivity was 76% for CT, 84% for PET and 89% for PET-CT but this came at a cost of a loss of specificity. Addition of CT imaging to fusion PET-CT may lead to further gains. In another study the sensitivity for the detection of metastatic disease by PET-CT, CT, and PET-CT plus CT was 61%, 57%, and 87%, respectively[111]. Enhanced PET-CT has also been shown to be superior to PET alone compared to unenhanced PET-CT imaging in two studies[107,112]. Use of the alternative radiotracer FLT has not been shown to be of benefit in pancreas cancer. In a small pilot study, FLT-PET demonstrated low levels of uptake in the primary tumor and detected only 40% of primary pancreatic tumors compared to 100% with FDG-PET[113].

CONCLUSION

FDG-PET imaging is now a standard practice in staging cancers of the esophagus. The role of FDG-PET/CT imaging in staging gastric carcinoma, however, is complicated by the higher rate of FDG-non-avid malignancies and by the false positive rate within the stomach due to inflammatory conditions. For each upper GI malignancy, depth of invasion and nodal status are not well evaluated by FDG-PET scans. However, for locally-advanced malignancies, an FDG-PET scan may be used to identify occult metastatic disease which may then significantly then change the treatment plan. A newer application of this imaging modality is the assessment of metabolic response, which correlates with chemotherapy sensitivity and survival. Preliminary prospective clinical studies suggest FDG-PET scans can predict response to therapy. With these data, the utility of FDG-PET scanning in upper GI malignancies is increasingly commonplace. With the identification of new FDG-PET tracers, we expect a further expansion of the application of PET imaging in upper GI malignancies.

Abstract

AIM: To investigate osteopontin expression and its association with hepatopathologic changes in BALB/C mice infected with *Schistosoma japonicum*.

METHODS: The schistosomal hepatopathologic mouse model was established by abdominal infection with schistosomal cercaria. Liver samples were obtained from mice sacrificed at 6, 8, 10, 14, and 18 wk after infection. Liver histopathological changes were observed with hematoxylin-eosin and Masson trichrome staining. The expression of osteopontin was determined with immunohistochemistry, reverse transcription-polymerase chain reaction, and Western blotting. The expression of α-smooth muscle actin (α-SMA) and transforming growth factor-β1 (TGF-β1) were determined by immunohistochemistry. Correlations of osteopontin expression with other variables (α-SMA, TGF-β1, hepatopathologic features including granuloma formation and degree of liver fibrosis) were analyzed.

RESULTS: Typical schistosomal hepatopathologic changes were induced in the animals. Dynamic changes in the expression of osteopontin were observed at week 6. The expression increased, peaked at week 10 ($P < 0.01$), and then gradually decreased. Positive correlations between osteopontin expression and α-SMA ($r = 0.720$, $P < 0.01$), TGF-β1 ($r = 0.905$, $P < 0.01$), granuloma formation ($r = 0.875$, $P < 0.01$), and degree of liver fibrosis ($r = 0.858$, $P < 0.01$) were also observed.

CONCLUSION: Osteopontin may play an important role in schistosomal hepatopathology and may promote granuloma formation and liver fibrosis through an unexplored mechanism.

Key words: *Schistosoma japonicum*; Granuloma; Liver fibrosis; Osteopontin; BALB/C mice

INTRODUCTION

Schistosomiasis remains a huge threat to human health in tropical areas. Almost 12% of the population is in danger of this disease, with more than 200 million people infected annually[1]. In the past few decades, this disease has re-emerged and is still endemic in marsh, lake, and even mountainous regions of China, causing social hardship and economic burden[2]. It is now believed that the immune response of humans to schistosome eggs and the granulomatous responses they induce are the major causes of pathology in schistosomiasis[3]. The granulomas that form around the eggs impair blood flow in the liver and consequently induce portal hypertension[4]. On the other hand, the granulomas destroy the eggs and sequester or neutralize pathogenic egg antigens, leading to fibrosis in host tissues[5]. Once the immune response is activated, it is unlikely to be self-limiting, and schistosomiasis liver damage will continue, even after effective insecticide treatment[6]. Increasing reports of praziquantel treatment failures have highlighted the need for advanced knowledge of schistosomal hepatopathologic mechanisms and for new therapeutic strategies.

Osteopontin is granulomatogenic and has chemokine functions (mediating T lymphocyte and macrophage migration), cytokine activity (modulating T-helper 1 and 2 cytokine production), and several inflammatory and anti-inflammatory effects (regulation of nitric oxide generation)[7]. Recent work has demonstrated the important role osteopontin plays in mediating hepatic inflammation[8]. Upregulation of osteopontin expression early in the development of steatohepatitis, and its possible role in signaling the onset of liver injury and fibrosis in experimental nonalcoholic steatohepatitis have been reported[9].

These limited findings led us to hypothesize that osteopontin may be engaged in the immunopathogenesis of schistosomiasis liver damage. In our current study, we investigated the dynamic changes in osteopontin expression in *Schistosoma japonicum* (*S. japonicum*)-infected mouse liver. We also examined the relationship between osteopontin and hepatopathology and potential promoters of fibrosis progression such as hepatic stellate cells (HSCs) and transforming growth factor-β1 (TGF-β1) to obtain possible clues for further studies on the cellular and molecular mechanisms involved in schistosomal hepatopathology.

MATERIALS AND METHODS

Parasite and laboratory animals

Six-week-old BALB/C female mice were purchased from the Experimental Animal Center (Central South University, Changsha, Hunan, China). All animal experiments were performed in accordance with the Chinese Council on the Animal Care Guide for the Care and Use of Laboratory Animals. *Oncomelania hupensis* harboring *S. japonicum* cercariae were obtained from the Center for Schistosomiasis Control and Prevention (Yueyang, Hunan, China).

Animal treatment

One hundred BALB/C mice were randomly divided into the control group and the model group (n = 50 each). Mice in the model group were percutaneously infected with *S. japonicum* by placing a glass slide carrying 15 ± 1 cercariae in non-chlorine water on its abdomen for 20 min. Mice in the control group were treated with non-chlorine water containing no cercariae. All mice were kept at 20-25 ℃ in a 12-h light/12-h dark cycle with free access to food and water. At 6, 8, 10, 14, and 18 wk after infection, 10 mice from each group were randomly selected and sacrificed. Liver tissues were extracted and cut into two parts: the left lobes of the liver were fixed in 4% paraformaldehyde for 12 h; the remaining portion of the liver was preserved at -80 ℃ until use.

Histopathological study

Paraformaldehyde-fixed liver specimens were dehydrated in a graded alcohol series. Following xylene treatment, the specimens were embedded in paraffin blocks, cut into 5-μm thick sections, and placed on glass slides. The sections were then stained with hematoxylin and eosin (HE) and Masson trichrome (MT) according to standard procedures. To describe and evaluate liver pathological changes, a pathologist who was blinded to the research design examined 10 different low-power fields of HE- and MT-stained sections (selected fields were in almost the same location) for each mouse. In addition, the percentage of collagen calculated by a multimedia color image analysis system (Image-Pro Plus 6.0) was measured as a relative objective index (because a histological/fibrosis score that is evaluated by pathologists is susceptible to the ability and subjective judgment of the pathologist) to evaluate the degree of liver fibrosis. Each MT-stained section was examined at 100 × magnification. Every field analyzed contained a granuloma, portal area, or a centrilobular vein. Fibrotic areas were scanned and summed by the software. The percentage of collagen was expressed as the ratio of the collagen-containing area to the whole area, and the result was determined as the mean of ten different fields of each section. Furthermore, the granuloma dimension was also measured at a magnification of 100× using an ocular micrometer. Only non-confluent granulomas containing eggs in their centers were measured[10]. Granuloma dimension = maximum width × maximum length. Mean granuloma dimension of each section = sum of all granuloma dimensions in each section/number of granuloma in each section.

Immunohistochemistry

Immunohistochemical staining was performed with the PV-6001/6002 Two-Step IHC Detection Reagent (ZSGB-BIO, China). The sections were dewaxed, dehydrated, immersed in citrate buffer (0.01 mol/L, pH 6.0), heated at 100 ℃ in a microwave oven 6 × 2 min, incubated in 3% H_2O_2 in deionized water for 10 min to block endogenous peroxidase activity, and washed 2 × 3 min with phosphate-buffered saline (PBS). The sections were

then incubated overnight at 4 ℃ with antibodies against osteopontin (mouse monoclonal; 1:300; Santa Cruz Biotechnology, United States), α-SMA (mouse monoclonal; 1:300; Santa Cruz Biotechnology), and TGF-β1 (rabbit polyclonal; 1:300; Santa Cruz Biotechnology). After washing 2 × 3 min with PBS, the appropriate second antibody was added to the sections and incubated at 37 ℃ for 30 min. Then, the sections were washed 2 × 3 min with PBS, and the color was developed with diaminobenzidine (DAB) for about 5 min. Nuclei were lightly counterstained with hematoxylin. Negative controls included incubation with PBS without the primary antibody. The integral optical density (IOD) was measured with Image-Pro Plus 6.0, and the result was determined as the sum of five different fields (one in the center and four in the periphery) of each section. The IOD of the target protein was defined as the sum of the optical densities of all the positive pixels in the image, which represents the quantity of the targeted protein. The IOD is considered to be more accurate than average optical density as it considers both the intensity and area.

Reverse transcription-polymerase chain reaction

Total RNA was extracted from frozen liver tissue with TRIZOL Reagent (Invitrogen, United States). Complementary DNA (cDNA) was synthesized from total RNA using a ReverTra Ace-α-TM First Strand cDNA Synthesis kit (Toyobo, Japan). Relative quantification of target gene expression was performed using the housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as an internal control. The primer sequences were osteopontin forward 5'-CCAGGTTTCTGATGAACAGT-3' and reverse 5'-GTGTGTTTCCAGACTTGGTT-3', which yielded a fragment of 193 bp, and GAPDH forward 5'-AACTTTGGCATTGTGGAAGG-3' and reverse 5'-GGATGCAGGGATGATGTTCT-3', which yielded a fragment of 132 bp. For the first step, the following components were mixed to obtain the specified concentrations in a final 20 μL reaction volume: 1 μL denatured total RNA (1 μg/μL), 4 μL 5 × buffer, 2 μL dNTP mixture (10 mmol/L), 1 μL RNase inhibitor (10 U/μL), 10 μL RNase-free H_2O, 1 μL Oligo $(dT)_{20}$ (10 pmol/μL), and 1 μL ReverTra Ace. The reaction was performed at 42 ℃ for 20 min, followed by 99 ℃ for 5 min, and 4 ℃ for 5 min. In the second step, 1 μL cDNA was mixed with 0.5 μL each sense and anti-sense primers (100 μmol/L each), 2 μL dNTP mixture (2 mmol/L), 1.5 μL $MgCl_2$ (25 mmol/L), 2 μL 10 × polymerase chain reaction (PCR) buffer, 0.5 μL Taq DNA Polymerase (500 U), and 12 μL PCR H_2O. PCR was performed as follows: denaturation at 95 ℃ for 5 min; 32 cycles of denaturation at 94 ℃ for 30 s, annealing at 55 ℃ for 30 s, and elongation at 72 ℃ for 30 s; and final elongation at 72 ℃ for 5 min. The PCR products were separated by electrophoresis on 1.5% agarose gels (sample volume: 10 μL, voltage: 120 V) and visualized with ethidium bromide staining and ultraviolet illumination. We used gel OD analysis software (Gel-Pro 4.0) to scan and calculate the IOD of strips. The relative mRNA expression of osteopontin was represented as the ratio of osteopontin:IOD and GAPDH:IOD.

Western blotting

Frozen tissue specimens (500 mg) were homogenized on ice in 1 mL lysate prepared from a Total Protein Extraction kit (ProMab, United States) and then ultrasonicated for 3 × 3 s. The crude protein fractions were obtained by centrifuging the homogenates at 9000 × *g* for 10 min at 4 ℃. The supernatant was used as the protein fraction. Gel samples were prepared by mixing protein samples with sample buffer and boiling at 100 ℃ for 3 min. Nuclear and cytoplasmic proteins were separated with 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis in running buffer. After electrophoresis, the proteins were transferred to nitrocellulose membrane (Pierce, United States) in transfer buffer at 300 mA constant current for 70 min on ice. Non-specific binding sites were blocked by incubating in PBS containing 5% nonfat milk for 2 h at 37 ℃. Membranes were then incubated with primary antibodies (mouse osteopontin monoclonal; 1:500; Santa Cruz Biotechnology and mouse monoclonal GAPDH; 1:1000; ProMab, United States) overnight at 4 ℃. The membranes were then washed 5 × 4 min with PBS-Tween 20 (PBST) and incubated with secondary antibody (horseradish peroxidase-conjugated goat anti-mouse IgG; 1:50 000; Zymed, United States) for 1 h at 37 ℃. After the membranes were washed 5 × 4 min in PBST, enhanced chemiluminescence detection of the target protein was performed. The film was scanned, and the image was analyzed with Gel-Pro 4.0. The relative levels of osteopontin were represented as the ratio of osteopontin:IOD and GAPDH:IOD.

Statistical analysis

Statistical analysis was performed using SPSS 13.0 software. Data were expressed as mean ± SD. A normality test was performed before statistical analysis. Comparisons between groups and time points were performed using one-way analysis of variation (homogeneity of variance: S-N-K; heterogeneity of variance: Tamhane). Correlation analysis was performed with linear regression. *P* values less than 0.01 (heterogeneity of variance) or 0.05 were considered statistically significant.

RESULTS

Schistosomal hepatopathology

Both HE and MT staining revealed a parallel change over time (Figure 1, left and middle). The control group showed normal hepatocyte morphology (Figure 1A), but the model group showed typical hepatopathological characteristics of schistosomiasis with remarkable acute granuloma formation and subsequent liver fibrosis from week 6 through week 18 (Figure 1B-F). At week 6, inflammatory cells had infiltrated around the schistosome eggs and formed granulomas, which were mainly distributed in portal areas; collagen fibers were only interspersed among the periphery of the granulomas (Figure 1B). The granuloma size and the quantity of inflammatory

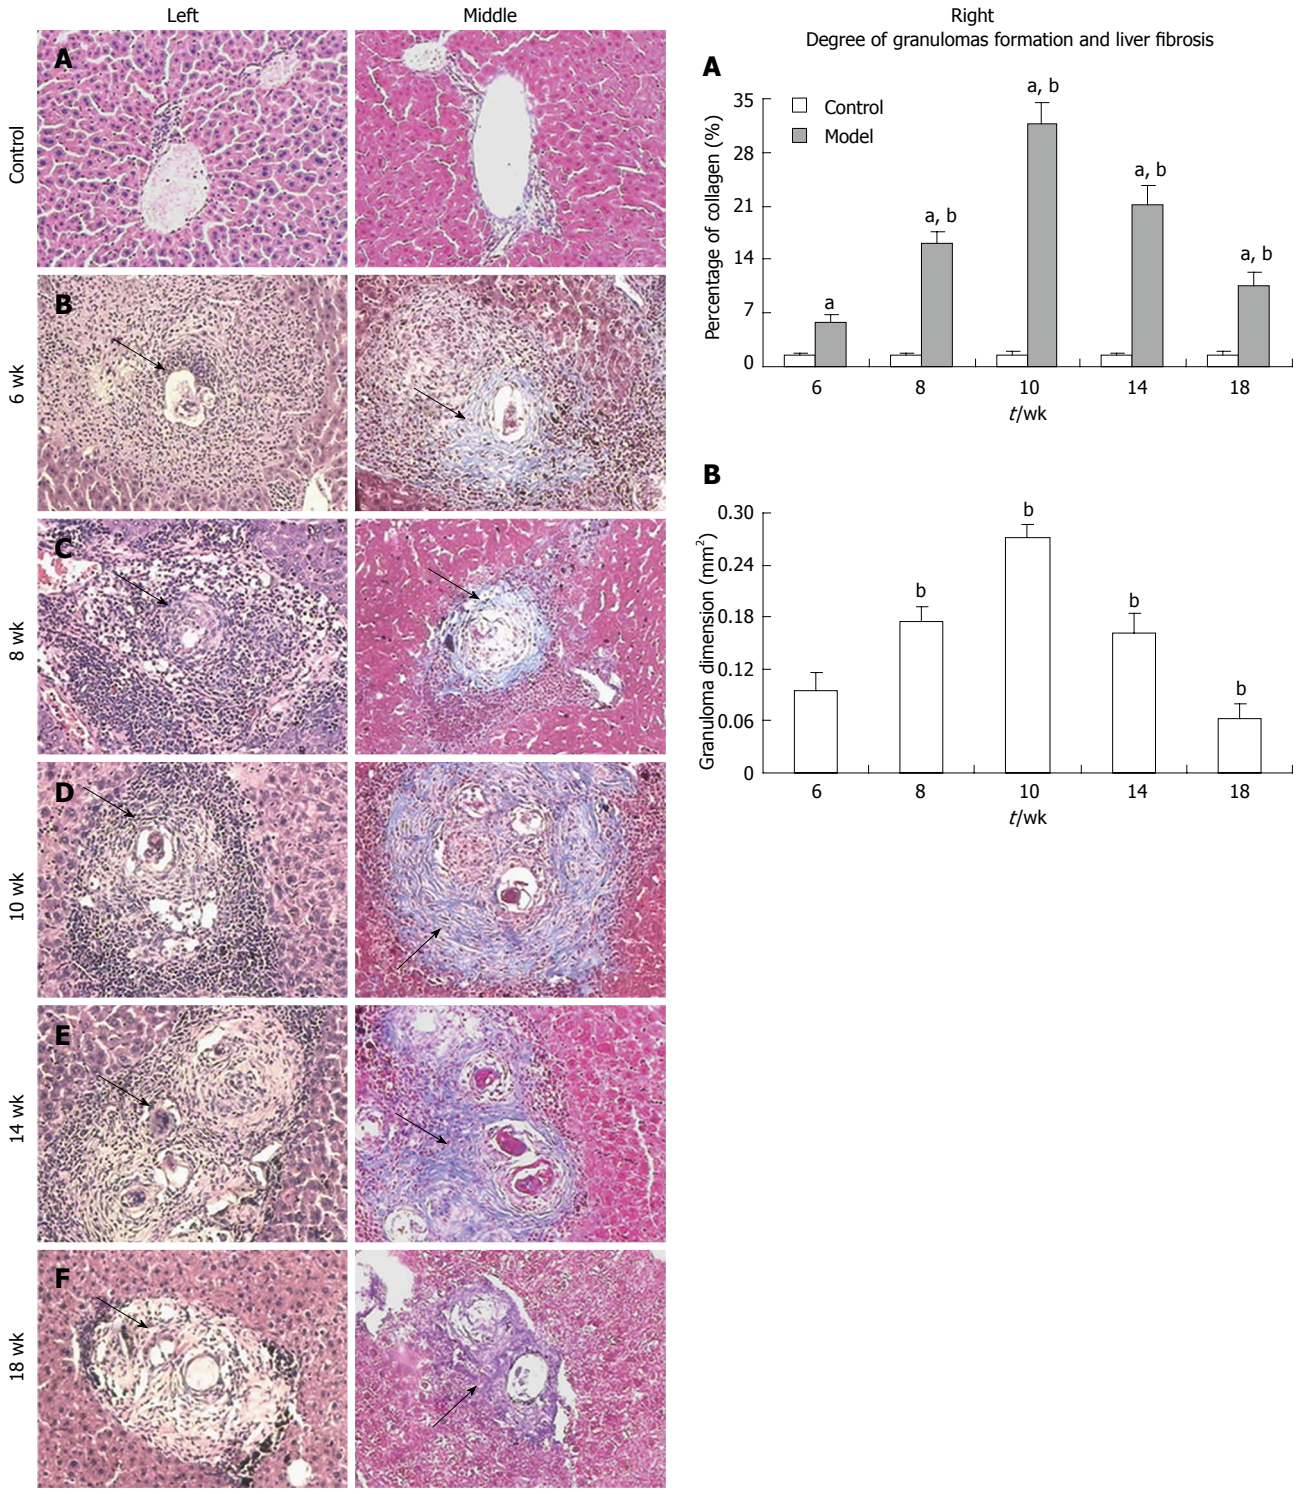

Figure 1 Representative images of hepatopathological changes over time. HE (left) and MT (middle) staining and data showing the degree of granuloma formation and liver fibrosis (right). Arrows show granulomas. Collagen fibers are stained blue (MT staining). 100 × original magnification. HE: Hematoxylin and eosin; MT: Masson trichrome. [a]$P < 0.05$ *vs* control; [b]$P < 0.05$ *vs* previous.

cells increased at week 8. Numerous fibrocytes appeared at the periphery of the lesions, and the collagen fibers became longer and thicker (Figure 1C). The granulomas reached their peak in size and quantity at week 10 (Figure 1D). Numerous inflammatory cells such as neutrophils, lymphocytes, and eosinophils were seen infiltrating in the granulomas, and numerous collagen fibers were wrapped or stretched into the interior of the granulomas. Some fibers extended from portal areas or inflammatory lesions to the lobule, which had been cut apart and re-built. In some serious cases, pseudolobules formed. At week 14, fibrocytes and collagen fibers eventually became the predominant feature of granulomas and formed typical chronic granulomas, whereas other cell types decreased in

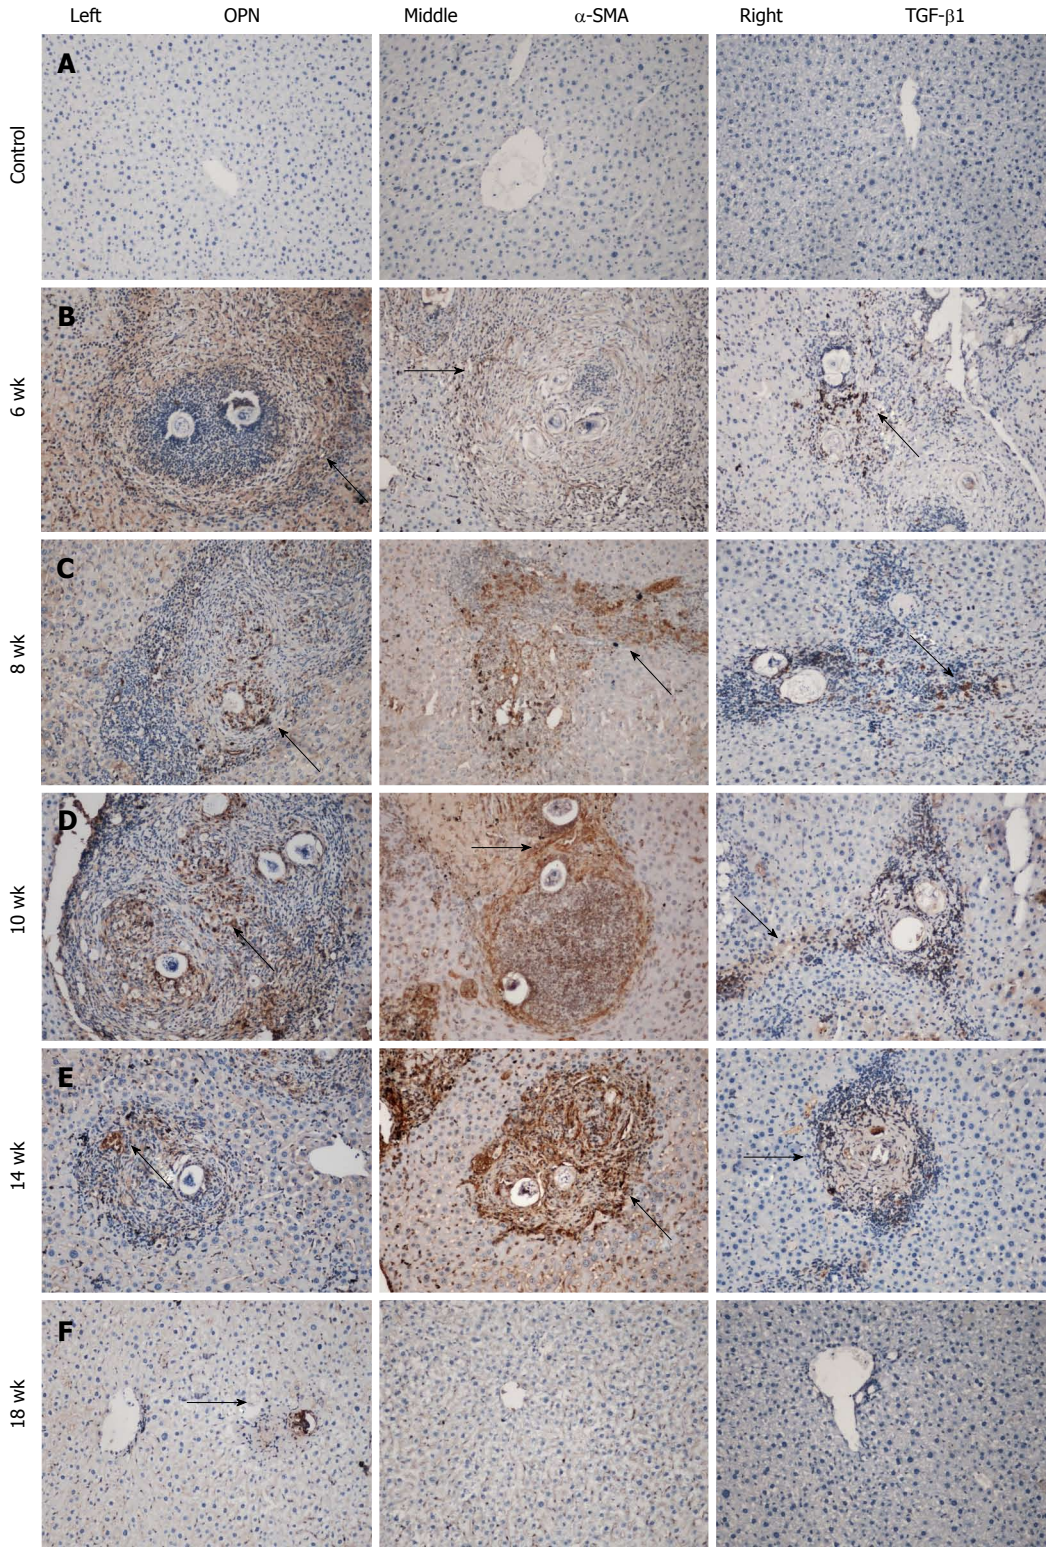

Figure 2 Representative images of immunostaining for osteopontin, α-SMA, and TGF-β1 over time in mouse liver. Positive staining is yellow brown, and arrowheads show positive cells. 100 × original magnification. OPN: Osteopontin; SMA: Smooth muscle actin; TGF: Transforming growth factor.

number (Figure 1E). The schistosome eggs degenerated and disintegrated at week 18, and fibrosis was obviously reduced but more stable (Figure 1F). The collagen percentage and the granuloma dimension in each group also showed a similar change over time (Figure 1, graphs A and B, right).

Expression of osteopontin, α-SMA, and TGF-β1 with immunohistochemistry

Immunohistochemistry for osteopontin, α-SMA, and TGF-β1 demonstrated a similar change that paralleled the development of hepatopathology over time (Figure 2A-F, left to right). Few if any, scarcely distributed cells with

[1]Compared with control group: $P < 0.01$; [2]Compared with previous time point: $P < 0.01$; [3]The staining of α-SMA in the control group was measured, and the result was zero. Results are expressed as the mean IOD (× 10^2 or × 10^3) ± SD. SMA: Smooth muscle actin; IOD: Integral optical density.

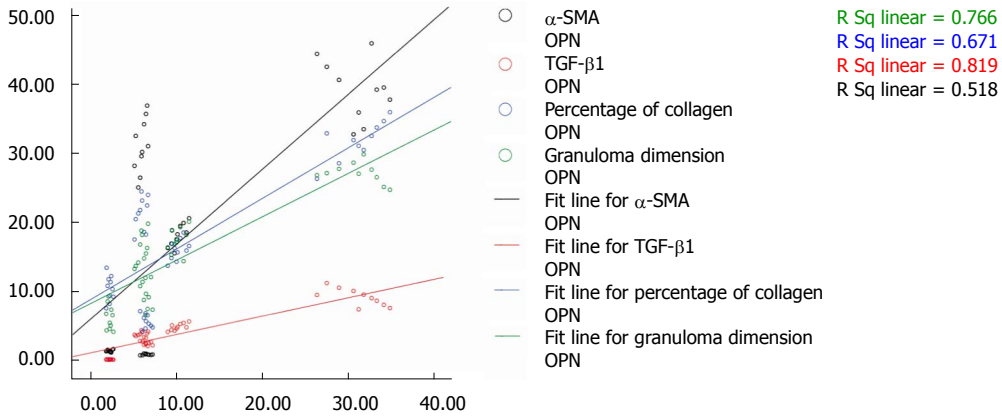

Figure 3 Correlation of osteopontin mRNA expression with α-SMA, TGF-β1, percentage of collagen, and the granuloma dimensions in the model group. x-axis: IOD of osteopontin (× 10^2); y-axis: Black line: IOD of α-SMA (× 10^2); Red line: IOD of TGF-β1 (× 10^3); Blue line: Collagen (%); Green line: Granuloma dimension, mm^2 (× 10^2). OPN: Osteopontin; SMA: Smooth muscle actin; TGF: Transforming growth factor.

faint staining were seen in the normal control group (Figure 2A, left to right) throughout the experiment. At week 6 in the model group, positively stained cells were widely distributed in the area of inflammatory cell infiltration, which formed acute granulomas (Figure 2B, left to right). Strongly upregulated expression of these proteins was seen from week 8 to week 10. Many densely stained positive cells surrounded and infiltrated into the egg granulomas, accumulated in fibrotic areas, and stretched along the fibrous septum (Figure 2C and D, left to right). At week 14, there were still many positive cells distributed in the fibrotic granulomas and dispersed at the periphery of the granulomas. However, the expression weakened and returned to near normal levels at week 18 (Figure 2E and F, left to right). The IODs of immunostaining of individual proteins in the groups over time are shown in Table 1.

Correlation analysis

Correlation analysis revealed that the expression of osteopontin was positively correlated with expression of α-SMA and TGF-β1, and with hepatopathological changes (Figure 3). The R-square values were 0.720, 0.905, 0.815, and 0.875 for osteopontin expression with α-SMA, TGF-β1, percentage of collagen, and granuloma dimension, respectively ($P < 0.01$), implying that the expression of osteopontin may play an important role in the development of liver damage in *S. japonicum*-infected mice in this study.

Expression of osteopontin mRNA (RT-PCR) and protein (Western blotting)

Consistent with the above results, parallel changes were seen in the expression of osteopontin mRNA and protein (Figure 4). The control group showed no changes in expression throughout the experiment, but the expression levels of both osteopontin mRNA and protein in the model group were upregulated at week 6, reached a peak at week 8 ($P < 0.05$), and decreased gradually. Expression levels remained higher than those in the control group ($P < 0.05$).

DISCUSSION

Osteopontin is considered a strong chemoattractant and proinflammatory molecule that is involved in a wide range of physiologic and pathologic events, including angiogenesis, tumor metastasis, wound healing, tissue remodeling, and fibrosis[11-13]. Osteopontin is believed to constitute the central pathway of HSC activation, a key step in the development of hepatic fibrosis[14,15]. However, the role of osteopontin in schistosomal liver damage should be explored further.

In our current study, typical hepatopathological changes were induced in *S. japonicum*-infected animals. Over time during the experiment, the infected liver showed granuloma formation and obvious fibrosis that appeared

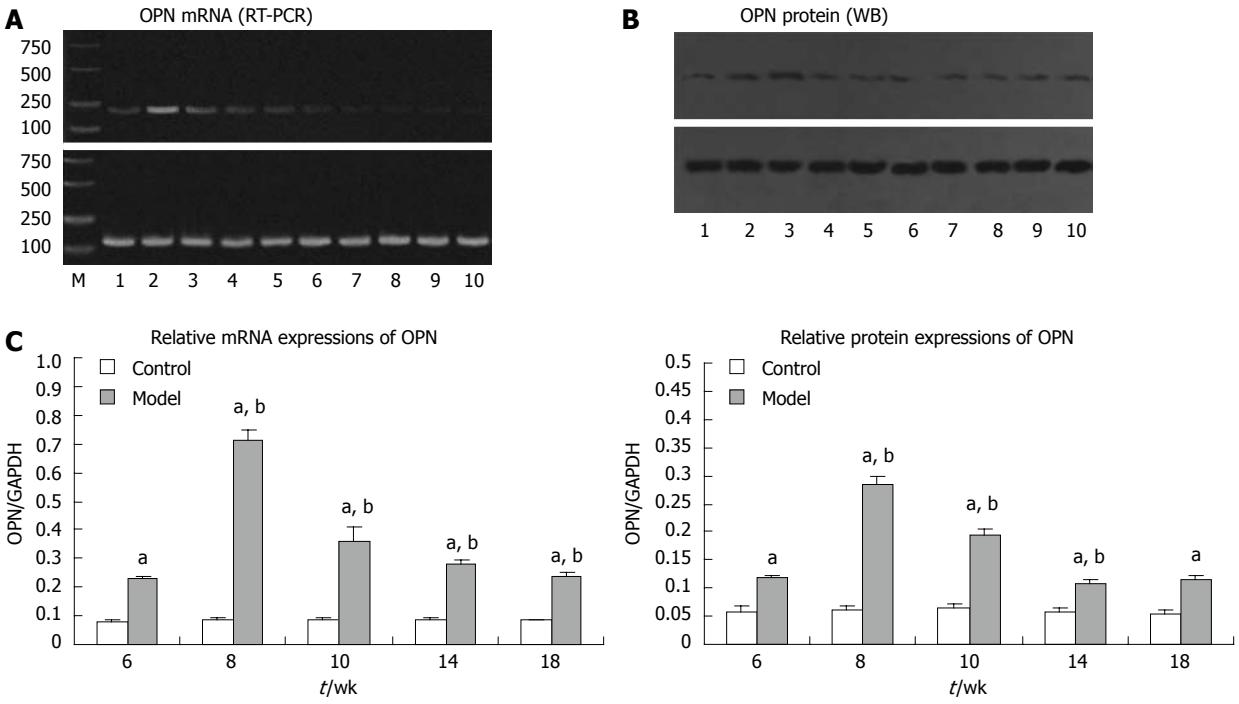

Figure 4 Profiles of osteopontin mRNA (RT-PCR) and protein (Western blotting) expression. No. 1-5 represent the model group at week 6, 8, 10, 14, and 18, respectively; No. 6-10 represent the control group at week 6, 8, 10, 14, and 18, respectively. A: Expression of osteopontin and GAPDH mRNA over time, the 100-bp GAPDH mRNA fragment was used as an internal control; B: Expression of osteopontin and GAPDH protein over time, the 37-kDa GAPDH band was used as an internal control; C: The IOD of osteopontin/GAPDH was expressed as the mean ± SD. M: Marker; n = 10 at each time. OPN: Osteopontin; RT-PCR: Reverse transcription polymerase chain reaction; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; IOD: Integral optical density. $^{a}P < 0.05$ *vs* control; $^{b}P < 0.05$ *vs* previous.

at week 6 and peaked from week 8 to 14. Accompanying this pathological change, osteopontin expression (mRNA and protein) was highly upregulated and showed a strong correlation with pathologic changes in the liver and with the immunohistochemistry profiles of α-SMA and TGF-β1. Thus, our data imply involvement of osteopontin in the development of schistosomal hepatopathologic changes.

Determining the mechanisms and the detailed biological role of osteopontin in the process of schistosomal hepatopathology is beyond the scope of our current experiment, but other reports suggest some possibilities. Niki *et al*[16] reported that α-SMA is significantly increased following HSC activation and is considered a marker for HSC activation. TGF-β1 is not only upregulated following HSC activation, but also directly activates HSCs through the TGF-β1/Smad signal transduction pathway, leading to hepatic fibrosis[17]. The upregulated expression of both α-SMA and TGF-β1 and their positive correlation with osteopontin expression observed in this study add more evidence supporting their important role in the process of schistosomal hepatopathology and liver fibrosis.

In summary, typical schistosomal hepatopathological changes occurred during this experiment. The development of hepatopathology, including granuloma formation and liver fibrosis, was accompanied by dynamic expression of osteopontin, which correlated well with the expression of both α-SMA and TGF-β1 over time. Thus, osteopontin may play a key role in schistosomal hepatopathology, the mechanisms of which will require additional studies.

COMMENTS

Background

There are currently few effective therapies for *Schistosoma japonicum* (*S. japonicum*)-infected patients due to a lack of understanding of appropriate intervention targets. Further studies on new cellular and molecular mechanisms are urgently needed as the global *S. japonicum* epidemic is becoming more serious.

Research frontiers

Osteopontin, which is a chemoattractant and proinflammatory molecule, has been shown to be involved in tissue injury and remodeling in other diseases. However, its roles in schistosomal liver damage have yet to be explored.

Innovations and breakthroughs

This study first reports the dynamic changes in osteopontin expression (mRNA and protein) and its associations with pathologic changes in the liver of BALB/C mice infected with *S. japonicum*. This study analyzes the correlations of osteopontin expression with α-SMA and TGF-β1 expression and hepatopathologic features including granuloma formation and liver fibrosis.

Applications

By increasing our understanding of whether and how osteopontin is involved in schistosomal liver damage, this study may provide clues for further studies on the cellular and molecular mechanisms of schistosomal hepatopathology.

Peer review

The study is novel and the methodology is good.

Abstract

AIM: To analyze the outcome of hepatocellular carcinoma (HCC) resection in cirrhosis patients, related to presence of portal hypertension (PH) and extent of hepatectomy.

METHODS: A retrospective analysis of 135 patients with HCC on a background of cirrhosis was submitted to curative liver resection.

RESULTS: PH was present in 44 (32.5%) patients. Overall mortality and morbidity were 2.2% and 33.7%, respectively. Median survival time in patients with or without PH was 31.6 and 65.1 mo, respectively (P = 0.047); in the subgroup with Child-Pugh class A cirrhosis, median survival was 65.1 mo and 60.5 mo, respectively (P = 0.257). Survival for patients submitted to limited liver resection was not significantly different in presence or absence of PH. Conversely, median survival for patients after resection of 2 or more segments with or without PH was 64.4 mo and 163.9 mo, respectively (P = 0.035).

CONCLUSION: PH is not an absolute contraindication to liver resection in Child-Pugh class A cirrhotic patients, but resection of 2 or more segments should not be recommended in patients with PH.

Key words: Liver surgery; Hepatic resection; Hepatocellular carcinoma; Portal hypertension

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third leading cause of cancer death worldwide[1-3]. Surgical treatment is an effective treatment for HCC and the mortality after surgery has decreased in recent years in relation to improved surgical techniques and peri-operative management of patients[4-6]. The overall survival at 5 years after liver resection varies from 33% to 69% according to recent surgical series, although recurrence is still the major issue after surgery[7-13].

The indications for surgical resection depend on the characteristics of the tumor (stage, number of nodules, size, presence of vascular invasion), on the general condition of patient, and on liver functional reserve[14].

The presence of liver cirrhosis is the most important risk factor for the development of HCC, as 85%-95% of HCCs arise in cirrhotic livers[15-17]. HBV and HCV infections and alcohol abuse are the most frequent causes of cirrhosis: about 80%-85% of cases[7]. Portal hypertension (PH) is related to an increase in intrahepatic resistance due to the structural subversion of the liver and loss of vascular bed, and bleeding from gastroesophageal varices is one of the most important complications of cirrhosis[18]. On the basis of several studies[19,20], the American Association for the Study of Liver Diseases (AASLD)[21] defined as clinical PH the presence of esophageal varices or thrombocytopenia (platelet count < 100 000/mm^3) associated with splenomegaly. The European Association for the Study of the Liver (EASL)/AASLD guidelines consider PH as a relative contraindication to liver resection, because of the high risk of postoperative liver failure, as reported in some clinical series[21,22]. These results, however, have not been confirmed in more recent clinical studies[23-25].

The aims of this study are to assess the results of liver resection in patients with HCC and cirrhosis with PH and the relationship in terms of survival between Child-Pugh stage, the extent of hepatic resection and the presence of clinical PH.

MATERIALS AND METHODS

We retrospectively analyzed clinical data of 135 patients with cirrhosis undergoing liver resection with radical intent for HCC from 1995 to 2008 at the single Surgical Division of the Department of Surgery of the University of Verona. The patients' liver function was assessed by Child-Pugh classification. Clinical PH was defined according to AASLD guidelines as the presence of esophageal varices or thrombocytopenia (platelet count < 100 000/mm^3) associated with splenomegaly[21]. The extent of resection was defined according to the classification of Brisbane[26]. After liver resection, patients underwent follow-up with serum α-fetoprotein levels and abdominal ultrasound every 6 mo and computed tomography scan every 12 mo. The mean follow-up after surgery was 38.3 mo.

Statistical analysis

Data were collected and analyzed with SPSS statistical software (SPSS version 16.0 Inc., Chicago Ⅲ). The differences between categorical variables were analyzed with a χ^2 test. The differences between continuous variables were also analyzed with a χ^2 test.

Survival analysis was carried out with the Kaplan-Meier method. Univariate analysis for survival was performed with the Kaplan Meier method, with the Log Rank test to verify significance of differences. The statistical analysis included two different steps; in the first we analyzed the prognostic significance of the PH in all patients and in the second step we analyzed the prognostic significance of PH in different subgroups according to the Child-Pugh class and the extent of liver resection (wedge/segmentectomy or ⩾ 2 segments). Finally, multivariate analysis with Cox's regression model was performed with the following variables: Child-Pugh class, PH and type of hepatectomy. A *P* value lower than 0.05 was considered significant.

RESULTS

The prevalence of PH in all patients was 32.5%. The analysis of our data showed that patients with PH who underwent surgery had worse liver function compared to those without PH (patients in Child-Pugh B class 33% *vs* 11% respectively, $P < 0.01$), with serum bilirubin level > 2 mg/dL in 29% *vs* 3% respectively, $P < 0.01$ and serum transaminases AST > 80 U/L in 52% *vs* 25%, $P = 0.01$ and ALT > 80 U/L in 48% *vs* 19% respectively, $P = 0.01$ (Table 1). The one and 3-mo mortality rates were 4.6% and 13.9% and 1.1% and 3.3% for patients with and without PH, respectively ($P = 0.20$ and $P = 0.05$). The morbidity rate reached no statistical significance for patients with and without PH respectively (37% *vs* 32%, $P = 0.59$). The liver-related morbidity (ascites, encephalopathy, jaundice) was significantly higher in patients with PH than in patients without PH, 32% *vs* 13% respectively ($P = 0.03$) (Table 2).

The 3-year and 5-year survival in patients without PH was higher than in patients with PH (68.4% and 61.2% *vs* 48.7% and 44.9% respectively, $P = 0.047$). These results are reported in Figure 1A.

Survival analysis in patients with Child-Pugh B cirrhosis did not demonstrate significant differences in patients with or without PH (3-year survival of 31.3% *vs* 11.9%, $P = 0.465$) (Table 3).

Also, in Child-Pugh class A patients the survival analysis did not show significant differences in patients with or without PH, with a 3-year and 5-year survival of 63.0% and 57.3% *vs* 72.0% and 63.2% respectively ($P = 0.257$). These results are summarized in Table 3.

Furthermore, we evaluated the relationship between survival, extent of liver resection and PH in Child-Pugh class A patients.

In limited resections (wedge or one segment) we found no statistical differences between patients with or without PH. In these patients the 5-year survival was 72.4% and 61.4% respectively ($P = 0.458$, Figure 1B, Table 3).

When resection of two or more segments was performed, survival was significantly longer in patients without PH with a 5-year survival of 64.5% compared to 25.0% in patients with PH respectively ($P = 0.035$, Figure 1C, Table 3).

Multivariate analysis with Cox's regression model confirmed that Child-Pugh class was related to survival with a HR of 2.57 ($P < 0.01$), whereas PH and type of hepatectomy were not related to survival (Table 4).

DISCUSSION

Liver resection is currently the treatment of choice for

single HCC and it is a safe treatment in terms of peri-operative complications, even in patients with liver cirrhosis[6,27]. The outcome of surgical resection is strongly related to hepatic functional reserve. For this reason, the majority of patients with liver cirrhosis cannot undergo surgery because of the high risk of postoperative liver failure.

Table 2 Mortality and morbidity rates according to the presence/absence of portal hypertension

	Portal hypertension		*P* value

PH (presence *vs* absence)	1.51	0.84-2.68	0.160

CI: Confidence interval; PH: Portal hypertension.

PH in cirrhotic patients is considered a relative contraindication for surgery in EASL/AASLD guidelines. Bruix *et al*[12] analyzed the outcome of 29 Child-Pugh class A patients with PH [defined as porto-hepatic gradient (HVPG) greater than 10 mm Hg] and observed a higher likelihood of postoperative liver failure in these patients compared to those without PH. The authors justified these results because liver resection in patients with PH can reduce the portal vascular bed without a reduction of portal flow and this condition can lead to a further increase of portal pressure. These hypotheses were not confirmed by a study by Fujisaki *et al*[28] that reported

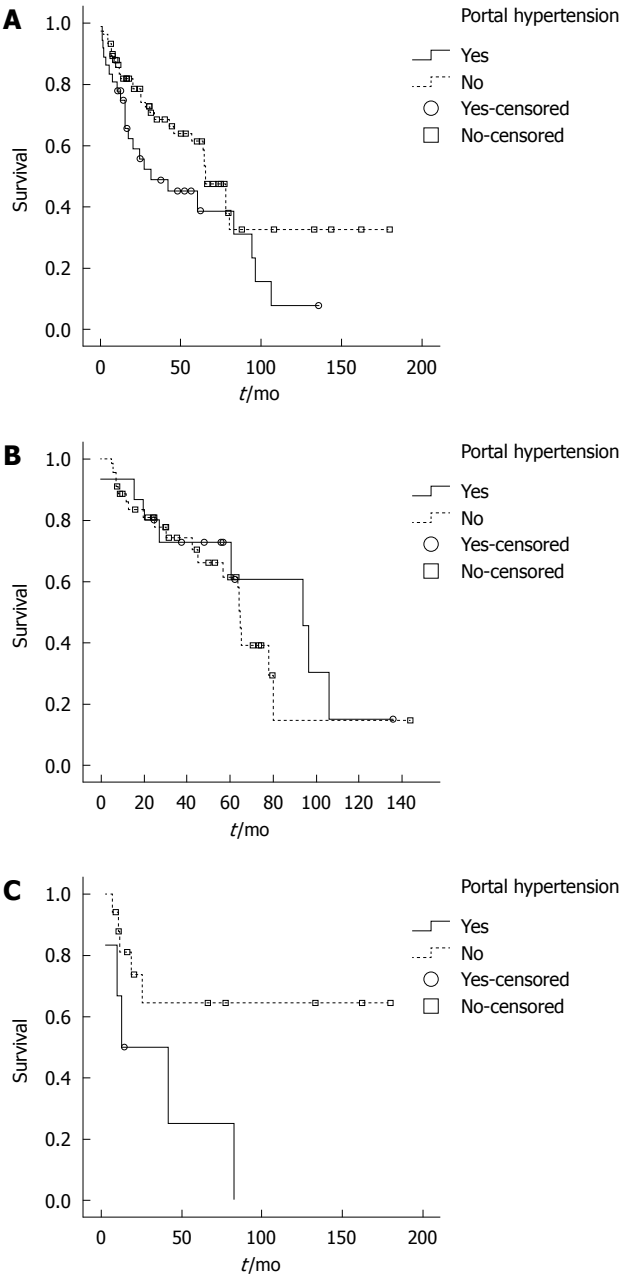

Figure 1 Overall survival analysis in patients. A: Overall survival analysis in patients with or without portal hypertension (PH); the difference between the two groups was statistically significant ($P = 0.04$); B: Overall survival analysis in Child-Pugh score (CP) A patients with or without PH, in the subgroup of patients submitted to limited resection ($P = 0.45$); C: Overall survival analysis in CP A patients with or without PH, in the subgroup of patients submitted to resection of 2 or more segments ($P = 0.03$).

on a group of 54 patients, in whom severity of PH was not worsened by liver resection. Llovet *et al*[29] in another study showed that clinical PH (assessed by the simultaneous presence of gastric-esophageal varices, thrombocytopenia lower than 100 000/mm^3 and splenomegaly, or on a portal-hepatic venous pressure gradient greater than 10 mm Hg) is a predictor of postoperative liver failure and that it is related to long term survival. These authors studied 77 patients divided into 3 groups based on the presence or absence of PH and bilirubin level. The 5-year survival of patients without PH was 74%, while the patients with PH and bilirubin lower than 1 mg/dL had a 5-year survival of 50%, and the patients with PH and bilirubin greater than 1 mg/dL had a 5-year survival of 25%. Other studies confirmed a correlation between PH and increased mortality and complications. Poon *et al*[30], in a study of 1222 patients undergoing liver resection for hepato-biliary cancers, showed that the presence of thrombocytopenia at the time of surgery is a risk factor in multivariate analysis for surgical complications. Similarly, Jarnagin *et al*[31] in a study of 1803 patients showed that preoperative thrombocytopenia is associated with a postoperative increased risk of mortality.

On the contrary, other authors did not detect a significant correlation between PH and liver failure after surgery[32,33]. Ishizawa *et al*[23] analyzed 322 Child-Pugh class A patients and found good long term results in patients with or without PH, (3- and 5-year survival of 71% and 56% *vs* 81% and 71% respectively, $P = 0.008$). Capussotti *et al*[24], in a study of 217 patients including 99 with PH at the time of surgery, showed that the 3- and 5-year survival rates are greater in patients without the presence of PH (62% and 40% *vs* 45% and 29% respectively, $P = 0.020$). However, resection in patients with PH and good hepatic function (Child-Pugh A) had similar results in terms of 3- and 5-year survival (65% and 41% *vs* 60% and 41%, $P = 0.503$). This study also shows that patients with PH have a higher incidence of postoperative complications, particularly those related to the deterioration of liver function (27% *vs* 15%, $P = 0.030$). Kawano *et al*[25] evaluated the results of liver resection in patients with esophageal varices. This study found that patients with esophageal varices had a better 5-year survival (70% *vs* 47%, $P = 0.045$); the authors underlined that patients with PH had a more frequent early diagnosis of HCC due to more careful follow up. More recently, Choi *et al*[34] reported that the 5-year survival rate of patients with clinical PH affected by single nodular HCC without macrovascular invasion was 78.4%, even if in Child-Pugh A cirrhotic patients, the presence of clinically significant PH was significantly associated with postoperative hepatic failure and poor prognosis after resection of HCC.

The data from our study confirm the recent experiences in the literature. Patients with PH at the time of surgery showed worse liver function and this justifies the increased number of complications related to the deterioration of liver function and the increased postoperative 3-mo mortality. Long term survival was significantly related to PH with significantly shorter survival ($P < 0.04$).

Among different Child-Pugh class patients we did not observe statistically significant differences in 3- and 5-year survival between patients with or without PH. In Child-Pugh class A patients submitted to minor resection, survival was not significantly affected by PH. Our study is the first in the literature to demonstrate the relationship between survival, PH and extent of hepatectomy. Surgery can produce good long term survival in patients with PH submitted to limited resection; conversely, PH had strong

adverse prognostic significance in patients who underwent resection of two or more segments. This data can help in the selection of patients and improve safety and long term results of surgery, as well as identify a group of patients who require resection of 2 or more segments, in whom resection is contraindicated and other non-surgical therapies should be applied.

This is a retrospective analysis from a single center. This allowed homogeneous data; however, multi-center studies are needed to confirm these results to reduce technical bias.

Our study confirms that the presence of PH at the time of surgery is not an absolute contraindication to resection in patients with liver cirrhosis. Although the rate of postoperative complications in patients with PH is greater, the results in terms of survival in the group of Child-Pugh class A patients is similar in patients without PH. Also, in patients with PH, limited liver resection can be performed with results comparable to those in patients without PH. Conversely, surgical resection of 2 or more segments in patients with PH results in significantly shorter survival and should not be recommended.

COMMENTS

Background

The presence of liver cirrhosis is the most important risk factor for the development of hepatocellular carcinoma (HCC): 85%-95% of HCCs arise in cirrhotic livers. Portal hypertension (PH) is related to increase in intrahepatic resistance due to the structural subversion of the cirrhotic liver and loss of vascular bed, and bleeding from gastro-esophageal varices is one of the most important complications of cirrhosis. The European Association for the Study of the Liver/American Association for the Study of Liver Diseases (AASLD) guidelines consider PH as a relative contraindication to liver resection, because of the high risk of postoperative liver failure, as reported in some clinical series. On the contrary, other authors have not detected a significant correlation between PH and liver failure after surgery.

Research frontiers

Surgical treatment is the most effective treatment for HCC and the mortality after surgery has decreased in recent years in relation to improved surgical techniques and peri-operative management of patients. Moreover, only about 30% of patients affected by HCC can be submitted to surgery, because of the characteristics of the tumor (stage, number of nodules, size, presence of vascular invasion), the general condition of the patient, or liver functional impairment, such as PH.

Innovations and breakthroughs

Recently, authors have not detected a significant correlation between PH and liver failure after surgery. The data from this study confirm the recent experiences in the literature. Survival analysis in patients with Child-Pugh A and B cirrhosis did not demonstrate significant differences in patients with or without PH. Moreover, limited resections (wedge or one segment) showed no statistical differences between patients with or without PH. When resection of two or more segments was performed, survival was significantly longer in patients without PH. Multivariate analysis with Cox's regression model confirmed that Child-Pugh, but not PH and type of hepatectomy class, was related to survival. This study is the first in the literature to demonstrate the relationship between survival, PH and extent of hepatectomy. Surgery can result in good long term survival in patients with PH submitted to limited resection; conversely, PH had strong adverse prognostic significance in patients who underwent resection of two or more segments.

Applications

This study confirms that the presence of PH at the time of surgery is not an absolute contraindication to resection in patients with liver cirrhosis. Results in terms of survival in the group of Child-Pugh class A patients are similar to patients without PH. Furthermore, in patients with PH, limited liver resection can be performed with results comparable to those in patients without PH. Conversely, surgical resection of 2 or more segments in patients with PH resulted in significantly shorter survival and is not to be recommended.

Terminology

Clinical PH is defined according to AASLD guidelines as the presence of esophageal varices or thrombocytopenia (platelet count < 100 000/mm^3), associated with splenomegaly.

Peer review

In this retrospective study, the authors compare the results of liver resection for HCC in patients with and without PH. The authors show that resection is safe in CTP. A patients regardless of PH, in patients undergoing limited resection. The authors show no difference in survival between those with and without PH in CTP A/B patients.

Abstract

AIM: To examine the links between quality of sleep and the severity of intestinal symptoms in irritable bowel syndrome (IBS).

METHODS: One hundred and forty-two outpatients (110 female, 32 male) who met the Rome Ⅲ criteria for IBS with no psychiatric comorbidity were consecutively enrolled in this study. Data on age, body mass index (BMI), and a set of life-habit variables were recorded, and IBS symptoms and sleep quality were evaluated using the questionnaires IBS Symptom Severity Score (IBS-SSS) and Pittsburgh Sleep Quality Index (PSQI). The association between severity of IBS and sleep disturbances was evaluated by comparing the global IBS-SSS and PSQI score (Pearson's correlation and Fisher's exact test) and then analyzing the individual items of the IBS-SSS and PSQI questionnaires by a unitary bowel-sleep model based on item response theory (IRT).

RESULTS: IBS-SSS ranged from mild to severe (120-470). The global PSQI score ranged from 1 to 17 (median 5), and 60 patients were found to be poor sleepers (PSQI > 5). The correlation between the global IBS-SSS and PSQI score indicated a weak association (r = 0.2 and 95% CI: -0.03 to 0.35, $P < 0.05$), which becomes stronger using our unitary model. Indeed, the IBS and sleep disturbances severities, estimated as latent variables, resulted significantly high intra-subject correlation (posterior mean of r = 0.45 and 95% CI: 0.17 to 0.70, $P < 0.05$). Moreover, the correlations between patient features (age, sex, BMI, daily coffee and alcohol intake) and IBS and sleep disturbances were also analyzed through our unitary model. Age was a significant regressor, with patients ⩽ 50 years old showing more severe bowel disturbances (posterior mean = -0.38, $P < 0.05$) and less severe sleep disturbances (posterior mean = 0.49, $P < 0.05$) than older patients. Higher daily coffee intake was correlated with a lower severity of bowel disturbances (posterior mean = -0.31, $P < 0.05$). Sex (female) and daily alcohol intake (modest) were correlated with less severe sleep disturbances.

CONCLUSION: The unitary bowel-sleep model based on IRT revealed a strong positive correlation between the severity of IBS symptoms and sleep disturbances.

Key words: Irritable bowel syndrome; Sleep disorders; Item response theory model; Bayesian model

INTRODUCTION

Irritable bowel syndrome (IBS) is quite prevalent in the general population (5%-20%) and is in fact the functional gastrointestinal disorder most frequently encountered in primary and secondary care[1,2]. IBS is characterized by abdominal discomfort, pain and changes in bowel habits (constipation and/or diarrhea)[3]. Visceral hypersensitivity, slowed gastrointestinal transit, and alterations in secretion activity are also often reported[4]. The direct and indirect costs of the syndrome are significant. IBS can have a serious impact on quality of life, and because it is often associated with other disorders, the patient may have to undergo expensive tests and treatments[5-7].

Sleep disturbances connected with gastrointestinal functional disorders, in particular IBS, have been reported[8-10], but no consistent abnormality in sleep patterns has been identified, apart from a significant increase in rapid-eye-movement (REM) sleep[11,12]. Many studies have associated sleep alterations with severity of IBS symptoms[12], but it is not yet known whether there is a direct pathophysiological relationship[13,14]. To date, a fundamental question remains - is sleep disturbance a cause or a consequence of IBS[15]?

Growing awareness of the importance of the "brain-gut axis" has led some gastroenterologists to investigate sleep as an independent factor in the pathogenesis and clinical expression of IBS[11,16].

The aim of the present study was to evaluate the association between the severity of sleep disturbances and intestinal symptoms, measured using two widely accepted questionnaires: the IBS Symptom Severity Score (IBS-SSS)[17] and the Pittsburgh Sleep Quality Index (PSQI)[18]. In addition, individual patient features were also analyzed to investigate their possible interaction with the severity of bowel and sleep disturbances and to exclude their potential confounding role.

MATERIALS AND METHODS

Study patients

Between October 2007 and September 2008, 142 patients who met the Rome Ⅲ criteria for IBS[3] with no confounding psychiatric comorbidity (diagnosed according to DSM Ⅳ axis I criteria) were consecutively enrolled from outpatients attending the Gastrointestinal Unit of the University of Pisa. All patients gave their informed written consent as required by the University Ethics Committee for Clinical Studies. The cohort was comprised of 110 female and 32 male patients (median age: 38 years; range: 18-79 years), of whom, 52 had constipation as the predominant symptom (C-IBS), 48 had diarrhea as the predominant symptom (D-IBS), and 42 had mixed symptoms (M-IBS).

We also evaluated physical and life-habit variables in each patient (Table 1): (1) sex and age; (2) body mass index (BMI)[19]; (3) smoking; (4) alcohol intake[20]; (5) coffee intake; (6) physical activity; and (7) water intake.

Table 1 Clinical subtypes, physical and life-habit variables of irritable bowel syndrome patients

	Item categories	Patients (%)
IBS subtype	M-IBS	29.6
	D-IBS	33.8
	C-IBS	36.6
Age (yr)	≤ 50	78.9
	> 50	21.1
Sex	Male	22.5
	Female	77.5
BMI (kg/m^2)	≤ 25	76.1
	> 25	23.9
Smoking	No	74.6
	Yes	25.4
Alcohol consumption	Non-/occasional drinkers	82.4
	Light drinkers (< 30 g ethanol/d)	17.6
Coffee consumption	< 2 cups/d	55.6
	≥ 2 cups/d	44.4
Physical activity	No	66.2
	Yes	33.8
Water consumption	< 1.5 L/d	61.3
	≥ 1.5 L/d	38.7

IBS: Irritable bowel syndrome; BMI: Body mass index.

IBS and sleep questionnaires

IBS symptoms were evaluated using the IBS-SSS questionnaire[17], which measured five separate items (Table 2): (1) presence and severity of abdominal pain or discomfort; (2) frequency of abdominal pain or discomfort; (3) presence and severity of abdominal distension; (4) degree of satisfaction with defecatory function; and (5) degree of interference of IBS symptoms with daily lifestyle. For each of the five items, the questions generated a score ranging from 0 to 100 that, for the purposes of analysis, was divided into three consecutive intervals: low, medium, and high (Table 2). The scores for the five items were summed to arrive at a global IBS-SSS (range: 0-500) and the IBS severity was then classified as mild (75-175), moderate (175-300) or severe (≥ 300).

Sleep quality was evaluated using the PSQI[18], a self-administered questionnaire based on seven items: subjective sleep quality, sleep latency, sleep duration, habitual

Table 2 Distribution of responses to the items in the irritable bowel syndrome Symptom Severity Score across categories (low, medium and high)

IBS-SSS items	Category (score interval)	Patients (%)
Pain severity	Low: ≤ 40	31.0
	Medium: 40-70	43.7
	High: > 70	25.4
Pain frequency	Low: ≤ 20	19.7
	Medium: 20-70	33.8
	High: > 70	46.5
Distension	Low: ≤ 40	30.3
	Medium: 40-70	28.2
	High: > 70	41.5
Dissatisfaction with defecatory function	Low: ≤ 40	12.7
	Medium: 40-70	26.8
	High: > 70	60.6
Interference with daily life style	Low: ≤ 40	28.9
	Medium: 40-70	32.4
	High: > 70	38.7

IBS-SSS: Irritable bowel syndrome Symptom Severity Score.

sleep efficiency, sleep disturbances, use of sleep inducers, and daytime dysfunction. Each item was scored from 0 to 3, and the PSQI global index was calculated by summing these scores (range: 0-21); a global score > 5 identified poor sleepers.

In both questionnaires, lower values indicated lower severity, and higher values a more severe condition.

Statistical analysis

The association between the severity of IBS symptoms and sleep disturbances was first verified by directly comparing the global IBS-SSS and PSQI score, and then by evaluating the links between individual items in the two questionnaires.

For the first approach, we used both the Pearson correlation coefficient and the generalized Fisher exact test[21]. The Pearson correlation measured the linear dependence between global scores, whereas the Fisher exact test verified the association between IBS-SSS and PSQI through a contingency table.

We adopted a unitary bowel-sleep model based on item response theory (IRT) that enabled us to investigate directly the dependences between IBS-SSS and PSQI single items. Furthermore, we also evaluated the weight of patient features and life habits in affecting the severity of IBS and sleep disturbances.

By focusing on individual items as the unit of analysis rather than the global score, the IRT model could circumvent the problem of different patterns of responses generating identical global scores. To this end, the values of both IBS-SSS single items and patient features were transformed in categories as indicated in the Tables 1 and 2. At variance, the PSQI items were not transformed since each item could have only four values (0-3), thus PSQI single item categories corresponded to the item values.

The output of our IRT model was the estimate of two latent variables: one related to the severity of IBS, and the other to sleep disturbances. In order to evaluate the possible intra-subject associations between IBS and sleep disturbances, the latent variables for the two were jointly modeled using a bivariate normal distribution. The strength of this association was quantified by the covariance parameter. Specifically, we adopted the partial credit model[22], which could be used for the polytomous ordered categories for each item. The partial credit model postulated that the probability of a given response with respect to the next response was a function (logistic curve) of the severity of the subject's symptoms and of structural parameters. The severity of symptoms, considered as a latent variable, was assumed to have a normal distribution[23]. Finally, we used a regression model to remove the effects of the patient features from the latent severities, and to identify the features with a significant effect on each latent severity variable.

In the partial credit model analysis, a sum-to-zero constraint was imposed on the structural parameters[24]. The model was estimated within a Bayesian framework by means of a Markov-chain Monte Carlo algorithm with Gibbs sampling (using WinBUGS 1.4)[25]. This estimation required that one specified the prior distributions of all parameters, but in the present study, no such a priori information was available; thus non-informative priors (i.e., parameter-flat a priori distributions) were used.

The Bayesian method enabled us to estimate the distribution of each parameter (posterior distribution), from which we could derive the central tendency (posterior mean) along with the Bayesian confidence (or Credibility) interval (CI).

In summary, the unitary bowel-sleep model yielded estimates for each patient of the latent severity of their IBS and sleep disturbances, with their covariance parameters.

Finally, the mean latent severity of IBS and sleep disturbances were correlated with patient features (including IBS subtypes). One category was maintained as the reference and we verified whether the regression coefficient (posterior mean), describing the change from the reference to every other category, was significantly different from zero.

RESULTS

Analysis of the global scores

Patients had IBS-SSS ranging from 120 to 470 (median 280): 10 subjects were classified as mild, 69 as moderate, and 63 as severe. In Table 2, the distribution of responses to the items in the IBS-SSS across categories (low, medium and high) is shown.

The sleep quality in our patients ranged from 1 to 17, with a median PSQI score of 5. Sixty patients were poor sleepers (global PSQI > 5). The distribution of the scores for the items in the PSQI is shown in Table 3.

The correlation between the severity of IBS and sleep disturbances was evaluated by comparing the global IBS-SSS and PSQI scores. Pearson's *r* was found to be 0.2

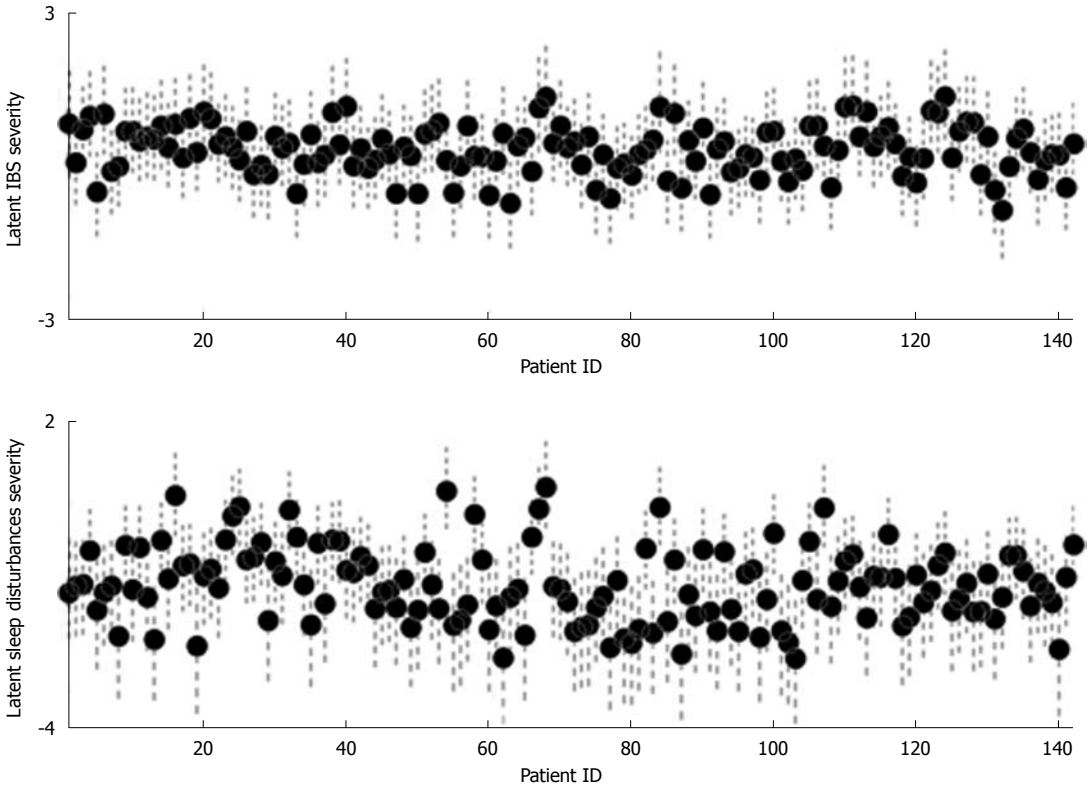

Figure 1 Irritable bowel syndrome latent severity in each patient, with 95% CI (top) and sleep disturbances latent severity in each patient, with 95% CI (bottom). Error bars indicate CI. ID indicates the label of each patient. IBS: Irritable bowel syndrome. CI: Confidence Interval.

Global IBS-SSS		
Mild	7	3
Moderate	44	25
Severe	31	32

IBS-SSS: Irritable bowel syndrome Symptom Severity Score; PSQI: Pittsburgh Sleep Quality Index.

(95% CI: 0.03 to 0.35), indicating a weak significant linear relationship between the two scores. Analysis of a contingency table for IBS-SSS *vs* PSQI categories using Fisher's exact test failed to detect any association between the two indices ($P = 0.18$) (Table 4).

Analysis of the latent severities

To complete the study of the questionnaires, the analysis was extended by modeling the responses to each single item with the partial credit models, and the regression analysis to determine the effect of the individual features on the estimated severity of IBS and sleep disturbances.

In Figure 1, the posterior means of the severity of IBS and sleep disturbances (expressed as latent variables) for the 142 patients are plotted (with their 95% CIs). The

Table 5 For each patient, feature regression coefficients (posterior means) and 95% confidence interval for the latent severities of both irritable bowel syndrome and sleep disturbances are shown

Patient features	Categories	IBS latent severity, coef (95% CI)	Sleep disturbances latent severity, coef (95% CI)
IBS subtype	Mixed	0	0
	Diarrhoea	-0.10 (-0.45 to 0.24)	0.02 (-0.42 to 0.46)
	Constipation	0.32 (-0.05 to 0.69)	0.16 (-0.30 to 0.65)

[1]Significant differences between covariables. IBS: Irritable bowel syndrome. CI: Confidence interval; BMI: Body mass index.

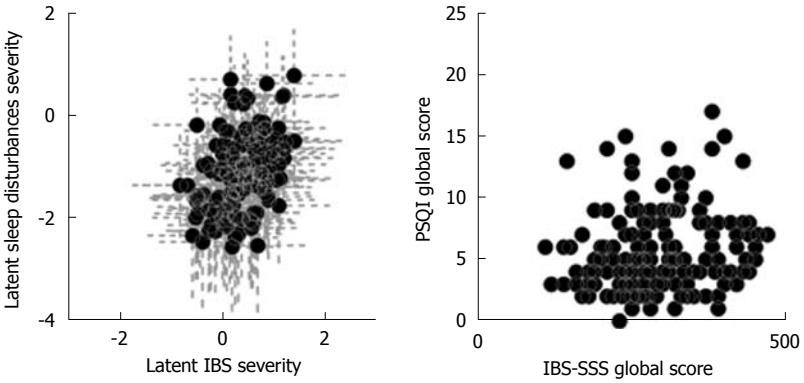

Figure 2 Scatter plot of the global Pittsburgh Sleep Quality Index score *vs* the global irritable bowel syndrome-Symptom Severity Score (left panel), and of sleep disturbances and irritable bowel syndrome latent severities (dots) (right panel). The grey lines indicate the 95% CI. CI: Confidence interval.

latent severity of sleep disturbances was a better discriminant between subjects than IBS, since it showed a more marked between-subject variability: all of the patients had a priori IBS symptoms, whereas the quality of their sleep was measured for the first time in this study.

Our unitary bowel-sleep model demonstrated a significant association between the severity of bowel symptoms and sleep disturbances. In contrast to the results of the global score comparison, a significant intra-subject correlation was found (posterior mean $r = 0.45$ and 95% CI: 0.17 to 0.70).

Figure 2 shows two scatter plots, on the left the IBS-SSS and PSQI global scores, whereas on the right, the two latent severities. The usage of the unitary bowel-sleep model provided a relationship between latent sleep disturbances severity and latent IBS severity. At variance, the usage of global scores did not provide any information about sleep and bowel dysfunction interactions. In the right panel of Figure 2, each black dot corresponds to a single patient and the dashed grey cross indicates the respective CI. Despite the variability between patients, the correlation between the two latent severities was evident, while the scatter plot on the left panel did not confirm any association between the global scores.

Furthermore, the unitary bowel-sleep model allowed us to identify a significant regression between IBS and sleep disturbances latent severities and patient features (Table 5).

The significance of a feature effect corresponded to a significant regression coefficient, and the sign of this coefficient indicated the direction of the relationship: a positive sign signified that the change of category (from the reference one to the other) came with a severity increase and *vice versa*; the 95% CI indicated the significance of the coefficient.

Among the individual features, age was a significant

regressor for both latent severities; young patients (≤ 50 years old) showed more severe bowel disturbances (posterior mean = -0.38) and less severe sleep disturbances (posterior mean = 0.49) than older patients. Daily coffee intake was significantly correlated with severity of bowel disturbances (posterior mean = -0.31); subjects who consumed ≥ 2 cups per day showed less severe bowel disturbances. Sex and daily alcohol intake were found to be significantly correlated with severity of sleep disturbances; female patients exhibited less severe sleep disturbances than male patients, while non-drinkers showed more severe sleep disturbances than those with a moderate alcohol intake. No other life-habit variables were found to be significantly correlated with latent severity of IBS or sleep disturbances.

DISCUSSION

The aim of this study was to evaluate the mutual influences between sleep disturbances and IBS in a large sample of IBS patients. The study provides a detailed statistical analysis of the possible association between bowel disorders, sleep disturbances and life habits.

Our sample may be considered as representative of the IBS population in Italy (this was confirmed by the distribution of IBS subtypes, age and BMI in the cohort). Therefore, our results can be compared and discussed in the light of the results of other studies on IBS patients.

Despite the fact that 42% of the participants had a global PSQI score > 5, only a weak and ambiguous association between IBS-SSS categories and PSQI categories was evident by using standard statistical analysis. Indeed, the correlation coefficient between the global scores was weakly significant and the Fischer exact test did not yield any association.

Conversely a strong link was highlighted by applying the IRT model[26,27] and linear regression.

IRT provides a framework to detect the effect of a series of variables (such as the responses to items on psychological tests) on latent traits of interest (IBS and sleep disturbances). In standard data analyses, the patient's raw score is calculated by summing the scores for the different items, without taking into account differences in the responses to specific items by different patients. It may arise that two patients have the same raw global score but different patterns of symptoms, or different raw global scores but similar symptom patterns. The inability to discriminate between the two possibilities can be resolved by using IRT model, which focuses on individual items rather than the global score. In addition, IRT allows one to introduce covariates (in our case age, BMI, and life habits) and analyze their effect on the parameters of interest.

The IRT model identified a latent link between sleep disturbances and IBS symptoms. These results showed that IBS patients suffered from a considerable degree of sleep impairment, and are in line with those of other studies[8,28,29]. In particular, a recent survey found that sleep disturbances were an independent predictor of IBS in nurses[8].

Through IRT analysis, we also determined that older age, male sex, and no alcohol intake were significant predictors of more severe sleep disturbances.

Our study found that female IBS patients complained with fewer sleep disturbances than males. This would appear to be inconsistent with studies in the general population, which show that females are more likely to suffer from sleep disorders[30], more susceptible to the effects of stress on sleep[31], and after menopause, run a higher risk of developing insomnia[30]. The present findings could be explained by the demographics of our sample, which were characterized by a relatively low mean age and hence a higher percentage of fertile women; indeed, IBS patients tend to be relatively young (< 50 years old)[3].

Evaluation of the predictive parameters for the latent severity of sleep disorders showed that age was positively correlated with sleep disturbances. These data come as no surprise, because aging is widely considered to be a triggering factor for insomnia[32-34].

Finally, this study showed that light alcohol intake was correlated with a lower latent severity of sleep disturbances. It has long been known that a little amount of alcohol consumed by healthy individuals before going to sleep shortens sleep latency, reduces REM sleep, and increases non-REM sleep[35-39]. Alcohol is frequently used as a form of self-medication by patients suffering from sleep disorders, especially insomnia[40].

More unexpectedly, we found that younger age and higher coffee intake were associated with less severe IBS symptoms. The first-line treatment for IBS usually consists of a change in lifestyle and diet, and drinking less coffee is often recommended, even though there are no studies demonstrating a link between the consumption of coffee and the severity of IBS symptoms. Sloots *et al*[41] have reported that the intake of 280 mL of coffee caused no change in rectal compliance or visceral sensibility. However, in our study, coffee drinkers actually consumed no more than two cups per day.

In conclusion, using IRT analysis we found that: (1) there was a positive association between the severity of IBS symptoms and sleep disturbances, and (2) some patient features were significant predictors of severity of IBS and sleep disturbances. These results are consistent with those of other studies[10,14]. The pathophysiological mechanism underlying this association is only partially understood, however. One possibility is that sleep disorders can induce visceral hyperalgesia, which increases the patient perception of gastrointestinal symptoms[8,15]. Several other factors could play a role, including endophenotypic traits such as those associated with stress susceptibility[42].

Further research is needed to clarify whether the association of IBS and sleep disturbances represents comorbidity or the expression of a single disturbance in the brain-gut axis.

COMMENTS

Background

Sleep disturbances connected with gastrointestinal functional disorders, in particular irritable bowel syndrome (IBS), have been reported and some studies have associated sleep alterations with the severity of IBS symptoms. It is not yet known whether it is a simple comorbidity or if there is a direct pathophysiological relationship. To date, a fundamental question has arisen: is sleep disturbance a cause or a consequence of IBS?

Research frontiers

Sleep disturbances represent a negative factor affecting the outcome of several medical and psychiatric conditions, therefore, growing awareness has led some gastroenterologists to investigate sleep as an independent factor also in the pathogenesis and clinical expression of IBS.

Innovations and breakthroughs

Item response theory (IRT) for the first time has been used to identify latent links between digestive symptoms and sleep quality. Furthermore, this unitary bowel-sleep model enabled us to evaluate better the weight of patient features and life habits in the severity of IBS symptoms and sleep disturbances.

Applications

The results of this study suggest: (1) the use of IRT models for uncovering latent links in clinical comorbidity; (2) the importance of studying sleep quality in functional digestive disorders; and (3) further surveys on the clinical mutual interaction between sleep disturbances and functional digestive disorders (i.e., if the treatment of sleep disturbances improves digestive symptoms and/or *vice versa*)

Terminology

IRT is a paradigm for the analysis of tests and questionnaires. IRT models are often referred to as "latent trait models". The term latent is used to emphasize discrete item responses not directly observed but inferred from the manifest responses. IRT brings greater flexibility and provides more sophisticated information and is generally considered an improvement of classical test theory. The Bayesian method enables one to estimate the distribution of each parameter from which one could derive the central tendency.

Peer review

The authors have looked at sleep quality in patients with IBS to evaluate the relationship between digestive symptoms and sleep quality by using IRT analysis. The results are analyzed in detail and the statistical tool of IRT is used to obtain significant associations. The data are solid, the paper is interesting, has clinical significance and is well written.

Abstract

AIM: To determine the associations between leptin and ghrelin concentrations and sustained virological response (SVR) in chronic hepatitis C patients with steatosis.

METHODS: We retrospectively assessed 56 patients infected with hepatitis C virus (HCV) genotype-1 and 40 with HCV genotype-3. Patients with decompensated cirrhosis, and those with other causes of chronic liver disease, were excluded. Serum HCV-RNA concentrations were measured before the initiation of treatment; at weeks 12 (for genotype 1 patients), 24 and 48 during treatment; and 24 wk after the end of treatment. Genotype was determined using INNO-LIPA HCV assays, and serum leptin and ghrelin concentrations were measured using enzyme-linked immunosorbent assay. Biopsy specimens were scored according to the Ishak system and steatosis was graded as mild, moderate, or severe, according to the Brunt classification.

RESULTS: Overall, SVR was positively related to the presence of genotype-3, to biopsy-determined lower histological stage of liver disease, and lower grade of steatosis. Patients $\geqslant$ 40 years old tended to be less responsive to therapy. In genotype-1 infected patients, SVR was associated with a lower grade of liver steatosis, milder fibrosis, and an absence of insulin resistance. Genotype-1 infected patients who did not achieve SVR had significantly higher leptin concentrations at baseline, with significant increases as the severity of steatosis worsened, whereas those who achieved SVR had higher ghrelin concentrations. In genotype-3 infected patients, SVR was associated only with fibrosis stage and lower homeostasis model assessment insulin resistance at baseline, but not with the degree of steatosis or leptin concentrations. Genotype-3 infected patients who achieved SVR showed significant decreases in ghrelin concentration at end of treatment. Baseline ghrelin concentrations were elevated in responders of both genotypes who had moderate and severe steatosis.

CONCLUSION: Increased serum leptin before treatment may predict non-SVR, especially in HCV genotype-1 infected patients, whereas increased ghrelin may predict SVR in genotype-1.

Key words: Hepatitis C virus; Steatosis; Leptin; Ghrelin; Sustained virological response

INTRODUCTION

Hepatic steatosis is a histopathological feature observed in > 50% of patients with chronic hepatitis C (CHC)[1,2], but occurs less frequently in patients with chronic hepatitis B (27%-51%) and autoimmune hepatitis (16%-19%)[3,4]. Steatosis in CHC patients has been attributed to a combination of mechanisms involved in the pathogenesis of non-alcoholic fatty liver disease, as well as to the direct effect of hepatitis C virus (HCV) on hepatic lipid metabolism leading to triglyceride accumulation[5,6]. In contrast, steatosis in patients chronically infected with hepatitis B virus (HBV) is associated with host metabolic factors[7].

Leptin is an adipokine that contributes to the pathogenesis of liver steatosis[8,9]. In patients with CHC, higher serum leptin concentrations have been associated with the presence of steatosis[10]. Although no clear correlation has been observed between leptin concentrations and the extent of steatosis[11], a recent study reported that high serum leptin concentrations correlated with more severe steatosis, lower viremia, and a lower antiviral response, mainly in patients infected with HCV genotype-1, which constituted 71% of the study population[12].

Leptin, the product of the obese (ob) gene, is mainly expressed by adipose tissue, although it is expressed in other organs, including the liver[13]. Leptin plays an important role in the regulation and metabolism of body fat and may induce insulin resistance, increase fatty acid concentrations in the liver, and enhance lipid peroxidation[5,8,9]. Leptin may act as an immunomodulator, inducing the release of cytokines, such as tumor necrosis factor (TNF)-α, interferon (INF)-γ, interleukin (IL)-18, and tumor growth factor (TGF)-β1, thus promoting liver steatosis and fibrosis[8].

Ghrelin is a peptide that acts as an endogenous ligand of the growth hormone secretatog receptor[14]. Ghrelin is involved in energy metabolism, food intake, and glucose homeostasis[14,15]. Recent studies have assessed whether ghrelin acts as an independent signal of adiposity or as a downstream mediator of leptin, affecting energy balance[16].

Little is known about serum ghrelin concentrations in patients with CHC and steatosis, or on the effects of ghrelin concentration on treatment response. We therefore assessed whether pretreatment serum leptin and ghrelin concentrations differ in steatotic patients infected with HCV genotypes-1 and -3, and whether these concentrations are associated with response to antiviral treatment. We also evaluated the correlations between pretreatment serum leptin and ghrelin concentrations and liver histology and metabolic factors, as well as determining whether the impact of antiviral treatment on leptin and ghrelin concentrations differed by HCV genotype.

MATERIALS AND METHODS

Patient population

We retrospectively assessed patients with serologically, virologically, and histologically confirmed CHC, recruited between 2005 and 2008. Patients were included if they had detectable anti-HCV antibody by enzyme-linked immunosorbent assay (ELISA) Ⅲ at least twice a year, detectable serum HCV-RNA by a sensitive PCR assay within 1 mo prior to the start of treatment, liver biopsy showing chronic hepatitis with steatosis within 6 mo before treatment, and elevated alanine aminotransferase (ALT) activity (> 40 IU/L and < 400 IU/L) at entry and at least once during the 6 mo before the first screening.

Patients with decompensated cirrhosis; other causes of chronic liver disease; a history of intravenous drug abuse or alcohol consumption; use of hepatotoxic drugs, herbal medications or immunosuppressive agents; diabetes; thyroid disorders; chronic renal failure; serious psychiatric disorders; HIV or HBV co-infection; or hepatocellular carcinoma, were excluded.

None of these patients had previously received antiviral treatment or steatosis-inducing therapy. The duration of HCV treatment with PEGylated INF-α and ribavirin was genotype-based. Genotype 1 patients who did not achieve undetectable HCV-RNA or a decrease in 2 logs of HCV-RNA at week 12 (early virological response or EVR), were considered non-responders but included in the study. All patients were clinically, hematologically and biochemically evaluated at weeks 2, 4, 8, 12, 24, 48, and 72 after the start of treatment.

The study protocol was approved by our institutional review board, and all patients provided written informed consent. The study conformed to the ethical guidelines of the 1975 Declaration of Helsinki.

Body composition measurements

Height and weight were determined at baseline, and body mass index (BMI), calculated as weight (in kg)/height (in m)^2, was determined at baseline and at the end of treatment. Waist circumference indicative of visceral obesity was defined as > 102 cm in men and > 88 cm in women.

Laboratory and virology assays

Blood samples were obtained from all subjects after overnight fasting, and serum was obtained after centrifugation and stored in aliquots at -70℃ until assayed. Routine biochemical (aspartate aminotransferase, ALT, γ-glutamyl transpeptidase, alkaline phosphatase, glucose, urea, creatinine, cholesterol, triglycerides, albumin) and

hematological (hemoglobin, white blood cells, platelets) were performed using automated techniques.

Serological markers (hepatitis B surface antigen, anti-HBs, hepatitis B e antigen, anti-HBe, anti-HBc total, anti-HCV, anti-HDV, anti-HIV1,2, and anti-HAV IgM and IgG) were assayed using commercially available enzyme immunoassays (Abbott Laboratories, United States). Serum HCV-RNA levels were measured with a PCR assay (Cobas Amplicor HCV version 2, Roche Diagnostics, United States), both qualitatively (lower detection limit of 50 IU/mL) and quantitatively (range of detection 600-10^6 IU/mL). HCV genotype was determined using an INNO-LIPA HCV assay (Innogenetics, Belgium). Serum HCV-RNA concentrations were measured before the initiation of treatment, at weeks 12 (for genotype 1 patients), 24, and 48 during treatment, and 24 wk after the end of treatment. Serum leptin and ghrelin concentrations were measured using ELISA kits (BioVendor Laboratory, United States), at screening and at the end of treatment and expressed as ng/mL. Insulin resistance index was calculated as: insulin resistance [homeostasis model assessment insulin resistance (HOMA-IR)] = fasting insulin (mIU/L) × fasting glucose (mmol/L)/22.5.

Liver histology

Liver biopsies were obtained at baseline using the Menghini technique (mean length of biopsy cores, 1.7 cm). Liver tissue was fixed in 10% neutral formalin and paraffin-embedded sections were stained with hematoxylin-eosin and Masson trichrome stains. Liver biopsies were scored by an experienced liver pathologist using the Ishak scoring system. Steatosis was quantified as the percentage of hepatocytes that contained fat droplets and was graded using a three-tier scale: grade 1/mild (1%-33%), 2/moderate (33%-66%), and 3/severe (> 66%). Patients with histopathological findings of steatohepatitis, including hepatocellular ballooning or perisinusoidal fibrosis in zone 3, were excluded.

Statistical analysis

All continuous variables are presented as mean ± SD or medians ± interquartile ranges (75th-25th percentiles) if they deviated from normality. The association between each genotype and continuous variables was determined by ANOVA (using post-hoc Scheffe's test when the omnibus test was significant) or Student's *t*-test. The association between each genotype and categorical variables was determined using the χ^2 test. Multiple logistic regression analyses were used to determine the association between response to therapy and leptin concentrations, ghrelin concentrations, hepatic steatosis, fibrosis, and HOMA-IR, with results presented as odds ratios and 95% CI. These analyses were performed separately for each genotype and for measurements at baseline and at the end of follow up. For reasons of multicollinearity, it was not possible to include steatosis and fibrosis in the same model. Therefore, fibrosis and steatosis were alternatively introduced (one at a time) into the core model. Mixed effect models were used to examine the relationship between baseline and end of follow-up leptin and ghrelin concentrations among responders and non-responders. There were no significant changes in weight or fat composition in the study population during treatment; therefore, there was no need to adjust leptin and ghrelin concentrations for BMI after treatment. All reported probability values (*P*-values) were based on two-sided tests, with significance set at 0.05. All statistical analyses were performed using the SAS statistical package (Version 9.1, SAS Institute Inc., NC).

Table 1 Clinical, virological, and histological data of the study population (mean ± SD) *n* (%)

	SVR (*n* = 62)	Non-SVR (*n* = 34)	*P*-value
Age	35.01 ± 1.57	39.21 ± 2.07	0.050
Sex (male/female)	36/26	21/13	
BMI	24.700 ± 0.179	25.530 ± 0.637	0.060
Genotype-1	32 (57.1)	24 (42.9)	
Genotype-3	30 (75)	10 (25)	
Stage (0-6)	1.661 ± 0.095	2.412 ± 0.141	< 0.001
Grade (0-18)	5.371 ± 0.136	5.265 ± 0.204	NS
Steatosis (1-3)	1.565 ± 0.082	2.060 ± 0.126	0.001

NS: Non-significant; SVR: Sustained virological response; BMI: Body mass index.

RESULTS

Of the 154 treatment-naive patients with CHC screened, 96 fulfilled our enrollment criteria and completed treatment. The study population consisted of 60 men and 36 women, all of Caucasian origin; of these, 56 were infected with HCV genotype-1 and 40 with HCV genotype-3.

HCV genotypes and response to treatment

All patients received combination therapy with PEGylated INF a-2b or a-2a, plus weight-adjusted ribavirin, for 24 (genotype-3) or 48 (genotype-1) weeks. All tolerated treatment well and completed treatment without any major side effects, significant reductions in drug dose, and significant changes in BMI (reduction more than 2 kg/m^2). Patients infected with HCV genotype-1 who did not achieve sustained virological response (SVR) stopped therapy, whereas those infected with HCV genotype-3 were treated for 24 wk without measurements of HCV-RNA at week 12, according to currently approved treatment guidelines. Of the 96 patients, 62 (64.6%) achieved SVR, whereas the remaining 34 (35.4%) did not.

Clinical, virological, and histological data of patients of both genotypes who did and did not attain SVR are presented in Table 1. Of the 56 patients with genotype 1, 32 (57.1%) achieved SVR, compared with 30 of 40 patients (75%) with genotype-3; thus SVR was significantly related to infection with genotype-3 ($P < 0.05$). In addition, SVR was significantly associated with lower histological stage of liver disease ($P < 0.001$) and lower grade of steatosis in liver biopsy ($P = 0.001$). Patients ⩾

[1]Adjusted for both leptin and ghrelin concentrations. NS: Non-significant.

40 years old tended to be less responsive to therapy (P = 0.05) (Table 1). Further analysis by genotype showed that, in genotype-1 infected patients, SVR was associated with a lower grade of liver steatosis (P = 0.0001), mild fibrosis (P = 0.001), and absence of insulin resistance (P = 0.01) (Table 2). In genotype-3 infected patients, SVR was associated with stage of fibrosis (P = 0.04) and lower HOMA-IR at baseline (P = 0.01), but not to degree of steatosis (Table 2).

Leptin, ghrelin and response to treatment

Baseline leptin concentrations did not differ between patients who did and did not attain SVR, but were significantly lower after successful treatment in patients who attained SVR (P = 0.01) (Table 3). Among patients infected with HCV genotype-1, non-responders had significantly higher serum leptin concentrations, both at baseline (P = 0.001) and at the end of follow-up (P < 0.0001) than those who attained SVR (Table 2). Using mixed effect model analysis, we observed a statistically significant difference between baseline and follow-up leptin concentrations among genotype-1 infected patients who achieved SVR (P = 0.001), as well as a borderline significant difference among non-responders (P = 0.06) (Table 4).

Among patients infected with HCV genotype-3, however, there were no significant differences in leptin concentrations at baseline and at end of follow-up between those who did and did not achieve SVR (Table 2). Using mixed effect model analysis, leptin remained unchanged, both in responders (P = 0.51) and non-responders (P = 0.61) (Table 4).

Overall, patients who achieved SVR had higher serum ghrelin concentrations, both at baseline (P = 0.01) and at the end of follow up (P = 0.05), than patients who did not achieve SVR (Table 3). Genotype-1 infected patients who achieved SVR had statistically significant higher ghrelin concentrations at baseline (P = 0.02) and at the end

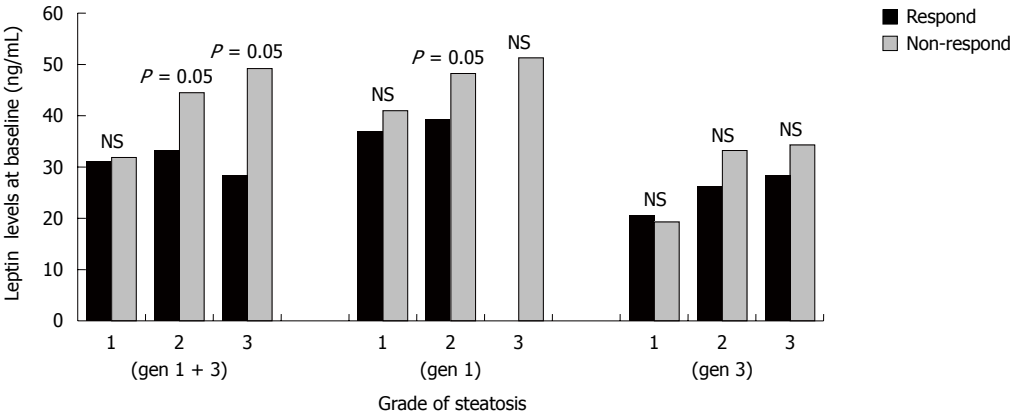

Figure 1 Correlation between leptin concentrations and steatosis in patients infected with hepatitis C virus genotypes-1 and -3 who did and did not achieve sustained virological response following treatment with PEGylated interferon a-2b or a-2a plus ribavirin. NS: Not significant.

Table 4 Leptin and ghrelin concentrations at baseline and at end of follow-up by response to treatment in patients with hepatitis C virus genotypes-1 and -3, as well as mixed effect model derived estimates of the differences in mean scores (mean ± SD)

Variable	Baseline	End of follow-up	*P*-value for the adjusted difference[1]
Genotype 1 SVRs			
Leptin (ng/mL)	37.66 (10.39)	26.69 (11.77)	0.001
Ghrelin (ng/mL)	0.286 (0.167)	0.456 (0.254)	0.001
Genotype 1 non-SVRs			
Leptin (ng/mL)	49.67 (13.44)	43.58 (16.17)	0.060
Ghrelin (ng/mL)	0.190 (0.119)	0.239 (0.213)	0.320
Genotype 3 SVRs			
Leptin (ng/mL)	24.33 (7.98)	23.27 (9.54)	0.510
Ghrelin (ng/mL)	0.778 (0.654)	0.420 (0.321)	0.001
Genotype 3 non-SVRs			
Leptin (ng/mL)	28.20 (9.72)	26.70 (6.82)	0.610
Ghrelin (ng/mL)	0.564 (0.324)	0.450 (0.261)	0.470

[1]Adjusted for both leptin and ghrelin concentrations.

of treatment ($P = 0.001$) than nonresponders (Table 2), with responders showing significantly higher ghrelin concentrations at end of treatment than at baseline ($P = 0.001$) (Table 4). In contrast, ghrelin concentrations in genotype-3 infected patients did not differ between responders and nonresponders, both at baseline and at the end of treatment (Table 2). Mixed effect model analysis showed that ghrelin concentrations were significantly lower at the end of treatment than at baseline in patients who achieved SVR ($P = 0.001$), but not in non-responders ($P = 0.47$) (Table 4).

Leptin, ghrelin and steatosis

Overall, steatosis grade at baseline was higher in non-responders than in patients who achieved SVR, with steatosis grade at baseline being significantly greater as leptin concentrations increased, a difference more obvious in patients with moderate and severe steatosis ($P = 0.05$). This correlation was also observed in genotype-1 non-responders, but not in genotype-3 non-responders or in patients of either genotype who achieved SVR (Figure 1).

Ghrelin concentration at baseline was higher in responders of both genotypes with moderate ($P = 0.05$) and severe ($P = 0.001$) steatosis. In non-responders, however, there was no significant correlation between the grade of steatosis and ghrelin concentrations. In genotype-1 infected patients, both in responders and non-responders, ghrelin concentrations decreased significantly as the grade of steatosis increased ($P = 0.01$), and responders with genotype-3 and moderate or severe steatosis had significantly higher serum concentrations of ghrelin ($P = 0.01$) (Figure 2). A strong correlation between the severity of steatosis and higher viral load at baseline was observed in patients infected with HCV genotype-3 ($P = 0.01$), but not in those infected with HCV genotype-1 (P = NS) (Figure 3).

Multivariate analysis

Using multivariate logistic regression analysis, we found that higher leptin concentrations at baseline were significantly associated with non-response to therapy in patients infected with HCV genotype-1, but not HCV genotype-3. There were no significant associations between response to treatment and ghrelin concentrations in patients of either genotype. Furthermore, HCV genotype-1 infected with moderate or severe steatosis, as well as those with more severe fibrosis, were less likely to respond to therapy (Table 5). In patients with genotype-3, however, there were no significant associations between response to treatment and steatosis, fibrosis, or leptin or ghrelin concentrations, both at baseline and at end of treatment. Only patients with higher levels of HOMA (IR) seemed less likely to respond to therapy (Table 6).

DISCUSSION

The mechanism by which HCV induces steatosis remains unclear. Steatosis in patients infected with the non-3 genotype has been associated with increased BMI, visceral obesity, increased cholesterol and triglyceride concentra-

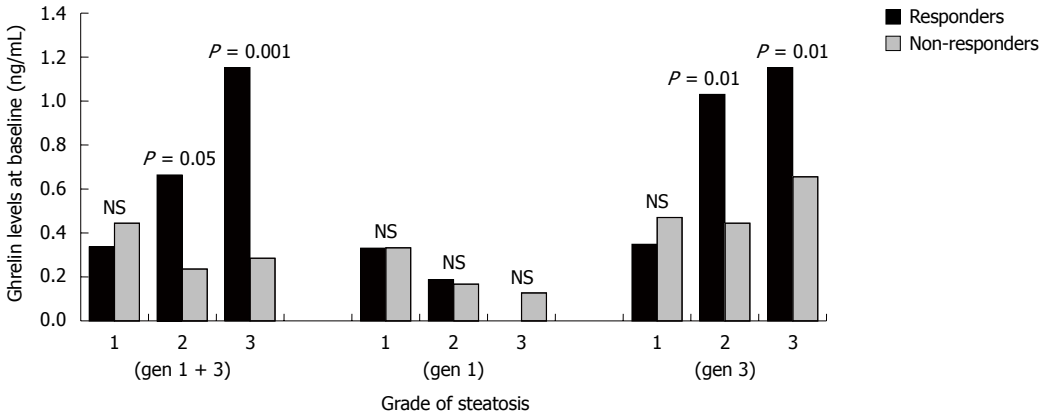

Figure 2 Correlation between ghrelin concentrations levels and steatosis in patients infected with hepatitis C virus genotypes11 and -3 who did and did not achieve sustained virological response following treatment with PEGylated interferon a-2b or a-2a plus ribavirin. NS: Not significant.

tions, insulin resistance, metabolic syndrome, diabetes, alcohol consumption, and increased sensitivity of the liver to oxidative stress or cytokine-mediated injury[17,18].

Leptin is a putative link between HCV infection and steatosis[19]. Although a high incidence of hyperleptinemia has been observed in HCV infected patients with liver steatosis[10,20], the underlying mechanism promoting this effect remains undefined. Leptin may increase insulin resistance and fatty acid concentrations in the liver, leading to enhanced lipid peroxidation and promoting steatosis[5]. Leptin may also induce the release of cytokines, such as TNF-α, INF-γ, IL-18, and TGF-β1, which are involved in the pathogenesis of both liver steatosis and fibrosis[8]. In steatosis, activated hepatic stellate cells, but not quiescent cells, can express leptin[21].

Our results clearly show that, in HCV infected patients with liver steatosis, serum leptin levels tend to increase as the grade of steatosis worsens. This finding is significant, especially in genotype-1 patients, suggesting that leptin increases during infection as a part of the host immune response, and may contribute to the development of steatosis. Although steatosis is more common

and more severe in patients infected with HCV genotype-3[17,18], we found that leptin concentrations were not correlated with either the grade of steatosis or response to treatment. Structural and nonstructural proteins of HCV genotype-3 may directly cause steatosis by provoking oxidative stress[6,22,23]. Alternatively, the viral core protein may target microsomal triglyceride transfer protein activity, modifying very low density lipoprotein assembly in, and secretion by hepatocytes[24,25]. The core protein may also affect the cytoplasmic domain of members of the TNF receptor family or act directly on the mitochondria, leading to increased oxidative stress and lipid peroxidation[26]. In patients infected with HCV genotype-3,

we found that the grade of steatosis was correlated with higher viral load at baseline, in agreement with the direct "steatogenic" effect of this genotype[6].

Although ghrelin is important in food intake, energy balance, and the regulation of the growth hormone releasing mechanism[15], its role in hepatic disease has not been extensively evaluated to date. Increased serum ghrelin concentrations have been reported in patients with cirrhosis and hepatocellular carcinoma, suggesting that this adipokine may be involved in the anorexia-cachexia syndrome during the terminal stages of liver diseases[27]. Data on ghrelin concentrations in patients with CHC are limited[28].

We found that genotype-1 responders had higher serum ghrelin concentrations at baseline than non-responders, and that its concentration increased significantly in the former at the end of treatment, indicating that ghrelin may prevent or reduce steatosis by negatively regulating leptin. This may enhance the likelihood of SVR, since responders also have lower baseline leptin concentrations. In genotype-3 infected patients, however, ghrelin may be considered an independently acting factor, based on our finding that responders with moderate and severe steatosis had high ghrelin concentrations at baseline and that these concentrations were reduced significantly after treatment. In contrast, no significant differences were observed in non-responders and there were no correlations with leptin concentrations.

Our findings are in accordance with previous reports, which found that steatosis was an independent negative predictor of response to antiviral therapy[29-32]. We also found that genotype 1 patients with elevated leptin concentrations before treatment had a lower likelihood of achieving SVR, irrespective of their viral load. This observation is in keeping with the role of leptin as a suppressor of cytokine signaling 3 in the liver[33], or as a factor that inhibits INF signaling.

In conclusion, our results suggest that the extent of hepatic steatosis, in addition to the stage of fibrosis and the viral genotype, may affect the likelihood of SVR in CHC patients. Leptin appears to contribute to the pathogenesis of steatosis, and we found that elevated serum leptin concentration may be an independent predictor of SVR in HCV genotype-1 infected patients. Increase ghrelin concentrations after successful treatment in genotype 1 patients indicate that this peptide plays a role in the achievement of SVR. Further investigations are needed to determine whether ghrelin acts as a downstream mediator of leptin and to assess the influence of ghrelin on liver steatosis and HCV infection.

COMMENTS

Background

Steatosis is a frequent histopathological feature in patients with chronic hepatitis C (CHC). Leptin and ghrelin are involved in body fat regulation and metabolism. Higher serum leptin concentrations have been associated with steatosis, but less is known about leptin and ghrelin concentrations in patients with CHC and steatosis or the effect of these peptides on response to treatment.

Research frontiers

Leptin is a putative link between hepatitis C virus (HCV) infection and steatosis in HCV genotype-1 infected patients; however, the underlying mechanism remains undefined. Increased ghrelin concentrations have been reported in patients with cirrhosis and hepatocellular carcinoma, but its role in hepatic steatosis has not been extensively evaluated. Steatosis is an independent negative predictor of response to antiviral therapy. Our results clearly show that, in HCV infected patients with steatosis, serum leptin levels tend to increase as the grade of steatosis worsens. Non-responding genotype-1 infected patients have elevated leptin at baseline and genotype-1 and -3 responders have higher ghrelin concentrations at baseline. In genotype-3 infected patients, neither the degree of steatosis nor leptin concentration had any effect on response to treatment.

Innovations and breakthroughs

Several studies have highlighted the importance of steatosis and hyperleptinemia in the achievement of sustained virological response (SVR), but this study is the first to find genotype-dependent associations between the degree of steatosis and leptin and ghrelin concentrations. These findings show the significance of baseline leptin and ghrelin concentrations in the achievement of SVR, as well as the impact of antiviral treatment on serum leptin and ghrelin levels.

Applications

These findings suggest that serum leptin concentrations may be an independent negative predictor of SVR in HCV genotype-1 infected patients with steatosis; the role of ghrelin requires be further investigation.

Terminology

Leptin, the ob gene product, is expressed mainly by adipose tissue, although it is expressed in other organs, including the liver. Leptin is important for body fat regulation and metabolism. Ghrelin, a peptide that acts as an endogenous ligand for the growth hormone secretatog receptor, is involved in energy metabolism, food intake and glucose homeostasis.

Peer review

The research study has an important outcome and could be further strengthened by exploring the existing data for an effect of sex on these parameters, if any.

Abstract

AIM: To investigate the *in vitro* effects of pantoprazole on rat lower esophageal sphincter (LES) tone.

METHODS: Rats weighing 250-300 g, provided by the Yeditepe University Experimental Research Center (YÜDETAM), were used throughout the study. They were anesthetized before decapitation. LES tissues whose mucosal lining were removed were placed in a standard 30-mL organ bath with a modified Krebs solution and continuously aerated with 95% oxygen-5% carbon dioxide gas mixture and kept at room temperature. The tissues were allowed to stabilize for 60 min. Subsequently, the contractile response to 10^{-6} mol/L carbachol was obtained. Different concentrations of freshly prepared pantoprazole were added directly to the tissue bath to generate cumulative concentrations of 5×10^{-6} mol/L, 5×10^{-5} mol/L, and 1.5×10^{-4} mol/L. Activities were recorded on an online computer *via* a 4-channel transducer data acquisition system using the software BSL PRO v 3.7, which also analyzed the data.

RESULTS: Pantoprazole at 5×10^{-6} mol/L caused a small, but statistically insignificant, relaxation in the carbachol-contracted LES (2.23% *vs* 3.95%). The 5×10^{-5} mol/L concentration, however, caused a significant relaxation of 10.47% compared with the control. 1.5×10^{-4} mol/L concentration of pantoprazol caused a 19.89% relaxation in the carbachol contracted LES ($P < 0.001$).

CONCLUSION: This is the first study to demonstrate that pantoprazole has a relaxing effect in isolated LESs. These results might have significant clinical implications for the subset of patients using proton pump inhibitors who do not receive full symptomatic alleviation from gastroesophageal reflux disease.

