ABOUT COVER De Iudicibus S, Franca R, Martelossi S, Ventura A, Decorti G. Molecular mechanism of glucocorticoid resistance in inflammatory bowel disease.
World J Gastroenterol 2011; 17(9): 1095-1108
<http://www.wjgnet.com/1007-9327/full/v17/i9/1095.htm>

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Ascites remain the commonest complication of decompensated cirrhosis. Spontaneous bacterial peritonitis (SBP) is defined as the infection of ascitic fluid (AF) in the absence of a contiguous source of infection and/or an intra-abdominal inflammatory focus. An AF polymorphonuclear (PMN) leucocyte count $\geq 250/\text{mm}^3$ -irrespective of the AF culture result- is universally accepted nowadays as the best surrogate marker for diagnosing SBP. Frequently the results of the manual or automated PMN count do not reach the hands of the responsible medical personnel in a timely manner. However, this is a crucial step in SBP management. Since 2000, 26 studies (most of them published as full papers) have checked the validity of using leucocyte esterase reagent strips (LERS) in SBP diagnosis. LERS appear to have low sensitivity for SBP, some LERS types more than others. On the other hand, though, LERS have consistently given a high negative predictive value ($> 95\%$ in the majority of the studies) and this supports the use of LERS as a preliminary screening tool for SBP diagnosis. Finally, an AF-tailored dipstick has been developed. Within the proper setting, it is set to become the mainstream process for handling AF samples.

INTRODUCTION

Ascites remains the commonest of the three major complications of advanced or decompensated cirrhosis (along with hepatic encephalopathy and variceal haemorrhage). Cirrhotics with ascites have, over a one-year period, 10% probability of developing the first episode of spontaneous bacterial peritonitis (SBP)^[1]. Conn first introduced the term SBP, publishing his clinical findings just one year after Kerr *et al* described (in 1963) 11 cases of seemingly unexplained infection of the ascitic fluid (AF)^[2].

SBP is defined as the infection of AF in the absence of a contiguous source of infection and/or an intra-abdominal (and potentially surgically treated) inflammatory focus. Depending on the patient population examined (outpatients or hospitalised), the prevalence of SBP varies from 3.5% and 30%^[3]. Around 50% of SBP episodes are present at the time of hospital admission, whilst the remainder are acquired during the hospitalisation period^[2]. The mortality of untreated SBP remains high ($> 80\%$), and a satisfactory patient course and clinical outcome is based on an aggressive approach aiming to rapid diagnosis and prompt initiation of antibiotic therapy.

DIAGNOSIS OF SBP

The clinical manifestations of SBP can be subtle and in-

sidious, and its diagnosis requires a high index of clinical suspicion. Abdominal paracentesis is considered necessary for all patients with ascites on hospital admission, in-patient cirrhotics with ascites who develop clinical signs of sepsis, hepatic encephalopathy, (sudden or unexplained) renal impairment and/or all cirrhotics who develop GI bleeding^[4]. Unfortunately, a clinical diagnosis of infected AF without a paracentesis is not adequate^[1].

An AF polymorphonuclear (PMN) leukocyte count $\geq 250/\text{mm}^3$, irrespective of the AF culture result, is universally accepted nowadays as the best surrogate marker for diagnosing SBP^[5]. The presence of positive AF cultures is confirmatory, but by no means a necessary prerequisite for instigation of antibiotic therapy. In fact, it is considered a “fatal” mistake to wait 48 h for culture results before initiating therapy, where it is indicated.

Frequently the results of the manual PMN count do not reach the hands of the responsible medical personnel in a timely manner^[6]. Such situations include busy night or weekend shifts, small hospitals with off-site laboratory facilities, or units with limited case-load and liver disease expertise. We have recently showed that the mean delay from paracentesis to a validated PMN result out-of-hours was more than 4 h^[7]. Furthermore, manual AF PMN counting is laborious and costly. The use of automated cell counters has now been backed-up by sufficient published evidence to become the common practice^[5,8].

However, even automated cell counts suffer generally from similar constraints to those described above for manual techniques. Therefore, any alternative test that may provide or, more importantly, exclude a diagnosis of SBP at the bedside and reduce the “tap-to-first shot” time is considered welcome. The leukocyte esterase reagent strips (LERS), commonly used in every day practice for the rapid diagnosis of urinary tract infections (UTIs), were certainly featuring as a promising candidate.