Key words: Pantoprazole; Lower esophageal sphincter, Gastroesophageal reflux disease

INTRODUCTION

The esophagogastric junction is located between the esophagus and the stomach. The high-pressure zone at the junction between the esophagus and the stomach is composed of the lower esophageal sphincter (LES) and

the crural diaphragm[1,2]. Circular smooth muscle from the esophageal body generates little if any tone at rest, whereas the circular smooth muscle of LES is characterized by a spontaneously generated basal tone that prevents the reflux of gastric contents into the esophagus[3,4]. The basal tone of the LES is primarily myogenic in origin, but can be modulated by both neural and hormonal factors[5]. In response to esophageal distension and swallowing, the LES relaxes[6]. The abnormal dynamics of LES function are considered to be the most important factors in the pathogenesis of gastroesophageal reflux disease (GERD)[7-10]. GERD is described as the reflux of gastric contents into the esophagus leading to reflux symptoms and esophagitis sufficient to affect patient wellbeing and/or induce complications. These complications range from esophagitis to adenocarcinoma of the distal esophagus. Furthermore it may cause extra esophageal symptoms, such as cough, laryngitis and asthma[11,12]. GERD is a highly prevalent in the general population, affecting up to 10%-30% of the adult population in western countries[13].

Pharmacological therapy is necessary in the majority of patients. GERD is currently treated with acid suppressing drugs, such as proton pump inhibitors (PPIs); however, for those refractory to pharmacological treatment, surgery is often recommended[13,14]. PPIs are the mainstay of medical management for GERD[11]. They have been widely used since the 1980s and have been considered as ideal drugs because of their highly specific pharmacologic actions[15,16]. Although PPIs have been used as a common treatment modality in GERD, there is a lack of experimental studies of their effects on isolated LES preparations.

The aim of this study was to investigate the effect of a PPI, pantoprazole, on the tone of the isolated rat LES preparations contracted by carbachol. This study provides a significant contribution to this somewhat ignored area of research.

MATERIALS AND METHODS

The experimental protocol was approved by the Ethical Committee of Yeditepe University Experimental Medicine Research Institute and the use of animals was in compliance with US National Institutes of Health Guide for Care and Use of Laboratory Animals.

Sixteen rats weighing 250-300 g, provided by the Yeditepe University Experimental Research Center (YÜDETAM), were used throughout the study. They were kept in plexiglass cages in a room whose temperature and humidity were controlled with 12-h light/dark cycle, and had free excess to food and water.

Rats were anesthetized with a combination of 10 mg/kg xylazine HCl (Rompun® 2%, Bayer HealthCare AG, Leverkusen-Germany) and 100 mg/kg ketamine HCl (Ketasol® 10%, Richter Pharma AG, Weis-Austria) before decapitation.

A midline incision was performed to open up the abdominal cavity and the LES was carefully dissected out and placed in a petri dish containing Krebs solution at room temperature. Thereafter, the mucosal lining was removed and the sphincteric muscle was set up, as a ring segment 2 mm in width, in Krebs solution contained in a standard 30-mL organ bath. The modified Krebs solution comprised NaCl, 118.07 mmol/L; KCl, 4.69 mmol/L; $CaCl_2$, 2.52 mmol/L; $MgSO_4$, 1.16 mmol/L; KH_2PO4, 1.2 mmol/L; $NaHCO_3$, 25 mmol/L, and glucose, 11.10 mmol/L. Krebs solution was continuously aerated with 95% oxygen-5% carbon dioxide gas mixture and kept at 37 ± 0.5 ℃ throughout the experimental period. The tissues were tied to stainless steel hooks at one end of the organ bath; the other end was connected to a force transducer (FDT 05, May, COMMAT Iletisim Co, Ankara-Turkey) under a resting tension of around 1 g. LES ring activities were recorded on an online computer *via* a 4-channel transducer data acquisition system (MP35, BIOPAC Systems Inc. Goleta, CA, United States) using the software BSL PRO v 3.7 (BIOPAC Systems Inc. Goleta, CA, United States), which also analyzed the data.

The following compounds were used: carbachol chloride (Carbamylcholine chloride, Sigma-Aldrich Chemical Co. St. Louis, MO, United States) and pantoprazole (Pantoprazole sodium, Dr. Reddy's Laboratories Ltd. Hyderabad-India). Solutions were prepared daily in distilled water and kept at 4 ℃ during the experiments. Pantoprazole was treated with 1 mol/L HCl and its pH was adjusted to 4.0 before application to the organ bath. Following a 60-min equilibration period for stabilization, the contractile response to carbachol was obtained by application of a single dose of charbachol to a final concentration of 10^{-6} mol/L in the organ bath. After the contractions reached a plateau, concentration-response relationships for pantoprazole (final organ bath concentrations of 5×10^{-6} mol/L, 5×10^{-5} mol/L and 1.5×10^{-4} mol/L, with 15 min allotted between each dose) were obtained in a cumulative manner. (These doses were calculated to be the equivalent of Human doses for the rats). Control experiments were also run with only acidified distilled water added to the organ bath. The relaxations were quantified by integrating the area under the curve for each concentration and control group. At the end of the each experiment, tissues were weighed and the final pH of the Krebs solution was measured.

Statistical analysis

For statistical evaluation, analysis of variance (One way ANOVA) was performed with the program SPSS for windows version 18 (SPSS Inc. Chicago, Illinois). Values of $P < 0.05$ were considered as statistically significant.

RESULTS

The experiment design is outlined in Figure 1. Pantoprazole caused dose dependent relaxation of the carbachol-contracted LES preparations. No such effect was observed in the control group (Figure 1B). The relaxations were quantified by integrating the area under the curve

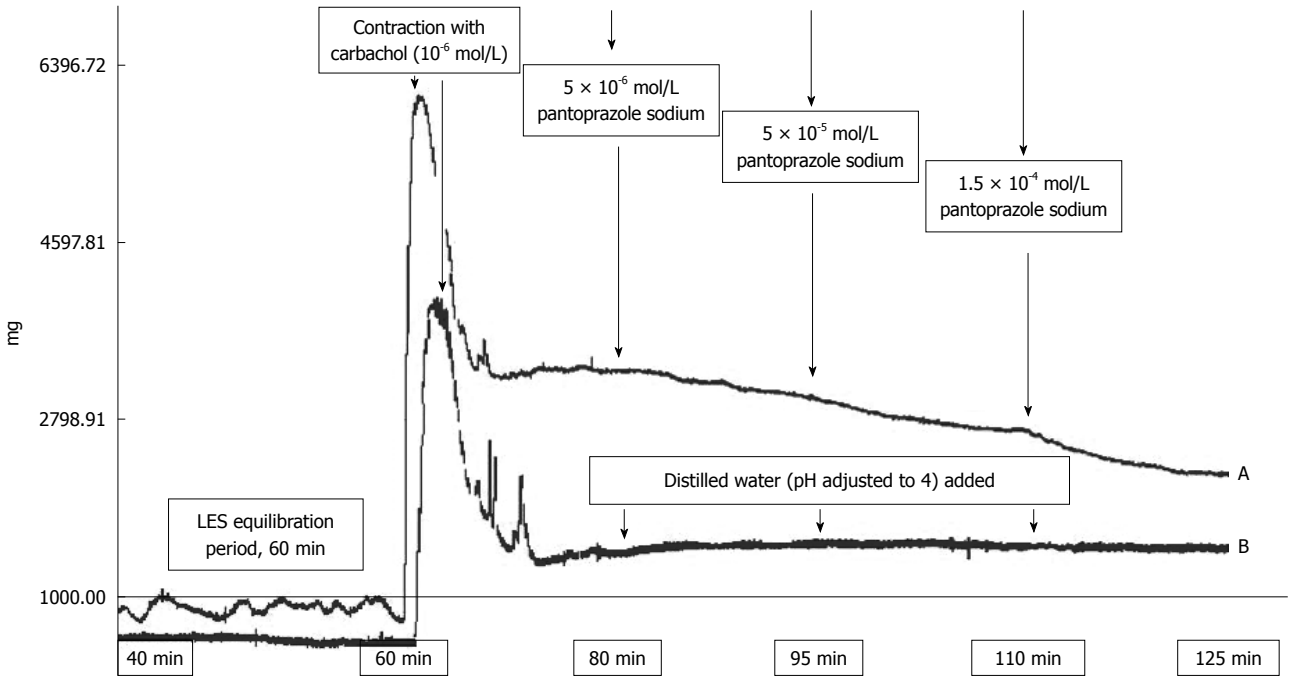

Figure 1 Outline of the experimental procedure. A: The tissues were allowed to stabilize for 60 min in Krebs-containing organ baths. Following that period, their contractile response to 10^{-6} mol/L carbachol was obtained. Pantoprazole was treated with 0.1 mol/L HCl and the pH of the drug solution was adjusted to 4.0. Different concentrations of pantoprazole were added directly to the tissue bath to generate cumulative concentrations of 5×10^{-6} mol/L, 5×10^{-5} mol/L and 1.5×10^{-4} mol/L. The relaxations were quantified by integrating area under the curve for each concentration; B: For the control experiments, acidified distilled water was added at the same time points. LES: Lower esophageal sphincter.

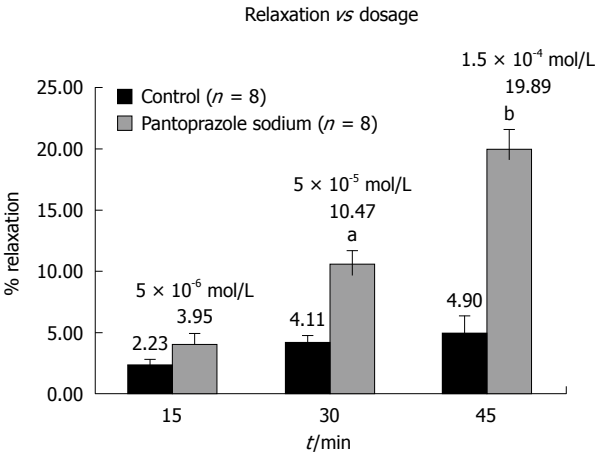

Figure 2 Relaxation *vs* Dosage. 5×10^{-5} mol/L and 1.5×10^{-4} mol/L pantoprazole sodium induced significant relaxation in lower esophageal sphincter preparations *in vitro* ($^{a}P < 0.05$ and $^{b}P < 0.001$). Each bar represents percent relaxation ± SEM for both control and experiment groups. Numbers in parentheses indicate the number of preparations used from different animals.

for each concentration.

The mean of integral values and percent relaxations of eight preparations were compared for statistical evaluation. As shown in Figure 2, application of pantoprazole sodium in a cumulative manner resulted in significant relaxations of LES preparations at 5×10^{-5} mol/L and 1.5×10^{-4} mol/L concentrations.

In the carbachol-contracted LES preparations 5×10^{-6} mol/L pantoprazole caused a 4% relaxation, while higher doses caused significant relaxations. Mean integral relaxation values were 4.11% ± 0.58% (SE) and 10.47% ± 1.2% (SE) for control and 5×10^{-5} mol/L pantoprazole, respectively ($P < 0.05$). Moreover, these values were 4.90% ± 1.4% (SE) and 19.89% ± 1.7% (SE) for control and 1.5×10^{-4} mol/L concentrations, respectively ($P < 0.001$) (Figure 2).

DISCUSSION

The aim of the present work was to assess the *in vitro* effects of pantoprazole on LES tone in rats. The reason why pantoprazole was chosen was the drug's frequent use in our Clinic. The major finding of our study was that pantoprazole caused a dose-dependent decrease in LES tone. This is the first study to demonstrate that pantoprazole has such an effect on isolated LES.

LES is an important specialized smooth muscle in the gastrointestinal tract and has been the subject of investigation by many authors[17-20]. GERD is a highly prevalent condition and is a major burden to society as well as the afflicted individual. Although numerous clinical studies have been conducted to clarify the mechanism of GERD, a clear consensus has not been reached. Regarding the pathophysiologies of GERD, decrease of LES basal tone and transient relaxations of the LES (TLOSRs) as a response to gastric distension[21], and excessive exposure of the esophagus to gastric acid, have been reported to be important[21-24].

GERD is, in most cases, successfully treated with PPIs, which have largely replaced Histamine H_2 receptor blockers because of their well documented efficacy

and because they are well tolerated, with relatively few serious adverse effects. However, a significant number of patients do not receive full symptomatic relief[25,26]. Thus, a significant question that has to be addressed is why some GERD patients are resistant to the effects of PPIs? In addition to neonates and infants who respond poorly to PPIs[27], some adults do not benefit from them either. In a study conducted by Hemmink *et al*[28] in 2008, there were fewer acid reflux episodes in patients on PPI therapy; however, weak acidic reflux episodes increased under the influence of PPIs. The total number of reflux episodes, on the other hand, was not affected. In addition to these, there have been recent papers regarding the adverse effects of PPIs[29,30]. Corley *et al*[31] showed that PPIs are associated with hip fractures among at-risk patients. They can also cause neutropenia in some patients[32]. Acid suppression also causes nosocomial *Clostridium* difficile infections in a dose-dependent manner[33].

These results point out the necessity of developing novel approaches for GERD. Coman *et al*[34] demonstrated the significance of adding prokinetic drugs to the treatment of GERD, in a study conducted on 1118 patients. The effects of specific GABA B receptor agonists have also been studied[35]. Drugs that reduce TLOSRs have also been suggested as pharmacological agents for GERD[36].

At present, the mechanism of the pantoprazole-induced relaxation of LESs can only be speculated. However, there are 2 types of muscles in the LES, circular muscle and sling muscle. Circular smooth muscle is tonically contracted with cholinergic stimulation. In response to swallowing, a peristaltic contraction travels down the length of the esophagus and the LES relaxes.

Nitric oxide (NO)[37,38] and vasoactive intestinal polypeptide (VIP)[39,40] are proposed as neurotransmitters that control relaxation. Both VIP and NO can be released from esophageal nerves with an appropriate stimulus, and NO synthase and VIP are found in myenteric neurons that innervate the circular smooth muscle of the esophagus. Sarioglu *et al*[41], showed the relaxant effect of omeprazole in rabbit corpus cavernosum *in vitro*. They concluded that the relaxant effect is probably due to the L-type Ca^{2+} channel blockage by omeprazole. We can speculate that a similar mechanism is responsible for the effect of pantoprazole on LESs.

The present study is the first to demonstrate a dose-dependent decrease in the carbachol-induced contraction of the LES by pantoprazole. Although this finding has been observed in an isolated tissue, it might have some clinical correlates and might help to understand why the treatment of GERD requires additional pharmacological interventions.

ACKNOWLEDGMENTS

The present study was supported by Yeditepe University. The authors are indebted to Ahmet Ayar Dr. Professor for his valuable methodological advice.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a highly prevalent condition in the general population, affecting up to 10%-30% of the adult population in Western countries[13]. The incidence of GERD is rising very rapidly due to the stressful lives. New approaches are necessary for its treatment.

Research frontiers

Not all patients benefit from the proton pump inhibitors (PPIs) that are frequently used for the treatment of GERD. The authors conducted an experiment to investigate the effects of these drugs on isolated rat lower esophageal sphincters (LESs). There was a dose dependent decrease in LES tone.

Innovations and breakthroughs

The study conducted is the first to demonstrate the effects of pantoprazole on the isolated LESs of rat, including the dose dependent decrease in the tone of LESs under the effect of the drug.

Applications

The study suggests that doctors should be cautious about long-term use of PPIs for the treatment of GERD.

Peer review

This paper should be of interest to a broad readership including gastroenterologists, pharmacologists, and physicians of internal medicine. It is also of interest to gastrointestinal surgeons. This paper is very interesting and is an important study to publish.

Abstract

AIM: To validate the clinical relevance of autofluorescence imaging (AFI) endoscopy for the assessment of inflammatory ulcerative colitis (UC).

METHODS: A total of 572 endoscopic images were selected from 42 UC patients: 286 taken with white light imaging (WLI) and 286 with AFI from the same sites. WLI images were assessed for overall mucosal inflammation according to Mayo endoscopic subscore (MES), and for seven characteristic endoscopic features. Likewise, AFI photographs were scored according to relative abundance of red, green and blue color components within each image based on an RGB additive color model. WLI and AFI endoscopic scores from the same sites were compared. Histological evaluation of biopsies was according to the Riley Index.

RESULTS: Relative to red (r = 0.52, P < 0.01) or blue (r = 0.56, P < 0.01) color component, the green color component of AFI (r = -0.62, P < 0.01) corresponded more closely with mucosal inflammation sites. There were significant differences in green color components between MES-0 (0.396 ± 0.043) and MES-1 (0.340 ± 0.035) (P < 0.01), and between MES-1 and ⩾ MES-2 (0.318 ± 0.037) (P < 0.01). The WLI scores for "vascular patterns" (r = -0.65, P < 0.01), "edema" (r = -0.62, P < 0.01), histology scores for "polymorphonuclear cells in the lamina propria" (r = -0.51, P < 0.01) and "crypt architectural irregularities" (r = -0.51, P < 0.01) showed correlation with the green color component of AFI. There were significant differences in green color components between limited (0.399 ± 0.042) and extensive (0.375 ± 0.044) (P = 0.014) polymorphonuclear cell infiltration within MES-0. As the severity of the mucosal inflammation increased, the green color component of AFI decreased. The AFI green color component was well correlated with the characteristic endoscopic and histological inflammatory features of UC.

CONCLUSION: AFI has application in detecting inflammatory lesions, including microscopic activity in the colonic mucosa of UC patients, based on the green color component of images.

Key words: Autofluorescence imaging endoscopy; Endoscopic activity; Histological activity; Microscopic inflammation; Green color component

INTRODUCTION

Ulcerative colitis (UC) activity is routinely assessed by a combination of clinical, endoscopic, and histological findings. However, systematic measurement of disease activity in UC patients is essential for determining the efficacy of treatment interventions. Endoscopy in particular is the most immediate and objective method for evaluating colonic mucosal damage. Furthermore, the severity of mucosal inflammation in UC is evaluated based on several disease activity indices, but there is no validated gold standard. To standardize the assessment of disease activity for clinical trials, in 1987, Schroeder *et al*[1] described the Mayo Score, which includes endoscopic findings. This index includes the factors "erythema", "vascular pattern", "friability", "erosion" and "spontaneous bleeding". "Edema" and "granularity" are also factored in other endoscopic indices, such as Matts' endoscopic activity index. These features are considered to be characteristic endoscopic findings in UC. However, inter- and intra-observer variations, and variations depending on the observer's experience in the endoscopic assessment of UC based on conventional endoscopy, have been reported[2].

Histological activity generally shows strong correlation with the activity evaluated by endoscopy. However, microscopic evaluations reflect clinical symptoms more accurately than endoscopic evaluations[3]. Endoscopic appearance alone tends to underestimate the severity of disease activity as compared with histological evaluation, and is not able to detect microscopic activity[4-6]. The features of mucosal lesions in UC are considered to include the presence of polymorphonuclear leukocytes in the lamina propria, the formation of crypt abscesses, ulcers and mononuclear cell infiltrate in the lamina propria together with crypt architectural irregularities[7]. In the Riley Index, 6 histological features of UC are factored and each feature is graded on a four-point scale[8]; this index has been applied in some clinical trials.

Autofluorescence imaging (AFI) videoendoscopy produces real-time pseudocolor images based on tissue autofluorescence emitted by excitation of endogenous tissue fluorophores, which mainly consist of collagen type- I [9]. If the change of hue on AFI indicated the extent and severity of UC activity, the analysis would be an objective and reproducible method regardless of the observer's experience. With this in mind, the aim of this study was to evaluate the correlations between the results of analysis of the change in hue on AFI with the results of white light imaging (WLI), together with histological findings on UC activity, to better understand the clinical relevance of AFI.

MATERIALS AND METHODS

Selection of images

This study included 42 patients with a diagnosis of UC, 31 male and 11 female, aged 36.2 ± 11.0 (mean ± SD) years who underwent colonoscopic examinations with a CF-FH260AZL/I colonovideoscope (Olympus Inc., Tokyo Japan). This endoscopic system comprised a high resolution white-light endoscope with optical zoom (magnification 75 ×) equipped with an AFI and narrow band imaging (NBI). The same sites were observed by WLI and AFI. Stored images were retrieved from the computerized database of the Endoscopy Centre at Juntendo University Hospital (Tokyo, Japan) by using an endoscopic filing system, Scope Reader M1 (AZ Co., Ltd., Sendai, Japan). A total of 572 endoscopic images, 286 with WLI and 286 with AFI, from the same sites where tissue biopsy specimens were subsequently taken were selected. The diagnosis of UC was based on the following criteria: history of recurrent bloody and mucous stools, endoscopic findings of ulceration, mucosal friability, loss of vascular architecture or presence of diffuse lesions increasing in severity towards the rectum, and no evidence of pathogenic micro-organisms in stool cultures. The images could be downloaded from the server in JPEG (Joint Photographic Experts Group) format without loss of quality. The file size of each downloaded image was about 100 kilobytes, with a pixel array of 640 × 480, and in 24-bit color.

Examination of images

Initially, all endoscopic examinations were done by one expert endoscopist. Subsequently, the images of WLI were provided for examination by two expert endoscopists (NS and TO), who discussed their assessments and reached a consensus view on the endoscopic activity. Each of these expert endoscopists had performed more than 5000 colonoscopy procedures, and was familiar with UC disease activity *via* endoscopy. Each WLI image was examined and graded for overall mucosal inflammation according to the Mayo endoscopic subscore (MES), scored on a scale of 0 to 3 (Table 1), and for seven endoscopic characteristic features of UC including vascular patterns, erythema, edema, granularity, erosions, ulcers and friability, scored on a scale of 0 to 10 (Table 2).

The optical findings with AFI colonoscopy were displayed as pseudocolored images, and laid over a composite image on the video display. All computer and video displays used the RGB additive color model in which red, green and blue lights are added together in various ways to produce a broad array of colors (256 × 256 × 256 = 16 million). AFI images were evaluated by analyzing the hue, and scored for the relative abundance of red [R/(R + G + B)], green [G/(R + G + B)] and blue

Table 1 Endoscopic scoring system scored from 0 to 3 (Mayo endoscopic subscore)

Score	
0	Normal or inactive disease
1	Mild disease (erythema, decreased vascular pattern, mild friability)
2	Moderate disease (marked erythema, absent vascular pattern, friability, erosions)
3	Severe disease (spontaneous bleeding, ulceration)

Table 2 Seven endoscopic features scored from 0 to 10 points

Vascular pattern	0 (normal) to 10 (absent)
Erythema	0 (absent) to 10 (marked)
Edema	0 (absent) to 10 (marked)
Granularity	0 (absent) to 10 (marked)
Erosions	0 (absent) to 10 (multiple)
Ulcerations	0 (absent) to 10 (multiple)
Friability	0 (absent) to 10 (marked)

Table 3 Histological scoring system (Riley index)

1	Round cells in the lamina propria
2	Polymorphonuclear cells in the lamina propria
3	Crypt abscesses
4	Mucin depletion
5	Surface epithelial integrity
6	Crypt architectural irregularities

Each item is scored from 0 (absent) to 3 points (severe).

(B/[R+G+B]) color components based on the RGB color model which involves the use of Adobe® Photoshop® Elements® 5.0. The color of the region on AFI, where tissue biopsy specimens were subsequently taken, was divided into red, green and blue color components. Although the actual count of each color varied as its brightness varied, the abundance of the actual count was fairly constant (Figure 1). All AFI and WLI images were displayed anonymously to the observers and revealed neither clinical data nor the date on which the images were taken.

Histological evaluations were done by two expert histopathologists (AA and HU) who were familiar with the histological activity in UC and had no knowledge of the clinical findings. They discussed their evaluation and determined the histological activity by using the Riley Index. Six histological features of UC were factored: acute inflammatory cell infiltrate (polymorphonuclear cells in the lamina propria), crypt abscesses, mucin depletion, surface epithelial integrity, chronic inflammatory cell infiltrate (round cells in the lamina propria), and crypt architectural irregularities. Each feature was graded on a four-point scale from 0 to 3 (Table 3).

The outcomes of the AFI analysis using the RGB color model were compared with the endoscopic activity, endoscopic and histological features at the same sites. In addition, the ability of AFI to detect the microscopic inflammatory lesions which were extensively infiltrated by polymorphonuclear cells within MES-0 was evaluated.

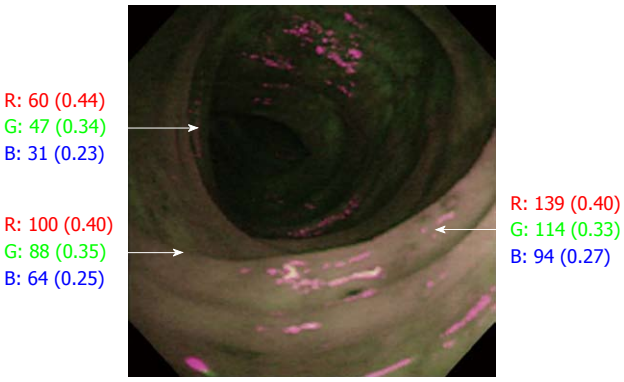

Figure 1 Endoscopic photograph by autofluorescence imaging showing the actual counts of red, green and blue colors based on the RGB additive model in different mucosal areas. The actual counts of red, green and blue colors varied depending on the brightness of the examined area, but the abundance of the actual counts, in parentheses, was approximately constant in the same picture.

Statistical analyses

The relative abundance of color components was expressed as the mean ± SD values. The relationships between endoscopic findings, histological evaluations, and the relative abundance of red, green and blue color components based on the RGB color model were determined by using the Spearman rank correlation coefficient (r). The Tukey-Kramer multiple comparison test was used for statistical analysis of the rate of color components based on the RGB color model among MES from 0 to 3. Before the Tukey-Kramer multiple comparison test, one-way analysis of variance (ANOVA) was performed. The Student's t-test (unpaired) was applied to compare the green color components based on the RGB color model between limited (combined grades 0 and 1) and extensive (combined grades 2 and 3) polymorphonuclear cell infiltration. Differences with P values < 0.05 were considered to be statistically significant.

RESULTS

The relationships between the RGB color components of AFI and WLI findings were evaluated in 572 endoscopic images from a total of 286 sites (Figure 2). Relative to the red (r = 0.52, P < 0.01) or blue (r = 0.56, P < 0.01) color component, the green color component (r = -0.62, P < 0.01) corresponded most often with sites of mucosal inflammation in different colonoscopy images (Figure 3A). However, there was an inverse relationship between the green color components and mucosal inflammation, so that the green color components of AFI diminished as the mucosal inflammation became more severe.

The average number of green color components for images classified into each MES subscore was 0.396 ± 0.043 for MES-0, 0.340 ± 0.035 for MES-1, 0.324 ± 0.034

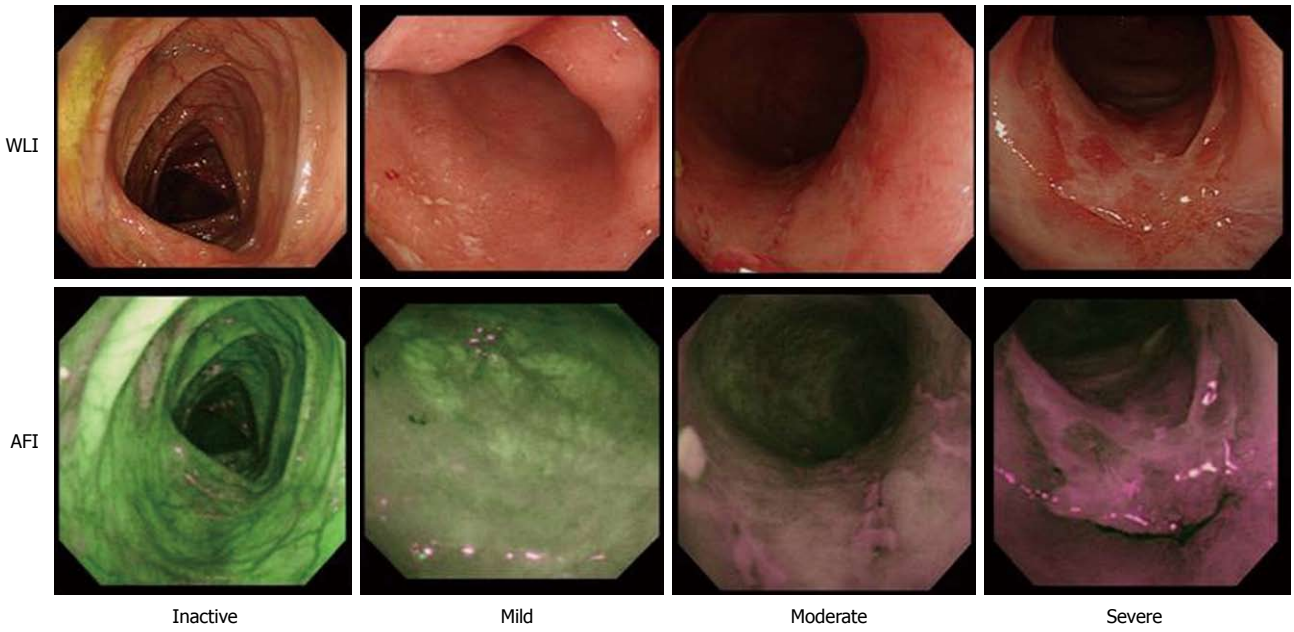

Figure 2 Representative endoscopic photographs of ulcerative colitis using white light imaging (upper row) and autofluorescence imaging (lower row) at the same sites according to the level of endoscopic ulcerative colitis activity (inactive, mild, moderate and severe). The color of the large intestinal mucosa on the autofluorescence imaging (AFI) changes by degrees, from green to grayish and magenta color. WLI: White light imaging.

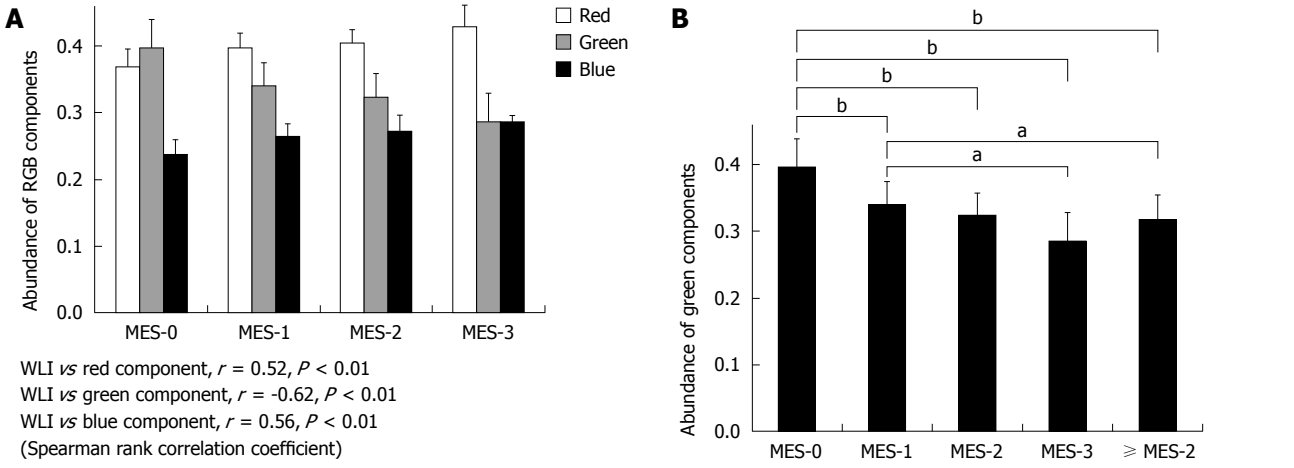

Figure 3 Comparison of overall mucosal inflammation on white light imaging and the abundance of RGB color components on autofluorescence imaging. A: The green color component corresponds most often with sites of mucosal inflammation in different colonoscopy images (according to Spearman rank correlation coefficient); B: There are significant differences in the green color component values between Mayo endoscopic subscore (MES)-0 and MES-1 ($^{b}P < 0.01$), between MES-0 and MES-2 ($^{b}P < 0.01$), between MES-0 and MES-3 ($^{b}P < 0.01$), between MES-1 and MES-3 ($^{a}P < 0.05$), between MES-0 and ⩾ MES-2 ($^{b}P < 0.01$) and between MES-1 and ⩾ MES-2 ($^{a}P < 0.05$), but not between MES-1 and MES-2 or between MES-2 and MES-3 (Tukey-Kramer multiple comparison test). WLI: White light imaging.

for MES-2, and 0.286 ± 0.043 for MES-3. There were significant differences in green color component values between MES-0 and MES-1 ($P < 0.01$), MES-0 and MES-2 ($P < 0.01$), MES-0 and MES-3 ($P < 0.01$), and MES-1 and MES-3 ($P < 0.05$), but not between MES-1 and MES-2, nor between MES-2 and MES-3. Likewise, there was a significant difference in green color component values between MES-1 and scores of ⩾ MES-2 (0.318 ± 0.037) as a combined group of MES-2 and MES-3 ($P < 0.01$) (Figure 3B). As the severity of the mucosal inflammation increased, the green color component of AFI decreased. However, the value of the color did not alter much between moderate and severe inflammation.

The relationships between the AFI green color component and WLI scores for the seven characteristic endoscopic features of UC are presented in Figure 4. The correlation coefficients for the AFI green color component with the scores of the seven characteristics were as follows: vascular pattern $r = -0.65$, $P < 0.01$; erythema $r = -0.55$, $P < 0.01$; edema $r = -0.62$, $P < 0.01$; granularity $r = -0.53$, $P < 0.01$; erosions $r = -0.45$, $P < 0.01$; ulcers $r = -0.23$, $P < 0.01$; and friability $r = -0.52$, $P < 0.01$. The AFI green color component was well correlated with the scores for vascular pattern and edema, but not with the

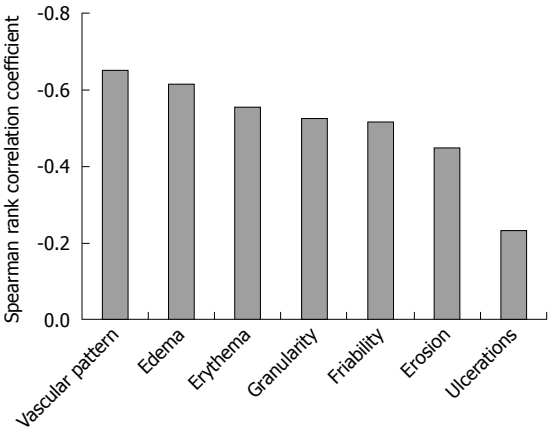

Figure 4 Comparison of seven endoscopic ulcerative colitis features on white light imaging and the green color component on autofluorescence imaging. The green color component on autofluorescence imaging is well correlated with vascular pattern (r = -0.65, P < 0.01) and edema (r = -0.62, P < 0.01) scores on WLI, but not with the ulcer score (r = -0.23, P < 0.01) (Spearman rank correlation coefficient). WLI: White light imaging.

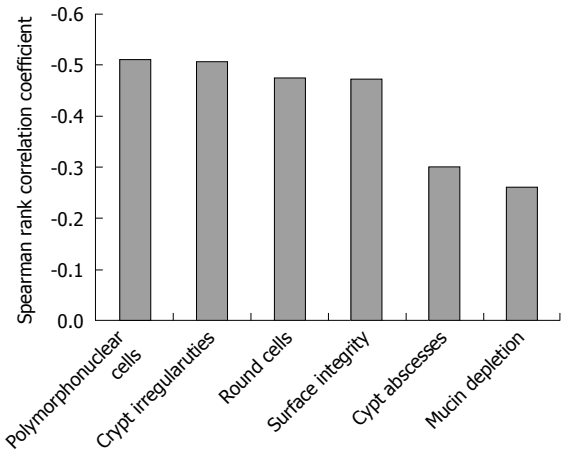

Figure 5 Comparison of histology scores, six histological characteristic ulcerative colitis features and the green color component on autofluorescence imaging. The autofluorescence imaging green color component is relatively well correlated with the scores for polymorphonuclear cells in the lamina propria (r = -0.51, P < 0.01) and crypt architectural irregularities (r = -0.51, P < 0.01), but not with the scores for crypt abscesses (r = -0.30, P < 0.01), and mucin depletion (r = -0.26, P < 0.01) based on Spearman rank correlation coefficient.

score for ulcers. It also showed relatively good correlation with the other endoscopic features of UC. The relationships between the AFI green color component and histology scores of six histological characteristic features of UC are shown in Figure 5. The correlation coefficients for the AFI green color component with the scores for the histological features were as follows: polymorphonuclear cells in the lamina propria r = -0.51, P < 0.01; crypt abscesses r = -0.30, P < 0.01; mucin depletion r = -0.26, P < 0.01; surface epithelial integrity r = -0.47, P < 0.01; round cells in the lamina propria r = -0.48, P < 0.01; and crypt architectural irregularities r = -0.51, P < 0.01. The AFI green color component was relatively well correlated with the scores for polymorphonuclear cells in the lamina propria

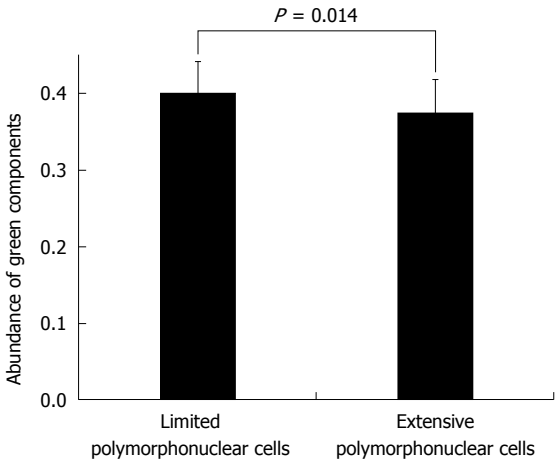

Figure 6 Comparison of limited (combined grades 0 and 1) and extensive (combined grades 2 and 3) polymorphonuclear cell infiltration of the green color components in Mayo endoscopic subscore-0. The mean number of green color components for images classified into the amount of polymorphonuclear cell infiltration in Mayo endoscopic subscore (MES)-0 is 0.399 ± 0.042 for limited and 0.375 ± 0.044 for extensive infiltration. There are significant differences in green color component values between limited and extensive polymorphonuclear cell infiltration in MES-0 (P = 0.014, by Student's t-test).

and with the crypt architectural irregularities, but not with the scores for crypt abscesses and mucin depletion.

The relationship between limited (combined grades 0 and 1) and extensive (combined grades 2 and 3) polymorphonuclear cell infiltration based on the green color components within MES-0 based on WLI are shown in Figure 6. The mean numbers of green color components for images classified according to the level of polymorphonuclear cell infiltration within MES-0 were 0.399 ± 0.042 and 0.375 ± 0.044 for limited and extensive infiltration, respectively. There were significant differences in green color component values between limited and extensive polymorphonuclear cell infiltration within MES-0 (P = 0.014). The abundance of green color components of AFI was also significantly different between microscopic inflammatory sites and histologically-quiescent UC lesions.

DISCUSSION

AFI has been used to highlight neoplastic tissue[10], minimal change in reflux esophagitis[11], the extent of chronic atrophic fundal gastritis[12], and Barrett's esophagus[13]. In all of these reports the lesions on the AFI are divided into two colors, such as green and magenta, green and pink, green and gray, green and purple, because investigators were concerned with the presence and the extent of the lesions, rather than with determining the severity of inflammation. In the present study, AFI pictures were scored according to the relative abundance of red, green and blue color components within each image based on an RGB additive model. Therefore, each component was expressed as a sequential variable number, and this facilitated evaluation of the severity of mucosal damage.

Further, the analysis was convenient to perform by using the Adobe® Photoshop® Elements® 5.0 software. Among the three color components, the green color component corresponded most often (and inversely) with sites of mucosal inflammation. Although fluorophores exist in both the mucosa and the submucosa, collagen in the submucosa emits strong green autofluorescence[14]. Our impression is that the presence of mucosal inflammation caused a high cell density and thickened the mucosal layer, making it difficult for the autofluorescence from the submucosa to penetrate the inflamed mucosa. Therefore, the green color component was reduced. The degree of the green color component might be valuable for assessing the extent of inflammation in the large intestine.

The overall mucosal inflammation in WLI, as assessed by MES, and the green color component in the AFI were well correlated. Specifically, there were significant differences in green color component values between MES-0 and MES-1, and between MES-1 and ⩾ MES-2, but not between MES-2 and MES-3. The degree of mucosal structural change around erosions and ulcers due to inflammation may differ only slightly between MES-2 and MES-3. Accordingly, the green color component of the AFI may not have been able to clearly distinguish moderate from severe inflammation.

Regarding the relationships between each of the seven characteristic endoscopic UC features on the WLI and the green color component of the AFI, vascular pattern and edema were well correlated with the green color component. These features are present from the early phase of UC, and decreased vascular pattern was particularly associated with MES-1, Baron score 1[15], modified Baron score 1[16], and Rachmilewitz index score 1[17]. This suggests that the green color component of the AFI is appropriate for detecting mucosal inflammation. In contrast, ulceration was not well correlated with the green color component of the AFI. The level of penetration of the green color component of the AFI from the submucosa through more than moderately inflamed mucosa might be constant regardless of the presence of ulcers. However, it was relatively simple to distinguish moderate from severe inflammation by using only WLI, based on the findings from spontaneous bleeding and multiple ulcers.

It has been reported that two measures of histological findings, such as architectural abnormalities including crypt architectural distortion and inflammatory features including large numbers of neutrophils, allow a distinction between inflammatory bowel disease and other causes of colorectal inflammation[18]. In our study, among six histological characteristic features of UC, polymorphonuclear cells in the lamina propria and crypt architectural irregularities were relatively well correlated with the green color component of the AFI. These two features are common in UC[19]. Polymorphonuclear cells in the lamina propria and crypt architectural irregularities are recognized in the active disease phase. The green color component of the AFI might reflect active mucosal inflammation. Other histological features of UC, especially mucin depletion and crypt abscesses, were not correlated with the green color component of the AFI. Although mucin depletion is a characteristic feature of UC, the degree of mucin depletion is not associated with the degree of inflammation. Crypt abscesses were observed in only about 7% of the biopsy specimens (26.2% of patients).

Although endoscopic remission was obtained after treatment, histological evidence of acute inflammatory cells often remained. The presence of microscopic inflammation contributed a 2- to 3-fold increase in the relapse rate[8]. The microscopic findings on inflammation were helpful in predicting relapse and for deciding on medical intervention. In this study, although the difference between microscopic inflammation and histological quiescence and the intensity of the green color components was relatively small, nevertheless the difference was significant. It is likely that microscopic inflammation was determined based on an evaluation of the green color component of the AFI.

In conclusion, the outcomes of the present investigation indicate that AFI is an appropriate new approach for detecting inflammatory regions and approximately estimating the severity of inflammation in UC patients, regardless of endoscopic experience. In particular, microscopic to moderate inflammation can be detected based on the green color component of the RGB additive color model. Further studies should strengthen our findings on the clinical relevance of AFI in patients with UC.

COMMENTS

Background

Endoscopic and histological findings define the degree of inflammatory activity in the clinical diagnosis of ulcerative colitis (UC). Although endoscopy is the most immediate method for assessing intestinal mucosal damage, the consistency of inter- and intra-observer findings and diagnoses have been reported to vary considerably. Substantial experience is necessary to accurately assess the disease activity in UC, particularly as microscopic inflammation cannot be detected by using conventional endoscopy.

Research frontiers

Autofluorescence imaging (AFI) videoendoscopy produces real-time pseudocolor images based on tissue autofluorescence emitted by excitation of endogenous tissue fluorophores. AFI has been used to highlight various lesions. There is no report on the change of hue related to AFI indicating extent and severity of UC activity.

Innovations and breakthroughs

AFI images were evaluated by analyzing the hue, and were scored relative to the abundance of red, green and blue color components of the RGB color model. As the green color components of AFI diminished, the mucosal inflammation was indicated to be more severe.

Applications

AFI appears to be an appropriate new approach and should be valuable for detecting inflammatory regions and approximately estimating the severity of inflammation in UC patients regardless of endoscopic experience, but based on the green color components of the RGB additive color model.

Terminology

AFI is a novel technique for detecting the autofluorescence emitted by the gastrointestinal tissues, mainly from collagen type-I in the submucosal layer, in real time. In an AFI mode, excitation light (395-475 nm) for inducing autofluorescence, together with green light (550 nm) and red light (610 nm) for obtaining reflection images, are generated by a light source equipped with a 300W xenon

arc lamp through a rotating filter. An excitation light cut filter is incorporated in the CCD for the AFI mode to allow only 490-625 nm light to reach the CCD.

Peer review

The present study demonstrates some technical progress when the AFI pictures were scored in a new way and the green color component correlated to the inflammatory changes on a significant level. However, the difference between mild inflammation and severe inflammation was small (about 10% in the abundance of green light components) and therefore our attitude to the results and conclusion should be cautious. As a preliminary and pioneering work this could be accepted for publication.

Abstract

AIM: To evaluate the influence of taking low-dose aspirin for 4 wk on small intestinal complications and to examine the preventive effect of rebamipide.

METHODS: This study was conducted as a single-center, randomized, double-blind, cross-over, placebo-controlled study. Eleven healthy male subjects were enrolled. Each subject underwent video capsule endoscopy after 1 and 4 wk of taking aspirin and omeprazole, along with either rebamipide or placebo therapy. The primary endpoint was to evaluate small bowel damage in healthy subjects before and after taking low-dose aspirin for 4 wk.

RESULTS: The number of subjects with mucosal breaks (defined as multiple erosions and/or ulcers) were 1 at 1 wk and 1 at 4 wk on the jejunum, and 6 at 1 wk (P = 0.0061) and 7 at 4 wk on the ileum (P = 0.0019). Rebamipide significantly prevented mucosal breaks on the ileum compared with the placebo group (P = 0.0173 at 1 wk and P = 0.0266 at 4 wk).

CONCLUSION: Longer-term, low-dose aspirin administration induced damage in the small bowel. Rebamipide prevented this damage, and may be a candidate drug for treating aspirin-induced small bowel complications.

Key words: Healthy subjects; Low-dose aspirin; Small bowel injury; Capsule endoscopy; Rebamipide

INTRODUCTION

Video capsule endoscopy (VCE)[1-2] is a practical technique that can be used to identify the causes and sites of obscure gastrointestinal bleeding. VCE allows for prospective investigation of small intestinal injuries, which frequently occur following the administration of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin. For example, Graham *et al*[3] used VCE and reported that small intestinal injury occurred in 71% of chronic NSAID users.

Low-dose aspirin is currently recommended for the secondary prevention of cardiovascular and cerebral diseases[4-6]. An observational registry reported that 70% to 80% of patients with a high risk of atherothrombosis

were receiving low-dose aspirin to prevent future vascular events[7]. Nonetheless, low-dose aspirin is not without risks. For instance, Lanas *et al*[8]reported that taking an anti-platelet agent induced lower, as well as upper, gastrointestinal (GI) events (16.9% and 15.5%, respectively). To date, there has been considerable interest in preventing upper gastrointestinal complications of NSAIDs; however, it has become clear that a strategy to prevent small bowel complications may also be needed[9].

It is not yet clear what duration of low-dose aspirin ingestion causes small bowel damage. Moreover, the frequency and severity of small bowel damage from taking low-dose aspirin is not yet known. Three recent reports investigating aspirin-induced small bowel damage were all short-term (1 to 2 wk) investigations[10-12]. These studies reported mild injuries (20% to 60%), such as erosion, in addition to more serious injuries (0 to 10%), such as ulcers[10-12]. The use of low-dose aspirin for cardiovascular prophylaxis is generally long-term, and it is clear that longer term observational studies are needed to examine damage to the small intestines.

The aims of this study were to investigate the frequency and type of small bowel damage associated with a 4 wk administration of low-dose aspirin in healthy subjects and to investigate the preventive effect of the cytoprotective agent, rebamipide, on aspirin-induced small bowel damage.

MATERIALS AND METHODS

The study protocol was approved by the Ethics Committees of Oita University, and written informed consent was obtained from all subjects. Eligible subjects were aged 20 to 65 years, who had taken no drugs during the one-month period prior to the start of this study and who had normal physical examinations. The exclusion criteria were as follows: (1) subjects who did not have a full length, small bowel VCE prior to the start of the study; (2) subjects with stenosis, tumors, ulcers, erosions, or bleeding in the small bowel; (3) subjects who had active GI disease or a history of ulcers, surgery, or bleeding; and (4) subjects who had used any medication, including NSAIDs or aspirin, within 4 wk of the start of the study.

Treatment protocol and post-treatment capsule endoscopy

This study was conducted using a cross-over design as shown in Figure 1. Medication groups A and B were defined as follows: group A: placebo plus aspirin (Bayer Pharmaceutical Co., Ltd., Tokyo, Japan) plus omeprazole (Sawai Pharmaceutical Co., Ltd., Osaka, Japan) for 4 wk; and group B: rebamipide (Otsuka Pharmaceutical Co., Ltd., Tokyo, Japan) plus aspirin plus omeprazole for 4 wk (rebamipide 300 mg or placebo tid, aspirin 100 mg od, omeprazole 20 mg od). Omeprazole was used primarily for ethical reasons to avoid the effect of aspirin on the stomach.

Medications were administered for 4 wk. Then following a 4-wk washout period, the treatments were reversed for the two groups, and the medications were administered for a second 4-wk period. The washout period was designed according to a previous study by Niwa[13]. VCEs of the small bowel were performed five times: prior to the intervention, at 1 and 4 wk during the first period, and at 1 and 4 wk during the second treatment period.

Allocation and randomization were conducted by an independent pharmacologist of Yamanami Pharmacy who had no connection to our institution or the results of this study. The placebo was prepared by Yamanami Pharmacy.

Evaluation of small intestinal injuries

In this study, erosion and ulcer were defined according to Graham's report[3]. Red spots were defined as red areas without clear mucosal break. Erosions were defined as circumscribed areas of mucosal disruption denuded of villi with or without exudates or red color that involved a diameter equivalent to the valvulae conniventes. Ulcers were defined as erosions with a central area with exudates typically having a surrounding border of elevated mucosa, producing a target lesion or coral polyp appearance[3]. Typical cases of red spots and erosion are shown in Figures 2A and B, and an example of an ulcer is shown in Figure 2C.

Mucosal break was defined as two or more erosions and/or an ulcer. Red spots were scored, but were not considered as a significant injury, since they can be observed normally. The location of the injury was also scored in terms of the locations as proximal (jejunal) or distal (ileal) based on the transit time. The transit time from the pylorus to cecum was divided in half, and the first portion was arbitrarily defined as the jejunal section. Cases with erosion, multiple erosions, and ulcers were calculated. Multiple erosions were defined as more than 2 erosions in a subject. Subjects were only analyzed if the entire small bowel was observable by VCE.

Endpoints

The primary endpoint was to evaluate healthy subjects before and after 4 wk of low-dose aspirin-induced small bowel damage. The secondary endpoint was to evaluate the preventive effect of rebamipide.

Capsule endoscopy

We used the Olympus video capsule system (EndoCapsule, Olympus Ltd.; Tokyo, Japan) for this study. The capsule endoscopy procedure and the methodology for reviewing the images were conducted as previously described. All video images were analyzed twice by each skilled reviewer (KM, TA, and KI). These three investigators were instructed to mark any significant lesions under blinded conditions, and to evaluate lesions according to criteria for determination of the endpoints. If the results differed between the reviewers, then they consulted one

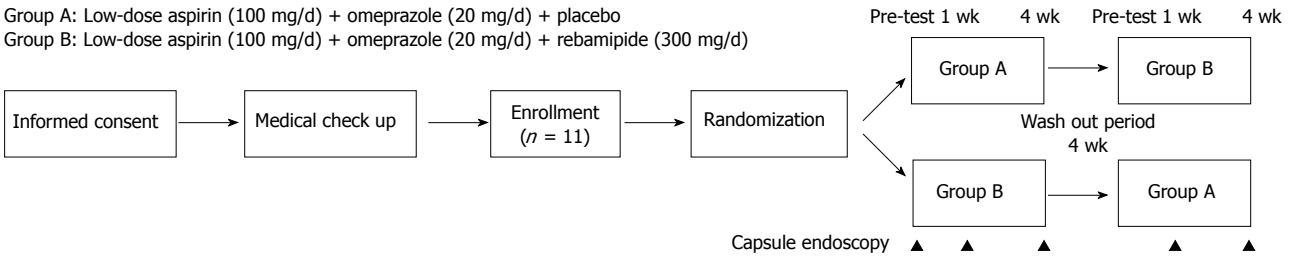

Figure 1 Study design.

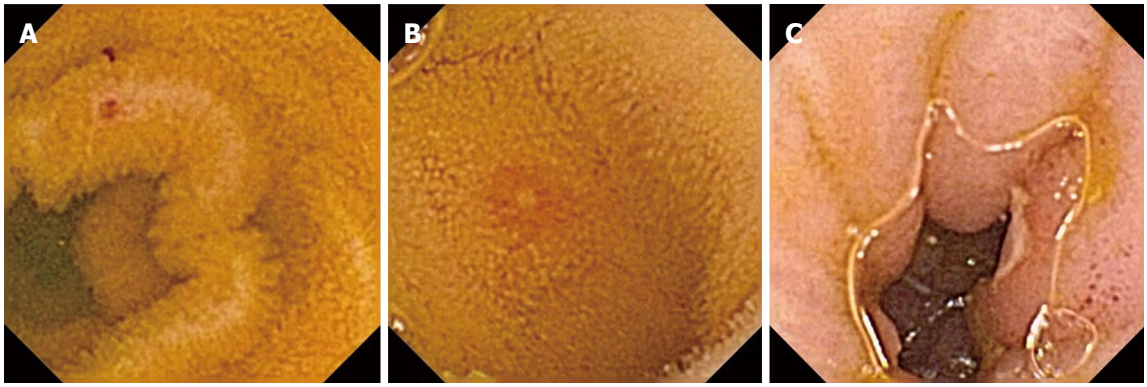

Figure 2 Typical small intestinal red spot, erosion and ulcer. A: Typical red spot; B: Typical erosion; C: Typical ulcer.

another to achieve a consensus. All images were saved for a final comprehensive analysis upon completion of all of the post-treatment capsule endoscopies.

Safety assessment

The subjects' symptoms were observed daily throughout the study periods, and the information was evaluated using a patient diary.

Statistical analysis

The primary endpoint was to evaluate the proportion of healthy subjects with small intestinal injury after 4 wk of low-dose aspirin therapy. The number of healthy subjects with small bowel mucosal breaks, ulcers, erosions, multiple erosions, and red spots were calculated and treated as parametric parameters. The small bowel area was divided into the jejunum and the ileum. The number of small bowel ulcers, erosions, and red spots were described as the mean ± SD. These values were analyzed at each measured point of the VCE in each group using Mann-Whitney's *U* test and compared with the evaluation prior to the aspirin administration.

The secondary endpoint was to compare the number of small intestinal injuries between the placebo and the rebamipide groups. The injuries were described as means ± SD and treated as nonparametric parameters. These injuries were analyzed at each measured point of the VCE in each group using Mann-Whitney's *U* test. In addition, the small intestinal injuries were compared between the placebo and rebamipide groups.

This study was a pilot study. Therefore, there were no reference data to calculate the sample size. A *P*-value < 0.05 was considered significant. All statistical analyses were performed using SAS version 8.2 (SAS Institute, Cary, NC, United States).

RESULTS

Eleven healthy subjects were enrolled in this study. The mean age of the subjects was 30 ± 6 years. The median age was 27 years, and the range was 24 to 43 years.

Influence of low-dose aspirin on small bowel mucosa in the placebo group

The number of subjects with multiple erosions, ulcers, and mucosal breaks of the small bowel are shown in Table 1. There were 8 subjects with red spots on the jejunum before the administration of aspirin, 10 subjects at 1 wk, and 10 at 4 wk. There were 8 subjects with red spots on the ileum before administration of aspirin, 11 subjects at 1 wk, and 11 at 4 wk. There were 2 subjects with small bowel erosion on the jejunum at 1 wk and 4 at 4 wk ($P = 0.0379$). There were 7 subjects with small bowel erosion on the ileum at 1 wk ($P = 0.0019$) and 9 at 4 wk ($P < 0.0001$).

The numbers of small bowel injuries before and after aspirin treatment are shown in Figure 3. There were 6.3 ± 6.9 small intestinal red spots at 1 wk and 9.6 ± 6.6 at 4 wk on the jejunum, and 68.0 ± 133.6 at 1 wk ($P = 0.0010$) and 48.4 ± 67.7 at 4 wk ($P = 0.0010$) on the ileum. There were 0.2 ± 0.6 small bowel erosions at 1 wk and 0.4 ± 0.6 at 4 wk on the jejunum, and 2.1 ± 2.6 at 1 wk ($P = 0.0156$)

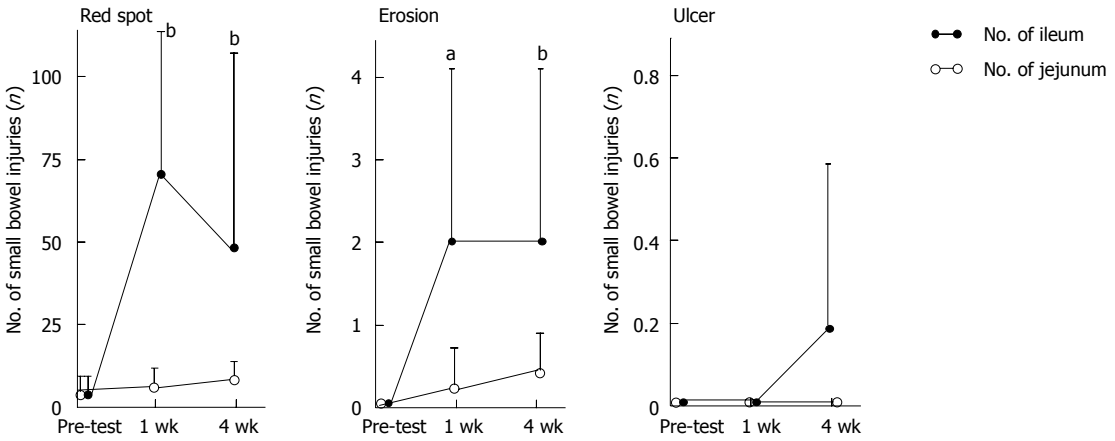

Figure 3 Low-dose aspirin-related small bowel injuries in the placebo group. The open circle indicates the number of low-dose aspirin-related small bowel injuries in the jejunum, and the closed circle indicates the number of injuries in the ileum at 4 wk. The data are represented as the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$.

Table 1 No. of healthy subjects presenting small bowel injuries following a 4 wk regimen of low dose aspirin in the placebo group and evaluation of preventive efficacy (n = 11)

	Jejunum			Ileum		
	Pre-test	1 wk	4 wk	Pre-test	1 wk	4 wk
Placebo group						
Multiple erosion (*n*)	0	1	1	0	6[b]	4[a]
Ulcer (n)	0	0	0	0	0	3
Mucosal break (*n*)	0	1	1	0	6[b]	7[b]
Rebamipide group						
Mucosal break (*n*)	0	0	1	0	1[c]	2[c]

Multiple erosion (*n*): No. of subjects with multiple erosions in jejunum or ileum; Ulcer (*n*): No. of subjects with ulcer in jejunum or ileum; Mucosal break (*n*): No. of subjects with multiple erosion and/or ulcer in jejunum or ileum. Statistical analysis was performed by Mann Whitney's *U* test, compared to before administration *vs* 1 wk and 4 wk. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.05$ compared with placebo and rebamipide group.

and 2.0 ± 2.5 at 4 wk ($P = 0.0039$) on the ileum. There were no small intestinal ulcers at 1 wk and at 4 wk on the jejunum, and there were no small intestinal ulcers at 1 wk and 0.2 ± 0.4 ulcers at 4 wk on the ileum.

Evaluation of the preventive effect of rebamipide

The preventive effect of rebamipide is shown in Table 1. There were no subjects with small bowel mucosal breaks on the jejunum at 1 wk and 1 subject at 4 wk, and there was 1 small bowel mucosal break on the ileum at 1 wk and 2 at 4 wk. Rebamipide significantly prevented small bowel mucosal breaks on the ileum compared with the placebo group ($P = 0.0173$ at 1 wk and $P = 0.0266$ at 4 wk). There were 15.7 ± 8.5 red spots on the ileum at 4 wk in the rebamipide group, which was significantly fewer than in the placebo group ($P = 0.0354$). There were 0.6 ± 1.2 erosions on the ileum at 4 wk, which was significantly fewer that in the placebo group ($P = 0.0362$).

Safety assessment

We examined symptoms daily for all subjects throughout the study period. Three subjects with ulcers were observed in the placebo group. Two of these subjects were symptomatic, but not anemic. The symptoms of these two subjects diminished 1 month after the study ended. One subject with an ulcer was observed in the rebamipide group, but the subject was neither symptomatic nor anemic.

DISCUSSION

In our study, we observed that the administration of low-dose aspirin induced small bowel red spots and erosions in healthy subjects in the early phase (1 wk). Red spots were observed in all subjects with a mean of 68.0 ± 133.6 at 1 wk and 48.4 ± 67.7 at 4 wk. There were 7 subjects with erosions on the ileum at 1 wk and 9 at 4 wk in the placebo group. These small bowel injuries were induced in the early phase and maintained while taking low-dose aspirin. On the other hand, small intestinal ulcers were observed in 3 subjects in the late phase (4 wk), although no ulcers were observed at 1 wk. These results indicate that serious small bowel injury, such as ulcers, may be induced by longer-term administration of low-dose aspirin. In addition, a very large ulcer was observed in one case at 4 wk (Figure 4), although no ulcer was observed in this subject at 1 wk. This may demonstrate a risk of longer-term low-dose aspirin ingestion. Patients taking low-dose aspirin should be given periodic management. In this study, small bowel bleeding was not observed; however, some patients may present small bowel bleeding due to the use of low-dose aspirin during treatment periods longer than 4 wk. The clinical implications of small bowel mucosal injuries are not yet clear. However, bleeding from mucosal injury can be fatal because aspirin is an anti-platelet agent. In this study, multiple erosions were also evaluated. They resulted in a more serious condition than a single erosion.

Our results indicate that most small bowel injuries occurred in the ileum rather than the jejunum area. There were 7 cases with a mucosal break in the ileum and 1 in the jejunum at 4 wk in the placebo group. Bjarnason *et al*[14] demonstrated that small bowel damage depended on various factors, such as microvascular aspects, neutrophil recruitment, mucosal prostaglandins,

Figure 4 Case with a large ulcer of the small intestine induced by low-dose aspirin. A large ulcer was observed in the small intestine as a result of 4 wk of low-dose aspirin ingestion. The ulcer occupied one-third of the interior of the small intestine.

decreased blood flow, increased permeability, and bacteria. The number and variation of bacteria in the ileum is reported to be greater than in the jejunum[15]. The results of this study may be a reflection of the different bacterial environment in the ileum compared with the jejunum.

We conducted a comparative study with placebo and rebamipide to observe whether rebamipide could prevent aspirin-induced small bowel injuries. Niwa *et al*[13] reported that rebamipide had a preventive effect on diclofenac-induced small-bowel injury compared to the placebo. The preventive ratio of diclofenac-induced small bowel mucosal breaks was 60% in the placebo group and 20% in the rebamipide group, and this difference was statistically significant. Moreover, Fujimori *et al*[16] demonstrated that the prostaglandin analogue misoprostol prevented diclofenac-induced small-intestinal complications. These two reports indicate the importance of prostaglandins.

Rebamipide {2-(4-chlorobenzoylamino)-3-[2-(1H)-quinolinon-4-yl]-propionic acid} is a cytoprotective antiulcer drug that stimulates the production of endogenous prostaglandins[17]. Here, we observed that rebamipide significantly prevented small bowel mucosal breaks in the ileum area compared to the placebo group at both 1 wk and 4 wk. There were 3 subjects with ulcers in the ileum area at 4 wk in the placebo group, compared with 1 subject with an ulcer at 4 wk in the rebamipide group. The administration of rebamipide showed potential in preventing the incidence of ulcers; however, rebamipide does not have an anti-bacterial effect. The action of rebamipide may be explained by Bjarnason's hypothesis[14]. Previous reports have indicated that rebamipide induces the production of intracellular prostaglandins[14], improves blood flow[18], suppresses increases in permeability[19], scavenges free radicals[20], and has an anti-inflammatory action[21]. Presently, there is no drug to prevent aspirin-induced small bowel complications or treat patients with these complications, so it is essential to research drugs with these properties in the future.

A limitation of this study is that the study size was small. We did not use a large number of patients, since this was a preliminary study. In addition, since the small bowel is a long organ, it will be necessary to further investigate the appropriate dosage for this candidate drug.

In conclusion, the use of long-term low-dose aspirin induced small bowel damage. Rebamipide prevented this damage, and this candidate drug may be suitable for preventing aspirin-induced small bowel complications.

ACKNOWLEDGMENTS

The authors thank Dr. Shunji Fujimori for assistance with capsule endoscopy.

COMMENTS

Background

Low-dose aspirin is currently recommended for the secondary prevention of cardiovascular and cerebral diseases. Recently, aspirin-induced small bowel complications have become the focus of investigations around the world.

Research frontiers

Few studies have observed healthy subjects with low-dose aspirin-induced, small bowel injuries using capsule endoscopy. These results demonstrated the prevalence of slight and low frequency small bowel injuries. However, these studies examined the effects of low-dose aspirin ingestion in the very short-term (1 or 2 wk). Here, we investigated the influence of small bowel damage following ingestion of low-dose aspirin for a longer period of 4 wk.

Innovations and breakthroughs

In this study, the ingestion of low-dose aspirin for 4 wk induced small bowel ulcers. In one case, a huge ulcer developed at 4 wk, although no ulcer was observed at 1 wk. Although it is common for patients to take low-dose aspirin for more than 4 wk, this duration of ingestion may be the limit in healthy subjects. Moreover, the results of this study demonstrate the differences in small bowel injuries after ingesting low-dose aspirin for 1 wk or 4 wk. Taking rebamipide was found to prevent aspirin-induced small bowel injuries.

Applications

The results of this study indicate that long-term use of low-dose aspirin can cause small intestinal injuries. Rebamipride could prevent this damage.

Terminology

Rebamipide is a cytoprotective antiulcer drug that stimulates the production of endogenous prostaglandins. Its actions include scavenging free radicals, elevating blood flow, and suppressing permeability. In this study, capsule endoscopy was performed using the Olympus video capsule system (EndoCapsule, Olympus Ltd.; Tokyo, Japan).

Peer review

This study focused on the influence of low-dose aspirin ingestion for 4 wk on small bowel damage in healthy subjects. The study was designed as a randomized, placebo-controlled, double-blind, cross-over study using video capsule endoscopy. The long-term (4 wk) use of low-dose aspirin induced small bowel damage. Rebamipide prevented this damage, and it may be a candidate drug for preventing aspirin-induced small bowel complications.

Abstract

AIM: To compare and evaluate the appropriate prognostic indicators of lymph node basic staging in gastric cancer patients who underwent radical resection.

METHODS: A total of 1042 gastric cancer patients who underwent radical resection and D2 lymphadenectomy were staged using the 6th and 7th edition International Union Against Cancer (UICC) N staging methods and the metastatic lymph node ratio (MLNR) staging. Homogeneity, discriminatory ability, and gradient monotonicity of the various staging methods were compared using linear trend χ^2, likelihood ratio χ^2 statistics, and Akaike information criterion (AIC) calculations. The area under the curve (AUC) was calculated to compare the predictive ability of the aforementioned three staging methods.

RESULTS: Optimal cut-points of the MLNR were calculated as MLNR0 (0), MLNR1 (0.01-0.30), MLNR2 (0.31-0.50), and MLNR3 (0.51-1.00). In univariate, multivariate, and stratified analyses, MLNR staging was superior to the 6th and 7th edition UICC N staging methods. MLNR staging had a higher AUC, higher linear trend and likelihood ratio χ^2 scores and lower AIC values than the other two staging methods.

CONCLUSION: MLNR staging predicts survival after gastric cancer more precisely than the 6th and 7th edition UICC N classifications and should be considered as an alternative to current pathological N staging.

Key words: Gastric cancer; Metastatic lymph node ratio; Prognosis

Xiao LB, Yu JX, Wu WH, Xu FF, Yang SB. Superiority of metastatic lymph node ratio to the 7th edition UICC N staging in gastric cancer. *World J Gastroenterol* 2011; 17(46): 5123-5130 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i46/5123.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i46.5123

INTRODUCTION

In recent years, more cases of gastric cancer have been diagnosed in China than in any other country[1]. Accurate prognosis prediction for gastric cancer patients enables doctors to determine the patients' expected clinical courses and to have more information when deciding whether to use adjuvant therapy and when comparing the therapeutic effects of different treatment modalities. A widely used classification proposed by the International

Union Against Cancer (UICC), the tumor-node-metastasis (TNM) system, combines the most powerful and reliable factors for analyzing tumor status[2,3]. Lymph node metastasis is one of the most important gastric cancer prognostic factors[4]. The identified number of involved lymph nodes depends on the number of lymph nodes removed and examined, which in turn depends on the surgical and pathologic procedures. Although TNM classification is a convenient and reproducible method for precise staging, it demands the examination of at least 15 lymph nodes. If the number of dissected and examined lymph nodes is small, downmigration of N stage may occur, and conversely, if the number is large, upmigration of N stage may occur, which is also referred to as stage migration in some references[5-10]. To improve prognosis prediction, the number of positive lymph nodes should be considered in the context of the number of nodes examined. The metastatic lymph node ratio (MLNR), defined as the number of positive lymph nodes divided by the number of lymph nodes retrieved, has been proposed as an alternative to classification systems that assess the absolute number of positive lymph nodes, such as the UICC (2002, 6th edition) or Japanese Gastric Cancer Association (JGCA) (1998, 2nd English edition) staging systems[11-16].

This year, gastric cancer lymph node metastasis staging was changed in both the UICC 7th edition and the JGCA 14th edition staging systems in that it now depends solely on the number of metastatic nodes found[3,17]. In the new UICC and JGCA systems, patients with one to two positive lymph nodes are classified as N1, patients with three to six positive lymph nodes are classified as N2, and patients with seven or more positive lymph nodes are classified as N3. Some authors have demonstrated that the 7th edition UICC staging system is superior to the 6th edition based on its homogeneity, discriminatory ability and prognostic value[18-20].

However, to date there has been no formal study that focused on comparing the prognostic significance of the MLNR with that of the 7th edition UICC N staging system. In the present article, we investigate whether patients with gastric cancer can be classified into meaningful risk categories based on MLNR by comparing this staging system with the 7th edition UICC N staging system.

MATERIALS AND METHODS

Patients

Between January 1996 and December 2007, 1042 patients with histologically diagnosed gastric cancer underwent surgery at the Department of Gastrointestinal-pancreatic Surgery, First Affiliated Hospital, Sun Yat-Sen University, China. The postoperative pathological results included tumor size, histological type, margin, adjacent tissues and neighboring organs, lymphatic/venous invasion, retrieved lymph nodes, metastatic lymph nodes, and pTNM staging. The inclusion criteria of the study were as follows: (1) gastric adenocarcinoma identified by histo-pathological examination; (2) histologically confirmed R0 resection, which was defined as no macroscopic or microscopic residual tumor; and (3) availability of complete follow-up data. Patients with distant metastases, a history of familial malignancy or other synchronous malignancy (such as gastrointestinal stromal tumor, esophageal cancer, colorectal cancer, *etc.*), or carcinoma of the gastric stump after gastric resection for benign disease or who died in the perioperative period were excluded from the study.

D2 lymphadenectomy was performed by experienced surgeons following the JGCA guidelines[21]. A total of 15 313 lymph nodes were retrieved, with a mean of 14.70 ± 10.25 lymph nodes per patient (25.14 ± 9.28 for patients with > 15 lymph nodes retrieved and 8.58 ± 3.87 for patients with ⩽ 15 lymph nodes retrieved) and a range from 3 to 66. The mean number of lymph nodes with evidence of metastasis was 6.40 ± 6.90 per patient (9.78 ± 9.42 for patients with > 15 lymph nodes retrieved and 4.15 ± 2.83 for patients with ⩽ 15 lymph nodes retrieved), with a range from 1 to 70. Lymph node involvement was classified according to the 7th edition UICC (2010) N staging system (N0: no metastasis; N1: 1-2 metastatic lymph nodes; N2: 3-6 metastatic lymph nodes; N3: ⩾ 7 metastatic lymph nodes) and 6th edition UICC (2002) N staging system (N0: no metastasis; N1: 1-6 metastatic lymph nodes; N2: 7-15 metastatic lymph nodes; N3: ⩾ 16 metastatic lymph nodes). All nodal material was separately dissected from the specimen by a surgeon at the end of the procedure. Our study does not include stage Ⅳ patients, graded according to the UICC 7th edition staging system, because all of the patients enrolled underwent radical resection and had no distant metastasis.

Follow-up

Postoperative follow-up at our outpatient department included clinical and laboratory examinations every 3 mo for the first 2 years, every 6 mo during the third to fifth years, and annually thereafter until at least 5 years after the operation or until the patient died, whichever came first. Overall patient survival, defined as the time from operation to death or final follow-up, was used as a measure of prognosis. The median follow-up for the entire cohort was 56 mo (range 3-178 mo).

Statistical analysis

To determine the appropriate MLNR cut-points in the entire cohort, our analysis for the best cut-points was conducted as follows: In the first step, we evaluated the prognostic value of the MLNR, adjusting for other clinicopathological covariates that are significantly associated with gastric cancer mortality. Second, patients having no involved lymph nodes (MLNR = 0) were assigned to one group because it has been well documented that their prognosis significantly differs from patients with metastatic lymph nodes[12,15,22,23]. After ascertaining that the MLNR was significantly associated with gastric cancer mortality, we determined two additional appropriate cut-points for categorizing the MLNR to make our cut-

points comparable with those for UICC N staging. For this, we recomputed the likelihood associated with all possible pairs of MLNR cutoffs ranging from 0.05 to 0.95 at intervals of 0.05. In our study, the two alternative cut-points for the MLNR were 0.30 and 0.50. Martingale residual analysis was also used to examine the function form of the MLNR, and our cut-points (0, 0.30 and 0.50) were found to be consistent. After extensive evaluations of our data, no other sets of cut-points performed better than those already described. Thus, four subgroups of the MLNR classification (MLNR0, 0%; MLNR1, 1%-30%; MLNR2, 31%-50%; MLNR3, 51%-100%) were used in our study.

To directly compare the 6th and 7th edition UICC N staging systems with the present MLNR staging system, we took advantage of two statistical methods. One method considers the homogeneity, discriminatory ability and monotonicity of the gradient test. Homogeneity was measured with the likelihood ratio χ^2 test related to the Cox regression model. The discriminatory ability and monotonicity of the gradient were measured with the linear trend χ^2 test. The likelihood ratio χ^2 test was used to assess homogeneity within each classification system and to estimate the gradient monotonicity. Additionally, the Akaike information criterion (AIC) value within a Cox proportional hazard regression model was used to measure the discriminatory ability of each system[24]. The AIC statistic was defined by AIC = -2 log maximum likelihood + 2 × the number of parameters in the model. A smaller AIC value indicates that the model is better at predicting outcome. The other method involves receiver operating characteristic (ROC) curves. ROC curves and the areas under the curves (AUC) were calculated for each of the aforementioned three N staging systems to assess the accuracy of their predictive ability. Differences between the AUC were tested for statistical significance based on the estimated areas and their standard errors[25].

The 5-year survival rate was calculated using the Kaplan-Meier method. The log-rank test was used to make statistical comparisons of different factors. Pearson correlations were examined with a two-tailed test. In multivariate analysis, forward stepwise regression analysis was performed with a Cox proportional hazards model. A P value of $\leqslant 0.05$ was considered statistically significant. All statistical analyses were performed using SPSS software version 16.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Of the 1042 patients, 708 were male (67.9%) and 334 were female (32.1%). The mean patient age was 57.4 ± 11.5 years (range 20-79 years). The overall 5-year survival rate for all patients was 47.5%, and 474 patients were alive when our follow-up was complete.

Univariate and multivariate survival analysis

After univariate analysis of the 1042 patients who underwent radical resection, ten factors were found to have statistically significant associations with overall survival (OS). They were: age, tumor location, tumor size, histological grade, lymphatic/venous invasion, pT, 6th edition UICC pN, 7th edition UICC pN, MLNR, and the number of retrieved lymph nodes (Table 1). We summarize the postoperative survival results as follows: (1) patients who were older had significantly shorter OS than those who were younger [hazard ratio (HR) = 1.019, $P < 0.001$]; (2) patients whose primary tumor was located in the distal third of the stomach had significantly longer OS than those whose primary tumor was located elsewhere in the stomach (HR = 0.735, $P < 0.001$); (3) patients with a larger primary tumor had significantly shorter OS than those with a smaller primary tumor (HR = 1.147, $P < 0.001$); (4) patients with poorly differentiated or undifferentiated adenocarcinoma had significantly shorter OS than those with well or moderately differentiated adenocarcinoma (HR = 1.254, $P < 0.001$); (5) patients with tumor lymphatic/venous invasion had significantly shorter OS than those without lymphatic/venous invasion (HR = 2.685, $P < 0.001$); (6) the deeper the primary tumor invasion, the shorter the OS of the gastric cancer patients (HR = 1.852, $P < 0.001$); (7) the higher the metastatic lymph node counts of the 6th edition UICC N stage, the shorter the OS of the gastric cancer patients (HR = 1.571, $P < 0.001$); (8) the higher the metastatic lymph node counts of the 7th edition UICC N stage, the shorter the OS of the gastric cancer patients (HR = 1.604, $P < 0.001$); (9) the higher the MLNR stage, the shorter the OS of the gastric cancer patients (HR = 1.776, $P < 0.001$); and (10) patients who had more than 15 lymph nodes retrieved had significantly longer OS than those who had $\leqslant$ 15 lymph nodes retrieved (HR = 0.616, $P < 0.001$). All of the aforementioned 10 variables were included in a multivariate Cox proportional hazards model (forward stepwise procedure) to adjust for the effects of covariates (Table 2). In that model, we demonstrated that age, tumor location, tumor size, histological grade, lymphatic/venous invasion, pT, the 7th edition UICC N staging, MLNR, and the number of retrieved lymph nodes were independent prognostic factors, while the 6th edition UICC N staging was excluded.

The survival curves developed according to the 6th and 7th edition UICC N staging systems and the MLNR staging system are shown in Figure 1. For all three staging systems, the Kaplan-Meier plot had good discriminatory ability in each group except in N2 and N3 of the 6th edition UICC N staging (Figure 1). The 5-year survival rates of N0, N1, N2, and N3 patients in the 6th edition UICC N staging were 71.1%, 43.3%, 21.4%, and 25.1%, respectively ($P < 0.001$, $P < 0.001$ and $P = 0.143$, respectively). The 5-year survival rates of N0, N1, N2, and N3 patients in the 7th edition UICC N staging were 71.1%, 50.7%, 37.5%, and 22.2%, respectively ($P < 0.001$, $P = 0.003$ and $P = 0.001$, respectively). The 5-year survival rates of MLNR0, MLNR1, MLNR2, and MLNR3 patients were 71.1%, 59.0%, 32.7% and 16.0%, respectively ($P < 0.001$, $P < 0.001$ and $P < 0.001$, respectively).

Table 1 Univariate analysis of various clinicopathologic factors in 1042 cases of gastric cancer

Variable	*n* (%)	5-yr survival rate (%)	Log rank χ^2 value	Hazard ratio	*P* value

CI: Confidence interval; UICC: International Union Against Cancer; HR: Hazard ratio; T: Tumor; N: Node; MLNR: Metastatic lymph node ratio.

We also investigated the impact of the number of lymph nodes retrieved on OS rates according to different N staging systems. In the 6th edition UICC N staging, the 5-year survival rate was significantly higher for patients with N0 compared with N1 and N2 in the ≤ 15 lymph nodes retrieved group, in which no patient was classified as N3 ($P < 0.001$ and $P < 0.001$, respectively). The Kaplan-Meier plot discriminated well between each N staging in the > 15 lymph nodes retrieved group ($P = 0.008$ and $P < 0.001$, respectively), except for N2 *vs* N3 ($P = 0.720$). As for the 7th edition UICC N staging, the Kaplan-Meier plot discriminated well between each N staging in both the ≤ 15 and > 15 lymph nodes retrieved groups, except for N0 *vs* N1 and N1 *vs* N2 ($P = 0.070$ and $P = 0.433$, respectively) in the > 15 lymph nodes retrieved group. When we investigated the MLNR in the ≤ 15 and > 15 lymph nodes retrieved groups, the Kaplan-Meier plot showed that the 5-year survival rate was significantly different for each MLNR stage. In the ≤ 15 lymph nodes retrieved group, the 5-year OS was 66.2%, 49.9%, 29.9%, and 11.2% for MLNR 0, 1, 2, and 3 ($P = 0.001$, $P < 0.001$ and $P < 0.001$, respectively). In the > 15

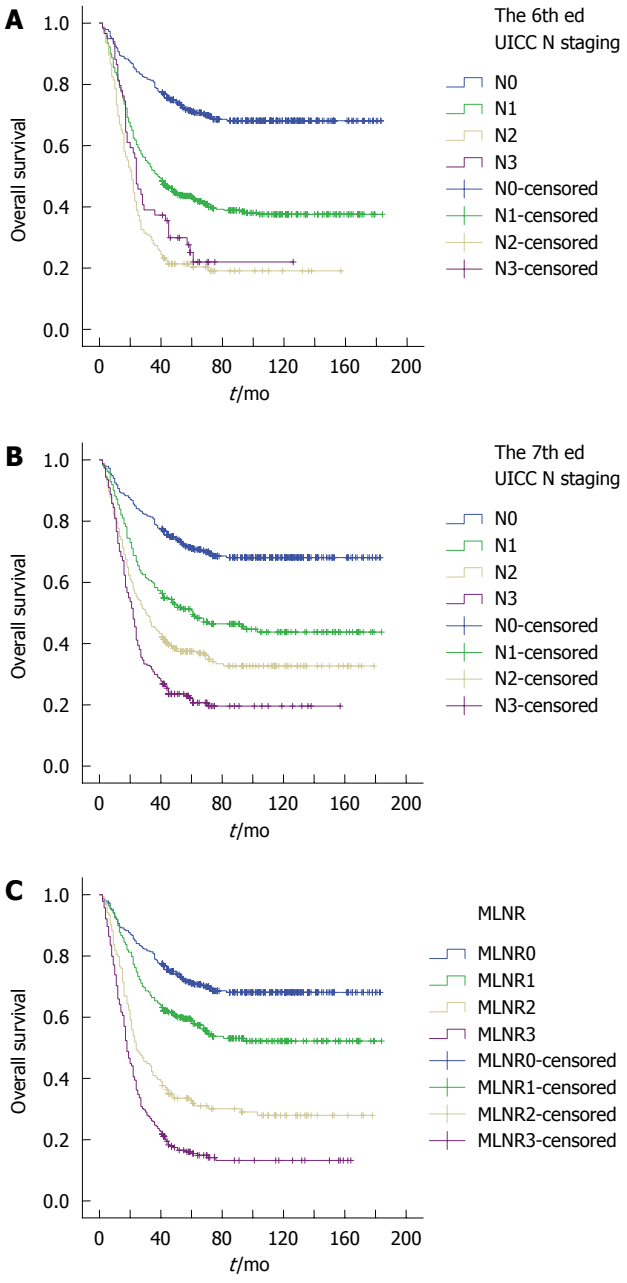

Figure 1 Impact of 6th and 7th International Union Against Cancer N staging systems (A and B) and metastatic lymph node ratio staging (C) on overall survival of gastric cancer patients who underwent radical resection. A: The 6th International Union Against Cancer (UICC) N staging: N0 *vs* N1, $P < 0.001$; N1 *vs* N2, $P < 0.001$; N2 *vs* N3, $P = 0.143$; B: The 7th UICC N staging: N0 *vs* N1, $P < 0.001$; N1 *vs* N2, $P = 0.003$; N2 *vs* N3, $P = 0.001$; C: Metastatic lymph node ratio (MLNR) staging: MLNR0 *vs* MLNR1, $P < 0.001$; MLNR1 *vs* MLNR2, $P < 0.001$; MLNR2 *vs* MLNR3, $P < 0.001$.

lymph nodes retrieved group, the 5-year OS was 82.5%, 68.3%, 38.7%, and 25.8% for MLNR 0, 1, 2, and 3 ($P = 0.001$, $P < 0.001$ and $P = 0.038$, respectively) (Figure 2).

The performance of the 6th and 7th edition UICC N staging systems and the MLNR staging, as assessed by the linear trend χ^2, likelihood ratio χ^2, and the AIC test, is described in Table 3. Compared with the 6th and 7th edition UICC N staging systems, the MLNR staging had better homogeneity (higher likelihood ratio χ^2 score), discriminatory ability, and monotonicity of gradients (higher linear trend χ^2 score). Furthermore, the MLNR staging had a smaller AIC value, representing the optimum prognostic stratification.

Table 3 Comparison of the performance of the 6th and 7th edition International Union Against Cancer node staging systems and the metastatic lymph node ratio staging system

Classification	Subgroups	Linear trend χ^2	Likelihood ratio χ^2	AIC
6th ed UICC N staging	N 0, 1, 2, 3	117.751	141.517	7364.073
7th ed UICC N staging	N 0, 1, 2, 3	138.342	146.796	7325.731
MLNR staging	MLNR 0, 1, 2, 3	203.476	219.912	7240.017

UICC: International Union Against Cancer; N: Node; MLNR: Metastatic lymph node ratio; AIC: Akaike information criterion.

Finally, we used the ROC curves of the three aforementioned N staging systems to calculate the AUC and thus to assess the accuracy of each system's predictive ability for gastric cancer patients who underwent radical resection (Figure 3). The AUC was 0.692 for the 6th edition UICC N staging, 0.705 for the 7th edition UICC N staging, and 0.754 for the MLNR staging, indicating that the MLNR staging was superior to the 6th and 7th edition UICC N staging systems and could be used as a more precise prognostic staging tool for gastric cancer patients.

DISCUSSION

Because the 6th edition UICC TNM staging system is simple, reliable, and reproducible, it is currently used all over the world. For cases in which < 15 lymph nodes are examined, N stage may be incorrect because of stage migration. A method for bypassing this problem is to consider the ratio between metastatic and examined lymph nodes. Studies have demonstrated that staging by the MLNR is superior to staging by the absolute number of metastatic lymph nodes (such as in the 6th edition UICC N staging) for predicting prognosis of gastric cancer patients[14,26,27]. Furthermore, some reports have demonstrated that the 7th edition UICC N staging is more suitable for prognosis than the 6th edition system[18,28]. For example, although all the patients in our study underwent D2 gastrectomy with R0 resection, the number of lymph nodes recovered in the majority of patients (63.1%) was no more than 15, and therefore, in these patients, the N stage cannot be classified as N3 according to the 6th edition UICC staging system. On the other hand, in the 7th edition system, patients may be classified as N3 as long as the number of retrieved lymph nodes is more than 7, and thus, this revised edition system may reduce stage migration. Whether the 7th edition UICC N staging is optimal is still unknown. To our knowledge, although a few documents claim that the 7th edition UICC N staging is superior to the 6th edition system, there are no formal studies

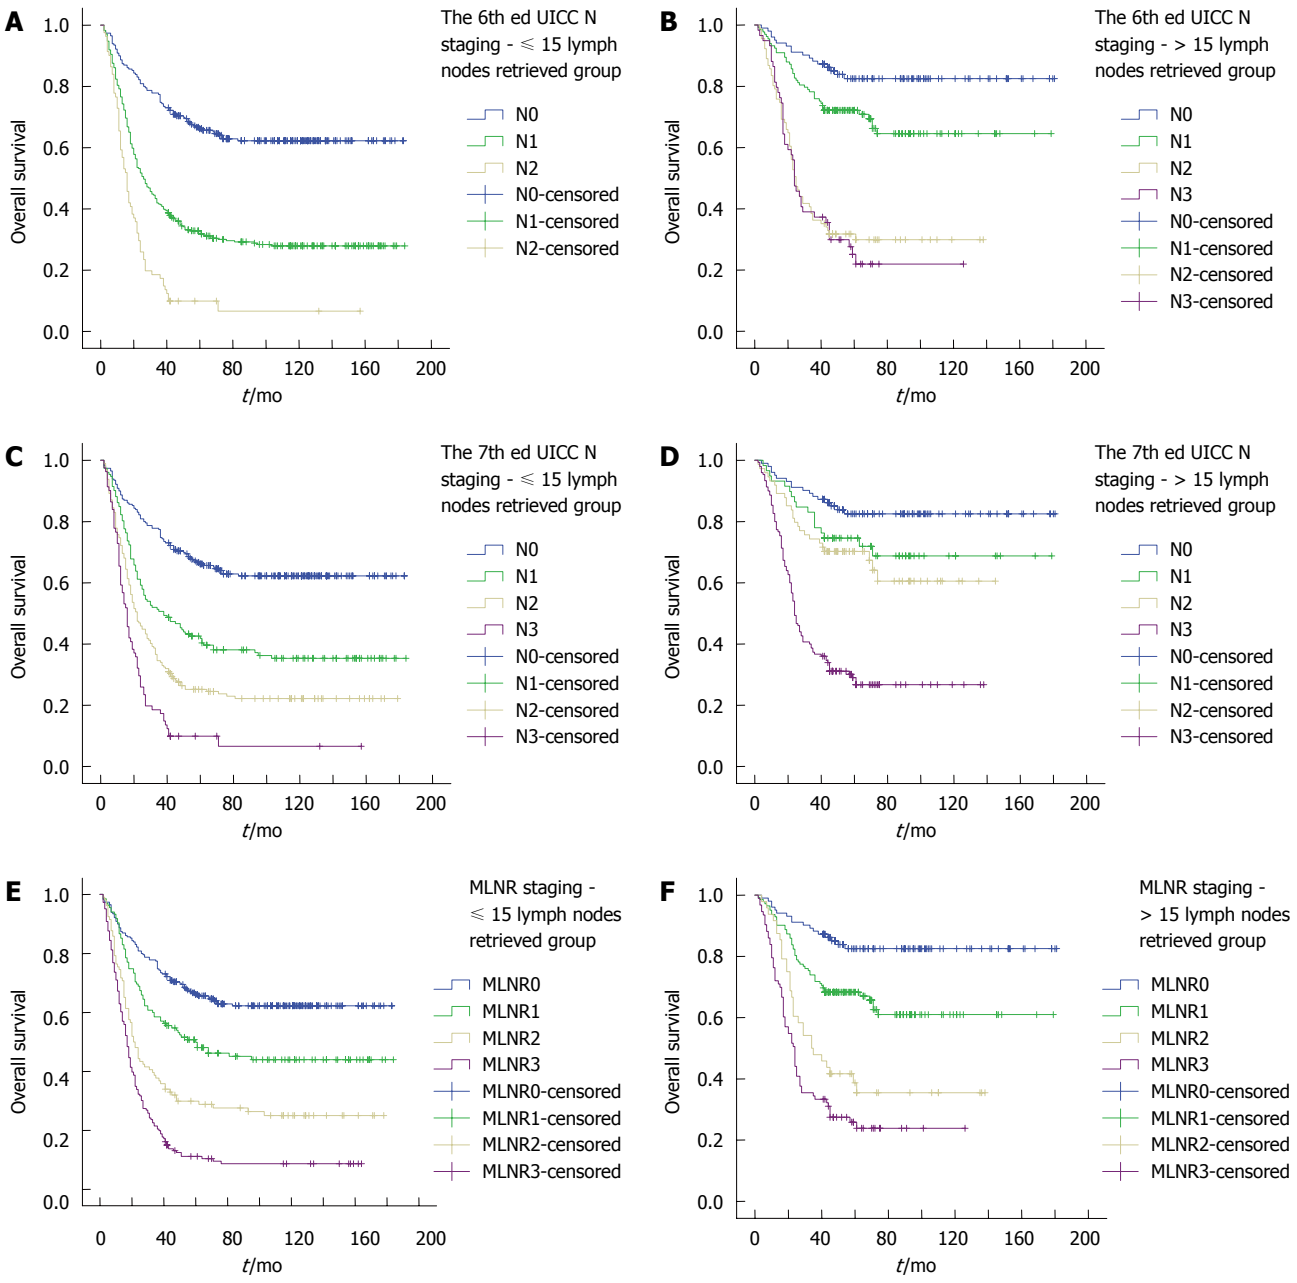

Figure 2 Analysis of the 6th (A and B) and 7th (C and D) International Union Against Cancer N staging systems and metastatic lymph node ratio staging (E and F) stratified according to the number of lymph nodes retrieved. A: The 6th International Union Against Cancer (UICC) N staging in the ≤ 15 lymph nodes retrieved group: N0 *vs* N1, $P < 0.001$; N1 *vs* N2, $P < 0.001$; B: The 6th UICC N staging in the > 15 lymph nodes retrieved group: N0 *vs* N1, $P = 0.008$; N1 *vs* N2, $P < 0.001$; N2 *vs* N3, $P = 0.720$; C: The 7th UICC N staging in the ≤ 15 lymph nodes retrieved group: N0 *vs* N1, $P < 0.001$; N1 *vs* N2, $P = 0.001$; N2 *vs* N3, $P < 0.001$; D: The 7th UICC N staging in the > 15 lymph nodes retrieved group: N0 *vs* N1, $P = 0.070$; N1 *vs* N2, $P = 0.433$; N2 *vs* N3, $P < 0.001$; E: Metastatic lymph node ratio (MLNR) stage in the ≤ 15 lymph nodes retrieved group: MLNR0 *vs* MLNR1, $P = 0.001$; MLNR1 *vs* MLNR2, $P < 0.001$; MLNR2 *vs* MLNR3, $P < 0.001$; F: MLNR stage in the > 15 lymph nodes retrieved group: MLNR0 *vs* MLNR1, $P = 0.001$; MLNR1 *vs* MLNR2, $P < 0.001$; MLNR2 *vs* MLNR3, $P = 0.038$.

that have examined the superiority of the MLNR to the 7th edition UICC N staging to date.

In this study, the MLNR was one of the most important prognostic factors of gastric cancer mortality. The MLNR provided a better classification of patient prognostic risk profiles than the 6th and 7th edition UICC N classification systems, particularly in the analysis stratified by the number of lymph nodes retrieved. The MLNR shows a clear advantage over the 6th and 7th edition UICC N staging systems for the following reasons: first, in univariate analysis, the log-rank χ^2 associated with the MLNR ($\chi^2 = 281.341$) was larger than that of the 6th and 7th edition UICC N staging systems ($\chi^2 = 160.982$ and $\chi^2 = 168.281$, respectively), indicating a higher statistical significance (Table 1); second, in multivariate analysis, the HR was higher in the MLNR (HR = 1.330, 95% CI: 1.149-1.538) staging than in the 7th edition UICC N staging (HR = 1.218, 95% CI: 1.037-1.430) (Table 2); third, although the 6th and 7th edition UICC N classifications discriminated well between each group,

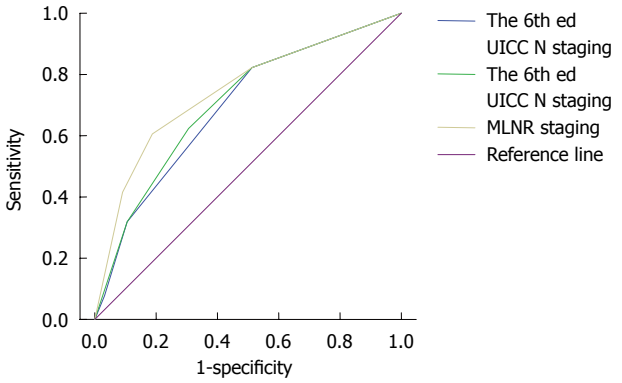

Figure 3 Receiver operating characteristics curve of the 6th and 7th edition International Union Against Cancer N staging systems and metastatic lymph node ratio staging for predicting survival of gastric cancer patients with radical resection. Area under the curve (AUC) of 1.0 represents a "perfect" diagnostic test that lacks false negative and false positive results. The AUC for the 6th and 7th edition International Union Against Cancer (UICC) N staging systems and metastatic lymph node ratio (MLNR) staging was 0.692, 0.705 and 0.754, respectively.

the MLNR provided a better classification of patient prognostic risk profiles than the pN stage, particularly in the analysis stratified by the number of lymph nodes retrieved (Figure 2); fourth, the MLNR staging had better homogeneity (higher likelihood ratio χ^2 score, 219.912 *vs* 146.796 *vs* 141.517), discriminatory ability, and monotonicity of the gradients (higher linear trend χ^2 score, 203.476 *vs* 138.342 *vs* 117.751) and a smaller AIC value (7240.017 *vs* 7325.731 *vs* 7364.073) (Table 3); and finally, the AUC under the ROC curve was larger in the MLNR staging (0.754) than in the 6th and 7th edition UICC N staging systems (0.692 and 0.705, respectively), indicating that MLNR staging was superior to the 6th and 7th edition UICC N staging methods and could be used as a more precise prognostic staging tool for gastric cancer patients.

According to Ueno *et al*[29], the performance of a staging system can be evaluated as follows: homogeneity within subgroups (small differences in survival among patients with the same stage), discriminatory ability between different groups (large differences in survival among patients in different stages), and monotonicity of the gradients shown in the correlation between stages and survival rates (within the same system, patients in earlier stages have longer survival than those in later stages). In our study, the MLNR staging had better homogeneity (higher likelihood ratio χ^2 score), discriminatory ability, and monotonicity of the gradients (higher linear trend χ^2 score) than did the 6th and 7th edition UICC N staging systems. Furthermore, in our study, the MLNR staging had a smaller AIC value, indicating that the MLNR staging has the optimum prognostic stratification and smallest loss of information for predicting outcome[30,31]. Additionally, the AUC under the ROC curve was larger in the MLNR staging than the aforementioned two N staging systems. These results demonstrate that the MLNR staging has better prognostic stratification and more precise prediction than do the 6th and 7th edition TNM staging systems.

Although the body of literature regarding the MLNR is growing, many studies have been performed using diverse patient groups and different surgical techniques. The cut-points for the MLNR have not necessarily been discussed adequately or validated in alternative data sets. We believe that systematic MLNR analyses of multi-institutional, randomized patient data with validation in similar independent data sets are required to clearly demonstrate the importance of the MLNR. Although the current UICC TNM staging system is the most basic and prevalent for predicting the survival of gastric cancer patients with radical resection, we believe that it will be essential to consider a staging system that includes accurate prognostic variables such as the MLNR in the near future. For all these reasons, the potential advantages of incorporating the MLNR in staging systems should be investigated in large, prospective data sets.

In conclusion, our study compared three lymph node based N staging systems for gastric cancer patients who underwent radical resection and D2 lymphadenectomy and then demonstrated that the MLNR categories could define gastric cancer prognosis more adequately and precisely than the 6th and 7th edition UICC N categories. We propose that nodal ratios should be considered as an alternative to the current UICC N staging.

COMMENTS

Background

In recent years, more new cases of gastric cancer are diagnosed in China each year than in any other country. The most powerful and reliable factors which have been widely used are the tumor-node-metastasis classification proposed by the International Union Against Cancer (UICC).

Research frontiers

Although UICC N staging is a convenient and reproducible method for precise staging, it demands the examination of at least 15 lymph nodes. If the number of dissected and examined lymph nodes is small or large, downmigration or upmigration of N stage may occur. The metastatic lymph node ratio (MLNR), defined as the number of positive lymph nodes divided by the number of lymph nodes retrieved, has been considered as an alternative to the absolute number of positive lymph nodes.

Innovations and breakthroughs

In the year 2010, staging of lymph node metastasis in gastric cancer has changed in both the UICC 7th edition staging system and in the Japanese Gastric Cancer Association 14th edition system to depend solely on the number of metastatic nodes found. Some authors have demonstrated that the 7th edition UICC staging system was superior to the 6th edition in aspects of homogeneity and discriminatory ability with prognostic value. However, there has been no formal proposal to date focused on comparing the prognostic significance between the MLNR and the 7th edition UICC N staging systems. In the present article, we investigated whether patients with gastric cancer can be classified into meaningful risk categories based on LNR, by comparing this staging with the 7th edition UICC N staging.

Applications

This study compared three lymph node based N staging systems for gastric cancer patients with radical resection and D2 lymphadenectomy, and then demonstrated that the MLNR categories could define gastric cancer prognosis more adequately and precisely than the 6th and 7th edition UICC N categories. The authors suggest that nodal ratios should be considered as a countermeasure to the current UICC N staging.

Peer review

This is a large study of 1042 gastric cancer patients undergoing radical resection plus D2 lymphadenectomy, with a mean follow-up of 56 mo. The authors have analyzed patient outcomes in considerable depth, their data is well characterized. They provide an in depth analysis of factors contributing to survival and have utilized multivariate analysis in doing this. The information in the manuscript is highly relevant and useful.

Abstract

Portal vein cannulation is a rare complication of endoscopic retrograde cholangiopancreatography (ERCP). It has been reported that it usually occurs after endoscopic sphincterotomy, whereas in cases without prior sphincterotomy, the presence of portobiliary fistulas has been shown. Here, we present a case in which cannulation of the portal vein occurred despite careful wire-guided cannulation and the absence of sphincterotomy. Although fatal cases of cerebral and pulmonary air and/or bile embolism have been reported in patients with combined portal and hepatic vein trauma after ERCP and sphincterotomy, isolated portal vein cannulation, as in the current case, does not usually result in mortality or serious morbidity. However, awareness of this rare complication is important so that no further intervention is performed.

Key words: Endoscopic retrograde cholangiopancreatography; Complications; Portal vein cannulation

TO THE EDITOR

A 68-year-old man presented acutely with a 2-wk history of right upper quadrant (RUQ) pain, fever, and dark urine. Physical examination revealed mild RUQ tenderness. Investigations demonstrated deranged liver function tests with raised alkaline phosphatase (481 U/L, reference < 130 U/L), alanine aminotransferase (371 U/L, reference < 55 U/L) and bilirubin (55 μg/L, reference < 22 μg/L). C-reactive protein was elevated (195 mg/L, reference < 10 mg/L) but full blood count and renal profile were normal. Transabdominal ultrasound scan showed dilated intrahepatic bile ducts and multiple calculi in the gallbladder. Endoscopic retrograde cholangiopancreatography (ERCP) was undertaken. The papilla was edematous (prior to instrumentation), which made cannulation difficult. When wire-guided cannulation was achieved, injection of 10 mL contrast failed to opacify the biliary tree (Figure 1). The procedure was aborted and abdominal computed tomography showed air in the portal venous system (Figure 2). The patient remained asymptomatic and was hemodynamically stable. He was observed as an inpatient, and 4 d later had a repeat ERCP. The common bile duct was cannulated and a cholangiogram showed multiple filling defects consistent with stones, but no opacification of the portal venous system occurred. All stones were removed after endoscopic sphincterotomy and the patient was referred for elective laparoscopic cholecystectomy.

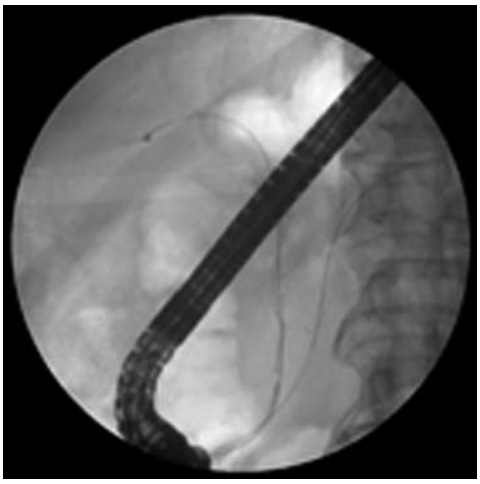

Figure 1 Sphincterotome in the portal vein after guide-wire cannulation. A two-wire technique was used as, initially, the pancreatic duct was cannulated.

Figure 2 Abdominal computed tomography scan obtained following index endoscopic retrograde cholangiopancreatography showing air in the portal venous system.

Opacification or deep cannulation of the portal vein is a rare complication of ERCP, which occurs in 1 of 6000-8000 procedures[1]. It has been reported to occur mainly, but not solely, in patients with pancreatic cancer[1-5]; usually after pre-cut and/or conventional sphincterotomy[1,3]. Portal vein cannulation may occur as a result of direct trauma to the papilla or mucosal and vascular laceration[1]. In cases in which sphincterotomy was not performed, investigators have noted the presence of portobiliary fistulas due to presumed tumor infiltration[2] or erosion by abscesses[4]. In the current case, cannulation of the portal vein occurred despite careful wire-guided cannulation and absence of sphincterotomy. Although fatal cases of cerebral and pulmonary air and/or bile embolism have been reported in patients with combined portal and hepatic vein trauma after ERCP and sphincterotomy[6], isolated portal vein cannulation, as in the current case, has not been reported to result in mortality or serious morbidity[5]. However, in the event of large defects in the portal vein with serious bleeding, balloon tamponade or stenting with a fully covered stent can be performed, prior to considering surgical repair. Finally, awareness of this rare complication is important, so that it is readily recognized by endoscopists, and no further intervention (e.g., sphincterotomy or stent insertion into the portal vein) is performed.

World J Gastroenterol 2011 December 14; 17(46): I-VI
ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Primary liver cancer is the fifth most common malignancy in men and the eighth in women worldwide. The liver is also the second most common site for metastatic spread of cancer. To assist in the diagnosis of these liver lesions non-invasive advanced imaging techniques are desirable. Magnetic resonance (MR) is commonly used to identify anatomical lesions, but it is a very versatile technique and also can provide specific information on tumor pathophysiology and metabolism, in particular with the application of MR spectroscopy (MRS). This may include data on the type, grade and stage of tumors, and thus assist in further management of the disease. The purpose of this review is to summarize and discuss the available literature on proton, phosphorus and carbon-13-MRS as performed on primary liver tumors and metastases, with human applications as the main perspective. Upcoming MRS approaches with potential applications to liver tumors are also included. Since knowledge of some technical background is indispensable to understand the results, a basic introduction of MRS and some technical issues of MRS as applied to tumors and metastases in the liver are described as well. *In vivo* MR spectroscopy of tumors in a metabolically active organ such as the liver has been demonstrated to provide important information on tumor metabolism, but it also is challenging as compared to applications on some other tissues, in particular in humans, mostly because of its abdominal location where movement may be a disturbing factor.

Key words: Metastasis; Metabolism; Proton magnetic resonance spectroscopy; Phosphorus magnetic resonance spectroscopy; Carbon-13 magnetic resonance spectroscopy; Magnetic resonance spectroscopy; Magnetic resonance

INTRODUCTION

Primary liver cancer is the fifth most common malignancy in men and the eighth in women worldwide. In 2000, it was estimated that there were about 564 000 new cases of liver cancer worldwide, and a similar number of patients died as a result of this disease[1]. Also, the liver is

the second most common site for metastatic spread of cancer[2]. In fact, liver lesions are more likely to represent a metastatic tumor than a primary liver tumor[3,4]. For further clinical management a proper diagnosis is crucial. Currently tissue sample analysis by histopathology is the golden standard for the diagnosis of suspected cancer in the liver. However, taking biopsies for histopathological analysis has some disadvantages. Besides patient discomfort, there is a change that the needle misses the cancer foci. Also, the needle might loosen cancerous cells which could result in tumor dissemination outside the liver along the needle track[5].

Thus, non-invasive advanced imaging techniques are desirable to assist in the diagnosis of liver lesions. A major modality to obtain anatomical information is magnetic resonance (MR). The MR technique is very versatile and it also offers many possibilities to acquire more functional information. Among these, MR spectroscopy (MRS) is particular interesting as it can provide specific information on tumor pathophysiology and metabolism. This may include data on the type, grade and stage of the tumor, which thus can assist in further management of the disease.

In this review, we will summarize and discuss the available literature on MRS of primary liver tumors and metastases. We will focus on the main nuclei employed in MRS, proton (^{1}H), phosphorus-31 (^{31}P) and carbon-13 (^{13}C). Since knowledge of some technical background is indispensable to appreciate the impact of the results described in this paper we first give an introduction into the basics of MRS and some technical issues of MRS as applied to tumors and metastases in the liver.

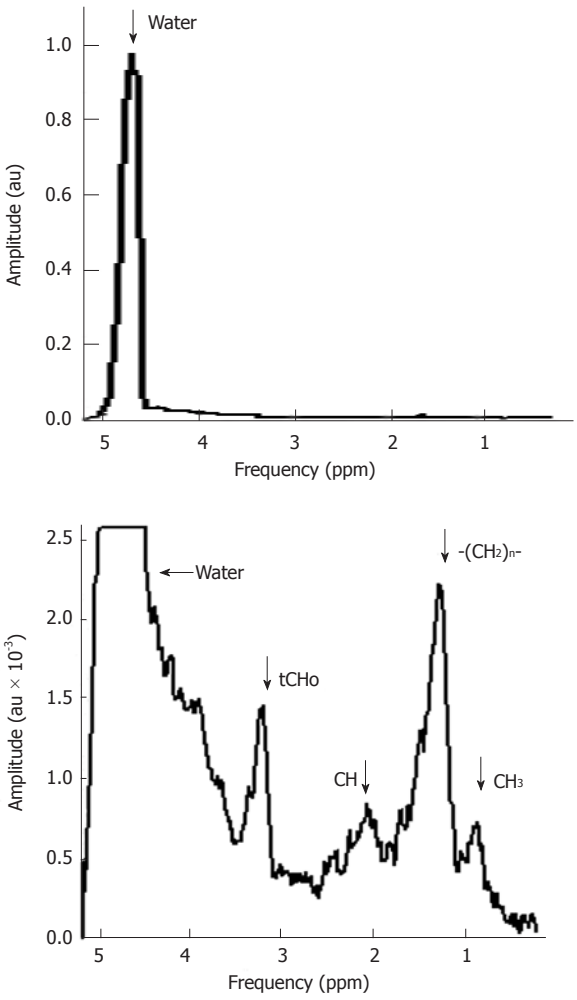

Figure 1 *In vivo* ^{1}H magnetic resonance spectra of human liver tissue obtained from a healthy volunteer on a 3.0T magnetic resonance system. Above: Spectrum with unsuppressed water signal; Below: Spectrum with partial suppressed water signal, showing the overlapping resonances for N-(CH$_3$)$_3$ protons at about 3.2 ppm occurring in choline compounds (tCho) and resonances for specific protons in lipids.

BASIC CONCEPTS OF MAGNETIC RESONANCE SPECTROSCOPY

In vivo MRS allows for the noninvasive measurement of the levels of some compounds in body tissues. It exploits the magnetic properties of certain atomic nuclei that are present in these molecules. The nuclei that are best accessible for *in vivo* MRS experiments are those of proton (^{1}H), phosphorus (^{31}P) and carbon-13 (^{13}C) atoms.

The following sections present a short introduction of MR spectroscopy to provide the reader with sufficient background to understand the biological and clinical applications of MR spectroscopy. For more in-depth information the reader is referred to other publications, see for example[6].

MR spectra

The key feature of MR spectroscopy is that certain biochemical compounds, mostly metabolites, can be identified in an MR spectrum by their specific spectral pattern, which is composed of one or more distinct signals. The intensity of the signal is proportional to the tissue amount of a certain nuclei and thus reflects the tissue levels of the compound in which it is present. An example of a typical *in vivo* ^{1}H MR spectrum of a healthy liver is shown in Figure 1. The horizontal axis of a spectrum represents the resonance frequency or chemical shift (both terms are explained below), the vertical axis represents the signal intensity. This spectrum is dominated by three main signals and in addition there are some smaller peaks, and broad underlying resonances. In the next few sections we explain in more detail how this spectrum is obtained and what particular information can be extracted from it.

Larmor frequency

Atomic nuclei with unpaired neutrons and/or protons, are detectable by nuclear magnetic resonance (NMR). As the nucleus is spinning around its axes and bears an electric charge it is associated with a magnetic dipole that can be seen as a tiny bar magnet (Figure 2). Outside a magnetic field these nuclear spins or tiny magnets have a random orientation; however, when placed in a strong constant external magnetic field B_0 they will become

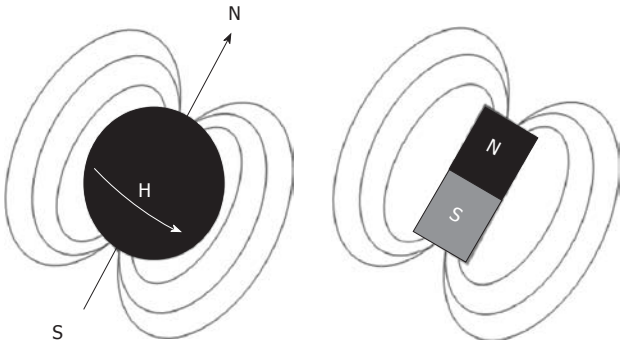

Figure 2 A ^{1}H nucleus spinning around its axes (left) can be regarded as a tiny bar magnet (right).

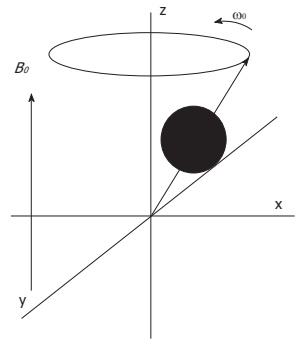

Figure 4 A spin precessing with the Larmor frequency around the axis of B_0 at a small angle with respect to this axis.

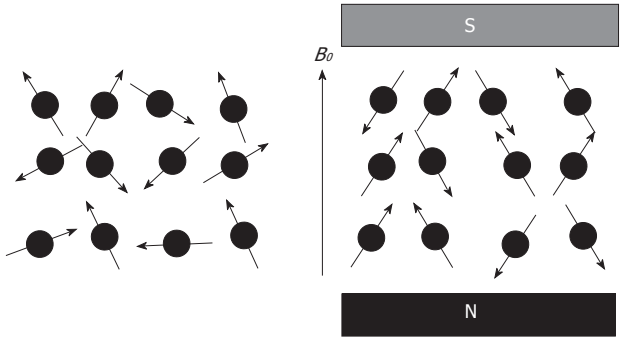

Figure 3 Outside a magnetic field spins have a random orientation (left) but spins inside a strong constant magnetic field B_0 will become aligned (right).

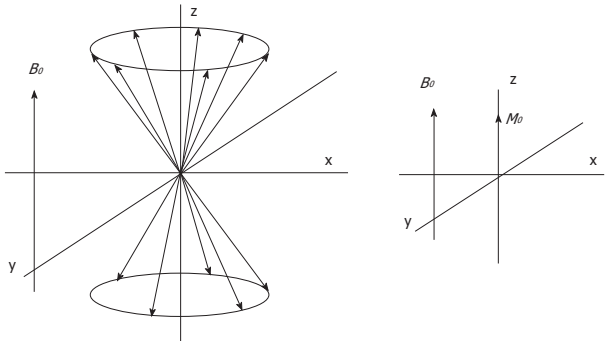

Figure 5 The direction of the main magnetic field B_0, is commonly placed along the z-axis and the magnetization along this axis is M_z, which at equilibrium, equals M_0. Left: Multiple individual spins precessing with the Larmor frequency around the axis of B_0. The spin vectors have a random, incoherent phase with respect to each other. Right: Magnetization vector M_z, which at equilibrium, equals M_0 (right).

aligned (Figure 3). The nuclear spins of the atoms ^{1}H, ^{31}P and ^{13}C can be oriented parallel or anti-parallel to B_0. However, the spins do not exactly align but are at an angle to B_0. This causes them to precess around the axis of B_0 with the so-called Larmor frequency $\nu_0 = \omega_0/2\pi = \gamma B_0/2\pi$ where the gyromagnetic ratio γ has a specific value for each nucleus (Figure 4). This implies that every type of nucleus has a different precession frequency, proportional to the B_0 field strength. At a field strength of 3T, which is commonly used for human applications, these frequencies for ^{1}H, ^{31}P and ^{13}C are: 127.7 MHz, 51.8 MHz and 32.1 MHz respectively, which is in the radiofrequency range.

Energy levels

The parallel and anti-parallel orientations are associated with a low and a high energy state respectively. The energy difference between the two spin states equals

$$E = h\,\gamma\,B_0 \qquad \text{[Equation 1]},$$

where h is Planck's constant ($h = 6.626 \times 10^{-34}$ J/s). At room temperature, there are slightly more spins in the lower energy level, N^{α}, than in the upper level, N^{β}. The distribution over these energy levels is given by Boltzmann statistics

$$N^{\beta}/N^{\alpha} = e^{-E/kT} \qquad \text{[Equation 2]},$$

where k is Boltzmann's constant (1.3805×10^{-23} J/K) and T is the temperature in Kelvin. The population difference results in a net macroscopic magnetization M_0. This so-called longitudinal magnetization is aligned parallel to B_0 (Figure 5). Only the net magnetization is detectable and its extent determines the achievable signal-to-noise ratio (SNR). At 1.5T and 37 ℃ (310 K), the population difference represents only a small fraction (about 10^{-6}) of the total spin population, which explains why MR is a relatively insensitive technique. It follows from Equations 1 and 2 that sensitivity can be improved with a higher magnetic field B_0 or a lower temperature.

Flip angle, free-induction decay, T_1 and T_2

The direction of the main magnetic field B_0, is commonly placed along the z-axis and the magnetization along this axis is M_z, which at equilibrium, equals M_0 (Figure 5). The longitudinal magnetization however is not detectable as it is "overruled" by the main magnetic field B_0. To detect the net macroscopic magnetization M_0, an radio frequency (RF) pulse with a magnetic field perpendicular to the main magnetic field B_0 and with a frequency equal to the precession frequency is sent with an RF transmitter coil. As a consequence of the applied RF pulse M_0 magnetization will rotate away from the z-axis toward the transverse plane (x-y plane). The angle to which the net magnetization is rotated relative to the main magnetic field direction is called the flip angle. A

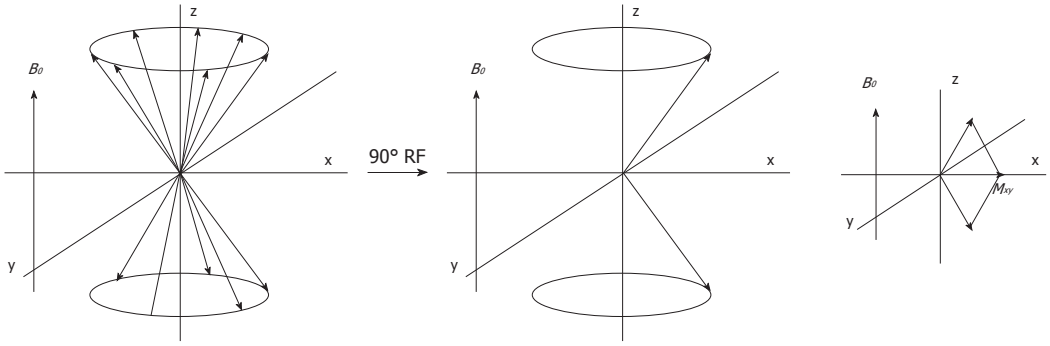

Figure 6 Multiple spins precessing with the Larmor frequency around the direction of B_0 (left). After a 90° radio frequency (RF) pulse, the spin population of the energy levels become equal and the spins precess coherently (middle). The magnetization vector M_0, rotates into the transverse (x-y) plane (right).

so called 90° RF excitation pulse will therefore rotate M_0 into the transverse plane. The spin population of the energy levels becomes equal and spins precess coherently (Figure 6). However, after the RF excitation pulse the spins start to return towards the original energy level distribution and towards incoherent precession (dephasing) and after a while the system will be in equilibrium again. The time constant which describes how the magnetization returns to the original longitudinal alignment is called the spin lattice relaxation time T_1: $M_z = M_0 (1\text{-}e^{-t/T1})$. The time constant which describes the return to incoherent precession is called the spin-spin relaxation time T_2: $M_{xy} = M_{xy0}\, e^{-t/T2}$. By definition T_1 is longer than T_2.

After the RF pulse, the transverse component of the M_0 magnetization precesses with the Larmor frequency at resonance and will induce a current in the RF coil which is now switched to receive mode. The decaying signal of this component is called the free-induction decay (FID) response signal. This digitally recorded FID signal is mathematically converted by a Fourier transform from the time to the frequency domain, which results in a so called MR spectrum, that may contain one or more resonances, signals or peaks at particular frequencies.

Shielding and chemical shift

An MR spectrum of the liver would not be very interesting if all nuclei of a certain type resonate at the same frequency. Fortunately, each nucleus in a given molecule is shielded from the main field by a weak opposing field from the surrounding electrons, induced by and also proportional to B_0. The amount of shielding by these electrons highly depends on the chemical environment of the nucleus. This shielding, which is generally unique for each chemically distinguishable site in a molecule, is expressed as the shielding constant σ, and the total effective field experienced by a given nucleus is: $B_{eff} = B_0 (1\text{-}\sigma)$. The resulting change in resonance frequency $\nu_{eff} = \omega_{eff}/2\pi = \gamma B_0 (1\text{-}\sigma)/2\pi$ relative to that of a chosen reference compound, ν_{ref}, is generally referred to as the chemical shift $\sigma = (\nu_{eff} - \nu_{ref})/\nu_{ref}$ expressed in units of ppm (1 ppm = 100 Hz at ν_0 = 100 MHz). Thus the chemical shift is the key property of MR spectroscopy which enables detection of a wide variety of chemical groups and metabolites containing these groups. Special RF pulses are used to excite a band of frequencies covering the chemical shift range of a particular nucleus in a biological sample.

^{1}H MR SPECTRUM OF THE LIVER EXPLAINED

As shown in Figure 1 the ^{1}H spectrum of the liver is dominated by 3 peaks. The peak on the right originates from the ^{1}H nuclei in methylene groups (-CH_2-) in lipids, the peak in the middle originates from the ^{1}H nuclei in the three methyl groups (CH_3) of choline containing compounds [$(CH_3)_3N^+CH_2CH_2O$-], and the peak on the left originates from the ^{1}H nuclei in water (H_2O). The electronegative oxygen atom in the water molecule shifts the electron density away from the ^{1}H nuclei, leading to a reduced shielding and thus to a higher resonance frequency compared to ^{1}H nuclei in the methylene groups of lipids. Thus ^{1}H nuclei in water have a higher chemical shift value then the ^{1}H nuclei in the methylene groups from lipids (compared to ^{1}H nuclei in a reference compound at 0 ppm) and appear on the left side. Note that the chemical shift scale on the horizontal axis increases from right to left.

The peak area rather than its amplitude is proportional to the amount of ^{1}H nuclei in the same chemical environment and thus the tissue content of that chemical group or metabolite. Quantification of metabolite concentrations is performed by comparing peak areas with those of known substances and concentrations.

The content of water in the liver is much higher than that of metabolites. Hence, the proton signals of the latter have a much lower SNR (Figure 1). For this reason signal averaging is usually required and it is also needed to measure larger voxels than commonly done with MR imaging of water.

WATER SIGNAL SUPPRESSION

As the water resonance in ^{1}H MR spectra is at least 200 times more intense than the resonances of hydrogen

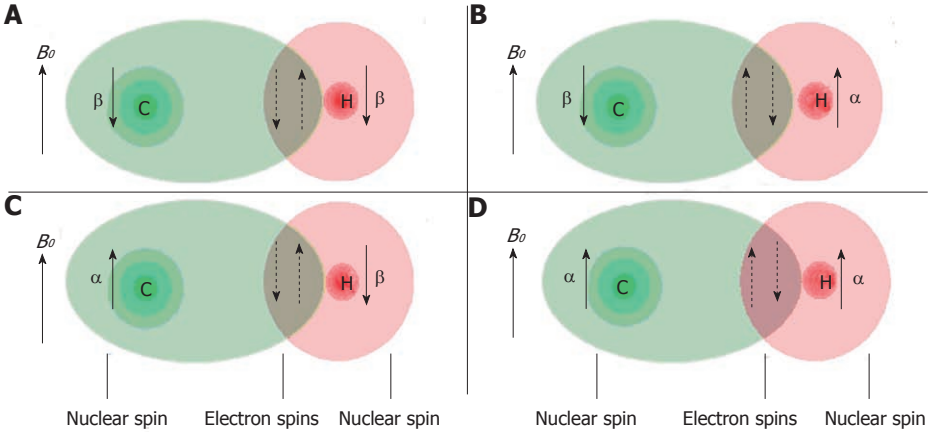

Figure 7 Two bonded nuclei, carbon (C) and hydrogen (H) in decreasing energy levels associated with spin states: ββ (A), βα (B), αβ (C) and αα (D). The electron clouds around each nucleus are indicated in light green and red. Arrows indicate individual spin states.

containing metabolites (Figure 1) it may hamper the proper detection of metabolite signals, e.g., by artifacts such as side bands of this huge signal[7], the suppression of the water signal is commonly performed. There are many ways to do this: a well-known sequence is chemical shift selective water suppression[8]. A frequency selective RF pulse excites the water spin magnetization into the transverse plane after which all coherences are dephased by magnetic field gradients. The spectrum shown in Figure 1 was obtained with only partial water signal suppression.

MAGNETIC FIELD HOMOGENEITY

As the purpose of MR spectroscopy is to separate signals with different chemical shift it is crucial for its proper application that good magnetic field homogeneity is obtained over the object of interest. However, due to the many different tissue types and air containing compartments, the magnetic field in the human body is usually not very homogeneous, leading to broadened spectral lines, which may overlap. Therefore optimizing field homogeneity (a process called shimming) is usually a required step in an MR spectroscopy experiment. Good homogeneity is most important in ^{1}H MRS as it has a relatively small chemical shift range and needs a well separated and defined water signal for proper suppression and to avoid artifacts. By selecting small volumes of interest, a limited amount of different tissues are included which will result in a more homogeneous magnetic field. The requirements for homogeneity are much less strict for ^{31}P and ^{13}C MRS because resonances in their spectra are more separated (larger spectral dispersion).

SPIN-SPIN COUPLING AND DECOUPLING

Nuclei which are close to one another exert an influence on each other's effective magnetic field through electrons in chemical bonds (Figure 7). If the distance between non-equivalent nuclei is less than or equal to three bond lengths, this effect may be observable in the *in vivo* MR spectrum. Instead of one peak for a certain nucleus several smaller peaks are observed in the spectrum. This interaction of nuclei is often referred to as scalar coupling, J coupling or spin-spin coupling. Because of this splitting the signal to noise decreases and spectral interpretation may become more complicated. However, the specific pattern may also be helpful to identify specific molecular groups and with special pulse sequences the phenomenon of spin-spin coupling may be used to identify the resonances of these groups in the presence of other overlapping resonances (so-called editing).

Spin-spin couplings are expressed in Hz. A typical value for a three bond proton-proton coupling in metabolites is 7 Hz. For example this can be used to identify the methyl doublet resonance of lactate in ^{1}H MR spectra. At magnetic fields above about 2T, line width broadening will obscure the direct visualization of this coupling. Two bond ^{31}P - ^{31}P couplings occur at about 17 Hz in adenosine triphosphate (ATP). Heteronuclear couplings commonly dealt with in *in vivo* MRS are between protons and ^{31}P or ^{13}C. To improve signal to noise and spectral resolution the spin-spin splitting can be removed by a technique called decoupling. Special RF pulses are used to irradiate selected resonance(s) of nuclear spins such that their field directionality is averaged out. As a result nearby spins in a molecule experience no field of these irradiated spins anymore and the resonance splitting disappears.

Decoupling is important in MRS of ^{31}P and ^{13}C as these atoms often show split resonances due to nearby hydrogen atoms. Irradiation of these protons for decoupling increases the signal to noise ratio and improves spectral resolution. Irradiation also induces a through space effect called nuclear overhauser enhancement (NOE), which can increase signal intensity even more[9-11]. Typical enhancement values reached *in vivo* by NOE are 1.3-2.9 and 1.4-1.8 for ^{13}C-^{1}H and ^{31}P-^{1}H interactions respectively[6].

DYNAMIC NUCLEAR POLARIZATION

^{13}C labeled (enriched) substrates combined with ^{13}C MRS have traditionally been used to monitor metabolic conversions during steady-state conditions and even has been used to assess active metabolism in human tumors[12-14]. The relative low sensitivity of ^{13}C MRS prevented imaging of these processes. However, with polarization transfer techniques sensitivity can be enhanced[14-16].

Recently a new method has been introduced in biomedical MR, dynamic nuclear polarization (DNP), that mostly makes use of ^{13}C MRS, to image metabolic conversions at reduced acquisition times (in an order of minutes or less). Inspection of Equation 2 (above) reveals that decreasing the temperature also will increase the population differences between energy levels. DNP is a hyperpolarization technique that increases the spin polarization obtained at room or body temperature in traditional MR, by orders of magnitude by cooling the sample to very low temperatures and using selective microwave irradiation for efficient transfer of spin polarization from electron spin to nuclear spin[6,17,18]. The substrate is then rapidly transferred to body temperature for administration. The major disadvantage of DNP is that the polarization decay is determined by the spin-lattice relaxation time T_1 of the nucleus (20-40 s for a ^{13}C nucleus in a carboxyl group). The consequence is that only conversions in which substrates are rapidly taken up by tissues and metabolized within minutes can be imaged successful. With efficient uptake usually one or two metabolic steps can be imaged, before the signal has decayed away.

LOCALISATION

To analyze different regions of interest in the liver with healthy tissue or tumor lesions by *in vivo* MRS it is required that only signals that originate from these locations appear in the spectra. This can be achieved in different ways. The most rudimentary one is to use only a surface coil on the body adjacent to the liver with a simple pulse sequence globally selecting the area next to the coil. However, in most cases a better localization is desired. More advanced spatial localization is possible with single voxel or multi-voxel methods.

Single voxel localization

The most common single voxel localization techniques are Image Selected *In Vivo* Spectroscopy (ISIS)[19], Stimulated Echo Acquisition Mode (STEAM)[20] and Point Resolved Spectroscopy (PRESS)[21].

ISIS uses three frequency-selective inversion pulses, in the presence of three orthogonal magnetic field gradients. By turning on and off the inversion pulses, according to an encoding scheme, eight different scans are recorded. Adding and subtracting the different scans will add signal from the desired location while canceling signal from other locations. A disadvantage of ISIS is its sensitivity to motion as eight scans need to be obtained for a full 3D localization. ISIS is rarely used for ^{1}H MRS, because of potential artifacts such as those arising from incomplete water signal suppression. However, it is the favored method in ^{31}P MRS localization as effects due to relatively rapid T_2 decay and to J-coupling are avoided.

For ^{1}H MRS the most common single voxel localization techniques are STEAM and PRESS, which both use three spatially slice selective RF pulses to produce an echo signal from a well-defined region. STEAM uses 90°-90°-90° pulses and PRESS 90°-180°-180° pulses to define three orthogonal slices. Only signal from the volume of interest remains in the final echo. In STEAM 50% of the original signal is lost as the second 90° pulse only rotates half of the transverse magnetization to the longitudinal axis, while the other half is dephased by crushers. The PRESS technique retains full signal intensity, but the minimal possible TE is commonly larger than for STEAM.

Multi voxel localization

Multi voxel localization allows the detection of localized spectra from a multidimensional array of locations. Disadvantages compared to single voxel localization concerns some more magnetic field inhomogeneities due to the many different tissue types in the field of view, intervoxel contamination, and the minimally required number of scans that may end up in long acquisition times. Spectroscopic imaging techniques acquire the signal from multiple voxels by using phase encoding gradients[22], analogous to the phase encoding technique used in MR imaging. The nominal voxel size is the field of view divided by the number of phase encoding gradient steps. The actual voxel size can deviate substantially from the nominal value as the signal is sampled only over a finite time. This introduces intervoxel contamination due to the characteristics of the Fourier transform. This voxel bleeding can be decreased by apodization functions like those with Gaussian or Hamming shapes, however at the expense of decreased spatial resolution.

Conventional encoding of $N_1 \times N_2 \times N_3$ volume elements (voxels) requires $N_1 \times N_2 \times N_3$ acquisitions. A typical $16 \times 16 \times 16$ dataset obtained with a repetition time of 2000 ms and 4 averages would require a measuring time of $(16 \times 16 \times 16 \times 2000 \times 4/3600 = 9$ h). Therefore techniques are developed that increase the temporal resolution, e.g., by special k-space trajectories. For example "circular 2D or spherical 3D k-space sampling with k-space apodization during acquisition". This also reduces the total acquisition time by spending less time acquiring the high k-space coordinates and more time acquiring the low k-space coordinates. Other methods are based on fast magnetic resonance imaging (MRI) sequences, e.g., EPI, RARE, spiral and steady-state sequences[6].

QUANTIFICATION

Although the tissue level of metabolites is proportional

to the area under its signal curve in the spectrum, it commonly requires some corrections and calibration with a signal of known concentration to obtain an absolute number (e.g., in mmol/L).

Such a reference signal maybe that of water or of another metabolite in the liver assuming a stable and known value for its tissue level. In the liver, the unsuppressed water signal is often used as an internal reference after correction for T_1 and T_2 relaxation. However, dietary regimes and liver pathologies may affect the amount of water. Li *et al*[23] reported a 1.8 fold difference in five normal liver studies between the largest and smallest water signal intensity obtained from localized liver tissues. In four hepatocellular carcinoma studies, they observed a 3.2-fold difference between the largest and smallest water signal intensities obtained from the localized liver tumors. Lipid peaks exhibited even larger variations than did the water peaks.

External phantoms with known concentrations sometimes are also used for calibration purposes, but this may be not so practical in a clinical environment. In addition differences in coil loading have to be taken into account in this approach. To avoid correction and calibration issues spectral quantities are sometimes also assessed as ratio's between integrals of signals of different compounds.

MOTION AND OTHER ARTEFACTS

Motion can lead to voxel misregistration and outervoxel contamination. Motion of tissue through inhomogeneous fields (e.g., air in the lungs) results in broadening of the spectral resonances. Broadening of the resonances increases the risk of signal overlap and also lowers the signal to noise ratio. Compared to other organs like brain and skeletal muscle, MR spectroscopy of the liver is challenging as there are potential field inhomogeneities and artifacts caused by respiratory movement, cardiac and aortic pulsations[24-26]. Although often applied, breath-hold acquisitions may be problematic. Long acquisition times are needed to increase the SNR and, since a breath-hold period can only last for about 15 s in patients, the acquisition will require multiple breath-hold periods. Even when the acquisition is performed at end-expiration, there is no guarantee that the tissue is at exactly the same position, leading to outervoxel contamination. Respiratory and cardiac gating can be applied to reduce motion artifacts at the cost of an increased scan time. Another option is to align individual spectra and/or exclude bad spectra before averaging during post processing. Some liver pathologies, e.g., due to long-term total parenteral nutrition may induce iron accumulation in the liver, which will result in field inhomogeneities and broadening of the spectral resonances.

REPRODUCIBILITY

In order to predict treatment outcome or monitor therapy, differences in *in vivo* MR spectroscopy outcome parameters should reflect true differences in tumor biology and not differences induced by variations in the MRS protocol or interfering body physiology. This issue is relevant, since the time of MR scanning during the day (e.g., before or after a meal) or differences in eating patterns might already influence the metabolic activity and thus the concentrations of metabolites in the liver. Large inter- and intrapatient variability of MRS outcome parameters have been described[23].

^{1}H MR SPECTROSCOPY

In MR, hydrogen (proton) is the most commonly studied nucleus. Compared to other MR sensitive nuclei it has the highest sensitivity and occurs at 100% isotopic abundance. Almost all metabolites in the human body contain protons. Therefore, in principle a large amount of metabolites can be investigated. However, in practice, sensitivity restrictions set the *in vivo* detection limit of metabolites to a minimum tissue concentration of about 0.1 mmol/L. An advantage of ^{1}H MRS is that it uses the same nucleus as MRI techniques. Therefore, it can be performed with the same hardware and there is no need for special equipment. The major drawback of ^{1}H MRS is the relatively small chemical shift range (about 10 ppm) for the many resonances of *in vivo* detectable compounds, resulting in limited spectral resolution. Moreover, these have to be resolved from a dominating water peak, in certain cases a large lipid peak, and at short echo times a high baseline due to macro-molecules.

Metabolites visible in ^{1}H MR spectra of liver tumors

Lipids: Outside the brain ^{1}H MR spectra of tissues usually show large signals of mobile lipids, mostly triglycerides: in particular a methylene peak at 1.2 ppm with smaller methylene peaks between 2.1 and 2.4 ppm and a peak for methyl protons at 0.9 ppm (Figure 1). Triglycerides occur in fatty liver, but also may be a marker of membrane breakdown and can be seen in tumors, abscesses and other pathological processes[27].

Lactate: Due to the Warburg effect tumor cells obtain relative less energy than normal cells from oxidative phosphorylation and have a more glycolytic character[28,29]. Pyruvate, the end product of glycolysis, is converted into lactate, which is further promoted by hypoxic conditions. Therefore MR spectra of tumor tissue often show signals for lactate. The three equivalent methyl protons of lactate give rise to a resonance at 1.31 ppm, which is a doublet due to coupling with the methylene proton, while the single methylene proton resonates as a quartet at 4.10 ppm due to coupling with the methyl protons. In liver and tumor tissue, the lactate signal at 1.3 ppm will overlap with large lipid resonances. However, with so-called spectral editing techniques it is possible to separate the lactate signal from the lipid signals.

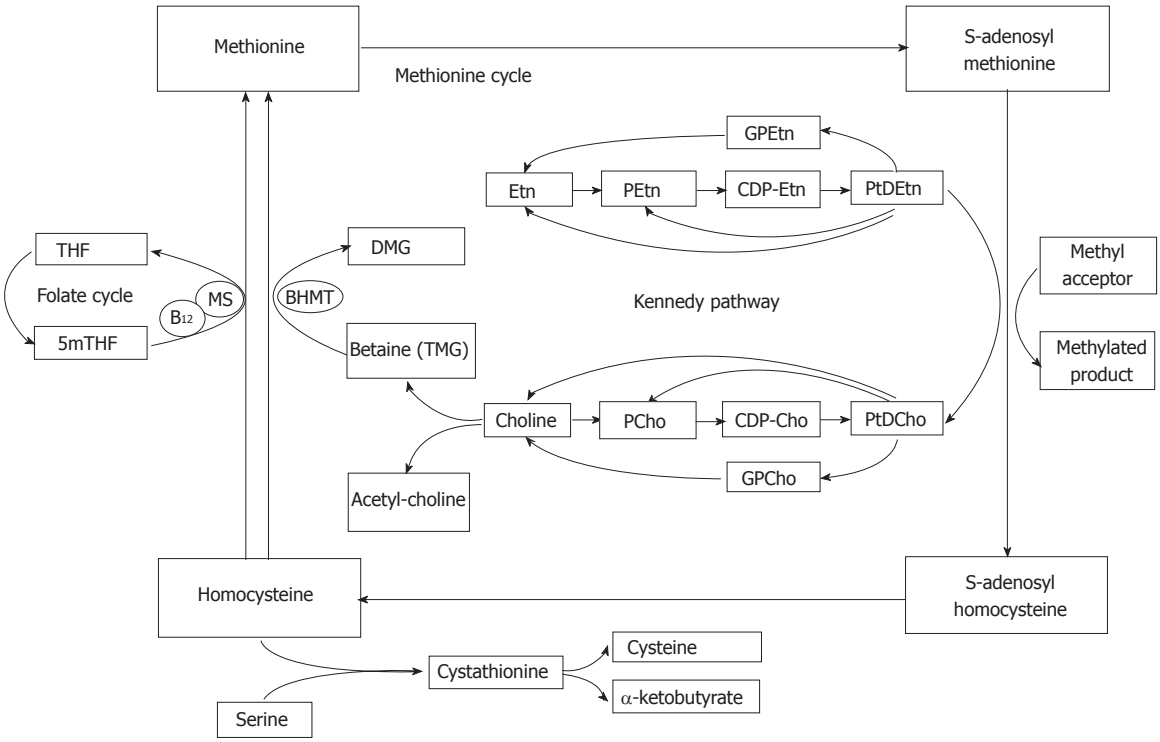

Figure 8 Simplified schematic overview of choline and ethanolamine metabolism including parts of the Kennedy pathway, the methionine and folate cycle. B12: Vitamin B12; BHMT: Betaine-homocysteine methyltransferase; CDP-Cho: Cytidine diphosphate-choline; CDP-Etn: Cytidine diphosphate-ethanolamine; DMG: Dimethylglycine; Etn: Ethanolamine; GPCho: Glycerol-3-phosphorylcholine; GPEtn: Glycerol-3-phosphorylethanolamine; MS: Methionine synthase; PCho: Phosphorylcholine; PEtn: Phosphorylethanolamine; PtdCho: Phosphatidylcholine; PtdEtn: Phosphatidylethanolamine; THF: Tetrahydrofolate; 5mTHF: 5-methyltetrahydrofolate; TMG: Trimethylglycine (betaine).

Creatine: Creatine (Cr) and phosphorylated creatine (PCr) play an important role in energy metabolism of many tissues. PCr serves as a spatio-temporal energy buffer, maintaining a constant level of ATP, facilitated by the creatine kinase reaction. The methyl protons of Cr and PCr resonate at about 3.03 ppm and the methylene protons resonate at approximately 3.9 ppm. Under normal conditions, the concentration of total creatine is relatively constant in muscle and brain and therefore often used as an internal reference. However, decreased Cr levels have been observed in tumors and other pathologies. Furthermore, hepatocytes do not express creatine kinase under normal circumstances[30], and therefore no creatine peak will be visible in the spectrum of healthy liver tissue. *In vitro* experiments at 9.4T have shown 5-10 times increased levels of Cr in liver metastasis compared to normal liver tissue[31].

Choline and ethanolamine containing compounds

The signals of choline containing compounds in MR spectra have been used as key biomarkers to identify malignant tumors[32-34]. *In vivo* ^{1}H MR spectra of the liver show the N-trimethyl [$^{+}N(CH_3)_3$] resonances of choline compounds at about 3.2 ppm. This resonance is also known as the total choline (tCho) peak as it may originate from several different choline compounds. The relative increase in the tCho signal seen in human tumors is due to an abnormal choline uptake and/or metabolism related to cell membrane turnover. However, metabolism of choline containing compounds in tissue cells is complex. Although far less prominent in ^{1}H MR spectra than choline, ethanolamine signals may also contribute to a characteristic spectral profile of tumor tissue. Therefore some important biochemical pathways involving choline metabolism and the closely related metabolism of ethanolamine in the liver are briefly described (Figure 8).

Choline and ethanolamine metabolism

Choline is a key precursor molecule in several metabolic pathways. It can be acetylated, oxidized, phosphorylated or hydrolyzed. Choline oxidation plays a major role in the provision of methyl groups *via* its metabolite, trimethylglycine (betaine) that participates in the synthesis of S-adenosylmethionine (SAM). Methylation reactions are involved in the biosynthesis of lipids, the regulation of several metabolic pathways, and detoxification in the body. Choline phosphorylation results in compounds such as phosphatidylcholine (PtdCho), lysophosphatidylcholine, choline plasmalogen, and sphingomyelin which are essential for structural integrity and signaling in cell membranes[35-38].

PtdCho, the major phospholipid component of cells is derived from the Kennedy pathway[39], which has two branches, one *via* cytidine 5'diphospho (CDP)-choline and the other *via* CDP-ethanolamine (Figure 8). In the CDP-choline branch choline is initially converted

to phosphorylcholine (PCho) and after some steps to PtdCho which can be converted into choline or into PCho again[36]. Alternatively, phosphatidylethanolamine (PtdEtn) is generated *via* the CDP-ethanolamine branch, employing similar biochemical reaction steps. The resulting PtdEtn can be methylated, using SAM as the methyl donor, to PtdCho[36-38,40]. The methylation pathway is, however, only relevant in liver. In rat hepatocytes it accounts for 20%-40% of PtdCho synthesis[41]. Besides entering the CDP-choline branch of the Kennedy pathway, choline can also enter another major pathway in the liver in which it is oxidized into betaine[42-44].

Contributions to the tCho peak

The contribution of the nine methyl protons of free choline, which resonate at 3.19 ppm, to the tCho peak is limited as the concentration of free choline is usually low. Another potential contribution to the tCho peak may come from PtdCho, which makes up a very high proportion of the cell plasma membrane. However, it is a large molecule with a relatively short T_2 relaxation time that becomes even shorter by being incorporated into a membrane. Therefore, it is almost invisible in the *in vivo* ^{1}H MR spectrum. Nevertheless, some evidence suggests that PtdCho may contribute to the tCho signal[45]. Precursors of PtdCho such as PCho and phosphorylethanolamine (PEtn) are more likely to contribute to ^{1}H MR spectra as these are small molecules with long T_2 relaxation times. Experimental evidence suggests that the tissue levels of PCho and PEtn increase during cell proliferation and tCho levels also have been correlated with tumor aggressiveness[46]. In addition to PCho and PEtn [together called phosphomonoesters (PME)] their glycerol derivatives glycerol-3-phosphorylcholine (GPCho) and glycerol-3-phosphorylethanolamine (GPEtn) [together called phosphodiesters (PDE)] also contribute to the tCho signal. Besides protons of choline and ethanolamine containing compounds, protons from other metabolites might also resonate around 3.2 ppm, e.g., glucose at 3.23 ppm, myo-inositol at 3.27 ppm, and taurine at 3.25 ppm. In liver and kidney the resonance at about 3.26 ppm is almost entirely composed of proton signals of betaine (trimethylglycine)[6].

Liver tumors and metastases

***In vitro* high field ^{1}H MR spectra of the liver:** Soper *et al*[47] performed a diagnostic correlation between MR spectra and histopathology. They analyzed liver tissue specimens from 54 patients undergoing partial or total hepatectomy. The samples included 31 normal, 59 cirrhotic and 32 hepatocellular carcinoma (HCC) histologically confirmed tissues and were analyzed by ^{1}H MRS at 8.5 Tesla. They found reduced amounts of lipids and carbohydrate residues and increased tCho in HCC compared to all normal and all cirrhotic liver tissue. Cirrhotic liver tissue and HCC were distinguished with a sensitivity and specificity of 95.8% and 88.9%, respectively. Lactate signals of variable intensity were found at 1.3 ppm, probably resulting from anaerobic metabolism after excision.

***In vivo* liver ^{1}H MR spectrum:** *In vivo* ^{1}H MRS is characterized by a much poorer spectral resolution and SNR than *in vitro* ^{1}H MRS (see above, technical issues). Kuo *et al*[48] investigated the value of *in vivo* ^{1}H MRS in the assessment of large focal hepatic lesions. They included 43 consecutive patients and 8 normal volunteers in a prospective MRS study. MRS was performed at 3.0T with shallow and regular breathing. Single voxel PRESS with TE = 30 ms, TR = 1500 ms, 256 averages, was used to select a volume of 2 cm × 2 cm × 3 cm. The voxel of interest was located in the largest solid portion of hepatic tumors in patients. Healthy liver data was collected from an area at the centre of the right hepatic lobe for normal volunteers, or in an uninvolved area of the right hepatic lobe in patients. Patients with diffuse-type HCC, with focal nodular hyperplasia and obvious fatty infiltration, and histological unconfirmed lesions were excluded. Thirty-three lesions (21 HCC, 2 angiosarcomas, 1 lymphoma and 9 hemangiomas) were included. They found that malignant tumors had elevated tCho resonances compared to uninvolved liver or benign tumors, but the difference in mean tCho/lipid ratio between malignant tumors or uninvolved liver did not reach statistical significance. Several factors may have contributed to these results. First of all, the tumors in this study may have contained significant necrotic areas with less viable cells. This may have diluted more prominent changes observed in areas of rapid cell turnover, within viable tumor tissue and may have caused low signal to noise for metabolite signals leading to larger errors. Physiological motion due to breathing and cardiac movement will have contributed, especially if the tumor was located in the left lobe or at the extreme end of the right hepatic lobe. Finally, three different tumor types were included in the malignant group, which may have resulted in a variation of different metabolites in phospholipid metabolism, and thus in a more variable tCho resonance. Thus, *in vivo* ^{1}H MRS is technically feasible at 3.0T for the evaluation of focal hepatic lesions, but the clinical application of the measurement protocol used by Kuo *et al*[48] is limited as normal liver, benign and malignant tumors cannot be clearly differentiated.

In the second part of their study Kuo *et al*[48] attempted to measure metabolic changes in HCC after transcatheter arterial chemoembolization (TACE). Eight HCC were evaluated before and two to five days after TACE. The tCho peak at 3.2 ppm was significantly decreased while the lipid and water signals at 1.3 and 4.7 ppm respectively, were increased. The mean tCho/lipid ratio significantly decreased from 0.23 ± 0.11 before to 0.01 ± 0.00 after TACE treatment. One of the post-TACE lesions showed recurrence three months later and MRS also revealed an elevated tCho/lipid ratio at that stage. Therefore, ^{1}H MRS at 3.0T may be used for treatment monitoring.

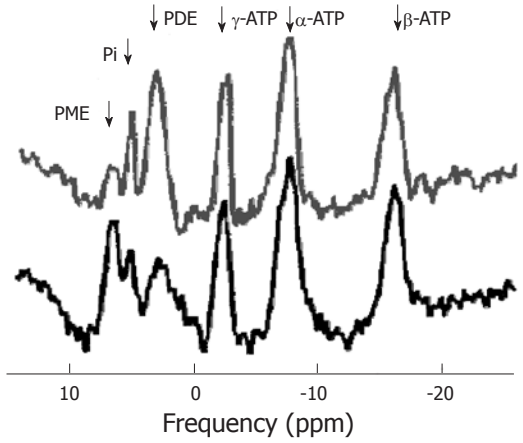

Figure 9 ***In vivo*** **^{31}P magnetic resonance spectra of human liver tissue obtained from a healthy volunteer (top) and from a patient with hepatocellular carcinoma (bottom).** PME: Phosphomonoesters; PDE: Phosphodiesters; Pi: Inorganic phosphate; ATP: Adenosine triphosphate. (Reproduced with permission of John Wiley and Sons, www.interscience.wiley.com, from[64].)

Fishbach *et al*[49] improved the MRS acquisition and processing protocol compared to previous studies by introducing a control of respiratory motion using breath-hold acquisitions and an abdominal compression belt. They also applied dedicated pre- and post-processing including automatic phase and frequency correction based on the residual and the unsuppressed water signal in order to remove potential distortions mainly introduced by motion. Apart from 39 volunteers, they included 55 patients with advanced cancer with lesions of more than 3 cm in diameter in their study (22 metastases of colorectal cancer, 11 hepatocellular carcinomas, 9 metastases of breast cancer, 3 metastases of pancreatic cancer and 1 metastasis of prostate cancer). Liver spectra were acquired at 3.0T using a body transmit/receive coil. Breath-hold at end-expiration spectra were acquired with the single voxel (2 cm × 2 cm × 2 cm) PRESS technique with TE=35 ms, TR=2000 ms, 128 averages and 16 additional unsuppressed water reference lines. The intra-individual reproducibility of this ^{1}H MRS acquisition in the liver was tested in 25 patients and volunteers and judged to be satisfactory. In total 186 spectra were acquired and 27 spectra had to be discarded because they did not meet the predefined quality specifications. The remaining 113 spectra were measured in normal-appearing parenchyma of 37 patients and 39 volunteers.

Although, remarkably, tCho signals relative to those of water seemed to be lower in metastatic lesions compared to normal liver tissue, no significant differences were observed between malignant liver tumors and normal liver parenchyma for any of the parameters analyzed, in particular tCho signals relative to water and lipid signals. This was attributed to the large variability of normal values.

The divergent results observed in the above mentioned studies might also be due to the multiple contributions from the unresolved tCho signal. In normal liver tissue low concentrations of PMEs and high concentrations of PDEs have been shown while in tumor tissue elevated levels of PMEs and decreased levels of PDEs have been observed[50]. This implies that in tumor tissue increased levels of PMEs may be canceled out by decreased PDEs, resulting in an unchanged overall tCho level. Different tumor types might also have divergent contributions to the unresolved tCho signal. In addition, alterations of the metabolite concentrations might not be due to malignancy, but due to proliferating healthy tissue such as a regenerating liver, benign tumors, and even some degenerative pathologies. With ^{31}P MRS PME and PDE signals can be studied separately as discussed below.

^{31}P MR SPECTROSCOPY

After ^{1}H MRS, phosphorus-31 MR spectroscopy is the most commonly used MRS technique to study tumors *in vivo*. Phosphorus has an MR sensitivity of 6.6% compared to proton. However, the chemical shift dispersion of its signals observed *in vivo* is larger (about 30 ppm *vs* about 10 ppm), resulting in a better spectral resolution. Also, ^{31}P MRS is capable of detecting some key metabolites in tissue energy metabolism such as ATP, PCr, and inorganic phosphate (Pi). In addition some important metabolites involved in membrane metabolism such as PCho and PEtn (together called PME) and their glycerol derivatives GPCho and GPE (together called PDE) may be resolved. In this respect ^{31}P spectra (Figure 9) are more informative than ^{1}H MR spectra in which signals of all choline compounds (tCho) usually are observed unresolved at about 3.2 ppm. Furthermore, from ^{31}P MR spectra physiological parameters like intracellular pH can be deduced from the chemical shift of the Pi resonance. The phosphoryl resonances from large and membrane bound compounds may only show up in a phosphorous-31 MR spectrum as broad underlying baseline signals due to their very short T_2 values[51].

Unfortunately, due to a lower sensitivity and less favorable spin relaxation the spatial resolution of ^{31}P MR spectra is an order of magnitude less than that of ^{1}H MRS. Higher magnetic fields provide improved experimental conditions for ^{31}P MRS.

Metabolites visible in ^{31}P MR spectra of liver tumors

Phosphocreatine: The largest peak in ^{31}P MR spectra of muscle, brain and other tissues originates from PCr. Its spectral position is used as an internal chemical shift reference and commonly has been assigned a chemical shift of 0.00 ppm. PCr is, however, not detectable in spectra of healthy liver since hepatocytes do not express creatine kinase under normal circumstances[30]. Tumors, however, might express creatine kinase and show some PCr.

Adenosine triphosphate: ATP is the main direct energy supply within cells. ATP consists of adenosine and three phosphate groups. The phosphoryl groups, starting with those closest to the adenosine moiety, are referred to as α, β,

and γ phosphates. ATP is produced by ATP synthase from inorganic phosphate and adenosine diphosphate (ADP) or adenosine monophosphate (AMP). Multiple processes in the cell can split ATP into ADP or AMP and inorganic phosphate, and use the energy that is released. At a pH of 7.2, with full magnesium complexation, the resonances of ATP appear at -7.52 ppm (α), -16.26 ppm (β), and -2.48 ppm (γ). The ATP resonances may overlap with the signals of other nucleotides: uridine triphosphate (UTP), guanosine triphosphate (GTP) and cytidine triphosphate (CTP). Therefore these resonances are sometimes referred to as nucleoside triphosphate (NTP), although the others usually occur at much lower concentrations.

Inorganic phosphate: Like the level of ATP that of inorganic phosphate (Pi) reflects the cellular phosphorylation potential. The chemical shift of Pi and some other phosphorus containing compounds is dependent on the intracellular pH (pHi) and magnesium concentrations[52]. The protonation or complexation with magnesium of phosphate affects the chemical environment of the ^{31}P nucleus and hence its chemical shift. As proton exchange is fast on the NMR timescale, the resonance frequency is indicative of the relative amount of protonated and unprotonated molecules, and hence the pH can be deduced. The shift in resonance of Pi relative to PCr is most commonly used as it has a large dependence in the physiological pH range whereas the chemical shift of PCr is constant in this range. At a pH of 7.2 and normal magnesium level it occurs at 5.02 ppm. The accuracy of pH determination from the Pi-PCr shift is typically 0.05 pH units[6]. However, as PCr is not detectable in the normal liver the α-ATP resonance is used instead as a reference.

Tumor pH: Due to the Warburg effect and/or hypoxic conditions tumor cells preferentially convert glucose to lactic acid. Lactic acid is largely dissociated *in vivo* to H^+ and lactate$^-$. Normal, as well as tumor cells, have multiple systems to continuously export H^+ ions to maintain a constant pHi, as well as a system for exporting lactic acid (but not lactate). This results in a neutral, or a slightly alkaline pHi of intact (tumor) cells. However, since tumors may be poorly vascularized the extracellular tumor pH (pHe) of tumors is more commonly acidic[53-59].

Phosphodiesters: Signals of PDE occur around 3 ppm in ^{31}P MR spectra. Tumor tissue sometimes contains significantly lower concentrations of PDE than healthy liver tissue. Some *in vitro* studies show that the PDE levels increase with decreasing growth fraction of the tumor. This suggest that PDE signals may be dominated by breakdown products of phospholipids[60], and the concentration may be an indicator of the necrotic fraction in tumors associated with phospholipid catabolism[61]. The phospholipid derivatives, particularly GPCho and GPEtn, were found to contribute to the PDE resonance[61]. Their phosphor spins resonate at 2.76 ppm and 3.20 ppm respectively.

Phosphomonoesters: Resonances of PME occur at about 6 ppm in ^{31}P MR spectra. Increased levels of PME have been hypothesized to be associated with intensified cell membrane synthesis, cellular growth, cell nutritional state and rate of cell replication. Several studies identified increased PME signals as a possible diagnostic marker for tumors. PME/PDE ratios were suggested to represent altered relative rates of membrane synthesis, catabolism and metabolic turnover[36,60,61]. Phospholipid derivatives, particularly PCho and PEtn, contribute to the PME resonance[61]. PCho and PEtn resonate at 5.88 ppm and 6.78 ppm respectively.

Liver tumors and metastases

***In vitro* high field ^{31}P MR spectroscopy of liver:** Many *in vitro* ^{31}P MRS animal studies and several *in vitro* ^{31}P MRS studies on human hepatic tumor tissues have been performed. Obtaining a fully representative human hepatic tissue sample for ^{31}P MRS is difficult as the surgical removal and extraction usually results in a period of ischemia/hypoxia, which affects metabolic processes resulting in decreased ATP and increased Pi levels. Nevertheless, *in vitro* ^{31}P MRS may be used to study signals in the PME and PDE peaks that are still unresolved in *in vivo* ^{31}P MR spectra, as these are less affected by short periods of hypoxia.

Bell *et al*[50] investigated the metabolic changes arising in hepatic tumors and the possible systemic effects of these tumors on the liver as a whole. Ten biopsy specimens were obtained from hepatic tumors (one cystadenoma, four hepatocellular carcinomas, four metastatic colonic adenocarcinomas and one metastatic squamous cell carcinoma from the lungs). Five histologically proven normal tissue samples from the same tumor-bearing hepatic lobe were obtained immediately after the blood supply had been clamped and before partial hepatectomy. Six control samples were obtained from morphologically normal liver tissue from patients with histologically proven chronic pancreatitis and known to be free of any hepatic malignancy. Both ^{31}P spectra with proton decoupling and ^{1}H MR spectra with partially water suppression were acquired using high-resolution 11.7T systems. Betaine is the most prominent resonance in the *in vitro* rat liver ^{1}H spectrum but no resonance for betaine was observed in any of the human biopsy samples, suggesting that its presence is species related. The *in vitro* ^{31}P MRS spectrum showed that over 10 different compounds contributed to the PME resonance. The five principal resonances were: PCho, PEtn, glucose-6-phosphate, AMP, and glycerol-3-phosphate. The PDE region included at least 3 different compounds. The two main components were: GPCho and GPEtn. Compared to control tissue, tumor tissue showed significantly lower concentrations of GPCho (0.59 ± 0.15 *vs* 2.46 ± 0.37) and GPEtn (0.57 ± 0.17 *vs* 2.25 ± 0.46), and elevated levels of PCho (1.36 ± 0.50 *vs* 0.17 ± 0.11) and PEtn (2.47 ± 0.84 *vs* 0.16 ± 0.10). It was suggested that the increase in PME/NTP observed in *in vivo* spectra of HCC and

Table 1 Number of different cases

	High PME	High PDE	High Pi	Low PCr
HCC	91% (of 11 cases)	75% (of 4 cases)	0% (of 4 cases)	100% (of 11 cases)
Liver metastasis	100% (of 7 cases)	33% (of 6 cases)	17% (of 6 cases)	100% (of 4 cases)
Liver lymphoma	100% (of 6 cases)	17% (of 6 cases)	100% (of 6 cases)	100% (of 6 cases)

"High" and "low" levels are relative to the amount in normal or benign tissue (from Negendank[70]). PME: Phosphomonoesters; PDE: Phosphodiesters; Pi: Inorganic phosphate; PCr: Phosphorylated creatine; HCC: Hepatocellular carcinoma.

liver metastasis (see next section) is due to increased levels of PCho and PEtn. The decrease in concentration in GPC and GPE observed in this study might be responsible for the change in PDE/NTP seen in *in vivo* spectra. However, the underlying cause of these changes remains partially unknown and requires further study.

Bell *et al*[50] also observed that spectra from histologically normal tissue from the liver tumor-bearing hepatic lobe contained more PCho (0.32 ± 0.18 *vs* 0.17 ± 0.06) and PEtn (0.34 ± 0.12 *vs* 0.16 ± 0.07) than spectra obtained from control tissue. The levels of GPC and GPE showed no significant change.

Previously, in 1993 Dagnelie *et al*[62] studied liver metabolic changes in rats bearing subcutaneous Dunning prostate tumors by *in vivo* and *in vitro* ^{31}P MRS. Although absence of metastatic tumor cells in the liver of all tumor-bearing animals was confirmed by histological examination, hepatic phosphorylation status, phospholipid metabolism, and gluconeogenesis was significantly affected in the tumor-bearing animals. Dagnelie *et al*[63] also investigated liver metabolism in humans with metastatic cancer without evidence of liver metastases by ^{31}P *in vivo* MRS. They included 23 cancer patients and 12 healthy subjects and found markedly elevated PME and reduced PDE levels in the non-metastatic liver compared to controls.

Thus this may complicate the use of increased PME (PCho and PEtn) levels as a sole diagnostic biomarker to detect (metastatic) liver cancer. In addition, as no significant differences between HCC and liver metastasis were observed in biopsy samples by *in vitro* ^{31}P MRS[50,64], the use of *in vivo* ^{31}P MRS seems limited in this differentiation.

***In vivo* ^{31}P MRS of the liver:** In 1985 Maris *et al*[65] combined the results of *in vivo* and *in vitro* ^{31}P MR spectroscopy studies to compare the spectral characteristics of the liver of 2 children, one infant with neuroblastoma stage Ⅳ-S and the other with neuroblastoma stage Ⅳ disease. The ^{31}P MR spectra from the primary tumor in the latter infant, and the spectra from the infiltrated liver regions in both the infants showed substantially elevated PME/β-NTP ratios compared with a spectrum from a normal control. The ratio increased during periods of rapid progression and persisted until treatment became effective. The PME/β-NTP ratio decreased to normal values, during either spontaneous or therapy-induced regression of the disease[66]. It was suggested that the increased PME (corresponding to PEtn and PCho) was due to the need for increased phospholipid synthesis in these tissues. This study demonstrated that ^{31}P MRS could be used to detect tumors and to monitor their response to treatment.

Dixon *et al*[67,68] studied whether hepatic involvement in lymphoma produced biochemical changes that could be detected by *in vivo* ^{31}P MRS of the liver. Twenty-two patients were included. Lymph node biopsies showed that eight patients had Hodgkin's disease and 14 non-Hodgkin's lymphoma. Eleven patients of these 14 had high grade lymphoma and three low grade disease. Six patients, diagnosed with lymphomatous infiltration of the liver on the basis of liver function tests and either ultrasound or CT imaging, had a significantly higher PME/Pi ratio (1.43 ± 0.37) or PME/ATP ratio (0.94 ± 0.27) compared to 25 controls (ages 20-50 years) (0.58 ± 0.11 and 0.37 ± 0.10, respectively) with normal livers. The PME/Pi ratio decreased following chemotherapy to an average of 66% of the initial value (range 40%-82%). In two patients the ratio fell to the normal range and these patients showed clinical remission. Four patients whose liver spectra showed persistently high ratios after therapy died subsequently of progressive disease. *In vitro* ^{31}P MRS studies of extracts of lymphomatous lymph nodes suggested that PEtn was largely responsible for the increased PME signal. In this study, however, no difference was observed between Hodgkin's and non-Hodgkin's lymphoma and between histological grades.

Meyerhoff *et al*[69] used ^{31}P MRS to assess the metabolic state of hepatic cancers and their metabolic response to chemoembolization. Their preliminary report described studies on five patients (two with colon cancer metastasis, two with HCC, and one with adenocarcinoma of unknown primary) and thirteen healthy volunteers. Untreated hepatic tumors showed elevated PME/ATP ratios, reduced ATP and Pi content, and normal PDE levels compared to normal controls. ATP, PME, and/or PDE levels diminished as an acute response to chemoembolization, whereas Pi content increased or stayed relatively constant. This could point to tumor regression and/or necrosis. Long-term follow-up after treatment showed decreased PME/ATP and increased ATP levels, even in the absence of changes on standard imaging. This could be the result of returning normal liver tissue and thus recovery.

Negendank[70] reviewed hundreds of cancer cases in ^{31}P and/or ^{1}H MRS studies that were published up to early 1992. In general he found that human cancers, other than brain, of different types in different locations had similar metabolic characteristics: 173 of 194 cases had high PME and levels, 121 of 166 cases had high PDE levels, 59 of 125 cases had high Pi levels and 96 of 117 cases had low PCr. Table 1 lists the cases with HCC, metastatic liver cancer and lymphoma in the

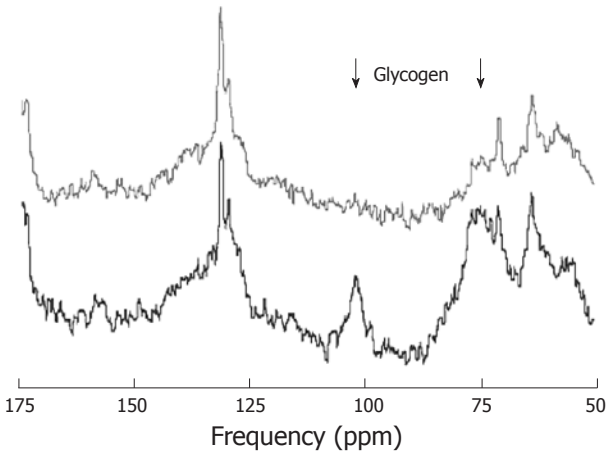

Figure 10 *In vivo* ^{13}C magnetic resonance spectra (1.5T) of human liver tissue obtained from a healthy volunteer before (bottom) and after exercise (top). Resonances of glycogen (101 ppm and around 75 ppm) are reduced after exercise. Other resonances are mainly lipids.

liver. The most frequently used characteristic that differentiated healthy liver tissue from liver lymphoma was an increased PME level, and an increased PME/Pi and increased PME/Pi for HCC, and increased PME/NTP and increased PDE/NTP ratios for metastasis in the liver. Also, an early decrease in PME (or in the PME/PDE ratio) was a good predictor of response to whatever treatment.

Concluding remarks

From these studies it appears that the increase of PME levels is associated with tumor progression and that successful treatment is associated with its decrease. Therefore ^{31}P MRS seems very suitable for treatment response monitoring. Since 2003, however, only a limited number of *in vivo* ^{31}P MRS studies on liver tumors and metastasis have been reported. The reason for this could be the low spatial and time resolution of *in vivo* ^{31}P MRS on 1.5T MR systems. Currently, 3T MR systems have become widely available, dual tuned multi-channel ^{31}P/^{1}H coils have been developed and several techniques, e.g., ^{1}H decoupling, nuclear overhauser enhancement, polarization transfer, have been demonstrated[16] to improve ^{31}P MRS sensitivity and spectral resolution. Finally, high field *in vitro* ^{31}P MRS of cell cultures might establish new markers to distinguish different tumor types and to separate benign from malignant tumors.

^{13}C MR SPECTROSCOPY

As carbon-12 has no net nuclear spin it cannot be detected by MR spectroscopy. In contrast, ^{13}C can be detected by MRS but it has a natural abundance of only 1.11%. Therefore ^{13}C has a relatively low MR sensitivity. In addition, the signal to noise ratio may be negatively affected by ^{1}H coupling. To obtain spectra with acceptable signal to noise it is needed to apply averaging, polarization transfer, and ^{1}H decoupling. The chemical shift dispersion of ^{13}C MRS *in vivo* is large (about 200 ppm) and is also characterized by narrow line widths, resulting in a very good spectral resolution (Figure 10). Although ^{13}C MR spectroscopy is primarily known for MRS of ^{13}C-labeled substrates (e.g., glucose), natural abundance ^{13}C MRS can also be applied.

Metabolites visible in natural abundance ^{13}C MR spectra

Almost all metabolites in the human body contain carbon and therefore in principle a large amount of metabolites can be investigated with ^{13}C MRS, but because of the 1.11% natural abundance this is restricted to only a few highly concentrated compounds such as lipids. Chemical shifts above 150 ppm are indicative of carbonyl groups; carbons adjacent to hydroxyl groups typically resonate in the 60-100 ppm range; CH, CH_2, CH_3 groups resonate in the 45-60 ppm, 25-45 ppm and < 25 ppm ranges, respectively. The resonances of -CH = CH- groups are located around 125 ppm. Dominant lipid resonances are usually found in non-brain tissue. Two distinct resonances at 63 and 73 ppm originate from the glycerol backbone[6].

^{13}C labled metabolites visible in ^{13}C MR spectra

^{13}C MRS with labeled substrates is the only way to study metabolic conversions in the living intact body. Substrates enriched with ^{13}C are usually administrated intravenously to reach a high and stable level in the blood. One of the most commonly used enriched substrate in humans is [1-^{13}C]glucose. Other known substrates are [1,2-$^{13}C_2$]-choline, [1,2-$^{13}C_2$]-ethanolamine, [3-^{13}C]pyruvate and lactate, [2-^{13}C]acetate, [2-^{13}C]glucose and [1,6-$^{13}C_2$]glucose. The latter, often used in studies involving rats and mice, results in two labeled [3-^{13}C]-pyruvate molecules, and thus more signal. Pyruvate is an intermediate common to three major metabolic and catabolic pathways. After i.v. injection, pyruvate is rapidly distributed in the body and taken up by most cells, and then converted into alanine, lactate, or carbon dioxide, depending on the intracellular energy status.

Liver tumors and metastases

Natural abundance ^{13}C MR liver spectrum: In 1983 Bottomley *et al*[71] demonstrated the feasibility of natural abundance ^{13}C MRS at 1.5T. The low sensitivity and the fact that most information could also be obtained from ^{1}H and ^{31}P MRS spectra has prevented widespread application of natural abundance ^{13}C MRS. However, there are areas where it has some advantages such as in the detection of glycogen. Carbohydrate reserves are mainly stored as glycogen in animals and humans, in particular in muscle and liver. Natural abundance ^{13}C MRS detection of glycogen is typically performed *via* the glycogen-C_1 resonance at 100.5 ppm[72]. Some studies on rats have indicated that glycogen levels in hepatic tumors were markedly less than those observed in livers of control animals[73,74].

^{13}C labled ^{13}C MR liver spectrum

^{13}C-labeled glucose: Infusion of enriched ^{13}C-labeled glucose in combination with ^{13}C MRS can provide highly specific information on metabolites and metabolic rates involved in energy metabolism. The ^{13}C-labeled glucose is transported into the cell in the same way as ^{18}FDG used in PET[75]. Where the derivative of ^{18}FDG is trapped inside the cell, indicating areas of high glucose transport and thus indirectly indicating glycolytic activity, the ^{13}C-labeled glucose will enter metabolic pathways like glycolysis and the TCA cycle. This allows the direct study of glucose uptake, the flux through labeled metabolites, relative contributions of glycolytic pathways and oxidative phosphorylation, as well as oxygen consumption[12,76].

^{13}C labeled glucose combined with ^{13}C MRS in human liver tissue is, however, not without difficulties and the number of studies with this technique is still very limited. In 2008 Tomiyasu *et al*[77] monitored liver glycogen synthesis in diabetic patients using ^{13}C MRS on a 3.0T system. The MR signals of liver [1-^{13}C]-glucose and glycogen were assessed and a correlation between the quantity of liver glycogen and the fasting plasma glucose levels was found. To investigate glucose metabolism of liver tumors would be of great interest, but such studies are still lacking.

^{13}C-labeled ethanolamine and choline in experimental tumors: Dixon *et al*[67,78] administrated [^{13}C$_2$]-ethanolamine to mice with lymphomatous liver to study the kinetics of PtdEtn synthesis[79]. The newly synthesized PEtn and PtdEtn could be distinguished from naturally-abundant compounds by their ^{13}C label. The results showed that PtdEtn synthesis in the normal liver largely follows the Kennedy pathway. The data extracted from the ^{13}C MR spectra were fitted to a kinetic model representing this pathway, which allowed them to determine the approximate rates of the various enzymes in the synthetic pathway *in vivo*. They also showed that the overall rate of PtdEtn synthesis from Etn was not increased in lymphomatous liver.

Katz-Brull *et al*[35] investigated the distribution of metabolites following infusion of [1,2-^{13}C]-choline by ^{13}C MRS in mice. In their study MCF7 human breast cancer cells were inoculated s.c. in the right flank of CD-1 female athymic mice. In the tumors significantly more PCho (labeled and unlabeled) was observed than in normal liver and kidney tissue. Therefore, ^{13}C MRS combined with modeling can be used to study choline and ethanolamine metabolism and enzymes rates in mice.

Hyperpolarization and tumor metabolism: Gallagher *et al*[80] performed a ^{13}C MRS *in vitro* study of glutaminase activity in human hepatocellular carcinoma cells using DNP hyperpolarized ^{13}C-labeled glutamine. They showed that the conversion of hyperpolarized [5-^{13}C]glutamine to glutamate senses intramitochondrial glutaminase activity in hepatoma cells. These results represented the first step in the development of an imaging technique for the detection of glutamine metabolism *in vivo*. The rate of glutamine uptake and metabolism to glutamate in HCC cells was shown to be up to 30-fold higher than in normal hepatocytes. And thus this approach has clinical potential such as in the detection of small HCC in the presence of a cirrhotic liver. This study also suggests a new technique to detect changes in tumor cell proliferation in response to cytotoxic treatment since glutamine utilization has been correlated with cell proliferation.

Golman *et al*[75] conducted a metabolic imaging study in P22 tumors implanted on the back of rats. The high signal, due to DNP hyperpolarization, allowed mapping of pyruvate, lactate and alanine in a 5 mm × 5 mm × 10 mm imaging voxel using a 1.5T scanner. Tumor tissue showed a significantly higher lactate content than normal tissue, possibly explained by the Warburg effect. The results indicate that fast noninvasive quantification may be possible. To show that the DNP technique can be used both in small and larger animals, Golman *et al*[81] also conducted nearly similar real-time metabolic imaging studies in rats and pigs. The pig study would provide important information as to whether [1-^{13}C] enriched hyperpolarized dynamics also could be visualized in a more clinically relevant setting. They showed that in both species, where pharmacokinetic parameters widely differ, it is possible to map pyruvate and some of its metabolites in resting skeletal muscle within a clinically useful time frame of about 10 seconds. This indicates the technique may work in humans as well.

Concluding remarks

Hyperpolarization is a promising technique in MR cancer research. Similar images as those in ^{18}FDG-PET can be obtained, but with the further advantages that, without radiation, real (glucose) metabolism is observed. Although this new MR method is far more sensitive than conventional ^{13}C MRS it only allows measurement of single step metabolic conversions associated with rapid cellular uptake of the administered substrate. Therefore, conventional ^{13}C MRS studies will remain valuable to understand and complement results from hyperpolarized ^{13}C MR imaging.

CONCLUSION

Hydrogen is the most commonly studied nucleus, as it has the highest sensitivity compared to ^{31}P and ^{13}C, and essentially can be performed with the same hardware as for standard MR imaging. In liver tumor studies the lactate resonance is related to energy metabolism (Warburg effect) of the tumor. Proton resonances of mobile lipids and the peak of total choline (tCho) have been explored as biomarkers to identify malignant tumors. However, the tCho peak is composed of several unresolved resonances of different choline containing compounds, which makes changes in this signal difficult to interpret.

With ^{31}P MRS phosphorylated choline and ethanolamine containing compounds can be resolved. From

several studies it is known that the increase of PME is associated with tumor progression and that successful treatment is associated with a decrease of PME levels. Therefore ^{31}P MRS could very well be used for treatment response monitoring. Besides the signals from phospholipid metabolism, ^{31}P MR spectra of liver also show signals of ATP and Pi which can be used to investigate tumor energy metabolism.

MRS with ^{13}C as label is a unique method to measure the dynamics of metabolic conversions *in vivo*, but it has hardly been used to examine human liver metabolism due to its technical complexity and relatively low sensitivity. However, developments such as hyperpolarization may open new ways of liver assessment and imaging.

In vivo MR spectroscopy provides a number of adequate research tools to study metabolism in liver tumors and metastasis. However, they are not yet applied often in a clinical setting for diagnosis and treatment monitoring. This may be due to technical challenges associated with the body location of the liver, relatively long scan times needed for a good signal to noise ratio, the need for additional hardware (except ^{1}H MRS) and the need for expertise in spectral interpretation. With higher magnet fields becoming available, new multi-element detection probes, new acquisition techniques for improved spatial and time resolution, better postprocessing, and with new biomarkers it is expected that the research and clinical usefulness of MRS of liver and tumors therein will increase.

Abstract

Islet transplantation is characterized by the transplantation of isolated islets from donor pancreata into a diabetic recipient. Although it is a viable choice in the treatment of insulin dependent diabetes mellitus, most patients (approximately 90%) require insulin five years after transplantation. Recently, the co-transplantation of mesenchymal stem cells (MSCs) and islets in animal studies has revealed the effectiveness of MSCs co-transplantation for improving islet function. The mechanisms underlying the beneficial impact of MSCs include immunomodulation and the promotion of angiogenesis. In this review, we discuss MSCs and how they support improved graft survival and function.

Key words: Mesenchymal stem cell; Islet transplantation; Bone marrow; Immunomodulatory; Regulatory T cell; Angiogenesis; Vascular endothelial growth factor; Diabetes mellitus

INTRODUCTION

According to the International Diabetes Federation (IDF) database, the number of patients with diabetes mellitus (DM) worldwide is 285 million, indicating that 6.4% of the global population have DM. Furthermore, the IDF predict that the number will increase to 438 million by 2030. DM is a serious disease; approximately 4 million people die each year from DM. In addition, DM is a major cause of serious complications such as blindness, renal failure, and ischemic heart disease. Type 1 diabetes is characterized by the irreversible autoimmune destruction of pancreatic β cells and is usually diagnosed in children and young adults[1]. Islet transplantation consists of the transplantation of pancreatic islets that have been isolated from a donor pancreas[2]. The therapeutic effect was regarded as insufficient for a long time; however,

since the use of the "Edmonton Protocol"[2], a markedly improved islet transplant protocol developed at Alberta University, islet transplantation has been performed widely for 10 years. However, according to a recent report, although approximately 70% of patients did not need daily insulin one year after transplantation, approximately 90% of patients required insulin after five years[3]. Therefore, studies aimed at improving the outcome of islet transplantation are still required.

One of the reasons for failure of insulin independence is islet graft loss due to a variety of causes including instant blood-mediated inflammatory reaction[4], acute rejection[5], islet toxicity by immunosuppressive agents[6], and ischemia caused by poor vascularity at transplantation[7] and the embolization effect of the islets[8]. Moreover, islet transplantation also faces the problem of a limited supply of suitable donor human pancreata[9]. Thus, to promote islet transplantation in the future, there is a need to establish a novel donor source and develop more effective treatments to prolong the function of transplanted islets.

WHAT ARE MESENCHYMAL STEM CELLS?

Mesenchymal stem cells (MSCs) are multipotent cells capable of self-renewal and differentiation into a various cell lineages. They are derived from many organs such as bone marrow, adipose tissue, skin, fetal liver, and umbilical cord blood[10,11]. Although the number of MSCs in the bone marrow is very small compared with other component cells (only 0.01%-0.001%)[12], MSCs regulate the maintenance and proliferation of hematopoietic stem cells (HSCs) in the bone marrow[13]. MSCs are able to differentiate into various cells derived from ectoderm (epithelial cells and neurons), mesoderm (connective stroma, cartilage, fat and bone cells), and endoderm (muscle cells, gut epithelial cells, and lung cells)[13]. A number of groups have demonstrated that insulin-producing cells could also be differentiated from MSCs[14-18]. The regeneration of insulin-producing cells is an important theme in research aiming to improve the outcome of cell replacement therapy and has been the focus of some groups. However, in an alternative approach, many studies have examined the effect of transplanting islets with MSCs and have demonstrated improved islet function when co-transplanted with MSCs[7,19-22]. The beneficial effects of MSCs in the context of islet transplantation could be attributed to immunomodulation and angiogenesis.

IMMUNOMODULATORY EFFECT OF MSCS

The pancreata used for clinical islet transplantation are allogeneic and recipients therefore require immunosuppressive drugs to prevent rejection. Recently, Solari *et al*[23] demonstrated that MSCs could promote the prolonged survival of allograft islets in a rat model with limited treatment with immunosuppressive agents. Allogeneic islets transplanted to diabetic rats with syngeneic MSCs survived for over one month whilst islets transplanted alone survived for only seven days. They also demonstrated prolonged graft survival of allogeneic islets transplanted with allogeneic MSCs compared to allogeneic islets transplanted alone. T cell production of interferon (IFN)-γ and tumor necrosis factor (TNF)-α was decreased in allogeneic islets transplanted with syngeneic MSCs. Furthermore, *in vitro* studies of cocultured MSCs and islets generated interleukin (IL)-10 which inhibited $CD4^+$ T cells. Melzi *et al*[20] performed allogeneic islet and allogeneic neural stem cell (NSC) transplantation in a murine model and showed significantly longer graft survival in allogeneic islet/NSC transplanted mice in the absence of immunosuppression, compared to mice transplanted with islets alone (> 100 d survival). Intriguingly, they detected expansion of regulatory T cells in the spleen of co-transplanted mice. These results indicate that MSCs exert an immunomodulatory role and can actively limit the rejection of co-transplanted islets.

The mechanism underlying the immunomodulatory effect of MSCs is likely to be multifactorial and result from the communication between various immune cells and cytokine generation (Figure 1). For example, MSCs can inhibit the proliferation and cytotoxicity of resting natural killer (NK) cells, which are key effector cells of the innate immune system and play an important role in antiviral and anti-tumor immune responses[24]. Spaggiari *et al*[25] demonstrated that the cytokine-induced proliferation of freshly isolated NK cells was inhibited by the presence of MSCs. MSCs also inhibited NK cell activation, cytotoxic activity, and IFN-γ production[26]. These effects are mediated by prostaglandin E_2 (PGE_2) and indoleamine 2,3-dioxygenase (IDO)[13,26].

Another important effect of MSCs is to inhibit the differentiation of monocytes to dendritic cells (DCs) that, following DC maturation, present antigens to naïve T cells[27,28]. MSCs also inhibit TNF-α production by DCs and upregulate IL-10 production by plasmacytoid DCs (pDCs)[29] - effects modulated by PGE_2. These effects of MSCs upon DC function undoubtedly contribute to their anti-inflammatory and immunoregulatory effects.

MSCs may also directly inhibit $CD4^+$ T cells, $CD8^+$ T cells, and B cells, immune cells involved in rejection of allogeneic cells, by releasing soluble mediators, including PGE_2, IDO, or soluble human leukocyte antigen (sHLA)-G5. Inhibition of $CD4^+$ T cells impairs B cell proliferation and antibody production[13]. $CD8^+$ cytotoxic T cells are involved in killing virus-infected or allogeneic cells, and MSCs are capable of inhibiting the induction of $CD8^+$ T cell responses and preventing cytotoxicity[30]. MSCs inhibit B cell proliferation and antibody secretion, as well as their differentiation to plasma cells[31]. On the other hand, MSCs may induce the generation of regulatory T cells, which suppress immune cell activation, and help to maintain homeostasis and promote self tolerance by inducing production of IL-10 from pDCs and by releasing HLA-G5[29,32]. In

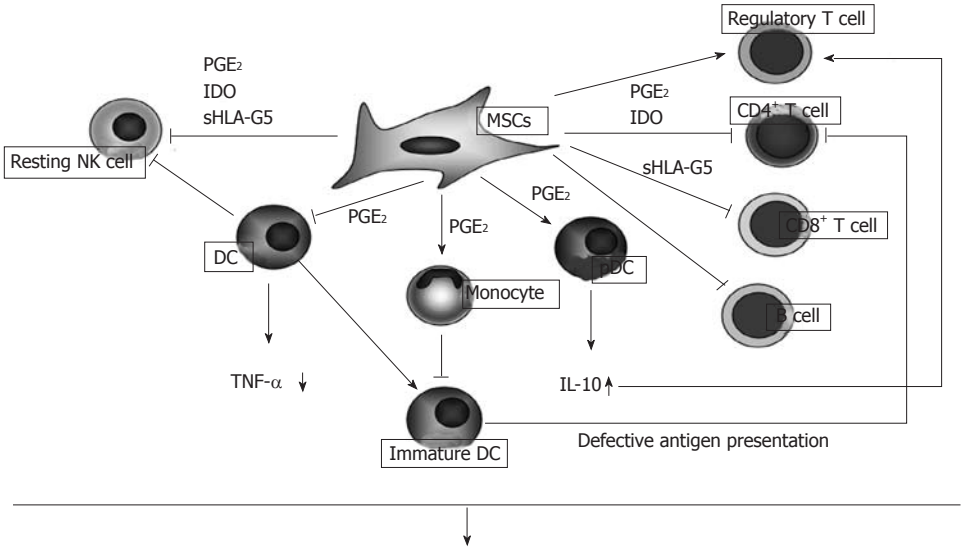

Figure 1 Immunomodulatory effect of mesenchymal stem cells (modified and quoted from Uccelli *et al*[13]). Mesenchymal stem cells (MSCs) can inhibit the proliferation and cytotoxicity of resting natural killer (NK) cells *via* the generation of mediators, including prostaglandin E_2 (PGE_2), indoleamine 2,3-dioxygenase (IDO) and soluble human leukocyte antigen (sHLA)-G5; MSCs inhibit the differentiation of monocyte to antigen presenting dendritic cells (DCs). MSCs also inhibit TNF-α production by DCs and upregulate IL-10 production by plasmacytoid DCs (pDCs): effects modulated by PGE_2; MSCs directly inhibit $CD4^+$ T cell, $CD8^+$ T cell, and B cells that are involved in allogeneic cell rejection by releasing PGE_2, IDO, or sHLA-G5. $CD4^+$ T cell inhibition limits B cell proliferation and antibody production whilst $CD8^+$ T cell inhibition prevents cytotoxicity. MSCs induce generation of immunomodulatory regulatory T cells that suppress immune activation, help to maintain homeostasis, and promote self tolerance by production of IL-10 from pDCs and by releasing HLA-G5. Thus, MSCs can promote immunotolerance and facilitate the engraftment of allogeneic islets.

summary, MSCs can promote immunological tolerance and facilitate the survival and function of allogeneic islets. It is likely, however, that the immunomodulatory roles of MSCs have not been fully clarified.

ANGIOGENIC EFFECT OF MSCS

Pancreatic islets have a rich vascular supply in the pancreas, with some reports indicating that islets receive 5%-10% of pancreatic blood flow, despite the islet mass only comprising 1%-2% of the total pancreas[33,34]. However, isolated islets are avascular, as the process of islet isolation destroys the vascular network between the islet and surrounding tissue[35]. As a result, islets undergo prolonged ischemia during the reconstruction of the vascular network, which may take approximately 14 d[36] and many islets become damaged. It is thus apparent that strategies to limit islet ischemia are necessary to improve the outcome of islet transplantation.

Some studies suggest that angiogenic factors, such as vascular endothelial growth factor-A (VEGF-A) and angiopoietin-1, are required to generate a vascular network around transplanted islets[37,38]. Recently, the pro-angiogenic effects of MSCs have been examined (Figure 2). The process of revascularization consists of proteolytic digestion of the vascular wall and subsequent migration, proliferation, and differentiation of endothelial cells (ECs)[39]. MSCs express platelet-derived growth factor (PDGF) receptors and respond to PDGF production by ECs during revascularization[40]. MSCs promote EC migration by producing proteases that facilitate immature EC sprouting[41] and upregulating the expression of angiopoietin and VEGF in ECs, as these factors promote angiogenesis and stability of the developing vasculature[42]. The roles of MSCs in angiogenesis have been explored in experimental models of ischemia. Martens *et al*[43] demonstrated that MSCs produced VEGF and induced neovascularization in the ischemic myocardium. Jiang *et al*[44] showed that transplantation of MSCs into ischemic limbs promoted angiogenesis. Johansson *et al*[45] explored the enhancement of angiogenesis by MSCs in the context of islets. They first examined cultures of human islets and ECs in the presence or absence of MSCs. The study indicated that the inclusion of MSCs promoted EC proliferation and migration of ECs to the surface of islets to form a "coat"[45]. Islets with this surrounding "coat" of endothelial cells survived for a long time in culture and exhibited improved insulin release[45]. The coated islets had many sprouts and were connected to other endogenous islets by vessel-like structures[45]. These findings indicated that MSCs act to promote EC proliferation in both donor and recipient sides, together with sprout formation and growth of ECs into the islet. Thus, MSCs may exert a potent angiogenic function and contribute to islet engraftment by promoting islet vascularization.

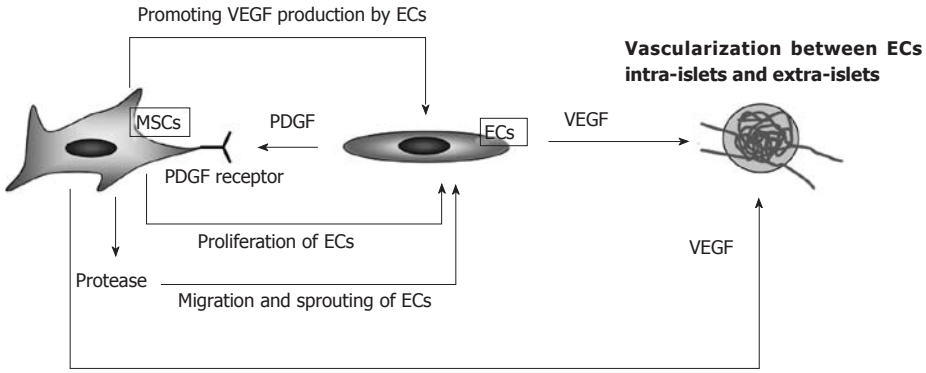

Figure 2 Pro-angiogenic effect of mesenchymal stem cells. The process of revascularization requires proteolytic digestion of the vascular wall and subsequent migration, proliferation, and differentiation of endothelial cells (ECs). Mesenchymal stem cells (MSCs) express platelet-derived growth factor (PDGF) receptors and respond to PDGF production by ECs during revascularization. MSC-derived proteases promote EC migration and immature EC sprouts and upregulate the expression of angiopoietin and vascular endothelial growth factor (VEGF) in ECs, thereby promoting both angiogenesis and vascular stability. MSCs also produce VEGF and induce neovascularization. MSCs promote both donor and recipient EC proliferation, EC sprout formation, the ingrowth of ECs into islets and the formation of a vascular network between intra- and extra-islet vessels.

Recently, Ito *et al*[21] co-transplanted rat islets and MSCs into diabetic severe combined immunodeficiency mice and evaluated the rate of normoglycemia and extent of islet vascularization. All the diabetic mice that received 500 islets with 10^7 MSCs exhibited normoglycemia, compared to 30% of mice transplanted with islets alone. Neovascular density was also increased in the islet/MSCs co-transplanted group and was associated with strong expression of VEGF and endothelial von Willebrand factor. Sakata *et al*[7] and Figliuzzi *et al*[22] also evaluated the impact of MSCs upon transplanted islets, and found a similar improvement of islet function and vascularization. The beneficial impact of vascularization is in accord with our previous work indicating that hyperbaric oxygen therapy prevented cellular apoptosis of islets[46]. These data indicate that promoting islet vascularization by co-transplanting MSCs acts to limit the duration and severity of islet ischemia, thereby limiting islet cell apoptosis and promoting islet integrity and function.

CONCLUSION

It is likely that MSCs may exert beneficial effects in addition to those previously outlined. For example, Olerud *et al*[19] demonstrated that neural crest stem cells, a kind of MSCs, augment islet cell proliferation and improve islet function. In addition, Melzi *et al*[20] showed that transplanted bone marrow cells stimulated pancreatic β-cell proliferation after streptozotocin-induced pancreatic injury.

In conclusion, MSCs may exert beneficial immunomodulatory and pro-angiogenic effects when co-transplanted with islets. Immunomodulatory effects include the functional inhibition of immunocompetent cells, such as NK cells, DCs, cytotoxic T cells, and B cells. MSCs may also induce the generation of regulatory T cells that promote immunological tolerance. The pro-angiogenic effects of MSCs result from the release of angiogenic factors and promotion of the vascular network linking islets to the surrounding tissue. This pro-angiogenic role limits the duration and severity of islet ischemia and improves islet function. We therefore believe that the co-transplantation of MSCs represents a viable method for improving islet transplantation. Recently, a clinical trial of combined islet and hematopoietic stem cell allotransplantation was performed[47]. The data did not support the effectiveness of HSCs co-transplantation in prevention of graft rejection and in avoiding side effects of immunosuppression. Moreover, Melzi *et al*[20] reported the risk of inducing cancer because of NSC co-transplantation, as well as proving the effectiveness of this strategy to prevent islet graft rejection. Thus, further studies examining the effect of MSCs in a clinical setting should be undertaken.

Abstract

AIM: To better understand the pathogenic role of *Helicobacter pylori* (*H. pylori*) in pre-eclampsia (PE), and whether it is associated or not with fetal growth retardation (FGR).

METHODS: Maternal blood samples were collected from 62 consecutive pregnant women with a diagnosis of PE and/or FGR, and from 49 women with uneventful pregnancies (controls). Serum samples were evaluated by immunoblot assay for presence of specific antibodies against *H. pylori* antigens [virulence: cytotoxin-associated antigen A (CagA); ureases; heat shock protein B; flagellin A; persistence: vacuolating cytotoxin A (VacA)]. Maternal complete blood count and liver enzymes levels were assessed at delivery by an automated analyzer.

RESULTS: A significantly higher percentage of *H. pylori* seropositive women were found among PE cases (85.7%) compared to controls (42.9%, $P < 0.001$). There were no differences between pregnancies complicated by FGR without maternal hypertension (46.2%) and controls. Importantly, persistent and virulent infections (VacA/CagA seropositive patients, intermediate leukocyte blood count and aspartate aminotransferase levels) were exclusively associated with pre-eclampsia complicated by FGR, while virulent but acute infections (CagA positive/VacA negative patients, highest leukocyte blood count and aspartate aminotransferase levels) specifically correlated with PE without FGR.

CONCLUSION: Our data strongly indicate that persistent and virulent *H. pylori* infections cause or contribute to PE complicated by FGR, but not to PE without feto-placental compromise.

Key words: *Helicobacter pylori*; Virulence factors; Pre-eclampsia; Fetal growth retardation; Cytotoxin-associated antigen A; Vacuolating cytotoxin A

Cardaropoli S, Rolfo A, Piazzese A, Ponzetto A, Todros T. *Helicobacter pylori*'s virulence and infection persistence define pre-eclampsia complicated by fetal growth retardation. *World J Gastroenterol* 2011; 17(47): 5156-5165 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i47/5156.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i47.5156

INTRODUCTION

Pre-eclampsia (PE) is a severe hypertensive pregnancy-re-

lated disorder that affects 5%-8% of women worldwide, thus representing the main cause of feto-maternal mortality and morbidity[1,2]. PE is often associated with fetal growth retardation (FGR), defined as failure of the fetus to achieve its genetically determined growth potential[3,4]. FGR is commonly considered a severe complication of PE, but whether or not PE and FGR are manifestations of the same disorder, or two distinct pathologies, still remains unclear.

PE is characterized by excessive maternal inflammatory response, with high circulating levels of pro-inflammatory cytokines and endothelial injury[1,2]. Despite being an object of intense investigation, the etiopathogenetic mechanisms of PE are still poorly understood. Several lines of evidence suggest that subclinical infections could play a role in the onset of PE[5,6].

We previously reported a strong association between *Helicobacter pylori* (*H. pylori*) infection and PE[7]. *H. pylori* is a Gram-negative bacterium responsible for the large majority of peptic ulcers, gastric cancer, and gastric mucosa-associated lymphoid tissue lymphoma[8]. It has been demonstrated that this pathogen enhances platelets activation and thrombus formation[9,10], thus inducing endothelial inflammation and injury. Therefore, *H. pylori* could directly cause or intensify the generalized inflammation and endothelial dysfunction typical of PE[7]. Furthermore, it was recently observed that *H. pylori* seropositive PE subjects are characterized by a more severe inflammatory status[11] and lipid peroxidation[12].

The role of cytotoxin-associated antigen A (CagA) in inducing a severe immunogenic response in patients infected by *H. pylori* is now well established[13]. Nevertheless, other virulence factors could be involved in the severe inflammatory response mediated by this bacterium. The vacuolating cytotoxin A (VacA) is a protein produced by *H. pylori* with several effects on vulnerable cells, such as vacuolation with alteration of the endo-lysosomal function and mitochondrial damage accompanied by cytochrome C release and apoptosis[14].

Ureases allow colonization of the gastric mucosa by catalyzing the hydrolysis of urea and help to recruit neutrophils and monocytes in the mucosa, thus inducing pro-inflammatory cytokines production[15].

Heat shock protein B (HspB) has been shown to increase the risk of gastric carcinoma, by directly inducing hyper-proliferation of gastric cells[16]. Moreover, it strongly activates the immune system and stimulates a massive immune response in patients with gastritis and gastric cancer[17-19].

To better understand the pathogenic role of *H. pylori* in pre-eclampsia, we investigated maternal serum positivity for antibodies against CagA, VacA, HspB, ureases A, C, E and H (UreA, UreC, UreE, UreH), and for flagellin A (FlagA). FlagA is the major *H. pylori* flagellin isoform, mainly expressed during late exponential growth phase and represents a good *H. pylori* virulence index[20].

To correlate *H. pylori* virulence with PE severity, and to detect differences in *H. pylori* profiles between PE and FGR pregnancies, we determined seropositivity for the above mentioned antigens in three populations: PE without FGR, PE complicated by FGR, and FGR without PE.

Finally, we verified the reported association between *H. pylori* infection and elevated leukocyte blood count and serum amino-transferases levels[21].

MATERIALS AND METHODS

Population and samples

The study was approved by our Hospital Ethics Committee "Comitato Etico Interaziendale AA.OO O.I.R.M./S.Anna di Torino and Ordine Mauriziano di Torino" and written informed consent was obtained from each participating woman.

Maternal blood samples (5 mL) were collected before delivery from 62 consecutive pregnant women with diagnosis of PE and/or FGR, and from 49 women with normotensive pregnancies with normal fetal growth and normal uterine and umbilical Doppler flow velocimetry (FVW).

PE was diagnosed when hypertension (systolic blood pressure $\geqslant$ 140 mmHg or diastolic blood pressure $\geqslant$ 90 mmHg) and proteinuria ($\geqslant$ 300 mg/24 h) appeared after 20 wk of gestational age in previously normotensive women, according to the American College of Obstetricians and Gynecologists criteria[22]. PE was considered severe when one or more of the following criteria were present: systolic pressure $\geqslant$ 160 mmHg or diastolic pressure $\geqslant$ 110 mmHg on two occasions at least 6 h apart, or significant proteinuria ($\geqslant$ 3 + on urine dipstick or > 5 g in a 24-h urine)[22]. Patients with PE were further classified as either having early-onset ($\geqslant$ 34 wk), or late-onset (> 34 wk) disease according to the gestational age of PE diagnosis.

The hemolysis-elevated liver enzymes-low platelets (HELLP) syndrome was defined by the following criteria: hemolysis (characteristic peripheral blood smear and serum lactate dehydrogenase $\geqslant$ 600 U/L), elevated liver enzymes (serum aspartate aminotransferase $\geqslant$ 70 U/L), and low platelet count (< 100 000/μL)[23].

The diagnosis of FGR was made according to the following criteria: ultrasound measurement of fetal abdominal circumference below the 10th centile[24] or growth velocity below the 10th percentile[25] and/or birth weight below the 10th centile, according to Italian reference values[26] with abnormal umbilical arteries Doppler FVWs[27] and/or abnormal uterine artery Doppler FVWs (resistance index of > 0.58)[28]. Exclusion criteria were: multiple pregnancies, congenital malformations, and prenatal or postnatal diagnosis of chromosomal anomalies in number and/or structure.

For all cases and controls, the following data were collected: maternal age at delivery, gestational age at birth, week of PE onset, mode of delivery, neonatal sex, birth weight, placental weight, parity, blood pressure, urinary protein, complete blood count and differentials (count and percentage of neutrophils, lymphocytes, monocytes, eosinophils, and basophils), liver enzymes levels, risk factors for PE (previous pregnancy with PE, autoim-

[1]P values were calculated by non-parametric Kruskal-Wallis H test, with post-hoc analysis by Mann-Whitney U test. [2]Comparison between controls and PE-only group; [3]Comparison between Controls and PE FGR group; [4]Comparison between controls and FGR-only group; [5]Comparison between PE-only and PE FGR groups; [6]Comparison between PE-only and FGR-only groups; [7]Comparison between PE-only and FGR-only groups. PE: Pre-eclampsia; FGR: Fetal growth retardation.

mune diseases, diabetes, cardiovascular diseases, or other common risk factors for PE), and family history of pre-eclampsia and/or cardiovascular diseases.

Venous blood samples were collected into Vacutainer tubes (Becton Dickinson, Plymouth, United Kingdom) without anticoagulant. Serum was separated by centrifugation immediately after clotting and stored at -30 ℃ until assayed.

Serology

Serum samples were evaluated for specific antibodies against *H. pylori* antigens by commercially available Heli-Blot assay (Nurex; Sassari, Italy). *H. pylori* seropositivity was determined according to manufacturer instructions. Briefly, diluted serum samples (1:100) were incubated with Heli-Blot strips for 30 min. The strips were then incubated consecutively with anti-IgG for 30 min, with substrate for range of minutes, and then dried. Results were read according to the standard control protein bands provided. The standard *H. pylori* antigens available in the strip included: 120 kDa (CagA), 89 kDa (VacA), 60 kDa (Urease C), 54 kDa (HSP), 35 kDa (Flagellin), 30 kDa (Urease H), 26 kDa (Urease A), and 19 kDa (Urease E). The presence of one of the three most specific antigens (CagA, VacA, or flagellin) or the presence of two of the three smallest antigens was considered a positive test for the diagnosis of *H. pylori* infection.

Statistical analysis

Data analysis was performed using SPSS version 17.0 (SPSS Inc., Chicago, Illinois, United States). Continuous variables were reported as medians and interquartile ranges (25th-75th percentiles). Medians among groups were analyzed by non-parametric Kruskal-Wallis H test, with post-hoc analysis by Mann-Whitney U test. Categorical variables are presented as frequencies (percentages) and the comparison between different groups was done with a χ^2 test by means of a 2 × 2 contingency table; Fisher's exact test was used for small sample sizes. All tests were 2-tailed and results were considered significant for a P value less than 0.05. The odds ratios (OR) and 95% confidence intervals (CI), adjusted for maternal age at delivery, pre-pregnancy body mass index, parity, presence of maternal and family risk factors, were calculated using logistic regression analysis to assess the risk of PE and/or FGR associated with *H. pylori* infection.

RESULTS

Population

A total of 111 serum samples from pregnant women were examined: 49 uneventful pregnancies (Ctrl) and 62 pathological pregnancies complicated by fetal growth retardation (FGR-only, n = 13), pre-eclampsia (PE-only, n = 17), or both (PE-FGR, n = 32). Characteristics of the study population are summarized in Tables 1 and 2.

We found that normotensive women with pregnancy complicated by FGR were significantly younger (median of 25 years with an interquartile range of 24-26 years) compared to controls and PE women (both with a median age of 30 years). As expected, pregnancies complicated by PE and/or FGR were delivered more often by caesarean section. Moreover, pathological cases led to lower neonatal and placental weight compared to controls, due to lower gestational age at delivery and reduced fetal growth.

Pre-eclamptic mothers presented higher blood pressure values and urine protein concentrations. The presence of family risk factors was increased in PE cases without FGR (Table 2), while maternal risk factors for PE did not differ among groups (Table 2). The percentage of nulliparous women was significantly higher in the PE group than in controls. In 45 PE mothers, hypertension and proteinuria appeared early (before 34 wk) and in 32 of them these symptoms were severe; moreover five PE pregnancies were complicated by HELLP syndrome.

Leukocyte blood count, platelet count, and serum amino-transferases values in normal and pathologic pregnancies

Pre-eclamptic pregnancies were characterized by significantly higher values of total leukocyte count (P = 0.004) and serum amino-transferases [alanine aminotransferase

[1]One patient presented both maternal risk factors (autoimmune and cardiovascular diseases); [2]Four patients presented two family risk factors (3 hypertension and diabetes; 1 diabetes and cardiovascular disease); [3]One patient presented two family risk factors (hypertension and diabetes); [4]Five patients presented two family risk factors (4 hypertension and diabetes; 1 hypertension and cardiovascular disease). [5]*P* values were calculated by chi-square test (χ^2). [6]Comparison between controls and PE-only group; [7]Comparison between controls and PE FGR group; [8]Comparison between controls and FGR-only group; [9]Comparison between PE-only and PE FGR groups; [10]Comparison between PE-only and FGR-only groups. NS: Non significant; PE: Pre-eclampsia; FGR: Fetal growth retardation; HELLP: Hemolysis-elevated liver enzymes-low platelets.

(ALT), aspartate aminotransferase (AST) $P = 0.006$ and $P = 0.029$, respectively], while eosinophil count and percentage were significantly lower ($P = 0.028$ and $P = 0.02$, respectively) compared to controls. However, if we exclude pathological cases complicated by HELLP syndrome, only ALT levels remained significantly higher in PE (Table 3). Normotensive pregnancies complicated by FGR showed significantly higher leukocyte levels compared to controls ($P = 0.045$, Table 3). Moreover, the FGR-only lymphocyte percentage was significantly higher relative to PE-only ($P = 0.047$, Table 3).

H. pylori seropositivity was increased in PE-FGR but not in FGR-only pregnancies

H. pylori seropositivity was significantly more frequent in PE women with or without FGR (85.7%) ($P < 0.001$; OR 9.22, 95% CI: 2.83-30.04), while it did not differ between FGR-only (46.2%) and controls (42.9%) (Table 4, Figure 1A). Further subdivision of PE group showed a higher prevalence of seropositive subjects among PE-FGR cases (93.8%) ($P < 0.001$; OR 35.56, 95% CI: 5.22-242.43) compared to controls; while in the PE-only group, the percentage of *H. pylori* seropositive women was higher, but not statistically significant (70.6%), relative to controls (Table 4, Figure 1A).

CagA and VacA seropositivity was increased in pre-eclamptic but not in FGR-only pregnancies

Similar to *H. pylori* seropositivity, the presence of antibodies against CagA antigen was prevalent only in PE pregnant women (81.6%) relative to controls (22.4%) ($P < 0.001$; OR 17.66, 95% CI: 5.25-59.49), while there were no differences between FGR-only cases (38.5%) and controls (Table 4, Figure 1B). CagA seropositivity was significantly more frequent in both PE-FGR (90.6%) ($P < 0.001$; OR 54.97, 95% CI: 9.24-326.88) and PE-only groups (64.7%) ($P = 0.038$; OR 5.20, 95% CI: 1.09-24.69), relative to controls. VacA seropositivity was significantly higher in PE-FGR cases (87.5%) ($P < 0.001$; OR 19.64, 95% CI: 3.75-102.98), while there were no differences between PE-only (55.6%) and FGR-only cases (53.8%), relative to controls (40%) (Table 4, Figure 1C).

Seropositivity for both CagA and VacA antibodies was associated with higher risk of PE-FGR (OR 45.44; 95% CI: 7.79-265.18). In fact, 87.5% of PE-FGR pregnancies were CagA and VacA seropositive, compared to 22.4% in Ctrl group (Table 5, Figure 1D). Patients seropositive for VacA, but not for CagA, were nine controls (18.4%), one FGR (7.7%), and no PE women, while seropositivity for CagA only was a specific feature of the PE-only group (Table 5). Seronegative women for both anti-CagA and VacA antibodies were only 9.4% in the PE-FGR group, while they were 59.2%, 35.3% and 53.8% in the Ctrl, PE-only and FGR-only groups, respectively (Table 5, Figure 1D). Importantly, CagA and VacA seronegativity was associated with a lower risk of developing pre-eclampsia complicated by fetal growth retardation (OR 0.04; 95% CI: 0.01-0.22).

UreC and UreE seropositivity was higher in PE-FGR pregnancies

We found significantly higher UreC and UreE seropositivity in PE-FGR patients (46.9%; $P = 0.018$ and 56.3%; $P = 0.003$, respectively) relative to controls (26.5% and 24.5%, respectively) (Figure 2B and C), while there were no differences among groups for HspB, FlagA, UreA, and UreH (Table 4, Figure 2A and D-F). Odds ratios calculation showed higher risk of developing PE-FGR in

patients seropositive for UreC (OR 4.02, 95% CI: 1.27-12.8) and UreE (OR 6.29, 95% CI: 1.88-21.04) (Table 4).

Association among CagA/VacA seropositivity and leukocyte blood count, platelet count, and serum amino-transferases values

Considering seropositivities for CagA and/or VacA antigens, we found that the total leukocyte count was significantly decreased in VacA only seropositive patients relative to seronegative, CagA+/VacA- and CagA+/VacA+ patients ($P = 0.003$; $P = 0.014$ and $P = 0.012$, respectively, Table 6). Moreover, the basophiles percentage, but not total count, was significantly increased in CagA/VacA double seropositive compared to seronegative patients ($P = 0.002$, Table 6). No differences among groups were found for the other investigated parameters (Table 6). Analyzing amino-transferases levels after HELLP cases exclusion, ALT was significantly increased in CagA only seropositive patients relative to the other groups ($P = 0.02$; $P = 0.025$; $P = 0.023$, respectively, Table 6), while no differences were found for AST levels (Table 6).

DISCUSSION

In the present study, we reported a direct association between *H. pylori* virulence and the onset of pre-eclampsia complicated by FGR. Moreover, by investigating seropositivity for *H. pylori* virulence factors, we were able to

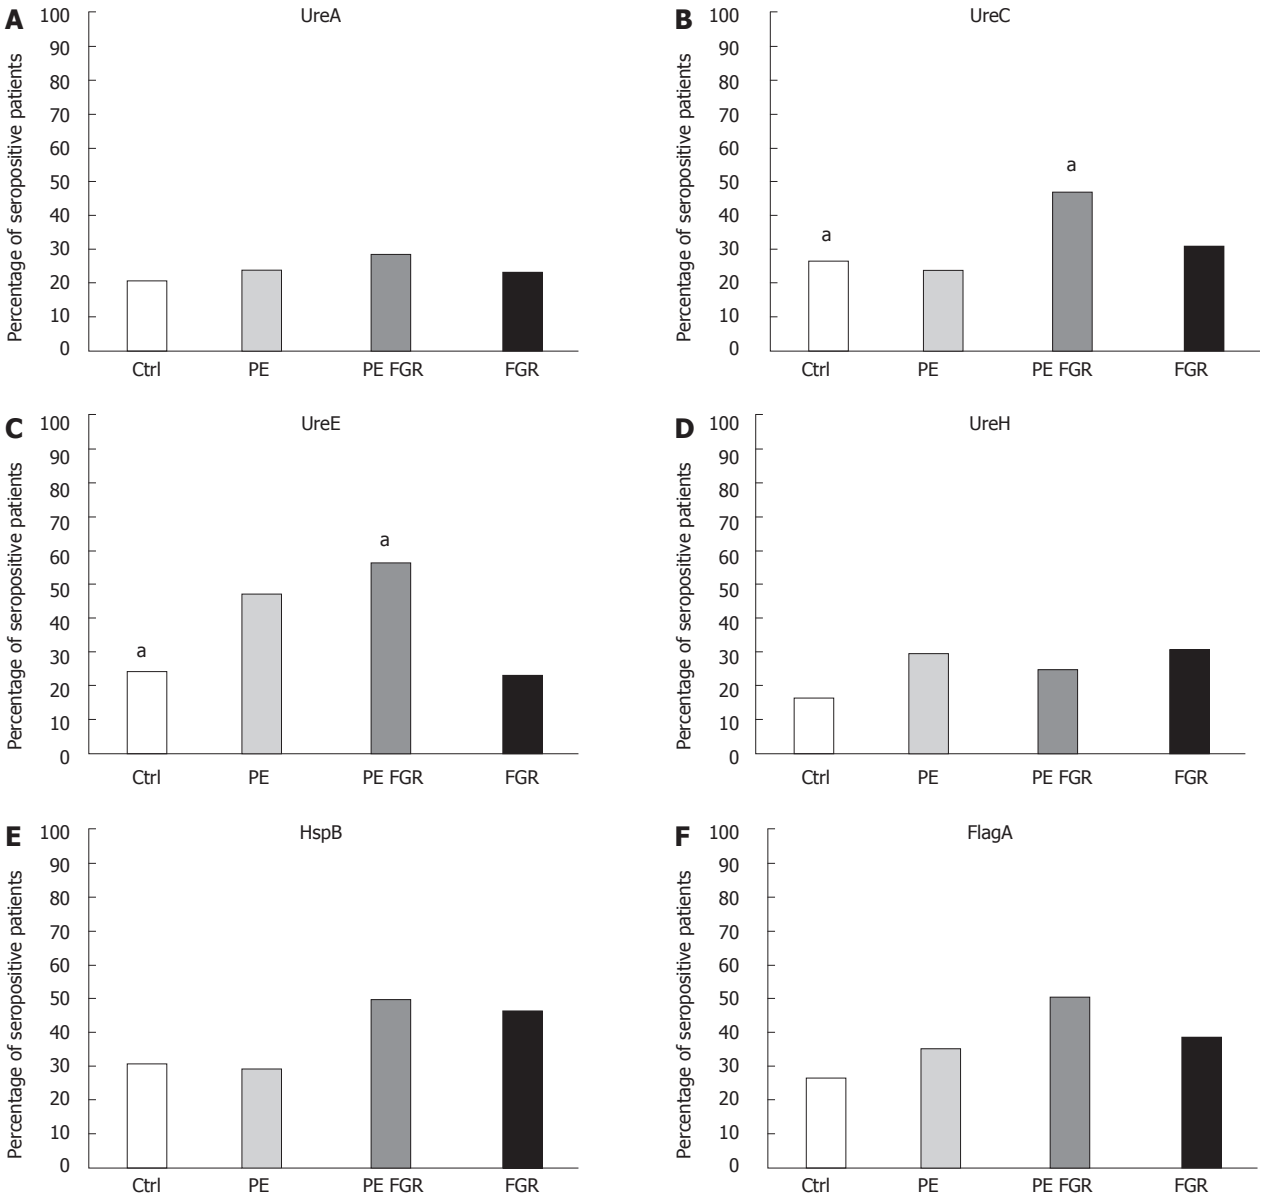

Figure 2 Percentage of Ureases (A-D), HspB (E), and FlagA (F) seropositive women in control, PE, PE FGR, and FGR groups. $^{a}P < 0.05$ *vs* controls. HspB: Heat shock protein B; FlagA: Flagellin A; Ure: Urease; PE: Pre-eclampsia; FGR: Fetal growth retardation.

distinguish pre-eclampsia and FGR without hypertension as different pathologies.