LERS IN SBP

LERS had already been successfully evaluated in the diagnosis of infection in other sterile body fluids i.e. synovial, pleural, cerebrospinal fluid and peritoneal dialysate^[9-11]. The LERS test is based on the esterase activity of the leucocytes. A pyrrole, esterified with an amino-acid is used as the substrate; hydrolysis of the ester (mediated by the esterase) releases the pyrrole which in turn reacts with a diazonium salt yielding a violet or purple azo dye in the relevant pad of the strip^[11]. LERS are not specific for PMNs and the interpretation of the colorimetric reaction is inherently subjective, therefore the method is considered qualitative or semi-quantitative at best. Butani *et al*^[12] were the first to present their results on the use of LERS in SBP diagnosis as an abstract in DDW 2000.

Since then, 26 publications followed (23 as full, peer-reviewed papers and 3 as either an abstract or a letter to Editor; of them, 22 are in English, 2 in French, 1 in Chinese & 1 in Korean), with the first full paper that of Vanbiervliet *et al*^[13] validating the Multistix[®]8SG.

Their results were very encouraging. Thus, various

LERS were eventually validated in what were mostly single or two-centre studies (Table 1), with one notable exception in the French multicentre study (Nousbaum *et al*^[28], 70 centres) published initially as an abstract and later as a full paper in 2007. It is important to note here that the grading is different for each dipstick, and therefore the cut-off leucocyte count should be used instead, in order to draw meaningful conclusions.

The French multicentre study pointed out the weakness of Multistix[®]8SG and, to a certain extent, of the concept of using dipstick in SBP diagnosis overall. Furthermore, 2 systematic reviews^[9,10] have been published in 2008, both pointing out that the heterogeneity in the number of patients included in each study, the AF samples tested and SBP episodes observed, as well as in all measures of LERS performance, did not allow pooling of the results via meta-analysis. Overall, the Aution[®] and Combur[®] dipsticks have performed better^[38] (in regards to the negative predictive value) than the Multistix[®]. The spectrophotometric analyser Clinitek[®] 50, compatible with the Multistix[®] dipstick, was used in only 6 studies.

The rather intense research on the field has brought up important details on the limitations of LERS. First, the results seem to be influenced by the number of PMNs in the AF, LERS performing less well if the PMN count $< 1000/\mu\text{L}$ ^[39]. Second, all LERS validated in the SBP studies were initially designed for use in the diagnosis of UTIs; in infected urine though, both the number of leucocytes and the protein content are quite different, the first being significantly higher than in most SBP^[39], while the latter does not exceed the 1 g/L level^[35]. The above 2 factors are considered significant for the observed low sensitivity of some LERS. I need to mention again here that, aside the fact there is significant inter-study variability in terms of the LERS brands used, as well as to the cut-off level examined, LERS are not specific for PMNs and the interchangeable use of PMNs and leucocytes (seen in the majority of the studies) is confusing to the reader. Finally, LERS are not suitable for the few cases of chylous ascites or peritoneal tuberculosis.

On the other hand, LERS have consistently given a high negative predictive value (NPV) of above 95% in the majority of the studies and, as in SBP, a false positive result (which might eventually lead to the ‘adverse’ administration of a single dose of an overall well-tolerated antibiotic^[28]) is considered ethically and medically acceptable advocating the use of LERS as a preliminary screening tool for SBP diagnosis. In addition, Castelote *et al*^[33] only recently showed that LERS, despite their qualitative nature, could be well used in the clinical management of SBP. The low cost of the strips can only be considered a significant advantage.

Only one study has checked the combine use of the LERS with the relevant pad for nitrites. There was no additional advantage by combining the two results. Finally, despite clear evidence to support its use^[5], no study has validated the combination results of LER pad with that of the pH^[3].