It is accepted that pre-eclamptic pregnancies, complicated or not by FGR, are characterized by severe maternal inflammation[1]. Less is known about "pure" FGR pregnancies, probably because of a biased classification system that considers FGR a secondary disease or a complication of pre-eclampsia. We found elevated maternal leukocytes count, typical sign of inflammation, in all pathological pregnancies relative to controls. However, while leukocytosis in PE patients, as previously reported[29,30], was mainly due to elevated neutrophils levels, a typical marker of bacterial infection[31], in FGR-only mothers, leukocytosis was due to increase in monocytes, eosinophils, and lymphocytes. Moreover, we found significantly higher transaminases levels in the PE group, even after the exclusion of HELLP cases, known to be characterized by elevated hepatic enzymes. The trigger of this exacerbated inflammatory response still remains unknown.

Graham *et al*[21] previously demonstrated a direct association between abnormal total leukocyte count and *H. pylori*-infection in patients with duodenal ulcer disease. They reported a significant fall in total white cell and neutrophils counts in patients successfully treated by *H. pylori* antibiotic therapy[21]. Moreover, they observed higher AST levels in CagA-positive patients, even after antibiotic treatment, thus assuming that AST levels are not directly associated with *H. pylori* infection[21]. Furthermore, we previously reported a correlation between *H. pylori* infec-

tion and the onset of pre-eclampsia during pregnancy, suggesting that this Gram-negative bacterium could cause or contribute to the etiopathogenesis of pre-eclampsia[7], by inducing the pro-inflammatory state.

In the present study, we further investigated *H. pylori* and pre-eclampsia association by considering the main markers of *H. pylori* virulence and infection persistence, which are useful for understanding the severity and characteristics of the infection.

H. pylori strains carrying the CagA antigen are known to be among the most virulent and are associated with increased inflammation[13]. VacA is a *H. pylori* toxin crucial to promote and maintain bacterial colonization[14]. Importantly, combined seropositivity for both CagA and VacA directly correlates with elevated morbidity[32-34]. We previously reported a strong association between CagA positive *H. pylori* infection and the onset of PE in Italian women[7]. In the present study, we also found that CagA/VacA dual seropositivity is specifically associated with pre-eclampsia and, in particular, with PE complicated by FGR. In contrast, the absence of both anti-CagA and anti-VacA antibodies is associated with a lower risk of PE. Interestingly, the association with CagA-/VacA+ was found only in controls and normotensive women with FGR pregnancies, while CagA+/VacA- patients belong to the PE groups. Our data suggest that the CagA antigen is associated with a more severe pattern, while VacA alone is not sufficient to cause the severe systemic inflammation typical of PE. The highest leukocyte count and ALT level observed in CagA+/VacA- patients further corroborated this hypothesis, while subjects seropositive only for VacA were characterized by the lowest median leukocyte values (Table 6). CagA/VacA dual seropositivity was the most frequent condition in PE complicated by FGR patients (Table 5), and was associated with intermediate leukocyte and ALT values (Table 6). Therefore, we speculate that CagA, with or without VacA, may contribute to the onset of pre-eclampsia, while VacA seropositivity could attenuate CagA virulence. Our results indicate that severe (CagA positive) and persistent (VacA positive) maternal *H. pylori* infections are strongly associated to pre-eclampsia complicated by feto-placental compromise, as indicated by FGR. Therefore, chronic and severe *H. pylori* infections could contribute not only to the exacerbated maternal inflammatory response leading to pre-eclampsia, but also to the abnormal placentation typical of FGR.

Importantly, FGR without PE does not present significant differences relative to physiological controls for either *H. pylori* (Table 3, Figure 1A) and CagA/VacA dual seropositivity (Figure 1D), suggesting that different etiopathogenetic mechanisms lead to "pure" FGR.

Another key *H. pylori* virulence factor is Urease, an enzyme that modifies environmental pH to allow *H. pylori* colonization[35]. Moreover, it helps to activate pro-inflammatory cytokines production[15]. We determined seropositivity for A, E and H urease subunits and for UreC in pre-eclamptic and/or FGR pregnant women relative to controls. In PE women relative to controls, we found significantly higher seropositivity only for the UreE subunit; the carrier of nickel ions and pivotal for proper enzyme activity[36-38]. The rate of seropositivity for UreC, the enzyme necessary for bacterial cell wall formation[39], was significantly higher in PE pregnancies complicated by FGR, as we previously showed for CagA/VacA dual-seropositivity. These data suggest that UreE and UreC contribute to the onset of both PE and PE-FGR.

Even though pre-eclampsia has been extensively investigated, the only effective therapeutic option remains a timed, programmed delivery. Our data clearly demonstrate a direct correlation between severe and persistent *H. pylori* infection and the onset of PE complicated by FGR, opening up attractive perspectives for the design of new preventive and therapeutic interventions for pre-eclampsia.

Although specific combinations of different antibiotics are effective in eradicating *H. pylori*, antibiotics-resistant strains are already emerging, thus decreasing the efficacy of existing therapies[40]. Pharmacogenomics-based treatments seem to increase the cure rates and new therapeutic approaches targeting *H. pylori* virulence factors are required[40]. In the case of pregnancy-related diseases, it would be preferable to prevent the exacerbated inflammation typical of PE, thus avoiding pharmacologic therapies during pregnancy. Recently, several clinical trials and animal studies have focused on generating *H. pylori* recombinant vaccines[41,42]. They demonstrated the possibility of eliciting an immunological response against *H. pylori* in humans, and to eradicate and protect against the infection in mice[43]. Experimental *H. pylori* vaccines have been created using bacterial urease and designed as oral preparations.

In conclusion, our results define pre-eclampsia complicated by FGR and "pure FGR" as different pathologies. Moreover, we demonstrated a direct role for *H. pylori* CagA/VacA positive strains in the etiopathogenesis of PE-FGR. Our data further emphasize the importance of an accurate classification of the multifactorial and multiform pre-eclamptic disease. It is generally accepted that PE is a syndrome that includes several pathologies with different etiopathogenesis but with similar clinical manifestations. For this reason, PE is usually classified on the basis of symptoms severity (moderate or severe) or of symptoms onset (early- or late-onset PE). We strongly believe that, as demonstrated by the present study, pre-eclampsia should also be classified as placental (with feto-placental involvement) or maternal (without feto-placental compromise)[44], both of which may have early or late onset. This classification will lead to a better management of this devastating pregnancy-related disorder. Further studies are required to identify specific *H. pylori*-related therapeutic targets.

COMMENTS

Background

Pre-eclampsia (PE), a severe hypertensive pregnancy-related syndrome that affects 5%-8% of women worldwide, represents the main cause of feto-maternal mortality and morbidity. Despite being the object of intense investigation, the etiopathogenesis of PE is still poorly understood, and no effective therapeutic interventions are available in clinical practice.

Research frontiers

Several lines of evidence suggest that maternal sub-clinical infections could play a pivotal role in the onset of PE. *Helicobacter pylori* (*H. pylori*) could directly cause or intensify the generalized inflammation and endothelial dysfunction typical of this syndrome.

Innovations and breakthroughs

The data represent a major advance in the understanding of PE etiopathogenesis and add pivotal information for an accurate classification of this multifactorial and multiform syndrome. In fact, the authors clearly demonstrated a direct correlation between severe and persistent *H. pylori* infection and the onset of PE complicated by fetal growth retardation (FGR).

Applications

The findings open up new, attractive perspectives regarding the design of effective preventive and therapeutic interventions for pre-eclampsia associated with *H. pylori* infection.

Terminology

FGR is defined as failure of the fetus to achieve its genetically determined growth potential and is commonly considered a severe complication of PE.

Peer review

The work is a contribution to the understanding of *H. pylori*'s pathogenic role in PE, associated or not with FGR. The association between maternal infection and PE has been evaluated by several researchers and is a good field to study the etiopathogenesis of this critical clinical condition. Authors confirmed that persistent and virulent *H. pylori* infections cause or contribute to PE complicated by FGR.

Abstract

AIM: To study the response to infliximab in pediatric inflammatory bowel disease (IBD), as reflected in fecal calprotectin levels.

METHODS: Thirty-six pediatric patients with IBD [23 Crohn's disease (CD), 13 ulcerative colitis (UC); median age 14 years] were treated with infliximab. Fecal calprotectin was measured at baseline, and 2 and 6 wk after therapy, and compared to blood inflammatory markers. Maintenance medication was unaltered until the third infusion but glucocorticoids were tapered off if the patient was doing well.

RESULTS: At introduction of infliximab, median fecal calprotectin level was 1150 μg/g (range 54-6032 μg/g). By week 2, the fecal calprotectin level had declined to a median 261 μg/g ($P < 0.001$). In 37% of the patients, fecal calprotectin was normal (< 100 μg/g) at 2 wk. By week 6, there was no additional improvement in the fecal calprotectin level (median 345 μg/g). In 22% of the patients, fecal calprotectin levels increased by week 6 to pretreatment levels or above, suggesting no response (or a loss of early response). Thus, in CD, the proportion of non-responsive patients by week 6 seemed lower, because only 9% showed no improvement in their fecal calprotectin level when compared to the respective figure of 46% of the UC patients ($P < 0.05$).

CONCLUSION: When treated with infliximab, fecal calprotectin levels reflecting intestinal inflammation normalized rapidly in one third of pediatric patients suggesting complete mucosal healing.

Key words: Crohn's disease; Ulcerative colitis; Surrogate markers; Pediatrics; Monoclonal antibodies; Infliximab

INTRODUCTION

The recent development of easily applicable fecal surrogate markers for intestinal inflammation has provided

new means for objective assessment of disease activity and treatment response in chronic inflammatory bowel disease (IBD), a disease becoming more prevalent among children[1]. This is especially important in pediatric patients with limited possibility for follow-up endoscopy due to invasiveness. The fecal levels of neutrophil-derived markers, such as fecal calprotectin or lactoferrin, reflect the mucosal influx of inflammatory cells in the intestine, thus associating with the presence of active inflammation. In IBD, fecal calprotectin levels relate to the findings in endoscopy but also with the grade of histological inflammation[1-4]. When compared to clinical scores and serum inflammatory markers, fecal calprotectin is the most accurate tool to detect the presence of active mucosal inflammation in the colon[4-6]. The negative predictive value for the presence of active inflammation is high (87%)[4]. In children, it has been shown that the level of fecal calprotectin[2,3,7,8] or lactoferrin[6,9] may guide the need for endoscopy.

The data on fecal markers during therapy of IBD are sparse. We showed recently that during glucocorticoid therapy in pediatric patients, fecal calprotectin levels rarely declined below the limit of a raised value, suggesting ongoing mucosal inflammation. However, in those clinically responding to therapy, fecal calprotectin values fell markedly during the first month of therapy[10]. In children presenting with clinically quiescent IBD, only one third of the patients have fecal calprotectin levels below the upper normal limit, whereas the others have raised values, although not reporting subjective symptoms[11]. In adults, fecal calprotectin values are associated with mucosal healing in Crohn's disease (CD) patients who respond to therapy with tumor necrosis factor (TNF)-α antagonists or other IBD medication[12,13]. In a pilot study by Buderus *et al*[14], the levels of fecal lactoferrin were measured in five children on infliximab therapy, who showed a decline after the first infusion in each case. The pattern of fecal calprotectin levels during introduction of TNF-α antagonist therapy in children has not yet been described.

In pediatric patients, TNF-α antagonists have emerged for therapy of severe IBD that does not respond to conventional treatment[15-17]. Fecal calprotectin provides a non-invasive means to assess the presence of intestinal inflammation, therefore, we conducted a prospective study in pediatric patients treated with TNF-α antagonist infliximab. Our aim was to study the pattern of fecal calprotectin concentrations during the early phase of therapy.

MATERIALS AND METHODS

Study population

We prospectively studied 36 children (median age 14 years, range 5.6-17.6 years; 20 boys 20, 16 girls) diagnosed with IBD according to the Lennard-Jones criteria[18], and consecutively introduced to therapy with infliximab. In two cases, the diagnosis of CD was based on extensive aphthous ulceration visualized by wireless capsule endoscopy. All patients had moderate to severe disease that did not respond to treatment with 5-aminosalicylic acid (5-ASA), immunosuppressants or glucocorticoids. In four cases, infliximab was introduced shortly after a diagnosis of extensive small bowel disease. In three patients, the indication for anti-TNF-α agent was fistulating disease, and in all the others, poor response to maintenance medication or steroid dependency. The study group comprised 23 pediatric patients with CD, and 13 with ulcerative colitis (UC). The background data, disease distribution, and medication of the patients are shown in Table 1. Fourteen patients underwent ileocolonoscopy, seven underwent wireless capsule endoscopy, and seven magnetic resonance imaging enterography within 1 m prior to the introduction of infliximab therapy, confirming active disease.

Table 1 Background data of 36 pediatric patients with inflammatory bowel disease treated with infliximab

Variable	Result
Age median (range)	14 (5.6-17) yr
Sex	20 boys, 16 girls
Diagnosis	
CD	23
Ileitis	8
Ileocolitis	8
Colitis	7
UC	13
Left-sided colitis	4
Pancolitis	9
Maintenance medication at baseline	
5-ASA	10
5-ASA + azathioprine/6-MP	12
Azathioprine/6-MP	7
None	7
Prednisolone/budesonide at baseline	19
Disease duration (median, range)	2.1 (0.4-7.6) yr

CD: Crohn's disease; UC: Ulcerative colitis; 5-ASA: 5-aminosalicylic acid; 6-MP: 6-mercaptopurine.

TNF-α antagonist infliximab (Remicade®) was scheduled at 5 mg/kg at weeks 0, 2 and 6. All infusions were administered at the Hospital for Children and Adolescents, Helsinki University, Finland during February 2008 to December 2010. The maintenance medication was unaltered until week 6, but if the patient improved clinically, glucocorticoids were tapered off. At each visit, the patients provided a stool sample for fecal calprotectin measurement and a blood sample for measurement of inflammatory marker erythrocyte sedimentation rate (ESR), and hemoglobin. Fecal calprotectin was measured in the routine clinical laboratory by a quantitative enzyme immunoassay (PhiCal Test, Calpro AS, Oslo, Norway; NovaTec Immunodiagnostica, Dietzenbach, GmBH, Germany) and the values quoted as normal were < 100 μg/g stool[10,19]. The clinical activity of the disease was assessed by physicians global assessment (PGA) score from 1 to 3[20].

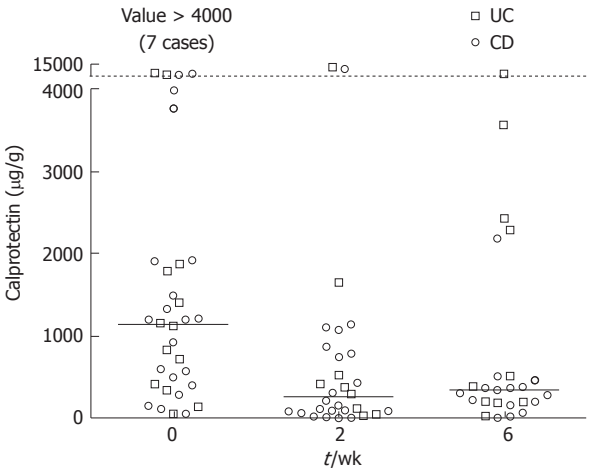

Figure 1 Fecal calprotectin levels at baseline, and 2 and 6 wk after introduction of infliximab therapy in children with Crohn's disease or ulcerative colitis. The decline in levels between baseline and week 2 was statistically significant ($P < 0.001$). CD: Crohn's disease; UC: Ulcerative colitis.

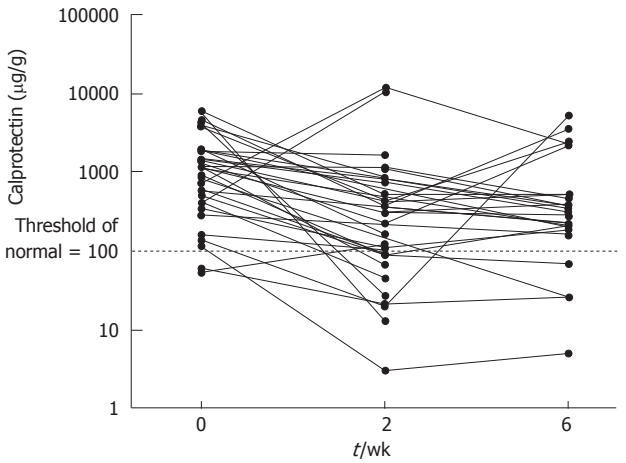

Figure 2 Fecal calprotectin levels at baseline, and 2 and 6 wk after introduction of infliximab therapy showing the individual variation in children with inflammatory bowel disease.

Ethical considerations

The ethics committee of Helsinki University Central Hospital approved the study protocol. The families attending the study signed an informed consent form.

Statistical analysis

Spearman non-parametric correlation test, Kruskal-Wallis test, Mann-Whitney *U* test, and Fisher's exact test were used. The level of statistical significance was $P < 0.05$. The values are presented as median and range.

RESULTS

Fecal calprotectin was high at the introduction of infliximab therapy, with a median value of 1150 μg/g (range: 54-6032 μg/g). Two patients had fecal calprotectin < 100 μg/g (reference limit for a raised value), and their indication for treatment was steroid-dependent colitis. By week 2, the median level of fecal calprotectin level had declined to 261 μg/g (Figure 1; $P < 0.001$, Mann-Whitney *U* test). In 11 of 30 (37%) patients, fecal calprotectin was below the reference limit (100 μg/g) by week 2. By week 6, there was no additional improvement in the median fecal calprotectin level (345 μg/g, range: 5-5253 μg/g, Figure 1). The individual variation of fecal calprotectin levels is shown in Figure 2.

Disease extension or diagnosis did not relate to fecal calprotectin levels or to treatment response (data not shown). Fecal calprotectin decreased in 21 of 22 (95%) of the CD patients, with a raised value during the introduction phase, but in one case, the response was temporary. By week 6, there was no response in two cases when compared to baseline. One patient with CD presented with low fecal calprotectin levels throughout the study period. In this particular case, the indication for treatment was steroid dependency and steroids were tapered off during induction. Thus, the effect of infliximab therapy on fecal calprotectin could not be assessed, and she was not included in the analysis. Of the UC patients with increased fecal calprotectin at baseline, the level decreased in 10 of 12 (83%) patients, but increased to pretreatment levels or above by week 6 in three of 10 (30%) children. Of the two children with no initial decline in fecal calprotectin level, there was no clinical response and the level stayed constantly high (> 1600 μg/g) or increased more than 10-fold within 6 wk. The child with steroid-dependent UC and low fecal calprotectin at the start of this therapy (high disease activity confirmed in colonoscopy 1.5 mo earlier) showed mild elevation in the level (up to 120 μg/g). Thus, by week 6, fecal calprotectin level suggested a response in 20 of 22 (91%) of the CD patients and in seven of 13 (54%) of the UC patients ($P < 0.05$, Fisher's exact two-tailed test), corresponding to a figure of 22% of non-responsive patients in total.

Blood inflammatory marker ESR decreased from a median value of 20 mm/h (range: 2-46 mm/h) at baseline to 9 mm/h (range: 2-34 mm/h, $P < 0.05$, Mann-Whitney *U* test) at 2 wk. At baseline, 19 of 31 patients (61%) had elevated ESR. By week 2, the respective figure was 28% (9/32). Median PGA score was 2 at baseline (range: 1-3), and by week 2 and 6, the score was 1 (range: 1-3, $P < 0.001$); by week 6, the majority of patients (33/36) presented with a score of 1. For hemoglobin levels, there was no significant increase in the median values [118 g/L (range: 95-152 g/L) at baseline and 124 g/L at 2 wk (range: 80-147 g/L)]. Glucocorticoids were tapered off in 10/19 patients during the induction phase.

DISCUSSION

Therapy with TNF-α antagonists has emerged in pediatric patients suffering from moderate to severe CD[21,22], but recently, a therapeutic response has also been reported in severe UC[16,23]. These therapies are effective but at present have high costs and carry a risk for the development of severe adverse effects, which possibly

hampers their clinical use[24,25]. Thus, it is of key importance to target the therapy on those who show a positive response and to discontinue administration of TNF-α antagonists if the patient is a non-responder[25]. In keeping with this, surrogate markers for the presence of intestinal inflammation such as fecal calprotectin[13,26] are promising and non-invasive means for the assessment of disease activity in IBD. There have only been a few studies on fecal calprotectin related to therapeutic response in IBD. Previously, we have assessed the pattern of fecal calprotectin in acute pediatric IBD from the start of glucocorticoid therapy until their discontinuation[10], and in adults during the first 12 wk of TNF-α antagonist therapy[12]. Here, we showed the pattern of fecal calprotectin in pediatric IBD during the induction phase of TNF-α antagonist therapy, demonstrating a rapid decline in fecal calprotectin levels within the first weeks of induction in the majority of pediatric IBD patients, suggesting an early response.

By week 2 after introduction of infliximab, the median level of fecal calprotectin had declined by 77% from baseline. Expectedly, this rapid decrease in fecal calprotectin in children paralleled the pattern seen in adults after introduction of TNF-α antagonist treatment. In a previous study in adults, endoscopy confirmed remission in 30% of CD patients when assessed at 3 mo[12]. In the present study, in one third of the children, the fecal calprotectin levels had declined to normal - suggesting remission - by week 2 after the start of infliximab therapy. Unexpectedly, there were only a few cases that showed normalization of fecal calprotectin by week 6, thus, the 2-wk result equaled the proportion of children with suggested mucosal healing - the target of IBD therapy[27] - and remission during the induction phase. The finding of an excellent therapeutic response in one third of the patients is comparable to our previous findings in children with acute IBD treated with glucocorticoids (showing a normalization of fecal calprotectin in 27% of patients[10]), and in adults treated with TNF-α antagonist therapy[12] (see above). In two thirds of the patients, fecal calprotectin did not normalize, suggesting incomplete mucosal healing during the induction phase of infliximab therapy. It is important to note that the fecal calprotectin level that is considered as a satisfactory therapeutic response remains undecided. Furthermore, the long-term treatment outcome in pediatric patients related to fecal calprotectin levels warrants further studies. In adult patients, mucosal healing predicts a better long-term outcome[28].

Although primary response to TNF-α antagonist therapy is excellent in children, covering 80%-90% of patients with CD, the therapeutic response according to clinical disease activity may deteriorate during the first year of therapy in a considerable proportion of children. It has been estimated that 34%-49% of initial responders need dose escalation or more intense therapy during the first year of infliximab therapy[15,22]. For infliximab therapy in adults, rates of dose intensification ranging from 31% to 36% at 12 mo are comparable to those in pediatric patients[29,30]. Here, the primary response was possibly lost already during the introduction phase in > 10% of the patients, as reflected in the fecal calprotectin levels. In these particular children, PGA did not decrease either. However, clinical activity indices have less correlation to the presence of mucosal inflammation than fecal neutrophil biomarkers, as shown in adult CD patients[31]. Thus, reliance solely on clinical assessment is insufficient, and constantly high fecal calprotectin concentration during therapy warrants endoscopic evaluation also in children. It should be noted that increased fecal calprotectin level does not discriminate between disease relapse and intestinal infection[32].

Blood hemoglobin levels did not significantly alter during the induction phase, but the median ESR decreased during the induction phase by week 2. However, 39% of the patients had normal ESR at baseline, and in these patients, ESR is not applicable for assessment of therapeutic response. In children with IBD, serum C-reactive protein (CRP) is seldom increased, and disappointingly, the measurement of high-sensitivity CRP does not bring additional benefit for the assessment of disease activity[33]. Thus, CRP levels were not measured systematically in the present study. It has also been shown in adult IBD that CRP is a poor marker in mild to moderate disease[34], and performance of fecal calprotectin is significantly better[6].

As in many pediatric studies, one of the major limitations of the present study was the small size of the study group. The majority of the patients had CD but as there were only 13 cases of UC, comparisons related to diagnosis of IBD should be interpreted with caution. Most patients with CD presented with ileocolitis, and the numbers of patients with terminal ileal disease or CD colitis were too small to allow proper comparisons related to therapeutic response to infliximab therapy.

In conclusion, fecal surrogate markers may provide objective and non-invasive means to determine the response to infliximab in individual patients early in treatment. Also, fecal calprotectin is more reliable than clinical activity indices or blood-borne markers of inflammation. It may be possible to identify responding patients by a rapid drop in fecal calprotectin levels, which can be seen already at week 2. By week 6, little improvement is evident and some patients even appear to lose their therapeutic response. Based on our results, fecal calprotectin is a promising marker for evaluating patient response to TNF-α antagonist therapy and may offer a tool for identifying responding patients at an early stage, for more efficient targeting of treatment.

ACKNOWLEDGMENTS

We thank Ms Anne Nikkonen, RN and Sari Honkanen, RN for excellent assistance in gathering the patient data.

COMMENTS

Background

In pediatric patients, tumor necrosis factor (TNF)-α antagonists have emerged for therapy of severe inflammatory bowel disease (IBD), in patients who do not respond to conventional treatment. In children, endoscopy is an invasive procedure, which limits its use in follow-up. Fecal calprotectin is a surrogate marker for the presence of intestinal inflammation and thus provides a non-invasive means to assess disease activity in children.

Research frontiers

The recent development of easily applicable fecal surrogate markers for intestinal inflammation has provided new means for objective assessment of disease activity and treatment response in chronic IBD, a disease becoming more prevalent among children. When compared to clinical scores and serum inflammatory markers, fecal calprotectin is the most accurate tool to detect the presence of active mucosal inflammation in the intestine, and it is easily applicable to pediatric clinical practice.

Innovations and breakthroughs

This is believed to be the first pediatric study to follow fecal calprotectin levels during the induction phase of therapy with TNF-α antagonist agent infliximab. The study showed that, in one third of pediatric patients, fecal calprotectin level normalized by week 2. However, in two thirds of the patients, fecal calprotectin levels stayed elevated by week 6, suggesting incomplete mucosal healing.

Applications

Based on the results, fecal calprotectin is a promising marker for objective evaluation of patient response to TNF-α antagonist therapy and may offer a tool for identifying responding patients at an early stage, for more efficient targeting of treatment. The long-term treatment outcome in pediatric patients related to fecal calprotectin levels after induction therapy warrants further study.

Terminology

IBD consists of Crohn's disease, ulcerative colitis and indeterminate colitis, and is a chronic illness that affects the intestines, with a partly TNF-α-driven inflammation that is effectively abated by TNF-α antagonists such as infliximab. Fecal calprotectin is a neutrophil-derived marker of inflammation that is present in the stools, and is a reliable surrogate for endoscopic evaluation of disease activity.

Peer review

The authors prospectively evaluated the therapeutic response in pediatric IBD patients during introduction to infliximab reflected in fecal calprotectin levels. It is a relevant study and the paper is well presented.

Abstract

AIM: To compare culture analysis, *Helicobacter pylori* (*H. pylori*) stool antigen (HpSA) test, polymerase chain reaction (PCR) and fluorescence *in situ* hybridization (FISH) for *H. pylori* detection.

METHODS: One hundred and thirty-two consecutive adult dyspeptic patients receiving diagnostic endoscopy at the department of gastroenterology were enrolled in this study. Culture and histological examination were performed on biopsy specimens. PCR and FISH tests were applied to histopathological samples. Stool samples that were simultaneously collected were tested for the *H. pylori* antigen using the HpSA test and bacterial DNA using stool PCR.

RESULTS: *H. pylori* was positively identified by histological examination in 85/132 (64.4%) of the patients, while positive samples were found in 56 (42.4%), 64 (48.5%), 98 (74.2%), 28 (21.2%) and 81 (61.4%) of the patients by culture, HpSA, PCR, stool PCR and FISH methods, respectively. The results of the culture, biopsy PCR, HpSA and FISH tests, with the exception of the stool PCR, were found to correlate with the histological examination as a gold standard.

CONCLUSION: The HpSA test is a rapid, simple, and noninvasive test for monitoring therapy. FISH is an accurate, rapid, cost-effective, and easy-to-use test for *H. pylori* detection.

Key words: *Helicobacter pylori*; Histology; Polymerase chain reaction; *Helicobacter pylori* stool antigen; Fluorescence *in situ* hybridization

INTRODUCTION

In 1984, Marshall and Warren[1] reported the discovery of a bacterium, which was subsequently named *Helicobacter pylori* (*H. pylori*)[2], whose habitat was the human gastric mucosa. This bacterium has been shown to play a role in gastritis, peptic ulcer disease, and gastric malignancies[3-5]. Colonization of the human gastric mucosa induces chronic gastritis and peptic ulcer disease[3,4]. In addition,

H. pylori plays a role in the etiology of gastric cancer and cancer of the mucosa-associated lymphoid tissue[5].

The accurate detection of *H. pylori* is essential for the management of patients and for the eradication of the bacterium following treatment. Since the discovery of *H. pylori*, several diagnostic methods have become available for determining the presence of *H. pylori* infection. These tests can be assessed by invasive and noninvasive methods[6]. Assessment of *H. pylori* infection is based on noninvasive tests, such as serological methods, C urea breath test, and bacterial DNA sequences or bacterial antigen detection in stool by the *H. pylori* stool antigen (HpSA) test[7]. Under many circumstances, noninvasive testing is preferred. These tests are attractive because of their simplicity and the ability to provide test results within a few minutes after administration, in a physician's office. In contrast, the direct detection and culturing of *H. pylori* for the diagnosis of infection requires gastric biopsy specimens obtained from invasive gastroduodenoscopy[5]. Culture methods require an incubation period of at least 4-7 d. However, it is important to note that *H. pylori* is a fastidious microorganism and is affected by environmental conditions[8,9]. The presence of *H. pylori* or resistance to antimicrobials can be investigated on gastric tissue samples with molecular methods, such as polymerase chain reaction (PCR) and fluorescence *in situ* hybridization (FISH).

The aim of this study was to compare culture analysis, HpSA test, PCR and FISH to histological examination for the detection of *H. pylori*.

MATERIALS AND METHODS

Clinical samples

One hundred and thirty-two consecutive adult dyspeptic patients receiving diagnostic endoscopy at the department of gastroenterology were enrolled in this study. Written informed consent was obtained from all of the patients before endoscopy, and sample collection and approval by the Local Ethical Committee was taken prior to initiation of the project. Patients who underwent partial or complete gastrectomy, those with prior *H. pylori* eradication therapy, or those who were treated with any antibiotics, colloidal bismuth compounds, proton pump inhibitors, or H_2 receptor blockers within the past 4 wk were excluded from the study.

Endoscopy and biopsy sampling

Endoscopy was performed with a PentaxFG-29W (Pentax, Germany) on patients after an overnight fast. Four gastric biopsies (two from the antrum and two from the corpus) were taken from each patient.

Culture

Two gastric biopsy specimens, one from the antrum and one from the corpus, were obtained and placed in Stuart's transport medium. Cooled samples were transported to the laboratory of the Department of Microbiology within 1-2 h after procurement, as previously described[10]. Specimens were inoculated onto brain-heart infusion agar supplemented with sheep blood (10%), vancomycin (10 mg/L), trimethoprim lactate (5 mg/L), cefsoludin (5 mg/L), and amphotericin (5 mg/L). The plates were microaerobically incubated using CampyGen (Oxoid, United Kingdom) at 37 ℃ for up to 7 d. Positive cultures were identified by colony formation and Gram stain morphology as well as positive catalase, oxidase, and urease tests.

Histology

Two gastric biopsy specimens, one from the antrum and one from the corpus, were fixed in 10% formalin in separate containers and were sent to the Pathology Laboratory. Samples were embedded in paraffin wax, cut at 5 μm thickness, and stained with modified giemsa and hematoxylin and eosin. Histological evaluation of the samples for *H. pylori* was performed according to the Modified Sydney system[11]. The pathologist was unaware of the patients' clinical conditions and other test results.

HpSA

Stool samples were tested for *H. pylori* antigen by the monoclonal antigen FemtoLab *H. pylori* Cnx kits (Connex GmbH, Martinsried, Germany) using the manufacturer's protocol. Approximately 0.1 g of stool sample was added to vials that contained 1 mL of sample diluent and then emulsified by vortexing for 15 s. The tip of the vial was snapped off and 50 μL sample and 50 μL conjugate were added to the test well. The strip was rinsed after incubation for exactly (60 ± 5) min at ambient temperature. After washing, 100 μL substrate was added and then incubated for 10 min. Finally, the stop solution was added and the samples were analyzed on a spectrophotometer at a wavelength of 450 nm.

PCR

Gastric biopsies from all of the study subjects were stored at temperatures at or below -70 ℃ until use. Each biopsy was digested with tissue extraction buffer at 55 ℃ for 3 h. Then, 200 μL phenol was added to the tissue lysate to extract genomic DNA. *H. pylori* genomic DNA from stool samples was extracted according to Gramley *et al*[12]. Genomic DNA was subsequently quantified by PCR with 16S rRNA. Amplified fragments were separated on a 1% agarose gel and visualized under ultraviolet light.

Fluorescence in situ hybridization

Formalin-fixed paraffin-embedded gastric biopsies were sectioned and dehydrated. The sections were then air-dried and hybridized using the commercially available test system Seafast® *H. pylori* Combi Kit (Izinta, Hungary) according to the manufacturer's instructions. The oligonucleotide probe Hpy-1, which targets a specific sequence of 16S rRNA from *H. pylori*, was hybridized to the sections. Evaluation was performed with a fluorescent microscope equipped with a filter for green fluores-

cence (Nikon Eclipse 600, Japan).

Statistical analysis

The χ^2 and Pearson correlation analysis were conducted and the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), *P* value, *r* value, odds ratio (OR) and relative risk (RR) were calculated using standard formulas for data using SPSS v. 10.0 (IBM, United States).

RESULTS

H. pylori was identified by histological examination in 85/132 (64.4%) of the patients, while 47/132 (35.6%) of the patients were classified as *H. pylori* negative. Furthermore, positive results were obtained in 56 (42.4%), 64 (48.5%), 98 (74.2%), 28 (21.2%) and 81 (61.4%) of patients by the culture method, HpSA analysis, PCR, stool PCR and FISH, respectively. Histological examination results were evaluated by the gold standard, and specificity, sensitivity, PPV and NPV were calculated for each test (Table 1). A high number of false-positive results was observed in the biopsy PCR (23/98; 23.4%). However, a higher rate of false-negative results was obtained with the culture method (33/76; 43.4%). The culture method, biopsy PCR, HpSA and FISH tests were found to correlate with the Pearson correlation analysis. Similarly, these tests were statistically comparable to the histological examination based on the *P* value with the χ^2 test. In contrast, the stool PCR test did not correlate or have a significant *P* value. These data are summarized in Table 2.

DISCUSSION

There are currently several different diagnostic tests that exist for detecting *H. pylori* infection. Each test has its own merits and demerits in terms of indication, sensitivity, specificity, cost and time. Several studies have examined the diagnostic performance of invasive and non-invasive methods[6,7,9,12,13]. However, these studies were biased or demonstrated a lack of agreement[13]. One possible reason for the discrepancies in diagnostic performance might be due to the selection of various reference methods. Currently, there is no established method to provide a definitive or standard diagnosis of *H. pylori* infection. The selection of tests or the use of a combination of tests without identifying any one specific test as a reference standard can introduce bias[14].

One limit of histological detection of *H. pylori* in gastric biopsy specimens is interobserver variability in assessment[15,16]. A meta-analysis has reported that histological examination results have an approximate sensitivity of 0.70 and specificity of 0.90[17]. This may be due to the discrepancies in the evaluation of features of *H. pylori* or the observations of the pathologist, because pathology results are based on subjective interpretation of different features and classification. Various studies on the reproducibility of histopathological data have reached a similar conclusion. However, the histological examination of the gastric biopsy specimen is accepted as the gold standard for the diagnosis of *H. pylori*[18]. In this study, histological examination resulted in 64.4% positivity for *H. pylori*, which showed a good correlation with the positive detection rates of other methods, with the exception of stool PCR.

Culturing biopsy specimens cannot be routinely used because it is time consuming and very difficult to maintain strict anaerobic conditions. However, bacterial cultures can surely provide specific results and informative data. Gisbert and Abraria have reported three studies with culture sensitivity of 0.45 and specificity of 0.98 in 2006[17]. Similarly, we found that the culture sensitivity and specificity was 0.61 and 0.91, respectively. In addition, the statistical analysis showed a PPV of 0.93, NPV of 0.43, OR of 16.94, and RR of 2.14 compared to histological examination.

The HpSA test is available and recommended in the Maastricht 2-2000 Consensus Report[19] for the pretreatment diagnosis of *H. pylori* infection and confirmation of a *H. pylori* cure following treatment. In a Japanese study, the HpSA test had a reported sensitivity of 93.9% and specificity of 95.7%, compared to a diagnosis of infection based on histological examination[20]. However, Blanco *et al*[21] have observed that another stool antigen test showed a low sensitivity (75%-79%), in patients with *H. pylori* infection who were tested after erradication therapy. We studied the accuracy of the HpSA test in the Turkish population. The HpSA test had a sensitivity of 0.72, specificity of 0.67, accuracy of 0.77, PPV of 0.81, OR of 5.20 and RR of 1.79. Thus, the HpSA test results had a low but acceptable correlation with the histological examination.

It has been reported that the FISH method is an accurate, inexpensive, rapid test for the detection of *H.*

pylori in paraffin-embedded gastric biopsy samples, with a high sensitivity and specificity[22-24]. In addition, it can be applied to fresh gastric tissue samples and *H. pylori* isolates from culture[25]. In this study, the FISH method had a strong correlation with the histological examination and exhibited a sensitivity of 0.93, specificity of 0.96, accuracy of 0.94, PPV of 0.98, OR of 296.25 and RR of 8.29. Furthermore, the FISH method may be a very useful *H. pylori* diagnostic tool in microbiology in the future.

In gastric tissue, the presence of *H. pylori* and resistance genes can be investigated by PCR. It has a high sensitivity and specificity, and can be used as a follow-up assessment after therapy[26,27]. In this study, biopsy PCR studies had a sensitivity of 0.88, specificity of 0.51, accuracy of 0.75, PPV of 0.77, OR of 7.83 and RR of 2.60. Moreover, we found that the specificity value was particularly low for the biopsy PCR results. However, there was a discrepancy between our study and previous reports in terms of the specificity of *H. pylori* detection[28,29]. Lunet *et al*[28] have reported a difference in *H. pylori* positivity by histology *vs* PCR from different populations, in Mozambique and Portugal of 63.7% *vs* 93.1% and 95.3% *vs* 98.1%, respectively. Two possibilities could explain this conflicting result. First, a low density of *H. pylori* colonization may explain the histological results. Alternatively, the PCR results may be reliable because of the use of a specific primer for the particular population.

The stool PCR results had a very low sensitivity and OR (0.21 and 0.99) and had no significant correlation with the histological examination. Previous studies and our data clearly indicate that there is no clinical value in the determination of *H. pylori* in human feces by PCR because of insufficient sensitivity, specificity, and accuracy[30].

There are a variety of tests available for the diagnosis of *H. pylori* infection. Therefore, it is important that laboratories choose the test or tests that are appropriate for the conditions of the laboratories, patient numbers, costs, and account for the need to prepare their own diagnostic algorithms.

In conclusion, the culture, biopsy PCR, HpSA test, and FISH methods for the detection of *H. pylori* in this study, with the exception of stool PCR, were found to correlate with histological examination as a gold standard. In addition, there was a conflicting result on biopsy PCR data when compared to histological examination. The HpSA test is a rapid, simple, and noninvasive test with acceptable results that can be used for monitoring therapy. The FISH method is an accurate, rapid, cost-effective and easy-to-use test for the detection of *H. pylori*, and also allows for the simultaneous determination of antibiotic resistance in the same gastric tissue. Therefore, histopathological examination as a gold standard and the FISH test may be the preferred methods to use together for the precise detection of *H. pylori*.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) plays a role in gastritis, peptic ulcer disease and also gastric malignancies such as gastric cancer and cancer of the mucosa-associated lymphoid tissue. The accurate detection of *H. pylori* is essential for the management of patients and eradication of the bacteria following treatment.

Research frontiers

Since the discovery of *H. pylori*, several diagnostic methods have been become available for determining the presence of *H. pylori* infection. However, there is no established method to provide a definitive or standard diagnosis of *H. pylori* infection.

Innovations and breakthroughs

The fluorescence *in situ* hybridization (FISH) test is an accurate, rapid, inexpensive and easy-to-use method for the detection of *H. pylori*, and allows determination of antibiotic resistance in the same gastric tissue simultaneously. In this study, FISH correlated well with histological examination. Therefore, histological examination and the FISH test may be preferred together for the precise detection of *H. pylori*.

Applications

This study suggests that, laboratories choose the test or tests that are appropriate for their own conditions, patient numbers and costs, and have to prepare their own diagnostic algorithms.

Terminology

For the detection of *H. pylori*, culture, *H. pylori* stool antigen test, polymerase chain reaction and FISH were used with histological examination.

Peer review

This was an interesting study, although a few problems need to be resolved before publication. The most important point is the reliability of their gold standard. The reasons for the false-positive and false-negative results of each test should be discussed further.

Abstract

AIM: To investigate how many discrepancies occur in patients before and after endoscopic treatment of referred adenoma and the reason for these results.

METHODS: We retrospectively reviewed data from 554 cases of 534 patients who were referred from primary care centres for adenoma treatment and treated for endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) at Chungnam National University Hospital, from July 2006 to June 2009. Re-endoscopy was examined in 142 cases and biopsy was performed in 108 cases prior to treatment. Three endoscopists (1, 2 and 3) performed all EMRs or ESDs and three pathologists (1, 2 and 3) diagnosed most of the cases. Transfer notes, medical records and endoscopic pictures of these cases were retrospectively reviewed and analyzed.

RESULTS: Adenocarcinoma was 72 (13.0%) cases in total 554 cases after endoscopic treatment of referred adenoma. When the grade of dysplasia was high (55.0%), biopsy number was more than three (22.7%), size was no smaller than 2.0 cm (23.2%), morphologic type was depressed (35.8%) or yamada type Ⅳ (100%), and color was red (30.9%) or mixed-or-undetermined (25.0%), it had much more malignancy rate than the others ($P < 0.05$). All 18 cases diagnosed as adenocarcinoma in the re-endoscopic forceps biopsy were performed by endoscopist 1. There were different malignancy rates according to the pathologist ($P = 0.027$).

CONCLUSION: High grade dysplasia is the most important factor for predicting malignancy as a final pathologic diagnosis before treating the referred gastric adenoma. This discrepancy can occur mainly through inappropriately selecting a biopsy site where cancer cells do not exist, but it also depends on the pathologist to some extent.

Key words: Discrepancy; Adenoma; High grade dysplasia; Endoscopic mucosal resection; Endoscopic submucosal dissection

INTRODUCTION

Since gastric adenoma can progress to higher grade dysplasia or cancer, as shown in long-term follow up studies, it should be treated by endoscopic resection or surgical resection[1-3]. Endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) have been approved as standard treatments for gastric adenoma[4]. Pathologic results from the mucosectomy specimens taken from endoscopic resection of gastric adenoma can be different from those of an endoscopic forceps biopsy[5,6]. As endoscopy has been examined more commonly and extensively, prevalence of adenoma referred from a primary care center for endoscopic resection has increased. However, there have been no reports on the histologic discrepancy between the endoscopy-based diagnosis of the referred gastric adenoma and the final pathologic diagnosis, and previous studies did not include analysis of other possible factors for discrepancy[5-7]. This study aimed to elucidate and analyze possible factors affecting discrepancy for referred gastric adenoma.

MATERIALS AND METHODS

A total of 1049 patients with gastric adenoma were endoscopically treated by EMR or ESD between July 2006 and June 2009 at Chungnam National University Hospital. Among these, 534 patients were referred from primary care centres, most of them from the Tae-jeon Chungchoeng province in South Korea. Because it was intended for all the referred patients to undergo endoscopic treatment, most patients were treated with EMR or ESD, except for an extreme few who had a tendency toward bleeding, or were untreatable due to size, location, or comorbidity. Endoscopists decided resection methods (EMR or ESD) from clinical information such as age, size, morphology, color, location and pathologic grade, but there were no strict criteria. Transfer notes, medical records, and endoscopic pictures of these cases were retrospectively reviewed and analyzed. One hundred and forty-two cases were examined by re-endoscopy and 108 cases underwent re-biopsy prior to endoscopic resection according to the judgment of the endoscopist. The main reason for pre-evaluations of endoscopic examination and biopsy before the resection was incomplete or confusing referred medical records for determining treatment methods. This is schematically described in Figure 1. Transfer reports were reviewed for information of histologic grade, biopsy number, date of the biopsy, and the name of the referring center. Pathologic reports on 54 patients were written as mild, moderate, or severe grade dysplasia of the adenoma, instead of low or high grade dysplasia. Grading terms of adenoma required unification for statistical analysis. "Mild grade"or "moderate grade" was classified as low grade and "severe grade" or "moderate to severe grade" was classified as high grade. Three endoscopists performed all EMRs or ESDs and three pathologists diagnosed most of the cases. Endoscopic reports and saved pictures of procedures were reviewed for morphologic type, color, size, and location.

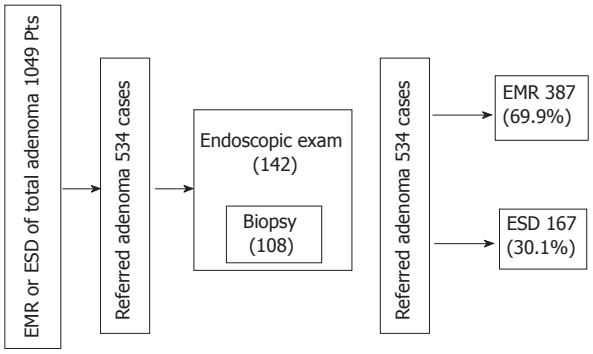

Figure 1 Schematic description of the study design. EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; Pts: Patients.

SPSS version 13.0 was used for statistic analysis. The one-way analysis of variance test was used for comparison of continuous variables; for example, age, size, day duration and biopsy number. The χ^2 test was used for other parameters of nominal variables.

RESULTS

Baseline characteristics, endoscopic features and treatment results of referred adenoma

Baseline characteristics and endoscopic features of referred adenomas from primary care centres are shown in Table 1. The mean age of the 554 cases was 66.1 years old. More than 86.4% of cases were located within and under the lower body. Results showed adenomas with no grading record in the transfer note in 92 cases (16.6%), low grade adenomas in 382 cases (69.0%), and high grade adenomas in 80 cases (14.4%). Treatment results of referred adenoma are shown in Table 2. Early gastric cancers were found in 72 cases (13.0%), no adenomatous lesions were found in 56 cases (10.1%), low grade adenomas were found in 356 cases (64.3%), and high grade adenomas were found in 68 cases (12.3%). One case involved mucosa associated lymphatic tissue lymphoma (MALToma) and one complicated case of bleeding were referred. Histologic results of pre-procedure re-endoscopic biopsy were various, from gastritis to adenocarcinoma. In the re-endoscopic biopsy, there were 18 cases (16.7%) of adenocarcinoma and one case of MALToma. The most common complication of EMR and ESD was bleeding (14 cases, 2.5%) which is defined as a case requiring an endoscopic procedure for bleeding control. Perforation (2 cases, 0.4%) and stricture (2 cases, 0.4%) were rare complications of EMR or ESD. There was one case of positive resection margin, in which surgery was

performed for completion of treatment. Sixteen patients had multiple adenomas, 12 patients had 2 adenomas and 4 patients had 3 adenomas (Table 2).

Agreement and discrepancy of histologic diagnosis

Comparison of histologic diagnoses between local clinic endoscopic biopsy and repeat endoscopic biopsy and post-procedure specimens are described in Table 3. The rate of discrepancy between primary care center and repeat biopsy was 42.4% (39 cases/92), 38.1% (176 cases/462) between primary care center and post procedure specimens, and 29.6% (32 cases/108) between repeat biopsy and post procedure specimens. The rate of complete agreement was 57.6% (53 cases/108), 61.9% (286 cases/554), and 70.4% (76 cases/108), respectively. In all comparisons, the discrepancy rate of high grade dysplasia was higher than that of other forms of adenomas.

Although the histologic diagnosis of referred adenoma was as low grade dysplasia, it could be high grade (11.0%) or adenocarcinoma (5.8%) in the post procedure. High grade adenoma of the primary care center could also be low grade adenoma (27.5%) or early gastric cancer (55.0%) as a final pathologic diagnosis. Consistent high grade adenoma was only 15.0% between local clinics and post procedure biopsy. All adenocarcinomas of repeat endoscopic biopsies were early gastric cancer in the post procedure, except for one case, which had no adenomatous lesion. When this one case was reviewed with pathologists, the specimen from the repeat endoscopic biopsy was not enough for adenocarcinoma. There were only a few atypical glands, but this could still be suggestive of malignancy (Table 3).

Detection of adenocarcinoma in re-endoscopic repeat biopsy prior to the procedure

Histologic results of re-endoscopic biopsy (108 cases) are shown in (Table 4), according to the endoscopists and pathologists. All of the adenocarcinoma biopsies were performed by endoscopist 1 ($P < 0.001$). Pathologist 1 diagnosed a much larger number of adenocarcinomas than pathologist 2 ($P = 0.048$).

Risk factors for predicting malignancy of referred adenoma

There was no difference between the malignancy group

and the non-malignancy group as a final pathologic diagnosis with regard to age, sex, histologic type, duration between local clinic biopsy and procedure, longitudinal and circular location, endoscopist, local clinics, and multiplicity. There was a difference with regard to histologic grade, number of biopsies, size, morphologic type, color, type of procedure, examination of repeat endoscopy, pathologist, and complications (Table 5).

Before the resection, predictive factors for a malignant result were high grade dysplasia (55.0%), a biopsy number of more than three (22.7%), a size of no less than 2.0 cm (23.2%), a morphologic type of depressed (35.8%) or yamada type Ⅳ (100%), and a red (30.9%) or mixed-or-undetermined (25.0%) coloration. There was no statistical significance between less than 1.0 cm and no less than 1.0 cm ($P = 0.124$).

Cases of ESD, repeat endoscopy, or complicated cases had many more malignant results than cases of EMR or direct procedures without re-endoscopy or non-complicated cases. The rate of malignancy was different according to the pathologist ($P = 0.027$). Mean duration from local clinic biopsy to endoscopic treatment did not differ between the malignancy group and the non-malignancy group. There was also no difference between cases (26 cases) with duration of no more than 14 d and cases (33 cases) of duration of more than 90 d. High grade dysplasia showed the highest odds ratio (19.5) with regard to risk factors for malignancy (Table 6).

DISCUSSION

Histologically, gastric adenomas are composed of cells with hyperchromatic, elongated nuclei arranged in a picket-fence pattern with cystic glands and nuclear atypia being occasionally present[8,9]. The malignant potential of adenomas has been demonstrated in long term follow up studies, even in low grade dysplasia, therefore, resection is recommended[3,10]. Since the introduction of EMR in Japan, techniques for endoscopic resection have been continuously advancing; therefore, EMR and ESD are now approved for use in standard treatment of gastric adenoma[4,11,12].

Predictive factors for malignancy

In univariate analysis, risk factors for malignant transformation included location, histologic type (tubulovillous), redness, and high grade dysplasia in the study by Park *et al*[5], and depressed type, high grade dysplasia, redness, ulceration in the study by Jung *et al*[6] in the univariate analysis. In multivariate analysis, only high grade dysplasia had a significant relationship with malignant transformation in the two studies. In our study, predictive factors for

Complications	4.6

ESD: Endoscopic submucosal dissection; Y: Yamada type.

malignancy as a final diagnosis included histologic grade, biopsy number, size, morphologic type and color. High grade dysplasia was the most important risk factor for malignancy, as in previous studies[5,6], with the highest odds ratio (Table 6).

Three out of ten cases (30%) of tubulovillous adenoma were malignancies, compared to only 69/475 cases (12.7%) of tubular adenoma, although this was not statistically significant. Cases with more than three biopsies were more often malignant than cases with fewer biopsies. This might be explained by the assumption that the endoscopist has taken more biopsies when he suspected a malignancy. ESD, re-endoscopy, and complicated groups had more many malignancies than EMR, direct procedure without re-endoscopy, and non-complicated groups, but those are not the cause of malignancy, but the result of strict treatment. Other possible factors affecting malignancy will be discussed below.

Possible causes affecting malignant discrepancy: (1) geographic variety of histology; forceps biopsy can be done only on the adenoma site, when cancer cells are mixed in the same lesion; (2) chronological difference between the time of forceps biopsy and the time of

resection; adenoma can be transformed to malignancy; (3) different criteria of pathologist with regard to malignancy; and (4) different location between forceps biopsy and resection.

Geographic variety of histology

Because relatively small forceps biopsy foci of the polyp cannot represent the entire lesion, there can be a discrepancy between the forceps biopsy and resection specimen of the polyp[13]. Discrepancies before and after endoscopic resection in adenoma are mainly due to the geographic distribution of malignant cells within the adenoma[5,6,14], which means that the discrepancy depends on the location of the initial endoscopic forceps biopsy. It is noteworthy that all of the adenocarcinomas (18 cases) in the re-endoscopic forceps biopsy before the procedure were performed by endoscopist 1, although there was no difference in the discrepancy rate between primary care center and post-treatment according to the endoscopist (Table 4). This may be due to the experience of the endoscopist. An expert endoscopist who can reduce the rate of discrepancy has the ability to determine the location of the cancer cells grossly, approximately to the real histology. A similar two studies on malignant transformation of adenoma presented different discrepancy rates in spite of similar study designs[5,6]. The rate of malignant transformation of adenoma was 6.8% (8/118) in the study by Park *et al*[5] and 55.3% (63/114) in the study by Jung *et al*[6]. These large differences can be understood in the same context.

Chronological difference between the time of forceps biopsy and the time of resection

Gastric adenoma can progress to early gastric cancer, as shown in long term follow-up studies[3,10,15]; even low grade dysplasia has malignant potential. This change can occur over a long period of time. Yamada *et al*[3] reported on one case of 37 low grade dysplasia and one case of 10 high grade dysplasia that progressed to invasive carcinoma over a period of 212 mo and 55 mo, respectively. In our study, duration from the time of initial biopsy to the time of resection was not different between the malignant group and the nonmalignant group. Statistically, the rate of malignancy was also not different between fewer than two weeks (7.7%, 2 cases/33) and fewer than 90 d (12.1%, 4 cases/26) in duration. This means that a treatment delay of roughly three months is not a problem.

Different criteria of pathologist with regard to malignancy

Because criteria between Japanese and Western pathologists are different, international workshops have been steadily and persistently organized in an effort to establish a consensus[16-18]. In 1996, eight pathologists from Japan and Western countries met in Tokyo and individually reviewed a set of 35 gastric biopsy and resection specimens of lesions with potential early neoplasias[16]. There was agreement between Japanese and Western viewpoints in only 11 of the 35 specimens. A different diagnosis can be made for the same specimen, even by an intraobserver in the time interval of three years[19]. Table 5 shows that the malignant discrepancy rate of pathologist 1 is approximately three times greater than that of pathologist 2. The rate of adenocarcinoma diagnosis for re-endoscopic forceps biopsy is also higher for pathologist 1 than pathologist 2 (Table 4). Although the forceps biopsy specimen was not reviewed, it can be assumed that forceps biopsy by the primary care center can be underestimated by the pathologist. However, no difference in the malignant discrepancy rate was observed between primary care centers (Table 5). It is a limitation of our study that the same specimens were not reviewed by pathologists.

Different location between forceps biopsy and resection

Logically, it is possible that either the patient or the sample changed, or that a different mucosectomy site was selected from the diagnostic biopsy site; however, this was not included in the discussion.

COMMENTS

Background

Endoscopic examination is performed more commonly in the primary care center, and gastric adenoma is more frequently referred to tertiary care units.

Research frontiers

There have been so many embarrassing events when previous and post-procedure diagnoses have been different. This research is performed to predict the treatment result and to discover the reasons for these events.

Innovations and breakthroughs

There have been no reports about the discrepancy of referred gastric adenoma and diverse predictive factors, and possible causes are included in this study.

Applications

The results of this study will help endoscopists to predict the results of treatment and to decide the proper treatment option.

Peer review

The authors studied various predictive factors for discrepancy of gastric adenoma and deeply analyzed possible causes of discrepancy.

Abstract

AIM: To determine whether adding vitamin D, a potent immunomodulator, improves the hepatitis C virus (HCV) response to antiviral therapy.

METHODS: Seventy-two consecutive patients with chronic HCV genotype 1 were randomized into two groups: the treatment group (n = 36, 50% male, mean age 47 ± 11 years) received Peg-α-2b interferon (1.5 μg/kg per week) plus ribavirin (1000-1200 mg/d) together with vitamin D3 (2000 IU/d, target serum level > 32 ng/mL), and the control group (n = 36, 60% male, mean age 49 ± 7 years) received identical therapy without vitamin D. HCV-RNA was assessed by real-time polymerase chain reaction (sensitivity, 10 IU/mL). The sustained virologic response (SVR) was defined as undetectable HCV-RNA at 24 wk post-treatment.

RESULTS: Clinical characteristics were similar in both groups. The treatment group had a higher mean body mass index (27 ± 4 kg/m^2 *vs* 24 ± 3 kg/m^2, P < 0.01), viral load (50% *vs* 42%, P < 0.01), and fibrosis score (> F2: 42% *vs* 19%, P < 0.001) than the controls. At week 4, 16 (44%) treated patients and 6 (17%) controls were HCV-RNA negative (P < 0.001). At week 12, 34 (94%) treated patients and 17 (48%) controls were HCV-RNA negative (P < 0.001). At 24 wk post-treatment (SVR), 31 (86%) treated patients and 15 (42%) controls were HCV-RNA negative (P < 0.001). Viral load, advanced fibrosis and vitamin D supplementation were strongly and independently associated with SVR (multivariate analysis). Adverse events were mild and typical of Peg-α-2b/ribavirin.

CONCLUSION: Adding vitamin D to conventional Peg-α-2b/ribavirin therapy for treatment-naïve patients with chronic HCV genotype 1 infection significantly improves the viral response.

Key words: Hepatitis C; Vitamin D; Sustained viral response; Genotype 1; Fibrosis

INTRODUCTION

The current treatment for hepatitis C virus (HCV) infection is pegylated interferon α combined with ribavirin

(Peg/RBV) administered for 24 wk for HCV genotypes 2 or 3, or 48 wk for HCV genotype 1, the most prevalent genotype in Israel, Europe, and North America[1]. The aim of HCV therapy is a sustained virologic response (SVR), defined as an undetectable serum HCV-RNA level at 24 wk after the cessation of therapy. For patients with HCV genotype 1, the rate of SVR ranges between 38% and 46%[2,3]. In subgroups of this population (e.g., Hispanics and African-Americans), the rate of SVR is even lower, reaching only 19%[4]. These differences are not explained by baseline viral load or compliance to treatment. Recent efforts to improve patient outcomes have focused on adding new antiviral therapies specifically targeted to HCV, including inhibitors of either HCV polymerase or protease[5]. However, few studies have addressed the issue of improving the host factors.

Vitamin D is a potent immunomodulator[6,7]. Increased production of 1, 25-dihydroxy vitamin D3 results in the synthesis of cathelicidin, a peptide capable of destroying many viral infectious agents as well as *M. tuberculosis*. Low serum levels of 25-hydroxyvitamin D (< 20 ng/mL) prevent macrophages from initiating this innate immune response, which may explain why African-Americans, who are often vitamin D deficient, are more prone to contracting tuberculosis and viral infections than Caucasians[8]. Moreover, vitamin D improves insulin sensitivity[9], suppresses proinflammatory cytokines, increases anti-inflammatory cytokines, and improves CD4 T cell hyperresponsiveness[10]. Vitamin D deficiency is very common (92%) among patients with chronic liver disease, and at least one-third suffer from severe vitamin D deficiency (< 12 ng/mL)[11]. Israeli subjects from various ethnic backgrounds are at higher risk of vitamin D deficiency[12]. Pettas and co-workers recently showed a low serum vitamin D level to be related to severe fibrosis and low responsiveness to interferon-based therapy in genotype 1 chronic hepatitis C (CHC)[13]. Its role and relationship to SVR and therapy in CHC are unknown. We reasoned that adding vitamin D to conventional therapy could improve treatment efficacy at weeks 4 [rapid viral response (RVR)] and 12 [early viral response (EVR)] during therapy, and 24 wk after cessation of therapy (SVR).

MATERIALS AND METHODS

Subjects

Study inclusion criteria were age 18-65 years, a chronic HCV genotype 1 infection, no previous treatment for hepatitis C, seronegative for HBV, HDV, and human immunodeficiency virus infections, an absolute neutrophil count of > 1500 per mm^3, a platelet count of > 90 000 per mm^3, and a normal hemoglobin level. Liver biopsies were required within 2 years prior to study entry, and the samples were examined by two pathologists who were unaware of patient identity and treatment regimen. The severity of hepatic inflammation and fibrosis was evaluated by the Ishak score in separate reports for grading and staging[14]. Exclusion criteria were decompensated liver disease (cirrhosis with a Child-Pugh score > 9), another cause of clinically significant liver disease, or the presence of hepatocellular carcinoma.

Study design

This was an intention-to-treat prospective randomized study. The experimental procedures were approved by the institutional review boards of the two participating medical centers. Informed consent was obtained from all participants (Clinical Trial Gov: NCT00804752)

The study included 72 consecutive CHC genotype 1 treatment-naïve patients who were stratified according to ethnic group (i.e., Russian/Jewish/Arab) due to possible differences in vitamin D levels. They were randomly assigned to one of two study groups. The treatment group comprising 36 patients (mean age 47 ± 11 years, 50% male) who received pegylated (peg)-interferon-α-2b (1.5 μg per kg body weight) plus oral ribavirin 1000 mg/d (for body weight < 75 kg) or 1200 mg/d (for body weight > 75 kg) and vitamin D3 (Vitamidyne D, Fischer Pharmaceuticals, Israel) 2000 IU/d, target serum level > 32 ng/mL) for 48 wk. Vitamin D3 was given by oral drops for 4 wk before the initiation of antiviral treatment and after serum levels had reached > 32 ng/mL in all patients in the treatment group. The supplemented vitamin D levels were maintained during the course of therapy with the same dosage as in the lead-in phase. The control group of 36 patients (mean age 49 ± 7 years, 60% male) received peg-interferon-α-2b (1.5 μg/kg body weight) plus ribavirin (1000-1200 mg/d) without vitamin D3 for 48 wk.

Efficacy assessments

Plasma HCV-RNA levels were measured using the COBAS Taq Man HCV assay, version 1.0 (Roche Molecular Systems), with a lower limit of quantification of 35-45 IU/mL and a lower limit of detection of 10 IU/mL. HCV-RNA levels were measured at the time of screening and during the treatment period at weeks 4, 12 and 48. All subjects had at least one follow-up visit at 24 wk after the completion of treatment. Those who had undetectable HCV-RNA levels had another follow-up visit 24 wk later, at which time HCV-RNA levels were measured again. Treatment efficacy was defined as SVR, i.e., undetectable HCV-RNA at 24 wk post-treatment. Clearance of HCV-RNA by real-time polymerase chain reaction (RT-PCR) was assessed at week 4 (RVR), week 12 (complete EVR), and at week 48 of treatment response (early treatment response, ETR). Patients with ETR who tested HCV-RNA positive during follow-up were classified as relapsers. Breakthrough was defined as an increase in the HCV-RNA level of one $\log_{10}$ unit compared with the lowest value. Therapy was discontinued if quantitative HCV-RNA levels at week 12 dropped by < 2 log compared with baseline values (non-responders), and at week 24 if HCV-RNA was still detectable in those patients in whom HCV-RNA dropped > 2 log at week 12[3,15].

Table 1 Baseline demographic, clinical and virologic characteristics of all patients

Baseline demographics	Peg/RBV (n = 36)	Peg/RBV + Vit D (n = 36)	P value
Age (yr)	49 ± 7	47 ± 11	0.123
Males (%)	60	50	0.015
Body mass index (kg/m^2)	24 ± 3	27 ± 4	0.014
HCV genotype: 1a/1b (n)	3/33	3/33	0.138
Baseline HCV-RNA (log IU/mL)	6.2 ± 0.8	6.1 ± 0.7	0.126
High viral load HCV-RNA > 800 000 IU/mL	15 (42%)	18 (50%)	0.033
Baseline ALT (U/L)	56 ± 31	55 ± 28	0.587
Advanced fibrosis (> F2)	7 (19%)	15 (42%)	0.001
Ethnicity (Russian /Jewish/Arab)	28/6/2	29/3/4	0.194

Peg/RBV: Pegylated interferon α and ribavirin; Vit D: Vitamin D; ALT: Alanine aminotransferase; HCV: Hepatitis C virus.

Safety assessments

Biochemical assessments were performed at each visit during the treatment period and at the post-treatment follow-up visit. Data on adverse events were collected and physical examinations were also performed each time. The safety assessment included complete blood count, antinuclear antibody, and thyroid-stimulating hormone levels. Peg-interferon α 2b was reduced to 1.0 μg/kg body weight in patients with a < 750 neutrophil count and withdrawn temporarily in patients with a < 500 neutrophil count. The same dose reduction was applied if platelet levels fell under 50 000 cells/mm^3, with peg-interferon being discontinued when the 25 000 cell/mm^3 threshold was reached. In both treatment arms, the ribavirin dose was tapered by 200 mg/d in patients with a hemoglobin level < 10 g/dL, and discontinued altogether in patients with a level < 8.0 g/dL.

Clinical and laboratory measurements

Vitamin D levels: 25 (OH)-vitamin D3 levels were determined by 125 I-radioimmunoassay (Dia-Sorin, Stillwater, MN, United States)[16]. 25-OH vitamin D is the major circulating form of vitamin D and is used as an indicator of vitamin D status. Vitamin D deficiency was defined as a 25 (OH)-vitamin D serum level < 12 ng/mL, vitamin D insufficiency as 25 (OH)-vitamin D levels of 12-32 ng/mL, and vitamin D sufficiency as levels > 32 ng/mL[12]. Insulin resistance was estimated using the homeostasis model assessment (HOMA-IR)[17]. HOMA-IR was measured at baseline and at 4 wk in both study groups. Body mass index (BMI) was calculated as weight in kilograms divided by the square of height in meters. Obesity was defined as a BMI exceeding 28 kg/m^2. C-reactive protein was determined by the nephelometric method[18]. Paraoxonase activity was measured according to a method using phenylacetate as a substrate[19]. α tocopherol (vitamin E) was estimated spectrophotometrically[20]. Malondialdehyde concentration was estimated spectrophotometrically using the thiobarbituric acid assay[21]. Calcium, phosphor, vitamin B12, thyroid-stimulating hormone, glucose, insulin, liver enzymes, albumin, bilirubin, prothrombin time, and creatinine were measured by standard biochemical tests.

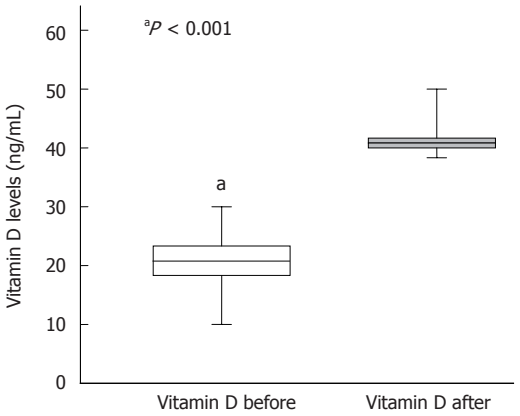

Figure 1 Vitamin D serum levels before and at 4 wk after the beginning of antiviral treatment + vitamin D supplementation (n = 36). Bars represent standard error.

Statistical analysis

Results were expressed as mean ± SD. The difference between the two groups was assessed by the chi-squared test for categorical variables and by the Mann-Whitney rank test for continuous variables. The Spearman correlation was used to express correlations between variables. The primary study endpoint was evidence of the influence of vitamin D on the viral response at weeks 4 and 12 during therapy and at week 24 post-treatment. Logistic regression analysis was performed to detect independent predictors for SVR. The significance level was set at $P < 0.05$. The statistical analyses were carried out with the WINSTAT (Kalmia, CA, United States) software program.

RESULTS

At baseline, 21% of the patients in the treatment group had severe vitamin D deficiency (< 12 ng/mL), 59% had insufficiency, and 20% had sufficient vitamin D levels. The control group baseline tests showed that 27% had vitamin D deficiency, 60% had insufficiency, and 13% had sufficient vitamin D levels. Table 1 shows the clinical and biochemical parameters of the patient populations.

The treatment group had higher BMI levels, viral loads, and fibrosis scores > F2 than the controls (27 ± 4 kg/m^2 *vs* 24 ± 3 kg/m^2, $P = 0.014$; > 800 000 IU/mL, 50% *vs* 42%, $P = 0.033$; 42% *vs* 19%, $P = 0.001$, respectively). There were no differences between the two groups in terms of age, HCV genotype, baseline HCV-RNA, ethnic background, or aminotransferases levels.

Figure 1 depicts the baseline and week 4 vitamin D levels at the beginning of antiviral therapy. Serum vitamin D levels were significantly lower at baseline (20.5 ± 9.0 ng/mL) and increased after 4 wk of vitamin D treatment to a mean level of 37 ± 10 ng/mL. Baseline

[a]P < 0.001 between HOMA-IR at baseline and HOMA-IR after 4 wk of treatment with vitamin D. HOMA-IR: Homeostasis model assessment of insulin resistance; Peg/RBV: Pegylated interferon α and ribavirin; Vit D: Vitamin D; CRP: C-reactive protein.

vitamin D levels were also lower in the control group (19 ± 6 ng/mL, Table 2).

Figures 2 and 3 show the rates of RVR, EVR, and SVR in the treatment and control groups. At week 4, 16 (44%) patients in the treatment group and 6 (17%) controls were HCV-RNA negative, and at week 12, 34 (94%) and 17 (48%), respectively, were HCV-RNA negative (P < 0.001 for each week). Twenty-four weeks after the cessation of therapy (SVR), 31 (86%) patients in the treatment group and 15 (42%) controls were HCV-RNA negative (P < 0.001). The percentage of relapses and non-responders and the biomarkers of insulin resistance, inflammation, pro-oxidant levels, antioxidant levels, and baseline vitamin D, vitamin E, and vitamin B12 serum levels are shown in Table 2 for both groups.

The rate of viral breakthrough was null. The rates of relapse and non-response were significantly lower in the treatment group compared with the control group [n = 3 (8%) *vs* n = 13 (36%), P < 0.001, and 2 (6%) *vs* 8 (22%), P < 0.01, respectively]. The HOMA-IR index decreased significantly after 4 wk of treatment with vitamin D compared with the control group (from 4.5 ± 1.4 to 2.3 ± 1.0, P < 0.01 *vs* 4.6 ± 5.7 to 5.0 ± 4.0, respectively, P < 0.1). There was no difference between groups for malondialdehyde, paraoxonase, vitamin E, vitamin B12, C-reactive protein, and triglyceride levels.

The adherence to vitamin D treatment was excellent during the entire course, and all patients in the treatment group achieved the target level. Vitamin D levels were maintained during the course of therapy with the same dosage (2000 IU/d) as in the lead-in phase. Predictive factors for SVR in patients treated with Peg/RBV combination therapy are shown in Table 3.

Viral load, advanced fibrosis, baseline vitamin D levels, changes in HOMA-IR, and vitamin D supplementation were significant univariate predictors of SVR. Viral load, vitamin D supplementation, advanced fibrosis and changes in HOMA-IR remained as independent predictors in the multivariate analysis. Thus, vitamin D supplementation emerged as being more responsible for higher SVR than the baseline vitamin D level.

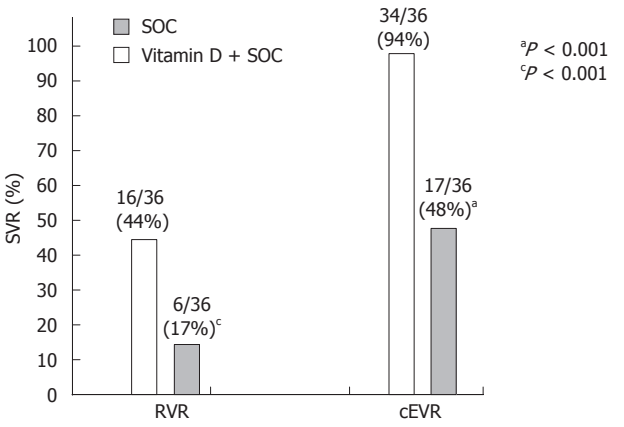

Figure 2 Rate (%) of the rapid viral response and rate of early viral response in the treatment (n = 36) and control (n = 36) groups. RVR was defined as undetectable HCV RNA at 4 wk during treatment. Complete EVR (cEVR) was defined as undetectable HCV RNA at 12 wk during treatment. SOC: Standard of care; RVR: Rapid viral response; EVR: Early viral response; HCV: Hepatitis C virus; SVR: Sustained viral response.

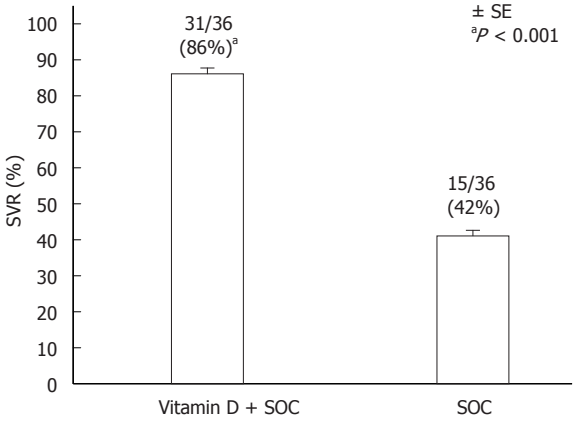

Figure 3 Rate of sustained viral response in the treatment group (Vitamin D + SOC, n = 31/36) and the control group (n = 15/36, SOC) 6 mo after cessation of treatment. SVR was defined as undetectable HCV-RNA at 24 wk post-treatment. Bars represent standard error. SOC: Standard of care; SVR: Sustained viral response; HCV: Hepatitis C virus.

The most common adverse events were mild in nature, similar in both groups, and consistent with typical Peg/RBV-induced systemic symptoms. They included nausea (n = 4), headache (n = 4), insomnia (n = 5), chills (n = 4), myalgia (n = 3), pyrexia (n = 3), pruritus (n = 2), mild neutropenia (n = 3), mild thrombocytopenia (n = 5), and mild anemia (n = 3). There were no serious adverse events. Adherence to Peg/RBV combination therapy was excellent, and there was no difference in dose reduction Peg/RBV combination therapy due to adverse events in either group. No patient discontinued treatment. Changes in laboratory values during the study were consistent with those reported in association with

Table 3 Predictors for sustained virologic response in treatment-naïve hepatitis C virus genotype 1 patients with pegylated interferon α and ribavirin combination therapy

	Odds ratio	95% CI	*P* value
Vitamin D treatment (Yes *vs* No)	2.5	2.0-4.9	< 0.001
Baseline vitamin D (< 20 or > 20 IU/mL)	1.5	1.2-3.8	0.080
Advanced fibrosis (< F2 or > F2)	2.0	1.0-3.6	0.001
High viral load (< 800 000 or > 800 000 IU/mL)	2.8	1.2-4.0	0.001
Baseline CRP (< 0.05 or > 0.5 mg/dL)	1.0	0.5-1.9	0.510
Changes in homeostasis model assessment (%)	1.8	0.5-3.0	0.030

CRP: C-reactive protein; CI: Confidence interval.

the combined use of Peg/RBV[3].

DISCUSSION

The results of this study suggest that the addition of a vitamin D supplement to current standard therapy can significantly improve the rate of RVR, EVR and SVR in treatment-naïve patients with HCV genotype 1 compared the rates with standard therapy alone. The observed SVR in the control group (42%) was consistent with previous reports[2,3]. Overall there was a marked increase in the virologic response at week 4 (44% *vs* 17%), week 12 (94% *vs* 48%), and week 24 after the cessation of therapy (86% *vs* 42%), and a low rate of relapse (8% *vs* 36%) with vitamin D supplementation compared with no supplementation. The rate of relapse in the control group was within the reported 18%-40% range for current standard HCV antiviral therapy[2,22].

There are only two reports examining the association between vitamin D status and outcome of antiviral therapy in patients with chronic HCV viral infection. Petta and co-workers retrospectively analyzed a cohort of 167 patients treated with Peg/RBV for hepatitis C, and detected an association between lower vitamin D serum levels and failure to achieve SVR[23]. Our results provide further support for that data. The second study by Bitetto and co-workers showed that vitamin D supplementation improved the response to antiviral treatment for recurrent HCV in liver transplant recipients[24]. Several differences between those two studies should be noted. Bitetto and co-workers' HCV patients were immunocompromised, and they were supplemented with low-dose vitamin D (800 IU/d) after liver transplantation. In addition, most of their HCV patients (75%) had low vitamin D levels despite treatment. Finally, that study was retrospective and focused on the prevention of osteoporosis, not on the treatment of hepatitis C.

The exact mechanism of action leading to improved RVR, EVR, and SVR in patients receiving vitamin D is unknown. Vitamin D is metabolized by the liver and converted to 1,25-dihydroxy-vitamin D3, which is the active form of the vitamin[6,7]. Individuals with chronic liver disease may have poor conversion from vitamin D3 or any of its other biologically active metabolites[11]. 1,25 vitamin D3 appears to modulate immunity principally *via* regulation of T-cell function[25]. The vitamin D receptor (VDR) is expressed on virtually every type of cell involved in immunity[26]. The immunomodulatory actions of vitamin D are elicited through its direct action on T-cell antigen-presenting cell function[27]. T helper cell type 1 (TH1) actions are intensified when vitamin D is insufficient, as in the majority of our patient population, or when signals through VDR are weak. Regulatory T cell and TH2 cells are diminished, thus favoring an autoimmune TH1 response[28]. This is a pro-inflammatory response which may impair IFN and insulin signaling, thus decreasing the viral response[29,30]. A recent study on 120 patients with chronic HCV genotype 1 infections reported that a TH1 to TH2 ratio of < 15.5 was significantly associated with SVR (odds ratio 9.6)[31]. TH1 and TH2 measurements were not performed in the present study. Persistent HCV infection modulates the balance between immune stimulatory and inhibitory cytokines which can prolong inflammation and lead to fibrosis and chronic liver diseases[32]. More recently, Gutierrez and co-workers showed that vitamin D3 increased VDR protein expression and inhibited viral replication in cell culture[33].

It is well known that people of African and Hispanic descent are less likely to respond to standard therapy[34]. This may be due to a polymorphism of the *interleukin (IL)-28B* gene, polymorphism of VDR or vitamin D deficiency[13,35]. The vast majority of the Russian/Jewish/Arab patients in the present study had vitamin D insufficiency, possibly related to paradoxically low exposure to the sun in this predominantly sunny country and/or to a low supply of vitamin D from their diet.

The impact of diet on liver fibrosis and on response to IFN therapy in patients with HCV chronic hepatitis has been reported before[36]. HCV patients also lack vitamins E and B12[37,38]. A recent study showed that higher levels of vitamin B12 were associated with SVR, but there was no difference in serum levels of those vitamins between the group treated with vitamin D and the controls[39].

Insulin resistance emerged as one of the most important host factors in the prediction of the response in non-diabetic HCV patients treated with Peg/RBV, and is a common factor in the features associated with difficult-to-treat patients[40]. Vitamin D is also known to help prevent type 2 diabetes, and it is possible that low levels of vitamin D lead to insulin resistance[9]. The direct effect of vitamin D may be mediated by binding of its circulating active form to the pancreatic B cell vitamin D receptor[41]. Vitamin D deficiency or insufficiency may alter the balance between the extracellular and intracellular cell calcium pools, which may interfere with normal insulin release[42]. Thus, a lack of either calcium or vitamin D can result in peripheral insulin resistance[41]. Moreover, oxidative stress leeches calcium, and vitamin

D helps absorb calcium[43]. Our current results confirm these findings: the HOMA-IR was higher at baseline in the vitamin D treatment group and improved after 4 wk of therapy compared to the control group. Moreover, the changes in HOMA-IR were strongly associated with SVR (multivariate analysis).

The definition of normal vitamin D serum levels is a subject of debate. In the current study, increasing the vitamin level D to > 32 ng/mL increased the response to antiviral therapy to the same extent in patients with vitamin D deficiency as well as those with vitamin D insufficiency. Multivariate analysis revealed that viral load, advanced fibrosis and vitamin D supplementation remained as independent predictors. Thus, it can be concluded that vitamin D supplementation is responsible for a higher SVR, rather than the baseline vitamin D level. It remains to be determined whether the addition of vitamin D acts by a mechanism other than improvement of insulin resistance or immune function such as the upregulation of toll-like receptors involved in the immune response in HCV-infected patients

Limitations of the present study include the small number of patients, lack of vitamin D level assessment during therapy for the treatment and control groups, and that this prospective and randomized study was not placebo-controlled, thus the patients knew whether or not they received a vitamin D supplement. Another limitation is the lack of data on the TH1 and TH2 immune response. The identification of determinants of the response, such as polymorphisms of the *IL-28B* gene, polymorphism of the VDR and immune function[13,35], may help explain the difference in response rates between patients with different ethnic backgrounds. This was not done in our study since data on IL-28B and on VDR polymorphism were not available at the time the study was designed.

In conclusion, the addition of vitamin D to Peg/RBV combination therapy in treatment-naïve patients who were infected with HCV genotype 1 significantly increased the rates of rapid, early, and sustained viral responses.

COMMENTS

Background

Treating chronic hepatitis C virus (HCV) (genotype1) patients with pegylated interferon and ribavirin, which is considered to be the standard of care, has achieved viral clearance in less than 50% of the patients. Vitamin D is a potent immunomodulator with a beneficial effect against viral and bacterial infections. The vast majority of patients with chronic hepatitis C have low levels of vitamin D. Different new drugs such as protease or polymerase inhibitors are still under investigation and are expensive and have many side effects like rash.

Research frontiers

Vitamin D deficiency is well documented in patients with chronic liver disease. However, treating patients with chronic HCV infection by adding a vitamin D supplement to the standard of care has not been addressed. There are only two reports dealing with the association between vitamin D status and outcome of antiviral therapy for chronic HCV infection.

Innovations and breakthroughs

The current study shows that adding a vitamin D supplement to pegylated interferon and ribavirin significantly increases the rapid, early and late clearance of the virus, in chronic hepatitis C genotype 1 treatment-naïve patients.

Applications

This study emphasizes the importance of vitamin D supplementation when added to standard treatment in all patients with chronic hepatitis C. Further studies are needed to explain the mechanism of vitamin D supplementation for these patients.

Terminology

Hepatitis C is a chronic liver infection that can be complicated by liver failure and liver cancer. Clearance of the virus from the blood is achievable by a combination of pegylated interferon and ribavirin in less than 50% of the patients. Vitamin D has an important role in the treatment of different bacterial and viral infections; this vitamin is synthesized in the skin by absorption of ultraviolet from the sun light. The mechanism of action of this vitamin is unknown, but it may improve the activities of immune cells that are important in the eradication of HCV.

Peer review

This is a well conducted study with a relevant finding, and it is well written.

Abstract

AIM: To evaluate the effect of posterior lingual lidocaine swab on patient tolerance to esophagogastroduodenoscopy, the ease of performance of the procedure, and to determine if such use will reduce the need for intravenous sedation.

METHODS: Eighty patients undergoing diagnostic esophagogastroduodenoscopy in a tertiary care medical center were randomized to either lidocaine swab or spray. Intravenous meperidine and midazolam were given as needed during the procedure.

RESULTS: Patients in the lidocaine swab group (SWG) tolerated the procedure better than those in the spray group (SPG) with a median tolerability score of 2 (1, 4) compared to 4 (2, 5) ($P < 0.01$). The endoscopists encountered less difficulty performing the procedures in the SWG with lower median difficulty scores of 1 (1, 5) compared to 4 (1, 5) in the SPG ($P < 0.01$). In addition, the need for intravenous sedation was also lower in the SWG compared to the SPG with fewer patients requiring intravenous sedation (13/40 patients *vs* 38/40 patients, respectively, $P < 0.01$). The patients in the SWG were more satisfied with the mode of local anesthesia they received as compared to the SPG. In addition, the endoscopists were happier with the use of lidocaine swab.

CONCLUSION: The use of a posterior lingual lidocaine swab in esophagogastroduodenoscopy improves patient comfort and tolerance and endoscopist satisfaction and decreases the need for intravenous sedation.

INTRODUCTION

Esophagogastroduodenoscopy (EGD) is an essential and very commonly used procedure for the evaluation of a

multitude of gastrointestinal (GI) symptoms including abdominal pain, hemorrhage, dysphagia, odynophagia, and reflux[1-3]. Although EGD is fairly safe, it carries a low risk of complications including perforation, bleeding, infection, and medication reactions/adverse effects[2,4,5]. Several studies showed that patients with advanced age and those with cardiopulmonary disease may carry an increased risk for the procedure especially when high doses of intravenous (IV) sedatives are used[2,6,7]. Various IV agents such as midazolam, meperidine, propofol, and fentanyl have been used over the past few decades for their anxiolytic, amnestic, and analgesic effects during the procedure[8-10]. However, these agents carry potential serious adverse effects especially in high risk patients. These complications include apnea, hypoxia, vomiting, hypotension, agitation, and allergic reactions[11-16]. In addition, complications of IV sedation contributed to cost increase due to unexpected hospitalizations and work related absenteeism on the procedure day. This has led to search for modes of anesthesia that carry less complication rates and, at the same time, provide satisfaction for both patient and endoscopist[12,15,17-24]. Few studies have used different forms of topical anesthesia including, spray, lollipop, and inhaler with mixed results. Some of these topical agents still carried a risk of retching, vomiting, and apnea[8,19,20,23,25-28]. Conventionally, topical lidocaine spray is used combined with IV analgesics and sedatives before and during the procedure to achieve a high level of patient comfort and endoscopist satisfaction[4,19,26,27,29].

The rationale behind the use of topical anesthesia is to suppress the gag reflex that may account for some of the EGD-related discomfort. The gag reflex is one of the normal reflexes induced by stimulation of the pharynx and velar area. It involves the contraction of pharyngeal constrictors induced by touching one of the five trigger zones that include: base of tongue, uvula, palate, posterior pharyngeal wall, and palatopharyngeal and palatoglossal folds[30]. The gag reflex consists of an afferent and an efferent arches. The afferent receives input from nerve fibers of the glossopharyngeal nerve which are relayed in the nucleus solitaris. The efferent arch is supplied by the nucleus ambiguus through the vagus nerve (Figure 1)[31]. These nuclei are at close proximity to the vomiting and salivating centers, which explains the experience of retching and excessive salivation when the gag reflex is elicited[30]. Both superficial and deep sensory receptors are involved in the physiology of the gag reflex, and this makes a pharyngeal plexus block superior to topical lidocaine spray in suppressing the reflex[32]. When a person eats, central voluntary action on the pharyngeal muscles dominates over the gag reflex and this is why there is no gagging when eating[30]. Therefore, if lidocaine is to be applied specifically to the above-mentioned five trigger areas in the pharynx, then the gag reflex would be markedly attenuated or even ablated during the procedure, which may further increase the patients' tolerance to EGD and in turn decrease IV sedation use. The use of lidocaine in the gel form may be ideal since a dense/sticky form of lidocaine may provide a more reliable local anesthesia compared to the spray.

In this study, the efficacy of posterior lingual lidocaine as a potential anesthetic technique in patients undergoing EGD was compared to that of the conventional lidocaine spray. Our main objective is to evaluate the effect of posterior lingual lidocaine application on patient tolerance to the procedure and the ease of performance of the procedure. Our secondary aim is to determine if such use will reduce the need for IV sedation.

MATERIALS AND METHODS

Patients

Our target population was patients undergoing diagnostic EGD for various indications at the American University of Beirut-Medical Center (AUB-MC). The study was approved by the Institutional Review Board committee at AUB-MC in accordance with Helsinki Declaration. The details regarding the study objectives and risks were fully explained to the patients and those who agreed to participate in the study were recruited and signed the informed consent.

Study design

After signing the informed consent, patients were randomly assigned to one of two study groups: the swab group (SWG) who received 150 mg of lidocaine gel or the spray group (SPG) who received 300 mg lidocaine spray. Lidocaine spray was administered using the same technique in 3 consecutive 30-s intervals, each consisting of 10 sprays (10 mg/dose) of Xylocaine® Pump Spray 10% (AstraZeneca AB, Sodertalje, Sweden). In the swab group, Xylocaine® Jelly 2% (AstraZeneca AB, Sodertalje, Sweden), with a lidocaine concentration of 20 mg/mL was used. A total of 7.5 mL (150 mg) of lidocaine gel was gradually applied to the base of the tongue and the peritonsillar areas. The endoscopist was totally blinded to the randomization. The endoscope used in the procedures was GIF-1T 240 (Olympus Optical, 11 mm diameter, Tokyo, Japan). All the patients had IV lines inserted and their vital signs (blood pressure, heart rate, respiratory rate) and pulse oxymetry were continuously monitored during the procedure. The data that was collected by the research fellow from all enrolled patients before the procedure included the following parameters: age, gender, past medical history, past surgical history, medications, allergies, alcohol use, smoking, illicit drug use, and history of previous endoscopy (including tolerance to it). None of the participants had any severe pulmonary disease (asthma and chronic obstructive pulmonary disease). The research fellow then determined the patients' anxiety level according to a scale from 1 to 5 (1 = no anxiety to 5 = extreme anxiety). After the topical anesthetics were applied, the time for the onset of the topical anesthesia was also noted (from the time the local anesthetic was applied till patients reported numb-

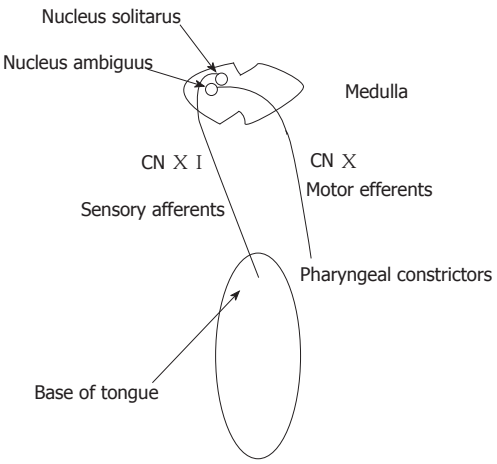

Figure 1 The gag reflex pathway: afferent fibers from the trigger areas in the pharynx and tongue carried by the glossopharyngeal nerve (cranial nerve X I) to the nucleus solitarus which sends the input to the nucleus ambiguus in the medulla oblongata. Efferent fibers from the nucleus ambiguus carried *via* the vagus nerve (CN X) to the pharyngeal constrictors to contract and cause gagging. CN: Cranial nerve.

ness in the oral cavity and the inability to swallow).

In both study groups, the decision to administer IV sedation during the procedure was made by the endoscopist depending on the patient's tolerance and the presence or absence of signs of discomfort, like excessive gag, retching, or restlessness. Sedatives used were midazolam and meperidine. The duration of the procedure was also noted.

Endoscopist's assessments

After the administration of the local anesthetics, the endoscopist rated the gag reflex based on a scale from 1 to 5 (1 = absent to 5 = strong). After the procedure, the endoscopist determined the ease of the procedure based on a scale from 1 to 5 (1 = easy to 5 = difficult). Finally, the amount of IV sedation given was recorded.

Patients' assessments

After the procedure was concluded, patients were monitored in the recovery room. Afterwards, a questionnaire was filled in by the participants to determine tolerance to the procedure based on a scale from 1 to 5 (1 = no difficulties encountered to 5 = very difficult). Also, symptoms during (retching, nausea, vomiting, abdominal pain, dyspnea, cough) and after (sore throat, nausea, vomiting, abdominal pain, dyspnea, cough) the procedure were recorded. Patients were also asked to specify the most uncomfortable phase of the procedure and their willingness to repeat the procedure using the same local anesthetic.

Statistical analysis

Statistical analysis was performed using SPSS for Windows version 16.0 (SPSS, Inc., Chicago, IL). The nonparametric Mann-Whitney test was used to compare ordinal variables (such as the gag reflex, procedure evaluation, *etc*.) and data that are not normally distributed (the doses of meperidine and midazolam) between SWG and SPG groups.

The χ^2 test was utilized to compare categorical variables between the 2 groups. Continuous variables were assessed with an independent sample *t* test. A P value < 0.05 was considered to be significant.

Table 1 Patient characteristics

	SWG (n = 40)	SPG (n = 40)	P value
Gender (M/F)	12/28	19/21	0.11
Mean age, yr (SD)	55.8 (18.1)	48.5 (18.2)	0.07
Smoking (yes/no)	15/25	23/17	0.07
Caffeine (yes/no)	37/3	32/8	0.19
Alcohol (yes/no)	12/28	14/26	0.63
Previous EGD (yes/no)	17/23	23/17	0.18

SWG: Swab group; SPG: Spray group; M: Male; F: Female; EGD: Esophagogastroduodenoscopy. P value for difference between groups using χ^2 or Fisher's exact tests.

Table 2 Pre-procedure evaluation, median (min, max)

	SWG (n = 40)	SPG (n = 40)	P value[1]
Anxiety	3 (1, 5)	3 (1, 5)	0.67
Time to onset of anesthesia (s)	80 (30, 300)	50 (20, 120)	< 0.01
Gag reflex	2 (1, 5)	4 (2, 5)	< 0.01

SWG: Swab group; SPG: Spray group. Anxiety rate: 1 = no anxiety to 5 = extreme anxiety; Gag reflex scale: 1 = absent to 5 = strong. [1]P value for difference between groups using nonparametric Mann-Whitney test.

RESULTS

Patient characteristics and demographics

Our study included 80 consecutive patients who underwent an elective EGD at AUB-MC. There were 31 males (38.8%) and 49 females (61.2%) with a mean age of 52.2 ± 18.4 years. There was no statistically significant difference in the patients' characteristics in both groups (Table 1).

Pre-procedure evaluation

Anxiety before the procedure was rated on an ascending scale from 1 to 5 as detailed in the method section. There was no significant difference between the two groups; the median anxiety scores were 3 (1, 5) for subjects in SWG and SPG.

The time interval between the lidocaine administration and the onset of anesthesia was significantly longer in the SWG as compared to the SPG, with median time 80 (30, 300) and 50 (20, 120) s (P < 0.01, respectively).

The SPG had significantly stronger gag reflex than the SWG with respective median scores of 4 (1, 5) and 2 (1, 5) (P < 0.01, Table 2).

IV sedation use

IV sedation was administered more frequently in the SPG than the SWG (95% *vs* 32%, P < 0.01).

Table 3 Use of intravenous sedation, median (min, max)

	SWG (n = 40)	SPG (n = 40)	P value
Use of IV sedation (yes/no)	13/27	38/2	< 0.01
Meperidine dose (mg)	0 (0, 50)	25 (0, 75)	< 0.01[1]
Midazolam dose (mg)	0 (0, 3)	2 (0, 4)	< 0.01[1]

SWG: Swab group; SPG: Spray group; IV: Intravenous. [1]P value for difference between groups using Mann-Whitney test.

Table 4 Procedure evaluation, median (min, max)

	SWG (n = 40)	SPG (n = 40)	P value
Ease of procedure - endoscopist	1 (1, 5)	4 (1, 5)	< 0.01
Procedure tolerance - patient	2 (1, 4)	4 (2, 5)	< 0.01[1]
Patient willingness to repeat procedure (yes/no)	32/8	2/38	< 0.01[1]

SWG: Swab group; SPG: Spray group. Endoscopist difficulty scale: 1= easy to 5 =difficult; Patient tolerance scale: 1 = no difficulties encountered to 5 = very difficult. [1]P value for difference between groups using nonparametric Mann-Whitney test.

The amount of meperidine administered was significantly lower in the SWG compared to the SPG, with median doses of 0 (0, 50) and 25 (0, 75) mg, respectively, $P < 0.01$. Similarly, the dose of midazolam was significantly lower in the SWG as compared to the SPG with median doses of 0 (0, 3) and 2 (0, 4) mg ($P < 0.01$, respectively, Table 3).

Endoscopists' evaluation

The endoscopist's assessment of the degree of procedure difficulty showed that the procedures were significantly easier to perform in the SWG than the SPG, with median difficulty scores of 1 (1, 5) and 4 (1, 5) ($P < 0.01$, respectively, Table 4).

Additionally, the procedure was significantly much easier to perform in subjects who did not receive IV sedation compared to those who received either meperidine or midazolam, with median difficulty scores of 1 (1, 3) and 4 (1, 5) ($P < 0.01$), respectively.

Patients' evaluation

Patients in the SWG tolerated the procedure more with a median tolerability score of 2 (1, 4) as compared to 4 (2, 5) in the SPG ($P < 0.01$, Table 4).

The most difficult part of the procedure was the introduction of the endoscope as reported by 68.8 % of patients. Thirty two (80%) subjects in the SWG expressed their willingness to repeat the procedure under the same local anesthesia, versus only 2 (5%) patients in the SPG ($P < 0.01$, Table 4).

Side effects

The side effects during and after the procedure were similar in both groups except for retching which was significantly lower in the SWG than in the SPG (13/40 *vs* 31/40 patients, respectively, $P < 0.01$, Table 5).

Table 5 Procedure-related symptoms

	SWG (n = 40)	SPG (n = 40)	P value
During the procedure			
Retching (yes/no)	13/27	31/9	< 0.01
Cough (yes/no)	10/30	12/28	0.62
Abdominal pain (yes/no)	1/39	1/39	1
Dyspnea (yes/no)	0/40	4/36	0.12
After the procedure			
Sore throat (yes/no)	5/35	8/32	0.55
Abdominal pain (yes/no)	1/39	5/35	0.2
Nausea/vomiting (yes/no)	0/40	1/39	1

SWG: Swab group; SPG: Spray group. P value for difference between groups using χ^2 or Fisher's exact tests.

Complications

None of the procedures was aborted due to complications, excessive agitation or major patient discomfort.

DISCUSSION

The use of conscious sedation along with lidocaine spray is the standard of care in upper GI endoscopy[4,19,26,27,29]. However, IV sedation may cause potential harm to the patients especially the elderly with co-morbidities. These side effects include hypotension, respiratory depression, and paradoxical agitation[7,11-16]. The potential risks of upper GI endoscopy are mostly related to the use of IV sedation[1,2,11,16,27,33-35]. Studies done by Campo *et al*[6] and Mulcahy *et al*[7] showed that a high level of anxiety, young age, and a strong gag reflex are risk factors for poor tolerance to upper GI endoscopy. On the other hand, a study done by Pereira *et al*[27] showed that patients' anxiety did not contribute to procedure tolerance. Local oropharyngeal anesthesia including lidocaine has been studied in several trials with the results showing that the use of the lidocaine spray or gel with IV sedation increased the tolerability and ease of the procedure and reduced the risk of discomfort during the procedure[23,26,28,29,36]. A single study, however, was done on the lidocaine lollipop which showed excellent efficacy in achieving patient comfort even without the use of IV sedation[28]. The action of local oropharyngeal anesthesia is achieved mainly by inhibiting the gag reflex which is one of the most important factors affecting the tolerability and ease of the procedure[6,28]. So in order to perform the procedure without possibly using IV sedation, an effective local agent that suppresses the gag reflex should be used.

Our study showed that when lidocaine gel is applied to the posterior lingual area, it effectively suppresses the gag reflex, significantly increases the patient tolerability to the procedure, improves endoscopist satisfaction of the procedure, and considerably decreases the need for IV sedation. The level of anxiety and age were similar in both groups; thus, these factors can be eliminated as confounding variables. Therefore, lidocaine gel could be

used as a sole agent in upper GI endoscopy sparing the use of IV sedation with its potential complications. In addition, this may help patients resume their daily activities immediately after the procedure. Although we did not compare the cost of the lidocaine gel and spray, the use of the gel appears to be more cost-effective since potential adverse events related to IV sedation are reduced. The maximal dose of lidocaine used in the spray group was 300 mg. This dose of lidocaine is within the recommended dose of 5 mg/kg and does not exceed the potentially toxic dose of 500 mg[37]. Moreover, higher doses of topical lidocaine had been used in prior studies. Sutherland *et al*[38], for instance, utilized topical doses of 380 mg of lidocaine and concluded that the blood levels were still within therapeutic range. The dose of lidocaine used in the gel group was much lower (150 mg) than that in the spray group. Despite that decrease in the dose, there was more effective suppression of the gag reflex in the gel group, and hence, better tolerance to the EGD.

Sample size was one of the few limitations in this study. Because it was a small sample, subgroup analysis could not be performed. Another limitation that might have affected our results can be attributed to the impairment in judgmental abilities caused by the sedatives used in some cases.

In conclusion, this study presented evidence that the use of lidocaine swab applied to the posterior lingual area was an effective mode of local anesthesia in upper GI endoscopy. This can lead to reduction in the use of IV sedatives (and potentially their complications) and may decrease the overall cost of the procedure. This may be a very promising modality especially in the elderly patients who have comorbidities, and in office-based upper GI endoscopy. However, larger, multicenter studies should be done to confirm and validate the results of our study.

The data of this study has been presented as a poster at the Digestive Disease Week in New Orleans, 2010.

COMMENTS

Background

Esophagogastroduodenoscopy (EGD) has become an essential and very commonly used procedure for the diagnostic and therapeutic evaluation of a multitude of upper gastrointestinal (GI) symptoms and diseases. EGD is considered a safe procedure with a very low risk of complications. Medication administered for local anesthesia and for conscious sedation during the procedure can pose some adverse effects especially in the elderly population. So finding ways to decrease the need for these drugs would decrease the complication rates. The rationale behind the use of topical anesthesia is to decrease the gag reflex that may account for a major part of EGD-related discomfort. Using lidocaine as a topical anesthetic in the gel form may be ideal since a dense/sticky form of lidocaine may provide a more reliable local anesthesia compared to the spray thus increasing the patients' tolerance to EGD and in turn decreasing the need for intravenous (IV) sedation.

Research frontiers

Improving the tolerance and ease of execution of EGD procedures has gained much interest recently. The primary objective of this clinical research approach is to decrease the need for drugs used for conscious sedation to spare patients the side effects and the costs of elevated doses of such agents. Research is currently focusing on increasing the effectiveness of drug administration, improving patients' tolerance, and using/developing ultrathin endoscopes.

Innovations and breakthroughs

This study showed that when lidocaine gel is applied to the posterior lingual area, it effectively suppresses the gag reflex, significantly increases the patient tolerability to the procedure, improves endoscopist satisfaction of the procedure, and considerably decreases the need for IV sedation.

Applications

The authors presented evidence that the use of lidocaine swab applied to the posterior lingual area was an effective mode of local anesthesia in upper GI endoscopy. This can lead to reduction in the use of IV sedatives (and potentially their complications) and may decrease the overall cost of the procedure. This may be a very promising modality especially in the elderly patients with comorbidities, and in office-based upper GI endoscopy.

Terminology

Conscious sedation: Defined as moderate sedation by the American Society of Anesthesiologists. It is the reduction of irritability or agitation by administration of sedative drugs such as midazolam with purposeful preservation of the response to verbal or tactile stimulation. Posterior lingual lidocaine swab: A technique whereby local anesthesia is achieved by the application of lidocaine gel to the base of the tongue and the peritonsillar areas as opposed to application *via* the aerosolized spray form routinely utilized.

Peer review

This article showed that the effectiveness of the posterior lingual lidocaine swab is statistically significant. The study design and analysis ensures the validity of achieved results and nearly eliminated causes of random error. Nonetheless, increasing the patients' number and possibly involving other centers in this study would undeniably increase its power and reliability.

Abstract

AIM: To investigate whether the use of statins is associated with colorectal cancer risk.

METHODS: We conducted a population-based case-control study in Taiwan. Data were retrospectively collected from the Taiwan National Health Insurance Research Database. Cases consisted of all patients who were aged 50 years and older and had a first-time diagnosis of colorectal cancer between the period 2005 and 2008. The controls were matched to cases by age, sex, and index date. Adjusted odds ratios (ORs) and 95% confidence intervals (CIs) were estimated using multiple logistic regression.

RESULTS: We examined 1156 colorectal cancer cases and 4624 controls. The unadjusted ORs for any statin prescription was 1.10 (95% CI = 0.94-1.30) and the adjusted OR was 1.09 (95% CI = 0.91-1.30). When statin use was categorized by cumulative dose, the adjusted ORs were 0.99 (95% CI = 0.78-1.27) for the group with cumulative statin use below 105 defined daily doses (DDDs); 1.07 (95% CI = 0.78-1.49) for the group with cumulative statin use between 106 and 298.66 DDDs; and 1.30 (95% CI = 0.96-1.75) for the group with cumulative statin use of 298.66 DDDs or more compared with nonusers.

CONCLUSION: This study does not provide support for a protective effect of statins against colorectal cancer.

INTRODUCTION

Statins are inhibitors of 3-hydroxy-3-methyl glutaryl coenzyme A reductase which is a key enzyme in the rate-limiting step in cholesterol synthesis[1]. Statins are commonly used as cholesterol-lowering medications and have shown effectiveness in the primary and secondary prevention of heart attack and stroke[2,3]. The extensive evidence in this field has led to widespread use of these drugs.

Rodent studies indicate that statins are carcinogenic[4]. In contrast, several recent studies on human cancer cell lines and animal tumor models indicate that statins may have chemopreventive properties through the arrest of cell cycle progression[5], induction of apoptosis[1,6], suppression of angiogenesis[7,8], and inhibition of tumor growth and metastasis[9]. Results of a meta-analysis and observational studies revealed either no association[10-17] or a decrease in cancer incidence[18-26]. The reasons for the varying results are unclear but may be related to methodological issues, including small sample size and short follow-up periods[27].

Several epidemiologic studies have investigated the association between statin use and risk of colorectal cancer and the results have been inconsistent. Ten studies reported no statistically significant association between statin use and colorectal cancer risk[10,12,15,17,20-21,27-30]. However, three recent case-control studies reported that statin use is associated with a significant reduction in the risk of colorectal cancer[22,31-32].

Since large numbers of people utilize statins on a long-term basis, and because epidemiologic data linking statin use and risk of colorectal cancer are conflicting, we undertook the present study in Taiwan to evaluate the association between statin use and colorectal cancer risk.

MATERIALS AND METHODS

Data source

The National Health Insurance (NHI) program, which provides compulsory universal health insurance, was implemented in Taiwan on March 1, 1995. Under the NHI, 98% of the island's population can receive all forms of health care services including outpatient services, inpatient care, Chinese medicine, dental care, childbirth, physical therapy, preventive health care, home care, and rehabilitation for chronic mental illness. In cooperation with the Bureau of NHI, the National Health Research Institute (NHRI) of Taiwan randomly sampled a representative database of 1 000 000 subjects from the entire NHI enrollees by means of a systematic sampling method for research purposes. There were no statistically significant differences in age, gender, and healthcare costs between the sample group and all enrollees, as reported by the NHRI. This dataset (from January 1996 to December 2008) includes all claim data for these 1 000 000 subjects, and offers a good opportunity to explore the relation between the use of statins and risk of colorectal cancer. These databases have previously been used for epidemiological research, and information on prescription use, diagnoses, and hospitalizations has been shown to be of high quality[33-35].

Because the identification numbers of all individuals in the NHRI databases were encrypted to protect the privacy of the individuals, this study was exempt from full review by the Institution Review Board.

Identification of cases and controls

Cases consisted of all patients who were aged 50 years and older and had a first-time diagnosis of colorectal cancer (International Classification of Diseases, 9th revision, Clinical Modification Code 153-154) over a 4-year period, from January 1, 2005 to December 31, 2008, and who had no previous diagnosis of cancer.

Controls comprised patients who were admitted to hospital for diagnoses that were unrelated to statin use including orthopedic conditions, trauma (excluding wrist and hip fractures), and other conditions (acute infection, hernia, kidney stones, cholecystitis)[12,36]. Wrist and hip fractures were excluded because previous studies have reported a reduced risk of osteoporosis among statin users[37-40]. We identified four control patients per case patient. Control patients were matched to the cases by sex, year of birth, and index date and were without a previous cancer diagnosis. For controls, the index date (date of hospital admission) was within the same month of the index date (date of first-time diagnosis of colorectal cancer) of their matched case.

Exposure to statins

Information on all statin prescriptions was extracted from the NHRI prescription database. We collected the date of prescription, the daily dose, the number of days supplied. The defined daily doses (DDDs) recommended by the WHO[41] were used to quantify use of statins. Cumulative DDDs were estimated as the sum of dispensed DDD of any statins (lovastatin, pravastatin, rosuvastatin, fluvastatin, simvastatin, or atorvastatin) from January 1, 1996 to the index date.

Potential confounders

For all individuals in the study population, we identified variables which might confound the associations between statin use and colorectal cancer, including diabetes mellitus, cholecystectomy, liver disease, colorectal polyps, and inflammatory bowel disease, recorded between January 1, 1996, and the index date. In addition, we also obtained

Table 1 Demographic characteristics of colorectal cancer cases and controls

Variable	Cases (n = 1156)	Controls (n = 4624)	Odds ratio (95% CI)
Age, yr (mean ± SD)	68.34 ± 10.40	69.29 ± 10.40	-
Female (%)	447 (38.67)	1788 (38.67)	-
No. of hospitalizations	0.29 ± 0.93	0.26 ± 0.74	P = 0.23
Diabetes (%)	422 (36.51)	1560 (33.74)	1.13 (0.99-1.29)
Cholecystectomy (%)	21 (1.82)	105 (2.27)	0.80 (0.50-1.28)
Liver disease (%)	422 (36.51)	1861 (40.25)	0.85 (0.75-0.98)
Colorectal polyps (%)	56 (4.84)	76 (1.64)	3.05 (2.14-4.33)
Inflammatory bowel disease (%)	82 (7.09)	315 (6.81)	1.04 (0.81-1.34)
Colonoscopy (%)	153 (13.24)	42 (0.91)	16.64 (11.75-23.57)
FOBT (%)	152 (13.15)	216 (4.67)	3.09 (2.48-3.84)
NSAID (%)	636 (55.02)	2767 (59.84)	0.82 (0.72-0.93)
Use of other lipid-lowering drugs (%)	31 (2.68)	180 (3.89)	0.68 (0.46-1.00)

FOBT: Fecal occult blood testing; NSAID: Non-steroidal anti-inflammatory drug; CI: Confidence interval.

prescription data for other lipid-lowering drugs (including fibrate, niacin, bile-acid binding resins, and miscellaneous medications) and non-steroidal anti-inflammatory drugs (NSAIDs) that could potentially confound the association between statin use and the risk of colorectal cancer. We defined users of the above-mentioned medications as patients with at least one prescription over one year prior to the index date. Furthermore, colonoscopy, fecal occult blood testing (FOBT), and number of hospitalizations one year before the index date were treated as confounders.

Statistical analysis

For comparisons of proportions, chi-square statistics were used. A conditional logistic regression model was used to estimate the relative magnitude in relation to the use of statins. Exposure was defined as patients who received at least one prescription for a statin at any time between January 1, 1996 and the index date. In the analysis, the subjects were categorized into one of four statin exposure categories: nonusers (subjects with no prescription for any statins at any time between January 1, 1996 and the index date), low (the lowest 50th percentile; ≤ 105 DDDs); medium (50th-75th percentile; 106-298.66 DDDs); and high (above the 75th percentile; > 298.66 DDDs) based on the distribution of use among controls. Odd ratios (ORs) and their 95% confidence intervals (CIs) were calculated using patients with no exposure as the reference. Analyses were performed using the SAS statistical package (version 8.02, SAS Institute Inc). All statistical tests were two-sided. Values of $P < 0.05$ were considered statistically significant.

RESULTS

Records from 1156 colorectal cancer cases and 4624 selected matched controls were included in the analyses.

Table 2 Associations between statin use and colorectal cancer risk in a population-based case-control study, Taiwan, 2005-2008

	Cases (n)/ controls (n)	Crude OR (95% CI)	Adjusted OR (95% CI)[1]
Overall			
No statin use	914/3727	1.00	1.00
Any statin use	242/897	1.10 (0.94-1.30)	1.09 (0.91-1.30)
Cumulative use			
0	914/3727	1.00	1.00
1-105 DDD	112/451	1.02 (0.82-1.27)	0.99 (0.78-1.27)
106-298.66 DDD	60/221	1.11 (0.83-1.49)	1.07 (0.78-1.49)
> 298.66 DDD	70/225	1.27 (0.96-1.68)	1.30 (0.96-1.75)

OR: Odds ratio; CI: Confidence interval; DDD: Defined daily dose. [1]Adjusted for matching variable, diabetes, number of hospitalizations, cholecystectomy, liver disease, colorectal polyps, inflammatory bowel disease, colonoscopy, fecal occult blood testing, non-steroidal anti-inflammatory drugs and use of other lipid-lowering drugs.

Table 1 shows the distribution of demographic characteristics and selected medical conditions of the cancer cases and controls. The mean age was 68.34 years for cancer cases and 68.81 years for the controls. Case subjects were more likely to have had preventive services (screening colonoscopy and FOBT). The case group had a significantly higher rate of colorectal polyps than control patients. Use of other lipid-lowering drugs and NSAIDs were not significantly different between cases and controls.

The observed associations between the use of statins and colorectal cancer are shown in Table 2. Ever-use of any statins was associated with a slight but not statistically significant increased colorectal cancer risk (adjusted OR = 1.09, 95% CI = 0.91-1.30). When statin use was categorized by cumulative dose, the adjusted ORs were 0.99 (95% CI = 0.78-1.27) for the group with cumulative statin use below 105 DDDs; 1.07 (95% CI = 0.78-1.49) for the group with cumulative statin use between 106 and 298.66 DDDs; and 1.30 (95% CI = 0.96-1.75) for the group with cumulative statin use of 298.66 DDDs or more compared with nonusers. Overall, we found no association between cumulative statin use and colorectal cancer risk. ORs for cancers of the colon and rectum considered separately were similar (data not shown).

DISCUSSION

In this population-based case-control study, we found that statin drug use was not associated with colorectal cancer risk. Our findings are consistent with ten recent studies which reported no associations between statin use and overall colorectal cancer risk[10,12,15,17,20-21,27-30].

Our results, however, conflict with three recent case-control studies. In a case-control study conducted in Israel, a reduced risk of colorectal cancer was found to be associated with the use of statins for at least 5 years, compared with less than 5 years of use (OR = 0.50, 95% CI = 0.40-0.63)[22]. Another population-based study from Germany showed that statin use was associated

with a 35% (OR = 0.65, 95% CI = 0.43-0.99) colorectal risk reduction occurring within 1-4 years of statin use and no further risk reduction was seen after 5 years or more[31]. Neither study characterized the dose or duration of statins in detail and both studies defined statin use by recall. In a nested case-control study consisting solely of veterans with diabetes, using national databases of the Department of US Veterans Affairs and Medicare-linked files, Hachem *et al*[32] reported an odds ratio 0.91 (95% CI = 0.86-0.96) for colorectal cancer in relation to any statin use. However, there is no clear dose-response or duration-response relationship between filled statin prescriptions and colorectal cancer risk.

Duration of statin use may be important when investigating the chemopreventive effects of statins. We assessed exposure to statins measured as cumulative DDDs. Cumulative DDDs is a time-independent variable in which the daily supplies of each statin prescription dispensed were summed over time from January 1, 1996 to the index date. Because cumulative DDDs and statin duration are highly interrelated, it was not possible to model them together. Similar findings were noted when statin users were stratified by duration (data not shown).

There are at least two differences between our study and the study of Hachem *et al*[32]. First, their study population was limited to mostly male veterans with active access to health care and thus they were more likely to be prescribed a statin than the general population. Statin use was present in 51% of the study population. In our study this number was 19.4%. Second, the above-mentioned study was conducted among patients with diabetes who are known to have a higher likelihood of developing colorectal cancer[42]. Therefore, it is possible that it was easier to show benefit owing to the generally elevated risk in patients with diabetes[32]. Using an epidemiologic study which is restricted to patients with major risk factors means that the results of the restricted study may not necessarily apply to the portion of the population that was excluded. Whether a protective effect only occurs among patients who are already at higher risk of colorectal cancer requires further study. Other studies have reported a possible protective effect of statins in patients with diabetes on lung (adjusted OR = 0.43, 95% CI = 0.38-0.49)[24], pancreatic (adjusted OR = 0.32, 95% CI = 0.23-0.44)[25], and liver cancer (adjusted OR = 0.74, 95% CI = 0.64-0.87)[26].

One of the strengths of our study is the use of a computerized database, which is population-based and is highly representative. Because we included all patients newly diagnosed with colorectal cancer from 2005 to 2008, and because the control subjects in this study were selected from a simple random sampling of the insured general population, we can rule out the possibility of selection bias. Statins were available only on prescription. Because the data on statin use were obtained from an historical database which collects all prescription information before the date of colorectal cancer, recall bias for statin use was thus avoided.

Several limitations of the present study should be noted. First, although we adjusted for several potential confounders in the statistical analysis, a number of possible confounding variables, including family history of colorectal cancer, dietary habits or physical activity, and alcohol and tobacco use, which are associated with colorectal cancer were not included in our database. Second, we were unable to contact the patients directly about their use of statins because of anonymization of their identification number. Using pharmacy records representing dispensing data rather than usage data might have introduced an overestimation of statin use. However, there is no reason to assume that this would be different for cases and controls. Even if the patients did not take all of the statins prescribed, our findings would underestimate the effect of statin use. Third, lovastain and pravastatin (available in 1990), simvastatin (available in 1992), and fluvastatin (available in April, 1996) became available prior to patient enrollment in the database. Prescriptions for these drugs prior to 1996 would not be captured in our analysis. This could have underestimated the cumulative DDDs and may weaken the observed association. In addition, some exposure misclassification was likely caused by the fact that information on prescription was available only from 1996. Such misclassification, however, was likely to be non-differential, which would tend to underestimate rather than overestimate the association. Fourth, we were unable to analyze the risks for users of distinct statins separately due to the relatively small number of cases and the relatively small number of statin users. Fifth, data on the accuracy of discharge diagnoses are not available in Taiwan. Potential inaccurate data in the claims records could lead to possible misclassification. However, there is no reason to assume that this would be different for cases and controls. Lastly, as with any observational study, residual confounding by unmeasured factors which are different between cases and controls is also possible. However, the confounding effect of medical attention could be corrected for by introducing the number of hospitalizations into the conditional logistic regression model.

In summary, the results of this study do not provide support for an association between statin use and colorectal cancer risk. Given the widespread use of statins, it is prudent public health policy to continue monitoring cancer incidence among statin users, particularly as the duration of use is increasing[12].

ACKNOWLEDGMENTS

This study is based, in part, on data from the National Health Insurance Research Database provided by the Bureau of National Health Insurance, Department of Health and managed by National Health Research Institutes. The interpretation and conclusions contained herein do not represent those of the Bureau of National Health Insurance, Department of Health or National Health Research Institutes.

COMMENTS

Background

Experimental studies have shown that statins have potential protective effects against cancer. Several epidemiologic studies have investigated the association between statin use and risk of colorectal cancer, and the results are inconsistent.

Research frontiers

This study was undertaken to examine the relationship between statin use and the risk of colorectal cancer.

Applications

Statins are widely used cholesterol-lowering drugs, and the duration of use is increasing. Further and larger studies are needed to determine the long-term effects of statin use on cancer development and to clarify whether statins are truly effective for cancer chemoprevention.

Peer review

This is a nice population-based study which strength is the fact that Taiwan National Health Insurance research program provides extensive data of one million patients. The methodology and statistical analysis is adequate and altogether the authors provide convincing evidence that statin use does not protect against the risk of colorectal cancer.

Abstract

AIM: To investigate the anti-fibrosis effect of IκB kinase-beta inhibitor (IKK2 inhibitor IMD0354) in liver fibrosis.

METHODS: Twenty male C57BL6 mice were divided into four groups. Five high-fat fed mice were injected with lipopolysaccharide (LPS, 10 mg/kg) intraperitoneally and five high-fat fed mice were without LPS injection to build models of liver injury, and the intervention group (five mice) was injected intraperitoneally with IKK2 inhibitor (IMD 30 mg/kg for 14 d), while the remaining five mice received a normal diet as controls. Hepatic function, pathological evaluation and liver interleukin-6 (IL-6) expression were examined. Western blotting and real-time polymerase chain reaction were used to detect the expressions of nuclear factor-κB (NF-κB), alpha-smooth muscle actin (α-SMA), tumor growth factor-beta1 (TGF-β1), tumor necrosis factor-alpha (TNF-α), type Ⅰ and type Ⅲ collagen proteins and mRNA.

RESULTS: A mouse model of liver injury was successfully established, and IMD decreased nuclear translocation of NF-κB p65 in liver cells. In the IMD-treated group, the levels of alanine aminotransferase (103 ± 9.77 μ/L *vs* 62.4 ± 7.90 μ/L, $P < 0.05$) and aminotransferase (295.8 ± 38.56 μ/L *vs* 212 ± 25.10 μ/L, $P < 0.05$) were significantly decreased when compared with the model groups. The histological changes were significantly ameliorated. After treatment, the expressions of IL-6 (681 ± 45.96 *vs* 77 ± 7.79, $P < 0.05$), TGF-β1 (Western blotting 5.65% ± 0.017% *vs* 2.73% ± 0.005%, $P < 0.05$), TNF-α (11.58% ± 0.0063% *vs* 8.86% ± 0.0050%, $P < 0.05$), type Ⅰ collagen (4.49% ± 0.014% *vs* 1.90% ± 0.0006%, $P < 0.05$) and type Ⅲ collagen (3.46% ± 0.008% *vs* 2.29% ± 0.0035%, $P < 0.05$) as well as α-SMA (6.19 ± 0.0036 μ/L *vs* 2.16 ± 0.0023 μ/L, $P < 0.05$) protein and mRNA were downregulated in the IMD group compared to the fibrosis control groups ($P < 0.05$).

CONCLUSION: IKK2 inhibitor IMD markedly improved non-alcoholic fatty liver disease in mice by lowering NF-κB activation, which could become a remedial target for liver fibrosis.

Key words: Liver fibrosis; IKK2 inhibitor; Nuclear factor-kappa B; Tumor growth factor-beta1; Interleukin-6; Alpha-smooth muscle actin; C57BL mouse

INTRODUCTION

The incidence rate of non-alcoholic fatty liver disease (NAFLD) has increased annually. Simple steatosis in the

early stage may gradually develop into fatty hepatitis[1,2], and subsequently develop towards hepatic fibrosis and liver cirrhosis[3]. In an advanced stage, the incidence rate of liver cancer, multiple organ failure and other fatal complications reaches up to 0.6%-3%[4]. Based on the World Health Organization prognostication, chronic liver disease is the ninth leading cause of death in western countries and this situation will not be improved in the coming decades[5]. Among patients with non-alcoholic steatohepatitis (NASH), there were 10%-25% of patients that developed hepatic fibrosis or even liver cirrhosis[6-9]. The nosogenesis of NASH remains unclear, but the hypothesis of "secondary strike" has been widely accepted[10,11]. Unfortunately, some treatments initially gradually improve liver adipose degeneration, but are unable to achieve long-term control[9,12].

IκB kinase (IKK) is a large protein complex that is 700-900 kDa, including the two kinase subunits IKKα (IKK1) and IKKβ (IKK2) and one regulatory subunit that is either nuclear factor-kappa B (NF-κB) essential modifier or IKKγ. IKK2 is part of the inhibitor of the κB (IκB) IKK complex, which activates NF-κB through phosphorylation of the IκBs, leading to a series of inflammatory reactions[13-16]. Many effective drugs can reduce the inflammatory reaction in the liver by inhibiting the nuclear factor IKK2-NF-κB pathway and reducing insulin resistance in the liver[17]. Mathers *et al*[5] have demonstrated that application of the IKK2 inhibitor reduces fat accumulation in the liver and body weight gain in the mice. It has been reported that antioxidants inhibit the activity of NF-κB and can reduce inflammatory reactions[18] or even change fibrotic tissue[19].

We speculated that specific inhibition of NF-κB activation by an IKK2 inhibitor could effectively suppress the expression of inflammatory factors and even improve hepatic fibrosis. Therefore, in our study, a NASH model was established by a high-fat diet in mice and intraperitoneal injection of lipopolysaccharides (LPS) promoted acute hepatic injury and the expression of inflammatory factors. An IKK2 inhibitor (IMD0354) was used to suppress the NF-κB signaling pathway. Liver function and histological changes were observed and expression levels of interleukin-6 (IL-6), tumor growth factor-beta1 (TGF-β1), tumor necrosis factor-alpha (TNF-α), as well as other pro-inflammatory and pro-fibrosis factors, were determined. We focused on measurement of the fibrosis index, which represented hepatic stellate cells (HSCs), alpha-smooth muscle actin (α-SMA) and the expression levels of collagen I , collagen Ⅲ and mRNA, which showed fibrotic hepatic changes. Accordingly, we investigated potential therapeutic prospects of the IKK2-NF-κB signaling pathway for reversing fibrosis in NAFLD.

MATERIALS AND METHODS

Experimental protocol and animal model

Twenty-four-week-old male C57BL6 mice, weighing approximately 12-16 g, were purchased from the Shanghai Experimental Animal Center of the Chinese Academy of Science. Mice were housed in a clean grade barrier systems laboratory in the Medical Laboratory Animal Center of Shanghai Jiao Tong University. Animals were randomized into four groups: the control group (n = 5), high-fat (HF) diet group (n = 5), HF + LPS group (n = 5), and HF + LPS + IMD (IKK2 inhibitor) group (n = 5). The mice in the control group were given a normal diet (ND) and the HF group animals were fed with an HF diet for 10 wk. The ND chow was supplied by the Animal Center of the Medical College of Subsidiary Basic Medical of Shanghai Jiao Tong University. The HF diet (50% fat, pork fat 18%, yolk 12%, sugar 8% and basal diet 62%) was supplied by SLAC Precision Equipment Inc. Mice in the intervention group were intraperitoneally injected with 30 mg/kg IKK2 IMD 0354 (Tocris Bioscience, Bristol, United Kingdom) for 14 d, and at the end of 12 wk this was combined with intraperitoneal injection of 10 mg/kg LPS (Sigma-Aldrich, St Louis, MO, United States). Mice were then sacrificed after fasting for 12 h. Subsequently, 1 mL eyeball blood was obtained and all mice were killed by cervical dislocation. The liver tissue was fast fixed and lightly washed in ice-cold phosphate buffered solution (PBS). Then, part of the liver was placed into 10% formalin fixation solution, while the other part of the liver was quickly stored at -70 ℃ for cryopreservation. The blood was sent to the laboratory of Renji Hospital for liver enzyme assays. Some liver tissue was embedded in paraffin for 24 h and was then observed by hematoxylin and eosin (HE) staining, Masson staining and immunohistochemistry (IHC). Other liver tissue was saved under an ultra low temperature for Western blotting and polymerase chain reaction (PCR) procedures.

Biochemical and liver enzymes assays

Serum was collected to analyze alanine aminotransferase (ALT) and aspartate aminotransferase (AST) using automatic biochemical instrumentation at Renji Hospital Lab, Shanghai, China.

Histopathological staining and analysis

For HE and Masson staining, 4-μm liver tissue sections were cut from the same position and embedded in paraffin after being stabilized in 10% formalin. Changes in liver tissues were observed under a light microscope.

Evaluation of inflammation activity: scores of inflammation activity were in accordance with chronic liver disease activity[20], and were divided into four parts; i.e., portal area inflammation (P), lobular inflammation (L), patch necrosis (PN) and bridging necrosis (BN, including lobular necrosis). Every item was recorded as 1, 2, 3 or 4 based on degrees of pathological changes. The scores counting formula was: $P + L + 2 \times (PN + BN)$.

Fatty hepatic fibrosis: fibrosis scores were divided into four stages according to the degree of fibrosis in three areas of the liver; i.e., the liver acinus, the portal vein, and bridging fibrosis, as well as the presence or

absence of liver cirrhosis. S1 indicated perisinusoidal space fibrosis of three areas of the local or extensive liver acinus; S2 indicated the above pathological changes with local or extensive periportal fibrosis; S3 indicated S2 pathological changes with local or extensive bridging fibrosis; and S4 indicated fatty liver cirrhosis, forming fibrous septa that divided lobuli hepatic and central veins to the portal area and formed false lobules.

Immunohistochemical analysis

Liver tissue sections (4 μm) were prepared for IL-6 immunohistochemical study. The glass was treated by polylysine to promote cell attachment. Microwave antigen repairing was carried out with 0.01 mol/L citrate buffer solution (pH 6.0). After blocking with rabbit serum, the sections were incubated overnight at 4 ℃ with monoclonal primary antibody against mouse IL-6 (PPMX, Tokyo, Japan). On the next day, liver sections were taken out and washed with PBS three times and were incubated with the second antibody for 1 h at room temperature. Coloration with freshly prepared diaminobenzidine (DAB) was performed, and then the tissues were counterstained with hematoxylin, dewatered, and then mounted with neutral gum. The second antibody in the ElivisionTM plus Polyer HRP (Mouse/Rabbit) IHC Kit and DAB developer were supplied by Manxin Bio Co®, Fuzhou, China. PBS taking the place of the primary antibody was considered as the negative control. We chose 10 views of each section under light microscopy to obtain the average positive absorbance using ImageProplus2.0.

Enzyme linked immunosorbent assay

Liver (1 g) was placed in PBS with 0.1 mmol/L phenylmethyl sulfonylfluoride (PMSF, Sigma) and was then manually homogenized, centrifuged at 100 000 r/min for 15 min at 4 ℃, and the supernatant was removed. Double antibody enzyme linked immunosorbent assay (ELISA) (ELISA kit TNF-α, BD Bioscience, Franklin Lakes, NJ, United States) was used for detection, and the procedure was strictly based on the guidelines provided by the manufacturer.

Western blotting analysis of NF-κB p65, TGF-β1 and α-SMA

Liver tissue was saved in a refrigerator at -80 ℃ after homogenization, and the tissue protein extract solution was prepared by centrifugation. Based on the operating instructions of the bicinchoninic acid protein quantitation kit (Sunbio, Beijing, China), the concentration of protein was detected. After denaturation, each tissue protein was sampled at 50 μg, and reducibility was performed with sodium dodecyl sulfate polyacrylamide gel electrophoresis cataphoresis in an 8% polyacrylamide gel. Sampling after denaturation was performed and electrophoresis was started. The electrophoresis voltage of the condensed glue and separation gel was 80 V and 120 V, respectively. The electrophoresis terminated after bromophenol blue electrophoresis moved to the bottom of the glue, and a damp-dry transmembrane (polyvinylidene fluoride membrane) was applied with a constant 50 mA current for 90 min. The membrane was sealed at room temperature with 5% defatted milk powder prepared with Tris-buffered saline Tween-20 (TBST) and primary antibodies (NF-κB p65, TGF-β1, α-SMA and β-actin, 1:1000, Santa Cruz Biotechnology, Santa Cruz, CA, United States) and was incubated overnight in a swing bed at 4 ℃. After the film was washed with TBST buffer solution in the swing bed, the second antibody 1:3000 (rabbit polyclonal antibody, Manxin Bio, Fuzhou, China) was incubated at room temperature for 1 h. After being repeatedly washed in TBST buffer solution, DAB staining was performed. After proper staining, the reaction was terminated by water. In a dark room, a nitrocellulose filter was put into a brightening agent with sufficient contact, and was then exposed to light with an X-ray device. The image was developed and fixed. Simultaneous determination of the expression level of β-actin in the same filter was carried out as an internal control. Separate analyses were performed for each sample and the experiment was repeated three times. We obtained the integrated density value by Microsoft BandScan, and the ratio of the target bands to β-actin substantiated the presence of the proteins NF-κB p65, TGF-β1 and α-SMA.

RNA extraction and analysis of mRNA expression of types Ⅰ and Ⅲ collagen, α-SMA and TGF-β1

Total RNA was isolated from snap-frozen liver tissue using Trizol reagent (Invitrogen, Carlsbad, CA, United States) and the ratio between the absorbance values at 260 nm and 280 nm gave an estimate of RNA purity. Real-time (RT)-PCR was performed using a one-step RT-PCR kit from the Shanghai Daweike Biotechnology Company. Two micrograms of the total RNA was chosen and reverse transcription was performed. Its reaction product was placed into a 50-μL PCR reaction system. α-SMA, TGF-β1, types I and Ⅲ collagen, and the specific primer of the internal reference β-actin was used in PCR amplification, and agarose electrophoresis was performed. Electrophoresis results were scanned with a BioSens GelImaging System. For the PCR primer sequences and fragment lengths (Table 1). The real-time survey meter (7500 Sequence Detection System) was obtained from ABI, United States. The PCR conditions were: predegeneration for 2 min at 50 ℃, denaturation for 20 s at 95 ℃, annealing for 45 s at 60 ℃, and extension for 30 s at 72 ℃, with a total of 40 cycles; an internal reference of β-actin was used with predegeneration for 3 min at 94 ℃, denaturation for 20 s at 95 ℃, annealing for 20 s at 60 ℃, extension for 30 s at 72 ℃, with a total of 35 cycles, and extension again for 10 min after the cycles, and then termination at 4 ℃.

Statistical analysis

Data were expressed as mean ± SD. Statistical analysis was performed with a one-way analysis of variance using SPSS17.0 software, followed by Scheffe's test, and com-

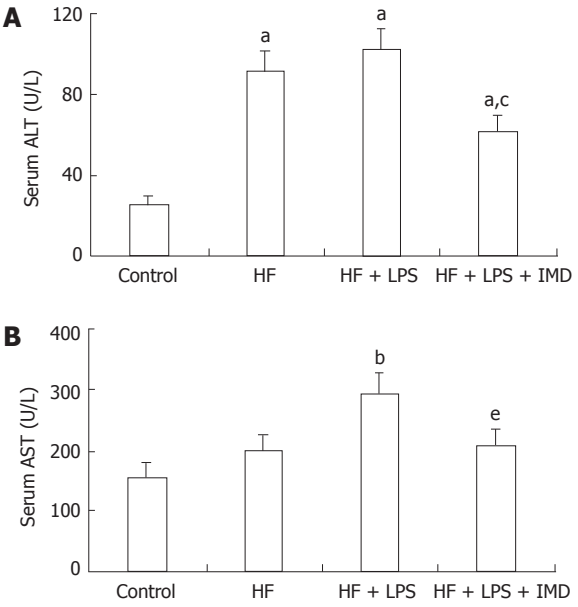

Figure 1 IKK2 inhibitor prevented HF + LPS-induced liver injury, as determined by serum ALT and AST levels. The normal values for ALT and AST were 45 U/L and 160 U/L. Serum ALT (A) and AST (B) were measured in different groups (control group, HF group, LPS-induced HF group and IMD-treated group), data are expressed as mean ± SD. A: $^{a}P < 0.05$ *vs* control group, $^{c}P < 0.05$ *vs* the HF and LPS + HF groups; B: $^{b}P < 0.01$ *vs* the control group, $^{e}P < 0.05$ *vs* the LPS + HF group. HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

parisons between groups was performed using the Mann-Whitney test. $P < 0.05$ was considered to be statistically significant.

RESULTS

Effects of IKK2 inhibitor (IMD0354) on serum ALT and AST

The levels of ALT and AST for each group are shown in Figure 1. In Figure 1A, the ALT levels of the HF and HF + LPS groups were significantly increased compared to the control group ($P < 0.05$). After treatment with the IKK2 inhibitor (IMD0354), the level of serum ALT in the mice was significantly decreased compared to the HF group ($P < 0.01$), as well as in the HF + LPS group ($P < 0.05$), but was still higher than that of the control group ($P < 0.05$). Figure 1B shows that the change in serum AST was not as significant as that of ALT. The level of serum AST in the HF + LPS group was significantly increased compared to the control group ($P < 0.01$). The level of serum AST when treated with IMD0354 was significantly decreased compared to that of the HF + LPS group ($P < 0.05$).

Effects of IKK2 inhibitor on liver inflammation and fibrosis during liver injury development

HE staining results showed that pathological changes in the mice were in line with the diagnostic gold standard of chronic NASH (Figure 2A). At the same time, typical hepatic fibrosis was observed with Masson staining (Figure 2B). In the control group, the structure of the hepatic lobules was clear without inflammatory cell infiltration in the portal area and without fibrotic tissue hyperplasia. The liver sections of the HF and HF + LPS groups showed that the normal structure of the hepatic lobules was lost, the structure of the blood vessels in the liver was disordered with severe liver cell degeneration, patch necrosis and bridging necrosis, and there were many inflammatory cell infiltrates in the portal area. There was also light to moderate hyperplasia of the broglia fibrils and fibrous septa were formed occasionally. Inflammation and fibrosis scores showed significant differences compared with the control group ($P < 0.05$). In the IMD-treated group, the structure of the hepatic lobules was normal, liver cell degeneration was significantly decreased, and liver cell necrosis and inflammatory cell infiltration were significantly improved. Fibrillar collagen sediment still existed, which was significantly reduced compared with the controls, and its inflammation score was also significantly decreased ($P < 0.05$), but was still higher than that of the control group ($P < 0.05$, Table 1). The results of the fibrosis scores were analyzed by Mann-Whitney statistical methods, and the results showed that there was a significant difference between the HF + LPS + IMD and HF + LPS groups ($Z = -2.35$, $P = 0.018$, $P < 0.05$, Table 1). There were no differences among the other groups.

Table 1 Pathological scores in liver tissues

Groups	$P + L + 2 \times (PN + BN)$	S0	S1	S2	S3	S4	Z
Control	0	5	0	0	0	0	
HF	10.70 ± 2.62^{a}	0	3	2	0	0	
HF + LPS	13.30 ± 3.83^{a}	0	1	3	1	0	
HF + LPS + IMD	$4.60 \pm 3.83^{a,c}$	0	4	1	0	0	-2.35^{e}

The score of inflammation is given by $P + L + 2 \times (PN + BN)$. $^{a}P < 0.01$ *vs* the control group; $^{c}P < 0.01$ *vs* the HF and HF + LPS groups; $^{e}Z = -2.35$, $P = 0.018$, $P < 0.05$ *vs* the HF + LPS group. *P*: Portal area inflammation; L: Lobular inflammation; PN: Patch necrosis; BN: Bridging necrosis; HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.

Immunohistochemistry assay for the changes in IL-6 expression in the livers of mice

Previous studies have demonstrated that many cell factors, such as TNF-α and IL-6, play important roles in the NF-κB dependent signaling pathway[21]. Some evidence has indicated that TNF-α, as well as IL-6, participated in the formation of hepatic fibrosis and had a positive correlation with the level of serum hyaluronic acid, laminin type Ⅳ, for example, suggesting that TNF-α, as well as IL-6, not only mediated inflammatory reactions but also participated in the formation of hepatic fibrosis during the promotion of extracellular matrix (ECM) synthesis. In this study, the average absorbance values (*A*) of liver cell positive immunity of mice in each group were analyzed by Image-pro plus 6.0 and statistical analysis was performed, showing that there was a small amount of IL-6 expression in the control and HF groups, and the expression of IL-6 was significantly increased in the HF

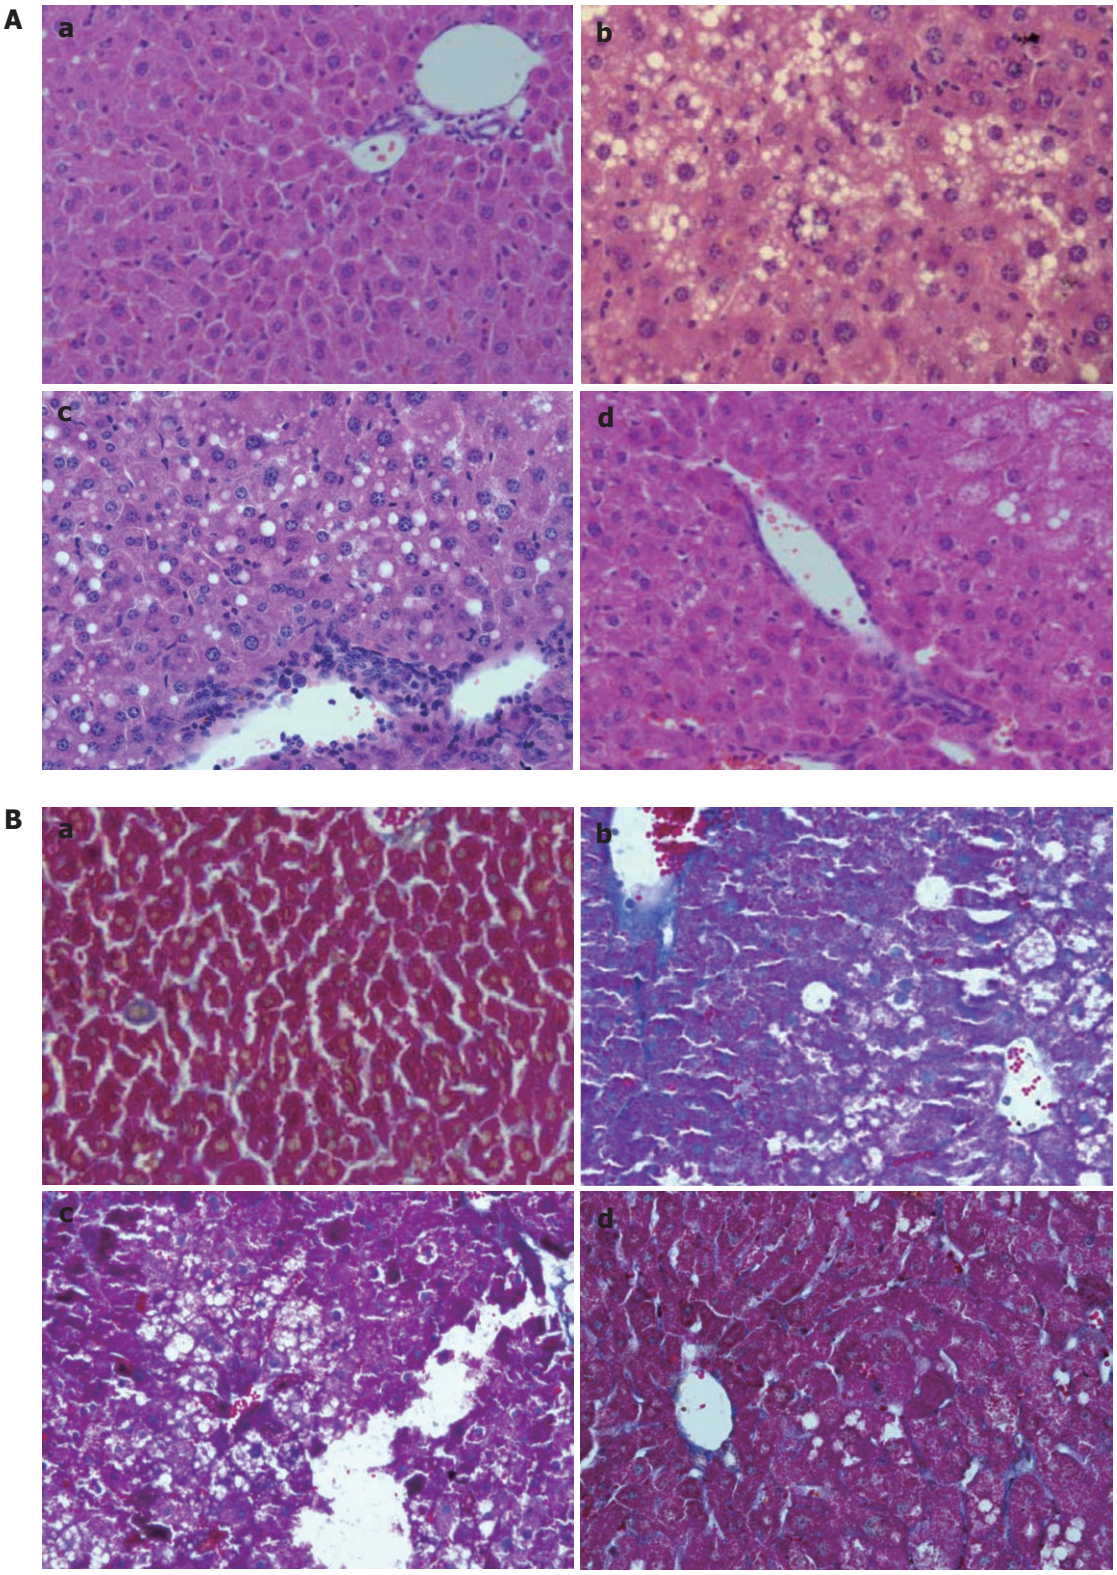

Figure 2 Hematoxylin and eosin stain and Masson staining in sections of (a) control group; (b) HF group; (c) HF + LPS group; and (d) HF + LPS + IMD group. A: Hematoxylin and eosin stain. Macrovesicular steatosis, lobular inflammation and balloon degeneration of hepatocytes were observed in liver sections of HF-treated mice and HF + LPS + treated mice with a significantly large amount of inflammatory cell infiltration surrounding the centrilobular veins of the liver. Significant amelioration was observed in the group treated with IMD (d); B: Masson staining. A thin lining of collagen was observed in the HF group, HF + LPS group and HF + LPS + IMD group. With LPS treatment, there was an increase in the amount of collagen accumulated along the central vein with the presence of collagen in the pericellular area. Treatment with IMD reduced LPS-induced collagen accumulation. HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.

group after being activated by LPS ($P = 0.013$, $P < 0.05$). IL-6 expression was mainly concentrated in the liver cell cytoplasm around the central veins and portal area, appearing as brown and grainy, and was also expressed

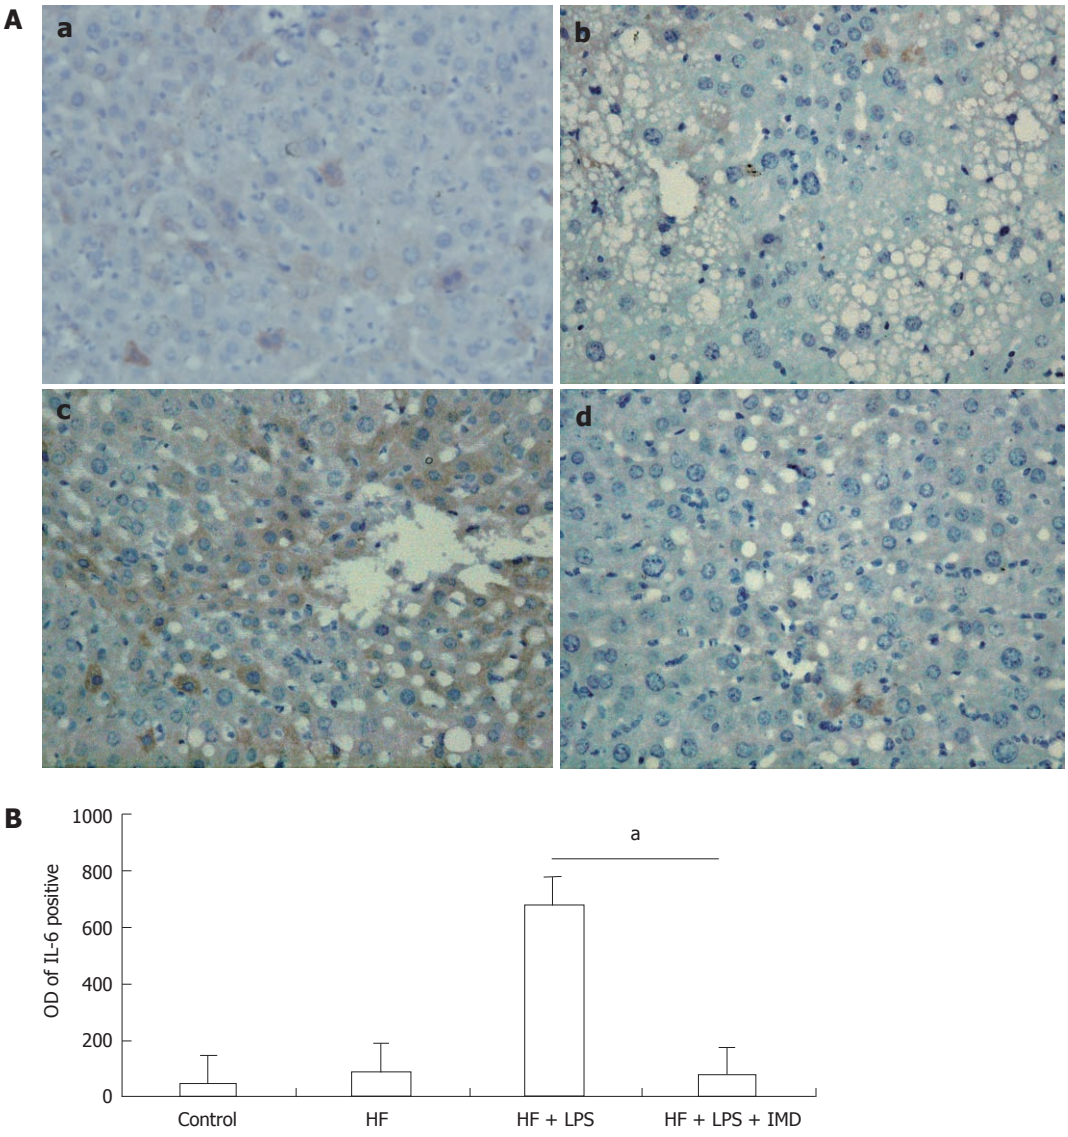

Figure 3 Interleukin-6 expression was assessed by immunohistochemistry. A: Positive staining was observed in hepatocytes in the control group (a), HF group (b), LPS-induced HF group (c) and IMD-treated group (d). B: The optical density (OD) of interleukin-6 (IL-6)-positive areas was measured with ImageProplu6.0 ($^{a}P < 0.05$). HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.

in the sinus hepaticus and parts of monocytes. In the HF + LPS group treated with the intervention of IMD, the expression of IL-6 was significantly decreased ($P = 0.012$, $P < 0.05$). There was no significant difference when compared with the HF group ($P = 0.70$, $P > 0.05$), and the expression of IL-6 was higher than the control group (Figure 3).

IKK2 inhibitor (IMD) inhibited an LPS-induced increase in the pro-inflammatory cytokine levels of TNF-α in mice livers

Recent research has shown that the IKK2-NF-κB signal pathway participate in insulin resistance, and cell factors of TNF-α and IL-6 play important roles dependent on NF-κB signals[21], especially in the pathological process of hepatic fibrosis[17,22]. Therefore, TNF-α was the key pro inflammatory factor, which was likely to induce the formation and development of hepatic fibrosis. The protein levels of TNF-α in mouse livers were detected by ELISA. With the development of liver injury, an increased expression of TNF-α was shown in the liver[23]. The levels of TNF-α in mouse livers of the HF and HF + LPS groups were significantly increased compared to the control group ($P < 0.05$). After intervention with the IKK2 inhibitor, the level of TNF-α was significantly reduced compared to the non-intervention group ($P < 0.05$, Figure 4).

IKK2 inhibitor (IMD) decreased nuclear translocation of NF-κB p65 in mice livers in response to LPS and HF exposure

When combined with IκBα in the cytoplasm, NF-κB was inactive. IKK2, as the major subunit of promotion, activated NF-κB and its subunit with phosphorylation, while IMD could inhibit the activation of NF-κB p65 and its nuclear transcription[24]. Therefore, expressions

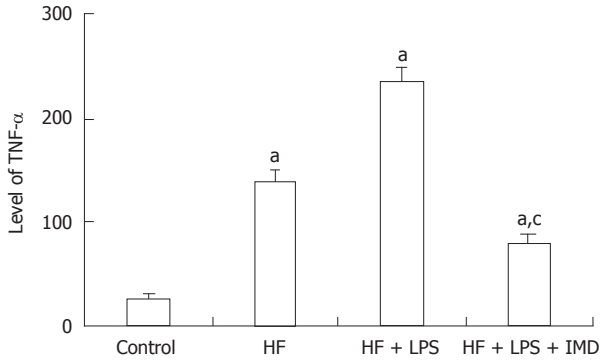

Figure 4 The levels of nuclear factor-κB-dependent pro inflammatory cytokines and tumor necrosis factor-alpha were measured in livers obtained from the control group, HF group, HF + LPS group and HF + LPS + IMD group. $^{a}P < 0.05$, compared with the control group. $^{c}P < 0.05$, significant compared with both the HF and LPS + HF exposed groups. HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor; TNF-α: Tumor necrosis factor-alpha.

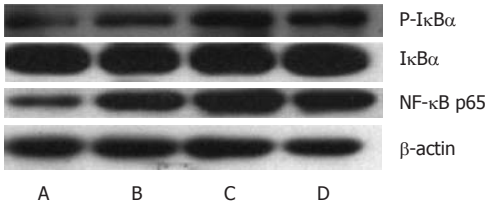

Figure 5 IKK2 inhibitor decreased lipopolysaccharide-induced nuclear translocation of nuclear factor-κB p65 and P-IκBα in livers. Nuclear levels of the p65 subunit of nuclear factor-κB (NF-κB) were measured by Western blotting in different groups (A: Control; B: HF group; C: HF + LPS group; D: HF + LPS + IMD group). β-actin was used as a loading control. Administration of IMD at 30 mg/kg doses decreased the DNA binding activity of NF-κB, which was induced by HF and LPS in mice livers. HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.

of NF-κB p65 and P-IκBα in the livers in each group was detected to determine the inhibitory action of IMD. Western blotting showed that the expression of NF-κB p65 in the HF group was increased compared to that of the normal diet group. In the HF group, LPS promoted the expression of NF-κB p65, and P-IκBα increased simultaneously, while intervention by the IKK2 inhibitor reduced the pro-inflammatory role of LPS and significantly reduced the expression of NF-κB p65 and its subunit (Figure 5).

IKK2 inhibitor (IMD) decreased protein levels of TGF-β1 and α-SMA related to fibrosis in livers

TGF-β1 is an important inflammatory factor that stimulates accumulation in the ECM and tissue fibrosis. Our results showed that TGF-β1 expression in the liver was increased under the condition of the HF diet and stimulation of LPS. While α-SMA was a marker of HSC activation, its variation tendency was similar to TGF-β1. In the mouse liver model group, the expression of α-SMA was significantly increased compared to the control group. After application of the IKK2 inhibitor, the protein expression of TGF-β1 in livers decreased, and the expression of α-SMA was reduced accordingly.

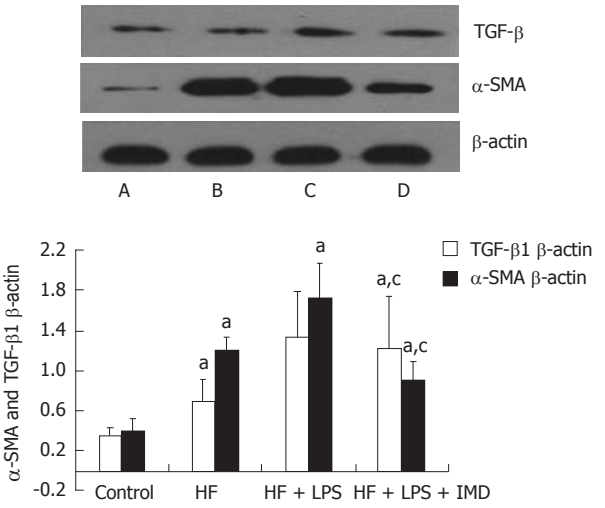

Figure 6 Western blotting analysis of tumor growth factor-beta1, alpha-smooth muscle actin proteins were measured that were involved in IKK2-nuclear factor-κB pathways in the liver in different groups (A: Control; B: HF group; C: HF + LPS group; D: HF + LPS + IMD group). β-actin was used as a loading control. The levels of tumor growth factor-beta1 (TGF-β1) and alpha-smooth muscle actin (α-SMA) measured in livers were increased in the HF and HF + LPS groups. IKK2 inhibitor significantly inhibited LPS and HF-induced expression of TGF-β1 and α-SMA in mouse livers. The ratio of TGF-β1 and α-SMA/β-actin in the liver was increased in other groups, compared with the control group, $^{a}P < 0.05$. IKK2 inhibitor normalized TGF-β1 and α-SMA significantly compared with the HF or LPS + HF groups. $^{c}P < 0.05$. HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.

Table 2 Oligonucleotide sequences used in real-time polymerase chain reaction

mRNA	Sequence	Length (bp)
Type Ⅰ (Ⅰ α) collagen	F: ACAGTGGTGAACCTGGTGCT	151
	R: CTCCTTTGGCACCAGTGTCT	
Type Ⅲ collagen	F: GGAGCCCCTGGACTAATAG	193
	R: ATCCATCTTTGCCATCTTCG

β-actin	F: TGTGTCCGTCGTGGATCTGA	126
	R: CTTGCGACCCACGTAGTAGA	

α–SMA: Alpha-smooth muscle actin; TGF-β1: Tumor growth factor-beta1.

Correspondingly, activation of HSCs and the formation of collagen decreased, leading to effectively preventing hepatic fibrosis (Figure 6).

IKK2 inhibitor IMD inhibited α-SMA, TGF-β1, types Ⅰ (α Ⅰ) and Ⅲ collagen and mRNA expression in LPS-stimulated mice

The formula described previously was used to measure mRNA relative expression (amount = $2^{-\Delta ct} \times 100\%$), and the relative expression levels of α-SMA, type Ⅰ (α Ⅰ) collagen, type Ⅲ collagen and TGF-β1 mRNA were obtained. RT-PCR was performed with the mouse primers shown in Table 2. The results showed that the expression of TGF-β1 mRNA in the HF group and the HF + LPS group was higher than the control group ($P < 0.05$),

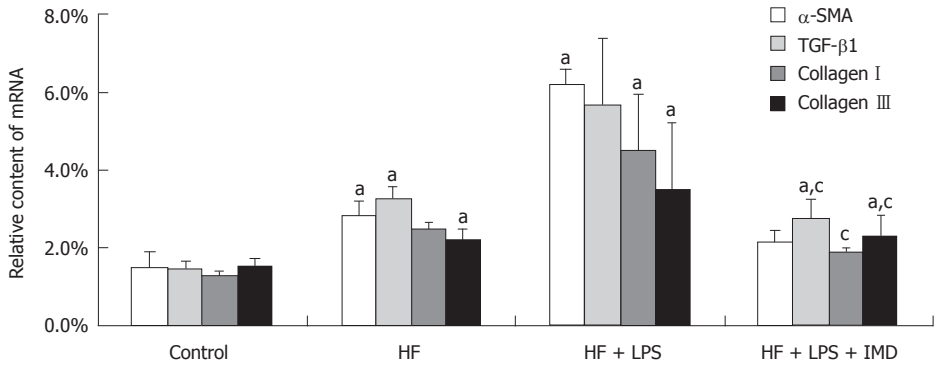

Figure 7 The IKK2 inhibitor inhibited LPS and HF-induced increases in pro inflammatory cytokine levels in mouse livers. The level of tumor growth factor-beta1 (TGF-β1) was measured in the livers of mice in the control, HF, HF + LPS and HF + LPS + IMD groups. Also, expression of the fibrosis index, such as alpha-smooth muscle actin (α-SMA), type Ⅰ collagen and type Ⅲ collagen, were detected in the four groups by real-time polymerase chain reaction. The level of TGF-β1 measured in livers was increased in the HF and HF + LPS groups, compared with the control group, $^{a}P < 0.05$. The mRNA content of type Ⅰ collagen in the HF group and type Ⅲ collagen in the HF + LPS group were significantly higher, $^{a}P < 0.05$, compared with the control group. Intraperitoneally administered IKK2 inhibitor normalized the expression of TGF-β1, as well as the contents of α-SMA, type Ⅰ and type Ⅲ collagen mRNA, compared with the HF or LPS + HF groups. $^{a}P < 0.05$, compared with the control group. $^{c}P < 0.05$, compared with both HF group and LPS + HF exposed group. **HF: High-fat; LPS: Lipopolysaccharide; IMD: IKK2 inhibitor.**

which was significantly decreased after intervention of IMD. In addition, the fibrosis indexes of α-SMA, type Ⅰ collagen and type Ⅲ collagen in the model group were also increased. In addition, the contents of type Ⅰ collagen in the HF diet group and type Ⅲ collagen in the HF + LPS group were significantly increased, independently, compared to the control group ($P < 0.01$, $P < 0.05$, respectively). After intervention with IMD, the levels of α-SMA, type Ⅰ (α Ⅰ) collagen and Ⅲ collagen were significantly decreased compared to the HF + LPS group ($P < 0.05$). However, there was no significant difference in α-SMA and type Ⅲ collagen with intervention of IMD and the normal group ($P > 0.05$, Figure 7).

DISCUSSION

NAFLD includes simple liver steatosis, NASH and liver cirrhosis, while NASH has become a central issue of chronic liver disease with worldwide attention[7]. Currently, the pathogenesis of NAFLD is not clear, and the hypothesis of "secondary strike" has been widely accepted. It is well known that insulin resistance is involved in the process, and inflammatory reaction, lipid peroxidation, and oxidative stress also play important roles[25-27]. The best measure for preventing the progression of hepatic fibrosis is to prevent or reverse the initial cascade reactions of fibrosis[28]. Therefore, inhibition of the generation of inflammatory factors effectively reduces HSC activation, decreases accumulation in the ECM, and fundamentally reverses fibrosis[29]. The expression of NF-κB is significantly increased in NASH patients, and TNF-α, IL-6, TGF-β, and other inflammatory factors also showed high expression levels[23]. Further research has found that activation of NF-κB is the key step in regulating gene expression of various kinds of pro inflammatory factors in NASH patients[23]. TNF-α is the key pro inflammatory factor and it induces the formation and development of hepatic fibrosis. TGF-β1 mediates the synthesis of different kinds of collagen with time dependence. However, inhibition of TGF-β1 significantly reduces the synthesis of collagen and sedimentation of the ECM[30].

It has been reported that blockage of IKKβ (IKK2) significantly reduces the incidence rate of liver steatosis and improves NASH pathologically[31]. Is it possible that IKKβ (IKK2)-NF-κB is also a key in improving and even reversing hepatic fibrosis? Various macromolecular protein-joining enzymes, including IKKβ (IKK2), IKK or NF-κB inhibitors, have become new types of anti-inflammatory agents; therefore, many researchers have tried to inhibit NF-κB-mediated proinflammatory responses based on these agents. The IKK2 inhibitor played a specific anti-inflammatory role through inhibition of the major subunit IKKβ, which served as a promotor in the IKK protein kinase complex center. In our study, the IKK2 inhibitor (IMD 0354) was used in liver injury in mice. We detected its inhibitory effect on liver NF-κB-dependent inflammatory factors, changes in liver function, histological changes and, at the same time, the expression of TGF-β1 involving fibrosis and relevant fibrosis indexes, such as α-SMA, type Ⅰ collagen and type Ⅲ collagen. It is warranted to investigate the potential therapeutic effect of IMD on hepatic fibrosis.

In our study, during HF-diet-induced chronic non-alcoholic hepatic injury in mice, the serology index of ALT was doubly higher than that of the control group. As for pathological changes, moderate to severe steatosis was observed, inflammatory infiltration was found in the lobules, local inflammatory infiltration was detected in the portal area, Masson staining showed fibrous tissue hyperplasia, Western blotting and RT-PCR results demonstrated that TGF-β1 expression increased, α-SMA content was raised, and there was sedimentation of types Ⅰ and Ⅲ collagen. Therefore, a hepatic injury model with typical inflammation and fibrosis pathological manifestation was successfully established by an HF diet and intraperitoneal injection of LPS, stimulating activation of NF-κB and promoting an inflammatory reaction[32-34].

When chronic hepatic injury occurs, different initial causative agents trigger the activation of HSCs, activation of the Janus kinase-signal transducers and activators of transcription signal transduction pathway[35], promotion of α-SMA expression in sinus hepaticus cells, further proliferation and activation, and synthesis and secretion of the ECM and collagen, which finally enhances the occurrence of hepatic fibrosis. Thus, expression of α-SMA has been considered as one of the dominant features of HSC activation, and has become an important evaluation index for hepatic fibrosis. In our study, when the mice were stimulated with LPS and an HF diet, the expression of α-SMA increased in the liver. At the same time, sedimentation of types I and Ⅲ collagen also occurred, suggesting that HSC was triggered and activated, and then started the process of hepatic fibrosis. However, the results for the group treated with IMD showed that expression of α-SMA, as well as sedimentation of types I and Ⅲ collagen, were significantly reduced, suggesting that inhibition of inflammatory factor expression also effectively suppressed HSC activation, and accordingly blocked the occurrence of hepatic fibrosis from the source.

Fatty tissue was the principle source of cell factors, liver steatosis promoted macrophage infiltration, and activation of HSC promoted the cascading release of many kinds of cell factors with an intensive pro inflammatory role, which further made the pathological changes and insulin resistance more serious[36,37]. We found that inflammatory cell and inflammatory factor expression after stimulation with LPS significantly increased compared to that in the HF group. Liver steatosis in the mice treated with intraperitoneal injection of the IKK2 inhibitor was significantly improved, and inflammatory factors released from the hepatic cell fat were correspondingly reduced compared to that of the HF and LPS groups. In addition, it was shown that the IKK2 inhibitor could significantly reduce pro inflammatory stimulation by LPS, and even reverse the fibrosis process in a mouse hepatic injury model. Western blots demonstrated that NF-κB p65 activation was significantly inhibited, and NF-κB-dependent pro inflammatory factors, such as IL-6, were simultaneously suppressed. Separation of NF-κB and its suppressor factor IκBα resulted in continuous activation of intercellular adhesion molecule-1 and other cell factors, and finally the up regulation of IL-6. The increase in IL-6 stimulated HSC proliferation, induced production of multiple acute-phase proteins, and promoted ECM sedimentation by facilitating matrix degeneration or interaction with its adhesion receptor, leading to significant hepatic fibrosis[38,39]. Similarly, the high expression of IL-6 significantly promoted liver apoptosis. In our study, it was found that after intervention with the IKK2 inhibitor, NF-κB p65 activation was significantly inhibited, IL-6 expression in the livers of LPS model mice was significantly decreased with the improvement of serology indexes and histological changes, and blocking IL-6 expression significantly improved hepatic injury, which could demonstrate that the IKK2 inhibitor could improve hepatic fibrosis by inhibition of the inflammatory factor IL-6.

It is known that TNF-α promotes insulin resistance and the development of liver inflammation, which is related to multiple cell factors, and induces the synthesis of IL-1, IL-6 and C-reactive protein, including caspase 3 and growth arrest and DNA-damage-inducible beta. Adiponectin inhibits expression of TNF-α, as well as other inflammatory factors, with positive feedback[40,41]. A peroxisome proliferator-activated receptor antagonist blocked TNF-α mediated insulin resistance, and it also had intensive anti-inflammatory action[42,43], which made the inflammation signal transduction pathway become a multiple cross and participated in the process of hepatic fibrosis[44]. The level of TNF-α could better reflect the regulatory condition of the inflammatory reaction in hepatic fibrosis. Hepatocellular carcinoma (HCC) invariably develops within a setting of chronic inflammation caused by metabolic liver disease or autoimmunity. Mechanisms that link these two processes are not completely understood, but transcription factors of the NF-κB family have been suggested to be involved. Cytokines such as IL-6 are clearly pivotal players, and high levels of serum IL-6 correlate positively with tumor size and with poor prognosis in HCC patients[45]. Our results showed that the levels of IL-6 and TNF-α in mouse livers in which hepatic fibrosis existed increased, while the IKK2 inhibitor reversed such an imbalance, and α-SMA expression in the liver and sedimentation of collagen I and collagen Ⅲ decreased, illustrating that TNF-α improved liver pathological changes in hepatic fibrosis in mice, relieved inflammatory cell infiltration, and reduced fiber hyperplasia by the IKK2-NF-κB-dependent signaling pathway.

During the process of HSCs activation, TGF-β1 plays a major role as a fibroblast growth factor[46], and the major stimulating factor promoting HSCs to accumulate ECM[47]. TGF-β1 receptors on the surface of HSC complete the signaling pathway combined with Smads[48], which continuously stimulates HSC activation, and finally transcribes target gene expression in the HSC nucleolus, mainly including type I collagen, which plays a key regulatory role in ECM metabolism and function. However, there is evidence demonstrating that NF-κB does not directly activate HSCs[39]. In our experiment, when injury and hepatic fibrosis occurred, protein and gene expression of TGF-β1 increased. While inhibiting the activation of NF-κB certainly reduced the activation of HSCs, TGF-β1 expression was decreased, and the expressions of various kinds of fibrosis factors, such as α-SMA and type I and type Ⅲ collagen, decreased. Therefore, we suggest that indirect correlation or other pathways exist between NF-κB and HSCs, which indirectly reduce TGF-β1 expression, decrease continuous activation of HSCs, and then improve the fibrosis process.

In brief, our *in vivo* experiment demonstrated that an IKK2 inhibitor could significantly decrease the expres-

sion of various inflammatory factors in mouse livers after exposure to LPS, which could play an anti-fibrosis role in inhibiting inflammation, reducing collagen content in liver tissues, and decreasing the expression of hepatic fibrosis correlation factors. IMD inhibited the phosphorylation activation of IκBα and NF-κB stimulated by LPS. Meanwhile, the expression of NF-κB-dependent inflammatory cytokines were suppressed, illustrating that inflammatory factors inducing hepatic injury were effectively reduced by inhibition of the NF-κB signaling pathway. In addition, we found that various fibrosis markers, such as TGF-β1 and α-SMA, as well as type I collagen and type Ⅲ collagen, were decreased in the liver, demonstrating that HSC activation was decreased and ECM accumulation was reduced. Therefore, it was presumed that the mechanism of the IKK2 inhibitor in anti hepatic fibrosis might be relevant, with the inhibition of cell factors promoting HSC activation, indirect inhibition of HSC proliferation, suppression of continuous activation of HSCs by TGF-β1, and then secretory volume and expression levels of α-SMA being reduced. Finally, the extent of hepatic fibrosis was decreased. The major pathological changes of chronic fatty liver disease are insulin resistance and inflammatory reactions[49,50]. In summary, the NF-κB signaling pathway participates with the IKK2 inhibitor playing an influential role in NASH and hepatic fibrosis. Inhibiting the production of a variety of inflammatory factors could effectively reduce HSC activation, decrease accumulation in the ECM, and then reduce fibrosis formation.

COMMENTS

Background

The nuclear factor-κB (NF-κB) signaling pathway improves insulin resistance and fat accumulation in the development of nonalcoholic fatty liver disease (NAFLD). Inhibition of NF-κB activation by an IKK2 inhibitor could effectively suppress the expression of many kinds of inflammatory factors, and even improve hepatic fibrosis. Therefore, the authors of this study investigated the potential therapeutic prospects of the IKK2-NF-κB signaling pathway in the reversion of fibrosis in NAFLD.

Research frontiers

The study is believed to be the first to evaluate the role of IKK2-NF-κB signals in NAFLD. The potential effect of an IKK2 inhibitor is likely to block inflammation through inhibiting NF-κB activation. The IKK2 inhibitor may play an important role in the occurrence and development of NAFLD.

Innovations and breakthroughs

This study explored one of the possible mechanisms of inflammation, which could produce a potentially facilitative effect in the occurrence and development of NAFLD.

Applications

This study provides an experimental basis for future studies on the role of IKK2 in NAFLD. Control of the expression level of IKK2 in the liver may become a new possibility for therapy of NAFLD.

Terminology

In the present study, the authors tested the effect of IKK2 in NAFLD in mice, and found a facilitative effect on the occurrence and development of NAFLD.

Peer review

The paper should be accepted with some minor revisions. IκB kinase-beta inhibitor attenuates hepatic fibrosis in mice liver injury and its potential mechanisms.

Abstract

AIM: To conduct a meta-analysis to determine the relative merits of robotic surgery (RS) and laparoscopic surgery (LS) for rectal cancer.

METHODS: A literature search was performed to identify comparative studies reporting perioperative outcomes for RS and LS for rectal cancer. Pooled odds ratios and weighted mean differences (WMDs) with 95% confidence intervals (95% CIs) were calculated using either the fixed effects model or random effects model.

RESULTS: Eight studies matched the selection criteria and reported on 661 subjects, of whom 268 underwent RS and 393 underwent LS for rectal cancer. Compared the perioperative outcomes of RS with LS, reports of RS indicated favorable outcomes considering conversion (WMD: 0.25; 95% CI: 0.11-0.58; P = 0.001). Meanwhile, operative time (WMD: 27.92, 95% CI: -13.43 to 69.27; P = 0.19); blood loss (WMD: -32.35, 95% CI: -86.19 to 21.50; P = 0.24); days to passing flatus (WMD: -0.18, 95% CI: -0.96 to 0.60; P = 0.65); length of stay (WMD: -0.04; 95% CI: -2.28 to 2.20; P = 0.97); complications (WMD: 1.05; 95% CI: 0.71-1.55; P = 0.82) and pathological details, including lymph nodes harvested (WMD: 0.41, 95% CI: -0.67 to 1.50; P = 0.46), distal resection margin (WMD: -0.35, 95% CI: -1.27 to 0.58; P = 0.46), and positive circumferential resection margin (WMD: 0.54, 95% CI: 0.12-2.39; P = 0.42) were similar between RS and LS.

CONCLUSION: RS for rectal cancer is superior to LS in terms of conversion. RS may be an alternative treatment for rectal cancer. Further studies are required.

INTRODUCTION

Over the past 30 years, laparoscopic surgery (LS) has revolutionized general surgical practice, above all affecting

surgery of the gastrointestinal (GI) tract[1,2]. However, with regard to rectal cancer, there are several technical drawbacks to LS, including limited range of motion of instruments in a narrow pelvic cavity, related loss of dexterity, and an inadequate visual field associated with unstable camera view and assistant's traction, which are not under the surgeon's control[3]. Technical advantages of the da Vinci robotic system could overcome the limitations of LS for rectal cancer, by giving the surgeon a 3D view, better ergonomics, enhanced dexterity, precision and control due to the 3D optical system and EndoWrist® Instruments.

Although surgical robots have been successfully applied to a number of disciplines, most notably urological and cardiac procedures[4,5], robotic rectal surgery remains in its infancy. Most studies have been limited by small sample size and a single institution design. To overcome these limitations, a meta-analysis of studies comparing robotic surgery (RS) and LS for rectal cancer should be performed. The aim of this meta-analysis was to determine the relative merits of RS and LS for rectal cancer.

MATERIALS AND METHODS

Study selection

The Pubmed, Embase, Cochrane Library, Ovid, and Web of Science databases were searched systematically for all articles published before June 2011 to compare RS and LS for rectal cancer. The terms used for the search were: "robotic" and "rectal cancer". Only studies in the English language were considered for inclusion. Reference lists of all retrieved articles were manually searched for additional studies. Two reviewers independently extracted the data from each study. All relevant text, tables and figures were reviewed for data extraction. Discrepancies between the two reviewers were resolved by discussion and consensus.

Criteria for inclusion and exclusion

For inclusion in the meta-analysis, a study had to fulfill the following criteria: (1) compare the outcomes of RS and LS, regardless of other diseases; (2) report on at least one of the outcome measures mentioned below; and (3) if dual (or multiple) studies were reported by the same institution and/or authors, either the one of higher quality or the most recent publication was included in the analysis.

Abstracts, letters, editorials and expert opinions, reviews without original data, case reports and studies lacking control groups were excluded. The following studies or data were also excluded: (1) the outcomes and parameters of patients were not clearly reported (e.g., with no clearly reported outcomes of SD; (2) it was impossible to extract the appropriate data from the published results; and (3) there was overlap between authors or centers in the published literature.

Outcomes of interest

The following outcomes were used to compare the two operative techniques: (1) intraoperative data, which included operative time, blood loss and conversion; (2) postoperative data, which included complication, days to passing flatus, and length of stay; and (3) pathological details, which included lymph nodes harvested, distal resection margin (DRM), and positive circumferential resection margin (PCRM) which was defined as a circumferential resection margin (CRM) of $\leqslant$ 1 mm.

Data extraction

Two reviewers independently extracted the following parameters from each study: (1) first author and year of publication; (2) study population characteristics; (3) number of subjects operated on with each technique; and (4) intraoperative data, postoperative data, and pathological details.

Statistical analysis

The meta-analysis was performed using the Review Manager (RevMan) software, version 4.2.2. We analyzed dichotomous variables using estimation of odds ratios with a 95% confidence interval (95% CI) and continuous variables using weighted mean difference (WMD) with a 95% CI. Pooled effect was calculated using either the fixed effects model or random effects model. Heterogeneity was evaluated by χ^2 and I^2. We considered heterogeneity to be present if the I^2 statistic was > 50%. $P < 0.05$ was considered significant.

RESULTS

Selection of trials

The initial search strategy retrieved 154 publications, after screening all titles, abstracts, and full-text. A total of eight studies met our entry criteria and were retrieved for more detailed evaluation. The characteristics of these eight studies are summarized in Table 1[6-13]. Eight studies [six non-randomized controlled trials (NRCTs), two randomized controlled trials (RCTs)] included a total of 661 patients: 268 in the RS group and 393 in the LS group. Two studies were conducted in United States[7,13], three in Korea[6,8,12], two in Italy[10,11], and one in Romania[9]. The sample size of each study varied from six to 123 patients. In the included studies, six were considered as level of evidence 3, and the remaining 2 as level of evidence 2 (according to the grading of the Centre of Evidence-Based Medicine, Oxford, United Kingdom; http://www.cebm.net/index.aspx?o=5653).

In these studies, patients in the two groups were matched for operation time[6,9,11,12], blood loss[9,11], conversion[6-13], complications[6-13], days to passing flatus[6,12], length of stay[6,11,12], lymph nodes harvested[6,9,11,12], DRM[6,11,12], and PCRM[6,7,10].

Meta-analysis of intraoperative data

In four studies, operative time showed that there was no significant difference between the two groups. Analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: 27.92, 95% CI:

Table 1 Characteristics of included studies

Study	Country	Group	No. of patients	Mean age (yr)	Gender (M/F)	Level of evidence
Park	Korea	RS	52	57.3 (± 12.3)	28/24	3
et al[6]		LS	123	65.1 (± 10.3)	70/53

NA: Not available; RS: Robotic surgery; LS: Laparoscopic surgery.

-13.43 to 69.27; $P = 0.19$) (Figure 1A).

In two studies, blood loss did not differ significantly between the two groups. Analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: -32.35, 95% CI: -86.19 to 21.50; $P = 0.24$) (Figure 1B).

In all eight studies, conversion was found to be significantly lower in the RS group than in the LS group. Moreover, analysis of the pooled data revealed that conversion for RS was significantly lower by 0.25-fold (WMD: 0.25; 95% CI: 0.11-0.58; $P = 0.001$) (Figure 1C).

Meta-analysis of postoperative outcomes

In two studies, number of days to passing flatus was significantly lower in the RS group *vs* the LS group. Meanwhile, analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: -0.18, 95% CI: -0.96 to 0.60; $P = 0.65$) (Figure 1D).

In three studies, length of stay was found to be no different in the RS group and the LS group. Meanwhile, analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: -0.04; 95% CI: -2.28 to 2.20; $P = 0.97$) (Figure 1E).

In all eight studies, complications were found to be no different in the RS group and the LS group. Meanwhile, analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: 1.05; 95% CI: 0.71-1.55; $P = 0.82$) (Figure 1F).

Meta-analysis of pathological details

In the four studies, lymph nodes harvested showed that there was no significant difference between the two groups. Analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: 0.41, 95% CI: -0.67 to 1.50; $P = 0.46$) (Figure 1G).

In three studies, DRM was found to be significantly lower in the RS group than the LS group. Meanwhile, analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: -0.35, 95% CI: -1.27 to 0.58; $P = 0.46$) (Figure 1H).

In three studies, PCRM showed that there was no significant difference between the two groups. Analysis of the pooled data revealed that the two groups did not differ significantly in this regard (WMD: 0.54, 95% CI: 0.12-2.39; $P = 0.42$) (Figure 1I).

Heterogeneity

A significant heterogeneity was recognized in the following two factors: operative time, blood loss, days to passing flatus, length of stay and DRM.

DISCUSSION

Meta-analysis could be used to evaluate the existing literature in both qualitative and quantitative ways by comparing and integrating the results of different studies and taking into account variations in characteristics that could influence the overall estimate of the outcome of interest[14]. Although meta-analysis has traditionally been applied and best confined to RCTs, meta-analytical techniques using NRCTs might be a good method in some clinical settings in which either the number or the sample size of RCTs was insufficient[15]. To the best of our knowledge, this was the first comprehensive meta-analysis comparing RS versus LS for rectal cancer.

RS is often perceived as being more time-consuming, because of the additional set-up time required[16]. It usually requires two steps for rectal cancer[17,18]. After dissection of the left colon and sigmoid colon and division and ligation of the inferior mesenteric vessels, the da Vinci system must be moved for the next step. However, moving the da Vinci system is a time-consuming and difficult procedure because the robotic devices are heavy and bulky. This meta-analysis revealed that there was no significant difference in operative time between RS and LS. This finding could be attributable to the shortened learning curve, and it has been suggested that the intuitive controls of robotic systems, more comparable with open surgery, could shorten the learning curve, even in the hands of relatively inexperienced laparoscopic surgeons[19]. As we overcame the learning curve with experience and prevented collisions by properly positioning the robotic ports, the operation time decreased. There was no significant difference in blood loss when comparing RS and LS.

Conversion to open surgery and complications are critical in minimally invasive rectal cancer surgery, because converted patients have higher complication rates[20] and, in one series at least, worse oncological outcomes[21]. Conversion rate was significantly lower in the RS group than in the LS group. Lower conversion with RS might have been due to superior exposure and visualization of the operating field in the pelvis, thanks to the ability of the fixed fourth arm to grip and maneuver organs; the ability of the surgeon to move the 3D camera as required; and the greater ease of dissection afforded by the

I

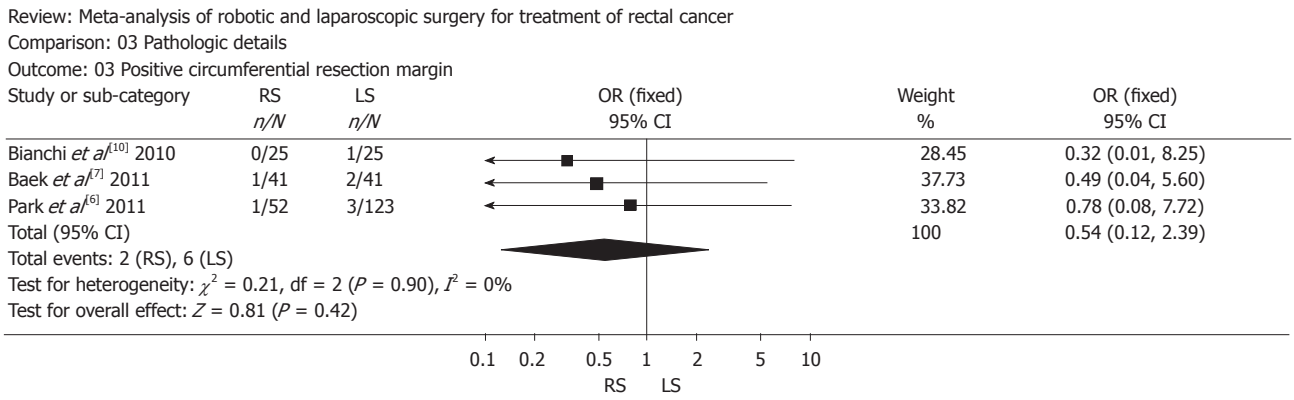

Figure 1 Forest plot displaying the results of the meta-analysis on operative time (A), blood loss (B), conversion (C), days to passing flatus (D), length of stay (E), complications (F), lymph nodes harvested (G), distal resection margin (H) and positive circumferential resection margin (I). RS: Robotic surgery; LS: Laparoscopic surgery; OR: Odds ratio; WMD: Weighted mean difference.

highly maneuverable EndoWrist instruments attached to the robotic arms.

Number of days to passing flatus was lower in the RS group than the LS group, meanwhile, length of stay was found to be no different between the two groups. However, analysis of the pooled data did not reveal any significant difference in this regard. These findings implied that the time required for patients to resume daily activities might not be shorter after RS than LS. There was no significant difference in complications when comparing RS and LS. On the contrary, it has been postulated that these characteristics of RS could make patients recover faster and reduce complications, because with the da Vinci surgical system, robotic arms are used for retraction and dissection during the total mesorectal excision procedure, and their use reduces unnecessary procedures and minimizes iatrogenic tissue injury during retraction. These findings are difficult to explain, and more advanced studies are needed before such conclusions can be drawn.

We postulated that specimen quality could be used as an indicator to predict long-term clinical oncological results. No significant differences were proved between RS and LS in the pathological details, including harvested lymph nodes, DRM and PCRM. The number of harvested lymph nodes, DRM, and PCRM did not differ significantly between the two groups in our meta-analysis. This demonstrated that RS could be performed safely and with a high success rate following oncological principles compared with LS. However, long-term follow-up evaluation is necessary to evaluate the exact oncological outcomes of RS for rectal cancer.

The cost of RS equipment is very high and likely to be a serious impediment to uptake in the foreseeable future[22]. However, it is important to perform a cost-effectiveness analysis between RS and LS. Only one trial has reported that the average total hospitalization costs were higher in the RS group ($83 915) than in the LS group ($62 601), and these differences were not statistically significant[7]. To the best of our knowledge, total hospitalization costs may be due to the greater expense and consumption of operating room resources such as space and the availability of skilled technical staff, and differ significantly between hospitals[23]. Therefore, insufficient data and great heterogeneity precluded a meta-analysis of cost-effectiveness.

Significant heterogeneity in those articles was observed in the operative time, blood loss, days to passing flatus, length of stay and DRM, which may be explained by the difference in skill, extension of lymph node dissection, and duration of learning curve. Regarding the heterogeneity between the articles, random-effect models were used in this meta-analysis.

The results of the present meta-analysis should be interpreted with caution because of several limitations. First, some data came from NRCTs, and the overall level of clinical evidence was low. It has been reported that NRCTs can either exaggerate or underestimate the magnitude of measured effects in a study of intervention regardless of quality scores[24]. However, Abrahama *et al*[25] have found that meta-analysis of well-designed NRCTs of surgical procedures was probably as accurate as that of RCTs. In fact, six studies included in the present study were NRCTs. Second, there was heterogeneity between the two groups, because it was impossible to match patient characteristics in all studies. We applied a random-effect model to take into consideration between-study variation, and it might have been expected to exert a limited influence. Finally, authors might be more likely to report positive results, and studies with significant outcomes were more likely to be published, so potential publication bias might have been present.

In conclusion, the results of this meta-analysis of 661 patients show that RS is superior to LS for rectal cancer in terms of conversion. Therefore, RS may be an alternative treatment for rectal cancer. Further studies are required to better define its role.

COMMENTS

Background

The da Vinci robotic system was introduced as the next advance in minimally

invasive surgery to overcome the technical limitations of laparoscopy, but robotic rectal surgery is controversial because of a lack of well-powered trials.

Research frontiers

Meta-analysis was used to evaluate the relative merits of robotic surgery (RS) and laparoscopic surgery (LS) for rectal cancer in this study.

Innovations and breakthroughs

The meta-analysis reported that RS had favorable outcomes considering conversion, compared with LS for rectal cancer. Meanwhile, operative time, blood loss, days to passing flatus, length of stay, complications and pathological details, including lymph nodes harvested, distal resection margin, and positive circumferential resection margin were similar between RS and LS. This is believed to be the first comprehensive meta-analysis comparing RS and LS for rectal cancer.

Applications

The results of this meta-analysis show that RS is superior to LS in terms of conversion. Therefore, RS may be an alternative treatment for rectal cancer.

Peer review

This paper addressed superiority of RS for rectal cancer, especially due to superior exposure and visualization of the intrapelvic field. This advantage means that surgeons complete the operation without conversion. This paper should be of interest to colorectal surgeons worldwide.

Abstract

AIM: To evaluate the effects and safety of combination chemotherapy with oxaliplatin (L-OHP) and S-1 (SOX regimen) in older patients with advanced gastric cardiac adenocarcinoma (GCA).

METHODS: Seventy patients with advanced GCA were classified according to age into an older group (≥ 75 years) and a control group (< 75 years). The SOX regimen was administered to the two groups as follows: S-1 (40 mg/m^2 po bid) on days 1 to 14 followed by a 7-d off period, plus L-OHP (65 mg/m^2 iv) for 2 h on days 1 and 8 of a 21-d cycle. This regimen was repeated for four to six cycles. Response and swallow statuses were evaluated after two cycles (6 wk). Effects and toxicity were evaluated four weeks after chemotherapy was completed.

RESULTS: The response rate was 65.6% (21/32) in the older group and 68.4% (26/38) in the control group (χ^2 = 0.062 and P = 0.804). Improvement in swallowing was 78.1% (25/32) in the older group and 76.3% (29/38) in the control group (χ^2 = 0.032 and P = 0.857). Efficacy was 68.8% (22/32) in the older group and 65.8% (25/38) in the control group (χ^2 = 0.069 and P = 0.793). Toxicities were reversible and similar in both groups (P > 0.05).

CONCLUSION: The SOX regimen is an effective, safe and well-tolerated regimen for older patients with advanced GCA.

Key words: Gastric cardiac adenocarcinoma; Oxaliplatin; S-1; Treatment effect

INTRODUCTION

With constant improvement in the quality of life in modern

society, people's life span has been prolonged. However, the incidence of elderly patients with gastric cardiac adenocarcinoma (GCA) is gradually increasing, and the majority of these patients have advanced disease when they are diagnosed. Thus, these patients have few opportunities for surgery[1]. The only available treatment choice for advanced GCA patients is systemic chemotherapy[2-4]. Although chemotherapy for advanced gastrointestinal cancer has been proven to be superior to best supportive care (BSC) in terms of survival and quality of life[5-7], there has been evidence supporting more serious adverse events observed among older patients than younger patients[8]. For these reasons, most older patients with metastasis are usually offered BSC and not chemotherapy[9]. However, patients who are 75 years old can still have a considerable number of years to survive (perhaps more than 10 years)[10]. Therefore, it is important to find a highly effective and minimally toxic chemotherapy regimen for elderly patients with advanced GCA.

In the last decade, 5-fluorouracil (5-FU) has been considered a cornerstone of therapy for advanced gastrointestinal cancer. Therefore, combining 5-FU with oxaliplatin (L-OHP) is logical because there is considerable evidence of preclinical synergy between the two agents[11]. S-1 is an orally active prodrug of 5-FU which is a fourth generation oral fluoropyrimidine[12]. Recent clinical studies have reported that S-1 in combination with L-OHP has a high response rate ranging from 53% to 59% and an excellent toxicity profile in the treatment of advanced gastric cancer[13-15]. In these studies, however, there were only a few patients of 75 years of age or older. Furthermore, few studies on the outcome of the S-1 and oxaliplatin (SOX) regimen in patients with GCA have been reported. Therefore, we designed this study to determine the response rate and toxicity profile of SOX regimen in GCA patients over the age of 75 years.

MATERIALS AND METHODS

Patients

GCA was confirmed in 70 patients by pathologic diagnosis in the First Affiliated Hospital, Henan University of Science and Technology from March 2008 to October 2010. All patients were treated with chemotherapy for the first time in this study, and they were experiencing symptoms such as difficulty in drinking, difficulty in eating, vomiting mucus, anemia, and emaciation. The degree of cardia stenosis was assessed using the Stooler Classification System[16] and the barium meal examination. The results of the barium meal examination are shown in Table 1. There were 54 cases of grade Ⅲ, 14 cases of grade Ⅳ, and 2 cases of grade Ⅴ dysphagia. All patients were classified as stage Ⅲ or Ⅳ according to the TNM staging, and they had Karnofsky Performance Status (KPS) scores greater than or equal to 60 points, predicted life spans greater than three months, no contraindications to chemotherapy, and no previous treatment with chemotherapy. Their routine blood examinations, electrocardiograms (ECGs), liver function, and kidney function were also normal. All patients were examined with a computed tomography (CT) before and after chemotherapy, and they were evaluated by the same physician.

Table 1 Degree of cardia stenosis

Clinical classifications	Diet conditions	Cardia diameters in the barium meal exam (mm)
Ⅰ	Ordinary diet	8-10
Ⅱ	Semi-liquid diet	6-8
Ⅲ	Liquid diet	4-6
Ⅳ	No drinking	2-4
Ⅴ	Saliva refluxing	0-2

According to the most recent World Health Organization (WHO) definition of aged people, people who are 65 to 74 years old are categorized as "young aged", and people who are 75 to 90 years old are classified as "older people". All the patients were divided into two groups as follows: patients older than 75 years were classified in the older group, and the remaining patients were classified in the control group. Of the 32 participants in the older group (ranging in age from 75 to 89 years old), 24 patients were male and 8 patients were female, with a median age of 79.5 years. Of the 38 participants in the control group (ranging in age from 55 to 74 years old), 29 patients were male and 9 patients were female with a median age of 64 years (Table 2).

Methods

The following chemotherapy program was used: L-OHP (65 mg/m^2 iv) was administered for 2 h on days 1 and 8; S-1 was orally administered at a dose of 40 mg/m^2 bid for 14 d (from the evening on day 1 until the morning on day 15); and a 7-d rest period followed the L-OHP and S-1 treatments in the 3-wk schedule. Treatment was repeated for four to six cycles. In every cycle, both omeprazole (40 mg iv bid) and tropisetron (5 mg iv qd) were administered before chemotherapy. Furthermore, large doses of oral vitamin B tablets were used to reduce side effects, and low doses of megestrol enhanced appetite and nutrition. Moreover, reconstituted cell colony-stimulating factor was given if needed. Participants were advised to avoid cold food, drinks and water. Blood, urine and stool routine examinations were carried out weekly, and ECG, liver function and kidney function were also checked weekly. Furthermore, a KPS score was determined weekly.

If patients had dysphagia to an extent greater than grade Ⅳ due to cardia stenosis, the stenosis was dilated with a conical Savary-Gilliard silica gel dilator one week before chemotherapy followed by insertion of a gastric canal. High protein and high vitamin liquid nasal feeds were then started. If the patient could swallow food after two chemotherapy cycles, the gastric canal was removed.

The sensitivity of the tumor to chemotherapy and improvement of dysphagia were evaluated after two cycles (6 wk). The effects and toxicity were evaluated at

four weeks with a repeat CT and barium meal examination after the chemotherapy was completed.

Evaluation criteria

Evaluation criteria for chemotherapy sensitivity: The evaluation criteria for chemotherapy sensitivity we used were proposed in 1998 by the European Association of Cancer Research and Treatment, United States National Cancer Institute, and National Cancer Institute of Canada. These evaluation criteria are called the Response Evaluation Criteria In Solid Tumors[17]. Participants had a repeat CT scan with contrast two weeks after the completion of chemotherapy to evaluate the therapeutic effects of the chemotherapy according to the maximum diameters of each tumor. A complete response (CR) was defined as the complete disappearance of all lesions after treatment. A partial response (PR) was defined as a decrease greater than or equal to 30% in the maximum diameters of all tumors after treatment. Progressive disease (PD) was defined as an increase greater than 20% in the maximum diameters of tumors or the emergence of more than one new lesion after treatment. When the tumor diameters were between the diameters found in the PR and PD classifications (< 30% decrease or ⩽ 20% increase) after treatment, the effect was classified as stable disease.

Evaluation criteria for improvement of dysphagia: The evaluation criteria for symptom improvement were based on diet intake and the increase/decrease in cardia diameter. The symptoms were assessed using the barium meal examination[18] with the following classifications: CR, post-treatment cardia diameter two times greater than or equal to the pre-treatment cardia diameter with the patient capable of eating ordinary food; PR, post-treatment cardia diameter one time greater than the pre-treatment cardia diameter with the patient capable of eating semi-liquid food; no change (NC), an increase in the cardia diameter by less than 6 mm with the patient capable of eating only liquid food; and PD, a decrease in the cardia diameter with the patient unable to eat liquid food.

Evaluation criteria for short-term effects: Participants had CT scans in the first and fourth week after the chemotherapy session ended. The area of each tumor (referring to the product of the two longest vertical diameters) was measured before and after chemotherapy. The following evaluation criteria were used[19]: CR, complete disappearance of visible lesions for more than one month; PR, a decrease greater than 50% in the tumor for more than one month; NC, a decrease less than 50% or an increase less than 25% in the tumor for more than one month; and PD, one or more lesions increased by greater than 25% or the emergence of a new lump.

Evaluation criteria for side effects: Toxicities were divided into degrees from 0 to Ⅳ according to the WHO criteria for acute and subacute toxic reactions of antineoplastic agents[19].

Statistical analysis

SPSS 10.0 statistical software (SPSS Company, Chicago, Illinois, United States) was used to perform the χ^2 test to evaluate the data. P values less than 0.05 were considered statistically significant.

RESULTS

Chemotherapy sensitivity

A repeat CT of the epigastrium two weeks after starting chemotherapy with the SOX program measured changes in the diameter of the largest tumor and evaluated the sensitivity to chemotherapy of the older group and control group (Table 3).

Symptom (dysphagia) improvement

After two cycles of chemotherapy with the SOX program, an upper gastrointestinal barium meal examination was repeated. Changes in cardia diameters were measured and calculated, and patients were asked about their diets. Symptom improvement was evaluated and compared between groups (Table 4).

Short-term therapeutic effects

After one week and four weeks of chemotherapy with

the SOX program, abdominal CTs were repeated. The maximum diameters of the tumors were measured, and the short-term therapeutic effects in both groups were evaluated (Table 5).

Side effects

The most frequent toxic therapy effects were hematological effects in both groups [grade 3 toxicity found in 13 patients (6 in the older group and 7 in the younger group)]. No grade 4 toxicity was reported. The L-OHP-related peripheral neuropathy appeared to be mild and reversible in the majority of cases. No severe cardiac toxicity or death was recorded among these patients during the study. Details of the side effects are shown in Table 6.

DISCUSSION

The health of the elderly varies from the health of younger patients. Older people are prone to having multiple organ dysfunctions, lower immunity, lower resistance to disease, and lower resistance to senile diseases, leading to reduced tolerance to chemotherapy and increased sensitivity to side effects of these drugs. Generally, caution is required when administering chemotherapy to older patients because they may not be able to tolerate a routine dose or may experience serious side effects. However, a suboptimal dose may not achieve the desired therapeutic effect. Therefore, many experts avoid treating elderly patients with chemotherapy[20].

There is evidence[9,21], however, that older patients with advanced gastroesophageal carcinoma may benefit from chemotherapy. Tougeron *et al*[9] reported that palliative treatment is superior to BSC (6.7 ± 2.1 mo *vs* 1.8 ± 0.4 mo) in older patients (> 70 years of age) with advanced esophageal cancer. The effect of S-1 and cisplatin combination therapy in an 80-year-old patient with gastric carcinoma has been reported in a case study, and the histopathological examination of this patient revealed CR of the disease with no cancer cells[21]. Nevertheless, data regarding GCA is limited.

In this study, the SOX program was used to treat elderly people with advanced GCA to achieve the following goals: (1) to enhance the efficacy of treatment by using a new drug; (2) to reduce toxicity and improve tolerance; and (3) to create an opportunity for treatment in elderly patients with poor health.

S-1 is an effective derivative that combines tegafur with the following two modulators of 5-FU metabolism in a 1:0.4:1 molar ratio: 5-chloro-2,4-dihydroxypyridine (CDHP), a reversible inhibitor of dihydropyrimidine dehydrogenase (DPD), and potassium oxonate[12]. Tegafur, an oral prodrug of 5-FU, is gradually converted to 5-FU and is rapidly metabolized by DPD in the liver. The maximum concentration (Cmax) and area under the concentration-time curve (AUC) of 5-FU in plasma during S-1 treatment have been found to be higher than the steady state concentration and AUC of 5-FU in plasma during protracted intravenous infusion of 5-FU at a dose of 250 mg/m^2 per day[22]. Potassium oxonate is an orotate phosphoribosyl transferase inhibitor, which is primarily distributed to the gastrointestinal tract. This component of S-1 decreases incorporation of 5-fluorouridine triphosphate into RNA in the gastrointestinal mucosa, and it reduces the incidence of diarrhea. F-b-alanine (FBAL) is the main metabolite of 5-FU. FBAL and fluorocitrate are thought to cause the neurotoxic and

cardiotoxic effects of 5-FU by inhibiting the tricarboxylic acid cycle[22]. The CDHP component of S-1 inhibits DPD, which is the rate-limiting enzyme in the catabolic pathway of 5-FU. Consequently, the plasma FBAL concentration after oral administration of S-1 is significantly lower than the concentration after continuous infusion of 5-FU[12]. Therefore, the use of S-1 may decrease the incidence of neurotoxicity and cardiotoxicity. Ajani *et al*[23] reported significant safety advantages in the S-1/cisplatin treatment as compared with the infusional fluorouracil/cisplatin treatment for advanced gastric or gastroesophageal adenocarcinoma. They reported the following frequencies resulting from the two treatments: grade 3/4 neutropenia (32.3% and 63.6%, respectively), stomatitis (1.3% and 13.6%, respectively), and hypokalemia (3.6% and 10.8%, respectively).

L-OHP[24-25] is a third generation platinum anticancer drug developed to improve tolerability and ease of administration when compared to cisplatin. The rate at which L-OHP combines with DNA in the body is more than 10 times faster than cisplatin. L-OHP adheres more strongly to DNA, and it has a stronger cytotoxic effect than cisplatin and carboplatin. In addition, the unique diaminocyclohexane group in oxaliplatin avoids some of the resistance mechanisms developed against cisplatin, such as the mismatch repair defect and bypass replication mechanism. A phase Ⅲ trial[26] for metastatic gastroesophageal adenocarcinoma has been conducted, with a treatment of fluorouracil and leucovorin combined with either oxaliplatin [fluorouracil, leucovorin and oxaliplatin (FLO)] or cisplatin [fluorouracil, leucovorin and cisplatin (FLP)] every two weeks. The results of this trial demonstrated that serious adverse events associated with FLO are significantly less than the events associated with FLP (9% and 19%, respectively) and that the median progression-free survival (PFS) improves with FLO when compared to FLP (5.8 mo and 3.9 mo, respectively). This trial also demonstrated that treatment with FLO results in significantly superior response rates (41.3% and 16.7%, respectively), improved median PFS (6.0 mo and 3.1 mo, respectively) and improved overall survival (13.9 mo and 7.2 mo, respectively) when compared to treatment with FLP in patients older than 65 years.

Studies have shown that L-OHP and S-1 are highly active against cancer and that they have a favorable toxicity profile. Furthermore, studies have also shown that L-OHP and S-1 are expected to replace cisplatin and fluorouracil, respectively, as a first-line treatment for advanced gastric cancer[13-15]. Moreover, the SOX program may be considered for treatment of older people because of the greater efficacy and low toxicity of this regimen when compared to cisplatin and fluorouracil.

The SOX regimen in this study resulted in no significant differences between the older and control groups with regard to chemotherapy sensitivity (65.6% and 68.4%, respectively, $P = 0.804$), symptom improvement (78.1% and 76.3%, respectively, $P = 0.857$), and short-term therapeutic effects (68.8% and 65.8%, respectively, $P = 0.793$). More severe side effects caused by the SOX regimen were not detected among the elderly patients when compared to the younger patients, and these side effects did not have a significant effect on treatment administration or quality of life. Therefore, these results suggest that there are treatment options available for elderly patients with cardia obstruction who cannot eat and that there is still an opportunity for these patients to survive if they can get adequate nutrition through nasal feeds.

In summary, the SOX regimen for advanced GCA has high efficacy and mild toxicity, and it can increase the survival and life span of patients with GCA. Moreover, the SOX regimen is a safe chemotherapy program for elderly patients in poor health. Therefore, it is not necessary to entirely avoid chemotherapy in elderly patients with advanced GCA because of their age. Instead, treatment recommendations should consider physiological age and standard KPS score. It is also reasonable to initiate chemotherapy if the patient can obtain sufficient nutrition (e.g., through nasal feeding). However, chemotherapy should not be administered to patients with KPS scores less than 60 points.

In this study, the therapeutic effects of the SOX regimen in both groups were higher than those reported in previous studies of patients with gastric cancer[13-15], which may have been due to the fact that this combination therapy was the first time any of the patients in this study were treated with chemotherapy, resulting in a higher sensitivity and minimal resistance to treatment. Other studies have included patients who had relapsed or failed treatment. Moreover, most of the patients in this study were classified as having stage Ⅲb GCA with only locally advanced cancer. In this study, there were only a few extensive cases of metastasized cancer. Additionally, the SOX program may be more effective at treating GCA than other types of gastric cancer.

COMMENTS

Background

The morbidity of gastric cardiac adenocarcinoma (GCA) in elderly people is gradually increasing, and most elderly GCA patients suffer from advanced carcinoma. Therefore, the opportunity for surgery is low, and only systemic chemotherapy is available for these patients. However, many experts disagree with treating elderly patients with chemotherapy because more serious adverse events have been observed in older patients than in younger patients.

Research frontiers

In the last decade, 5-fluorouracil (5-FU) has been considered a cornerstone for treating advanced gastrointestinal cancers. S-1 is a new orally active prodrug of 5-FU, and clinical studies with S-1/L-OHP (SOX regimen) have reported a high response rate ranging from 53% to 59% and an excellent toxicity profile in the treatment of advanced gastric cancer. In these clinical studies, however, there were only a few patients who were 75 years of age or older. Moreover, only a few studies on the outcome of the SOX regimen in patients with GCA have been reported.

Innovations and breakthroughs

This is the first study to evaluate the effects and safety of the SOX regimen in older patients with GCA. The study showed that the SOX regimen is a safe chemotherapy program for elderly patients with advanced GCA and that this regimen provides a treatment option for elderly patients with GCA.

Applications

The SOX regimen may be an ideal strategy in the future for treatment of older patients with advanced GCA.

Peer review

It is a very interesting topic for the readers.

Abstract

The presence of hepatic portal venous gas (HPVG) is associated with numerous diseases, and has been regarded as a serious, even catastrophic condition. However, anecdotal reports mention that some patients with inflammatory bowel disease (IBD), who developed HPVG after diagnostic examinations of the colon, were successfully managed with antibiotic therapy and have followed benign courses. In contrast, among IBD patients, the development of HPVG is rarely caused by enterovenous fistula. We describe a 32-year-old man with Crohn's ileocolitis who presented with hypotension and fever associated with HPVG, as well as superior mesenteric vein thrombosis, possibly caused by enterovenous fistula, who was successfully managed by surgery. We also review the literature concerning portal venous gas associated with Crohn's disease.

Key words: Crohn's disease; Enterovenous fistula; Portal venous gas

INTRODUCTION

Hepatic portal venous gas (HPVG), as first described in 1955[1], has been reported in many illnesses, ranging from benign conditions to potentially lethal diseases that require urgent surgical intervention[2]. Overall mortality depends on the underlying disease[3].

Among the various diseases, HPVG associated with Crohn's disease (CD) has rarely been described. With regard to the treatment of patients with CD complicated with HPVG, some anecdotal reports suggested that conservative treatment with antibiotics might be effective. However, early recognition and urgent operative intervention at the time of presentation are still important in patients with complicated CD. We report a 32-year-old patient with CD who presented with fever and hypotension associated with HPVG and mesenteric vein thrombosis who was successfully managed surgically. To our knowledge, this is the first report of HPVG and mesenteric vein thrombosis possibly caused by enterovenous fistula complicated by CD in South Korea. The literature concerning PVG associated with CD is also reviewed.

CASE REPORT

A 32-year-old man was referred for evaluation of mesenteric and portal venous gas detected by abdominal

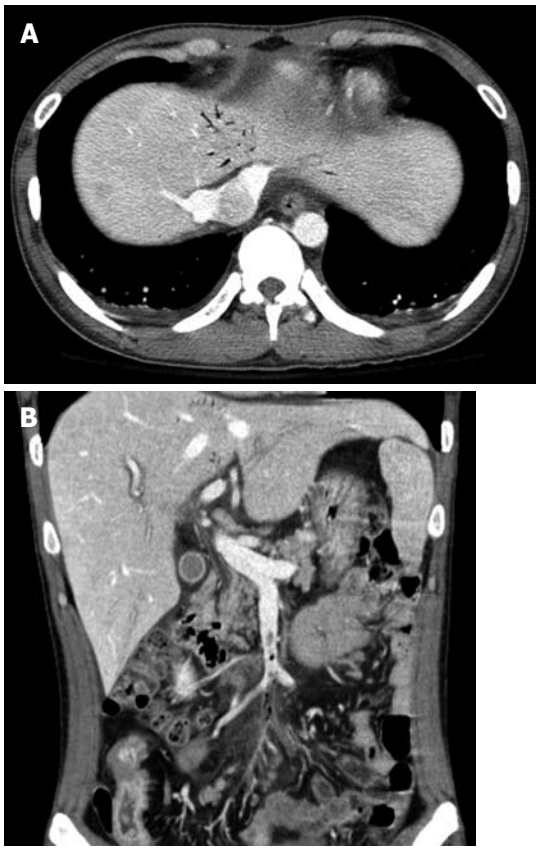

Figure 1 Computed tomography of the abdomen showing evidence of (A) portal venous gas, and (B) superior mesenteric venous gas and thrombus.

Figure 2 Computed tomography of the abdomen showing evidence of prominent wall thickening with perienteric infiltration in the mid-ileum.

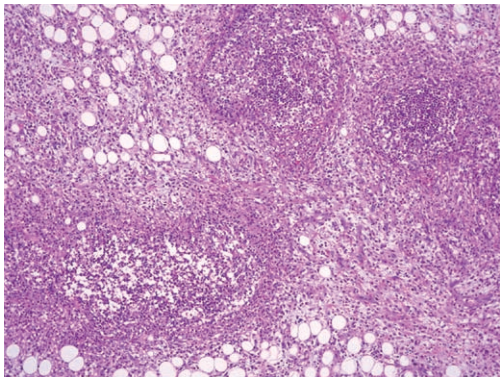

Figure 3 Photography of the pathology, showing the accumulation of many neutrophils in the intravascular lumen (hematoxylin and eosion stain, × 100).

computerized tomography (CT). The patient had complained of lower abdominal pain, nausea, vomiting, and fever. He was diagnosed with CD complicated by perianal fistula 12 years prior to admission, and was treated with azathioprine (25 mg/d) and 5-aminosalicylate (ASA; 3.2 g/d). He had been in his usual state of health on azathioprine and ASA until abdominal pain developed 21 d before admission at which time budesonide (9 mg/d) was added to his regimen of azathioprine and ASA. He continued on all three medications for three weeks until developing fever 2 d prior to admission. At that time, an abdominal CT showed mesenteric and portal venous gas. He was then referred to this hospital.

At admission, his body temperature was 38.5 ℃, blood pressure was 82/47 mmHg, and pulse rate was 105 beats per minute. There was moderate tenderness on the lower abdomen, but no abdominal distension or signs of peritoneal irritation. His white blood cell count was 4600/mm^3 (normal range 4000-10 000/mm^3) with 87% segmented forms. Protein was 4.9 g/dL (normal range 3.5-5.2 g/dL), albumin was 2.1 g/dL (normal range 6.0-8.5 g/dL), C-reactive protein was 21.19 mg/dL (normal range < 0.3 mg/dL), prothrombin time was 1.41 international normalized ratio (INR) (normal range 0.84-1.21 INR), and activated partial thromboplastin time was 37.3 s (normal range 26.3-39.4 s). Plain abdominal films were unremarkable. Abdominopelvic CT revealed the presence of air bubbles in the hepatic portal vein, superior mesenteric vein (SMV), and its contributaries. Intravenous thrombi were also noted (Figure 1). With regard to the bowel, multiple segments of the small bowel were thickened in the mid to the distal ileum and distal colon, especially in a 20 cm segment of the mid-ileum, near the mesenteric venous gas (Figure 2). The abdominopelvic CT findings were compatible with CD complicated with thrombophlebitis of the SMV. Hence, an explorative laparotomy was performed. At operation, a small amount of serous ascites was noted throughout the peritoneal cavity with multiple strictures and areas of inflammation which were also noted along the mid to distal ileum. Moreover, a short segment of mid-ileum showed phlegmonous change. Ileocecal resection was performed. Pathologic examination disclosed transmural inflammation with lymphoid aggregates, multiple microgranulomas and a fistulous tract. In addition, many neutrophils had accumulated in the intravascular space, suggesting the presence of an enterovenous fistula (Figure 3).