CONCLUSION

In conclusion, there is reasonable amount of evidence

Table 1 Studies, patients included, ascitic fluid samples tested, inpatients/outpatients, type of leukocyte esterase reagent strips used, leukocyte esterase reagent strips cut-off grade of the study with Sens, Spec, PPV and NPV

Sens: Sensitivity; Spec: Specificity; PPV: Positive predictive value; NPV: Negative predictive value; LEERS: Leucocyte esterase reagent strips; SBP: Spontaneous bacterial peritonitis; n/s : Not stated; n/f : Not found; G : Grade (as per LEERS); In/out: Inpatients/outpatients; M/F : Male/female; s-group: subgroup

to support the use of LEERS in the work-up of patients suspected of having SBP. The PMN count (be it manual or automated) is not to be abolished from SBP diagnostic algorithm. Remote hospitals, less affluent health systems and busy junior clinicians should realise the benefit of LEERS and incorporate them in their AF handling routine. A “new kid on the block” has just appeared^[40] in the race against SBP; if further validation studies worldwide are supportive, it is set to become the mainstream process for handling AF samples^[41].

Abstract

Natural and synthetic glucocorticoids (GCs) are widely employed in a number of inflammatory, autoimmune and neoplastic diseases, and, despite the introduction of novel therapies, remain the first-line treatment for inducing remission in moderate to severe active Crohn's disease and ulcerative colitis. Despite their extensive therapeutic use and the proven effectiveness, considerable clinical evidence of wide inter-individual differences in GC efficacy among patients has been reported, in particular when these agents are used in inflammatory diseases. In recent years, a detailed knowledge of the GC mechanism of action and of the genetic variants affecting GC activity at the molecular level has arisen from several studies. GCs interact with their cytoplasmic receptor, and are able to repress inflammatory gene expression through several distinct mechanisms. The glucocorticoid receptor (GR) is therefore crucial for the effects of these agents: mutations in the GR gene (NR3C1, nuclear receptor subfamily 3, group C, member 1) are the primary cause of a rare, inherited form of GC resistance; in addition, several polymorphisms of this gene have been described and associated with GC response and toxicity.

However, the GR is not self-standing in the cell and the receptor-mediated functions are the result of a complex interplay of GR and many other cellular partners. The latter comprise several chaperonins of the large cooperative hetero-oligomeric complex that binds the hormone-free GR in the cytosol, and several factors involved in the transcriptional machinery and chromatin remodeling, that are critical for the hormonal control of target genes transcription in the nucleus. Furthermore, variants in the principal effectors of GCs (e.g. cytokines and their regulators) have also to be taken into account for a comprehensive evaluation of the variability in GC response. Polymorphisms in genes involved in the transport and/or metabolism of these hormones have also been suggested as other possible candidates of interest that could play a role in the observed inter-individual differences in efficacy and toxicity. The best-characterized example is the drug efflux pump P-glycoprotein, a membrane transporter that extrudes GCs from cells, thereby lowering their intracellular concentration. This protein is encoded by the ABCB1/MDR1 gene; this gene presents different known polymorphic sites that can influence its expression and function. This editorial reviews the current knowledge on this topic and underlines the role of genetics in predicting GC clinical response. The ambitious goal of pharmacogenomic studies is to adapt therapies to a patient's specific genetic background, thus improving on efficacy and safety rates.

De Iudicibus S, Franca R, Martellosi S, Ventura A, Decorti G. Molecular mechanism of glucocorticoid resistance in inflammatory bowel disease. *World J Gastroenterol* 2011; 17(9): 1095-1108 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1095.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1095>

INTRODUCTION

Glucocorticoids (GCs) are a well-accepted therapy for inflammatory, autoimmune and proliferative diseases^[1-3]. Despite the large clinical use, the benefits of these agents are often narrowed by inter-individual variability. Indeed, some patients show a poor or absent response, and in these subjects, GCs have to be employed in high doses. The clinical use of these compounds is associated with a number of serious complications, including osteoporosis, metabolic disease and increased risk of cardiovascular disease^[4-6]; therefore, patients, and in particular those who respond poorly to these agents, are at high risk of side effects. In addition, besides being a problem for patients and a challenge to clinicians, inadequate GC therapy also represents a socio-economic matter because of the consequent considerable impact on health care costs^[7,8].