After surgery, the patient had an uneventful recovery and was discharged 9 d post surgery. The patient has been on 3 g of mesalazine and 25 mg of 6-mercaptopurine for his colonic disease and has been well for 4 mo after surgery.

DISCUSSION

HPVG has been reported in association with numerous conditions in adults, including intestinal ischemia or necrosis[4], intra-abdominal abscess[5], diverticulitis[6], pneumatosis intestinalis[7], and blunt trauma[8]. When HPVG occurred in association with necrotic bowel, the overall mortality rate rose to about 75%[9]. Thus, in the past, HPVG has been considered as an indicator for urgent surgical intervention with a poor prognosis. However, the development of highly advanced imaging techniques enables earlier detection of potentially severe pathologies, such as bowel ischemia, and allows prompt diagnosis and treatment, which results in significantly reduced mortality rates[10]. HPVG is not always a surgical condition, and its treatment should be based on the underlying disease and the patient's current clinical condition. HPVG in patients with inflammatory bowel disease can be caused by mucosal damage alone, or can occur in combination with bowel distension, sepsis, invasion by gas-producing bacteria, or after colonoscopy, upper gastrointestinal barium examination, barium enema or blunt abdominal trauma. Not all of these conditions require surgical intervention, especially in the absence of peritoneal signs or free gas in the peritoneal space[2].

The prognosis is related to the pathology itself and is not influenced by the presence of HPVG. Among 182 case studies reported by Kinoshita *et al*[2], patients with ulcerative colitis or CD comprised 4% of the total. To our knowledge, 21 cases of PVG associated with CD were reported in the English literature[11-13].

The formation of HPVG in patients with CD can be explained by the following hypothesis; first, elevated intracolonic pressure can permit bowel gas or gas-forming bacteria to gain access to the portal venous circulation. Elevated intracolonic pressure caused by blunt abdominal trauma, or by diagnostic procedures such as colonoscopy or barium enema occurred in 2 and 6 out of 21 patients, respectively, that had relatively benign clinical courses and rarely needed surgical intervention; only one of the eight required surgery. Second, the enterovenous fistula, which is an extremely rare complication of CD, can directly transfer bowel gas to the portal venous system. To date, HPVG associated with enterovenous fistula has been reported in 2 patients[14,15]. Two CD patients with enterovenous fistula required surgery, and one died due to sepsis. Third, HPVG can be the result of mucosal injury and sepsis associated with bowel inflammation and portal pyemia. Mucosal damage secondary to bowel inflammation provides an entry for intraluminal gas into the portal venous system. In addition, sepsis alone without necrotic bowel can be the cause of HPVG[9]. The remaining 11 patients included in that study, who had no identifiable predisposing factors, may have developed HPVG by this mechanism.

In our patient, the second mechanism is the most plausible explanation for HPVG based on surgical pathology and CT findings. Although there was no definite communication between bowel and vessel shown on the abdominal CT scan, a thrombosed vessel along with a thickened bowel suggests possible communication. The fistula between the small bowel and small branches of the superior mesenteric vein was not easily identified on CT because of its small size. Furthermore, histopathology showed many neutrophils accumulated in the intravascular space, an occluded small mesenteric vein caused by inflammatory thrombus, and no evidence of bowel ischemia. Based on the clinical features, histopathology, and imaging findings, mesenteric venous thrombosis was not a plausible diagnosis.

In eleven patients without a predisposing condition, eight (73%) presented with signs of intra-abdominal catastrophe or systemic toxicity and required surgery. One of eight died of disseminated cytomegalovirus infection, and the remaining three out these eleven patients were conservatively managed.

Two cases were reported with a combination of PVG and thrombophlebitis of the portal vein or SMV. These patients presented with septic shock and needed surgical treatment[11,16]. Although PVG itself is not a prognostic indicator, PVG combined with thrombophlebitis of the portal or mesenteric veins can be regarded as an indicator of poor prognosis.

Although the incidence of CD in Asians is still much lower than in Western patients, recent studies have reported that the incidence of CD in Asian populations is gradually increasing[17,18]. As the number of patients with CD increases, the proportion of complicated CD patients also increases. Although PVG accompanied by mesenteric venous thrombosis occurs very rarely in patients with CD, it complicates treatment decisions for the gastroenterologist. Thus, we should exercise caution regarding the clinical management in cases of CD with HPVG. HPVG associated with CD does not always mandate surgical intervention, especially in the absence of peritoneal signs or free intraperitoneal gas. Those patients found to have significant intestinal pathology, as in this case, as seen from imaging studies, or all other symptomatic patients who do not improve after medical treatment, should undergo urgent laparotomy[10]. The clinical course seems to be associated with predisposing factors, such as in this case, where hypotension and fever necessitated urgent surgery.

In conclusion, the finding of PVG is not always an indication for surgical intervention in CD, but PVG caused by enterovenous fistula requires urgent surgical treatment.

ISSN 1007-9327 (print) ISSN 2219-2840 (online)

Events Calendar 2011

January 14-15, 2011
AGA Clinical Congress of Gastroenterology and Hepatology: Best Practices in 2011 Miami, FL 33101, United States

January 20-22, 2011
Gastrointestinal Cancers Symposium 2011, San Francisco, CA 94143, United States

January 27-28, 2011
Falk Workshop, Liver and Immunology, Medical University, Franz-Josef-Strauss-Allee 11, 93053 Regensburg, Germany

January 28-29, 2011
9. Gastro Forum München, Munich, Germany

February 4-5, 2011
13th Duesseldorf International Endoscopy Symposium, Duesseldorf, Germany

February 13-27, 2011
Gastroenterology: New Zealand CME Cruise Conference, Sydney, NSW, Australia

February 17-20, 2011
APASL 2011-The 21st Conference of the Asian Pacific Association for the Study of the Liver
Bangkok, Thailand

February 22, 2011-March 04, 2011
Canadian Digestive Diseases Week 2011, Vancouver, BC, Canada

February 24-26, 2011
Inflammatory Bowel Diseases 2011-6th Congress of the European Crohn's and Colitis Organisation, Dublin, Ireland

February 24-26, 2011
2nd International Congress on Abdominal Obesity, Buenos Aires, Brazil

February 24-26, 2011
International Colorectal Disease Symposium 2011, Hong Kong, China

February 26-March 1, 2011
Canadian Digestive Diseases Week, Westin Bayshore, Vancouver, British Columbia, Canada

February 28-March 1, 2011
Childhood & Adolescent Obesity: A whole-system strategic approach, Abu Dhabi, United Arab Emirates

March 3-5, 2011
42nd Annual Topics in Internal Medicine, Gainesville, FL 32614, United States

March 7-11, 2011
Infectious Diseases: Adult Issues in the Outpatient and Inpatient Settings, Sarasota, FL 34234, United States

March 14-17, 2011
British Society of Gastroenterology Annual Meeting 2011, Birmingham, England, United Kingdom

March 17-19, 2011
41. Kongress der Deutschen Gesellschaft für Endoskopie und Bildgebende Verfahren e.V., Munich, Germany

March 17-20, 2011
Mayo Clinic Gastroenterology & Hepatology 2011, Jacksonville, FL 34234, United States

March 18, 2011
UC Davis Health Informatics: Change Management and Health Informatics, The Keys to Health Reform, Sacramento, CA 94143, United States

March 25-27, 2011
MedicReS IC 2011 Good Medical Research, Istanbul, Turkey

March 26-27, 2011
26th Annual New Treatments in Chronic Liver Disease, San Diego, CA 94143, United States

April 6-7, 2011
IBS-A Global Perspective, Pfister Hotel, 424 East Wisconsin Avenue, Milwaukee, WI 53202, United States

April 7-9, 2011
International and Interdisciplinary Conference Excellence in Female Surgery, Florence, Italy

April 15-16, 2011
Falk Symposium 177, Endoscopy Live Berlin 2011 Intestinal Disease Meeting, Stauffenbergstr. 26, 10785 Berlin, Germany

April 18-22, 2011
Pediatric Emergency Medicine: Detection, Diagnosis and Developing Treatment Plans, Sarasota, FL 34234, United States

April 20-23, 2011
9th International Gastric Cancer Congress, COEX, World Trade Center, Samseong-dong, Gangnam-gu, Seoul 135-731, South Korea

April 25-27, 2011
The Second International Conference of the Saudi Society of Pediatric Gastroenterology, Hepatology & Nutrition, Riyadh, Saudi Arabia

April 25-29, 2011
Neurology Updates for Primary Care, Sarasota, FL 34230-6947, United States

April 28-30, 2011
4th Central European Congress of Surgery, Budapest, Hungary

May 7-10, 2011
Digestive Disease Week, Chicago, IL 60446, United States

May 12-13, 2011
2nd National Conference Clinical Advances in Cystic Fibrosis, London, England, United Kingdom

May 19-22, 2011
1st World Congress on Controversies in the Management of Viral Hepatitis (C-Hep), Palau de Congressos de Catalunya, Av. Diagonal, 661-671 Barcelona 08028, Spain

May 21-24, 2011
22nd European Society of Gastrointestinal and Abdominal Radiology Annual Meeting and Postgraduate Course, Venise, Italy

May 25-28, 2011
4th Congress of the Gastroenterology Association of Bosnia and Herzegovina with international participation, Hotel Holiday Inn, Sarajevo, Bosnia and Herzegovina

June 11-12, 2011
The International Digestive Disease Forum 2011, Hong Kong, China

June 13-16, 2011
Surgery and Disillusion XXIV SPIGC, II ESYS, Napoli, Italy

June 14-16, 2011
International Scientific Conference on Probiotics and Prebiotics-IPC2011, Kosice, Slovakia

June 22-25, 2011
ESMO Conference: 13th World Congress on Gastrointestinal Cancer, Barcelona, Spain

June 29-2, 2011
XI Congreso Interamericano de Pediatria "Monterrey 2011", Monterrey, Mexico

September 2-3, 2011 Falk Symposium 178, Diverticular Disease, A Fresh Approach to a Neglected Disease, Gürzenich Cologne, Martinstr. 29-37, 50667 Cologne, Germany

September 10-11, 2011
New Advances in Inflammatory Bowel Disease, La Jolla, CA 92093, United States

September 10-14, 2011
ICE 2011-International Congress of Endoscopy, Los Angeles Convention Center, 1201 South Figueroa Street Los Angeles, CA 90015, United States

September 30-October 1, 2011
Falk Symposium 179, Revisiting IBD Management: Dogmas to be Challenged, Sheraton Brussels Hotel, Place Rogier 3, 1210 Brussels, Belgium

October 19-29, 2011
Cardiology & Gastroenterology | Tahiti 10 night CME Cruise, Papeete, French Polynesia

October 22-26, 2011
19th United European Gastroenterology Week, Stockholm, Sweden

October 28-November 2, 2011
ACG Annual Scientific Meeting & Postgraduate Course, Washington, DC 20001, United States

November 11-12, 2011
Falk Symposium 180, IBD 2011: Progress and Future for Lifelong Management, ANA Interconti Hotel, 1-12-33 Akasaka, Minato-ku, Tokyo 107-0052, Japan

December 1-4, 2011
2011 Advances in Inflammatory Bowel Diseases/Crohn's & Colitis Foundation's Clinical & Research Conference, Hollywood, FL 34234, United States

World J Gastroenterol 2011 December 21; 17(47): I-VI
ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

In spite of the well-established understanding of the phenotypic lesions occurring in the shift from native epithelia to invasive (adeno) carcinoma, the molecular typing of the precancerous changes in the gastrointestinal tract remains unreliable. In recent years, no biomarkers have aroused as much interest as the miRNAs, a class of non-coding RNA molecules that function as endogenous silencers of numerous target genes. Aberrant miRNA expression is a hallmark of human disease, including cancer. Unlike most mRNAs, miRNAs are both long-living *in vivo* and very stable *in vitro*. Such characteristics allow their testing in paraffin-embedded tissue samples, which is essential in the biological profiling of small (phenotypically characterized) preneoplastic lesions of the gastrointestinal tract (as well as in other fields of human pathology). The upcoming challenge lies in the reliable identification of disease-specific targets of dysregulated miRNAs, to enable miRNA testing in the clinical management of the secondary prevention of gastrointestinal cancer.

Key words: miRNA; Dysplasia; Barrett's esophagus; Atrophic gastritis; Inflammatory bowel disease

Peer reviewer: Wendy Wilhelmina Johanna de Leng, PhD, Department of Pathology, Internal address H04.312, Heidelberglaan 100, Postbox 85500, Utrecht, 3508 GA, The Netherlands

INTRODUCTION

The molecular mechanisms involved in the multistep processes of gastrointestinal (GI) cancers are one of the most intriguing research fields in pathology.

In spite of our well-established understanding of the phenotypic lesions occurring in the shift from native epithelia to invasive (adeno)carcinoma, the molecular typing of the precancerous changes in the GI tract remains unreliable due to: (1) discrepancies in their histological classification; (2) their inherent biological heterogeneity; and (3) their variability on molecular biology testing. As a result, no reliable molecular data are currently available that can be implemented with confidence in GI cancer secondary prevention strategies[1,2].

Molecular profiling, as achievable using well-characterized histology samples, would ideally be done using formalin-fixed, paraffin-embedded (FF-PE) tissue

Table 1 miRNAs associated with different histological lesions of the gastrointestinal tract

samples. Unfortunately, molecular profiling from FF-PE samples is patchy, which makes it difficult to integrate molecular data (gene expression arrays, among others) with histological information consistently[3-5].

Hence the priority to overcome this methodological impasse. Despite efforts made by the scientific community to identify biomarkers for human cancer, no such biomarkers have aroused as much interest as the miRNAs, a class of endogenous, small, non-coding RNAs that modulate gene expression by causing target mRNA degradation or inhibiting their translation[6-10]. Since their initial discovery in *Caenorhabditis elegans* (*C. elegans*) in 1993[11], an enormous amount of research has been published, indicating that the biological function of miRNAs is crucial to most cellular processes. In humans, aberrant miRNA expression is a hallmark of various diseases, including cancer[9,10]. Unlike most mRNAs (due to their molecular structure), miRNAs are long-living *in vivo* and very stable *in vitro*[3-5]. These particular features are fundamental to their analysis in FF-PE samples, supporting a potentially central role for miRNAs in the molecular study of preneoplastic GI lesions.

Focusing on the similar, multistep carcinogenic cascade occurring in both esophageal and gastric adenocarcinomas, and on the colorectal carcinogenic processes, this Editorial briefly discusses the role of miRNAs in preneoplastic GI pathology.

miRNAs AS DIAGNOSTIC TOOLS

miRNA expression profiling has the potential for differentiating between normal and pathological lesions, and among preneoplastic lesions, it may be able to classify different subtypes[9,10].

Several reports have already demonstrated the excellent reproducibility and accuracy of miRNA expression profiling in archived FF-PE specimens. In gastroenterology, as in other fields of human pathology, integrating genome-wide profiling with the functional characterization of miRNAs (their overexpression or downregulation) and the identification of miRNA-specific gene targets currently represents the approach most likely to yield advances in the new field of non-coding RNA research[6-8,12].

In FF-PE specimens, miRNA expression could also be visualized at cellular/sub-cellular level (*in situ* hybridization) and this particular characteristic makes miRNAs potentially suitable for supporting routine diagnostic surgical pathology practice[13,14].

Aberrant miRNA expression signatures have been extensively investigated in preneoplastic GI diseases and several key oncogenic miRNAs have consistently been found dysregulated (Table 1)[6-8,12,15-21]. In some cases, specific miRNA expressions have been linked to cancer-associated pathways, indicating a role for them in GI carcinogenesis. The systematic molecular evaluation of the GI mucosa (always supported by the "advanced" histological and clinical characterization of the specimens) not only provides new basic biological information, but can also pave the way to risk-stratified patient management programs and innovative therapeutic measures (Figure 1).

Therefore, miRNAs represent both potential cancer prognostic markers and therapeutic targets for the treatment of human malignancies. Further understanding of the biological roles of miRNAs in cancer is required, particularly the experimental validation of miRNA targets.

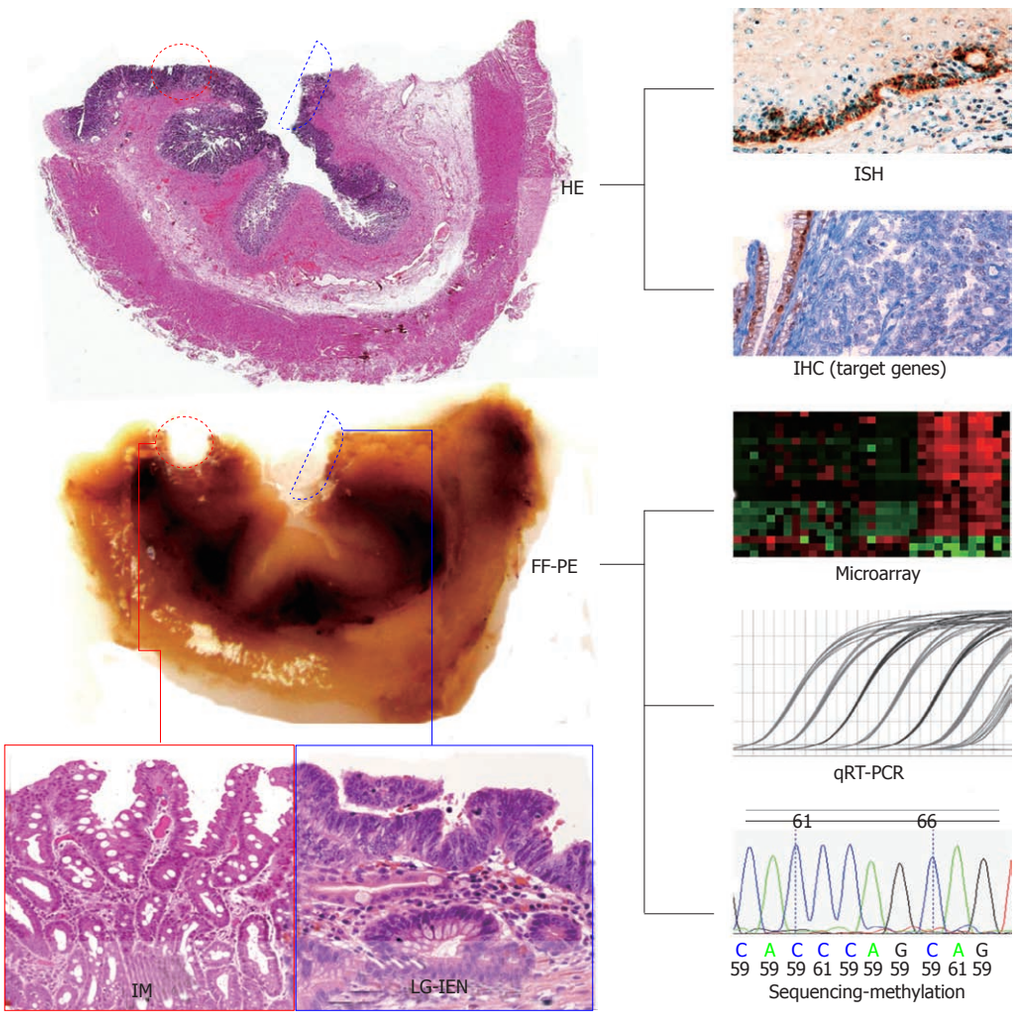

Figure 1 miRNA analysis in formalin-fixed, paraffin-embedded samples. Routine histological analysis (hematoxylin and eosin) enables adequate selection of preneoplastic lesions (in this case, intestinal metaplasia and low-grade-intraepithelial neoplastic lesions obtained from a resected Barrett's adenocarcinoma specimen). Either miRNA-specific *in situ* hybridization or immunohistochemical analysis of the miRNA gene targets could be performed starting from the original paraffin block. To obtain total RNA or DNA, lesions are macro-dissected from the paraffin block (or micro-dissected from unstained formalin-fixed, paraffin-embedded sections). The genome material can be further analyzed using modern genomic techniques. HE: Hematoxylin and eosin; FF-PE: Formalin-fixed, paraffin-embedded; IM: Intestinal metaplasia; LG-IEN: Low-grade-intraepithelial neoplastic lesions; ISH: *in situ* hybridization; IHC: Immunohistochemistry; qRT-PCR: Quantitative reverse transcription-polymerase chain reaction.

ONCOGENIC CASCADES IN GASTRO-ESOPHAGEAL CARCINOMA

In the last 25 years, it has been demonstrated that full-blown gastroesophageal cancers are the final outcome of long-standing biological processes that include a progressive accumulation of genotypic and phenotypic changes triggered by persistent inflammatory conditions, i.e., chronic acid/bile reflux in the esophagus and longstanding gastritis, due primarily to *Helicobacter pylori* (*H. pylori*) infection, in the stomach[1,2].

Such natural histories have been described as Barrett's model of carcinogenesis for esophageal adenocarcinoma and Pelayo Correa's multistage cascade for gastric adenocarcinoma[1,2].

At first, both conditions lead to the replacement of native by metaplastic epithelia [columnar epithelia in Barrett's esophagus (BE) and intestinal metaplasia of the native gastric glands][1,2]. The phenotypic shift involved in these processes is due to the combined effect of changes in the expression of genetic factors, epigenetic silencing, transcription factors, signaling pathways and growth factors. None of the biological mechanisms underlying the metaplastic transformation have been clarified in detail as yet, however, and genome-wide microarray expression analysis seems to be the most promising line of investigation.

There are significant differences in the pathogenetic, morphological (histochemical and immunohistochemical) and clinical impact of metaplasia in the two above-mentioned anatomical settings. Intestinal metaplasia (IM), however, is known as the "carcinogenic field" in which both esophageal and gastric intraepithelial neoplastic lesions (IENs), be it low-grade-IENs or high-grade (HG)-IENs and subsequent adenocarcinomas may develop[22-27].

The Barrett's cascade

BE is characterized by the native stratified squamous epi-

thelium lining the esophagus being replaced by a columnar epithelium with intestinal differentiation [Barrett's mucosa (BM)][2]. From the clinical point of view, only a histological diagnosis of IEN is currently considered in the definition of high-risk BE populations, confirming the need for prognostically useful, novel molecular biomarkers[28]. In this scenario, several reports have investigated miRNA expression profiling in Barrett's carcinogenesis[15,29-33].

In their seminal work, Feber *et al*[29] investigated miRNA expression profiling in a small series of frozen specimens (nine native squamous esophageal mucosa, five BM, one HG-IEN, and 10 Barrett's adenocarcinoma). Among the miRNA expression signatures observed, miR-203 and miR-205 were downregulated and miR-21, miR-192 and miR-194 were overexpressed in esophageal adenocarcinoma samples[29]. It is important to bear in mind that miR-194 is involved in the lineage commitment decisions of the intestinal epithelium system, with a major role in the maturation of the intestinal epithelium[34]. The authors also considered 10 squamous cell carcinoma specimens in their analysis, showing that specific miRNA expression profiles correspond to specific esophageal tumor histotypes[29].

Two further papers with consistent results focused on the miRNA expression signatures associated with disease progression[30,31]. Our group provided comprehensive information on the miRNA profile coupled with each single step in the natural history of Barrett's carcinogenesis[32]. To confirm our microarray and quantitative RT-PCR data, we also performed miRNA-specific *in situ* hybridization analyses on FF-PE tissues and identified HMGA2 (a let-7c mRNA target, which is a small, non-histone chromosomal protein that can modulate transcription by altering chromatin architecture) as a promising biomarker of BM transformation on immunohistochemical analysis. Based on these microarray findings, Bansal *et al*[33] recently have investigated the prognostic impact of miRNA expression in determining BE progression, demonstrating that miRNAs could pinpoint high-risk BE patients with a reasonable clinical accuracy.

In exploring the molecular mechanisms implicated in BM transformation and progression, Maru *et al*[35] have particularly focused on the role of miR-196a. As previously demonstrated by the same research group, miR-196a is overexpressed in neoplastic samples, and its expression levels increase proportionally with the dedifferentiation of the IEN[35]. Moreover, they have shown that miR-196a plays a part in the downregulation of the *SPRR2C*, *S100A9* and *KRT5* genes, the expression of which is characteristically decreased or lost during the neoplastic transformation of esophageal tissue[35]. These findings strongly support a role for miR-196a as a novel therapeutic target in the treatment of esophageal cancers and as a valuable early marker of cancer-prone BE.

Another important oncomiR is miR-21, which is upregulated in various human tumors, and has been found to be involved in Barrett's adenocarcinoma[29,31]. Recent studies have shown that miR-21 promotes cell transformation by repressing tumor suppressor genes such as *PTEN*, *PDCD4*, *RECK* and *TPM1*[3]. Our group has demonstrated significant miR-21 upregulation in samples of HG-IENs and adenocarcinoma, consistent with *PDCD4* downregulation[36].

The dysregulation of not just one, but multiple miRNAs could be implicated in cancer progression. miRNAs could be organized as a cluster of genes expressed by a single transcription unit (i.e., polycistron), which goes to show how complex miRNA research may be. The miR-106b-25 polycistron on chromosome 7q22.1 (i.e., miR-25, miR-93 and miR-106b) has been found to be increasingly activated in successive stages of Barrett's carcinogenesis, with potentially proliferative, antiapoptotic, and cell cycle promoting effects *in vitro* and tumorigenic effects *in vivo* by targeting *p21* and *Bim*[37].

From the therapeutic standpoint, argon plasma coagulation (thermal ablation) is one of the options for the surgical treatment of BE patients. BM ablation usually eventually results in the formation of neosquamous epithelium. IM can recur, however (so cancer could subsequently develop too) even after apparently complete BM ablation. Biomarkers might therefore be helpful in clinical decision-making for BE patients, by providing information on the likely clinical behavior of the mucosa after ablative therapy. That is why Dijckmeester *et al*[38] investigated miR-143 and miR-205 expression in neosquamous epithelium and BM. Only miR-143 expression was significantly higher in neosquamous and native squamous esophageal mucosa than in samples of BM[38]. It is worth adding that miR-143 is highly expressed in colonic tissues and has a significant role in suppressing colorectal cancer cell growth by inhibiting *KRAS* translation[39].

Different genetic polymorphisms could be implicated in miRNA-related carcinogenesis. The biogenesis of miRNAs is complex and involves multiple proteins and RNAs. Although miRNA expression profiles have frequently been reported to correlate with the etiology, classification, progression and prognosis of numerous human cancers, the effect of common genetic variants [i.e., single nucleotide polymorphisms (SNP)] of miRNA-related genes on susceptibility to cancer remains unclear[9,10]. Ye *et al*[40] have demonstrated that seven SNPs were significantly associated with the risk of esophageal adenocarcinoma, pointing to intriguing new fields of translational research.

Correa's cascade

Despite a steady decline in the related mortality in the past few decades, gastric cancer is still the second cause of death due to cancer worldwide[41]. *H. pylori*-associated gastritis is the most common gastric adenocarcinoma precursor (leading to intestinal-type, or the so-called "epidemic"gastric cancer)[42].

Matsushima *et al*[43] have investigated the miRNA expression profiling of *H. pylori*-positive mucosa samples, finding 31 significantly dysregulated miRNAs. The severity of both active and chronic inflammatory infiltration

significantly correlated with the expression of several miRNAs, supporting a biological role for miRNAs in host immune response to *H. pylori* infection[44]. Among others, miR-155 has been suggested as a central effector of *H. pylori*-induced immune response: *H. pylori* infection raises miR-155 expression levels in gastric epithelial cell lines and gastric mucosal tissues by activating nuclear factor-κB and the activator protein-1 pathway, and *via* the Foxp3 transcription factor in T cells[45,46]. The overexpressed miR-155 could also negatively modulate the release of the proinflammatory cytokines interleukin-8 and GRO-a, leading to chronic *H. pylori*-related infection[47].

Another important *H. pylori*-induced miRNA is miR-146a, which seems to have a role in a negative feedback loop that modulates the inflammatory damage by targeting *IRAK1* and *TRAF6*[47]. Two common SNPs in its pre-miRNA sequence (rs2910164 and rs11614913) have also been associated with a greater susceptibility to gastric cancer in the Chinese and Japanese populations[48].

Among healthy volunteers, individuals with *H. pylori* infection show higher methylation levels of miR-34b, miR-34c, miR-124a-1, miR-124a-2 and miR-124a-3[49,50]. These data strongly suggest that *H. pylori* infection (in addition to protein-coding genes) induces DNA methylation of miRNA genes, also indicating that miRNA silencing is an early event in the oncogenic process and the result of a global epigenetic field defect.

Another important miRNA that is dysregulated in chronic gastritis is miR-27a. Arisawa *et al*[51] have shown a close correlation between miR-27a genome polymorphism and the onset of advanced gastric mucosa atrophy in Japanese men, suggesting a definitive role for miR-27a in the development of the "cancerization field. These findings are further supported by the fact that miR-27a has been found upregulated in gastric cancer samples; it correlates with gastric cancer lymph node metastasis; and functions as an oncogene by targeting the tumor suppressor gene prohibitin[52].

miR-21 seems to play a fundamental part in gastric carcinogenesis, being constantly upregulated in gastric adenocarcinoma (as already demonstrated in others miscellaneous solid tumors, as well as Barrett's adenocarcinoma)[53]. *In vitro*, miR-21 upregulation has been shown to enhance significantly migration and capacity for invasion of gastric cancer cell lines[53]. On the other hand, miR-21 knockdown causes a significant reduction in cell proliferation and a significant increase in apoptosis[53]. miR-21 is also significantly overexpressed in *H. pylori*-infected gastric mucosa, suggesting an early, important involvement of miR-21 in the development of gastric cancer[53].

The tumor suppressor let-7a is one of the founder members of the miRNA family, which was first identified in *C. elegans*. In gastric cancer, let-7a is downregulated and negatively regulates HMGA2 expression (like let-7c)[54,55]. let-7a downregulation has already been identified in chronic atrophic gastritis samples[56].

The oncogenic miR-106a, a member of the miR-106a-92 cluster, has been found upregulated in gastric cancer tissues and it has been significantly associated with negative clinicopathological parameters[56,57]. The miR-106a-92 cluster has a marked gene structure homology with other miRNA clusters recognized as being oncogenic, i.e., miR-17-92 and miR-106b-25. On this point, Petrocca *et al*[58] have observed dysregulation of the miR-106b-25 cluster (i.e., miR-106b, miR-92 and miR-25) determined by transcription factor E2F1 expression in *H. pylori*-related gastric carcinogenesis and gastric cancer cell lines. miR-206b and miR-93 directly regulate E2F1 expression, establishing an miRNA-related negative feedback loop[58]. The upregulation of these miRNAs interferes with the transforming growth factor (TGF)-β tumor suppressor pathway, hindering the expression of CDKN1A and BCL2L11[58]. TGF-β controls the turnover of intestinal, as well as gastric, cells leading them to cell cycle arrest followed by apoptosis. By downregulating two of the most important downstream effectors in the TGF-β pathway, the miR-106b-25 cluster ensures the development of a resistance to TGF-β-mediated cell cycle arrest and apoptosis, and may represent an interesting novel therapeutic target for the treatment of gastric cancer. In the same study, the authors identified a seven-miRNA signature associated with chronic *H. pylori*-related gastritis, which included the above-mentioned miR-155[58].

ONCOGENIC CASCADES IN COLORECTAL ADENOCARCINOMA

The historically well-established pathway of sporadic colorectal cancer is the so-called adenoma-carcinoma sequence, formally described by Morson in 1962[59]. Approximately 60% of sporadic colorectal cancers (CRCs) are consistent with this phenotypic sequence. The lesions included in this "cascade" are tubular, tubulovillous and villous adenomas (with different IEN grades)[60].

More recently, however, molecular genetic findings have highlighted two further pathways: (1) serrated carcinogenesis, in which the sessile serrated adenoma is considered the precursor lesion; and (2) the mixed-type sequence, combining the molecular features of both the traditional and the serrated pathways[60,61].

A fourth route is the one resulting from longstanding/relapsing inflammation associated with inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC)[62,63]. The first report of CRC in IBD came from Crohn and Rosenberg in 1925[64]. From a molecular point of view, the IBD-related carcinogenic process seems to follow a temporal sequence of genetic alterations different from the situation seen in sporadic cancers. The IBD-related CRC risk increases in long-standing colitis and parallels the anatomical extent and severity of the related inflammation. From the pathological standpoint, IBD-associated CRC can arise from: (1) raised dysplastic lesions or dysplasia-associated lesions or masses; and (2) endoscopically flat dysplastic lesions. In both cases, the lesions can blend easily with the gross inflammatory abnormalities commonly encountered in IBDs, making their endoscopic detection difficult even for the experienced

endoscopist, resulting in the need for innovative dysplasia-specific biomarkers[61].

Sporadic colorectal cancer

A whole constellation of experimental studies on CRC has provided insight into the miRNA-mediated, regulatory links to well-known oncogenic and tumor suppressor signaling pathways[20,65-67].

Global miRNA downregulation is a common feature of colorectal carcinogenesis. As described previously for gastroesophageal diseases, CpG island hypermethylation has been described as a mechanism for miRNA silencing in CRC samples too. Balaguer *et al*[68] also have demonstrated high rates of miR-137 CpG island methylation in colorectal adenomas, suggesting that the epigenetic silencing of specific tumor-suppressor miRNAs is an early event in the multistep colorectal carcinoma cascade.

Several investigations on paired samples of colorectal neoplasia and normal mucosa have demonstrated reduced levels of miR-143 and miR-145 in both colonic adenoma and carcinoma[39]. These two miRNAs reveal a tumor suppressor-like activity *in vitro* by targeting *KRAS* (miR-143) and the insulin receptor substrate 1 (*IRS-1*; miR-145), among others[39].

Among the overexpressed miRNAs, miR-21 (an important regulator of PDCD4 expression) has frequently been found dysregulated in CRC samples[3,69]. Consistent with these data, we found that miR-21 was significantly upregulated in IEN and CRC biopsy samples, suggestive of a diagnostic role for this miRNA in discriminating between neoplastic and non-neoplastic lesions[70]. We observed a similar PDCD4 dysregulation in serrated adenomas too, suggesting a major oncogenic function for miR-21 that is acquired early in different pathways of colorectal carcinogenesis. Similar results were have been reported by Schmitz *et al*[71], who have found significant miR-21 overexpression in sessile serrated adenomas by comparison with both normal mucosa and hyperplastic polyps (though miR-21 expression alone failed to distinguish between the histological lesions considered).

Sequence variations in the miRNA-binding sites of *CD86* and *INSR* have been associated with a higher risk of CRC (with ORs of 2.74 and 1.94, respectively)[72,73]. These data, integrated with genome-wide association studies supported by high-resolution SNP arrays and next-generation sequencing technology, could help clinicians to assess CRC genetic susceptibility more accurately, with the prospect of stratifying patients according to their "molecular" cancer risk.

Inflammatory bowel diseases

IBDs result from an abnormal immune response to environmental factors in genetically susceptible hosts. miRNAs have been increasingly recognized as important in the development of both the innate and the adaptive immune system, and dysregulated miRNA expression has already been described in several immune-related diseases. miRNA expression profiling in active CD and UC has been the object of several studies, which have consistently shown unique disease-specific miRNA signatures[74-77]. Supporting the role of miRNAs in immune system dysregulation, Wu *et al*[78] have demonstrated that miR-192 (which is significantly upregulated in UC) blocks tumor necrosis factor α-induced stimulation by targeting the chemotactic cytokine *MIP-2a*. Fasseu *et al*[79] have studied both active and inactive IBD samples, and have demonstrated that miRNAs are crucial players in the onset/relapse of active inflammation. In particular, they have found two subsets of 14 (UC) and 23 (CD) miRNAs with a significant dysregulation in comparison to healthy controls (Table 1), and among these, eight that were commonly dysregulated in non-inflammed UC and CD (miR-26a, miR-29a, miR-29b, miR-30c, miR-126*, miR-127-3p, miR-196a, and miR-324-3p)[79]. What is more, underlying the importance of miRNA dysregulation in IBD onset, several miRNA genes with altered expression co-localized with acknowledged IBD-susceptibility loci[79].

miR-31a has been indicated as a specific marker of IBD-related dysplasia[80]. It is overexpressed in both IBD-related dysplasia and IBD-associated CRC (and also significantly increased in sporadic CRC, although to a lesser degree than in IBD-related neoplasia). Preliminary studies have demonstrated the angiogenic potential of miR-31 *via* the targeting of *FIH-1* in CRC-derived cell lines[80].

Beyond their histopathological applications, miRNAs offer a number of practical advantages due to their relatively high stability *in vivo*, and in the circulation in particular. In addition, they do not require the use of specific antibody-linked detection reagents of protein biomarkers, and they offer the specificity of nucleic acid detection methods such as RT-PCR. In IBD patients, differences in circulating immune cells in CD and UC are reflected by altered miRNA expression, supporting the usefulness of peripheral blood miRNA analysis as an innovative non-invasive class of biomarkers[81].

CONCLUSION

Preneoplastic lesions within the GI tract include a broad spectrum of phenotypic alterations, which may be difficult to assess only on the basis of their phenotypical features and are hard to stratify in different prognostic classes.

As this review shows, miRNAs and miRNA-related gene expression and polymorphism have a central role in assessing the individual (patient-specific) cancer susceptibility and cancer progression. The upcoming challenge lies in the reliable identification of disease-specific targets of dysregulated miRNAs, to enable miRNA testing in clinical practice. The miRNA revolution is only just beginning!

Abstract

The prevalence of type 2 diabetes mellitus (T2DM) is higher in patients who have liver diseases such as nonalcoholic fatty liver disease, chronic viral hepatitis, hemochromatosis, alcoholic liver disease and cirrhosis. It is suggested that there is a pathogenic link between the presence of T2DM and the severity of liver injury. However, evidence related to the impact of hepatic inflammation on the development of T2DM has not yet emerged. This article provides an overview of the evidence for an increased prevalence of diabetes in a range of liver diseases, the impact of liver diseases on insulin resistance and β cell dysfunction, and the potential mechanisms whereby coexistent liver diseases exacerbate the development of T2DM.

Key words: Hepatic inflammation; Insulin resistance; β cell dysfunction; Type 2 diabetes mellitus

INTRODUCTION

The prevalence of type 2 diabetes mellitus (T2DM) is higher in patients who have suffered from certain liver diseases. Therefore, it is speculated that there is a pathogenic link between liver disease progression and T2DM. For instance, nonalcoholic fatty liver disease (NAFLD) has been proposed as a term that encompasses a spectrum of fatty liver disease from steatosis to non-alcoholic steatohepatitis (NASH) through cirrhosis to end-stage liver disease[1,2]. Clinical investigations and epidemiologic studies have associated NAFLD and NASH in particular with the metabolic syndrome[3,4], with T2DM[1] as the pivotal pathogenic factor. However, the cause-effect relationship between NAFLD/NASH and diabetes remains elusive. On the other hand, cross-sectional and longitudinal studies have shown that chronic hepatitis C virus (HCV) infection is associated with an increased risk of developing insulin resistance and T2DM[5]. Moreover, high alanine aminotransferase level is associated with decreased hepatic insulin sensitivity and predicts the development of T2DM[6]. Pradhan *et al*[7] have reported that elevated levels of the inflammatory markers interleukin 6 (IL-6) and C-reactive protein (CRP, hepatic acute phase protein) were associated with the development of T2DM in healthy middle-aged women in a prospective, nested-control study. However, only limited evidence is emerging to identify the possible impact of liver diseases on the development of T2DM.

IMPACT OF LIVER DISEASES ON INSULIN RESISTANCE

Fatty liver diseases and insulin resistance

Fatty liver disease (FLD), whether it is alcoholic fatty liver disease (AFLD) or nonalcoholic fatty liver disease (NAFLD), encompasses a morphological spectrum consisting of hepatic steatosis (fatty liver) and steatohepatitis. The indistinguishable spectrum of histological features of both AFLD and NAFLD suggests a possible convergence of pathogenetic mechanisms at some critical juncture that enables the progression of steatohepatitis toward cirrhosis and liver cancer. Moreover, fat accumulation in the liver is, independent of body mass index and intraabdominal and overall obesity, characterized by several features of insulin resistance in normal weight and moderately overweight subjects[8].

Although NAFLD/NASH is generally considered as the result of insulin resistance syndrome including obesity, T2DM and hyperlipidemia, some recent studies implicate that NAFLD could also be a prediabetic condition. For example, Fan *et al*[9] conducted a retrospective study on a cohort of 358 individuals with hepatic ultrasound-defined fatty liver and 788 age-, sex- and occupation-matched controls for 4-7 years, which showed that metabolic syndrome components were present at a greater frequency among those with fatty liver than among controls. Population-based studies showed an association between elevated liver enzymes (as inflammatory markers of NAFLD) and a future potential for development of the metabolic syndrome[10,11].

On the other hand, it has also been reported that subjects with alcoholic liver disease have been shown to be at increased risk for T2DM[12]. Wei *et al*[13] showed that subjects with high alcohol intake (> 270 g/wk) have a 2-fold increased risk of developing T2DM compared with those with moderate alcohol intake (60-120 g/wk) in a prospective follow-up study of 8663 men. This association was independent of other risk factors, such as age, obesity, blood pressure, smoking and family history of diabetes. However, a similar relationship was not shown in a study with female subjects[14].

The pathogenesis of alcoholic fatty liver disease and NASH is multifactorial and includes several overlapping events. The accumulation of fat in hepatocytes (steatosis) and the onset of steatohepatitis may reflect successive stages in FLD. The "two-hit" hypothesis proposed by Day and James in 1998[15] postulates that the steatotic liver is susceptible to secondary insults including a vulnerability to reactive oxygen species, gut-derived endotoxins, and adipocytokines such as tumor necrosis factor-α (TNF-α) and other cytokines. The first "hit" is thought to be an accumulation of fatty acids and triglycerides within the liver, possibly due to insulin resistance. Chronic stress such as portal endotoxemia (the second "hit") leads to mitochondrial dysfunction and Kupffer cell adaptive changes[16,17], which in turn result in hepatocyte survival adaptation[18] and subsequent necrosis and/or apoptosis. Concomitant release of liver-derived inflammatory cytokines, i.e., TNF-α[19] and acute-phase proteins such as CRP, LPS binding protein and serum amyloid-P component[20] may induce some extrahepatic effects and then affect the development of T2DM. However, this hypothesis has not been directly examined in human and animal studies.

Viral hepatitis and insulin resistance

Recent studies have suggested that HCV infection is associated with an increased risk of development of T2DM, and that T2DM is more common among patients with chronic HCV infection than in patients with other liver diseases or in the general population, irrespective of whether or not hepatic cirrhosis is present[21]. Moreover, the conclusion of a prospective, case-cohort study conducted within a community-based cohort of 1084 persons aged 44-65 years suggests that pre-existing HCV infection may increase the incidence of T2DM in persons with known risk factors[22]. A community-based cohort survey performed in southern Taiwan enrolled 4958 persons aged ⩾ 40 years without T2DM. After a follow-up of 7 years, 474 cases of incident T2DM were recorded: overall, 14.3% of anti-HCV positive, 7.5% of HBsAg positive, and 8.6% of seronegative individuals developed T2DM during the study. Compared to anti-HCV negative individuals, anti-HCV positive persons had a higher cumulative incidence of T2DM ($P < 0.0001$)[23].

Hepatogenous diabetes

Up to 96% of cirrhotic subjects have impaired glucose tolerance or diabetes[24]. The term "hepatogenous diabetes" is used to describe the close association between cirrhosis and impaired glycemic control. There is less association with other T2DM-related risk factors such as age, obesity, smoking history, family history of diabetes and hypertension[24]. Cirrhosis may contribute to the development of T2DM through numerous factors such as reduced insulin clearance with peripheral hyperinsulinemia[25], which could contribute to the development of insulin resistance through the down-regulation of insulin receptors. Nevertheless, interaction of the cause of liver cirrhosis with environmental factors may also play a significant role in the link between cirrhosis and diabetes rather than development of cirrhosis alone.

IMPACT OF LIVER DISEASES ON β CELL DYSFUNCTION

The pancreas and the liver are in close proximity and many of the blood vessels and ducts in these organs are anatomically associated with each other. It was suggested that liver disease, regardless of the etiology, may predispose the patient to develop acute or chronic pancreatitis in an analysis of 107 754 adult autopsies in Japan[26]. In addition, exocrine pancreatic function has been reported to be damaged in chronic liver disease[27] and chronic viral hepatitis[28]. An animal study showed exacerbation of

acute pancreatitis in the presence of chronic liver injury in rats[29].

On the other hand, pancreatogenic diabetes, regarded as a form of "secondary diabetes"[30], accounts for 1% to 2% of all diabetic patients in North America but as many as 15% to 20% of diabetic patients in the Southeast Asian continents[31]. Many issues remain unknown regarding the etiology of pancreatic inflammation in pancreatogenic diabetes. In addition, clinical studies showed that the impairment of exocrine pancreatic function was more frequently seen in subjects with alcoholic and non-alcoholic liver diseases[32]. A recent investigation has been undertaken to clarify the effect of the inflammatory change of fatty liver on the development of β cell dysfunction in T2DM. It showed that the inflamed liver induced by mild portal endotoxemia was concomitantly combined with an impairment of pancreatic insulin secretion[33], suggesting that this may be a detrimental factor in the pathogenesis of β cell failure during development of T2DM and also pancreatogenic diabetes.

MECHANISMS UNDERLYING THE EFFECTS OF LIVER DISEASES ON T2DM

Gut microbiota

Wigg *et al*[34] reported a higher prevalence of small intestinal bacterial overgrowth (SIBO) and increased circulating TNF-α levels in patients with NASH. In addition, inflammatory liver damage in various rat models of SIBO is improved by antibiotic treatments[34,35]. A recent study from Brun *et al*[36] has demonstrated that genetically obese mice (*ob*/*ob* and *db*/*db* mice) display enhanced intestinal permeability leading to increased intraportal endotoxemia that can contribute to the liver inflammatory damage. These studies provide evidence to suggest that portal endotoxemia is a major risk factor in the pathogenesis of NASH. Furthermore, a recent investigation demonstrated that mild portal endotoxemia induced by low-dose intraportal LPS infusion intensified the inflammatory changes of fructose-induced fatty liver and also caused low-grade systemic inflammation in the absence of an increase in blood endotoxin levels, providing strong evidence to support the causal role of portal endotoxemia in development of NASH[37] .

On the other hand, Backhed *et al*[38] showed that germ-free mice gained significantly less weight and fat mass than conventionalized mice, and were protected against high-fat diet-induced glucose intolerance and insulin resistance, suggesting that a bacterially related factor/mechanism other than energy harvesting may be responsible for the development of diet-induced obesity and diabetes. In addition, gut microbiota, especially bacterial LPS, has recently been speculated to contribute to the low-grade inflammation in obesity, diabetes, NAFLD and cardiovascular disease[39]. Cani *et al*[40,41] showed that there was a significant increase in circulating LPS levels in mice on high-fat feeding for 2-4 wk. They reproduced metabolic endotoxemia in these high-fat fed mice by chronically infusing low-dose LPS for 4 wk to develop the same phenotype as those on a high-fat diet such as obesity, insulin resistance, diabetes, hepatic steatosis and adipose tissue macrophage infiltration. However, this high-fat associated phenotype was not exhibited in LPS receptor knockout mice (CD-14KO) with a high-fat diet. Moreover, CD14KO mice were hypersensitive to insulin, even when they were fed a normal diet, suggesting that CD14 could be a modulator of insulin sensitivity under physiological conditions.

Furthermore, recent study using chronic low-dose portal LPS infusion in rats to simulate low-grade portal endotoxemia and hepatic injury showed that increasing oxidative (malondialdehyde) and inflammatory TNF-α and IL-6 markers with pathogenic changes were not only exhibited in liver but also in the pancreas of experimental rats[33]. This data also showed that the sequential effects of inflamed fatty liver could further impair pancreatic β cell function in the absence of change in homeostasis model assessment-insulin resistance index, suggesting that the low-grade hepatic inflammation induced by intraportal low-dose LPS infusion is the significant detrimental factor for the early development of T2DM.

HCV infection

It is suggested that HCV may alter glucose homeostasis by its direct action[42], or *via* indirect mechanisms such as through cytokine stimulation. For instance, in the transgenic mouse model[43], the core-encoding region of HCV is sufficient to induce insulin resistance. The effect was reversed by treatment with anti-TNF-antibodies, which suggested an increased level of serine phosphorylation of IRS-1 as induced by TNF-α. Nevertheless, direct but genotype-specific mechanisms have been reported[44], in which down-regulation of peroxisome proliferator-activated receptor-γ (PPARγ) and up-regulation of SOCS-7 were observed in cells transfected with the core protein of genotype 3, whereas the core protein of genotype 1b activated the mammalian target of rapamycin. These findings were confirmed by using agonists for PPARγ or short interfering RNAs for SOCS-7[45]. Accordingly, the *in vitro* study of Kawaguchi *et al*[46] demonstrated that HCV proteins inhibit insulin signaling.

In addition, studies on chronically infected patients have suggested that increased oxidative stress and intrahepatic inflammation may also play a role[47]. In fact, an increased intrahepatic TNF-α response, which results in insulin resistance and a higher risk of developing T2DM in chronic HCV, has been described[48]. It is necessary to further investigate at a more in-depth level the causal relationship between HCV-induced hepatic inflammation and the development of T2DM.

Hepatic inflammation and obesity-associated insulin resistance

Subclinical inflammation is predictive of both cardiovascular diseases and T2DM. Inflammatory changes in visceral adiposity in obesity and chronic hepatic inflammation are etiologically and functionally intertwined, and

both may be associated with chronic systemic inflammation in the pre-diabetic state. To isolate the potential systemic effects of chronic subacute hepatic inflammation, Cai *et al*[49] conducted a study with non-obese transgenic mice expressing constitutively active I-Kappa-B kinase-β (IKK-β) in hepatocytes. Their data suggest that chronic low-grade hepatic inflammation could cause systemic insulin resistance mediated by elevated circulating IL-6 levels. Arkan *et al*[50] recently presented similar findings in mice lacking IKK-β in hepatocytes. Liver-specific deletion of IKK-β resulted in relative insulin sensitivity in the liver when animals were placed on a high-fat diet or were intercrossed with the *ob/ob* model of genetic obesity, but development of insulin resistance in muscle and fat occurred.

Hepatic fat accumulation

However, a recent study in rats with hepatic overexpression of glycerol-sn-3-phosphate acyltransferase 1 demonstrated that increased flux through the pathway of hepatic *de novo* triacylglycerol synthesis can cause hepatic and systemic insulin resistance in the absence of increased hepatic inflammation, suggesting that an excess flux of lipid intermediates in the pathway of triacyglycerol synthesis are sufficient to cause insulin resistance[51]. Accordingly, studies showing that liver fat content, much more strongly than visceral fat mass, determines insulin sensitivity in humans, support a direct and major role of fatty liver in the pathogenesis of insulin resistance[52,53].

Reactive oxygen species

Oxidative stress due to generation of reactive oxygen species and/or decreased antioxidant defenses[54] has been proposed as the root cause underlying the development of insulin resistance, β cell dysfunction, impaired glucose tolerance and T2DM. In both nonalcoholic steatohepatitis and experimental steatohepatitis, hepatic expression of CYP2E1 is increased, leading to oxidative stress, which has been demonstrated to impair insulin signaling[55].

Hepatokines

Recent studies have suggested that the mechanisms of fatty liver-induced metabolic diseases may differ from those of expanded adipose tissue mass. The new concept proposed is that the fatty liver releases factors in the circulation, similarly to expanded and inflamed adipose tissue (adipokines), which can be called hepatokines, and they have direct effects on target tissues. There is strong evidence to support the concept that hepatokines such as protein fetuin-A, sex hormone-binding globulin and selenoprotein P play an important role in the pathogenesis of insulin resistance and also subclinical inflammation[56,57].

CONCLUSION

The prevalence of T2DM is higher in patients who have liver diseases such as NAFLD, chronic viral hepatitis, alcoholic liver disease and cirrhosis. However, the cause-effect relationship between liver diseases and T2DM remains ambiguous. This article provides an overview of the evidence for the impact of chronic liver diseases on T2DM and examines up-to-date studies about the possible underlying mechanism. A better understanding of the deleterious factors which affect progression of chronic liver diseases are of clinical importance in order to monitor and treat T2DM patients with liver diseases.

Abstract

Considering the epidemiological, genetic and immunological data, we can conclude that the inflammatory bowel diseases are heterogeneous disorders of multifactorial etiology in which hereditability and environment interact to produce the disease. It is probable that patients have a genetic predisposition for the development of the disease coupled with disturbances in immunoregulation. Several genes have so far been related to the diagnosis of Crohn's disease. These genes are related to innate pattern recognition receptors, to epithelial barrier homeostasis and maintenance of epithelial barrier integrity, to autophagy and to lymphocyte differentiation. So far, the strongest and most replicated associations with Crohn's disease have been demonstrated with *NOD2*, *IL23R* and *ATG16L1* genes. Many genes have so far been implicated in the prognosis of Crohn's disease and many attempts have been made for classification of genetic profiles in Crohn's disease. *CARD15* seems to be not only a susceptibility gene, but also a disease-modifier gene for Crohn's disease. Enriching our understanding of Crohn's disease genetics is of value, but when combining genetic data with functional data the outcome could be of major importance to clinicians.

EVOLVING ROLE OF GENETICS IN CROHN'S DISEASE

Despite decades of research the etiology of inflammatory bowel diseases (IBD) remains largely unexplained, but considering together the epidemiological, genetic and immunological data, we can conclude that IBD are heterogeneous disorders of multifactorial etiology in which hereditability (genetic) and environment (microbial, behavior) interact to produce the immunological background of the disease. It is probable that patients have a genetic predisposition for the development of the disease

coupled with disturbances in immunoregulation. The disease can then be triggered by any of a number of different unknown environmental factors and sustained by an abnormal immune response to these factors. Accordingly, the intensive interaction between intestinal epithelial cells and immune competent cells is critical to maintain and perpetuate the chronic inflammatory process characteristic for IBD[1].

Early epidemiologic evidence for the role of genetic factors in the pathogenesis of Crohn's disease (CD) came from studies demonstrating higher rates of CD among individuals of Caucasian and Jewish ethnicity, familial aggregation of CD and higher concordance rates for both twins developing CD in monozygotic compared with dizygotic twins. The search for specific CD susceptibility genes, however, has been difficult due to complex genetics, including factors such as the lack of simple Mendelian inheritance patterns, involvement of several genes, and the influence of environmental factors and intestinal microflora on disease development. More than 30 distinct genomic loci encode genes involved in a number of homeostatic mechanisms and have been suggested to be involved in CD etiopathogenesis and prognosis[2].

Until very recently, two main approaches could be undertaken to identify genes in complex diseases: the positional cloning approach, based on linkage analysis, and the candidate gene approach, based on association studies. Linkage analysis studies the co-segregation of the disease with a marker within families. The candidate gene approach uses case-control cohorts or trios of affected offspring with both parents. Here, a specific gene with known or potential interest for the disease is studied. The allelic frequencies (in the case of case-control study) or the transmission of a single nucleotide polymorphism (SNP) towards affected offspring (in the case of trios) are analyzed, and differences between patients and controls, or distortion of transmission towards affected children, will point towards implication of the gene in the pathogenesis of the disease under investigation.

Despite the large numbers of genome-wide association studies (GWAS) established to date, most diseases have only managed to explain some additional percentage of the hereditability estimates. In an attempt to explain some of this missing hereditability, researchers have adopted several complementary strategies. Larger cohorts of cases are being collected, through either further patient recruitment or collaborations. The meta-analysis data generated to date have demonstrated how increasing the cohort sample size generates additional statistical power to detect smaller and smaller odds ratios[3]. Advances in technology, and particularly bioinformatics, have now made it possible to perform GWAS using common copy number variation probes. Many groups are looking to high-throughput sequencing technology, with the aim of sequencing candidate gene regions identified by GWAS, to hopefully identify either the causal or rare variants[4,5]. Several GWAS have been published in the last decade and have identified many genes associated with Crohn's disease (Table 1). Among these, there are recognition-related genes such as *NOD1* and *TLRs*, other susceptibility genes including *DLG5, OCTN* and *HLA,* and the newest susceptibility genes in CD resulting from GWAS: *IL23R* gene, *ATG16L1* gene and *IRGM* gene[6].

THE ROLE OF GENES IN THE DIAGNOSIS OF CROHN'S DISEASE

Several genes have so far been related to the diagnosis of Crohn's disease. These genes are related to innate pattern recognition receptors, to epithelial barrier homeostasis and maintenance of epithelial barrier integrity, to autophagy and to lymphocyte differentiation. So far, the strongest and most replicated associations with CD have been demonstrated with *NOD2*, *IL23R* and *ATG16L1* genes.

Genes related to innate pattern recognition receptors

***NOD2/CARD15* gene:** *NOD2/CARD15* (Caspase Recruitment Domain Family member 15) acts as a pattern recognition receptor (PRR); this locus has been characterized as the *IBD1* locus on 16q12-13[7].

Fine mapping of the *IBD1* locus identified the underlying gene on chromosome 16 as the *CARD15* (previous *NOD2*) gene. *CARD15* represents homology with the *R* genes in plants; genes that confer resistance to infection[8]. Thirty nonconservative polymorphisms have been identified within the gene, which are associated with CD, but only three are common (Arg702Trp, Gly908Arg and Leuc1007insC). These three common variants account for approximately 82% of the mutated alleles. *CARD15* is associated with CD only and not with ulcerative colitis. *CARD15* codes for a protein expressed in monocytes, macrophages, dendritic cells, epithelial cells and Paneth cells. *CARD15* is involved in the recognition of bacterial peptidoglycan-derived muramyl dipeptide through the leucine-rich repeat region. Of importance, the frameshift mutation 1007fsinsC that leads to a truncated protein lacking the 33 distal amino acids was associated with impaired activation of the transcription factor NF-kappa B after stimulation.

It has been shown that Paneth cells play an important role in innate host defense *via* their ability to secrete antimicrobial peptides and proteins. Although nucleotide-binding oligomerization domains (NODs) are expressed at low levels in absorptive and secretory intestinal epithelial cells, Paneth cells in the small intestine have been recognized as the predominant site of expression of *NOD2* in the epithelium. Furthermore, *NOD2* mutations have been associated with decreased expression of antimicrobial peptides, the α-defensins, by Paneth cells. In addition, a distinct gene polymorphism resulting in low β-defensin 2 gene copy number has been associated with a predisposition to colonic Crohn's disease. In addition, *NOD2* plays important roles in the promotion of antibacterial T-helper-17 (Th-17) cells in the IL-23-IL-1-IL-17 axis.

CARD15 variants are found in 35% to 45% of white

Table 1 Genetic polymorphisms related to Crohn's disease

Diagnosis of CD	
Innate pattern recognition receptors	*NOD2/CARD15, OCTN, TLR*
Epithelial barrier homeostasis	*IBD5, DLG5*
Molecular mimicry and autophagy	*ATG16L1, IRGM, LRRK2*
Lymphocyte differentiation	*IL23R, STAT3*
Secondary immune response and apoptosis	*MHC, HLA*
Prognosis of CD	
Age of CD onset	*TNFRSF6B, CXCL9, IL23R, NOD2, ATG16L1, CNR1, IL-10, MDR1, DLG5, IRGM*
CD behavior	
Stenotic/stricturing behavior	*NOD2, TLR4, IL-12B, CX3CR1, IL-10, IL-6*
Penetrating/fistulizing behavior	*NOD2, IRGM, TNF, HLADRB1, CDKAL1*
Inflammatory behavior	*HLA*
Granulomatous disease	*TLR4/CARD15*
CD location	
Upper gastrointestinal	*NOD2, MIF*
Ileal	*IL-10, CRP, NOD2, ZNF365, STAT3*
Ileocolonic	*ATG16L1, TCF-4 (TCF7L2)*
Colonic	*HLA, TLR4, TLR1, -2, -6*
CD activity	*HSP70-2, NOD2, PAI-1, CNR1*
Surgery	*NOD2, HLA-G*
Dysplasia and cancer	*FHIT*
Extraintestinal manifestations	*CARD15, FcRL3, HLADRB*103, HLAB*27 HLA-B*44, HLA-B*35, TNFα-308A, TNF-1031C, STAT3*
Pharmacogenetics in CD	*CARD15, NAT, TPMT, MDR1, MIF, DLG5, TNF, LTA*

NOD: Nucleotide binding and oligomerization domain; CD: Crohn's disease; LRR: Leucine-rich repeat; OCTN: Organic cation transporter; TLR: Toll-like receptor; DLG5: Discs large homolog 5; LTA: Lymphotoxin α; CARD: Caspase recruitment domain; STAT3: Signal transducer and activator of transcription 3; MHC: Major histocompatability complex; PAI-1: Type 1 plasminogen activator inhibitor; FHIT: Fragile histidine triad; NAT: N-acetyltransferase; MIF: Macrophage migration inhibition; HLA: Human leucocyte antigen; TPMT: Thiopurine methyltransferase; MDR1: Multidrug resistance gene 1; TNF-α: Tumour necrosis factor-α; Tcf: T-cell factor; Atg: Angiotensinogen; FCRL: Fc receptor-like; ZNF: Zinc finger; TNFRSF: Tumor necrosis factor receptor superfamily; IRGM: Immunity-related GTPase family, M; HLA: Human leukocyte antigen; LRRK2: Leucine-rich repeat kinase 2; CNR: Cadherin-related neuronal receptor.

CD patients, with the exception of Scandinavian, Irish and Scottish patients[9,10], in whom the prevalence is much lower. Genotype relative risks of 3 (simple mutation) and 10-44 (double mutations) have been reported in European Caucasians[9,10]. However, *CARD15* mutation is not frequent or even absent in African-American populations, and in Indian, Chinese and Japanese populations[11-13]. Other *CARD* related genetic loci that have been associated with CD diagnosis are the *CARD4* (*NOD1*), *CARD8* and *CARD9* loci[14,15].

Organic cation transporter genes: Organic cation transporters (OCTNs, 5q31-33) are membrane transporters for drugs and positively charged endogenous metabolites. The novel OCTN subfamily may also transport carnitine, which is essential for metabolism of lipids and is involved in transport of light chain fatty acids into mitochondria for beta-oxidation. Early studies in this field reported on two functional mutations in the carnitine/*OCTN* cluster on *5q31* (the *IBD5* locus) that were associated with Crohn's disease. As membrane transporters of organic cations, OCTNs are therefore important in the maintenance of intracellular homeostasis. In humans *OCTN1* and *OCTN2* map to *IBD5* on *5q31*. An *OCTN3* has recently been described in humans[16].

Toll-like receptor genes: Host response to microbial pathogens includes self-defense mechanisms such as defensins, PRRs, pathogen-associated molecular patterns and toll-like receptors (TLRs). TLRs recognize conserved motifs on pathogens that are not found in higher eukaryotes and initiate "innate" (rapid and non-specific) immune responses[17]. Subsequently, specific receptors recognizing chemo-attractant molecules mobilize phagocytic leukocytes and induce their migration to inflammatory sites. There, leukocytes encounter the invading microorganisms and ingest them through the activation of phagocytic receptors that mediate the uptake process. Innate immune responses are linked to the generation of corresponding adaptive immune responses and studies of genetically engineered or cellularly manipulated animal models have generated a great deal of new information[18].

Leucocyte-epithelial interactions are of special interest, as exposure of epithelial TLRs to microbial ligands has been shown to result in transcriptional upregulation of inflammatory mediators, whereas ligation of leucocyte TLRs modulates specific antimicrobial responses[19]. It has been shown that Paneth cells play an important role in innate host defense *via* their ability to secrete antimicrobial peptides and proteins. In addition, it has been shown that *NOD2* mutations lead to loss of negative regulatory effects on TLR signaling while activation of the *CARD* domain results in activation of NF-κB[20].

TLRs are the most important receptors of the innate immune system. They are expressed by immune cells and by intestinal epithelial cells in IBD patients. In humans, at least 10 different TLRs are described and each recognizes a specific pathogen-associated molecular pattern. A trans-

mission disequilibrium test on Belgian IBD trios with CD demonstrated preferential transmission of the *TLR4* Asp299Gly polymorphism from heterozygous parents to affected children[21]. *TLR9* modulates CD susceptibility and there is interaction between other polymorphisms such as *NOD2*, *IL23R* and *DLG5*[22,23].

Genes related to epithelial barrier homeostasis

The gastrointestinal tract uses a system of tolerance and controlled inflammation to limit the response to dietary or bacteria-derived antigens in the gut[24]. When this complex system breaks down, by means of either a chemical or pathogenic insult in a genetically predisposed individual, the resulting immune response may lead to IBD[25]. Genes or loci involved in the maintenance of epithelial barrier integrity and associated with Crohn's disease are the *IBD5* and the Discs large homolog 5 (*DLG5*)[26].

The *DLG5* gene is a 180-kb protein containing 1900 amino acids. DLG5 protein harbors a caspase activation and recruitment domains (*CARD*), is a further CD susceptibility gene of the *CARD* family and contributes to *CARD*-mediated mechanisms of host defense. In fact, the *DLG5* gene associated protein is a member of the MAGUK (Membrane Associated Guanylate Kinase) family of scaffolding proteins. Scaffolding proteins organize protein complexes at cellular junctions to integrate the tethering of adhesion molecules, receptors and intracellular signaling enzymes. Of interest is a population variation regarding *DLG5* variants. For example, the *DLG5* R30Q variant has not been confirmed in other European studies[27,28]. Other genes of potential importance in the same panel are the *PTGER4*, *ITLN1*, *DMBT1*, *BPI* and *XBP1* genes[29].

Genes related to molecular mimicry and autophagy

The innate immune system is the first line of defense against infection. Of interest, virulence factors from bacteria and viruses have been identified that manipulate host innate immune signaling pathways through molecular mimicry. These microbial proteins contain signaling domains that bear sequence and structural similarity to their host targets, thereby potentially sabotaging host immunity by hijacking crucial signaling pathways and uncoupling receptor activation from effector induction. Several protein families have evolved to function as receptors or sensors of pathogen invasion. There are two types of signaling domains for the above receptors: the TIR domain for the TLRs, and the Pyrin domain or *CARD* for the *NOD*-like receptors (*NLRs*) and retinoic acid-inducible gene 1-like receptors or helicases.

Molecular mimicry has been invoked as one of the mechanisms responsible for the activation of autoreactive cells by microbial peptides that have structural similarities to self peptides, but there is also evidence that antigenically unrelated infections or specific inflammatory signals can result in autoaggressiveness and induction of organ-specific autoimmunity, including the gut. The extent and severity of this loss of tolerance is still being defined, as it has been demonstrated that loss of tolerance in IBD patients is not exclusive for bacterial antigens and occurs also for orally administered soluble proteins[30]. This subversion of innate immune signaling through molecular mimicry is closely related to the phenomenon of autophagy. Autophagy is the tightly orchestrated cellular 'housekeeping' process responsible for the degradation of damaged and dysfunctional cellular organelles and protein aggregates, and is well recognized to play an important role in maintaining cellular homeostasis under physiological and pathophysiological conditions. Regulated degradation and turnover of subcellular components is essential for normal cellular function, growth and development. The major catabolic pathway responsible for the disposal of obsolete or damaged organelles and protein aggregates is autophagy (i.e., "self-digestion"). During this process organelles and proteins are encircled in a double-membrane vesicle (the autophagosome), delivered to lysosomes and the substrates for adenosine-triphosphate generation, and products can be recycled to synthesize new proteins, high-energy phosphates and other cellular components. Autophagy has evolved as a conserved mechanism for cell survival under conditions of starvation and stress. In addition to (macro)autophagy, characterized by the sequestration of organelles and proteins within an autophagosome, there are two additional subtypes of self-digestion: microautophagy which refers to protrusion of the lysosomal membrane *per se* around a region of cytoplasm; and chaperone-mediated autophagy in which degradation is restricted only to those proteins with a consensus peptide sequence recognized by specific chaperone complexes[31]. Autophagy is now considered to be important for host defense against intracellular microorganisms. The associations of the autophagy-associated genes with Crohn's disease strongly support the hypothesis that abnormal innate immune responses to intracellular pathogens contribute to the pathogenesis of Crohn's disease. In fact, the pathological characteristics of human Crohn's disease represent "granuloma" formation. The mechanisms of granuloma formation remain unclear. Recent studies have demonstrated functional roles for IL-23 in the differentiation and promotion of Th-17 cells. Autophagy genes that have been related to CD diagnosis are the *ATG16L1*[32,33], *IRGM* and the *LRRK2* genes[34]. Unraveling the mechanisms of such molecular mimicry is crucial to our understanding and clinical intervention of infectious diseases and inflammatory disorders of unknown etiopathogenesis, including Crohn's disease.

Genes related to lymphocyte differentiation

***IL23R* gene:** Dysregulated cytokine production by mucosal lymphocytes and macrophages has been implicated in the pathogenesis of CD. In fact, an exclusive increase of $CD4^+$ T cells in inflammatory bowel disease and their recruitment as intraepithelial lymphocytes has been demonstrated[35]. $CD4^+$ T cells secreting interleukin-17 [T helper type 17 (Th-17) cells] have emerged as a key effector population driving colitis in animal models previously

associated with exaggerated T helper type 1 responses.

Of the genes involved in the differentiation of Th-17 lymphocytes the *IL23R* gene has been proved of great importance and has been related to Crohn's disease[36,37].

IL23R, consisting of an *IL-12β1* and an *IL23R* chain, is highly expressed on memory T cells. *IL23* is a novel cytokine formed *via* the binding of *IL12p40* to a p19 protein. After binding to the *IL23* receptor, *IL23* preferentially activates memory T cells. IL23 does exhibit some similar biological activities to *IL-12*; however, *IL-12* is more involved in the differentiation of naïve T-cells into Th1 lymphocytes and subsequent *IFNγ* production. *IL23*, on the other hand, mediates proinflammatory activities in part by the production of *IL17* through activation of Th17 lymphocytes[38].

Signal transducer and activator of transcription 3 gene: Signal transducers and activators of transcription 3 (*STAT3*) play an important role in various autoimmune disorders including IBD[39,40]. *STAT3* was initially identified as an acute phase response factor, an inducible DNA binding protein that binds to the *IL-6* responsive element within the promoters of hepatic acute phase protein genes, and is involved in IL-6 dependent T-cell proliferation through prevention of apoptosis. Subsequent studies indicate that *STAT3* becomes activated in response to a wide variety of cytokines and growth factors. Recent studies have revealed that *STAT3* activation plays distinctly different roles between innate immune responses and acquired immune responses in colitis. *STAT3*-mediated activation of acquired immune responses plays a pathogenic role in colitis by enhancing the survival of pathogenic T-cells. In contrast, *STAT3*-mediated activation of innate responses contributes to the suppression of colitis. Emerging data indicate that *STAT3* is one of the crucial targets for the treatment of IBD. However, as the receptors of these cytokines and growth factors are present in both innate and acquired cells, activation of *STAT3* is likely to occur in both cell types. Therefore, as the function of *STAT3* is a double-edged sword, careful attention should be directed toward the cell population that is being targeted when one contemplates *STAT3* inhibition or activation in human IBD[41]. Within the same panel, other than *STAT3* genes, and with probable importance, are the *TNFSF15*, *JAK2*, *CCR6* and *ICOSLG* genes[42-44].

Genes related to secondary immune response, apoptosis and other pathways

Chemokines play a central role in the pathogenesis of IBD as they are able to trigger multiple inflammatory actions including leukocyte activation and chemoattraction, granule exocytosis, production of metalloproteinases for matrix degradation and upregulation of the oxidative burst[45]. Therefore, further support is given for genes that relate to secondary immune response, apoptosis and other pathways. For example, in the *IBD4* locus 4 several interesting candidate genes, which may be relevant in the pathogenesis of CD, lie within this region (e.g., genes regulating apoptosis, signal transduction proteins, chemokine receptors, T cell receptors, metalloproteinases).

Gene expression profiles from colon lamina propria fibroblasts have demonstrated several functional changes in some proteins coded from the corresponding genes: collagen types I , IV, XIV; matrix metalloproteinase 1; cathepsin K; stroma cell-derived factor-1; chitinase3-like-1; and many others[46]. The major histocompatibility complex (MHC) has been extensively investigated. Human leucocyte antigen (HLA) class II molecules present partially digested antigen to the T-cell receptor and play a central role in the immune response. In CD, the MHC and HLA studies have yielded conflicting and heterogenous results. *HLADR1* has been implicated in CD[47].

Many other genes, loci and chromosomes involved in CD have also been advocated in several studies that, however, still require wide replication and association with clinical practice. These include *CNR1, MCP-1*[48], *PTPN2* (protein tyrosine phosphatase)[49], *PTPN22*, *NKX-3, IL-18 RAP/IL-18R1, IL12/IL23* pathway[50], *PTGER4, MST1/BSN/MST1R*[50-52], *IL-2/IL-21*[53], *TYK2, JUN, NAT2*[54], *IL-10, NELL1, NKX2-3*[55], *Cyclin Y*, Hect domain, 1q24, 10q21, 5p13, RCC1-like domain, *ICOSLG, CDKAL1*[56], 13q13.3, 1p35.2, 3p29, 5p13.1[57,58], X chromosome[59], *NLRP3*[60], Vitamin D receptor (*VDR*) polymorphisms[61] and many others as well.

Genes in family and ethnic group studies

Linkage studies performed in complex genetic disorders such as CD frequently use model-free analytic methods, which are non-parametric analyses that do not assume Mendelian recessive or dominant models of inheritance.

The strongest risk factor for IBD is having a relative with the same disease. First-degree relatives of patients with CD have a 12-to-15 times greater risk of developing CD than do people of comparable age in the general population[61]. Familial clustering can also result from exposure to common environmental risk factors. Twin studies are very useful to determine the degree of genetic *vs* non-genetic etiologies for a trait. Today, there is no evidence of a separate entity of familial IBD[62,63]. Based on the current literature, phenotypic differences between familial and sporadic cases of IBD are weak. Available data are to be accepted with caution, however, as they are mostly retrospective and may be biased. *CARD15* explains around 20% of the genetic predisposition to Crohn's disease[64]. The relative risk of developing CD in the presence of one mutation is 2-4, but increases dramatically in the case of two mutations (compound heterozygous or homozygous).

Although *NOD2* provides no clear familial predisposition, unaffected relatives do carry an increased rate of *CARD15* variants (37.1%) compared to controls, and it would be interesting to see if they will eventually develop symptoms[65-67]. In addition, maternal transmission of *CARD15* variants seems protective with a lower ratio of affected/unaffected children when compared to fathers[68,69]. In the light of the foregoing data, it seems that genetic counseling should be carried out with caution. In addition, families should not receive genetic counsel-

ing/information about age at onset and disease severity. Ethnic group studies and ethnic variation were firstly demonstrated in Jewish populations, and those studies are of major importance in this context[70].

THE ROLE OF GENES IN PROGNOSIS OF CROHN'S DISEASE

This is a major issue that greatly concerns patients. Many genes have so far been implicated in the prognosis of Crohn's disease and numerous attempts have been made to classify the genetic profiles in Crohn's disease. Of interest, *CARD15* seems not only a susceptibility gene, but also a disease-modifier gene for CD. Of the many studies published on the clinical relevance of *CARD15* mutations, there are several providing data on disease location, and the majority of them support a significant association of *CARD15* mutations with ileal disease site, while some demonstrate a connection with the absence of colonic location. Some studies also provide data supporting the relevance of *CARD15* variants with stricturing disease behavior, and also penetrating behavior. Other pertinent studies have revealed an association with early onset of the disease. These investigations also support the theory that pediatric Crohn's is a "more genetic disease" consistent with other polygenic disease models. Other reports provide data on an increased risk or need of surgery related to CD[71].

Differences among studies are difficult to explain, and we could argue about the low number of patients in some of the studies, the disease variability among Caucasians and, finally, differences regarding disease assessment and interobserver agreement. Whether the described relationship between the *CARD15* variants and both stenosing phenotype and increased need for surgery in CD patients is a true association, or only reflects the high proportion of ileal CD developing bowel stenosis and, therefore, requiring surgery, is still a matter of controversy.

Genes related to age of Crohn's disease onset

With respect to age of CD onset and more specifically to childhood or early-onset Crohn's disease, many genes/loci have been implicated: *TNFRSF6B*, *CXCL9*[72], *IL23R*[73,74], *NOD2*[75], *ATG16L1 rs2241880*[76], *CNR1*[77], *IL-10*[78], *MDR1*[79]. Of interest, *DLG5* seems protective for female children[80], while there are also studies not supporting the relationship of genes and early onset of CD[81] or supporting the relation of *IL-10* and *IRGM* with adult onset[82].

Genes related to Crohn's disease behavior

Genes related to stenotic/stricturing behavior in CD are: *NOD2/CARD15*[83], *TLR4*[84], *IL-12B*[85] and *CX3CR1*[86,87]. Of importance, *NOD2/CARD15* has been also related to acute intestinal obstruction[88]. *IL-10* and *IL-6* are also potentially related to stenotic/structuring behavior in CD, while genetic variants of several metalloproteinases and their inhibitors would be excellent candidate genes, since these molecules are considered to play a key role in the abnormal fibrogenesis that underlies the development of bowel stenosis in CD patients. Genes related to penetrating/fistulizing behavior in CD are as follows: *NOD2*, *IRGM*, *TNF*[89], *HLADRB1*[90], the C-allele in *CDKAL1* rs6908425 SNP is associated with *NOD2*(-) perianal fistula, whereas *OCTN* and the near *IL-12B* gene rs12704036 T-allele have a relationship with non-perianal fistula[91]. Inflammatory CD behavior has been related to *HLA* variation[92] while granulomatous disease has been related with *TLR4/CARD15* variants[93].

Genes related to Crohn's disease location

Upper gastrointestinal Crohn's disease has been related to *NOD2*[94] and *MIF* variants[95]. Ileal CD has been related to the following genes: *IL-10*[96], *CRP* gene[97], *NOD2*, *ZNF365* and *STAT3*[98]. Genes/loci associated with ileocolonic CD are 3p21, *ATG16L1*[98] and *TCF-4* (*TCF7L2*)[99]. No role for phenotype in *IL23R* gene has been demonstrated[100] while a detailed genotype-phenotype analysis revealed weak associations of the *IL23R* rs10024819 variant with ileal involvement and stenoses in carriers of the TT genotype. Finally, the *HLADRB1*0701* has been associated with ileal CD, but only in patients who have no *CARD15* variants[101]. Colonic CD has been related to the following genes: *HLA* region (associated with inflammatory colonic phenotype); and *TLR4*[102], *TLR1*, *-2*, *-6*[103]. The *TNF* gene showed a negative association with stricturing behavior or colonic location[104]. For *IBD5* and *OCTN1* and *2*, results have not been consistent but associations with perianal and ileal disease have been reported.

Genes related to Crohn's disease activity

Genes implicated in disease activity are the following: *HSP70-2* heat shock protein gene[105], *NOD2*[106], *PAI-1* (Type 1 plasminogen activator inhibitor[107]), while the combination of *NOD2* and *PAI-1* predicted complicated disease behavior[108]. Of importance, *NOD2* predicted lower weight in children[109], and *CNR1* low body mass index[110].

Genes related to surgery

The *NOD2* gene has been related to early pediatric surgery[111], stenosis and need for surgery[112], previous surgeries[113], increased number of surgeries[107] and surgical costs[114]. *NOD2* has no relation to the risk of re-operation[115]. Finally, *HLA-G* has been associated with higher risk for ileocolonic resectio[116].

Genes related to dysplasia and cancer

The *FHIT* gene (fragile histidine triad gene) located at 3p14.2 has been identified as a candidate tumor-suppressor gene. The gene spans the t(3;8) translocation breakpoint of familial renal cell carcinoma and contains the FRA3B fragile site. It encodes the human diadenosine triphosphate hydrolase, which *in vitro* cleaves the diadenosine substrate into ADP and AMP. It has been suggested that *FHIT* gene plays a role in the pathogenesis of IBD and the development and progression of a subgroup of IBD-related carcinomas at an early phase[117-119].

Genes related to extraintestinal manifestations and concomitant diseases

Extraintestinal manifestations are common in CD. Genes related to CD extraintestinal manifestations have been reported, as follows. Peripheral arthritis was related to *FcRL3*[120], *HLADRB*103, HLAB*27 HLA-B*44*, *HLA-B*35*, *TNFa-308A*[121]. *CARD15* has been related to spondylarthropathy[122] and uveitis[123] but not to sacroileitis[124]. *TNF-1031C* was associated with erythema nodosum while certain *HLA* alleles (*HLA-B27, HLA-B35* and *HLA-B44*) were connected with different disease behavior and extraintestinal manifestations such as arthropathy, eye and skin manifestations. Genes/loci related to other chronic diseases concomitant to CD are 10p12.2 (sarcoidosis and CD)[125], *STAT3* (multiple sclerosis and CD)[126] and a parallel genetic fingerprint between leprosy and CD[127].

Pharmacogenetics in Crohn's disease

Pharmacogenetics is of major importance in CD therapeutics and prognosis. Genes have been implicated in influencing the efficacy and side effects of drugs and reflect a complex interplay regarding absorption, elimination and transport. Future studies need to be large and prospective with uniformly phenotyped patients, and correlating genetic associations with functional data. In addition, hypotheses such as whether observations about drug response in IBD lead us to IBD etiology or whether the genes that control the drug response are related to genes that control the disease still remain unanswered. Pharmacogenetic studies to date have found no association between *CARD15* variants and prediction of response to various IBD therapies. In addition, responses to azathioprine (AZA), steroids and infliximab are not related to *NOD2*[128]. Of note, *NOD2* was only related to antibiotic failure[129]. For mesalazine, variability in drug acetylation was demonstrated many years ago with patients divided into slow and rapid acetylators, because of polymorphisms in the N-acetyltransferase (*NAT*) genes. Two isoenzymes NAT1 and NAT2 have been identified in humans and more than 50% of Caucasians are NAT2 slow acetylators. Mesalazine is acetylated in the liver by NAT1 into N-acetyl-5 aminosalicylates and excreted in the urine[47].

The clinical usefulness of pharmacogenetics in CD is limited to AZA and thiopurine methyltransferase (TPMT) at this moment. The human *TPMT* gene, consisting of 10 exons, is located on chromosome 6p22.3. The hereditary nature of *TPMT* deficiency in humans was initially identified in a study of *TPMT* activity in red blood cells (RBC). This and subsequent studies determined the distribution of *TPMT* activity in RBC to be trimodal; 90% of persons have high activity, 10% have intermediate activity and 0.3% have low or no detectable enzyme activity. To date, numerous mutant *TPMT* alleles have been identified, including the three most frequent alleles (*TPMT*2, TPMT*3A* and *TPMT*3C*), which account for 80%-95% of intermediate or low TPMT enzyme activity cases. The prevalence of the most frequent SNPs in the *TPMT* gene has been reported to vary worldwide. However, it is of interest that studies on the prevalence of *TPMT* SNPs in large IBD cohorts are lacking.

Although AZA is an effective drug for maintenance of remission in IBD, it is associated with side effects. Clinically sound pharmacogenetic studies over the last two decades have shown that polymorphisms in the *TPMT* gene locus play a significant role in the occurrence of various side effects of thiopurine drugs including life-threatening bone marrow toxicity, a serious dose-related toxicity[130-134].

The G2677T variant in the *MDR1* gene predicted gastrointestinal and unspecified intolerance to azathioprine and methotrexate in inflammatory bowel disease patients. These findings suggest a role for MDR1/P-gp in the mechanism of action of azathioprine and methotrexate[135,136].

Twin studies have linked polymorphisms of the *VDR* gene with bone mineral density in healthy women, and in addition *VDR* is an important regulator of calcium metabolism and bone cell function and influences calcium absorption from the intestine. *VDR* polymorphisms have also been implicated in susceptibility to Crohn's disease[137].

The *HLADR* region has been associated with failure to budesonide[138] while *DLG5R30Q* predicted response to steroids[139]. Other genes such as *MIF* (macrophage migration inhibition)[140] and *MDR* have also been related to steroid therapy[136]. In addition, 1082 AA *IL-10* genotype was associated with steroid dependency, whereas the allele 113A of the *DLG5* gene conferred resistance to steroids.

Regarding response to infliximab, the data for the *TNF* gene are conflicting. Specifically, there are conflicting data regarding the role of *FcGR3A*, which has been supported by some authors[141,142], but was not confirmed in patients in the ACCENT I study. Response to infliximab is not related to *TNFa-308*[143] or *TNFR1* and *TNFR2*[144] or *NOD*[145] or *CRP* gene[136]. The association between the Fas ligand-843 TT genotype and lack of response to infliximab seemed to be the most relevant observation[136]. The relationship between infliximab response and the lymphotoxin alpha gene is also conflicting[144].

WHAT LIES AHEAD

Gene-to-gene crosstalk and epistasis

With new methodologies such as genome-wide association studies, microarrays and fine SNP analysis becoming available during the last decade, our investigative armamentarium has been considerably enriched. As many studies with complex statistics arise, we understand increasingly the real crosstalk present among genes and the need for a genetic panel for disease diagnosis and prognosis. It is now evident that gene-to-gene interaction and epistasis modulate disease activity and susceptibility[146]. Some data have come to light. A genome-wide scan in a Flemish population of IBD affected families supports the

existence of *IBD4* on 14q11, and has shown additional evidence for the existence of other susceptibility loci (1p, 4q and 10p). This study has further demonstrated that epistasis and gene-to-gene interactions (*CARD15-TLR4*) are also present in IBD and that population heterogeneity is not to be underestimated[147]. Crosstalk has been demonstrated for *TLR9* with *NOD2, IL23*R and *DLG5*, and epistasis has been shown between *IL23*R and *DLG5*. Also, potential epistasis between *IL23*R variants and the three other previously described CD susceptibility genes *CARD15*, *SLC22A4* and *SLC22A5* (*OCTN 1* and *2*) has been shown[116].

Genetic consortium studies and genome-wide scans

Over the past few years, a combination of progress in high-throughput genotyping technology and growing knowledge about the human genome through the International HapMap project and the Human Genome Project have enabled GWAS for several complex diseases. To understand the approach to conducting GWAS in this setting, it is important to expound on the concept of linkage disequilibrium, which refers to the nonrandom association of alleles at nearby loci. Specifically, linkage disequilibrium refers to adjacent alleles assorting together nonindependently from generation to generation because they are tightly linked and thus less likely to become separated by recombination. Genetic consortium studies are of major importance, and homogeneity in methodology issues is of paramount value[148-151]. Appropriate study design[152], power analysis[153] and overall data analysis and meta-analysis[154] are mandatory. Accurate estimation of sample sizes required in a genetic association study is essential before commencing genotyping, to ensure that the study is sufficiently powered to detect the subtle genetic effects that contribute to most complex diseases. The extensive genetic variation and complex linkage disequilibrium across even a small genomic region will give rise to several alternative scenarios. Genetic variation across a region studied should be carefully evaluated and consideration should be given to possible linkage disequilibrium and allelic heterogeneity when evaluating power of an association study. As larger datasets are studied and combined, as genotyping platforms provide even greater depth of coverage of the genome, and as modest hits are followed up in large independent panels, so the vast majority of true signals should be identified. These robust genetic data will truly provide a solid platform for functional studies to understand the mechanisms by which these genetic variants predispose to Crohn's disease. Finally, studies at post-transcriptional level become more and more urgent[155]. Enriching our understanding of CD genetics is important, but when combining genetic data with functional data the outcome could be of major importance. In fact, improved understanding of immune mechanisms, on which manifold genetic and environmental traits might converge, and which ultimately mediate all phenomena in inflammatory bowel disease, holds promise (Table 2).

CONCLUSION

The recent advances in the understanding of CD genetics have been tremendous[156]. Starting with the susceptibility area, whole genome linkage and association scans have already led to the identification of a number of susceptibility genes (*NOD2/CARD15, DLG5, OCTN1* and *2, NOD1, IL23R, PTGER4*, *ATG16L1* and *IRGM*) of which the *NOD2/CARD15* gene is the most replicated and understood at present. Although it is clear that genetic research in IBD has advanced our understanding of the clinical heterogeneity of the disease, new efforts are required and point towards the complex combination of a panel of clinical, biochemical, serological and genetic factors, in order to achieve the optimal prediction of both clinical behavior and response to therapy.

Genome-wide association studies have allowed an unprecedented rapid unraveling of the genetic basis of IBD; however there will be much more follow-up work needed in this field. First, ongoing work including meta-analysis of the CD genome-wide association studies will probably reveal additional CD susceptibility genes. It will then be essential to investigate the functional consequences of polymorphisms in these genes so that the molecular and cellular mechanisms leading to CD can be better characterized. Finally, genotype-phenotype correlation studies should help clinicians predict disease outcomes with more accuracy, including the risk for complications, need for surgery, and response to therapy, and finally lead to redesigning the methods of treatment of CD patients.

Abstract

AIM: To evaluate the safety and clinical efficacy of a new immunotherapy using both α-Gal epitope-pulsed dendritic cells (DCs) and cytokine-induced killer cells.

METHODS: Freshly collected hepatocellular carcinoma (HCC) tumor tissues were incubated with a mixture of neuraminidase and recombinant α1,3-galactosyltransferase (α1,3GT) to synthesize α-Gal epitopes on carbohydrate chains of the glycoproteins of tumor membranes. The subsequent incubation of the processed membranes in the presence of human natural anti-Gal IgG resulted in the effective phagocytosis to the tumor membrane by DCs. Eighteen patients aged 38-78 years with stage Ⅲ primary HCC were randomLy chosen for the study; 9 patients served as controls, and 9 patients were enrolled in the study group.

RESULTS: The evaluation demonstrated that the procedure was safe; no serious side effects or autoimmune diseases were observed. The therapy significantly prolonged the survival of treated patients as compared with the controls (17.1 ± 2.01 mo *vs* 10.1 ± 4.5 mo, $P = 0.00121$). After treatment, all patients in the study group had positive delayed hypersensitivity and robust systemic cytotoxicity in response to tumor lysate as measured by interferon-γ-expression in peripheral blood mononuclear cells using enzyme-linked immunosorbent spot assay. They also displayed increased numbers of CD8-, CD45RO- and CD56-positive cells in the peripheral blood and decreased α-fetoprotein level in the serum.

CONCLUSION: This new tumor-specific immunotherapy is safe, effective and has a great potential for the treatment of tumors.

Key words: Hepatocellular carcinoma; α-Gal epitope; Dendritic cell; Tumor-associated antigen; Dendritic cell-activated cytokine-induced killer cell

INTRODUCTION

Primary hepatocellular carcinoma (HCC), the most common neoplasm of the liver, is generally resistant to conventional treatment. The prognosis of the patients is poor, especially at the late stage, with a mean survival of less than ten months[1-3]. This poor prognosis has led to the interest in various alternative therapies. Immunotherapy is particularly appealing because of its specificity against tumor cells, absence of serious side effects and its potential to eradicate residual tumors after conventional treatment.

One area of active research is immunotherapy with cytokine-induced killer cell (CIK)[1-3]; unfortunately, its efficiency is limited because of low specificity to tumor cells. Another approach is tumor-associated antigen (TAA)-pulsed dendritic cell (DC) therapy, but the outcome is still not satisfactory because of the low immunogenicity of TAA[4-6].

DCs are the most effective antigen-presenting cells (APCs) responsible for initiating an immune response[7]. Upon exposure to tumor cells, isolated tumor antigen, and even to tumor mRNA, DCs are capable of presenting endogenous and exogenous antigens to naïve T cells in a human leukocyte antigen (HLA)-restricted manner and expressing several adhesive and costimulatory surface molecules. However, the poor immunogenicity of TAA may be the reason why tumor cells fail to adequately stimulate DCs for effective presentation to immune cells[8]. A possible method for increasing the uptake of TAAs by DCs is to complex them with an IgG antibody. These immune complexes would bind to Fcγ receptors (Fcγ-Rs) on DCs and induce phagocytosis of TAAs. The augmentation of antigen processing, presentation by immune complex and subsequent activation of immune responders has been demonstrated in several studies. For example, targeting tetanus toxoid (TT) to APC Fcγ-Rs by complexing it with anti-TT IgG results in a 10- to 1000-fold increase in Th-cell activation[9,10]. Similarly, the targeting of autologous tumor cell vaccines by DC Fcγ-Rs uptake would also lead to an effective immune response against the tumor cells[11]. Such targeting was achieved by complexing the tumor cell membranes *in situ* with naturally existing antibodies against the α-Galactosyl epitope (Gal-α1, 3Gal-β1, 4-GlcNAc-R, α-Gal)[12]. These anti-Gal antibodies have been shown to be detrimental in xenotransplantation[13] and to destroy retroviral vectors used for gene therapy[14]. In humans, the α-Gal epitope on the cell membrane is absent, but the natural anti-Gal antibody is abundant in serum[15]. Expression of the α-Gal epitope on tumor cells could result in *in situ* binding of the patient's natural anti-Gal IgG. The binding complex can then opsonize DC phagocytosis and enhance TAA presentation to naïve T or CIK cells, which are then activated and attack the remaining tumor cells *in vivo*. However, patients with malignancies usually have very low immunity, especially in cellular immune responses. The cause of the low immunity is not quite clear. One possible explanation is that the patient's T cells have been anergized by tumor antigens in the absence of APCs and cannot be activated again with the same antigen *in vivo*.

To maximize APC phagocytosis and the activation of tumor-specific T/CIK cells, we used newly differentiated T/CIKs from bone marrow stem cells instead of circulating T cells. Here, we present a new therapy for HCC using α-Gal epitope-expressing tumor cell-pulsed DCs to activate tumor-specific T/CIKs *in vitro*. The activated immune responders were then expanded in the presence of a high concentration of cytokines *ex vivo*.

MATERIALS AND METHODS

Patients

Written informed consent was obtained from all the patients who participated in the study before treatment according to the guidelines of the Ethics Committee of the Armed Police General Hospital, which approved this study. Inclusion criteria were a Karnofsky score of ≥ 60[16], the lowest possible maintenance dose of glucocorticoid therapy (prednisone < 5mg/d) and normal baseline hematological parameters before treatment. These parameters included: hemoglobin ≥ 10.0 g/dL; total granulocyte count ≥ 4000/μL; platelet count ≥ 100 000/μL; blood urea nitrogen ≤ 30 mg/dL; creatinine ≤ 2 mg/dL; alkaline phosphatase and aspartate aminotransferase levels less than 2 times the normal upper limit; prothrombin and activated partial thromboplastin not more than 1.4 times higher than the control; and total bilirubin < 35 μmol/L. Exclusion criteria included cachexia, severe jaundice, a large amount of ascites, human immunodeficiency virus positive status, drug addiction, pregnancies, severe pulmonary and cardiac diseases, treatment with a large dose of steroids and a history of an autoimmune disorder or prior history of other malignancies.

Nine patients with clinical stage Ⅲ, histologically-proven primary HCC were enrolled in the study group. There were 2 women and 7 men ranging in age from 38 to 78 years (56.8 ± 13.9 years, Table 1). After surgical removal of the tumor masses, the patients received radio-, chemo- or interventional therapies. They were monitored after the treatment by computed tomography (CT). None of the patients was receiving steroids at the time of treatment.

There were 9 patients with clinical stage Ⅲ, histologically-proven HCC in the control group. This group con-

AFP: α-fetoprotein; PR: Partial response; PD: Progress disease, NC: No change; A: Still alive; D: Dead; KPS: Karnofsky performance status; DTH: Delayed-type hypersensitivity.

sisted of one woman and 8 men, aged 45-66 years. They all underwent similar conventional treatment as those of the study group.

Preparation of primary hepatocellular carcinoma cell suspension

The surgically removed tumor samples were immediately placed in ice-cold phosphate buffered saline (PBS) containing 3 mmol ethylenediaminetetraacetic acid (EDTA). A fine scalpel was used to remove as much adjacent non-tumor tissues as possible. The tumor tissue was then dispersed using a curved needle to create a cell suspension, which was filtered using a 70 μm cell strainer (BD Biosciences, United Kingdom). The cells were resuspended (2×10^8 cells/mL) in ice-cold PBS containing 3 mmol EDTA. The cells were irradiated five times at a total dose of 100 Gy, with a 5-min break during which the cells were placed on ice. They were then washed twice with ice-cold PBS.

Synthesis of α-Gal epitopes on intact tumor cells

Tumor cells prepared as described above were first resuspended at a concentration of 2×10^8 cells/mL in saline containing 0.1 mol Tris-HCl pH 7.0, 15 mmol $MnCl_2$, and 1 mmol UDP-Gal (Sigma-Aldrich, United Kingdom) and then incubated with 1 mU/mL neuraminidase (Sigma-Aldrich, United Kingdom) and 50 μg/mL recombinant bovine α1,3-galactosyltransferase (α1,3GT, produced in our lab) at 37 ℃ for 1 h with constant rotation. The cells were washed with RPMI-1640 medium, resuspended in RPMI-1640 medium (Gibco, Beijing) supplemented with 10% AB serum and incubated on ice for 1 h to promote maximum binding of the natural anti-Gal antibody to newly synthesized α-Gal epitope on the tumor cell surface. The cells (2×10^8 cells/mL) were washed and sonicated in ice water using a Sonicator-3000 (Misonix, Inc., United States) to destroy all tumor cells and centrifuged briefly to remove the viscous DNA. Finally, the tumor cell lysate was aliquoted and stored at -80 ℃ for future use.

Synthesis of the α-Gal epitope on tumor cells was analyzed by flow cytometry with 10 μg/mL purified human natural anti-Gal antibody[17], followed by staining with fluorescein isothiocyanate (FITC)-conjugated mouse anti-human immunoglobulin antibody (Dako, Denmark). Intact tumor cells incubated with neuraminidase only were used as a negative control because they lack the α-Gal epitope.

Generation of dendritic cells from peripheral blood mononuclear cells

A concentrated 50-mL leukocyte fraction was generated through restricted peripheral blood leukapheresis. The peripheral blood mononuclear cells (PBMCs) were then purified using Ficoll-Hypaque (Sigma-Aldrich, United Kingdom) density gradient centrifugation. The cells were resuspended in RPMI-1640 medium supplemented with 10% human AB group serum, plated at a concentration of 5×10^6 cells/mL and allowed to adhere to tissue culture plates for DC preparation. The adherent cells were further cultured at 37 ℃ for 5 d in PRMI-1640 in the presence of 1000 U/mL recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF) (Amoytop Biotech, Xiamen, China), 500 U/mL recombinant human IL-4 (Amoytop Biotech, China), and 1% penicillin/streptomycin (Sino-American, Beijing). They were next grown for an additional 2 d in the presence of 1000 U/mL tumor necrosis factor-α (TNF-α) (R&D Systems, Inc., Shanghai). The semi-adherent and non-adherent cells were harvested by pipetting and used as DCs for pulsing with the tumor cell lysate prepared as described above[18].

The DCs were incubated with mouse anti-human CD3, CD4, CD8, CD14, CD16, CD19, CD40, CD86, CD80, CD83, CD56, CD45RO, MHC I and HLA-DR monoclonal antibodies (BD Biosciences, Shanghai) for 30 min at 4 ℃. Species- and isotype-matched monoclonal antibodies were used as negative controls. Subsequently, the cells were washed and incubated with FITC-conjugated rabbit anti-mouse antibody (Dako, Denmark) and analyzed using FACSCalibur (Becton Dickinson, United States).

Pulsation of autologous dendritic cells by α-Gal expressing tumor cell lysate

The abovementioned DCs (1×10^7 - 4×10^7/mL) were co-cultured with the α-Gal-expressing HCC cell lysate (equal to 2×10^8 cells) in PRMI-1640 medium supplemented with 10% human AB group serum and incubated in 5% CO_2 at 37 ℃ overnight. The co-incubated DCs

were washed twice and resuspended in PRMI-1640 medium at a concentration of 1×10^7 cells/mL in preparation for the activation of tumor-specific T/CIKs.

Generation of tumor-specific T/cytokine-induced killer cells

The non-adherent mononuclear cells obtained from patient bone marrow were resuspended in PRMI-1640 supplemented with 10% human AB group serum at a concentration of 1×10^7 cells/mL. IFN-γ (Amoytop Biotech, Xiamen, China; 1000 U/mL) was added on day 1; Muromonab CD-3 (OKT3) monoclonal antibody (Sunbio, China; 50 ng/mL), IL2 (Canerotc, China; 500 U/mL) and rIL-1α (Amoytop Biotech, Xiamen, China; 100 U/mL) were added on day 2. Fresh complete medium containing IL2 was added every two or three days to expand the CIKs.

The CIKs were collected on day 12 and co-cultured with the tumor cell lysate-pulsed DCs in PRMI-1640 (a ratio of DC:CIK, 1:30) supplemented with 10% AB serum for an additional 72 h in the presence of IFN-γ, OKT3, and IL2. The co-cultured cells were harvested in 2% human albumin saline for injection.

Clinical study design

The patients of the study group received the first injection on the third day after completing the radio- or chemotherapy, and the subsequent doses were administered every week. The first single dose was initiated with 2×10^9 T/CIK cells and increased to 20×10^9 cells per injection.

Patients were monitored for immediate and delayed toxicities. The survival in months was calculated from the time of hospitalization to the time of death or to the present time. Treatment responses were evaluated by clinical observations, laboratory tests and radiological findings. CT scan was performed every 3 mo to evaluate the lesions after the injections. Tumor size was estimated by direct measurement of the volume of the abnormal enhancement region on the CT. The responses were classified into the following categories: (1) disappearance of the entire tumor, classified as complete response; (2) a reduction in tumor size by 25% or more, as partial response (PR); (3) either a decrease in tumor size by less than 25% or an increase in tumor size by less than 25%, classified as no change (NC); and (4) an increase in tumor size by 25% or more, classified as progressive disease (PD).

Delayed-type hypersensitivity reaction

To test the delayed-type cytotoxicity response, 1 μg of autologous tumor cell lysate with no α-Gal epitopes was administered intradermally into the forearm before and after the injections. A positive DTH reaction was recorded as ≥ 5 mm in diameter of rash or any size of blister at the injection site after 48 h.

Interferon-γ enzyme-linked immunospot assay

Human interferon-γ secretion by effectors was assessed by enzyme-linked immunosorbent spot assay (ELISPOT). Multiplescreen 96-well assay plates (Dakewe, Shenzhen, China) were precoated overnight at 4 ℃ with anti-IFN-γ antibody according to the manufacturer's instructions. After washed with PBS and 0.05% Tween-20, the plates were blocked for 1 h at 37 ℃ with 100 μL of RPMI-1640 supplemented with 1% bovine serum albumin (Sigma-Aldrich, Beijing). Mononuclear cells from the patients were plated in triplicate wells at a density of 1×10^4 cells/100 μL of PRMI-1640 medium supplemented with 10% AB serum, cultured overnight, washed and incubated with anti-IFN-γ mAb-biotin (Dakewe, Shenzhen, China). After washing, goat anti-biotin antibodies (Dakewe, Shenzhen, China) were added and incubated for 1 h at 37 ℃, and then 30 μL of activator solution (Dakewe, Shenzhen, China) was used to develop the spots. The number of spots in each well was counted using the Bioreader 4000-PRO-X (Bio-Sys, Germany). The cutoff criterion for positive spots was defined as a spot size more than 3 times the SD greater than the mean value of the spot diameter obtained in the absence of the DCs.

RESULTS

Dendritic cells phenotype

Peripheral mononuclear cells (1.5×10^8 - 6.6×10^8) were induced to differentiate into DCs in the presence of GM-CSF, IL-4 and TNF-α. The final yield of DCs was 1×10^7 - 4×10^7 cells after 7 days of incubation. The phenotype of the purified DCs was 100% HLA class I positive, > 90% CD1a, CD80, and HLA-DR positive, > 70% CD83 and CD86 positive, and CD3, CD4, CD8, CD14, CD19 and CD56 negative.

Synthesis of α-Gal epitopes on intact HCC cells

Intact tumor cells from the 9 patients were isolated for the synthesis of α-Gal epitopes (Figure 1). The tumor cells expressed abundant α-Gal epitopes on their surface after incubation with both neuraminidase and recombinant bovine α1, 3GT as indicated by the extensive binding of human purified natural anti-Gal antibody. However, the cells incubated with recombinant α1,3GT in the absence of neuraminidase weakly expressed the α-Gal epitope at a level that was 10-50 folds lower than the cells incubated with both neuraminidase and recombinant α1,3GT. The reason for this result is that most of the N-acetyllactosamine units on HCC cells were capped by sialic acid and could be exposed by neuraminidase.

Safety of α-Gal-pulsed dendritic cells and tumor-specific cytokine-induced killer cells

The DCs pulsed with tumor cell membrane expressing synthesized epitopes were co-cultured with autologous CIKs to induce tumor-specific CIKs. The cell mixture was administered to the patients for 2-7 times with a mean of 5.

The patients did not develop any grade Ⅲ or Ⅳ adverse effects associated with the treatment. These effects are defined by the National Cancer Institute Common Toxicity Criteria. No other serious side effects were ob-

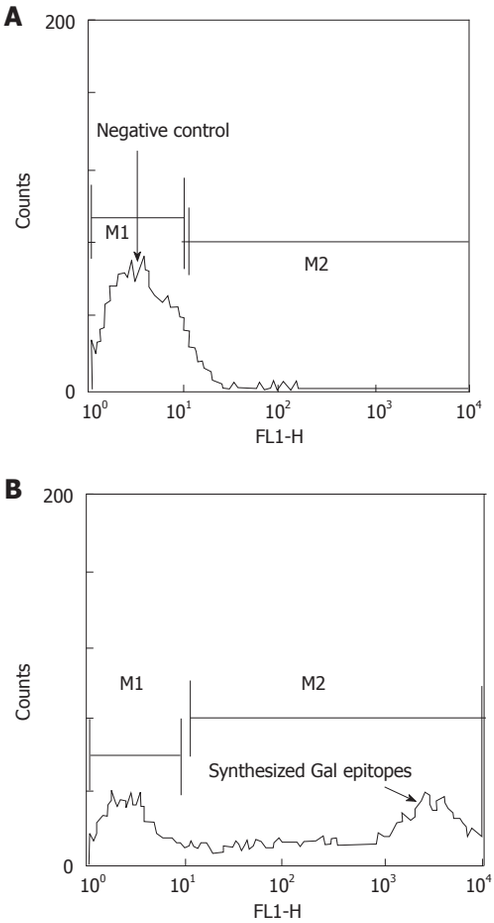

Figure 1 Synthesis of α-Gal epitopes on tumor cell membranes. A: Negative control, tumor cells treated with neuraminidase only, cells with no synthesized epitopes; B: Tumor cells treated with both neuraminidase and α1,3GT, > 60% tumor cells with synthesized α-Gal epitopes.

served other than death from tumor progression. There were no substantial changes in blood tests, such as anti-dsDNA, anti-ANA antibodies, *etc.* All patients developed a mild fever, which lasted 1-3 d after the second and third injections. Five patients showed mild to median rash or multiple erythema, suggesting the presence of delayed-type DTH. All symptoms vanished within 1-2 wk (Table 1).

Delayed-type hypersensitivity reaction

To test the cell-mediated immune responses, tumor lysate with no α-Gal epitopes was administered intradermally into the forearm before and after treatment. A positive DTH skin test reaction was defined as ⩾ 5 mm in diameter after 48 h arbitrarily. As a result, the reaction was less than 5 mm in diameter in all studied patients before immunotherapy. However, after treatment, only one patient demonstrated a negative response and all other patients showed a positive reaction; patients 1, 2, 4, 6, 7 and 9 displayed a reaction of more than 50 mm in diameter (Table 1).

Clinical responses

There were no statistically significant differences between the study and control groups in age (56.8 ± 13.9 years *vs* 49.7 ± 19.7 years; $P = 0.39$). The overall survival in

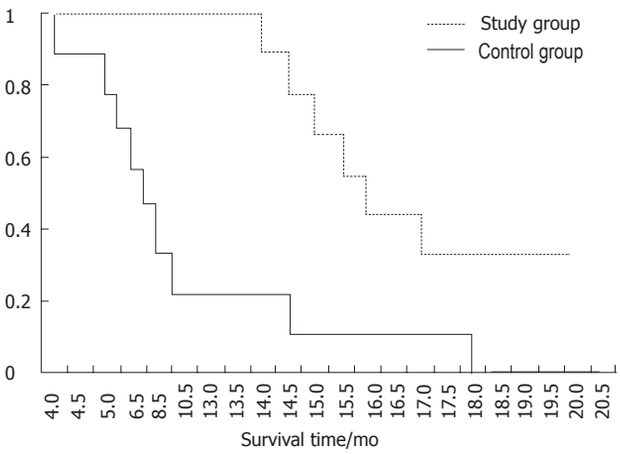

Figure 2 Kaplan Meier survival curves of the patients with stage Ⅲ hepatocellular carcinoma. Study group, $n = 9$; control group, $n = 9$; $P = 0.00121$.

months was determined from the date of hospitalization to the date of death or present time. The response to the treatment was evaluated by clinical observations and laboratory findings.

The quality of life in the study group improved significantly, e.g., the Karnofsky performance status score increased to 90 in 8 patients after treatment. The median survival time for the study and control groups was 17.1 mo and 10.1 mo, respectively. The Kaplan Meier test showed that the survival curves were significantly different between the two groups ($P = 0.00121$) (Figure 2). Three patients in the study group were still alive and in stable condition at the time the paper was written, and they have survived for more than 2 years (Table 1); and three patients showed a partial response in the size of the tumor as shown on CT. The lab test indicated that the AFP in the serum decreased in 8 patients after three injections (Table 1).

Increase of tumor-specific T cells in patients' peripheral blood

The phenotype (CD3, CD4, CD8, CD16, CD19, CD45RO and CD56) of the patients' peripheral blood lymphocytes was analyzed using flow cytometry before and after treatment. A moderate increase in the number of CD3- and CD4-positive cells was observed after immunotherapy; the increase in number of CD45RO+, CD8+ and CD56 cells was significant (Table 2).

The tumor-specific cytotoxicity of PBMCs was assessed by IFN-γ ELISPOT assay. PBMCs were isolated and stimulated with α-Gal-expressing tumor cell lysate. Untreated PBMCs were used as a negative control. The tumor antigens were found to generate strong tumor-specific T cell responses by virtue of their ability to induce increased frequencies of IFN-γ-producing T cells after immunotherapy (Table 2).

DISCUSSION

Previous immunotherapy treatment for primary HCC used passive[19], adoptive[20], and non-specific strategies

Table 2 Ratios of post- and pre-immunotherapy in cell populations and interferon-γ expression levels

Patient no.	CD8+ post *vs* pre	CD45RO+ post *vs* pre	CD56+ post *vs* pre	IFN-γ fold increase post *vs* pre

that yielded limited benefits[21]. There are several possible reasons for the weak and inefficient immune responses against tumor cells. The first and perhaps the most important reason is that the antigenicity of TAA is not strong enough to stimulate the host immune system and cannot be recognized as "foreign"[22]; thus, TAA cannot generate strong tumor-specific immune responses. Another explanation for the inability of TAAs to induce an efficient tumor-specific immune response is the lack of costimulatory molecules on tumor cells[23,24]. The activation of naïve T cells requires recognition by the T-cell receptors (TCRs) of TAA peptides in association with the major histocompatibility complex (MHC) (Signal 1), as well as a costimulatory signal (Signal 2) that is not antigen-specific. The interaction of TCRs on naive T cells with TAAs on tumors without the delivery of signal 2 is thought to result in T cell anergy; this anergy leads to the tolerance of TAAs[23,24], which is similar to the tolerance of normal self-antigens during development. In contrast, if the antigenicity of TAA has been artificially amplified, the uptake of tumor cell membranes by APCs would result in proteolytic degradation of the TAAs, followed by presentation of the TAA peptides in association with MHC class I and class Ⅱ molecules. These molecules together with costimulatory molecules on APCs would activate naive T helper (Th) cells[25].

The second reason is that T cell function is impaired in most patients with malignant tumors[26]. The immunity in tumor patients is generally quite low, and it may be difficult for the circulating T cells to be activated due to anergy to tumor antigens. To overcome these problems, an ideal method is to enhance the TAA, pulse patient DCs with TAA-enriched tumor cells and use the newly differentiated naïve T/CIK cells from bone marrow stem cells. The DCs then activate the patients' naïve T/CIK cells to produce tumor-specific immune responders *ex vivo*.

This new approach consists of four steps to fulfill the ideal requirements for immunotherapy described above. The first step was to increase the antigenicity of TAA based on the bio-synthesis of α-Gal epitopes on the tumor membrane. In the second step, the adhesive cells from PBMCs were induced to differentiate into DCs. At the same time, the isolated non-adhesive mononuclear cells from bone marrow were induced to naïve T/CIKs. In the third step, α-Gal epitope TAAs pulsed DCs. In the final step, the TAA-pulsed DCs and the T/CIKs were co-cultured for a short time to promote TAA delivery to naïve T/CIKs.

In this study, the naïve T/CIKs activated by TAA-pulsed DCs elicited significant cytotoxic responses against tumor cells in 8 of the 9 patients as determined by ELISPOT in the restimulated PBMCs. IFN-γ increased over 10 folds after three injections in patients 1, 2, 3, 4 and 9. While determining whether the injection of DCs and CIKs could increase the T cell reaction against a tumor antigen, we found that the numbers of CD3-, CD4-, CD8-, CD4RO- and CD56-positive cells increased after treatment. Another important finding is that patients treated with the tumor-specific immune cells had a prolonged survival than the control patients. These findings indicate the therapeutic relevance of the observed enhancement of tumor-specific cytotoxicity to HCC.

However, the immunotherapy increased the tumor marker AFP in the serum after the first treatment. We hypothesize that the injection of the immune responders destroyed tumor cells and gradually released the AFP. The specific binding of α-Gal epitope and its natural anti-Gal antibody promotes DC delivery of TAA to T lymphocytes and CIKs *in vitro*. The *ex vivo*-activated, tumor-specific immunoresponse cells may account for the robust increase in the survival of late-stage HCC patients in this study as compared with the control group. This study used α-Gal epitopes added to the tumor cell surface to increase tumor antigenicity, TAA-pulsed DCs and *ex vivo*-activated CIKs rather than TAA-pulsed DCs alone or CIKs alone, which represented a divergence from previously reported immunotherapeutic trials.

In summary, this new therapeutic technique can significantly increase the tumor-specific immune responders in circulation and the survival of advanced HCC patients with no serious side effects. At the same time, clinical studies in other tumors, such as pancreatic carcinoma, lung cancer and lymphoma, are being conducted to reassess the role that the therapy may play in prolonging the survival of the patients.

COMMENTS

Background

Hepatocellular carcinoma (HCC), the most common primary neoplasm of the liver, is generally resistant to conventional treatment. This led to the interest in studies of alternative approaches. Immunotherapy is particularly appealing because of the potential specificity of the immune response in eradicating residual tumor cells after conventional treatment. However, the biggest obstacles of tumor immunotherapy are the low antigenicity of tumor cells and the weak immunity of the patients.

Research frontiers

Previous reports have suggested that synthesis of the immunostimulatory xenoantigen α-Gal on malignant cells could be used as a means to enhance tumor-associated antigen (TAA) immunogenicity and that treatment with cytokine-

induced killer cells (CIKs) may benefit patients with various types of tumors. Although the α-Gal epitope can increase the antigenicity of tumor cells and CIKs can kill tumor cells, the combination of α-Gal epitope-capped TAAs pulsed dendritic cells (DCs) with the newly differentiated naive T/CIKs to treat tumors has never been reported. In this study, the authors demonstrate that the novel technique has a great potential for tumor treatment.

Innovations and breakthroughs

The authors described a novel immunotherapy for advanced HCC. DCs were pulsed by co-culturing with patient's α-Gal epitope expressing tumor cells to promote phagocytosis *in vitro*. The pulsed DCs were employed to activate newly differentiated T cells from bone marrow stem cells which had not been anergized by the tumor antigen. The highly active, tumor-specific immunoresponders were expanded *ex vivo*.

Applications

The combination of the α-Gal epitope-expressing tumor cell-pulsed DCs and the newly differentiated naive T/CIKs could increase specific anti-tumor immune responses and prolong the survival of HCC patients with no serious side effects. This study represents a new strategy for therapeutic intervention in the treatment of patients with HCC.

Terminology

α-Gal epitope-pulsed dendritic cells (DCs): DCs are potent antigen presenting cells (APCs) that possess the ability to stimulate naïve T cells. The α-Gal epitope expressing tumor cells are co-cultured with DCs in the presence of natural anti-Gal antibody to promote phagocytosis and presentation of tumor antigens to T lymphocytes. Cytokine-induced killer cells (CIKs): CIKs are a heterogeneous subset of *ex-vivo* expanded T lymphocytes which present a mixed T phenotype. They have been described as highly efficient cytotoxic effector cells capable of recognizing and lysing tumor cell targets in a non-major histocompatibility complex restricted fashion. CIKs could also be activated and attack tumor cells specifically after contact with tumor specific DCs.

Peer review

This is a study looking for the role of *ex vivo* activated tumor specific CIK therapy on HCC. This is definitely a well planned and performed and well written study. The authors describe a novel immunotherapy for advanced HCC, and the data is compelling.

Abstract

AIM: To investigate the role of hepatic peroxisome proliferator-activated receptor-γ (PPAR-γ) in increased susceptibility to endotoxin-induced toxicity in rats with bile duct ligation during endotoxemia.

METHODS: Male Sprague-Dawley rats were subjected to bile duct ligation (BDL). Sham-operated animals served as controls. DNA binding were determined by polymerase chain reaction, Western blotting analysis, and electrophoretic mobility shift assay, respectively. BDL and sham-operated rats received a non-lethal dose of intraperitoneal lipopolysaccharide (LPS) injection (3 mg/kg, i.p.). Additionally, the potential beneficial effects of the PPAR-γ agonist rosiglitazone were determined in BDL and sham-operated rats treated with a non-lethal dose of LPS. Survival was assessed in BDL rats treated with a non-lethal dose of LPS and in sham-operated rats treated at a lethal dose of LPS (6 mg/kg, i.p.).

RESULTS: PPAR-γ activity in rats undergoing BDL was significantly lower than in the sham-controls. Hepatic *PPAR-γ* gene expression was downregulated at both the mRNA and protein levels. In a parallel group, serum levels of pro-inflammatory cytokines were nearly undetectable in the sham-operated rats. When challenged with a non-lethal dose of LPS (3 mg/kg), the BDL rats had approximately a 2.4-fold increase in serum IL-6, a 2.7 fold increase in serum TNF-α, 2.2-fold increase in serum IL-1 and 4.2-fold increase in serum ALT. The survival rate was significantly lower as compared with that in sham-operated group. Additionally, rosiglitazone significantly reduced the concentration of TNF-α, IL-1β, IL-6 and ALT in sham-operated rats, but not in BDL rats, in response to LPS (3 mg/kg). Also, the survival was improved by rosiglitazone in sham-operated rats challenged with a lethal dose of LPS, but not in BDL rats, even with a non-lethal dose of LPS (3 mg/kg).

CONCLUSION: Obstructive jaundice downregulates hepatic PPAR-γ expression, which in turn may contribute to hypersensitivity towards endotoxin.

Key words: Obstructive jaundice; Endotoxemia; Liver; Peroxisome proliferator-activated receptor-γ; Rosiglitazone

Lv X, Song JG, Li HH, Ao JP, Zhang P, Li YS, Song SL, Wang XR. Decreased hepatic peroxisome proliferator-activated receptor-γ contributes to increased sensitivity to endotoxin in obstructive jaundice. *World J Gastroenterol* 2011; 17(48): 5267-5273 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i48/5267.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i48.5267

INTRODUCTION

The high incidence of perioperative septic complications in patients with obstructive jaundice is well documented. This may be related to the high frequency of endotoxemia during cholestasis. It has been reported that up to 50%-70% of patients with obstructive jaundice, even without identifiable source of infection in many cases, have endotoxemia [1-3]. Increased bacterial translocation and absorption of endotoxins, caused by changes in plasma lipoproteins that bind endotoxin, loss of intestinal mucosal integrity, and lack of bile salts in the intestinal lumen, may result in endotoxemia[4-7]. On the other hand, enhanced susceptibility toward endotoxin-induced toxicity, characterized by exaggerated release of several proinflammatory cytokines, more severe organ damage, and reduced survival after non-lethal endotoxemia, is also believed to be responsible for the high morbidity and mortality of patients with obstructive jaundice[8-11]. Previous studies have suggested that prolonged stimulation or over-activation of the Kupffer cells (KCs), the largest numbers of resident macrophages in the liver, is a critical factor in the exaggerated inflammatory response to endotoxin[12-14].

Peroxisome proliferator-activated receptor-γ (PPAR-γ) is a ligand activated transcription factor that belongs to the nuclear receptor family. It is a key regulator of adipocyte differentiation, lipid metabolism, glucose homeostasis, and cell proliferation. Activation of PPARγ could produce anti-inflammatory effects by repressing the expression of inflammatory cytokines in activated macrophages and monocytes[15,16]. In endotoxemia and sepsis, it has been reported that hepatic PPAR-γ expression in KCs is downregulated, possibly by increased plasma tumor necrosis factor-α (TNF-α). Decreased PPAR-γ expression, in turn, increased the production of proinflammatory cytokines and tissue injury[17]. During obstructive jaundice, portal or systemic endotoxemia is frequently observed. Also, circulating proinflammatory cytokines (e.g., TNF-α and interleukin-6) are increased even in the absence of exogenous stimuli under cholestatic conditions[18-21]. We therefore speculated that the PPAR-γ expression and function in the liver are decreased by endotoxemia and/or increased proinflammatory cytokines during obstructive jaundice.

Here we examined whether hepatic PPAR-γ expression and function are decreased in a rat model of obstructive jaundice, to seek for a possible correlation between alteration of PPAR-γ expression and increased susceptibility to endotoxin.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats (250-300 g) were purchased from the Animal Center of Shanghai Jiao Tong University School of Medicine (Shanghai, China) and were housed in an air-filtered room at 22-25 ℃ on a 12-h light/dark cycle, with unlimited access to water and standard rat chow. All experimental procedures were in accordance with the institutional animal care guidelines and approved by the local ethic committees.

Bile duct ligation

Rats were anesthetized with sodium pentobarbital (50 mg/kg, i.p.). The common bile duct was ligated and divided after laparotomy. Sham-operated rats underwent the same procedure without bile duct ligation.

Experimental protocol

Three sets of experiments were carried out. In the first experiment, rats were sacrificed at day 7 after the surgery to analyze PPAR-γ expression and activation in the liver. In the second experiment, endotoxemia was established by a non-lethal dose of lipopolysaccharide (LPS) (*Escherichia coli* 0111:B4; Sigma, 3 mg/kg, i.p.) in the BDL or sham-operated rats. Blood was collected for analysis of pro-inflammatory cytokines (e.g., TNF-α, IL-6 and IL-1β) and alanine aminotransferase (ALT) 2 h after LPS challenge. Survival was also monitored in another group. In the third experiment, the potential beneficial effects of the PPAR-γ agonist rosiglitazone were examined in BDL and sham-operated rats treated with a non-lethal dose of LPS (3 mg/kg, i.p.). Survival was examined in BDL rats treated with a non-lethal dose of LPS and in sham-operated rats treated at a lethal dose of LPS (6 mg/kg, i.p.). Rosiglitazone (3 mg/kg, i.p.) or vehicle (10% dimethyl sulfoxide) was administered intraperitoneally as a bolus 15 min prior to LPS injection.

RNA extraction and peroxisome proliferator-activated receptor-γ gene expression

Total RNA was extracted from hepatic tissues using TRIzol reagent (Invitrogen, United States) according to the manufacturer's protocol. Primers were obtained from Shanghai Sangon Biologic Engineering and Technology and Service (Shanghai, China). The following primer sequences were used: for PPAR-γ mRNA (forward: 5'-ACACCATGCTGGCCTCCCTGA-3'; reverse: 5'-AAGCCTGGGCGGTCTCCACT-3'; size 220 bp), and for β-actin (forward: 5'-CCACACCCGCCACCAGTTCG-3'; reverse: 5'-CTTGCTCTGGGCCTCGTCGC-3'; size 205 bp). Amplifica-

tion and detection were performed with an ABI PRISM 7300 real-time polymerase chain reaction (PCR) System (Applied Biosystems, Foster City, California, United States) as follows: 30 s at 95 ℃, and 40 cycles at 95 ℃ for 5 s and at 60 ℃ for 31 s. The DNA-binding dye SYBER Green I for the detection of PCR products was used. The reaction mixture (RT-PCR kit, Code DRR063A, Takara) contained 25 μL Premix Ex Taq, 1 μL forward and reverse primers, 1 μL ROX reference dye, 4 μL cDNA (equivalent to 20 ng total RNA) in a final volume of 50 μL. The amount of gene transcript was measured using a comparative (2-[DELTA][DELTA]CT) method by Applied Biosystems. The reference gene β-actin was used for normalization of the expression data.

Western blotting analysis of peroxisome proliferator-activated receptor-γ proteins

The nuclear extracts were prepared from liver tissues using a nuclear extract kit (Active Motif, Carlsbad, CA), following the manufacturer's protocol. Protein concentration was measured by the bicinchoninic acid assay method (Pierce). Liver nuclear extracts containing equal amounts of protein were separated in a 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (PAGE). Separated protein bands were transferred onto a nitrocellulose filter. The filter was blocked with 5% non-fat milk, primary rabbit-anti-mouse PPAR-γ antibody (1:200 dilution, Santa Cruz Technologies, Santa Cruz, CA) and β-actin monoclonal antibody (1:4000 dilution, Sigma-Aldrich) were used. After incubation with a horseradish peroxidase-conjugated secondary antibody, chemoluminescence agent A was mixed with B at equal volumes and evenly smeared onto the filter. The chemiluminescence signals were quantified using a Chemi-Smart 3000 (Vilber Lourmat; Marne-la-Vallée, France).

Electrophoretic mobility shift assay of peroxisome proliferator-activated receptor-γ activation

Electrophoretic mobility shift assay (EMSA) was used to detect specific binding of the transcription factor PPAR-γ to its specific DNA consensus sequence. Nuclear protein/DNA binding reactions were conducted for 20 min at room temperature in a 20-μL reaction volume containing 2 μL 10 × binding buffer, 1 μL polydI-dC, 1 μL 50% glycerol, 1 μL 1% NP-40, 1 μL of 1 mol/L KCl, 1 μL 100 mmol/L $MgCl_2$, 1 μL 200 mmol/L EDTA (all the reagents are included in the LightShift Chemiluminescent EMSA kit; Pierce), 20 fmol biotin-labeled probe (PPAR-γ consensus sequence 5'-GGGGTCAGTAAGTCAGAGGCCAGGGA-3'), and 2 μL nuclear extract. Binding reactions were analyzed using 8% PAGE. After blotting to a nylon membrane, the labeled oligonucleotides were detected with the LightShift Chemiluminescent EMSA kit (Pierce). The relative intensity of the bands was analyzed using an LAS-1000 luminoimage analyzer (Fuji Film, Tokyo, Japan).

Measurement of serum cytokines and alanine aminotransferase

Serum concentrations of TNF-α, IL-1β, or IL-6 were quantified using enzyme-linked immunosorbent assay (R&D Systems). Serum ALT levels were determined with an autoanalyzer (Model 7600, Hitachi Co., Tokyo, Japan).

Statistical analysis

The data were expressed as means ± SE. Data were analyzed by analysis of variance, followed by the Student-Newman-Keuls test. The survival curve was estimated by the Kaplan-Meier method and statistical significance was assessed by log-rank test. *P* values less than 0.05 were considered as significant.

RESULTS

Peroxisome proliferator-activated receptor-γ activation and expression are decreased upon bile duct ligation-induced cholestasis

We started the investigation by measuring modification of *PPAR-γ* activation and expression upon BDL and consequent cholestasis. We measured levels of PPAR-γ activation through electrophoretic mobility shift assay of PPAR-γ DNA binding in nuclear extracts from liver of treated and control rats (Figure 1A). PPAR-γ activity in rats undergoing BDL was significantly lower than in the sham-controls (0.62 ± 0.07 *vs* 1.00 ± 0.08, $P = 0.0257$). Hepatic *PPAR-γ* gene expression was downregulated at both the mRNA (1 ± 0.09 *vs* 0.09 ± 0.03, $P = 0.0000002$, Figure 1B) and protein levels (0.70 ± 0.02 *vs* 0.59 ± 0.01, $P = 0.0089$, Figure 1C).

Enhanced susceptibility toward endotoxin-induced toxicity in rats with pre-existing cholestasis

In a parallel group, serum levels of pro-inflammatory cytokines were nearly undetectable in the sham-operated rats. Biliary obstruction *per se* resulted in the induction of pro-inflammatory cytokines, such as TNF-α, IL-1β and IL-6 (66.0 ± 6.5 *vs* 27.9 ± 3.2, $P = 0.00036$; 56.0 ± 7.6 *vs* 19.7 ± 2.6, $P = 0.0011$; 60.2 ± 5.8 *vs* 30.7 ± 3.5, $P = 0.0014$, Table 1), and liver injury, as indicated by increased circulating level of ALT (119.7 ± 11.1 *vs* 41.2 ± 3.2, $P = 0.00005$, Table 1). When challenged with a non-lethal dose of LPS (3 mg/kg), the BDL rats had approximately 2.75-fold increase in serum TNF-α, 2.21-fold increase in serum IL-1β, 2.41-fold increase in serum IL-6 and 4.17-fold increase in serum ALT (2364.7 ± 196.3 *vs* 861.1 ± 44.2, $P = 0.00006$; 2373.0 ± 265.1 *vs* 1073 ± 97.7, $P = 0.00098$; 10802.0 ± 853.2 *vs* 4476.7 ± 430.2, $P = 0.00005$; 305.0 ± 37.5 *vs* 73.2 ± 7.7, $P = 0.0001$, Table 1). The survival rate was significantly lower than in the sham-operated group (20% *vs* 90%, $P = 0.000009$, Figure 2). These results indicated that enhanced susceptibility toward endotoxin-induced toxicity is present in BDL rats, which is consistent with previous studies.

Peroxisome proliferator-activated receptor-γ agonist rosiglitazone does not protect jaundiced rats from endotoxemia

To further verify a possible correlation between alterations of PPAR-γ function and increased susceptibility

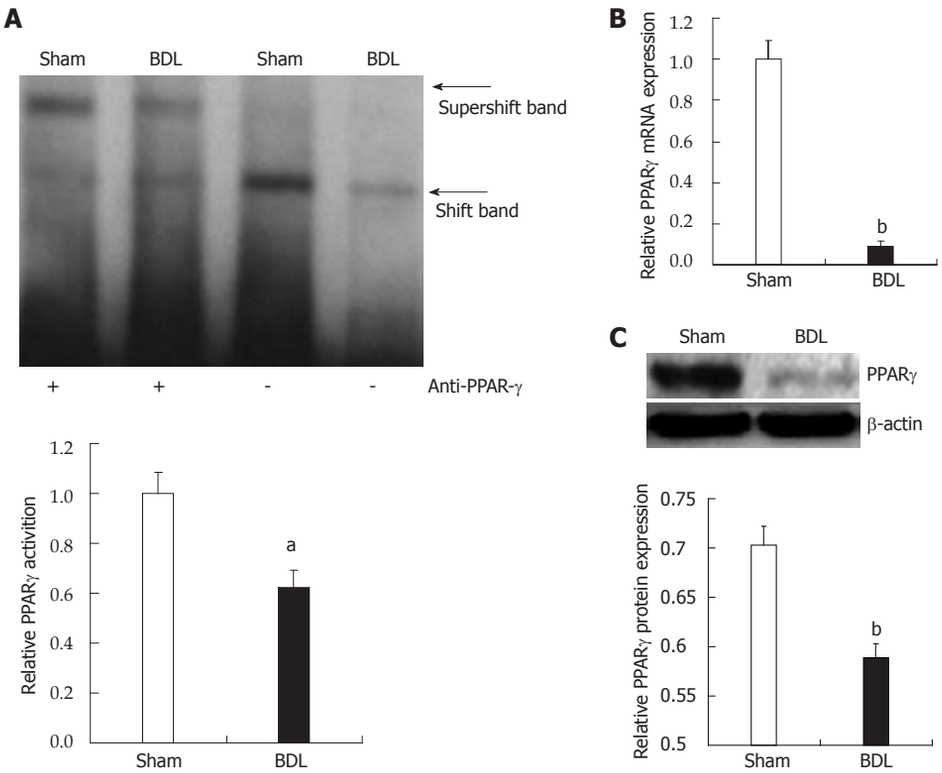

Figure 1 Modified measurement of peroxisome proliferator-activated receptor-γ activation and expression upon bile duct ligation and consequent cholestasis. A: Electrophoretic mobility shift assay (top panel) of peroxisome proliferator-activated receptor (PPAR)-γ. DNA binding in nuclear extracts from liver, and relative densitometric analysis (lower panel). Data are expressed as mean ± SE (n = 3). [a]P < 0.05 for bile duct ligation (BDL) group *vs* sham group; B: PPAR-γ mRNA expression in the liver. PPAR-γ expression in the liver of BDL rats decreased significantly compared with the sham-group determined by quantitative real-time reverse transcription-polymerase chain reaction. Data are expressed as mean ± SE (n = 6). [b]P < 0.01 for BDL group *vs* sham group; C: Western blotting analysis (top panel) of PPAR-γ in nuclear extracts from liver, and relative densitometric analysis (lower panel, n = 3). Data are expressed as mean ± SE (n = 3). [b]P < 0.01 for BDL group *vs* sham group.

Table 1 Serum alanine aminotransferase, tumor necrosis factor-α, IL-1β and IL-6 levels in rats after administration of lipopolysaccharide (n = 6, mean ± SE)

	Sham	BDL	Sham + LPS	BDL + LPS
ALT (U/L)	41.2 ± 3.2	119.7±11.1[a]	73.2 ± 7.7	305.0 ± 37.5[a]
TNF-α (pg/mL)	27.9 ± 3.2	66.0 ± 6.5[a]	861.1 ± 44.2	2364.7 ± 196.3[a]
IL-1β (pg/mL)	19.7 ± 2.6	56.0 ± 7.6[a]	1073 ± 97.7	2373.0 ± 265.1[a]
IL-6 (pg/mL)	30.7 ± 3.5	60.2 ± 5.8[a]	4476.7 ± 430.2	10802.0 ± 853.2[a]

[a]P < 0.01 for bile duct ligation group *vs* Sham group. BDL: Bile duct ligation; LPS: Lipopolysaccharide; ALT: Alanine aminotransferase; TNF-α: Tumor necrosis factor-α.

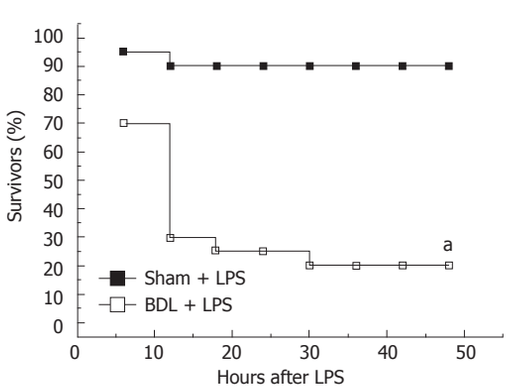

Figure 2 Survival rates of rats after administration of lipopolysaccharide (3 mg/kg, i.p.). The survival curve was estimated by the Kaplan-Meier method and the log-rank method was used to compare differences in survival rates between groups (n = 20). [a]P < 0.01 for bile duct ligation group *vs* sham group. BDL: Bile duct ligation; LPS: Lipopolysaccharide.

to endotoxin, we investigated whether PPAR-γ agonist rosiglitazone had anti-inflammatory effects in BDL rats. Treatment with rosiglitazone significantly reduced the concentration of TNF-α, IL-1β, IL-6, and ALT in sham-operated rats, but not in BDL rats, in response to LPS (3 mg/kg) (Table 2). The survival was improved by rosiglitazone in sham-operated rats challenged with a lethal dose of LPS (6 mg/kg) (50% *vs* 20%, P = 0.040) but not in BDL rats, even with a non-lethal dose of LPS (35% *vs* 25%, P = 0.49) (Figure 3). These data indicated that endogenous anti-inflammatory pathway of nuclear receptor PPAR-γ is impaired by obstructive jaundice, which in turn may be at least in part, responsible for the increased susceptibility to endotoxin.

DISCUSSION

In this study, both the expression and function of PPAR-γ in the liver were significantly depressed in rats with BDL as compared with the sham-operated rats. Concomitant to the decrease in PPAR-γ DNA binding, we observed a markedly increased susceptibility to endotoxin, evidenced by higher degree of liver injury, enhanced proinflammatory cytokine release, and a higher mortality. The PPAR-γ

agonist rosiglitazone failed to protect BDL rats against endotoxemia.

Despite the use of broad-spectrum antibiotics and improvement in surgical technique, patients with cholestatic liver disease continue to experience a high incidence of postoperative morbidity and mortality[22,23]. Belghiti *et al*[24] showed that the mortality of patients with obstructive jaundice is much higher (21%) than that of the patients with normal liver function. Among the multiple complications from obstructive jaundice, gram-negative bacterial sepsis is the most common cause of secondary morbidity and mortality[25]. Animal studies have demonstrated that obstructive jaundice exaggerates the release of several cytokines after endotoxin administration, including TNF-α, IL-1β, and IL-6[8-11].

KCs are the largest macrophage population and form the first line of defense against microorganisms entering the portal circulation. It has been demonstrated that the KCs are the primary source of circulating TNF-α and IL-6 in response to LPS[26]. In the context of appropriate immune response, KC activation plays a protective role during the acute phase of hepatopathies. However, in response to prolonged bacterial or endotoxin challenge, KC over-activation may increase the severity of organ damage and lethality. With regards to obstructive jaundice, previous studies indicate that liver KCs are involved in the exaggerated cytokine secretion after endotoxin challenge[12,13]. In jaundiced animals undergoing endotoxin challenge, blockade of KC function with gadolinium chloride or TNF-α antibody has been shown to improve survival and to suppress the systemic proinflammatory response[14]. Consequently, altered function of KCs during cholestasis is thought to play a decisive role in the increased susceptibility to endotoxin-induced toxicity.

PPARs are ligand-activated transcription factors belonging to the nuclear hormone receptor superfamily. Recently, it has been found that PPAR-γ activation inhibits the expression of several inflammatory response genes in activated macrophages, including the genes encoding inducible nitric oxide synthase, TNF-α, gelatinase B, and COX-2[27,28]. Moreover, activation of PPAR-γ reduces the organ injury/dysfunction caused by endotoxin[29] and by hemorrhage and resuscitation[30], as well as systemic inflammation caused by zymosan[31] and by cecal ligation and puncture[32] in rodents. In this study, the expression and function of hepatic PPAR-γ were decreased during obstructive jaundice. PPAR-γ agonist rosiglitazone failed to protect BDL rats from lethal endotoxemia, suggesting that the downregulation of PPAR-γ in jaundiced rats is of functional significance.

It should be pointed out that hepatic PPAR-γ is expressed in both KCs and hepatocytes (HCs). We did not examine the source of PPAR-γ activity in this study. Nevertheless, previous studies have indicated that PPAR-γ gene expression decreased significantly in KCs at 20 h after sepsis by cecal ligation and puncture, whereas PPAR-γ expression in HCs was not altered. Moreover, when isolated KCs or HCs from normal rats were stimulated with LPS or TNF-α for 20 h, KC PPAR-γ protein levels were all significantly decreased. In contrast, neither LPS nor TNF-α affects PPAR-γ protein levels in HCs either in monoculture or in co-culture with KCs. These findings suggest that the KCs and HCs respond to LPS and TNF-α differentially[17]. Therefore, we believe that the downregulated PPAR-γ expression in the liver during obstructive jaundice is most likely due to decreased PPAR-γ in KCs but not in HCs.

Recent studies have indicated the potential efficacy of PPAR-γ ligands as novel therapeutic approaches in sepsis, inflammation and reperfusion injury. However, our observation that treatment with a PPAR-γ ligand fails to provide protection in cholestatic animals suggests that activation of the endogenous PPAR-γ pathway may need to be tailored to the specific conditions, e.g., obstructive jaundice.

Evidence suggests that the PPAR-γ expression is a function of the inflammatory response. For instance, in rats subjected to sepsis by cecal ligation and puncture or

double-hit hemorrhage and sepsis, PPAR-γ expression is downregulated in the liver, bronchial epithelium, and vascular endothelium[33-35]. In mice subjected to endotoxin administration, PPAR-γ expression is also markedly reduced in adipose tissues, heart and lungs[36-39]. Consistent with these reports, the current study demonstrated that biliary obstructive jaundice significantly increases serum amounts of TNF-α, IL-6 and IL-1β. Thus, increased proinflammatory cytokines (e.g., TNF-α) during cholestasis may result in downregulation of the PPAR-γ in the liver.

In conclusion, biliary obstructive jaundice downregulates hepatic PPAR-γ expression and function, which in turn may contribute to enhanced susceptibility to endotoxin-induced toxicity.

COMMENTS

Background

Biliary obstructive jaundice increases susceptibility to endotoxin-induced toxicity. However, the underlying molecular mechanisms are not fully understood.

Research frontiers

Peroxisome proliferator-activated receptor-γ (PPAR-γ) is a member of the nuclear receptor family of ligand-activated transcription factors. Activation of PPARγ could produce anti-inflammatory effects. In this study, the authors demonstrated that hepatic PPAR-γ is down-regulated upon obstructive jaundice, and provided some evidence suggesting that the down-regulation of PPAR-γ contributes to the hypersensitivity to endotoxin.

Innovations and breakthroughs

The expression and function of hepatic PPAR-γ were significantly decreased in the bile duct ligation rats compared with the control rats. Down-regulation of PPAR-γ was accompanied by exaggerated inflammatory response. Treatment with the PPAR-γ agonist rosiglitazone protected sham-operated, but not BDL rats, from endotoxemia.

Applications

Recent studies have suggested the potential efficacy of PPAR-γ ligands as novel therapeutic approaches in sepsis, inflammation, and reperfusion injury. The treatment with a PPAR-γ ligand fails to provide protection of cholestatic animals suggests that activation of the endogenous PPAR-γ pathway needs to be tailored to the specific conditions, e.g., obstructive jaundice.

Peer review

This is an elegant study from a biological observation to a potential clinical aspect.

Abstract

AIM: To investigate the outcomes of early and delayed elective resection after initial antibiotic treatment in patients with complicated diverticulitis.

METHODS: The study, a non-randomized comparison of the two approaches, included 421 consecutive patients who underwent surgical resection for complicated sigmoid diverticulitis (Hinchey classification Ⅰ-Ⅱ) at the Department of Surgery, University Medical Center Hamburg-Eppendorf between 2004 and 2009. The operating procedure, duration of hospital and intensive care unit stay, outcome, complications and socioeconomic costs were analyzed, with comparison made between the early and delayed elective resection strategies.

RESULTS: The severity of the diverticulitis and American Society of Anesthesiologists score were comparable for the two groups. Patients who underwent delayed elective resection had a shorter hospital stay and operating time, and the rate of successfully completed laparoscopic resections was higher (80% *vs* 75%). Eight patients who were scheduled for delayed elective resection required urgent surgery because of complications of the diverticulitis, which resulted in a high rate of morbidity. Analysis of the socioeconomic effects showed that hospitalization costs were significantly higher for delayed elective resection compared with early elective resection (9296 € ± 694 € *vs* 8423 € ± 968 €; $P = 0.001$). Delayed elective resection showed a trend toward lower complications, and the operation appeared simpler to perform than early elective resection. Nevertheless, delayed elective resection carries a risk of complications occurring during the period of 6-8 wk that could necessitate an urgent resection with its consequent high morbidity, which counterbalanced many of the advantages.

CONCLUSION: Overall, early elective resection for complicated, non-perforated diverticulitis is shown to be a suitable alternative to delayed elective resection after 6-8 wk, with additional beneficial socioeconomic effects.

INTRODUCTION

Diverticular disease of the sigmoid colon is common in Western countries with a prevalence of 27%[1,2]. It increases with age from approximately 10% in those younger than 40 years to 33% in those older than 45 years, and then to 50%-70% in those older than 80 years. The average age of presentation with diverticulitis is 62 years. In the United States, approximately 130 000 patients per year are admitted to hospital due to diverticulitis. The increase in the number of cases diagnosed in recent years is, in part, due to improvements in non-invasive diagnostic techniques, especially the use of computed tomography (CT) scanning[3].

The risk of recurrence after a first attack of diverticulitis ranges from 5%-43%[4]. Complications (which include fistula formation, abscess, bleeding or perforation) occur in 15%-20% of cases and require surgical intervention[5,6]. The treatment of patients with complicated sigmoid diverticulitis is associated with a significant morbidity and mortality that is mainly influenced by the severity of the disease and the global medical status of the patient. For elective sigmoid resections, the postoperative morbidity rate is 15%-20%[5] and the mortality rate ranges from between 0%-17%, compared to 30% in patients with perforated diverticulitis[6-8].

The appropriate timing of elective resection for uncomplicated diverticulitis is a subject of controversy, with discussion focused mainly on the number of previous attacks. Surgery is generally suggested after one to four episodes of diverticulitis[9]. The American Society of Colon and Rectal Surgeons recommends that the decision regarding resection be made on a case-by-case basis[10]. Even in patients with clear indication for elective resection, the optimal timing of the operation remains unclear as little data exists, especially for cases of complicated diverticulitis. Therefore, this trial analyzed the impact of both delayed and early elective resections on outcome, mortality and morbidity, and socioeconomic cost.

MATERIALS AND METHODS

Study design and patients

The study analyzed 421 consecutive patients in whom elective surgical resection for complicated sigmoid diverticulitis had been planned at the Department of Surgery at the University Medical Center Hamburg-Eppendorf between 2004 and 2009. The study was approved by the institutional review board of the hospital. The stage of the diverticulitis was classified according to the modified Hinchey score[11], which is based on the CT scan at the time of diagnosis. Only patients with clear indication for surgery with complicated diverticulitis, but without perforation (Hinchey Ⅰ-Ⅱ), were included in this trial. Data, which included the sex and age of the patient, medication and the complications experienced, were obtained from clinical records. Data concerning previous medical history, co-morbidities and the American Society of Anesthesiologists (ASA) score at the time of the presentation and classification of the disease were recorded, along with the operating procedure and duration of the operation, durations of the hospital and intensive care unit stays, outcome and complications. Clinical follow-up data was obtained by review of the hospital records and by direct communication with the patients or their attending physicians. The socioeconomic costs of the treatment were evaluated in all cases by review of the total amount invoiced to the health insurance companies.

Operation and antibiotic treatment

On the basis of clinical features and CT scan, elective resection of the sigmoid was planned, with laparoscopic resection the operation of choice, where possible, for all patients except those who had undergone previous major abdominal surgery. The operating surgeon decided whether to perform a primary anastomosis with or without diverting stoma, or a Hartman's procedure depending on the intraoperative findings. The patients were assigned by their surgeon to either early or delayed elective surgery without randomization. The group assigned to early elective resection was treated with antibiotics (ceftriaxone and metronidazole) for 2-4 d before the early elective resection was performed. The delayed elective group was treated with intravenous antibiotics (ceftriaxone and metronidazole) for 5-7 d depending on the clinical course of the patient. Once their symptoms had settled, the patients were discharged and an elective resection was performed 6-8 wk later.

Statistical analysis

SPSS® for Windows® Version 13.0 (SPSS Inc., Chicago, IL, United States) was used for statistical analysis. Data are presented as mean ± SD. The continuous data for the different groups were compared using the Student's *t* test. For all non-continuous variables, cross-tables were generated, followed by calculation of the *P* value by using the χ^2 test/Fisher's exact test. Statements of significance refer to *P* values for two-tailed tests of less than 0.05.

RESULTS

Patient characteristics

Overall, 421 patients who underwent surgical resection for sigmoid diverticulitis were included. To analyze the impact of the timing of the operation, early elective surgery was compared to delayed elective surgery after 6-8 wk. Early elective surgery was performed in 272 patients at a median of 2 d after admission to hospital. Elective resection after 6-8 wk was planned for 149 patients; however, eight of these required urgent surgery during this period because of the occurrence of severe complications following their initial conservative management.

At the time of surgery, the mean age of the patients was 63 ± 13 years; 184 patients (44%) were men, 237 patients (56%) women. Preoperatively, 14 patients (3%) were classified as ASA 1239 (57%) as ASA 2159 (38%) as ASA 3 and 9 patients (2%) as ASA 4. In 362 patients (86%), complicated diverticulitis or a small confined pericolic or

mesenteric abscess was diagnosed (Hinchey I); while 59 patients (14%) presented with a distant or complex abscess without perforation (Hinchey II).

The distribution of patients who underwent early and delayed elective resection was largely comparable with regards to sex, age, ASA classification and severity of the diverticulitis (Hinchey classification, Table 1).

The operation performed

Overall, 323 patients (77%) underwent laparoscopic resection, while open surgery, including conversions, was performed in 98 patients (23%). Primary anastomosis without a diverting stoma was possible in 387 patients (92%), while 30 patients (7%) received a primary anastomosis and diverting stoma. In four patients (1%) a Hartman's procedure with descendostomy was necessary due to peritonitis. No significant difference in mortality rates between the various procedures (primary anastomosis, with or without diverting stoma, or Hartman´s procedure) was identified.

In patients who underwent delayed elective resection after 6-8 wk, the rate of successfully completed laparoscopic resection was significantly higher, as the inflammation had settled down compared with the early elective resection group (80% *vs* 75%, $P = 0.032$).

Outcome

Three patients (0.7 %) died in hospital. For delayed elective resection, the rate of wound infections was 7.1% *vs* 11.0% for early surgery; the rate of re-operations 5.7% *vs* 8.1%; these differences were not statistically significant. However, the operating time (149 min *vs* 166 min; $P < 0.001$) and the hospital stay (13 d *vs* 16 d, $P = 0.002$) were significantly shorter (Table 2).

Complications whilst waiting for delayed elective surgery

It is important to note that in eight patients initially planned for delayed elective surgery, urgent surgery was necessary before the 6-8 wk period had elapsed. Reasons for proceeding to urgent surgery were recurrent episodes with covered perforation or perforation with fecal peritonitis in four patients (on days 24, 29, 34 and 41), clinical deterioration in three patients (on days 3, 5 and 6) and re-presentation with acute diverticular bleeding in one patient. This subgroup of patients had a higher rate of complications. Three patients underwent a Hartman´s procedure and four underwent re-operations either for a planned second look and lavage, or because of anastomotic leakage; one of these patients died. On analysis of outcome based on the intention to treat, the advantages of delayed elective resection are lost with the exception of the shorter operating time and hospital stay (Table 3).

ICU: Intensive care unit.

Socioeconomic effects

The socioeconomic costs of the hospital stay for the two treatment approaches were compared. Early elective resection was found to reduce the overall costs from 9296 € ± 694 € to 8423 € ± 968 € ($P < 0.001$). This is mainly due to costs incurred during the initial intravenous antibiotic treatment. With the inclusion of the eight patients who needed urgent surgery, the advantage for early surgery is even greater.

DISCUSSION

New insights from this study

Taken together, our results suggest that delayed elective resection has a better outcome in complicated diverticulitis than early elective resection as long as no acute complications occur during the 6-8 wk. The occurrence of an

acute complication is associated with a very unfavorable outcome. Therefore the decision to proceed to early or delayed elective resection should still be made on a case-by-case basis. In patients who are scheduled for delayed elective resection, close clinical monitoring is recommended until the definitive surgical treatment, to allow for early management of any possible clinical deterioration.

The risk of recurrence

In uncomplicated diverticulitis, medical treatment, which consists of broad-spectrum antibiotic therapy for 5-10 d and resting of the bowel with parenteral nutrition, is usually successful. The indication for elective resection and its most appropriate timing in uncomplicated diverticulitis is the subject of controversial discussions. Surgery is primarily suggested after one to four episodes of diverticulitis[9,12-14]. There is little prospective data on the natural course of diverticulitis[15,16] and the risk of a recurrence after the first attack ranges from 5%-46%[4]. Various controversial risk factors for recurrence, such as age and numbers of acute attacks, or preoperative morbidity have been reported[4,13,17-20].

Therefore, in 2006, the American Society of Colon and Rectal Surgeons stated that the decision regarding elective resection should be made on a "case-by-case basis," no general recommendation was given for elective resection to prevent additional attacks[10]. The age of the patient, their medical condition, response to treatment and wishes should all be considered when making decisions regarding the indication for and timing of such treatment.

The main reason for performing elective resection is the prevention of serious complications, which include recurrent diverticulitis and the possible perforation that are associated with high morbidity and mortality. These factors must be estimated as part of the risk of an elective operation, which has a postoperative morbidity rate of 15%-20%[5].

Delayed or early elective resection for complicated non-perforated diverticulitis

There is a consensus of opinion that urgent surgery is indicated in perforated diverticulitis; whilst elective resection is the treatment of choice for complicated diverticulitis, there is limited data concerning the timing of elective resection.

It is most common for patients to be treated conservatively with parenteral nutrition and antibiotics for 5-10 d initially, followed by a period of recuperation and readmission to hospital, typically 6-8 wk later, for a delayed elective resection of the sigmoid colon to be performed. Alternatively patients may be treated for approximately 2-5 d with parenteral nutrition and antibiotics, with an early elective resection performed during the same hospital stay. A correlation between the risk of recurrence and the severity of the initial episode has been described. In complicated diverticulitis characterized by phlegmon or a pericolic abscess, a more aggressive approach is recommended because of the high risk of recurrence, and the high rate of severe complications, such as perforation, with a potentially fatal outcome[4,21,22].

In a comparison of these approaches in patients with complicated and non-complicated diverticulitis, Nataranjan found no relationship between outcome and timing[23], while Reissfelder *et al*[24] detected an advantage for delayed elective resection. Zingg reported a higher conversion rate in early elective resection compared with delayed elective resection, but the rate of complicated diverticulitis was higher in the early elective group (73% *vs* 13%); the outcome and major complications were similar[25]. Patients with inflammation were reported to have a significantly higher conversion rate (35.4% *vs* 13.5%)[25]. These results partially contradict our findings, but this may be explained by the selection of the patients as in previously reported studies, patients with both complicated and uncomplicated diverticulitis were included; only patients with complicated diverticulitis were included in our study.

The disadvantage of early elective surgery seems to be caused by the continuing presence of the acute inflammation with adhesions, which makes the procedure more technically demanding and therefore results in a higher conversion rate and longer operating time. In addition, the disadvantage of early elective resection detected in our trial may be caused by the selection bias in the other previously reported retrospective non-randomized trials[23-25] toward a higher severity of diverticulitis in the ear-

ly intervention group. The rate of patients with Hinchey Ⅱ stage disease was 15.4% in the early elective group, compared with 9.2% in the patients who actually underwent delayed elective resection, which may therefore explain the tendency towards higher rates of complications in this particular group.

Apart from the possibility of selection bias, delayed elective resection does have one major disadvantage that was identified in this trial; the period of 6-8 wk that is intended to allow the inflammation to settle can be associated with clinical deterioration or a recurrent attack; three patients underwent Hartman's procedure because of severe complications during this period.

Socioeconomic effects

To analyze the socioeconomic costs of both approaches, the total hospital costs that were billed to the insurance companies were compared. In the delayed elective group, the costs of the initial hospital stay for intravenous antibiotic treatment and the subsequent admission for surgical resection were both included. The analysis of the socioeconomic costs of the treatment was based on the diagnosis related groups in Germany during the relevant periods. It should also be mentioned that any costs of treatment by general practitioners between or after the hospitalizations were not included, nor were any indirect costs due to the inability of the patient to work.

There was no detailed analysis of the direct costs to the hospital for the hospitalization of each patient, so the financial profit for the hospital cannot be calculated from our data. Irrespective of these limitations, this trial suggested a socioeconomic advantage for early elective resection, which became even greater when the patients who required urgent surgery instead of their scheduled delayed elective resections were included in the analysis.

Limitations

Our trial is the first to analyze the impact of the timing of this operation in patients only with complicated diverticulitis; however, this study also has its limitations. The analysis is retrospective and observational, and the interventions were not randomized. Although the patients in the two groups showed largely comparable co-morbidities and disease stage according to Hinchey, a selection bias may be present since the decision to proceed with early or delayed elective surgery was based on clinical data, the preference of the surgeon and the medical condition of the patient.

Delayed elective resection showed a trend toward lower complication rates; compared with early elective resection, the operation appeared simpler to perform. Nevertheless, delayed elective resection carried a risk of complications occurring during the period of 6-8 wk that could necessitate an urgent resection with its consequent high morbidity which counterbalanced many of the advantages. Overall, early elective resection for complicated, but non-perforated diverticulitis was found to be a suitable alternative to delayed elective resection after 6-8 wk, with additional beneficial socioeconomic effects. Following the style of the recommendations made by the American Society of Colon and Rectal Surgeons regarding the indication for elective resection, we suggest a case-by-case decision with respect to early or delayed elective resection is similarly appropriate in patients with complicated diverticulitis.

COMMENTS

Background

The optimal management of complicated diverticulitis without perforation remains unclear. The trial, which was the first to include only patients with complicated diverticulitis, compares the outcomes of early elective resection with delayed elective resection after initial antibiotic treatment.

Research frontiers

It is most common for patients to be treated conservatively with parenteral nutrition and antibiotics for 5-10 d initially, followed by a period of recuperation and re-admission to hospital, typically 6-8 wk later, for a delayed elective resection of the sigmoid colon to be performed. Alternatively patients may be treated for approximately 2-5 d with parenteral nutrition and antibiotics, with an early elective resection performed during the same hospital stay. A correlation between the risk of recurrence and the severity of the initial episode has been described. In complicated diverticulitis characterized by phlegmon or a pericolic abscess, a more aggressive approach is recommended because of the high risk of recurrence, and the high rate of severe complications, such as perforation, with a potentially fatal outcome. There is limited data concerning the timing of elective resection.

Innovations and breakthroughs

This trial, which was the first to include only patients with complicated diverticulitis, compares the outcomes of early elective resection with delayed elective resection after initial antibiotic treatment. Overall, early elective resection for complicated, non-perforated diverticulitis is shown to be a suitable alternative to delayed elective resection after 6-8 wk, with additional beneficial socioeconomic effects.

Applications

To investigate the outcomes of early and delayed elective resection after initial antibiotic treatment in patients with complicated diverticulitis.

Peer review

The article reports interesting information on the surgical treatment of complicated diverticulitis. The authors report an adequate series and proper statistical analysis. The authors' comments are very interesting and of great help for the surgeons. The article deserves publication. It is an interesting topic with an analysis on the correct management of a very common disease.

Abstract

AIM: To shed some light on the relationship between anti-apoptotic serum Bcl-2 concentrations and metabolic status, anthropometric parameters, inflammation indices, and non-alcoholic fatty liver disease severity were investigated in 43 young individuals with fatty liver (FL) and 41 with nonalcoholic steatohepatitis (NASH).

METHODS: Circulating levels of Bcl-2 were detected in 84 patients with ultrasonographic findings of "bright liver" and/or hyper-transaminasemia of unknown origin and/or increase in γ-glutamyl-transpeptidase (γ-GT) strictly in the absence of other acute or chronic liver disease, whose age was not advanced, who gave consent to liver biopsy and were then divided on the basis of the histological results into two groups (43 with FL and 41 with NASH). Twenty lean subjects, apparently healthy and young, were chosen as controls.

RESULTS: Serum Bcl-2 concentrations were significantly higher in the FL group than in the NASH group. Insulin resistance and γ-GT activity were significantly higher in NASH subjects. Apoptotic hepatocytes were significantly more numerous in NASH patients. NASH patients presented with larger spleens and augmented C-reactive protein (CRP) concentrations than healthy subjects. Steatosis grade at histology was similar in both NASH and FL populations. The number of apoptotic cells was significantly related to anti-apoptotic Bcl-2 protein values in FL patients. Bcl-2 serum levels positively correlated to body mass index (BMI) values ($P \leqslant 0.0001$) but not to age of the population. Triglycerides/HDL ratio correlated well to waist circumference in males ($P = 0.0008$). γ-GT activity was associated with homeostatic metabolic assessment (HOMA) ($P = 0.0003$) and with serum ferritin ($P = 0.02$). Bcl-2 concentrations were not related to either spleen size or CRP values. NASH patients presented a weak negative correlation between lobular inflammation and Bcl-2 levels. A prediction by low values of serum Bcl-2 towards a greater presence of metabolically unhealthy overweight/obese patients (MUOs) was evidenced. HOMA, BMI and uric acid, in that sequence, best predicted serum Bcl-2 concentrations.

CONCLUSION: MUOs could be detected by Bcl-2 levels. By favoring the life span of hepatocytes, and enhancing triglyceride formation, the anti-apoptotic process inhibits free fatty acids toxicity in FL.

Key words: Bcl-2; Nonalcoholic fatty liver disease; Metabolically unhealthy overweight/obese

INTRODUCTION

High serum levels of triglycerides/free fatty acids (FFA) and insulin resistance (IR) are features of non-alcoholic fatty liver disease (NAFLD), an additional manifestation of the metabolic syndrome[1]; the former is extremely common in patients suffering from overweight/obesity (O/O), and ranges from fatty liver (FL) to nonalcoholic steatohepatitis (NASH) and liver cirrhosis. In determining NASH, a role is thought to be played by FFAs that directly engage the core apoptotic machinery by activating the proapoptotic protein Bax, in a c-jun N-terminal kinase-dependent manner[2]. Moreover, increased apoptosis in liver specimens from NASH patients is associated with iron overload[3], which clearly correlates with IR and inflammation. Indeed, interesting approaches to study pro-apoptotic and anti-apoptotic processes at the level of the liver are the use of *in vitro* models to explore the molecular events, tissue expression and circulating levels of the single factors. The first procedure partially limits the translation to the human scenario, mainly when moving from FL to NASH, because NAFLD reflects the long-lasting, complex dynamics orchestrated by various cells, such as adipocytes, β cells, muscle cells, macrophages and natural killer T cells. Apoptosis being a composite system regulated in a complex fashion with the contribution of many different factors, the expression of a single protein in liver specimens gives only a snapshot of a process that is hardly static. In favor of the serum concentrations stands the fact that either the stimulatory or the counter-regulatory circuits might eventually determine the net global effect of a given component. In conditions of chronic inflammation or oxidative stress, as for metabolic syndrome (MS), it is conceivable that the entire network is in a long-term persistent state of activation leading to increased circulating levels. In the serum of NAFLD patients, cytochrome c, an indicator of apoptosis-related mitochondrial damage, has been scarcely detected[4]. Among the anti-apoptotic factors, circulating levels of soluble Fas have been studied in some acute and chronic liver diseases[5,6]. The expression of Bcl-2 in the liver tissue of NAFLD patients has been evaluated by real-time PCR or, alternatively, by immuno-histochemical staining, highlighting surprisingly different patterns. In fact, in patients with NASH the expression of the Bcl-2 protein in liver specimens is mildly increased[7]. In contrast, in rats with high-fat diet-induced NASH, the hepatic expression of Bcl-2 did not differ from that of animals on control diet[8]. Similarly, no significant difference in the expression of Bcl-2 in NASH and biopsy-proven FL patients was observed[2]. Other authors have shown that the tissue expression of this anti-apoptotic protein diminished with the advancement of liver steatosis[9]. Recent data have shown that NAFLD patients with elevated gamma glutamyl-transpeptidase (γ-GT) activity have significantly higher Bcl-2 staining levels compared to patients evidencing normal γ-GT[10]. We firstly hypothesized that serum Bcl-2 levels reflect the steady state of this anti-apoptotic protein. A recent study, showing that urinary Bcl-2 concentrations are elevated in females suffering from ovarian cancer regardless of their creatinine levels or age[11], supports this hypothesis. A further confirmation is given by the fact that decreased apoptosis is in part associated with increased serum Bcl-2 levels in patients with melanoma[12]. Secondly, novel evidence suggests that low-grade chronic inflammation, in which spleen volume plays a key role[13], is the cause of IR in O/O patients, whose serum levels of soluble Fas interfere with the apoptotic pathway[14]. Finally, serum levels of Bcl-2 and cellular oxidative stress have already been studied in patients with viral hepatitis, showing a close link[15]. On the other hand, a "metabolically benign obesity" which is not accompanied by IR has recently been postulated to exist in humans[16-18], although this hypothesis has been challenged by some authors[19]. As a consequence, some researchers have started considering NAFLD, independent of its severity, as a divide between metabolically healthy O/O and metabolically unhealthy O/O (MUO)[20] individuals. Against this background, we felt the need to shed some light on the relationship between anti-apoptotic serum Bcl-2 concentrations and metabolic status, anthropometric parameters, inflammation indices, such as C-reactive protein (CRP) and spleen volume[13], as well as NAFLD severity in the vast complex of O/O and MS, in young adults and middle aged individuals.

MATERIALS AND METHODS

This research was performed by initially screening 178 consecutive subjects referred to our out-patient Metabolic Unit with established (at least 4 years) O/O, from February 2006 to December 2009. The study was carried out according to the principles of the Declaration of Helsinki and informed written consent was obtained from each patient.

Enrollment criteria

Out of the 178 initial participants 15 were excluded due to marked intestinal meteorism which made it difficult to perform abdominal ultrasound (first step to screening NAFLD), 16 patients because they had undergone steroid therapy (seven for bronchial asthma, five for rheumatoid arthritis, two for neuritis and two for inflammatory bowel disease), and 28 because they had received one or more drugs (i.e., aspirin, metformin, statins and

fibrates) that may have altered their laboratory data. Fourteen others were excluded because of the presence of hepatic co-morbidities in their medical history (HCV infection, alcohol abuse), and finally twenty subjects were considered drop-outs, because they refused to undergo full laboratory-instrumental examinations. Eighty-four of the 119 patients, with ultrasound findings of "bright liver" and/or hyper-transaminasemia of unknown origin and/or increase in γ-GT strictly in the absence of other acute or chronic liver disease, whose age was not advanced (Table 1), gave consent to liver biopsy and were then divided on the basis of the histological results (see below) into two groups (43 with FL and 41 with NASH) that formed the final study population. Twenty lean subjects, apparently healthy and young, were chosen as controls to avoid any confounding factor with circulating levels of Bcl-2 (see below).

Exclusion criteria

Any viral, autoimmune, metabolic liver disease (Wilson disease, hemochromatosis or antitrypsin deficiency) was ruled out by using appropriate testing, following the accepted diagnostic guidelines. Celiac disease was excluded by estimates of IgA anti-tissue transglutaminase antibodies. Alcohol abuse was ruled out, according to the DSM-IV diagnostic criteria, by means of screening tests such as MAST (Michigan alcohol screening test) and CAGE (Cut down, Annoyed, Guilty, and Eye opener), as well as random tests for blood alcohol concentration and the use of a surrogate marker, e.g., Mean Corpuscular Volume. Patients on antihypertensive drugs maintained a balanced therapeutic regimen throughout the study.

Metabolic profile

The degrees of obesity was established on the basis of BMI cut-off points of 25-29.9, 30-34.9, 35-39.9 and > 40 kg/m^2, respectively. Visceral obesity was identified by measuring waist circumference (WC) at the midpoint between the lower border of the rib cage and the iliac crest. MS was defined according to the revised Adults Treatment Panel Ⅲ (2001), and three or more criteria were considered: plasma glucose concentration of at least

100 mg/dL, WC > 88 cm, serum HDL concentration < 50 mg/dL for women and < 40 mg/dL for men, blood pressure of at least 130/85 mm Hg, and serum triglyceride concentration of at least 150 mg/dL. IR status was determined by the Homeostatic metabolic assessment (HOMA), which was assessed by the formula: fasting insulin (μU/mL) × fasting glucose (mg/dL)/405[21]. As a stringent measure of IR, a value of HOMA > 2 was introduced, according to the cut-off value of surrogate measures of IR for MS in non-diabetic adults[22]. Moreover, as the repeated HOMA measurements presented high within-person variability in O/O patients, HOMA values were averaged on the basis of at least five determinations to avoid misclassification. When reporting triglycerides values, only the data of examinees who had fasted a minimum of 9 h before the morning examination were included to avoid false increases, averaging the results of at least two determinations made on different days. To avoid the high intra-individual variability the triglyceride/HDL cholesterol ratio was evaluated (see below). MUO subjects were categorized in such a way in the presence of IR, MS, high levels of serum uric acid (UA),[23] and if their triglyceride/HDL cholesterol ratio was ⩾ 1.65 (men) or ⩾ 1.32 (women)[24].

Ultrasound evaluation

Ultrasonographic (US) measurements were performed by two operators, using a general electric vivid system. Spleen longitudinal diameter (SLD) was chosen to evaluate spleen volume and was carried out by postero-lateral scanning. Maximum length (the optically greatest overall longitudinal dimension obtained from one of the two poles) and cranio-caudal length (the optically maximal transversal dimension intercepting one of the two poles) were measured; the resulting values were then averaged, since the two measurements do not always coincide. The classification of "bright liver" or hepatic steatosis (HS) was based on the following scale of hyper-echogenicity: 0 = absent, 1 = light, 2 = moderate, 3 = severe, pointing out the difference between the densities of the liver and the right kidney. Technically, echo intensity can be influenced by many factors, particularly by gain intensity. To avoid confounding factors that could modify echo intensity and thus bias comparisons, the mean brightness levels of both the liver and the right kidney cortex were obtained on the same longitudinal sonographic plane. The levels of brightness of the liver and the right kidney were calculated three times directly from the frozen images.

Blood pressure measurements

Systolic/diastolic blood pressure was the average of three consecutive readings taken by the physician during the day, during the usual practice hours, after subjects had rested for 5 min in the sitting position.

Laboratory data

Serum triglycerides, HDL, basal insulin, ALT, γ-GT, UA, glycemia and ferritin were performed by in-house standard procedures. Hs-CRP values were determined by ELISA test, with reference values between 0.3 and 8.6 mg/L in healthy men and between 0.2 and 9.1 mg/L in healthy women (BioCheck, Inc CA, United States). Bcl-2 was determined using a Human Bcl-2 ELISA Kit (producer Bender MedSystems, Austria, EU) with a coefficient of variation ranging from 5.1 to 17.7, a sensitivity of 2.5 ng/mL, an overall intra-assay coefficient of 8.6 and a reference interval calculated on 21 healthy subjects (Table 1) by the non-parametric percentile method (CLSI C28-A3) of 7.4-22.6 ng/mL.

Liver histology

The diagnosis of NASH was made when three of the following five criteria were proven by liver biopsy: steatosis, hepatocyte ballooning, lobular inflammation, portal inflammation and mallory bodies. Data on Mallory bodies were collected as inclusion criteria to pinpoint the accuracy of diagnosis, but they were not used for evaluation. A 4-point scale for each of the four following criteria resulted in a sum score ranging from 0 to 12. Specifically, the scores were: Steatosis: 0 = None; 1 = Up to 33% of acini, mainly macrovesicular; 2 = 34%-66% of acini, commonly mixed steatosis; 3 = Over 66% of acini (panacinar), commonly mixed steatosis; Hepatocyte ballooning: 0 = None; 1 = Occasional in zone Ⅲ; 2 = Obvious in zone Ⅲ; 3 = Marked, predominantly in zone Ⅲ; Lobular inflammation: 0 = None; 1 = Scattered neutrophils, occasional mononuclear cells, 1 or 2 foci per 20 × objective; 2 = Neutrophils associated with ballooned hepatocytes, mild chronic inflammation, 3 or 4 foci per 20 × objective; 3 = Acute and chronic inflammation, neutrophils may concentrate in zone Ⅲ, over 4 foci per 20 × objective. Portal inflammation: 0 = None; 1 = Mild, some portal areas; 2 = Mild to moderate, most portal areas; 3 = Moderate to severe, most portal areas. Fibrosis was staged as follows: Stage 0 = None; Stage 1 = Zone Ⅲ perivenular, perisinusoidal (pericellular); Stage 2 = Stage 1 changes plus periportal fibrosis; Stage 3 = Bridging fibrosis; Stage 4 = Cirrhosis. Biopsy samples were taken within eight weeks prior to inclusion. FL was diagnosed when only steatosis was present, using the same grades previously reported[1-3]. The biopsy sample had to be at least 1.5 cm long with a minimum diameter of 0.8 mm. Inclusion of a NASH patient in the study required a sum score of at least 6 points.

Apoptosis detection

Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) is a common method for detecting DNA fragmentation that results from apoptotic signaling cascades. We used the Click-iT® TUNEL Alexa Fluor® 647 Imaging Assay (Invitrogen). This method utilizes a dUTP modified with an alkyne, a small, bio-orthogonal functional group that enables the nucleotide to be more readily incorporated by TdT than other modified nucleotides, including BrdUTP, biotin-dUTP or fluo-

rescein-dUTP. Detection is based on a click reaction, i.e., a copper catalyzed reaction between an azide and alkyne.

Cells displaying TUNEL-labeled fluorescent nuclei were quantified by counting the number of positive cells per high-power field. A total of 10 high-power fields were analyzed for each patient with excitation and emission wavelengths of 380 and 430 nm, respectively, using an inverted laser scanning confocal microscope (Carl Zeiss) equipped with a ×40 NA 1.4 lens. Data are expressed as the number/mm^2 of TUNEL-positive cells.

Statistical analysis

Age data, derived from a normally distributed population [Kolmogorov-Smirnov test (K-S), $P = 0.15$], ferritin (K-S, $P = 0.6$), BMI (K-S, $P = 0.2$), WC (K-S, $P = 0.18$), SLD (K-S, $P = 0.52$), UA (K-S, $P = 0.105$) are given as mean plus SD. Variables not normally distributed, such as triglycerides (K-S, $P = 0.0013$), triglycerides/HDL (K-S, $P \leqslant 0.0001$), HOMA (K-S, $P = 0.0016$), ALT (K-S, $P = 0.0001$), CRP (S-W, $P = 0.001$) are expressed as median (range). Grades at histology and US were considered ordinals and managed in the same way. The difference in medians was assessed by the Mann-Whitney test for independent samples. One-way analysis of variance (ANOVA) was used to test the difference between the means of several subgroups of a variable (multiple testing). If the ANOVA test was positive ($P < 0.05$) then a Student-Newman-Keuls test for pairwise comparison of subgroups was performed. The ANOVA K-W test was used to calculate the differences between the medians of several subgroups of a variable. If K-W was positive ($P < 0.05$) then a test for pairwise comparisons of subgroups according to Conover was adopted. When adjusted for a covariate the ANOVA was transformed into ANCOVA and the significance was expressed as F-ratio. The Two-Way Tables cross-tabulated one categorical row variable with one categorical column variable and the significance was set by the Pearson χ^2. When cross-tabulation was stratified for another dichotomous variable, the Mantel-Haenszel χ^2 was carried out. Tracking the degree of association between single parameters, Spearman's coefficient of rank correlation (rho) for non uniform intervals was used. The Pearson's coefficient (r) was employed to analyze the correlation between data derived from a normally distributed population. To predict a binary variable, the logistic regression (Enter Method), with relative Odds ratios and 95% confidence intervals (CI), was employed utilizing data from an independent variable. To assess the independent effect of a quantitative variable on the prediction of the values of another variable, the linear regression analysis (least squares) was used, evaluating the standardized coefficient β (β) and t, which is a measure of the precision with which the regression coefficient is measured. A tolerance of less than 0.20 and/or a variance inflation factor of 5 and above indicated a multicolinearity problem. When confronted with the question of how accurate a parameter was in identifying MUO cases, the discrimination was evaluated using receiver operating characteristic curve analysis (ROC), expressed as area under the ROC (AUC). A criterion or cut-off was set and then sensitivity, specificity and positive likelihood ratio were estimated. Negative predictive value with the Bayes method was also calculated. The factor analysis was applied to detect the structure in the relationships among variables, selecting a subset of variables having the highest correlations with the principal component factors. The Cattell Scree plot, with relative eigen values, was performed to screen the real factors. Extraction of the main components amounted to a variance maximizing (varimax) the rotation of the original variable space. The critical value was calculated by doubling Pearson's correlation coefficient for 1% level of significance (5.152)/square root of patients (84) minus 2, i.e., 0.568. The concordance correlation coefficient (ρ_c), which measures precision and accuracy, was adopted to evaluate the degree of pair observations at US. Statistical analysis was performed operating on Systat 13 (Richmond, CA, United States) and MedCalc Version 11.4® (Frank Schoonjans) software packages.

RESULTS

Prevalence

The number of individuals affected by being overweight, or by 1st, 2nd and 3rd grade obesity was comparable in NASH and FL populations and was well-balanced for gender. NASH patients were characterized by older age and a larger percentage of MUO cases, having the largest number of MS among males (Mantel-Haenszel Chi-Square $P = 0.005$), a greater BMI and a larger WC in males (ANOVA, $F = 55.5$, $P = 0.0001$ and $F = 59.5$, $P = 0.0001$, respectively). Both insulin resistance and γ-GT activity were significantly higher in subjects diagnosed with NASH. Raised values of ALT activity were hardly detected in NASH and FL patients. Men with NASH were affected by hyperferritinemia and had the lowest levels of HDL and the highest triglycerides/HDL ratio. Serum uric acid was increased in FL and NASH patients without any difference between the two groups (Table 1). Apoptotic hepatocytes were significantly more numerous in NASH patients. NASH patients presented with larger spleens and augmented CRP concentrations compared with healthy subjects. In both populations of NASH and FL the steatosis grade at histology was similar, so was the steatosis severity at US. Serum concentrations of Bcl-2 were significantly higher in the FL group than in the NASH group and patients of both groups showed increased values compared to healthy subjects (Table 2 and Figure 1). The significance did not change after adjusting the values of Bcl-2 for γ-GT activity, with only the diagnosis being significant (ANCOVA, $F = 14.9$, $P = 0.0001$).

Associations and prediction

The number of apoptotic cells was significantly related to the anti-apoptotic Bcl-2 protein values (rh0 = 0.43, $P = 0.003$) in FL patients but not in NASH ones (rh0 = 0.17, $P = 0.27$). Bcl-2 serum levels correlated well with the BMI values of the whole population (rh0 = 0.55, $P = <$

Table 2 Serum concentrations of the anti-apoptotic protein Bcl-2, histology features and inflammation parameters of the patients enrolled

	Diagnosis			
	H	FL	NASH	*P* value
Subjects (*n*)	21	43	41	
Bcl-2 (ng/mL)	2.5 (1.4-13)	25 (2.5-168)	14 (2.5-89)	< 0.001[3]
Hepatocyte ballooning grade	NA	NA	2 (1-3)	NA
Steatosis score	NA	2 (1-3)	2 (1-3)	0.49[2]
Lobular inflammation grade	NA	NA	2 (1-3)	NA
Portal inflammation grade	NA	NA	1 (1-3)	NA
Fibrosis score	NA	NA	1 (1-2)	NA
Apoptotic cells (n/mm^2)	NA	290 (120-900)	780 (110-1650)	< 0.0001[2]
HS at US grade	NA	3 (0-3)	3 (0-3)	0.064[2]
CRP (mg/L)	0.9 (0.4-5.4)	3.9 (0.1-21.1)	5 (0.1-27)	0.0001[1]

[1]Kruskal-Wallis test [significance between healthy (H) and fatty liver (FL) and between H and non alcoholic steato hepatitis (NASH)]; [2]Mann-Whitney test; [3]Kruskal-Wallis test (significance between H and FL, between H and NASH and also between FL and NASH). *n*: Number; H: Healthy; FL: Fatty liver; NASH: Non alcoholic steato hepatitis; NA: Not applicable; HS: Hepatic steatosis at ultrasound; US: Ultrasound; SLD: Spleen longitudinal diameter at ultrasound; CRP: C-reactive protein.

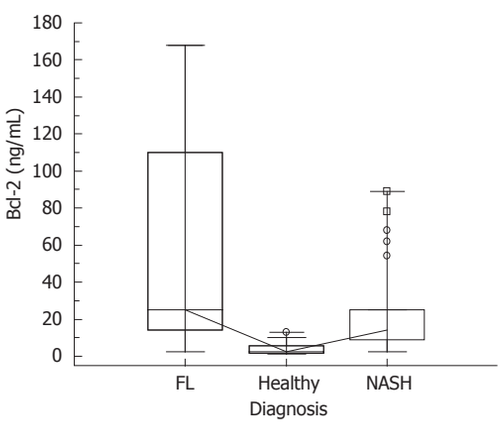

Figure 1 Serum concentrations of Bcl-2 in the whole population. Kruskal-Wallis test (significance between healthy and fatty liver (FL), between healthy and non alcoholic steato hepatitis (NASH) and also between FL and NASH); the highest median value was found in the FL group, $P \leqslant 0.001$.

0.0001). The correlation between serum concentrations of Bcl-2 and age was not significant (rh0 = 0.14, $P = 0.15$). Triglycerides/HDL ratio correlated well with WC in males (Pearson's $r = 0.51$, $P = 0.0008$). γ-GT activity was associated with HOMA values (rh0 = 0.345, $P = 0.0003$), as was γ-GT with serum ferritin (rh0 = 0.22, $P = 0.02$). Bcl-2 concentrations were not related with either SLD or CRP values (rh0 = 0.10 and 0.13 with $P = 0.3$ and $P = 0.2$, respectively). A non significant correlation was found between lobular inflammation and Bcl-2 levels in NASH patients (rh0 = -0.21, $P = 0.2$).

As to age, at linear regression, advancing years did not completely predict Bcl-2, β = -0.19, $t = -2$, $P = 0.053$ (Figure 2A). UA predicted Bcl-2 values well, β = 0.35, $t = 3.8$, $P = 0.0002$ (Figure 2B).

At multiple regression analysis, HOMA, BMI and UA, in this sequence, best predicted Bcl-2 serum concentrations, as higher IR corresponded to lower Bcl-2 values, whereas considerable BMI and elevated amount of UA matched with higher Bcl-2 serum concentrations (Table 3). A sufficient prediction by low serum Bcl-2 values towards a higher rate of MUOs was evidenced in logistic regression, OR = 0.98, CI 0.97-0.995, $P = 0.004$. Obviously, HOMA alone did not predict the status of MUO, OR 1.38, CI 0.87-2.2.

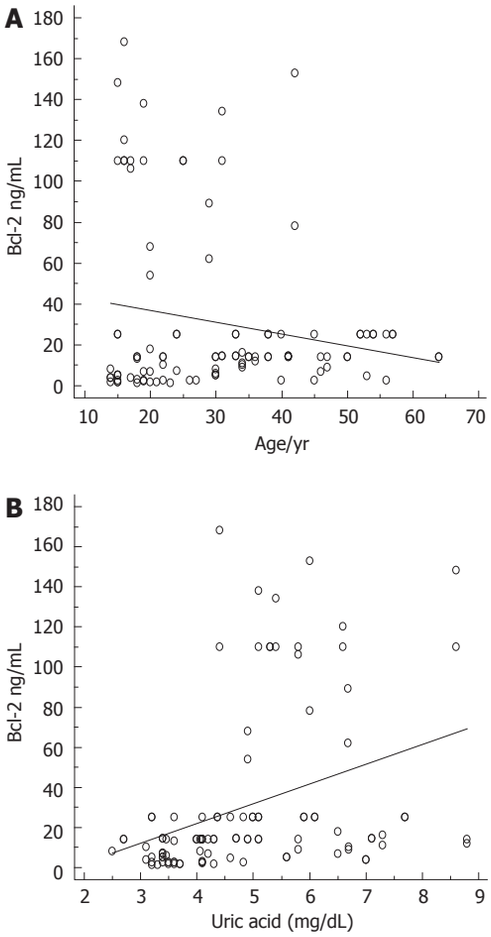

Figure 2 Prediction of Bcl-2 serum levels by age and uric acid. A: Prediction of antiapoptotic Bcl-2 protein serum concentrations by age, β = -0.19, $t = -2$, $P = 0.0527$; B: Prediction of antiapoptotic Bcl-2 protein serum concentrations by uric acid, β = 0.35, $t = 3.8$, $P = 0.0002$.

Insulin resistance was closely related to inflammation and lipid asset; apoptosis did not seem related to age (Table 4 and Figure 3). The concentrations of serum Bcl-2 were not predicted by the number/mm^2 of TUNEL-positive cells in NASH patients (β = 0.013, $t = 0.13$, $P = 0.9$, Figure 4).

Reliability

Grades of hepatic steatosis at US correlated with those at histology (rh0 = 0.45, $P \leqslant 0.0001$). The AUC of serum Bcl-2 only modestly predicted MUOs, i.e., 0.65%, CI 0.53 to 0.75, with a sensitivity of 87% and a specificity of 50%, a positive likehood ratio of 1.73 using as cut-off 106 ng/mL. The negative predictive value was 94% on the basis of a disease (MS) prevalence in the population

Table 3 Prediction of anthropometric parameters, apoptosis detection and laboratory data by Bcl-2 concentrations

Effect	β	*t*	*P* value	Tolerance
HOMA	-0.505	-4.27	0.000	0.440
HDL	0.22	1.4	0.16	0.242
WC	0.25	1.7	0.09	0.288
BMI	0.35	2.65	0.009	0.344
Triglycerides	-0.07	-0.17	0.86	0.040

Insulin resistance is closely related to inflammation and lipid asset; apoptosis does not seem related to age. Percent of total variance explained for factor 1:26; for factor 2:14; the critical value is 0.568. HS: Hepatic steatosis; US: Ultrasound; SLD: Spleen longitudinal diameter at ultrasound; CRP: C-reactive protein; BMI: Body mass index; MS: Metabolic syndrome; ALT: Alaninamino transferase; γ-GT: γ-glutamyl transferase; HDL: High density lipoprotein; HOMA: Homeostatic metabolic assessment; WC: Waist circumference.

of 20%. The intra-inter-observational reproducibility of the sonographic estimations for bright liver was high, with a ρ_χ of 0.93 and 0.89, respectively.

DISCUSSION

Medical reports emphasize that MS, of which NAFLD is a further expression, is a major health problem in western countries. This research was conducted to establish whether serum Bcl-2 concentration could help clarify the role of the anti-apoptotic process in this common disease, not to detect a further marker to diagnose NASH.

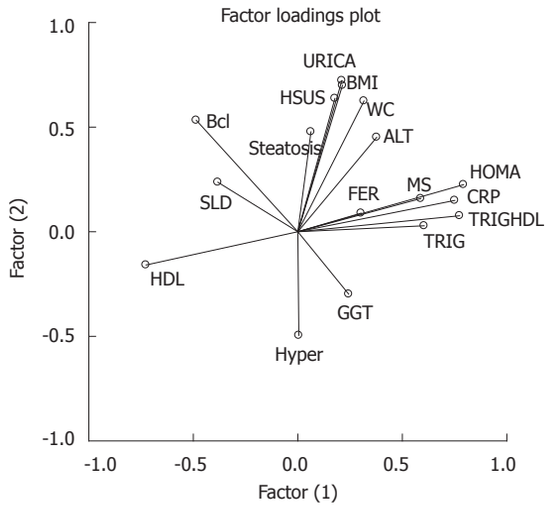

Figure 3 Variables clustered around factors. Homeostatic metabolic assessment, C-reactive protein, triglycerides, triglycerides/high density lipoprotein ratio, ferritin and metabolic syndrome clustered around factor 1. HDL: High density lipoprotein. WC: Waist circumference; BMI: Body mass index; HOMA: Homeostatic metabolic assessment; HDL: High density lipoprotein; GGT: γ-glutamyl-transpeptidase; TRIG:Triglycerides; TRIGHDL: Triglycerides/high density lipoprotein; CRP: C-reactive protein; MS: Metabolic syndrome; FER: Ferritin; ALT: Alaninamino transferase; BMI: Body mass index; URICA: Uric acid; HSUS: Hepatic steatosis at ultrasound; SLD: Spleen longitudinal diameter.

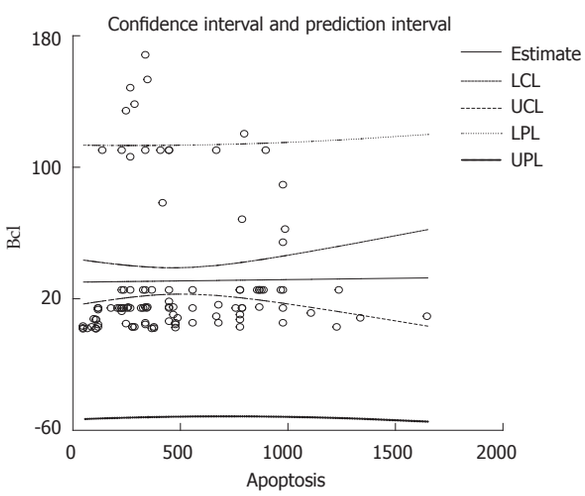

Figure 4 The concentration of serum Bcl-2 was not predicted by the number/mm2 of terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling-positive cells. LCL: Low confidence limit; UCL: Upper confidence limit; LPL: Low prediction limit; UPL: Upper prediction Limit.

The main finding was that low HOMA values predicted high Bcl-2 levels. Furthermore, high levels of this anti-apoptotic protein were found in patients with FL, which is also characterized by fewer apoptotic cells than the more severe form, i.e. NASH. First of all, to avoid a possible bias[25], the authors stress that the population's age did not affect anti-apoptotc protein Bcl-2 concentrations, as confirmed by regression equation and factor analysis. UA levels modestly prognosticate serum Bcl-2 concentrations according to previous research on serum soluble Fas concentrations, which correlated significantly with UA levels[26]. These findings indicate that the antioxidant properties of UA[27,28] are of biological importance *in vivo*.

Comparing the present results with relevant findings from other studies dealing with NASH, having found lower Bcl-2 concentrations, we support a low liver expression of Bcl-2[28]. To reinforce this finding, apoptosis is recognized as common in liver injury and may also contribute to tissue inflammation, fibrogenesis, and development of cirrhosis. The intensification of inflammation in NAFLD is accompanied by an inhibition of antiapoptotic Bcl-2[9]. Accordingly, in our study anti-apoptotic Bcl-2 protein concentrations showed an inverse trend towards lobular inflammation grades.

Contrary to current theory, hepatic steatosis appears to be a detoxification process, as FFAs are directly cytotoxic for the hepatocyte. The anti-apoptotic process, favoring the life span of hepatocytes, and enhancing triglyceride formation, inhibits FFAs toxicity. Probably this is the reason for the major concentrations of Bcl-2 in FL. On the other hand, our laboratory findings do not necessarily mirror the processes happening in liver due to the lack of correlation between apoptosis as well as inflammation and Bcl-2 levels in NASH patients. The strict association between IR, as well as BMI and Bcl-2 levels, could at least partially be explained as follows. All individuals possess a maximum capacity for adipose expansion which is determined by both genetic and environmental factors. Once the limit of adipose tissue expansion is reached, this ceases to store energy efficiently, with the subsequent accumulation of lipids in other tissues. Ectopic lipid accumulation in non-adipocyte cells causes lipotoxic insults including IR, apoptosis and inflammation. The adipose tissue expandability hypothesis states that a failure in the capacity of adipose tissue expansion, rather than obesity per se, is the key factor linking positive energy balance and MS[29]. MUOs could represent subjects who are unable to sustain the expandability of adipose tissue but are burdened by an abundant extra adipose tissue localization, for instance in liver. An alternative hypothesis suggests that a hyperleptinemic status, generally present in obese patients, might be involved. Now, since leptin reduces apoptosis, possibly via its ability to increase Bcl-2 and decrease Bax, altering the Bcl-2/Bax ratio, this status could explain the elevated concentrations of Bcl-2[30]. Some results show that IGF-1 increases mRNA levels and protein expression of antiapoptotic Bcl-2[31-33] even though, in obese subjects all the main components of the GH/IGF-1 axis might be widely variable[34]. In fact, serum IGF-1 levels inversely vary with severity of hepatic steatosis[35]. Coming back to serum concentrations of Bcl-2, a shift towards an antiapoptotic process could be protective in other areas[14]. By which mechanisms is Bcl-2 supposed to act? The endoplasmic reticulum (ER) is the main site for lipid biosynthesis in the cell. Disturbances of this critical cellular function lead to ER stress. Several recent observations suggest a role for Bcl-2 at the ER. Bcl-2 located at the ER was shown to interfere with apoptosis induction. In fact, Bcl-2 at the ER may regulate calcium flow between the ER and the mitochondria. In addition, Bcl-2 is able to interact with the endoplasmic protein Bap31, thus avoiding caspase activation at the ER. Bcl-2 may also hinder the function of ER located pro-apoptotic Bcl-2[36].

Limitations to this study are having detected a single protein in the apoptosis universe, and the use of US as first screening method for O/O. In fact, although US has acceptable sensitivity and specificity, nevertheless, it has drawbacks that include its inaccuracy in exact quantification of fat accumulation, possibly excluding patients with light hepatic steatosis. Furthermore, the sample size is apparently too small (the minimal required sample size per group with a type I error of 0.05 and a Type Ⅱ error of 0.05 for Bcl-2-analyzed as mean ± SD was calculated at 42 patients). Finally, in our study there is some overlap in the Bcl-2 values seen in NASH and FL patients, the minimum in both groups being 2.5 ng/mL(detection limit).

In conclusion, IR is strictly linked to serum Bcl-2 values. Those were higher in FL than in NASH patients suggesting a protective role of the anti-apoptotic process in liver and perhaps in other areas[37].

COMMENTS

Background

High serum levels of triglycerides/free fatty acids and insulin resistance are features of non-alcoholic fatty liver disease, an additional manifestation of the metabolic syndrome; the former is extremely common in patients suffering from overweight/obesity, and ranges from fatty liver to nonalcoholic steatohepatitis and liver cirrhosis. In determining nonalcoholic steatohepatitis, a role is thought to be played by free fatty acids that directly engage the core apoptotic machinery. Moreover, increased apoptosis in liver specimens from nonalcoholic steatohepatitis patients is associated with iron overload, which clearly correlates with insulin resistance and inflammation. Obviously, there is a certain balance between apoptosis and anti-apoptosis in determining the net effect on hepatocytes survival.

Research frontiers

The authors hypothesized that serum BCL-2 levels reflect the steady state of this anti-apoptotic protein.

Innovations and breakthroughs

The expression of Bcl-2 in the liver tissue of non-alcoholic fatty liver disease patients has previously been evaluated by real-time PCR or, alternatively, by immuno-histochemical staining, highlighting surprisingly different patterns. Serum Bcl-2 increase is a likely response to the apoptotic process to improve survival of hepatocytes. If the response to the metabolic injury was good (increased serum levels of Bcl-2) probably the more severe form. i.e., non-alcoholic steatohepatitis would not develop.

Applications

Metabolically unhealthy obese/overweight subjects could be further detected by Bcl-2 levels. By favoring the life span of hepatocytes, and enhancing triglyceride formation, the anti-apoptotic process probably inhibits free fatty acids toxicity in fatty liver.

Terminology

Bcl-2 (B-cell lymphoma 2) is the founding member of the Bcl-2 family of apoptosis regulator proteins encoded by the *BCL2* gene.

Peer review

This is a very well carried out study and well written paper. However it needs a few clarifications from the authors.

Abstract

AIM: To clarify whether the incidence of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis (PEP) after pancreatic guidewire placement (PGW) can be reduced by using a different cannulation method.

METHODS: Between April 2001 and October 2009, PGW was performed in 142 patients with native papilla to overcome difficult biliary cannulation. Our cannulation method for ERCP was changed from contrast injection (CI) using a single-lumen catheter (April 2001-May 2008) to wire-guided cannulation (WGC) using a double-lumen catheter (June 2008-October 2009). The CI protocol was also changed during the study period: in the first period it was used for routine pancreatography for detecting small pancreatic cancer (April 2001-November 2002), whereas in the second period it was not (December 2002-May 2008). In PGW with CI using a single-lumen catheter, the contrast medium in the catheter lumen was injected into the pancreatic duct. The success rate of biliary cannulation, the incidence of PEP according to the cannulation method, and the impact of CI using a single-lumen catheter on PEP in comparison with WGC using a double-lumen catheter were investigated.

RESULTS: CI with routine pancreatography, CI without routine pancreatography, and WGC were performed in 27 patients, 77 patients and 38 patients, respectively. Routine pancreatography did not contribute to the early diagnosis of pancreatic cancer in our study period. In CI without routine pancreatography and WGC, diagnostic pancreatography was performed in 17 patients and no patients, respectively. The success rate of biliary cannulation by PGW alone was 69%, and the final success rate was increased to 80.3% by the addition of consecutive maneuvers or a second ERCP. PEP occurred in 22 patients (15.5%), and the severity was mild in all cases. When analyzed according to cannulation method, the incidence of PEP was 37.0% (10/27) in the patients who underwent CI with routine pancreatography, 14.3% (11/77) in those who underwent CI without routine pancreatography, and 2.6% (1/38) in those who underwent WGC. In all patients who underwent CI using a single-lumen catheter, the incidence of PEP was 20% (21/104), which was significantly higher than that in WGC using a double-lumen catheter. In univariate and multivariate analysis, CI using a single-lumen catheter showed a high, statistically significant, odds ratio for PEP after PGW.

CONCLUSION: The practice of a cannulation method involving the use of a double-lumen catheter minimizes the CI dose administered to the pancreatic duct and reduces the incidence of PEP after PGW.

Impact of changing our cannulation method on the incidence of post-endoscopic retrograde cholangiopancreatography pancreatitis after pancreatic guidewire placement. *World J Gastroenterol* 2011; 17(48): 5289-5294 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i48/5289.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i48.5289

INTRODUCTION

Recently, it has been emphasized that the use of wire-guided cannulation (WGC) in endoscopic retrograde cholangiopancreatography (ERCP) is associated with a reduced incidence of post-ERCP pancreatitis (PEP) compared with contrast injection (CI)[1-3]. In Japan, ERCP is usually performed under CI using a single-lumen catheter and a duodenoscope with a 15-degree backward-oblique angle because this technique allows selective biliary cannulation[4]. On the other hand, pancreatic guidewire placement (PGW) is one of the rescue maneuvers used to overcome difficult biliary cannulation[5-11]; however, it carries a risk of PEP[9-11]. We changed our cannulation method from CI using a single-lumen catheter to WGC using a double-lumen catheter and investigated whether the incidence of PEP after PGW was reduced by this change.

MATERIALS AND METHODS

Patients

Between April 2001 and October 2009, 2060 ERCP procedures were performed in patients with pancreatobiliary disease at Saku Central Hospital. PGW was performed in 142 patients with native papilla, in whom CI or guidewire insertion into the pancreatic duct *via* biliary cannulation was unintentional on at least three occasions, which was defined as difficult biliary cannulation. We did not establish a maximum number of cannulation attempts. Our strategy for difficult biliary cannulation is shown in Figure 1. When PGW did not successfully achieve biliary cannulation, pancreatic stenting, transpancreatic sphincterotomy, or another maneuver was attempted. In cases in which it was not possible to access the bile duct within 30 min, the procedure was stopped.

Endoscopic procedure

Our cannulation method for ERCP was changed from CI using a single-lumen catheter (April 2001-May 2008) to WGC using a double-lumen catheter (June 2008-October 2009). The CI protocol was also changed during the study period: in the first period it was used for routine pancreatography for detecting small pancreatic cancer (April 2001-November 2002), whereas in the second period it was not (December 2002-May 2008). The procedure was performed using a duodenoscope with a 15-degree backward-oblique angle (JF230, 260V: Olympus Optical Co., Tokyo, Japan). Biliary cannulation was attempted with a single-lumen catheter (Contour: Microinvasive, Boston Scientific Corp., Natrick, MA, United States; PR-4Q-1, PR-10Q-1: Olympus Optical Co., Tokyo, Japan)

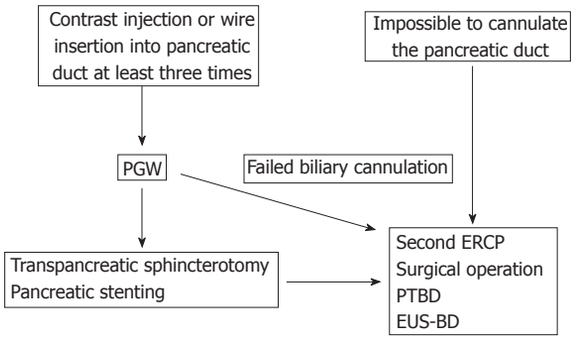

Figure 1 Our strategy for difficult biliary cannulation. PGW: Pancreatic guidewire placement; ERCP: Endoscopic retrograde cholangiopancreatography; PTBD: Percutaneous transhepatic biliary drainage; EUS-BD: Endoscopic ultrasound-guided biliary drainage.

under CI, a double-lumen catheter (MTW Endoskopie, Wesel, Germany), or a sphincterotome (CleverCut: Olympus Optical Co., Tokyo, Japan) for WGC.

In PGW, the tip of a 0.025 or 0.035 inch-guidewire (Revowave: Olympus Optical Co., Tokyo, Japan; Jagwire: Microinvasive, Boston Scientific Corp., Natrick, MA, United States) was placed between the pancreatic body and tail. In CI using a single-lumen catheter, the contrast medium in the catheter lumen was injected into the pancreatic duct during guidewire insertion, as shown in Figure 2. After PGW, biliary cannulation was attempted in the region towards the upper left of the pancreatic guidewire.

In WGC, the tip of the guidewire was passed through the catheter lumen and exposed/fixed at 2 mm from the tip of the catheter. The operator controlled the catheter and used it to adjust the axis between bile duct terminal and the catheter. In principle, the use of CI into the pancreatic duct was limited except during diagnostic pancreatography in WGC. When guidewire resistance arose during PGW, the minimum amount of contrast medium was used to identify the running direction of the main pancreatic duct to prevent the branch ducts from being injured by the tip of the guidewire.

All patients were administered a protease inhibitor drip infusion (ulinastatin, 100 000 units for 1 d) during and after the ERCP, and their serum amylase levels were measured before the ERCP and at 3 h, 6 h, and 18-24 h after. The diagnosis and grade of PEP were defined according to the international consensus criteria[12].

All procedures were performed by one operator (Hisa T), who experienced about 250-300 ERCPs per year.

Outcome

In the 142 patients subjected to PGW, the success rate of biliary cannulation, the incidence of PEP according to the cannulation method, and the impact of CI using a single-lumen catheter on PEP in comparison with WGC using a double-lumen catheter were investigated.

Statistical analysis

The patients' basic characteristics and the outcome of PGW were compared between CI using a single-lumen catheter and WGC using a double-lumen catheter using the χ^2 test. Logistic regression modeling was used to eval-

Figure 2 Fluoroscopic image taken during pancreatic guidewire placement using a single-lumen catheter. A: The injection of contrast medium into the pancreatic duct was repeated for difficult biliary cannulation; B: During pancreatic guidewire placement (PGW), the guidewire pushes contrast medium from the catheter lumen and into the pancreatic ductal system; C: PGW straightens the terminal bile duct and achieves successful biliary cannulation.

Table 1 Patient characteristics and endoscopic procedures used in pancreatic guidewire placement

	Total (n = 142)	Cannulation method		
		CI using a single-lumen catheter (n = 104)	WGC using a double-lumen catheter (n = 38)	P value
Mean age (mean ± SD)	72.7 (11.5)	68.5 (10.9)	75.3 (13.2)	
Male sex (%)	71 (50)	48 (46)	23 (61)	0.18
Periampullary diverticulum (%)	28 (20)	21 (20)	7 (18)	1.00
Diagnosis (%)				
Choledocholithiasis	55 (39)	33 (32)	22 (58)	0.01
Biliary cancer	33 (23)	25 (24)	8 (21)	0.90
Pancreatic cancer	24 (17)	20 (19)	4 (11)	0.33
Ampullary cancer	4 (2.8)	4 (3.8)	0 (0)	0.57
ERCP maneuvers (%)				
Biliary sphincterotomy	69 (49)	50 (48)	19 (50)	0.99
Transpancreatic sphincterotomy	2 (1.4)	1 (0.96)	1 (2.6)	0.87
Papillary ballon dilatation	4 (2.8)	4 (4)	0 (0)	0.63

ERCP: Endoscopic retrograde cholangiopancreatography; CI: Contrast injection; WGC: Wire-guided cannulation.

uate the impact of CI using a single-lumen catheter on the incidence of PEP after PGW, compared with that of WGC using a double-lumen catheter. First, a crude odds ratio was estimated by univariate analysis in Model 1, and then it was adjusted for basic characteristics such as sex and age by multivariate analysis in Model 2. Finally, it was also adjusted for potential confounding variables including failed cannulation, bile duct stone removal, pancreatic brush cytology, and biliary sphincterotomy by multivariate analysis in Model 3. These potential confounders were selected as risk factors for PEP.

Statistical analysis was performed using SPSS software, version 14.0J (SPSS Inc, Japan). Odds ratios and 95% confidence intervals were used, and two-sided P values of less than 0.05 were considered statistically significant.

RESULTS

The patients' characteristics and the endoscopic procedures used for PGW was illustrated in Table 1. There were no significant differences in these parameters, except for the incidence of choledocholithiasis, between CI using a single-lumen catheter and WGC using a double-lumen catheter.

CI with routine pancreatography, CI without routine pancreatography, and WGC were performed in 27 patients, 77 patients and 38 patients, respectively. Routine pancreatography did not contribute to the early diagnosis of pancreatic cancer in our study period. In CI without routine pancreatography and WGC, diagnostic pancreatography was performed in 17 patients and no patients, respectively.

The success rate of biliary cannulation by PGW alone was 69% (98/142), and the final success rate increased to 80.3% (114/142) after the addition of consecutive maneuvers or a second ERCP. In the 28 patients for whom biliary cannulation failed, a surgical operation was performed in 6 patients, percutaneous transhepatic biliary drainage was performed in 12 patients, endoscopic ultrasound-guided biliary drainage was performed in 2 patients, and an alternative examination or a follow-up

Table 2 Outcome of pancreatic guidewire placement *n* (%)

	Total (*n* = 142)	Cannulation method		
		CI using a single-lumen catheter (*n* = 104)	WGC using a double-lumen catheter (*n* = 38)	*P* value
Successful biliary cannulation	98 (69)	69 (66)	29 (76)	0.35
Post-ERCP pancreatitis	22 (16)	21 (20)	1 (2.6)	0.012

study was performed in 8 patients. When analyzed according to the cannulation method, the success rate of biliary cannulation by PGW alone was 66% (69/104) in the patients who underwent CI using a single-lumen catheter and 76% (29/38) in the patients who underwent WGC using a double-lumen catheter, as shown in Table 2. There were no significant differences between the two cannulation methods with regard to the success rate of biliary cannulation.

PEP occurred in 22 patients (15.5%), and the severity was mild in all cases. When analyzed according to the cannulation method, the incidence of PEP was 37.0% (10/27) in the patients who underwent CI with routine pancreatography, 14.3% (11/77) in those who underwent CI without routine pancreatography, and 2.6% (1/38) in those who underwent WGC. In all patients who underwent CI using a single-lumen catheter, the incidence of PEP was 20% (21/104), and it was significantly higher than that in the patients who underwent WGC using a double-lumen catheter, as shown in Table 2. In univariate and multivariate analysis, CI using a single-lumen catheter showed a high, statistically significant, odds ratio for PEP after PGW, as shown in Table 3. PEP did not occur in any patient who underwent pancreatic stenting.

DISCUSSION

In the present study, the incidence of PEP in the patients treated with PGW was 15.5%. When analyzed according to cannulation method, it was 37.0% in the patients who underwent CI with routine pancreatography, 14.5% in those who underwent CI without routine pancreatography, and 2.6% in those who underwent WGC. When CI using a single-lumen catheter is followed by PGW, the contrast medium in the catheter lumen is injected into the pancreatic duct and causes opacification of the entire pancreatic duct, as shown in Figure 2. Adding routine pancreatography to PGW is equal to performing two pancreatic ductal opacification procedures. Our data indicate that contrast injection into the entire pancreatic duct strongly correlates with the incidence of PEP after PGW. Cheon *et al*[13] also emphasized that a progressively higher frequency of PEP was detected as the extent of pancreatic ductal system opacification increased. In univariate and multivariate analysis, CI using a single-lumen catheter showed a high, statistically significant, odds ratio for PEP after PGW. Hence, a cannulation method involving the use of a double-lumen catheter to minimize the CI dose delivered into the pancreatic duct would be expected to reduce the incidence of PEP after PGW compared with CI using a single lumen catheter.

Herreros de Tejada *et al*[10] performed a multicenter, randomized, controlled trial involving 188 patients who had been subjected to 5 unsuccessful biliary cannulation attempts by WGC alone and divided them into the standard cannulation group (*n* = 87) and the attempted PGW group (*n* = 76). They emphasized that the incidence of PEP in the attempted PGW group was 17% (13/76), compared with 8% (7/87) in the standard cannulation group. However, as their attempted PGW group included 19 patients for whom PGW was unsuccessful and they did not explain in which cases PEP occurred, the incidence of PEP in the patients who successfully underwent PGW might have been lower. Ito *et al*[11] performed a prospective, randomized, controlled trial involving 70 patients who underwent PGW with CI, and they divided their subjects into the pancreatic stent group (*n* = 35) and the no-pancreatic stent group (*n* = 35). They concluded that the frequency of PEP in the pancreatic stent group was significantly lower than that in the no-pancreatic stent

Table 4 Study on pancreatic guidewire placement

Primary author	Study design	No. of patients	Cannulation method	Success rate fo biliary cannulation	Incidence fo post-ERCP pancreatitis
Maeda[8]	RCT	Control (n = 26), attempted PGW (n = 27)	CI	54%, 93%	0%, 0%
Ito[9]	OS	PGW (n = 113)	CI	73%	12%
Herreros de Tejada[10]	RCT	Control (n = 87), attempted PGW (n = 76)	WGC	56%, 47%	8%, 17%
Ito[11]	RCT	PGW with no-PS (n = 35), PGW with PS (n = 35)	CI	94%, 80%	23%, 2.9%
Present study	OS	PGW (n = 142)	CI/WGC (104/38)	69% (CI 66%, WGC 76%)	16% (CI 20%, WGC 2.6%)

RCT: Randomized controlled trial; OS: Observational study; PGW: Pancreatic guidewire placement; PS: Pancreatic stent; CI: Contrast injection; WGC: Wire-guided cannulation.

group (2.9% *vs* 23%). Hence, this suggests that papillary edema and/or CI into the pancreatic duct are strongly associated with the risk of PEP after PGW combined with CI. If PEP occurs due to pancreatic branch duct injuries caused by the PGW, pancreatic stenting will not be useful for preventing PEP. One concern about WGC without CI, especially in cases involving tortuous pancreatic ducts, is the risk of duct injury due to accidental guidewire insertion into a pancreatic branch duct. When guidewire resistance arises during PGW, we inject the minimal dose of contrast medium into the pancreatic duct in order to adjust the direction of the GW. It is interesting that the frequency of PEP in the pancreatic stent group in Ito's study[11] was similar to that in the WGC group treated with a double-lumen catheter in our study (2.9% *vs* 2.6%). Nevertheless, pancreatic branch duct injury caused by PGW can lead to PEP. Therefore, it is necessary to investigate PGW cases in combination with information about accidental guidewire insertion/placement into the branch pancreatic duct in order to clarify whether PGW has a powerful effect on PEP.

Our study has the following limitations: it is not a prospective controlled study; the routine administration of protease inhibitors or improvements in the operator's technique might have influenced the reduction in the incidence of PEP; information regarding the extent of pancreatic ductal system opacification is not investigated. However, our results suggest that the incidence of PEP after PGW is reduced by the use of a double-lumen catheter as it minimizes the CI dose delivered into the pancreatic duct.

In our study, the success rate of biliary cannulation by PGW alone was 69%. There have been 3 previous studies on PGW[8-11], as shown in Table 4, and the success rate of biliary cannulation by PGW alone ranged from 47% to 93%. The lowest success rate, which was found in Tejada's study[10], can be attributed to the setting of a maximum number of cannulation attempts (15 attempts), since there was no limitation on the number of cannulation attempts in other studies. In contrast, the highest success rate, which was found in Maeda's study[8], may have arisen from the small study population and the use of the vasodilator isosorbide dinitrate to improve the biliary cannulation rate. Our study is similar to Ito's study[9] as it had a large study population; there were no limitations on the number of cannulation attempts; and it obtained a success rate of approximately 70% for PGW alone, which is acceptable. If PGW alone cannot successfully achieve biliary cannulation, PGW permits the use of another rescue technique such as transpancreatic sphincterotomy, another attempt at biliary cannulation, or precut sphincterotomy under pancreatic stenting. PGW is useful as a rescue maneuver for patients in whom biliary cannulation is difficult, providing the pancreatic duct is accessible.

In conclusion, when PGW is used as the initial rescue technique for difficult biliary cannulation, a cannulation method involving the use of a double-lumen catheter is recommended to minimize the dose of contrast medium injected into the pancreatic duct and hence reduce the incidence of PEP after PGW.

The authors thank Hirokazu Komatsu for his statistical advice, and Kuniyuki Horigome and Yuji Sakurai for their skillful technical assistance.