GCs are effective inhibitors of cytokine secretion and T-cell activation, and are consequently largely employed in different inflammatory conditions, including inflammatory bowel disease (IBD). In these diseases, GC resistance or dependence is particularly frequent. Clinical reports in pediatric IBD patients have shown that up to 90% of subjects have a rapid improvement of symptoms when prednisone is given^[9]. However, after 1 year, only 55% of early steroid-treated patients are still in remission and can be considered steroid-responsive. Around 38% of patients are not able to discontinue the therapy and experience an increase in disease activity when the dose is reduced (steroid-dependent); 7% of subjects are resistant and do not respond to GC therapy^[9,10]. Among the adult IBD population, a prospective analysis has described the 1-year outcome in patients with Crohn's disease (CD) treated with a first oral prednisolone course (40-60 mg/d) and tapering to a maintenance dose of 10-15 mg/d^[11]. In this study, prolonged steroid response was obtained in 44% of patients, 36% of subjects were steroid dependent and 20% steroid resistant, and a high frequency of surgery was reported within 1 mo after steroid treatment. Similar results have been obtained in a retrospective American study: immediate outcomes for CD and ulcerative colitis (UC) respectively, were complete remission in 58% and 54%, partial remission in 26% and 30%, resistance in 16% of patients^[12]. Outcome at 1 year showed a prolonged response in 32% of CD patients, GC dependence in 28%, and surgical intervention in 38%. In UC patients, 1-year outcomes were prolonged response in 49%, dependence in 22%, and surgery in 29% of subjects.

In 1999, a pivotal study by Hearing *et al.*^[13] demonstrated a poor *in vitro* response to GCs of circulating lymphocytes in UC patients who exhibited a reduced or absent clinical response to these agents. *In vitro* lymphocyte resistance to GCs has been demonstrated to correlate with clinical outcome in other inflammatory diseases such as asthma^[14], systemic lupus erythematosus^[15], rheumatoid arthritis^[16] and renal allograft rejection^[17]. A wide variation in lymphocyte steroid sensitivity is evident even in healthy individuals^[18]. This suggests that the observed variability is a stable intrinsic property of an individual that becomes important when the subject has to be treated with GCs for

an inflammatory disease^[19], and is therefore likely to have a genetic basis.

Over the past years, significant advances have been made in understanding the molecular mechanisms by which GCs act and the basis of such inter-patient variability. This editorial describes the mechanisms of GC anti-inflammatory action and discusses the molecular and genetic basis for GC resistance in chronic inflammatory diseases, especially IBD.

MOLECULAR MECHANISM OF GC ACTION

Due to their high lipophilicity, exogenous GCs are widely bioavailable; these agents, as well as the endogenous compound cortisol, are transported in the blood predominantly bound to the corticosteroid-binding globulin and, to a lesser extent, to albumin^[20]. Free GCs are able to diffuse passively across plasma membranes and interact specifically with a cytosolic receptor (GR), expressed in virtually all tissues. The GC receptor is a member of the nuclear receptor (NR) superfamily, which includes receptors for steroid hormones (e.g. corticosteroids, androgens, estrogens and progesterone), as well as other hydrophobic molecules (such as bile acids, vitamins A and D, retinoic acid and thyroid hormones). All these molecules induce their actions by the same molecular mechanism: at the basis of this mechanism stands the physical interaction between the lipophilic ligand and its own cytosolic/nuclear receptor that, in turn, activates a multistep signal transduction pathway to end up in specific genomic transcriptional effects^[21]. Receptors belonging to the NR superfamily are highly homologous to each other and share structural features with a common modular domain organization: they present a transactivation domain at the N-terminal part (NTD), a central zinc finger DNA-binding domain (DBD) and a ligand-specific binding domain (LBD) at the C terminus.

The ligand-free GR is not self-standing in the cell, but exists in heteromeric complex with molecular chaperones and co-chaperones. In the functionally mature form of the heterocomplex, the free GR is associated with an Hsp90 dimer, with p23 and with any of the Hsp90 co-chaperones, except Hsp70/Hsp90 organizing protein. Such associations are essential for keeping the receptor in the correct folding for a hormone-responsive state^[22]. Upon ligand binding, receptors undergo conformational changes and expose the DBD, which is otherwise hidden in the ligand-free conformation. Cytosolic receptors also provide nuclear localization signals (NLSs) that are comprised of a closely spaced arrangement of 5-8 basic amino acids^[23], which co-localize with DBD and, once exposed, interact with nuclear transport factors (importins).