COMMENTS

Background

In Japan, endoscopic retrograde cholangiopancreatography (ERCP) is usually performed under contrast injection (CI) using a single-lumen catheter and a duodenoscope with 15-degree backward-oblique angle. Pancreatic guidewire placement (PGW) is one of the rescue maneuvers used to overcome difficult biliary cannulation. In CI using a single-lumen catheter, the contrast medium in the catheter lumen is injected into the pancreatic duct during PGW, and it carries a risk of post-ERCP pancreatitis (PEP).

Research frontiers

It has been emphasized that the use of wire-guided cannulation (WGC) is associated with a reduced incidence of PEP compared with CI. WGC using a double-lumen catheter can minimize the dose of contrast medium injected into the pancreatic duct during PGW.

Innovations and breakthroughs

The authors changed their cannulation method from CI using a single-lumen catheter to WGC using a double-lumen catheter. In the patients who underwent CI using a single-lumen catheter, the incidence of PEP after PGW was significantly higher than that in WGC using a double-lumen catheter (20% *vs* 2.6%). In univariate and multivariate analysis, CI using a single-lumen catheter showed a high, statistically significant, odds ratio for PEP after PGW.

Applications

When PGW is used as the initial rescue technique for difficult biliary cannulation, a cannulation method involving the use of a double-lumen catheter is recommended to reduce the incidence of PEP after PGW.

Terminology

PGW is used to overcome difficult biliary cannulation during ERCP. After PGW,

biliary cannulation **is attempted in the region towards the upper left of the pan**creatic guidewire. **WGC is a cannulation method in ERCP using a guidewire** passed through the catheter lumen under fluoroscopic guidance.

Peer review

This is an interesting article describing the utility of PGW without injection of the contrast for achieving biliary cannulation.

Abstract

AIM: To clarify human papillomavirus (HPV) involvement in carcinogenesis of the upper digestive tract of virological and pathological analyses.

METHODS: The present study examined the presence of HPV in squamous cell carcinomas of the oral cavity (n = 71), and esophagus (n = 166) collected from Japan, Pakistan and Colombia, with different HPV exposure risk and genetic backgrounds. The viral load and physical status of HPV16 and HPV16-E6 variants were examined. Comparison of *p53* and $p16^{INK4a}$ expression in HPV-positive and HPV-negative cases was also made.

RESULTS: HPV16 was found in 39 (55%) oral carcinomas (OCs) and 24 (14%) esophageal carcinomas (ECs). This site-specific difference in HPV detection between OCs and ECs was statistically significant ($P < 0.001$). There was a significant difference in the geographical distribution of HPV16-E6 variants. Multiple infections of different HPV types were found in 13 ECs, but multiple infections were not found in OCs. This difference was statistically significant ($P = 0.001$). The geometric means (95% confidence interval) of HPV16 viral load in OCs and ECs were 0.06 (0.02-0.18) and 0.12 (0.05-0.27) copies per cell, respectively. The expression of $p16^{INK4a}$ proteins was increased by the presence of HPV in ECs (53% and 33% in HPV-positive and -negative ECs, respectively; $P = 0.036$), and the high-risk type of the HPV genome was not detected in surrounding normal esophageal mucosa of HPV-positive ECs.

CONCLUSION: Based on our results, we cannot deny the possibility of HPV16 involvement in the carcinogenesis of the esophagus.

Human papillomavirus in upper digestive tract tumors from three countries. *World J Gastroenterol* 2011; 17(48): 5295-5304 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i48/5295.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i48.5295

INTRODUCTION

Human papillomaviruses (HPVs) belong to the *Papillomaviridae* family and are non-enveloped icosahedral viruses with a diameter of 55 nm and have more than 100 types[1]. The International Agency for Research on Cancer considers that there is convincing evidence indicating that infection with *HPV16*, *18*, *31*, *33*, *35*, *39*, *45*, *51*, *52*, *56*, *58*, *59 or 66* can lead to cervical cancer[2]. To date, approximately 20 types have been identified as high-risk HPVs that increase the risk of cervical cancer. Among them, HPV16 and HPV18 are considered to be associated with 70% of all cervical cancer cases[2]. In contrast, low-risk HPV types such as *HPV6* and *HPV11* cause genital warts but not cancer.

The association of HPV with cancers of the upper digestive tract (UDT) is also suspected. Major malignancies observed in the UDT include cancers of the oral cavity, oropharynx, larynx and esophagus. Meta-analysis of 4680 samples from 94 reports published between 1982 and 1997 has shown that HPV was 2-3 times more likely to be detected in precancerous oral mucosa and approximately five times more likely to be detected in oral carcinoma (OC) than in normal mucosa[3]. Among the studies used in this meta-analysis, the largest and best-designed study was that by Maden *et al*[4]. They examined 112 normal mucosal specimens and 118 OCs and detected HPV16 in six (5%) cases of OC but in only one (0.9%) normal mucosal specimen. In contrast, *HPV6* was detected in 12 OCs and 10 normal mucosal specimens. High-risk HPV has also been detected in esophageal carcinomas (ECs). A review of studies published between 1982 and 2001 has shown that 15.2% of the 2020 squamous cell carcinomas (SCCs) of the esophagus tested using polymerase chain reaction (PCR) were *HPV* positive[5]. However, previous studies have shown various *HPV*-positive rates in non-genital cancers worldwide. One argument is that this difference was caused by different HPV-detection methods with different sensitivity and specificity among studies. Another possible explanation is different HPV exposure risk and/or susceptibility of disease/infection across study populations.

Furthermore, the role of *HPV* in UDT carcinomas, particularly ECs, remains unclear and controversial[6]. Two European prospective serological studies that used stored serum specimens[7,8] and a Chinese case-control study[9] have found a strong association between the risk of ECs and seropositivity for *HPV16*. In contrast, two retrospective studies conducted in Europe[10,11] and a large prospective serological study in China[12] have found no significant association of *HPV16* or *HPV18* with ECs.

In the present study, cases of oral cavity and esophageal cancer were examined for concomitant HPV infection, the type of HPV involved, and multiple infection with different types of *HPV* in Japan, Pakistan and Colombia, with different *HPV* exposure risks and genetic backgrounds, using the same methods. In order to shed light on the etiological significance of *HPV* in the development of OCs and ECs, the viral load and physical status of *HPV16* (which is the most commonly found HPV type worldwide) and HPV16-E6 variants were examined. Comparison of *p53* and $p16^{INK4a}$ expression in HPV-positive and HPV-negative OCs and ECs was also made.

MATERIALS AND METHODS

Ethics

Institutional Review Board of the Faculty of Medicine, Kagoshima University, Japan, approved the present study.

Subjects

This study examined 261 formalin-fixed and paraffin-embedded tissues of SCC of the UDT: 92 cases (17 OCs and 75 ECs) diagnosed at Kagoshima University Hospital, Kagoshima, Japan during 1987-2005; 90 cases (48 OCs and 42 ECs) diagnosed at King Edward Medical University, Lahore, Pakistan during the period 1996-2002; and 55 cases (6 OCs and 49 ECs) diagnosed at Hospital Universitario del Valle in Cali, Colombia during 1996-2001. For 11 HPV-positive EC cases from Japan, additional formalin-fixed and paraffin-embedded tissues of the esophagus, with or without cancer cells, were analyzed. The histological classifications for OCs and ECs were made using the guidelines determined by Japan Society for Head and Neck Cancer[13] and Japanese Society for Esophageal Diseases[14], respectively. These Japanese classifications follow their corresponding WHO classifications.

DNA extraction

Five-micrometer-thick sections of each tissue, containing a minimum of 60% (typically 70%-90%) tumors cells, were prepared. In each tissue sample, 0.8 mL lemosol and 0.2 mL ethanol were added. Subsequently, the samples were washed with 1 mL ethanol. After centrifugation, the pellet was resuspended in digestion buffer (50 mmol/L Tris-HCl, pH 8.0, 1 mmol/L EDTA, pH 8.0, 0.5% Tween 20) containing 200 μg Proteinase K (Invitrogen, Carlsbad CA, United States) and incubated at 56 ℃ for 24 h.

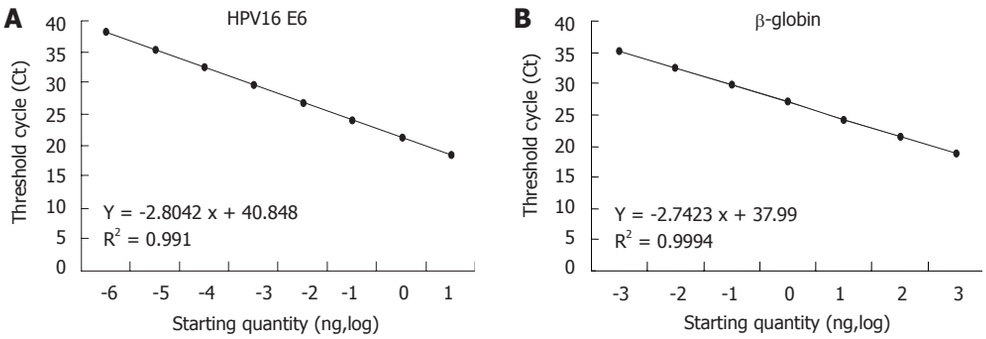

Figure 1 Real-time polymerase chain reaction standard curves. A: Human papillomavirus (HPV)-16 E6 DNA standard calibration curve was generated automatically by plotting Ct values against the logarithm of the copy numbers of eightfold serially diluted of HPV-16 cloned in pUC19 plasmid; B: A seven fold dilution series of a human DNA control (Dynal UK) was used to generate the standard curve for β-globin.

After incubation, the solution was heated at 100 ℃ for 10 min and centrifuged. Phenol-chloroform and DNA ethanol precipitation was made in all HPV16-positive samples in order to determine the DNA amount by using an ND-1000 spectrophotometer (Nano Drop Products, Wilmington, DE, United States). Since the quantity of tissue embedded in the paraffin blocks varied between samples, *β-globin* gene amplification was made for all the samples to check the presence of PCR amplification inhibitors and of amplifiable DNAs. The *β-globin* gene amplification with a set of PCO3/PCO4 primers[15] was conducted under the following PCR conditions: initial denaturation at 95 ℃ for 4 min, 40 cycles with the cycling profile of 95 ℃ for 1 min, 52 ℃ for 1 min and 72 ℃ for 2 min, and final extension for 5 min at 72 ℃.

HPV detection and genotyping

The prevalence of *HPV* DNA was analyzed with the broad-spectrum SPF1/2 *HPV* primers PCR method as described previously[16]. The reaction was performed in a final volume of 25 μL containing 3 μL DNA template and 1.5 U AmpliTaq gold (PerkinElmer, Waltham, MA, United States). The mixture was incubated for 15 min at 95 ℃, followed by 40 cycles of 1 min at 94 ℃, 1 min at 45 ℃, and 1 min at 72 ℃, and a final extension of 5 min at 72 ℃. The PCR products were run on a 3% agarose gel and the 65-bp product was visualized with ethidium bromide staining. The *HPV* types were determined using the INNO-LiPA *HPV* genotyping v2, which is based on the reverse hybridization principle. Part of the *L1* gene region of the *HPV* genome was amplified using SPF10 forward and reverse primers tagged with a biotin at the 5' end, and denatured[17]. Biotinylated amplicons were hybridized with specific oligonucleotide probes immobilized on the strip. In total, there were 25 genotypes (HPV6, 11, 16, 18, 31 33, 35, 39, 40, 42-45, 51-54, 56, 58, 59, 66, 68, 70, 73 and 74). After hybridization and stringent washing, streptavidin-conjugated alkaline phosphatase was added and bound to any biotinylated hybrid previously formed. Incubation with 5-bromo-4-choro-3-indolyl phosphate/nitro blue tetrazolium chromogen gave a purple/brown precipitate and results could be interpreted visually.

HPV16 viral load

The quantitative real-time PCR analysis was performed with an ABI Prism 7000 Sequence Detection System (Applied Biosystems, Foster City, CA, United States). Each HPV16 DNA positive sample was amplified for 76 bp of the *E2* gene using the following primers: forward 5'-AACGAAGTATCCTCTCCTGAAATTATTAG-3' (3361-3389 nt); reverse 5'-CCAAGGCGACGGCTTTG-3' (3427-3443 nt), as well as 81 bp of the *E6* gene, primers forward 5'-GAGAACTGCAATGTTTCAGGACC-3' (94-116 nt); reverse 5'-TGTATAAGTTGTTTGCAGCTCTGTGC-3' (150-169 nt), in the presence of specific hybridization probes for *E2*-(FAM-CACCCCGCCGCGACCCATA-TAMRA) (3406-3424 nt) and *E6*-(FAM-CAGGAGCGACCCAGAAAGTTACCACAGTT-TAMRA) (119-147 nt). The reaction was performed in a 25 μL mixture containing 1 × TaqMan Master Mix (Applied Biosystems), 300 nmol primers, 100 nM dual-labeled *E2* or *E6* fluorogenic hybridization probe, and 1-2 μL DNA template. Incubation for 10 min at 95 ℃ allowed activation of the AmpliTaq Gold DNA polymerase and denaturation of nucleic acids; 40 cycles of denaturation at 95 ℃ for 15 s and annealing-extension at 60 ℃ for 1 min were then carried out to amplify the *E2* and *E6* genes. Serial dilutions of full-length HPV16 genome cloned in *pUC19* plasmid (kindly given by Dr. Massimo Tommasino, IARC, France) containing equivalent amounts of *E2* and *E6* genes from 86 to 862 million copies per reaction served as a standard control (Figure 1A). Each sample was assayed two or three times. DNAs extracted from SiHa cell SiHa cells was used as control for *E2* (negative) and *E6* (positive) amplification. This cell line derived from a cervical carcinoma is known to harbor one HPV16 genome or two per cell[18]. Since this cell has only an integrated viral genome, its *E2* gene is disrupted. To adjust for the differences in the amount of input genomic DNA between samples, quantitative real-time PCR for human *β-globin* gene was performed by 2× QuantiTect SYBR Green PCR kit (QIAGEN, Hilden, Germany) using the PC03/PC04 primers set[15]. A sevenfold dilution series of a human DNA control (Dynal UK, Bromborough, Wirral, United Kingdom) was used to generate the

standard curve (Figure 1B). The amount of *β-globin* DNA present in each sample was divided by the weight of one genome equivalent (i.e. 6.6 pg/cell) and a factor of two (because there are two copies of *β-globin* DNA/genome equivalent or cell) to obtain the number of genome equivalents or cells in the sample. The viral load of each sample was expressed as the number of *HPV16* copies per cell.

HPV16 physical status

The HPV16 physical status was determined on the assumption that the *E2* gene is disrupted in integrated viral genome, and therefore, the expected ratio of *E2* to *E6* copy numbers was zero. On the other hand, episomal viral genome had equivalent copy numbers of the *E2* and *E6* genes (an *E2*/*E6* ratio was nearly equal to unity) and mixed presence of integrated and episomal forms of *HPV16* had an *E2*/*E6* ratio between 0 and 1[19].

HPV16 E6 sequencing and variant analysis

HPV16 E6 gene was divided into two fragments and amplified by two semi-nested PCRs, using outer primers 5' -TTGAACCGAAACCGGTTAGT-3' (forward, 46-66 nt) and 5'-GCATAAATCCCGAAAAGCAA-3'(reverse,236-256nt), and inner primers 5'-GCACCAAAAGAGAACTGCAA-3'(forward, 85-105 nt) for the first half. The outer primers of the second half were 5'-GGGATTTATGCATAGTATATAGAGA-3'(forward, 246-270 nt) and 5'-CTTTGCTTTTTGTCCAGATGTC-3' (reverse, 453-474 nt), and inner primers 5'-CAGGACACAGTGGCTTTTGA-3' (reverse, 421-440 nt). The primers were designed using the web-based tool Primer3[20]. Each reaction mix for *E6* amplification contained 5 μL template DNA, 200 μmol/L dNTP, 0.5 μmol/L each primer, and 1 U Hot star Taq DNA polymerase (QIAGEN) in a total volume of 25 μL reaction buffer (50 mmol/L KCl, 20 mmol/L Tris-HCl, pH 8.3). The first-round PCR condition was 95 ℃ for 15 min, followed by 40 cycles of 95 ℃ for 1 min, 55 ℃ for 1 min, and 74 ℃ for 1 min, and a final cycle of 74 ℃ for 10 min. The second-round PCR condition was essentially the same as the first round, except that 1 μL of the first-round PCR products was used as template and that the number of PCR cycles was 35. The amplified products were confirmed through electrophoresis with 2% agarose gels at 100 V for 25 min. The positive amplicon was purified using the QIAGEN PCR purification kit and directly sequenced by fluorescent dye-labeled dideoxynucleotides and cycle sequencing methods using the Big Dye Terminator Cycle Sequencing Kit (PE Applied Biosystems, NJ, United States). The HPV16 *E6* sequences were aligned by CLUSTAL W multiple alignments package[21], and compared with sequences of HPV16 variants that have been published elsewhere. HPV16 variants Genbank accession numbers were as follows: *K02718*, E-*350T* prototype; *AF536179*, *E-350G* variant; *AF402678*, Asian-American variant; *AF534061*, Asian variant and *AF536180*, African variant 1.

Immunohistochemistry for $p16^{INK4a}$ and p53

The paraffin-embedded samples were cut in 2-3-μm-thick slices, deposited on coated glass slides, and dewaxed using xylene. After rinsing with ethanol, the slides were incubated for 30 min in 0.3% H_2O_2/methanol and for 5 min in a microwave oven at 95 ℃ in 0.01 mol sodium phosphate/citrate buffer (pH 8.0). In order to block the nonspecific binding of the antibody, the slides were incubated for 30 min with 5% bovine serum albumin (BSA) in phosphate buffered saline (PBS) at room temperature. A 1:200 dilution in 5% BSA-PBS of monoclonal anti-$p16^{INK4a}$ antibody was used (BD PharMingen, San Jose, CA, United States). The slides were incubated overnight at 4 ℃, washed with PBS, incubated with biotinylated horse anti-mouse IgG for 30 min, and then washed with PBS and incubated with 1:50 dilution of the avidin-biotin-peroxidase complex (Vectastain Elite ABC kit; Vector Laboratories, Burlingame, CA, United States) for 30 min at room temperature. The reaction was visualized by adding diaminobenzidine (Dako, Carpinteria, CA, United States) for 10 min. The sections were counterstained with hematoxylin and visualized. Immunostaining was considered negative when 0%-9% of the carcinoma cells were stained, and was considered positive when 10%-100% of the cells were stained, according to criteria reported previously[22]. For p53, the procedure was the same as for $p16^{INK4a}$, but primary antibodies of p53 (1:50 dilution) was used (DO-7; Dako Japan, Kyoto, Japan). The interpretation of the positive signal was the same as that used for $p16^{INK4a}$ immunostaining.

Statistical analysis

The χ^2 test, Fisher's exact test, Kruskal-Wallis test, and calculations of geometric mean of viral load and corresponding 95% confidence intervals were calculated with STATA software, version 9.2. (STATA Corp., College Station, TX, United States). All the *P* values presented were two sided.

RESULTS

The present study examined cases of SCC of the oral cavity (n = 71) and esophagus (n = 166) collected from Japan, Pakistan and Colombia. Sex distribution and mean ages by country are shown in Table 1. Although there was no sex difference in OCs among the countries, the proportion of male Japanese EC cases was higher than those of other countries. Pakistani OC and EC cases were younger than those in other countries.

The results of HPV detection using PCR with SPF1/2 consensus HPV primers are shown in Table 2. Although Colombian and Pakistani cases showed relatively higher HPV-positive rates in OCs and ECs, respectively, these differences were not statistically significant even after adjusting for sex and age distributions. In total, HPV was detected in 56% and 19% of SCCs of the oral cavity and the esophagus, respectively. The prevalence of HPV in

carcinomas was significantly higher in OCs than in ECs ($P < 0.001$), and similar trends were observed in all countries.

HPV16 was by far the most frequently detected HPV type. Except for one case, all HPV-positive SCC cases of the oral cavity harbored HPV16 only (39/40); the exception was an OC case in which HPV6 was detected. There were no multiple infections of different HPV types in a single carcinoma specimen among OCs (Table 2). Among 31 HPV-positive ECs, 24 were HPV16-positive. Table 3 lists 19 EC cases with HPV of a type other than HPV16; of these, 13 involved multiple infections of different HPV types. All multiple-infection cases except one involved combinations of HPV16 and other HPV genotypes (12/13). The exceptional case involved multiple infection with HPV51 and HPV68.

The physical status of HPV16 was determined by the ratio between copy numbers of the viral *E2* and *E6* genes, which were measured by real-time PCR. Among the 63 HPV16-positive cases examined, only four had HPV16 in the episomal form (two OCs and two ECs), as shown in Table 4. In eight carcinomas (three OCs and five ECs), the HPV16 genome was present in both the episomal and integrated forms. In the remaining cases, the viral

genome was considered to be present in the integrated form only. The frequency of HPV16 genome integration into the host genome was not related to sex, age or cancer site. However, the distribution of HPV16 physical status in ECs significantly differed among the three countries. All Japanese HPV16-positive cases showed an integrated form, but the frequency of integrated HPV16 was low in Pakistani and Colombian ECs.

HPV16 E6 variant analysis was also conducted (Table 4). The specimens in some cases had insufficient DNA, therefore, only 39 HPV16-positive cases were analyzed.

[1]*P* values were obtained by χ^2 test. [2]Information of histological grading was missing for 10 human papillomavirus (HPV)-negative and 14 HPV-positive oral carcinomas (OCs), and two HPV-negative esophageal carcinomas (ECs). [3]Tissue specimens were not enough to examine *p53* expression in two HPV-negative and seven HPV-positive OCs, and two HPV-negative ECs. [4]Tissue specimens were not enough to examine $p16^{INK4a}$ expression in two HPV-negative and five HPV-positive OCs, and seven HPV-negative and one HPV-positive ECs.

In Japan, only the *E-350T* prototype and the *E-350G* variant were detected. The predominant HPV16 variant was E-350G in Pakistani cases. In contrast, the Asian-American variant was more frequently found in Colombia, and these differences were statistically significant for both OCs and ECs ($P = 0.048$ and $P < 0.001$, respectively).

The geometric means of HPV16 were 0.064 and 0.121 per cell for OCs and ECs, respectively, and this difference was not statistically significant ($P = 0.552$). The HPV16 viral loads were also compared by country and the presence of the HPV16 integrated form and E-350G variant (Table 5). HPV16 in Colombian cases or cases with the E-350G variant tended to show higher viral loads in both OCs and ECs. The geometric means of the virus in OCs were 1.081, 0.147, 0.138 and 0.075 per cell for the E-350G variant, E-350T prototype, Asian-American variant, and Asian variant, respectively.

Comparison of $p16^{INK4a}$ and p53 protein expression in HPV-positive and HPV-negative OCs and ECs suggested that the $p16^{INK4a}$ expression was affected by the presence of the HPV genome in ECs (Table 6). However, the expression of these tumor suppressor genes was not related to HPV status in OCs.

It is difficult to deny the possibility that high-risk HPV was harbored in non-cancerous tissue adjacent to HPV-positive carcinoma, therefore, additional paraffin-embedded tissues of the 11 HPV-positive ECs from Japan were examined (Table 7). None of the normal esophageal epithelia adjacent to HPV-positive EC harbored a high-risk type of HPV genome.

DISCUSSION

The HPV genome was detected in 56% and 19% of SCCs of the oral cavity and esophagus, respectively, in cases collected from Japan, Pakistan and Colombia. The HPV prevalence in both OCs and ECs did not significantly differ by country (Table 2). On the other hand, there was a significant geographical difference in the distribution of HPV16 E6 variants, which was also related to the viral load (Table 5). HPV16-positive OC cases with the E-350G variant showed a higher viral load than those with non-E-350G variants. Similar trends were observed in ECs although the difference was not statistically significant. One of the reasons for this difference is nucleotide alterations in primers and probes sequences. Among HPV16 intratypes, there is one polymorphism in the sequence of the E6 probe at nucleotide 145, and the Asian-American variant harbors this nucleotide substitution (C to T). However, this polymorphism is unlikely to cause a difference in viral load because the copy number of HPV16 in the Asian-American variant was similar to other intratypes except E-350G (data not shown). The HPV16 E-350G variant contains a polymorphism at residue 83, leucine to valine (L83V), which is associated with the risk of invasive cancers of the cervix in European studies[23,24]. Yamada *et al*[25] have identified five phylogenetic clusters of HPV16 with distinct geographic distributions by analyzing sequences of *E6, L1* and *LCR* regions isolated from cervical samples collected worldwide. HPV16 is the most prevalent HPV type detected in UDT cancer, therefore, different geographic distribution patterns of HPV16-E6 variants with differing copy num-

bers might affect the detection rate of HPV genome if different methods for HPV detection were applied.

HPV involvement in UDT carcinogenesis is unclear. In the present study, a significant positive association between the presence of the HPV genome and $p16^{INK4a}$ expression was observed in ECs but not in OCs (Table 6). In cervical carcinomas, $p16^{INK4a}$ protein expression is known to be upregulated by HPV[26], where retinoblastoma protein is inhibited by HPV E7 protein, causing the release of E2F protein, which in turn leads to $p16^{INK4a}$ upregulation. Although the results of the present study suggest an etiological involvement of HPV in EC development, this association should be confirmed.

HPV detected in normal specimens or low-grade squamous intraepithelial lesions has been found not to be integrated into the host genome[27]. However, it has been reported in many studies[19,28] that HPV16 is often integrated into the host genome in cervical carcinomas and is frequently accompanied by episomal HPV. These findings suggest an etiological involvement of HPV when integrated into the host genome. In most HPV16-positive cases in the present study, the viral DNA was integrated into the host genome. This finding is compatible with studies conducted in areas of high EC incidence in China, in which > 90% of high-risk HPV detected in ECs was found to be integrated into the host genome[29,30].

In Japanese ECs, high-risk type HPV genomes were not detected in surrounding normal epithelial tissues of HPV-positive ECs (Table 7). This result is similar to a recent study from Australia[31], showing that none of the 55 samples of normal esophageal squamous epithelium were HPV-positive. Although we cannot deny the possibility that tumor cells are more susceptible to the infection with high-risk type of HPV, these observations indicate a possible association between HPV infection and carcinogenesis in some ECs.

The geometric mean HPV16 load in ECs was 0.121 per cell in the current study. It is unlikely, however, that the low viral load was a consequence of formalin fixation because the parallel amplification of a housekeeping gene (*β-globin*) gave an estimate of the amount of amplifiable genomic DNA in individual samples. Our findings are compatible with Chinese studies on ECs that have reported a viral load of < 1 to 157 copies per cell[32].

The prevalence of HPV was evidently higher in OCs than in ECs ($P < 0.001$). HPV typing analysis established that HPV16 was most common among SCCs with concomitant HPV infection. In fact, HPV16 was the only high-risk type detected in OCs. In ECs, although HPV16 was the most frequently detected, other high-risk HPV types such as HPV18, 45 and 51 were also detected. In this study, multiple infection with different HPV types was observed in 37% of HPV-positive ECs, but multiple infection was not found in OCs. Double infection with different HPV types in ECs has also been reported in a study from China[33]. These findings are in contrast to those reported in a Japanese study that showed multiple-type HPV infection in 17/30 (56.7%) specimens of the oral cavity mucosa[34].

Infection with multiple HPV types is not rare in cervical samples. Studies have shown that 10% or more of clinical lesions contain at least two different HPV types[35,36]. Interestingly, the prevalence of multiple infections has been reported to decrease with increasing severity of cervical neoplasia[37,38]. A study has shown that the frequency of multiple-type HPV infection is related to many factors, such as age and sexual behavior, as well as to variables affecting immune response, e.g., immunosuppressive conditions and *HLA* genotypes[38]. In the present study, ECs with multiple-type HPV infection did not exhibit different clinicopathological features from ECs with single HPV infection. Silins *et al*[39] have suggested that infection with HPV6 might interfere with HPV16 in terms of cervical carcinogenesis. In the present study, there were three ECs with co-infection of HPV16 and HPV6. These cases did not have any common clinical features.

In a previous study of HPV16 variants using cervical specimens[25], the Asian-American variant was isolated mainly from Central and South America and Spain. African variants 1 and 2, and the Asian variant were present mainly in samples from Africa and Southeast Asia, respectively. In all regions other than Africa, the E-350T prototype and the *E-350G* variant were detected. In the present study, only the *E-350T* prototype and the *E-350G* variant were detected in Japan. On the other hand, in Pakistan, *E-350G* was the predominant *HPV16* variant. In Colombia, the Asian-American variant was the most commonly found type, but this variant was not found at all in Japan and Pakistan. Our findings are similar to those of Yamada *et al*[25], who detected the *E-350G*, *E-350T*, and Asian-American variants in 52%, 25%, and 20%, respectively, of 228 HPV16-positive cervical cancer specimens from Central and South America. No particular *HPV16 E6* variant predisposed those infected to OCs or ECs.

One important question regarding the presence of HPV in UDT carcinomas is the route of HPV infection. HPV is known to be sexually transmitted in the case of the anogenital organs[40], as well as in some cases of HPV infection of the oral cavity[41]. In addition, several other possible routes of infection have been proposed for HPV infection of the oral and pharyngeal cavities. These include intrapartum infection during passage through an infected birth canal, transplacental infection *in utero* prior to birth, and postnatal infection by contact[42,34]. For instance, HPV can be transmitted from a mother to her newborn baby during vaginal delivery, and this can result in recurrent respiratory papillomatosis. In addition, HPV DNA has been detected in the foreskin of normal newborns[43], in a high percentage of neonates vaginally delivered by HPV-infected mothers, and in the amniotic fluid[44]. These findings favor the mechanisms for HPV transmission at birth.

In the present study, HPV16 was frequently integrated into the host genome in patients with OCs and ECs. However, the viral loads in these malignancies were much lower than those found in cancer of the cervix. It should be noted, however, that human cancer can be regarded as a stem cell disease originating from a small fraction of cancer cells that show self-renewal and pluripotency and are capable of initiating and sustaining tumor growth[45]. HPV may be present in only a small fraction of cancer cells with a stem cell-like nature present even in advanced tumors.

In conclusion, there was no significant difference of HPV prevalence in SCC of the UDT among populations at different risk of HPV exposure. The present study cannot deny a possibility of HPV16 involvement in the development of EC.

COMMENTS

Background

Human papilloma virus (HPV) is suspected to play causal roles in a variety of human malignancies, mainly in cervical cancer. Recently, scientific studies have suggested an etiologic role HPV in a subset of cancers in the upper digestive tract (UDT), such as cancers of the oral cavity, oropharynx, larynx and esophagus. These studies have now recognized that HPV infection in oral cavity is a strong risk factor for head and neck squamous cell carcinoma; mostly for oropharyngeal cancer, but also for esophageal carcinoma, but this remains unclear and controversial.

Research frontiers

The evaluation of causality for the infectious agents as human carcinogens is difficult given their ubiquitous nature, the substantial length of time between infection and the cancer event, the nature of cofactors, and the rarity of malignancy among those infected. Thus, a central problem for the epidemiologist is to define the natural history of infection and to identify those factors that are related to the development of cancer. Hence, informative biomarkers of the agent (such as viral load), of the host (such as abnormal antibody pattern), and of other oncogenic exposures (such as tobacco use) are required for understanding the virus-human interactions and for developing interventions.

Innovations and breakthroughs

In the present study, cases of oral cavity and esophageal cancer were examined for concomitant HPV infection, the type of HPV involved, and multiple infection with different types of HPV in three countries, Japan, Pakistan and Colombia, with different risks of HPV exposure and genetic backgrounds, using the same methods. To shed light on the etiological significance of HPV in the development of oral cancer (OC) and esophageal cancer (EC), the viral load and physical status of HPV16 (which is the most commonly found HPV type worldwide) and HPV16-E6 variants were examined. Comparison of p53 and p16INK4a expression in HPV-positive and HPV-negative OCs and ECs was also made.

Applications

The prophylactic vaccine against HPV16 could prevent HPV16-associated malignancies if the vaccine were demonstrated to be capable of preventing oral HPV16 infection. Thus, these findings have created new potential opportunities for the primary prevention of other HPV-related malignancies.

Terminology

HPV is a member of the papillomavirus family, which is capable of infecting humans. Viral load is a measure of the severity of viral infection that can be calculated by estimating the amount of virus in a cell or tissue. Viral physical status: the HPV genome can be found in two physical states: integrated into the host genome or not integrated as an episomal molecule. E6 is the HPV protein associated with cancer development. p53 protein prevents cell growth and stimulates apoptosis in the presence of DNA damage. p16 protein is involved in tumor suppression.

Peer review

Currently, the HPV vaccines potentially hold promise for the prevention of a greater majority of HPV-positive cervical cancers in woman. Thus, studies that attempt to clarify the association between HPV with cancers of the oral cavity and esophagus are important. They give us reason to be optimistic that HPV vaccines may be protective against UDT HPV infection, and consequently, effective in preventing HPV-associated UDT cancers in both men and women.

Abstract

AIM: To investigate the existence and levels of sH2a, a soluble secreted form of the asialoglycoprotein receptor in human serum.

METHODS: Production of recombinant sH2a and development of a monoclonal antibody and an enzyme-linked immunosorbent assay (ELISA). This assay was used to determine the presence and concentration of sH2a in human sera of individuals of both sexes and a wide range of ages.

RESULTS: The recombinant protein was produced successfully and a specific ELISA assay was developed. The levels of sH2a in sera from 62 healthy individuals varied minimally (147 ± 19 ng/mL). In contrast, 5 hepatitis C patients with cirrhosis showed much decreased sH2a levels (50 ± 9 ng/mL).

CONCLUSION: Constant sH2a levels suggest constitutive secretion from hepatocytes in healthy individuals. This constant level and the decrease with cirrhosis suggest a diagnostic potential.

Key words: Asialoglycoprotein receptor; Hepatitis C virus; Liver function; Cirrhosis; Liver diagnosis

INTRODUCTION

The human asialoglycoprotein receptor (ASGPR) is expressed on the sinusoidal membrane of hepatocytes and serves in the clearance of asialoglycoproteins from the plasma[1]. As evaluated through whole-body scintigraphy, using a radioactive ASGPR ligand, a technetium-99m-labeled asialoglycoprotein analog, only the liver shows any significant expression of the ASGPR[2]. The levels of the ASGPR are much reduced upon hepatocyte dedifferentiation[3,4], upon chronic alcohol consumption[5] and in liver fibrosis and cirrhosis[6,7]. We had previously described a soluble form of the ASGPR, termed sH2a, se-

creted from the human hepatoma cell line HepG2. SH2a is formed by cleavage in the endoplasmic reticulum of its precursor[8], encoded by an alternatively spliced variant of the ASGPR H2 subunit mRNA[9], and does not arise by shedding at the cell surface. Here we show for a group of healthy individuals that ASGPR sH2a is secreted to the serum at surprisingly constant levels, and that these are much reduced in hepatitis C virus (HCV) patients with liver cirrhosis.

MATERIALS AND METHODS

Materials

Immobilon-P paper was purchased from Millipore Corp (Bedford, MA). Protein A-sepharose was from Repligen (Cambridge, MA). N-glycosydase-F was obtained from Roche Applied Science. Succinimidyl 4-(N-maleimidomethyl)cyclohexane-1-carboxylate and dimethylpimelidate were from Pierce (Rockford, IL). A solution of 3,3',5,5' -tetramethylbenzidine (TMB) was purchased from Kirkegaard and Perry Laboratories Inc. (Gaithersburg, MD). Alkaline phosphatase (ALP) substrate p-nitrophenylphosphate was from Chemicon International (Temecula, CA). Imperial protein stain was from Pierce. Common reagents were from Sigma.

Antibodies

Polyclonal antibodies specific for a peptide corresponding to the carboxyterminus of sH2a or to a peptide unique to sH2a (169 antibody) were described in earlier studies[8].

A monoclonal antibody was prepared by intraperitoneal immunization of BALB/c mice with a conjugate of keyhole limpet hemocyanin (KLH) with the carboxyterminal peptide of H2 and complete Freunds adjuvant. Conjugation was performed using succinimidyl 4-(N-maleimidomethyl) cyclohexane-1-carboxylate. Hybridoma cells, resulting from fusion of the mouse splenocytes with NS/O myeloma cells, were screened by ELISA, selecting a clone (B9) that reacted strongly with the peptide but not with KLH. The isotype of B9 was IgG3, as analyzed using an Isostrip kit (Roche). Ascitic fluid, obtained by injection of hybridoma cells to mice was used in all experiments due to difficulties in IgG3 purification by standard methods. It did not show any significant background. Goat anti-mouse IgG conjugated to agarose was from Sigma. ALP- or HRP-conjugated goat anti-mouse or anti-rabbit IgG antibodies were from Jackson Laboratories (West Grove, PA).

Recombinant sH2a

Recombinant sH2a was generated by PCR using the primers GAACCATCAGGAGGATCCCAAAGTGAGGGTC and GGAATTCTCAGGCCACCTCGCC and cloned into pET28a (Novagen), which adds an N-terminal 6XHis tag, using *Bam*HI and *Eco*RI. Expression was in *Escherichia coli* Rosetta DE3 pLysS at 37 ℃ until A_{600} = 0.6 and then with isopropyl β-D-1-thiogalactopyranosid induction for 2 h at 32 ℃. After cell sonication and addition of 6 mol guanidinium-hydrochloride, tagged sH2a was purified on Ni^{2+}-NTA-agarose (Qiagen) followed by dialysis. Protein concentration was determined by the bicinchoninic acid assay (Pierce).

Cell culture

NIH 3T3 cells and a stable transfectant expressing H2a (2-18 cell line)[8] were grown in Dulbecco's modification of Eagle's medium (DMEM) supplemented with 10% newborn calf serum. HepG2 cells were grown in MEM plus 10% fetal calf serum.

Immunoprecipitation and immunoblotting

Immunoprecipitations from cell supernatants (1.2-1.5 mL from 90 mm plates), using rabbit anti-H2a carboxyterminal or 169 antibodies were done as described before[8]. Immunoprecipitations from serum samples were done in a similar manner or using anti-H2a antibody crosslinked to protein A-sepharose with dimethylpimelidate where indicated. Immunoprecipitation with B9 was followed by goat anti-mouse IgG bound to agarose. Treatment of immunoprecipitates with N-glycosidase-F and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) were done as described before[8].

Immunoblotting was done as described before[10] using anti-H2a carboxyterminal antibody and detection was performed with TMB solution or using the electrochemiluminescence procedure and a Bio-Rad ChemiDoc XRS system.

Competitive enzyme-linked immunosorbent assay

Corning ELISA plate wells were coated with the carboxyterminal peptide of sH2a (5 μg/mL) and blocked with 3% bovine serum albumin in Tris-buffered saline (TBS), pH 7.5. B9-containing ascitic fluid (1:1500) was preincubated overnight at 4 ℃ with serial dilutions of the serum sample and then incubated on the coated ELISA plate wells for 1 h at room temperature (RT). After TBS wash wells were reacted with goat anti-mouse IgG conjugated to ALP for 1 h at RT. P-nitrophenyl phosphate was added and *A* quantified at 405 nm.

Study subjects

Retrospective samples were from a group of healthy blood donors and a group of HCV-infected patients with cirrhosis, at the Liver Unit, Tel Aviv Sourasky Medical Center. Cirrhosis was determined by percutaneous liver biopsy, performed using a Tru-Core Ⅱ [R] biopsy instrument under ultrasound guidance. The study had a priori approval by the hospital ethical committee according to the Helsinki Declaration and written informed consent was obtained from all participants.

RESULTS

sH2a in human sera

We had seen that sH2a is normally secreted from the human hepatoma cell line HepG2[8]. To analyze whether

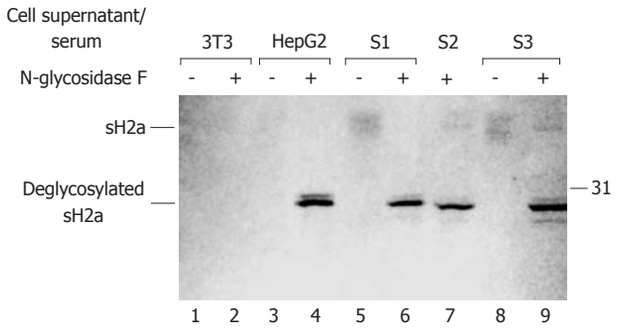

Figure 1 sH2a is detected in normal human sera. Cell supernatants from 90 mm petri-dishes of NIH 3T3 (lanes 1-2) or HepG2 cells (lanes 3-4) or 0.3 mL of normal human sera from 3 donors (S1, lanes 5 and 6; S2, lane 7; S3, lanes 8 and 9) were immunoprecipitated with polyclonal anti-H2a carboxyterminal antibodies that were crosslinked to protein A-agarose, and the immunoprecipitates were subjected to 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis. Immunoblotting was then done with anti-H2a carboxyterminal antibody followed by horseradish peroxidase-conjugated goat anti-rabbit IgG and color development with 3,3',5,5'-tetramethylbenzidine. Samples on lanes 2, 4, 6, 7 and 9 were treated with N-glycosidase-F after immunoprecipitation. On the right is the molecular weight of a protein standard in kilodaltons. On the left are the migrations of sH2a before or after deglycosylation.

sH2a is present in human serum, we subjected samples of normal human sera to immunoprecipitation with anti-H2a carboxyterminal antibody, treatment with N-glycosidase-F, SDS-PAGE and western blotting with the same antibody (Figure 1, lanes 6, 7 and 9). We detected a band of about 28 kDa, similar in size to the one observed for sH2a in media from HepG2 cells (Figure 1, lane 4). Media from a control cell line that does not express sH2a (NIH 3T3 cells) showed no signal. Without the N-glycosidase-F treatment a disperse band of glycosylated sH2a of about 40 kDa is seen (lanes 3, 5 and 8), which probably represents heterogeneously glycosylated species. We also analyzed for the presence of ASGPR H1 in normal human serum and none was detected (data not shown).

Production of recombinant sH2a and development of an enzyme-linked immunosorbent assay to quantify the serum levels of sH2a

We produced a recombinant 6xHis-tagged sH2a (Figure 2A and B), which allowed us to estimate the level of sH2a in serum. sH2a contained in a sample of normal human serum was compared with recombinant sH2a by immunoprecipitation followed by immunoblot, giving an estimated sH2a concentration of 148 ± 22 ng/mL of serum (Figure 2C and D).

For comparative analysis of the concentration of sH2a in serum we developed a new specific mouse monoclonal anti-peptide H2a antibody. The B9 hybridoma produced a monoclonal antibody that recognized specifically sH2a secreted from transfected NIH 3T3 cells (2-18 cell line) or present in human serum (Figure 3A). The B9 antibody was used to develop an ELISA assay based on the binding of this antibody to its peptide. The binding could be competed by 81% after preincubation of the antibody with a solution containing 0.5 μg/mL of the same peptide, but not of a control peptide (Figure 3B). The bind-

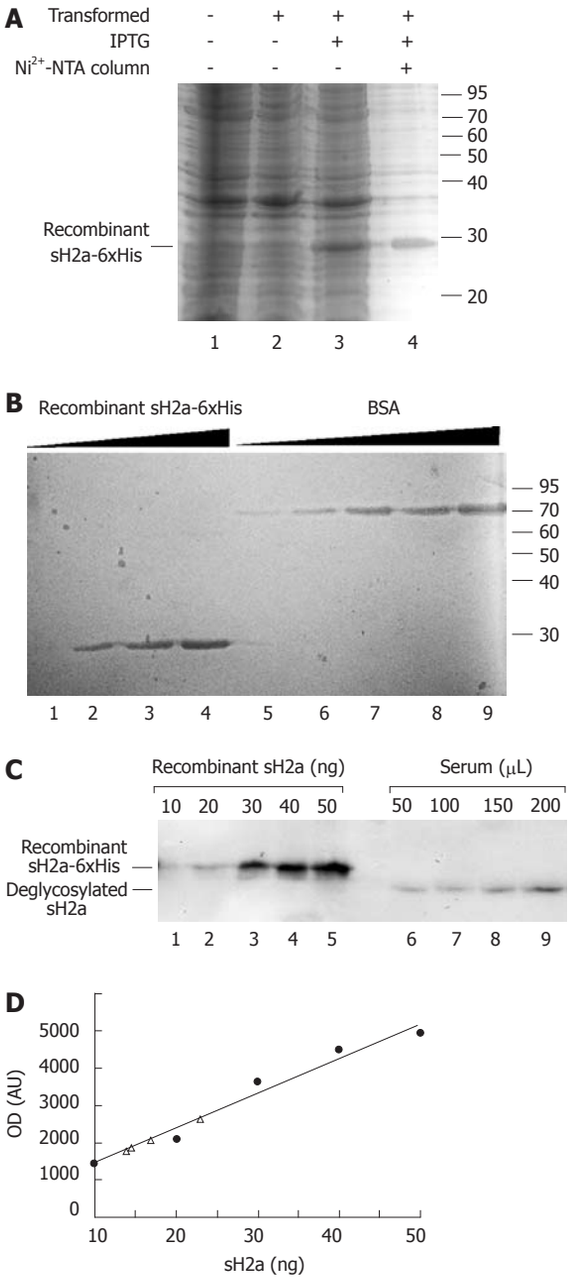

Figure 2 Recombinant sH2a concentration in serum. A: *Escherichia coli* Rosetta DE3 pLysS were either left untransformed or transformed by heat shock with a plasmid carrying 6xHis-tagged sH2a and induced with 0.3 mmol isopropyl β-D-1-thiogalactopyranosid as explained in Materials and Methods. Cell lysates were treated with 6 mol guanidinium-hydrochloride, dyalized and run on 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), comparing with an aliquot of tagged sH2a purified on a Ni2+-NTA-agarose column (lane 4). The gel was stained with imperial blue; B: Increasing amounts of recombinant affinity purified 6xHis-tagged sH2a (lanes 1-4 correspond to 127, 635, 1270 and 1905 ng) were compared with increasing amounts of bovine serum albumin (lanes 5-9 are 100, 200, 500, 1000 and 2000 ng) on 12% SDS-PAGE, stained with Imperial blue; C and D: The indicated increasing concentrations of recombinant 6xHis-tagged sH2a were run on SDS-PAGE after immunoprecipitation with B9 antibody (lanes 1-5) and compared with B9-immunoprecipitates from increasing volumes of normal human serum treated with N-glycosidase-F (lanes 6-9) and analyzed by immunoblot as in Figure 1, except that detection was done using the electrochemiluminescence procedure. The immunoblot was quantified and the graph (D) shows a curve of recombinant sH2a (full circles) and extrapolation of the concentration of sH2a in 50, 100, 150 and 200 μL of serum (triangles). Shown is an immunoblot representative of three repeat experiments.

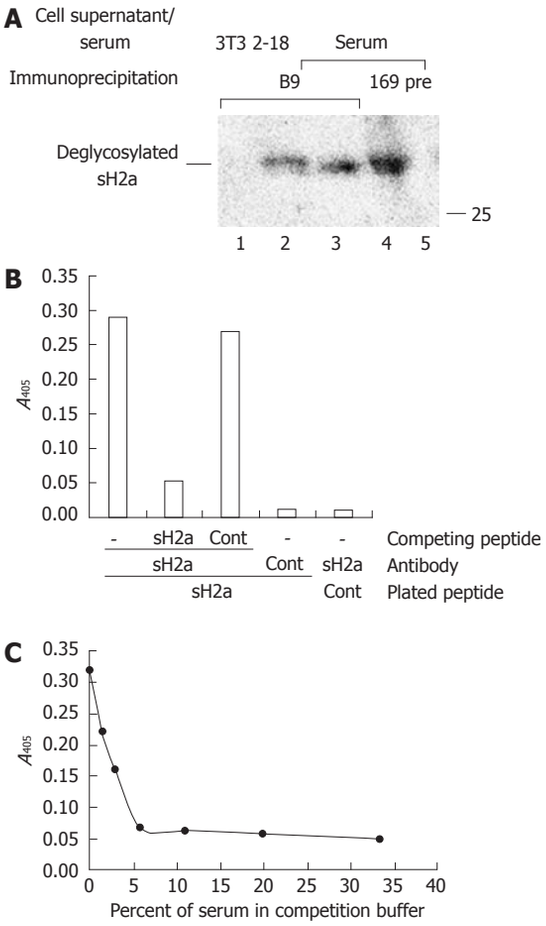

Figure 3 Monoclonal antibody and enzyme-linked immunosorbent assay for detection of sH2a in human sera. A: Medium from two 90 mm dishes of control NIH 3T3 cells (lane 1) or of the same cells stably expressing sH2a (2-18 cell line, lane 2) or 0.5 mL of normal human serum (lanes 3-5) were immunoprecipitated with B9 monoclonal antibody (lanes 1-3), or with a mixture of polyclonal anti-H2a 169 and anti-carboxyterminal antibodies (lane 4) or with control preimmune rabbit serum (lane 5). All immunoprecipitates were treated with N-glycosidase-F and analyzed as in Figure 2C. Shown is an immunoblot representative of three repeat experiments; B: Competitive enzyme-linked immunosorbent assay (ELISA) was performed as described in Materials and Methods, binding the anti-sH2a monoclonal B9 antibody (sH2a) or a control antibody (cont) to the specific sH2a or control (cont) peptides plated on a 96 well plate, after competition with the same sH2a or control peptides (0.5 μg/mL). Values are averages of quadruplicates; C: A similar ELISA assay was done with the B9 antibody and plating the sH2a peptide, but competing the antibody with different dilutions of human serum from a healthy individual (indicated as percent serum of the total volume).

ing could also be competed in a concentration-dependent manner by preincubation of the antibody with normal human serum; a 1:32 dilution of serum resulted in 50% reduction in the binding (Figure 3C).

Serum levels of sH2a in healthy individuals and in hepatitis C patients with cirrhosis

Using the ELISA assay described above we analyzed samples of serum obtained from 62 healthy individuals, with both male and female individuals with a wide range of ages. The levels of sH2a were very constant, 147 ± 19 ng/mL, giving a median of 146.5, with an interquartile range of 137-158 ng/mL (Figure 4A).

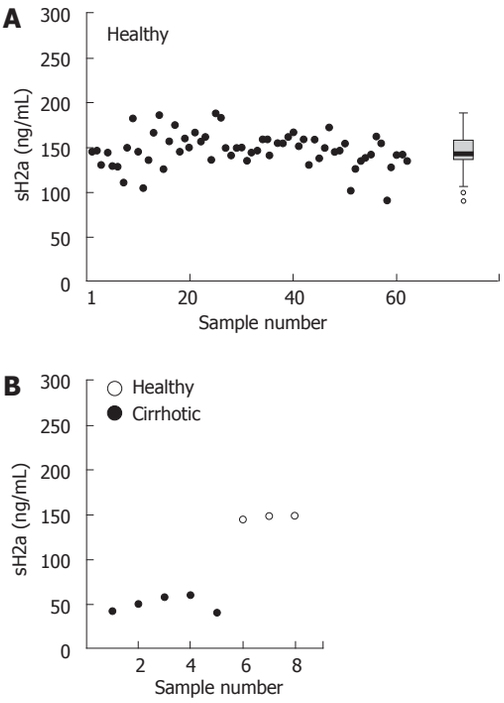

Figure 4 Levels of sH2a in healthy individuals and in hepatitis C virus patients with cirrhosis. A: The enzyme-linked immunosorbent assay (ELISA) described in Figure 3 was used to measure the concentration of sH2a in 62 healthy individuals, male and female, with a wide range of ages. The box height indicates the interquartile range (IQR). The thick horizontal bar is the median. The whiskers extend to the farthest non-outlier value smaller than 1.5 x IQR. Empty circles indicate "mild" outliers (< 3 x IQR); B: The concentration of sH2a in sera was measured blindly by ELISA, from 5 hepatitis C virus patients with cirrhosis compared to 3 healthy individuals.

We then analyzed sH2a levels blindly in sera from a group that included 3 healthy subjects and 5 hepatitis C patients with cirrhosis, as determined by biopsy. All patients had a very low level of sH2a, 50 ± 9 ng/mL, about a third of that in the healthy individuals (Figure 4B).

DISCUSSION

Our results show for the first time the presence of ASGPR sH2a in human serum, with surprisingly constant levels in healthy individuals and a striking decrease in cirrhosis. Although the number of samples from cirrhotic patients that were available to us is very small, the fact that in healthy individuals sH2a is so constant and in all patients analyzed it is dramatically reduced suggests that this might be a general phenomenon.

Hepatocytes are targets for most insults to the liver, including hepatitis viruses and alcohol[11]. The damage caused abrogates the function of the hepatocytes and leads to a fibrogenic process that further impairs liver function and develops to cirrhosis[12,13]. In this context we suggest that sH2a, secreted to constant levels in healthy individuals, is a marker of liver function, correlating to the mass of functional hepatocytes. Reduction of the levels of sH2a could reflect early events in the fibrogenic process, affecting hepatocyte function.

Release of soluble ASGPR fragments to human se-

rum had been described previously[14,15]. These fragments were recognized by polyclonal anti-ASGPR antibodies or by a mixture of monoclonal ones, for which it was not elucidated if they detect H1, H2a or H2b. They probably recognize mainly the H1 subunit (the most abundant) after release from damaged hepatocytes. Indeed it was shown in mice that ASGPR H1 subunit is released increasingly upon hepatocyte damage[16]. This is different from the case of sH2a, which arises from an mRNA that is made specifically for the production of a constitutively secreted protein, the levels of which are reduced by impaired function of the hepatocytes that secrete it. Because of the presence and constancy of sH2a in serum of healthy individuals, it is probably not a favored antigen for autoantibodies that appear in autoimmune hepatitis against the membrane ASGPR, which were found to recognize mainly the H1 subunit[17,18].

The levels of sH2a in serum are reduced in a manner that resembles the reduction in hepatocyte membrane ASGPR in cirrhosis[6,7]. Therefore, sH2a could have a potential for noninvasive diagnosis of liver disease.

ACKNOWLEDGMENTS

We would like to thank Shimon Reif for help in the writing of the Helsinki protocol.

COMMENTS

Background

A specific and sensitive non-invasive indicator of liver function has long been sought after, as the classical markers like albumin levels and prothrombin time can reveal only severe liver disease. The asialoglycoprotein receptor is specifically expressed in the liver and sH2a is a soluble secreted form.

Research frontiers

Several proposed experimental markers or combinations of routine tests are being evaluated, to measure the degree of liver fibrosis in the pathway to cirrhosis. Some of these markers are already commercially available. Nevertheless, the gold standard continues to be the invasive and risky procedure of biopsy.

Innovations and breakthroughs

This study describes for the first time that sH2a is present in human serum. The levels of sH2a were found to be surprisingly constant in a healthy group and dramatically reduced in liver cirrhosis.

Applications

SH2a could be a potential non-invasive diagnostic reporter that reflects the functional mass of the major liver cell type, the hepatocytes.

Terminology

The asialoglycoprotein receptor serves in the clearance of asialoglycoproteins from the plasma. Asialoglycoproteins derive from many glycoproteins in circulation (hormones, growth factors, *etc.*) that at some point have lost the terminal sialic acids in their glycans, by the action of sialidases. Cirrhosis is the end stage of liver disease caused by a wide range of factors like infectious hepatitis, alcoholism, obesity, *etc.*

Peer review

The authors present an important step in the potential development of more sensitive and accurate non-invasive markers to assess functional liver mass.

Abstract

AIM: To evaluate the clinical parameters and identify a better method of predicting pathological complete response (pCR).

METHODS: We enrolled 249 patients from a database of 544 consecutive rectal cancer patients who underwent surgical resection after preoperative chemoradiation therapy (PCRT). A retrospective review of morphological characteristics was then performed to collect data regarding rectal examination findings. A scoring model to predict pCR was then created. To validate the ability of the scoring model to predict complete regression.

RESULTS: Seventy patients (12.9%) achieved a pCR. A multivariate analysis found that pre-CRT movability (P = 0.024), post-CRT size (P = 0.018), post-CRT morphology (P = 0.023), and gross change (P = 0.009) were independent predictors of pCR. The accuracy of the scoring model was 76.8% for predicting pCR with the threshold set at 4.5. In the validation set, the accuracy was 86.7%.

CONCLUSION: Gross changes and morphological findings are important predictors of pathological response. Accordingly, PCRT response is best predicted by a combination of clinical, laboratory and metabolic information.

INTRODUCTION

The treatment strategy of rectal cancer has substantially changed in recent decades. Historically, postoperative

chemoradiation was considered to be the first-line therapy for stage Ⅱ and Ⅲ rectal cancers[1,2]; however, preoperative chemoradiation therapy (PCRT) is now considered to be the optimal therapy regimen for locally advanced distal rectal cancer due to its improved local control, reduced toxicity, and increased rate of sphincter preservation[3-6].

Notably, most evidence suggests that patient response to PCRT is largely variable, as pathological complete response (pCR) occurs in approximately 15% to 30% of all individuals who are treated with PCRT[7,8]. As an outcome measure, the rate of pCR is significant at multiple levels: it not only represents a surrogate endpoint for comparisons of treatment regimen efficacy, but it also may affect the actual course of treatment. Furthermore, pCR has been associated with improved local control, increased recurrence-free survival rates, and better sphincter preservation[9-14]. A study by Habr-Gama *et al*[15] has reported excellent long-term results in the non-operative treatment of patients with clinical evidence of complete response after PCRT. Nevertheless, even though surgery is recommended after PCRT regardless of tumor response, the ability to predict an individual's chance of achieving pCR before commencing therapy would probably enable a more tailored treatment plan[16,17].

To date, although the abilities of many techniques to predict treatment response after PCRT have been evaluated, including endorectal ultrasound (ERUS), computed tomography (CT), ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) and magnetic resonance imaging (MRI), no single modality has been proven to be efficacious, and while several molecular markers, including epidermal growth factor expression, have been associated with PCRT response[18,19], the current data are not definitive enough to support the clinical use of any of these biomarkers.

Accordingly, to identify a better method of predicting pCR, this study evaluated several clinical parameters that have previously been shown to influence pCR.

MATERIALS AND METHODS

Patients

Of the 3194 consecutive patients who underwent surgical resection for rectal cancer at the Samsung Medical Center, Korea between October 1998 and May 2009, 544 underwent surgical resection after PCRT. For this study, the inclusion criteria included: (1) histologically confirmed rectal adenocarcinoma; (2) tumors located within 10 cm of the anal verge; (3) locally advanced (cT3-4 or N1) tumors; (4) curatively resected tumors; and (5) no evidence of distant metastatic disease. Additionally, individuals were excluded according to the following criteria: (1) history of any other malignancy or hereditary colon cancer syndrome; (2) history of rectal cancer requiring emergency surgery; and (3) multiple missing data points in the database or an inability to evaluate pathological tumor response.

Of the initial 544 patients with rectal cancer who underwent PCRT, 70 (12.9%) patients achieved a complete pathological response, whereas the remaining 474 did not. Of these 474 patients, 295 patients were excluded from the study for the following reasons: the presence of another malignancy (one patient); a history of hereditary colon cancer syndrome (three patients); transanal local excision including transanal endoscopic microsurgery (nine patients); a lack of sufficient clinical information in the database (14 patients); and an inability to evaluate tumor regression grade (TRG) after repeated pathological examinations (268 patients). Thus, 249 individuals with rectal cancer were included in the present study; all of whom had undergone PCRT and curative surgery.

Treatment

All of the subjects underwent PCRT. Radiation therapy was administered using a three-field technique within 6-wk periods, delivering 40.4-50.4 Gy. Chemotherapy was also initiated on the first day of pelvic radiotherapy and was delivered concurrently using two chemotherapeutic regimens: (1) 5-fluorouracil (500 mg/m^2 per day) for 3 d during the first and last weeks of radiotherapy; and (2) oral capecitabine (825 mg/m^2) given twice daily during radiotherapy without weekend breaks. The median interval between PCRT and surgery was 55 d (range: 26-120 d).

All of the subjects also underwent radical surgery, including total mesorectal excision, high vascular ligation and *en bloc* resection of any adjacent involved organ after complete PCRT. The operative techniques that were employed in this study included abdominal perineal resection and low anterior resection with colorectal or coloanal anastomosis.

Evaluation

Before PCRT, clinical staging was determined by CT, MRI and/or endorectal ultrasound. Clinical restaging was then conducted 6 wk after the completion of PCRT *via* CT, MRI and ^{18}F-FDG-PET/CT using the protocols described in our previous study[20]. Therapeutic responses with ^{18}F-FDG-PET/CT were evaluated *via* the maximal standard uptake value (SUV). In 66 patients, the SUV could not be evaluated, either because ^{18}F-FDG-PET/CT was not ordered (50 patients) or was performed at a different hospital (16 patients).

After radical surgery, the final tumor pathological staging was evaluated by experienced pathologists. Tumors were classified according to the TNM grading system, 6th edition. Responses to treatment were evaluated according to the TRG, as described by Mandard *et al*[21]. Specifically, the TRG classification system was defined as follows: grade 0, no regression; grade 1, dominant tumor mass with obvious fibrosis and/or vasculopathy (minimal regression); grade 2, dominant fibrotic changes with few tumor cells or groups (moderate regression); grade 3, very few tumor cells in the fibrotic tissue with or without mucous (near total regression); grade 4, no observed tumor cells with only fibrotic masses or acellular mucin pools present (complete regression).

We evaluated several variables to estimate the relationship between gross findings and tumor response. Prior to PCRT (pre-CRT) tumor location, the movability, size, morphology and involved bowel circumference were recorded. Next, after the PCRT (post-CRT), the tumor size and morphology were reassessed at a follow-up hospital visit 6 wk after completion of PCRT. The involved bowel circumference was subdivided into "encircling" and "unidirectional" categories by digital rectal examination (DRE), wherein encircling was defined as occupying more than half of the lumen. Tumor movability was also subcategorized into "movable," "tethered," and "fixed." The pre-CRT tumor size was assessed using DRE in combination with any available colonoscopic or radiologic imaging results. The post-CRT tumor size was measured according to the pathological tumor or scar size. The tumor morphology was classified as being either "benign-like" or "malignant-like" in shape. By definition, benign-like shapes were observed to only consist of scar tissue, discolored lesions, erosions and shallow ulcers, whereas, in malignant-like shapes, infiltrative, fungating and ulcerofungating lesions were present. Pre-CRT tumor morphology was assessed using DRE and colonoscopic results. The resected specimens were used to classify the post-CRT morphology. Gross changes were determined to be present if malignant-like specimens had transitioned into benign-like specimens after PCRT.

Statistical analysis

All statistical analyses were performed using either the χ^2 or Fisher's exact test in addition to logistic regression modeling. Significant differences were defined as $P < 0.05$. To predict complete regression, we used scoring models with parameters that revealed statistical significance, wherein scoring model performance was assessed by receiver operating characteristic (ROC) curve plots for risk scoring and area under the curve (AUC) estimation. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for each variable were calculated.

Validation

An independent sample set of patients with primary rectal cancer who underwent PCRT was used to evaluate the performance of the scoring model in predicting complete regression. For this validation, 15 patients were enrolled between May 2009 and July 2009. Scores from this preliminary analysis were tested for sensitivity, specificity, PPV and NPV.

RESULTS

Patient demographics

The demographics of the included patients are described in Table 1. In total, 177 men (71.1%) and 72 women (22.9%) were enrolled with a median age of 55 years (range: 24-81 years). Of these individuals, 210 presented with T3 grade tumors, whereas 39 had T4 grade disease. The demographics of subjects who were enrolled in the separate validation set are also described in Table 1.

Treatment response

After PCRT, the following pathological tumor staging distribution was observed: ypT0, n = 74 (including ypTis in four patients); ypT1, n = 11; ypT2, n = 51; ypT3, n = 105; and ypT4, n = 8. At this point in time, 189 patients were found to be node-negative, whereas 60 patients were node-positive, as per the pathological N staging criteria (including ypT0N1 in three patients). TRG grading was as follows: grade 0 in two patients, grade 1 in 49, grade 2 in 86, grade 3 in 42, and grade 4 in 70.

Clinicopathological factors predicting pathological tumor response

The pre-CRT size (P = 0.001), pre-CRT movability (P < 0.001), pre-CRT carcinoembryonic antigen (CEA) (P = 0.021), ycT (P < 0.001), ycN (P < 0.001), post-CRT size (P < 0.001), post-CRT morphology (P = 0.004), gross change (P < 0.001), and post-CRT SUV (P < 0.001) were all identified to be univariate predictors of complete regression (Table 2). Multivariate predictors for complete regression included pre-CRT movability (P = 0.024), post-CRT size (P = 0.018), post-CRT morphology (P = 0.023) and gross change (P = 0.009). The data from pre-CRT CEA and post-CRT SUV were incomplete, therefore, we did not include these variables in the multivariate analysis (Table 3).

Prediction of complete regression

Scoring models were established to predict pCR using pre-CRT CEA and post-CRT SUV, which identified four statistically significant variables: pre-CRT movability, post-CRT tumor size, post-CRT morphology, and gross change. Each parameter was scored as either 0 or 1 according to

each criterion. Although the pre-CRT CEA and post-CRT SUV were not included in the multivariate analyses, they were included in the risk score calculation, due to their assumed clinical importance. The scoring model was calculated by summing these six scores, defining the minimum scoring model as 0 and the maximum as 6 (Table 4). Next, a risk score was calculated for each subject, given

that no missing data points existed for that selected risk factor. After excluding for the 98 subjects for whom ^{18}F-FDG-PET/CT and pre-CRT CEA were not measured, scoring was performed in a total of 151 individuals. The AUC of the scoring model was 80.5%, suggesting that this was a reasonable predictor of complete regression (Figure 1). When the cutoff point was set at 4.5, the sensitivity and specificity rates for predicting complete regression were 64.5% and 80%, respectively, with a PPV of 45.5%, an NPV of 89.7% and an accuracy of 76.8% (Table 5).

Validation of risk score

The ROC curve for the risk score performance that was obtained from the validation set had an AUC = 0.875, which can be seen in Figure 1. These results indicate that this scoring model performed well in an independent sample. Using a cutoff point of 4.5, the prediction of complete regression had a sensitivity of 75%, specificity of 90%, PPV of 75%, NPV of 90.91%, and accuracy of 86.7%.

DISCUSSION

Even though the response to PCRT is believed to be important in predicting prognosis and treatment strategy decisions, no reliable technique has been shown to predict accurately pCR after PCRT, and only limited data exist for each modality[22]. Various imaging modalities, including ERUS, CT, MRI and PET, have been evaluated in terms of their ability to predict the response to treat-

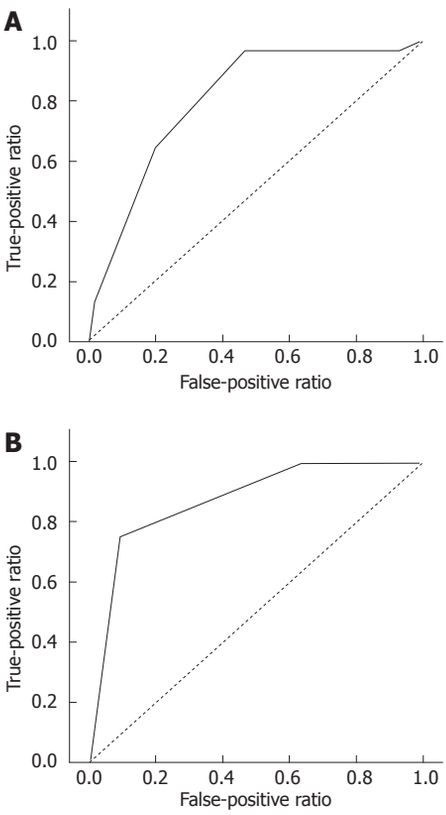

Figure 1 Area under the receiver operating characteristic curve. A: Risk score in the test set was 80.5%, suggesting it was a reasonable predictor of complete regression ($P < 0.001$, 95% confidence interval = 0.723-0.886, $n = 151$); B: In the validation set, risk score was 87.5%. ($P < 0.031$, 95% confidence interval = 0.672-1.078, $n = 151$).

ment after PCRT. Recent studies have reported a limited accuracy for ERUS (48%-72%)[23,24], and the accuracy of CT and MRI in assessing the depth of tumor infiltration after PCRT has also been shown to be limited at approximately 50%[25].

Our retrospective analysis evaluated the influence of certain pretreatment parameters on pCR after PCRT, and identified an accurate method for predicting pCR. Specifically, we hypothesized that a combination of clinical, laboratory and metabolic information would best predict pCR. Particular attention was given to gross changes and morphological evaluations by surgeons or other clinicians. These data were then classified and analyzed to verify the predictive value of radiosensitivity. Previously, some reports have indicated that gross assessments by DRE had a low PPV for assessing complete response. In one retrospective review of 488 rectal cancer patients who underwent PCRT and subsequently were followed by clinical re-evaluation (DRE and sigmoidoscopic examination under anesthesia), the clinical CR rate was 19%, with only 25% of the subjects achieving pCR (10%)[26]. In another study from Guillem and colleagues, DRE was found to underestimate the response of rectal cancer to PCRT[27]. Furthermore, other evidence indicates that DRE is not a reliable technique for distinguishing between post-radiation fibrosis and residual cancer[28]. To date, the majority

Table 5 Predicting score accuracy

Measure of accuracy	Cut off value, 4.5	
	n	%
Sensitivity	20/31	64.5
Specificity	96/120	80
Positive predictive value	30/44	45.5
Negative predictive value	96/107	89.7

of studies have evaluated the efficacy of DRE as a single modality for predicting pCR through predictive value calculations. Although we concluded that DRE alone may be able to distinguish pCR, we hypothesized that the supplementation of DRE with other clinical findings would increase the accuracy of pCR predictions.

A German study has definitively shown that FDG-PET metabolic imaging is superior to CT and MRI morphological imaging in predicting response to PCRT[29]. In this particular study, the therapeutic response was evaluated through comparisons of FDG-PET imaging that was conducted pre- and post-treatment with the SUV, resulting in a sensitivity of 100% and a specificity of 60% (the PPV and NPV were 77% and 100%, respectively). Notably, another study has reported the overall accuracy of FDG-PET to be 60%, although imaging was only performed after PCRT[20]. The primary limitation of FDG-PET in predicting tumor response is the relatively low specificity, therefore, it is viewed as somewhat risky to base treatment decisions on FDG-PET exclusively. Furthermore, to achieve the best predictive rates for CR with FDG-PET, imaging must be performed twice.

To improve the accuracy of pCR predictions, we designed a scoring model using important clinical and gross parameters. The pre-CRT CEA and post-CRT SUV were identified to be significant in a univariate analysis in our study, therefore, in addition to prior reports that these variables affect pCR, we included these parameters in the scoring model[8,22,29]. In fact, the scoring model facilitated the identification of four statistically significant variables in the multivariate analysis, including pre-CRT movability, post-CRT size, post-CRT morphology and gross change, and the AUC of the scoring model was 76.5% in the test set. After the pre-CRT CEA and post-CRT SUV were added to the scoring model, the accuracy of the pCR prediction increased (AUC of the risk score was 80.5%). In addition, these parameters are objective, easily applied, and already widely used. In this respect, we included the pre-CRT CEA and post-CRT SUV in the scoring model, although these parameters were not revealed to be significant in the multivariate analysis.

After the data analysis, our scoring model was found to be significantly correlated with pCR in both the test and validation sets. At a cutoff point of 4.5, the overall accuracy of our scoring model was 76.8% for predicting pCR in the test set; however, the accuracy of the model in predicting pCR decreased to 62.85% in the test set when ^{18}F-FDG-PET/CT (post-CRT SUV) was the only variable used. This secondary finding suggests that the

predictive ability of the scoring model probably requires both ^{18}F-FDG-PET/CT and DRE or colonoscopy morphological assessments. Furthermore, when compared with the aforementioned German study that evaluated the predictive ability of FDG-PET, our model had a superior specificity, a similar NPV, and an inferior sensitivity and PPV[29]; however, although our scoring model only used the post-CRT SUV, the German FDG-PET study required pre- and post-treatment SUV measurements. Moreover, the accuracy of our model was substantially improved in the validation set, suggesting that the ability to predict CR can be improved by combining clinical and radiological findings, including metabolic information obtained through DRE, colonoscopy and ^{18}F-FDG-PET/CT.

Our study had some limitations that warrant discussion. First, our results may have been affected by external bias, because the investigation was not prospective. Specifically, although all data were mined from a prospective database that adopted clear definitions for gross changes, the actual classification of gross change could easily be affected by surgeons' subjective determinations. Second, the exclusion of some individuals could have resulted in a sampling bias, although our model was vetted by a separate validation set. Despite these drawbacks, our model had significant value because it allowed clinicians to predict accurately pCR without performing any additional examinations.

In conclusion, our results indicate that gross tumor change and other associated morphological findings may represent important predictors for pathological tumor response, wherein both clinical parameters are easily estimated *via* physical examination. Moreover, because our scoring model includes both gross findings and clinical variables, we contend that PCRT response is best predicted by a combination of clinical, laboratory and metabolic findings.

COMMENTS

Background

Pathological complete response (pCR) has been associated with improved oncologic outcome. Although surgery is recommended after preoperative chemoradiation therapy (PCRT), regardless of tumor response, the ability to predict an individual's chance of achieving pCR before commencing therapy would probably allow for a more tailored treatment.

Research frontiers

Although it is important to predict therapeutic responses, there is no reliable technique to accurately predict pCR after PCRT. This study demonstrates that a combination of clinical, laboratory and metabolic information would best predict pCR.

Innovations and breakthroughs

Recent reports have highlighted the importance of tailored treatment in rectal cancer, including "wait and watch" after chemoradiation. In this study, the authors designed a scoring model using clinical and gross parameters for predicting pCR. The developed scoring model was found to be significantly predictive in both test and validation sets.

Applications

This study demonstrates that gross tumor changes and other associated morphological findings may represent important predictors of pathological tumor responses with both clinical parameters being easily estimated *via* physical examination.

Peer review

The study aimed to evaluate a number of clinical parameters and identify a method of predicting pCR after CRT in patients with advanced rectal cancer. It is an interesting study, meticulously carried out and reported.

Abstract

AIM: To explore mutations around the interferon sensitivity-determining region (ISDR) which are associated with the resistance of hepatitis C virus 1b (HCV-1b) to interferon-α treatment.

METHODS: Thirty-seven HCV-1b samples were obtained from Hong Kong patients who had completed the combined interferon-α/ribavirin treatment for more than one year with available response data. Nineteen of them were sustained virological responders, while 18 were non-responders. The amino acid sequences of the extended ISDR (eISDR) covering 64 amino acids upstream and 67 amino acids downstream from the previously reported ISDR were analyzed.

RESULTS: One amino acid variation (I2268V, $P = 0.023$) was significantly correlated with treatment outcome in this pilot study with a limited number of patients, while two amino acid variations (R2260H, $P = 0.05$ and S2278T, $P = 0.05$) were weakly associated with treatment outcome. The extent of amino acid variations within the ISDR or eISDR was not correlated with treatment outcome as previously reported.

CONCLUSION: Three amino acid mutations near but outside of ISDR may associate with interferon treatment resistance of HCV-1b patients in Hong Kong.

Key words: Hepatitis C virus 1b; Extended interferon sensitivity-determining region; Interferon-α; Resistance; Hong Kong; Mutation

Zhou XM, Chan PKS, Tam JS. Mutations around interferon sensitivity-determining region: A pilot resistance report of hepatitis C virus 1b in a Hong Kong population. *World J Gastroenterol* 2011; 17(48): 5317-5323 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i48/5317.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i48.5317

INTRODUCTION

The interferon (IFN)-α/ribavirin combination treatment for hepatitis C virus (HCV) can achieve a sustained virological response rate of 20%-50%. The effectiveness of the combination treatment is partly correlated with HCV genotypes[1]. HCV genotype 6a shows a more favorable response with a sustained virological response rate around 50%-70%[2,3], while HCV genotype 1 is hard to be treated with a low sustained virological response

rate between 20% and 40%[4]. Pegylated (PEG)-IFN-α can improve the sustained virological response. But HCV genotype 1 is still more difficult to treat than other HCV genotypes, i.e., 2 and 3 by PEG-IFN-α[4,5].

The interferon sensitivity-determine region (ISDR, amino acid position 2209-2248, refers to HCV-J, GenBank accession no: D90208) for HCV 1b was previously identified to be associated with resistance to IFN-α-based treatment[6,7]. However, this observation was not reproducible in the studies in Europe, China and United States[8-12]. The host genetic background may be one of the reasons accounting for the discrepancies[13]. Furthermore, isolates of HCV 1b circulated in Japan may have substantial genetic difference compared with those circulating in Europe or United States[14]. The genetic difference of virus strains may be another reason for the discrepancies[15].

Several functional domains were identified within NS5A encoding region[16]. One of them can bind to Protein Kinase-R (PKR)[17,18]. This domain encloses the entire ISDR, with additional 26 amino acids extended downstream. PKR can be activated by IFN-α, then phosphorylates elongation-initiation-factor-2, which is an essential component of cellular protein translation complex, resulting in stopping the synthesis of intracellular proteins[19]. When NS5A binds to PKR, the synthesis of proteins will be restored, then the replication of HCV within host cells can be rescued[18]. This hypothesis suggests that the PKR binding domain is still a good candidate to look for variations that are associated with outcomes of IFN-α-based treatment[20].

No study on the IFN resistance-associated mutation in HCV-1b has yet been carried out in the Hong Kong population[21]. Although result from this population may conform to other geographic regions, HCV-1b strains circulated in Hong Kong had a more conservative genomic pattern than its counterpart in any other regions due to its specific geographic location and political history. Thus we carried out this study to explore amino acid variations within extended ISDR (eISDR) associated with the IFN-α/ribavirin combination treatment[22].

MATERIALS AND METHODS

Ethics

This work was conducted in accordance with the Declaration of Helsinki (2000) of the World Medical Association. Recruited patients all submitted written consent to take part in the study. The study was approved by the local Joint Chinese University of Hong Kong-New Territories East Cluster Clinical Research Ethics Committee (ref. CRE-2006.405).

Study population

Samples were collected from Hong Kong patients between 1998 and 2004. Their HCV genotypes were determined by the type-primer-specific reverse transcription-polymerase chain reaction (RT-PCR) genotyping method as described before.

All patients included in this study were previously naive to HCV treatment. After HCV-1b genotyping determination, they received 5 million international units IFN-α three times per week and ribavirin (1000 mg for those weighing less than 75 kg and 1200 mg for those weighing more than 75 kg) for one year. If HCV-6a genotyping was determined, they would receive a short-term treatment for 6 mo. The HCV RNA load was measured once every six months during treatment and then every year after the completion of treatment. Patients with HCV RNA detected in the serum six months after treatment were defined as non-response/resistant (NR). Patients with negative HCV RNA results for at least one year after treatment were defined as having sustained virological response (SVR).

Altogether 19 NR and 18 SVR patients with determined endpoint of treatment were recruited in this pilot study. These patients had no recorded history of injecting drug use or liver transplantation.

Polymerase chain reaction primers for extended interferon sensitivity-determining region

The eISDR within HCV 1b genome starts from amino acid loci 2145 to 2315 (refers to HCV-J, GenBank accession no: D90208). This region extends 64 amino acids upstream and 67 amino acids downstream to the ISDR (2209-2248 in HCV-J). With the downstream extension, this eISDR includes the entire PKR-binding domain.

This region was amplified by a nested RT-PCR reaction. Primers used were: outer forward primer (NS5A-1b-1F): 5'-TGGATGGAGTGCGGTTGCACAGGTA-3'; outer reverse primer (NS5A-1b-1R): 5'-TCT TTC TCC GTG GAG GTG GTA TTG G-3'; inner forward primer (NS5A-1b-2F): 5'-TGTAAAACGACGGCCAGTCAGGTACGCTCCGGCGTGCA-3'; inner reverse primer (NS5A-1b-2R): 5'-CAGGAAACAGCTATGACCGGGGCCTTGGTAGGTGGCAA-3'. The underlined inner-primer sequences represent the M13 sequencing primers.

Amplification of extended interferon sensitivity-determining region

HCV RNA was extracted from each serum sample using the High Pure Viral Nucleic Acid Kit (Roche Diagnostics GmbH, Mannheim, Germany) following the manufacturer's protocol. Five microliters of viral RNA were used in a final 50-μL single-tube single-step RT-PCR reaction using SuperScript™ One-Step RT-PCR system with Platinum® *Taq* kit (Invitrogen, Life Technologies, Carlsbad, CA). Cycling conditions were: reverse transcription at 50 ℃ for 30 min, 94 ℃ for 2 min followed by 30 cycles of denaturation at 94 ℃ for 1 min, annealing at 55 ℃ for 1 min, extension at 68 ℃ for 1 min. Second round nested PCR reactions were carried out using 1 μL of the first round RT-PCR product as template and using HotStar *Taq* polymerase (Qiagen, Hilden, Germany) in a final 50-μL reaction with 1 × Q-solution. The HotStar *Taq* polymerase was used at a working concentration of 5 U

per 50-μL reaction. Cycling conditions were: 95 ℃ for 15 min to activate the HotStar *Taq* polymerase followed by 30 cycles of denaturation at 95 ℃ for 1 min, annealing at 55 ℃ for 1 min, extension at 72 ℃ for 1 min, and a final extension cycle at 72 ℃ for 5 min.

Sequencing for extended interferon sensitivity-determining region

The 609-bp PCR amplicons were purified from agarose gel using the GFX™ PCR DNA and Gel Band Purification kit (Amersham Bioscience UK limited, Little Chalfont, United Kingdom), and directly used for BigDye® Terminator v3.1 Cycle Sequencing reaction (Applied Biosystems, Foster City, CA). The nucleotide sequences were translated to amino acid sequences following the right open-reading-frame. All the sequences were deposited into GenBank.

Alignment of amino acid sequences

The amino acid sequences were aligned by the multiple-alignment algorithm under Clustal-X (version 1.83) using a protein weight matrix of BLOSUM 62.

Calculation of amino acid variations

Consensus amino acid sequences were deduced from all the eISDR sequences. The number of amino acids that were different between each query sequence and the consensus eISDR sequence was added up as the degree of amino acid variations for this query sequence in the eISDR (1b-VAR2). The number of amino acids that were different within the ISDR was added up as the degree of amino acid variations for this query sequence in the ISDR (1b-VAR1).

Statistical analysis

The difference in patient age between the IFN-NR group and the IFN-SVR group was assessed by two-tailed Student's *t* test. The sex distribution between patients of the IFN-NR group and the IFN-SVR group was assessed by two-tailed Fisher's exact test (mid-*P* approach). The association of the amino acid variations within eISDR with treatment outcomes was evaluated by two-tailed Fisher's exact test. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS 11.1.0, SPSS Inc., Chicago, IL) and Two-by-two (http://www.med. uio.no/imb/stat/two-by-two/manual.html) for two-tailed Fisher's exact test.

RESULTS

Patient information

The mean age of the 37 patients was 48.4 years (SD = 9.3 years, range 28-67 years). There was no significant difference in age between the IFN-NR and the IFN-SVR patients (47.9 years *vs* 49.0 years, $P = 0.73$). There was no significant difference in sex distribution between the IFN-NR (male/female: 11/7) and the IFN-SVR (male/female: 11/8) patients ($P = 1.00$).

Analysis of interferon sensitivity-determining region and extended interferon sensitivity-determining region

The sequence differences between the IFN-SVR and the IFN-NR patient groups are illustrated in Figure 1. Amino acid variations were found distributed over 56 different loci. Six loci, at which more variations existed between the two groups, were examined by two-tailed Fisher's exact test (Table 1). One amino acid variation (I2268V, $P = 0.023$) was significantly correlated with the treatment outcome, while the two amino acid variations (R2260H, $P = 0.05$ and S2278T, $P = 0.05$) were weakly associated with treatment outcomes.

Prediction of interferon treatment outcomes by individual variation

Prediction of the treatment outcome by I2268V has a specificity of 100%, but a low sensitivity of 22.2%. Prediction by R2260H or by S2278T has a sensitivity of 100%, but a low specificity 21.1%.

Association of treatment outcome with degree of amino acid variations within interferon sensitivity-determining region or extended interferon sensitivity-determining region

Previous studies have suggested that the degree of amino acid variations within the ISDR was associated with resistance to IFN-α treatment. We examined the correlation between the number of amino acid variations within the ISDR and the eISDR and the treatment outcome. A consensus resistant amino acid sequence was deduced from the conserved sequence of the IFN-NR group. This sequence has one amino acid different from reference strain HCV-J within the ISDR and seven amino acids within the entire eISDR. The degree of amino acid variations within the ISDR (1b-VAR1) and the eISDR (1b-VAR2) was calculated and compared. 1b-VAR1 ranged from 0 to 9 and 1b-VAR2 ranged from 1 to 24, both showing no correlation with the treatment outcome ($P = 0.958$, $P = 0.563$) with a previously defined cutoff of four amino acid variations.

DISCUSSION

In this pilot study with a limited number of cases, amino acid variations in three loci within the eISDR but outside the ISDR were identified to be possibly correlated with the resistance to the IFN-α/ribavirin combination treatment. R2260H ($P = 0.05$) and I2268V ($P = 0.023$) were located within PKR-binding domain[23,24]. S2278T ($P = 0.05$) was located within a hyperphosphorylation signal motif "PPALP"[25]. All these three loci were located within the putative NS5A transcriptional activation domain[16].

Based on these preliminary results, R2260H and I2268V suggested that PKR binding ability of NS5A may still play a major role in determining the IFN-α resistance of HCV-1b[20]. S2278T may imply that modification of the NS5A protein, which eventually alters the interaction of NS5A with other proteins like PKR, can contribute to the resistance to treatment[26,27].

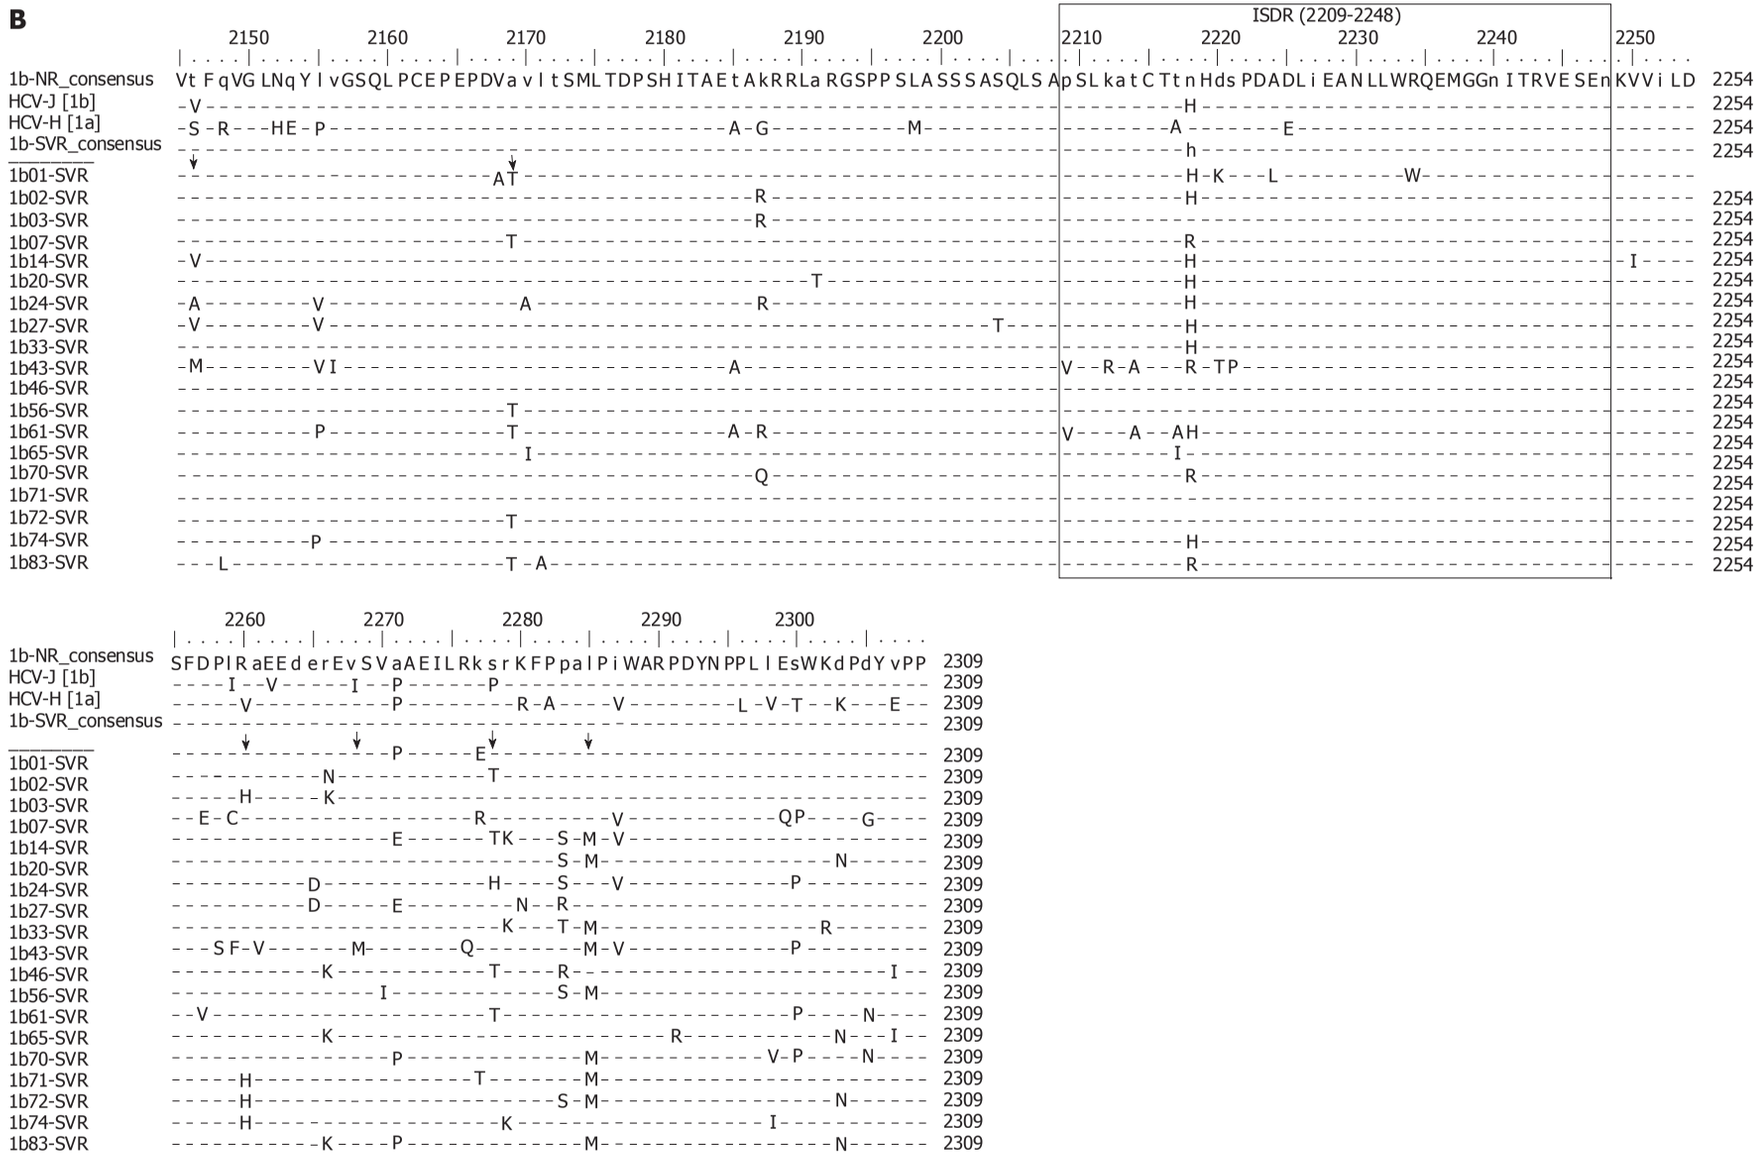

Figure 1 Amino acid variations within the extended interferon sensitivity-determining region for interferon-non-response group (A) and interferon-sustained virological response group (B). In the line of "1b-NR_consensus", capital letters denote the conserved amino acids for all sequences while lower-case letters denote the most frequent amino acid in that position. In other lines, letters denote amino acids different from IFN-NR (non-response) consensus sequence, while "-" means the same amino acid as in IFN-NR consensus sequence. Suffix "NR" follows the hepatitis C virus (HCV) strains which were resistant to IFN-α treatment. Suffix "SVR (sustained virological response)" follows the HCV strains which responded to IFN-α treatment. The previously defined interferon sensitivity-determining region was labeled by a square-line box. Arrows indicate the loci where amino acid variations were potentially associated with outcomes of IFN-α treatment and were examined in this study.

Table 1 Amino acid variations within extended interferon sensitivity-determining region of hepatitis C virus 1b

Locus	Amino acid variations		mid-*P*	Prediction	
	IFN-NR (*n* = 18)	IFN-SVR (*n* = 19)		Sensitivity (%)	Specificity (%)
2146	T (10/18, 55.6%)	T (15/19, 78.9%)	0.085		
	V (4/18, 22.2%)	V (2/19, 10.5%)	0.20		
	A (4/18, 22.2%)	A (1/19, 5.3%)	0.09		
		M (1/19, 5.3%)	-		
2169	A (16/18, 88.9%)	A (13/19, 68.9%)	0.12		
	T (2/18, 11.1%)	T (6/19, 31.6%)	0.12		
2260	R (18/18, 100%)	R (15/19, 78.9%)	0.05

	P (1/18, 5.6%)	H (1/19, 5.3%)	-		
2285	L (14/18, 77.8%)	L (10/19, 52.6%)	0.085		
	M (4/18, 22.2%)	M(9/19, 47.4%)	0.085		

Locus position refers to the amino acid position in hepatitis C virus-J. *P* values were calculated by two-tailed Fisher's exact test (mid-P). "-" in the column of "*P*" means no *P* value calculated for this rare amino acid in that position. Sensitivity and specificity were calculated for the amino acid variations associated with treatment outcome. IFN: Interferon; NR: Non-response; SVR: Sustained virological response.

This trans-activating activity of the NS5A transcriptional activation domain was identified in an *in vitro* GAL4 system, and had not been demonstrated *in vivo*[28,29]. Some studies have shown that this NS5A trans-activating activity can stimulate the expression of IL8, an antagonist of IFN-α *in vivo*[30]. Whether the variations in these three loci can affect the expression of IL8 remains to be studied.

In contrast to previous reports, no correlation was found in the current study between the degree of amino acid variations within the ISDR or eISDR and IFN-α resistance of HCV-1b.

The association of IFN-α resistance and the amino acid variations was different from the reports from Europe and United States[15]. Previous reports did not find any amino acid variations within the ISDR that were correlated with treatment resistance. This difference may be due to the concurrent circulation of multiple subtypes of HCV-1b. The similarities between HCV-1b strains in Europe or United States were 90.3%, while in Hong Kong were 94.3% in average. Thus, HCV-1b strains distributed in Europe or United states were more diversified than those in Hong Kong. The convergency of HCV-1b population in Hong Kong introduces less genomic confounding factor. This may lead to different observations among studies involving a small number of samples.

Therefore, an expanded study is needed to further clarify the observations acquired from the Hong Kong population.

The association can be further ascertained in future studies by a larger group of registered HCV-1b patients, for those patients infected with IFN-resistant type of HCV-1b would be pursuable to abandon IFN treatment as early as possible. Alternative treatment, i.e., traditional Chinese medicine may be used instead, which may improve patient living status without the side-effects caused by IFN simultaneously. For the patients infected with IFN-sensitive type of HCV-1b, less IFN dosage should be administered to achieve the same efficiency of treatment.

COMMENTS

Background

Currently, an interferon-α (IFN-α) based regimen is the most effective and widely accepted therapy for hepatitis C virus (HCV) infections. When combined with ribavirin, IFN-α typically can achieve a 20% to 50% sustained virological response (SVR) in HCV-infected patients. The effect of HCV sequence variation in response to therapy is less clear.

Research frontiers

The association of a region of 40 amino acids in length within HCV 1b genome, termed as the interferon sensitivity-determining region (ISDR). However, similar studies performed with cohorts of American, European and Chinese patients reached discrepancy results. This discrepancy may resulted from high divergence of HCV 1b strains distributed worldwide.

Innovations and breakthroughs

The authors had early found that mutations within eISDR but outside of ISDR are in association with interferon treatment failure for HCV genotype 6a. This exploration were carried out in scope of full genomewide analysis. Thus, the authors explored mutations within eISDR in HCV-1b patients from Hong Kong, wish to reach a relative firmly report.

Applications

The study results suggest that we also can predict the prognosis of interferon treatment to HCV-1b patients. Interferon dosage can be regulated based on HCV-1b sequences, so reach to a balance between treatment effectiveness and tolerance of the side-effect of this drug.

Terminology

ISDR: Interferon sensitive-determine region, located within HCV NS5A. HCV NS5A had been firmly demonstrated that it can interact with various signal proteins induced by interferon. The relation of NS5A with interferon resistance were firmly established in HCV patients. But certain mutations had not ever been determined for predicting the prognosis of interferon treatment.

Peer review

This is a good study in which authors analyze the association of mutations within eISDR of HCV-1b with the resistance of treatment by IFN-α in Hong Kong. The results are interesting and suggest that three mutations may associated with treatment success/failure. These mutations could be used for predicting prognosis before the start of treatment. Thus, prescription of IFN-α may be improved for future treatments to HCV-1b patients.

Abstract

Ischemic colitis can mimic a carcinoma on computed tomographic (CT) imaging or endoscopic examination. A coexisting colonic carcinoma or another potentially obstructing lesion has also been described in 20% of the cases of ischemic colitis. CT scan can differentiate it from colon cancer in 75% of cases. However, colonoscopy is the preferred method for diagnosing ischemic colitis as it allows for direct visualization with tissue sampling. Varied presentations of ischemic colitis have been described as an ulcerated or submucosal mass or as a narrowed segment of colon with ulcerated mucosa on colonoscopy. Awareness and early recognition of such varied presentations of a common condition is necessary to differentiate from a colonic carcinoma, and to avoid unnecessary surgery and related complications.

Key words: Colon pathology; Colitis; Ischemic pathology; Colonic neoplasms/diagnosis; Differential Diagnosis; Biopsy; X-Ray computed tomography

INTRODUCTION

Ischemic colitis is the most common cause of ischemic injury in the colon with an estimated incidence of 4.5-44 cases per 100 000 person-years[1]. This commonly presents with moderately severe, crampy abdominal pain, mostly localized to the left lower quadrant, sometimes associated with diarrhea or rectal bleeding[2]. Rarely, ischemic colitis can mimic a carcinoma on computed tomographic (CT) imaging or endoscopic examination. This case report highlights this rare presentation along with a practical approach to the management based on a review of literature.

CASE REPORT

A 92 year old man presented to the hospital with complaints of fatigue, past medical history significant for hypertension and congestive heart failure. Physical examination revealed an irregularly irregular pulse with electrocardiogram demonstrating atrial fibrillation with rapid ventricular rate. He was started on a therapeutic dosage of low molecular weight heparin, however had five episodes of bright red blood per rectum the next day requiring transfusion of 2 units of blood with mild abdominal pain. He had no prior history of weight loss, loss of appetite, change in bowel habits or gastrointestinal bleeding. Physical exam at this time revealed stable vital signs with an unremarkable abdominal exam and bright red blood

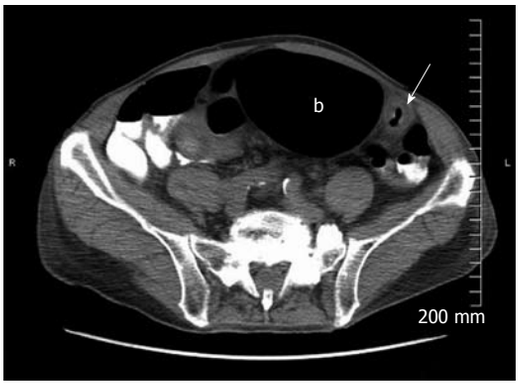

Figure 1 Computed tomography of the abdomen demonstrating circumferential thickening of a long segment of the distal colon (marked with white arrow) with a proximal dilated segment (marked with "b" inside the lumen of the dilated segment).

Figure 2 Colonoscopy image demonstrating friable mass occupying up to half the circumference of the splenic flexure.

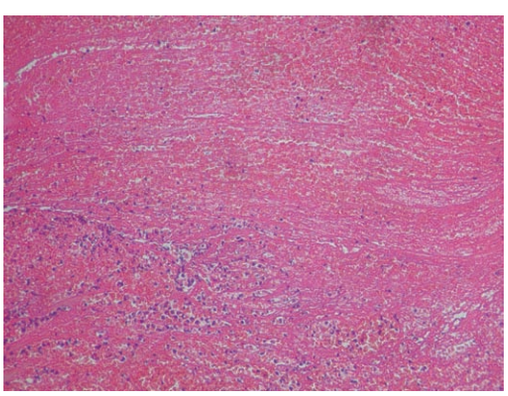

Figure 3 Hematoxylin and eosin high power microscopic image demonstrating acute colitis with marked fibrinopurulent exudates.

on the gloved finger on rectal examination. Laboratory tests revealed a normal white blood count and hemoglobin of 10.3 mg/dL with a normocytic normochromic peripheral blood smear. CT revealed circumferential thickening of a long segment of the distal colon with a proximal dilated segment suggestive of a stricture or a malignancy (Figure 1). He then underwent a colonoscopy which demonstrated a friable mass occupying up to half the circumference of the splenic flexure (Figure 2). Biopsy of the mass demonstrated acute colitis with marked fibrinopurulent exudates, consistent with acute ischemic colitis (Figure 3). He was treated with a regimen of bowel rest, intravenous fluids, and antibiotics, recovered completely and was discharged home.

DISCUSSION

Acute onset bleeding after anticoagulation originates from the colon in 25% of cases, commonly from polyps, diverticular disease, vascular malformations or cancer[3]. Rectal bleeding as a presentation of ischemic colitis is usually mild, not requiring transfusion[4]. CT scan is usually not performed for the diagnosis of ischemic colitis and can differentiate it from colon cancer in 75% of cases based on length and thickness of the thickened colonic segment, enhancement of the segment and the presence of target or double halo sign[5]. Colonoscopy or sigmoidoscopy is the preferred method for diagnosing ischemic colitis as it allows for direct visualization with tissue sampling[6]. However colonoscopy is preferred over sigmoidoscopy as lesions are found proximal to the sigmoid colon in 50% of cases except in the setting of aortic surgery where it is limited to the distal colon. Biopsies demonstrate vascular congestion, submucosal hemorrhage, interstitial edema, inflammatory infiltration, loss of superficial cells, and intravascular platelet thrombi. Acute ischemia is suggested by hyalinization of the lamina propria, full-thickness mucosal necrosis, the presence of atrophic microcrypts, and hemorrhage in the lamina propria whereas hemosiderin deposition, along with transmural fibrosis and mucosal atrophy, is a pathognomonic of a chronic phase of the ischemic colitis[7]. Colonoscopy demonstrates edematous, hemorrhagic, hyperemic or necrotic colonic mucosa in the acute phase, and strictures, or loss of haustrations in the chronic phase.

In 20% of the cases of ischemic colitis, a coexisting colonic carcinoma or another potentially obstructing lesion has been described[8]. In these cases the lesion is distal in location and separated from it by a variable segment of normal colon. The mechanism may involve an increased intra-colonic pressure proximal to the lesion with decreased colonic blood flow. Previous case reports[9-13] have described varied presentations of ischemic colitis as an ulcerated or submucosal mass or as a narrowed segment of colon with ulcerated mucosa on colonoscopy. The objective of our case report is to create awareness and early recognition of such varied presentations of a common condition in order to differentiate from a colonic carcinoma, avoid unnecessary surgery and related complications.

Treatment of mild cases involves bowel rest and parenteral fluids with antibiotics to cover usual bowel flora. Ischemic colitis involving the right side of the colon occurs in 23% of cases and these patients more often need surgical intervention[14]. Complications include bowel gangrene, ulcerations, strictures, and fulminant colitis. It has been suggested that in the rare scenario where colo-

noscopy also suggests a neoplasm with biopsy specimens negative for a tumor, repeating imaging and colonoscopy studies 7-10 d later may identify the evolving nature of the acute ischemic lesion and obviate the need for surgery.

Abstract

We agree that the covered self-expanding metal stents (SEMSs) fare better than the uncovered stents as recurrent dysphagia due to tumor ingrowth is common with uncovered stent. Recent American College of Gastroenterology Practice Guideline on the Role of Esophageal Stents in Benign and Malignant Diseases concludes that SEMSs cannot be routinely recommended in conjunction with chemo-radiation. The comparison of ultraflex and choostent in the Italian study found no difference in the palliation of dysphagia, rate of complications and survival rate.

Key word: Self-expanding metallic esophageal stents; Dysphagia; Esophageal stents

TO THE EDITOR

We read with interest the article "Covered nitinol stents for the treatment of esophageal stricture and leaks" by Bona *et al*[1] in the May 14, 2010 issue of *World Journal of Gastroenterology*. We agree that covered self-expanding metal stents (SEMSs) fare better than uncovered stents as recurrent dysphagia due to tumor ingrowth is common with uncovered stent[2]. Partially covered SEMSs are superior to uncovered SEMSs in the palliation of dysphagia due to unresectable esophageal tumor[3].

Although the study discussed the positive role of temporary stent placement in patients undergoing neoadjuvant therapy, recent American College of Gastroenterology Practice Guideline on the Role of Esophageal Stents in Benign and Malignant Disease concludes that SEMSs cannot be routinely recommended in conjunction with chemo-radiation[4]. The data on use of SEMSs for gastroesophageal junction cancers with concomitant radiation are retrospective, discordant and limited[5,6].

The self-expanding plastic stents are preferable over SEMSs as temporary stent insertion in case of anastomotic complications or post-radiotherapeutic stricture because the option of retrieval is better, there is limited local tissue reaction and is of lower costs[7].

SEMSs are useful in patients with poor functional status who cannot tolerate chemotherapy or radiotherapy, who have advanced metastatic disease or in whom previous therapy has failed[8]. This data was lacking in the study, and it would have given a better way to compare ultraflex and choostent.

Bona *et al*[9] in their study of comparison of ultraflex and choostent found no difference in the palliation of dysphagia, rate of complications and survival rates. Both stents were safely removable in short term follow-up. The benefit of temporary insertion of both types of stents was documented in patients with esophageal carcinoma prior to chemotherapy or chemoradiotherapy and in those with anastomotic strictures or leaks. The ideal timing for metallic stent removal is not well defined and varies from

2 wk to 4 mo. However, it is safe to remove within 2 mo after stent placement[10].

So, further studies are required before firm recommendation regarding the choostent can be made.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.