Nuclear heterocomplex translocation is necessary for transactivating target genes. Translocation is a tightly regulated process that occurs through nuclear pore complexes in a ligand- and energy-dependent manner, and is mediated by specific nuclear transport factors that belong to the evolutionarily conserved importin β family of nuclear transporters^[23]. Among these, importin-13 (IPO13) has

Table 1 Factors involved in glucocorticoid resistance

| P-gp | Hyperexpression of P-gp in lymphocytes and epithelial cells from GC-resistant IBD patients ^[167] |

GR: Glucocorticoid receptor; GC: Glucocorticoid; Hsp: Heat-shock protein; Hop: Hsp70/Hsp90 organization protein; P-gp: P-glycoprotein; NR3C1: Nuclear receptor subfamily 3, group C, member 1; NALP1: NACHT leucine-rich-repeat protein 1; SNP: Single nucleotide polymorphism; TNF- α : Tumor necrosis factor α ; IL: Interleukin; ALL: Acute lymphoblastic leukemia; IBD: Inflammatory bowel disease.

been functionally characterized as a primary regulator of the translocation of the GC-bound GR across the nuclear membrane^[23].

The zinc finger motifs of the DBD allow the interaction of the activated receptor with specific DNA sequences, termed GC-responsive elements (GRE, 5'-GGTACAnnTGTTCT-3' where n refers to any nucleotide^[24]), located within regulatory regions of GC-responsive genes. GR homodimerizes on GRE and recruits transcriptional co-activators, as well as basal transcription machinery, to the transcription start site. These co-activators, that include CREB (cAMP response element-binding) binding protein (CBP), steroid receptor co-activator-1 (SRC-1), GR-interacting protein (GRP-1), p300 and switching/sucrose non fermenting chromatin remodeling complex (SWI/SNF)^[25], induce histone acetylation, thus allowing the transactivation of GC-responsive genes. Although some GC anti-inflammatory effects are achieved through induction of anti-inflammatory genes, such as interleukin (IL)-10, annexin 1 and the inhibitor of nuclear factor (NF)- κ B^[26,27], transactivation enhances mainly the expression of genes involved in metabolic processes^[28,29], and is therefore, responsible for the majority of unwanted side effects^[30,31].

Although positive GREs mediate transcriptional up-regulation in response to GCs, negative GREs (5'-ATYACnnTnTGATCn-3'^[32]) downregulate the transcription of responsive genes. Indeed, the presence of GR on GRE might competitively prevent the binding of activator protein (AP)-1 and NF- κ B on the same promoter regions or might transactivate their inhibitor proteins. Furthermore, GRE-independent mechanisms of transrepression also exist: the GR physically interacts with AP-1^[33], NF- κ B^[34] and signal transducers and activators of transcription^[35]. Transrepression is believed to be responsible for the majority of the beneficial anti-inflammatory effects of GCs^[30,36-38].

The molecular mechanisms of GC action are further complicated by the realization that these hormones can also induce rapid non-genomic effects within the cytoplasm; for example, they induce the release of Src kinase from the GR heterocomplex, which results in lipocortin activation and inhibition of arachidonic acid release^[39], and altered cytoplasmic ion content^[40].

MOLECULAR MECHANISM OF GC RESISTANCE IN IBD

The phenomenon of GC resistance in chronic inflammatory diseases is, as stated above, quite common, however the precise molecular mechanism is still unclear. First of all, it should be separated from the rare familial condition of primary generalized GC resistance, for which the name of Chrousos syndrome has been recently proposed^[41]. This is a rare, sporadic or familial syndrome caused by mutations in the nuclear receptor subfamily 3, group C, member 1 (NR3C1, Nuclear Receptor Nomenclature Committee, 1999) gene. The disease is characterized by target tissue insensitivity to GCs due to reduction or lack of functional GC receptors and by compensatory elevation in adrenocorticotrophic hormone (ACTH). This results in an increased secretion of cortisol, albeit in the absence of signs of Cushing syndrome, as well as of other adrenal hormones with mineralocorticoid and androgenic activities, which is responsible for the main symptoms (hypertension and signs of hyperandrogenism). As stated above, this syndrome is, however, extremely rare, and no cases in IBD patients have been described in the literature.

In consideration of the complexity of GC mechanisms of action (Figure 1), the most common forms of resistance observed in chronic inflammatory conditions, and in IBD in particular, may occur at several levels, and some candidate areas have been identified (Tables 1 and 2): (1) the GR receptor heterocomplex and proteins involved in nuclear translocation and transcription; (2) the pro-inflammatory mediators in the downstream signaling pathway of the GC-GR complex; and (3) P-glycoprotein (P-gp) and other proteins involved in the extrusion and metabolism of GCs.

The GR heterocomplex and proteins involved in nuclear translocation and transcription

The GR is an interesting candidate for GC resistance in IBD, and a significant lower expression of GR mRNA has been reported in the intestinal mucosa in patients with steroid-resistant UC^[42]; in addition, GC binding affinity in mononuclear cells is reduced in patients with GC resistant diseases^[43].

Table 2 Factors involved in glucocorticoid resistance in inflammatory bowel disease

| | |
|----------------------------|---|
| GR | Significantly lower expression of GR mRNA in the intestinal mucosa in patients with GC-resistant IBD ^[42] In colonic biopsies of UC patients, significantly more GRβ positive cells in the resistant group than in the GC sensitive control group ^[60] Significantly higher frequency of <i>BclI</i> polymorphism in GC-responsive IBD patients ^[61] |
| Pro-inflammatory mediators | TNF-α G-308A polymorphism significantly associated with steroid resistance and requirement for surgery ^[152] Association between this polymorphism and steroid dependency in a large population of CD patients ^[155] Higher probability of non-response to GCs in pediatric IBD patients carriers of the NALP1 variant genotype ^[72] |
| P-gp | Hyperexpression of P-gp in circulating lymphocytes and epithelial cells from patients with GC resistant IBD ^[167] Association between GC refractory CD and P-gp intronic polymorphisms ^[173] C3435T polymorphism in pediatric IBD Italian patients treated with GC not associated with response to therapy ^[152] |

GR: Glucocorticoid receptor; GC: Glucocorticoid; UC: Ulcerative colitis; IBD: Inflammatory bowel disease; TNF-α: Tumor necrosis factor α; NALP1: NACHT leucine-rich-repeat protein 1; P-gp: P-glycoprotein; CD: Crohn’s disease.

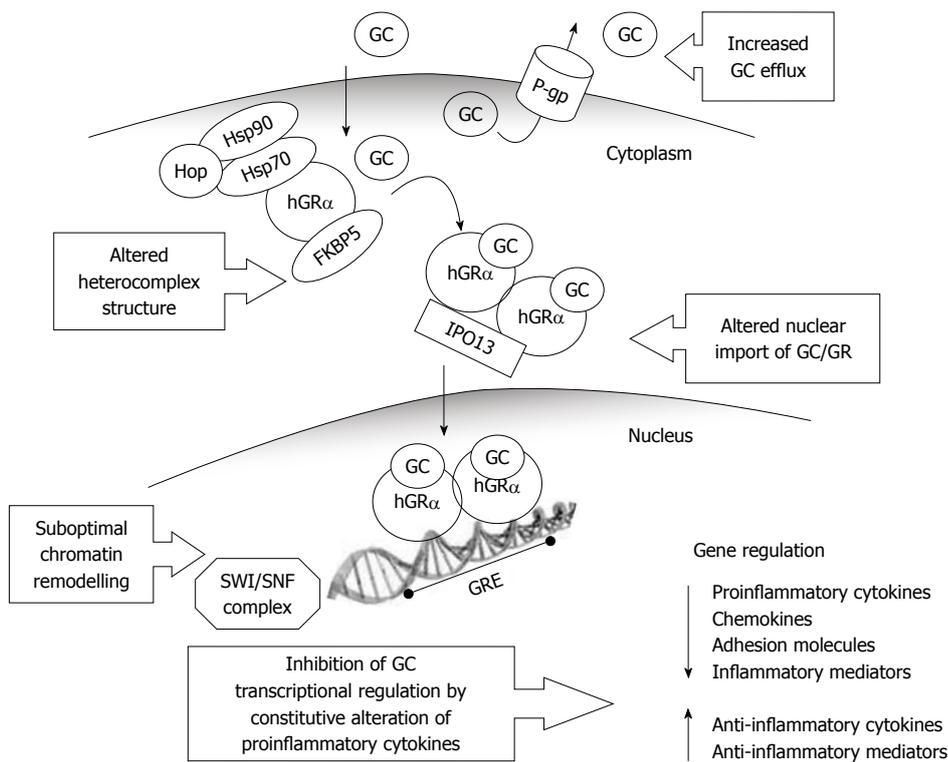

Figure 1 Mechanism of glucocorticoid resistance in inflammatory diseases. GR: Glucocorticoid receptor; GC: Glucocorticoid; FKBP5: FK506-binding protein 5; GRE: Glucocorticoid responsive elements; hGRα: Human glucocorticoid receptor α; Hsp: Heat-shock protein; Hop: Hsp70/Hsp90 organization protein; IPO13: Importin 13; P-gp: P-glycoprotein; SWI/SNF complex: Switching/sucrose non-fermenting chromatin remodeling complex.

GR: The human GR gene NR3C1 is located on chromosome 5q31.3 and includes nine exons^[44]. Polymorphisms, that is, variations in the DNA sequence with a frequency of more than 1% in the healthy population, of the human GR gene may impair the formation of the GC-GR complex and subsequently alter transactivation and/or transrepression processes.

A large number of polymorphisms in this gene have been described: according to the dbSNP build 130 database of National Center for Biotechnology Information (NCBI), 1152 entries are known at the moment, but only a few are functionally relevant. The *TtbIII* (rs10052957), ER22/23EK (rs6189/rs6190), N363S (rs6195), *BclI* (rs41423247) and GR-9β (rs6198) polymorphisms have been the most studied and have been associated with differences in metabolic parameters and body composition,

and with autoimmune and cardiovascular disease. These genetic variants have been also related with changes in GC sensitivity or altered cortisol level^[45] and may therefore account for the variability in the response to GC therapy.

Three polymorphisms are associated with a reduced sensitivity to endogenous and exogenous GCs.

TtbIII is a restriction fragment length polymorphism (RFLP) caused by a C>T change in the GR gene promoter region; it is located in a large intron of approximately 27 kb, 3807 bp upstream of the GR start site^[22]. The polymorphism has been associated with elevated diurnal cortisol levels^[46] and with a reduced cortisol response to 1 mg dexamethasone (DEX), as well as lower insulin and cholesterol levels^[47].

The ER22/23EK polymorphisms are located in the N-terminal transactivation domain of the GR and involve

two nucleotide changes in codon 22 and 23 of exon 2 (GAG AGG to GAA AAG), which are changing the amino acid sequence from glutamic acid-arginine (E-R) to glutamic acid-lysine (E-K). Since the polymorphism is located in the transactivation domain, the amino acid change might affect the tertiary structure of the receptor, which influences the transactivational and/or transrepressional activity on target genes^[48]. A relative GC resistance, with a reduction of GR transcriptional activity in transfected COS-1 cells and in peripheral blood mononuclear leukocytes of homozygous carriers, has been described^[49]. *In vivo*, an association with higher post-DEX cortisol levels as well as less cortisol suppression after a 1 mg DEX suppression test in ER22/23EK carriers, has also been shown. In addition, the polymorphism is associated with a better metabolic and cardiovascular health profile and an increased survival^[50,51].

The GR-9 β polymorphism is located in the 3'-untranslated region (UTR) of exon 9 β , where an ATTTA sequence is changed into GTTTA. This polymorphism was first characterized by Derijk *et al.*^[52] and functional studies have revealed a stabilizing effect on the mRNA of the GR β isoform, which leads to enhanced expression of the inactive GR β protein. GR β is one of several GR protein isoforms and is generated through an alternative splicing pathway that links further downstream sequences of exon 9, termed exon 9 β , to the end of exon 8. In contrast to the functionally active and most abundant isoform GR α ^[53], GR β is unable to bind ligand, is transcriptionally inactive, and exerts a dominant negative effect on transactivation by interfering with the binding of GR α to the DNA^[54-58]. Honda *et al.*^[59] have reported GR β -specific mRNA expression in lymphocytes of 83% of patients with steroid-resistant UC, compared to only 9% in responsive subjects and 10% in healthy controls and chronic active CD patients. This observation has recently been confirmed by Fujishima *et al.*^[60] who have found, in colonic biopsies of UC patients, significantly more GR β -positive cells in the resistant group than in the GC sensitive and control groups. However, in IBD, GR β is expressed 100-1000 times less than GR α , and this challenges its role in the genesis of steroid resistance in this disease.

Only a few studies, so far, have evaluated the role of the *TtbIII*, ER22/23EK and GR-9 β polymorphisms in the response to exogenous GCs in IBD or in other diseases. In 119 pediatric patients with IBD, no association has been found between the ER22/23EK polymorphism and GC response^[61]. In addition, the polymorphism did not appear to confer protection against the occurrence of respiratory distress syndrome in 62 preterm infants born to mothers treated with a complete course of betamethasone^[62], or to play a role in the toxicity induced by GCs in 36 children with acute lymphoblastic leukemia (ALL)^[63]. The three polymorphisms have been also studied in haplotype: in 646 patients with multiple sclerosis treated with GCs, the haplotype consisting in *TtbIII*, ER22/23EK, and 9 β -G was associated with GC resistance, with a more rapid disease progression. However this seemed to result from the presence of ER22/23EK, and not from the other two polymorphisms^[64].

Two single nucleotide polymorphisms (SNPs) in the *NR3C1* gene, the N363S and *BcI* polymorphisms, are associated with an increased sensitivity to GCs.

The N363S polymorphism is located in exon 2 and consists of an AAT>AGT nucleotide change at position 1220, which results in an asparagine to serine change in codon 363. A significantly higher transactivating capacity of the mutant has been described *in vitro* in human peripheral blood mononuclear cells^[65] and is associated with an increased sensitivity to GCs *in vivo*^[66]. Few studies have investigated the role of this polymorphism in the response to exogenous GCs. Szabó *et al.*^[67] have investigated whether variants of the *NR3C1* gene may contribute to steroid-induced ocular hypertension. In 102 patients who underwent photorefractive keratectomy and received topical steroids as part of postoperative therapy, a significant correlation was found between N363S heterozygosity and ocular hypertension. Furthermore, in 48 patients with Duchenne muscular dystrophy treated with prednisolone or deflazacort, the N363S carriers showed a trend towards a later age at loss of ambulation in comparison with non-carrier patients^[68]. Only one study so far has evaluated the role of this polymorphism in GC response in IBD: but no relation was observed between the presence of this SNP and response to GCs in a population of 119 pediatric patients^[61].

As extensively reported in the literature, the most clinically relevant polymorphism of the *NR3C1* gene is the *BcI* SNP. Initially described as a polymorphic restriction site inside intron 2, the nucleotide alteration was subsequently identified as a C>G substitution, 646 nucleotides downstream from exon 2^[69]. This polymorphism is also associated with hypersensitivity to GCs in both heterozygous and homozygous carriers of the G allele. An association with unfavorable metabolic characteristics, such as increased body mass index and insulin resistance has been also described^[70,71].

The *BcI* SNP has been studied in 119 pediatric patients with IBD (64 with CD, and 55 with UC). Patients were divided into two groups based on their response to GC treatment: GC dependence (45 patients) was defined by an initial response to prednisone with relapse on dose reduction, not allowing steroid discontinuation, and GC-responsiveness (67 patients), equivalent to therapeutic success, was defined as GC withdrawal without the need for steroids for at least 1 year. A significantly higher frequency of *BcI* mutated genotype was observed in the GC-responsive patients than in the GC-dependent group, which confirms an increased sensitivity to GCs in subjects with the *BcI* mutated genotype^[61]. These results have been subsequently confirmed in a larger cohort of young patients with IBD^[72].

GR heterocomplex: The integrity of the mature GR heterocomplex is required for optimal ligand binding and subsequent activation of the transcriptional response, and abnormalities in the chaperones and co-chaperones that make up the heterocomplex may contribute to altered GC responsiveness^[73].

Although no study has considered the role of these abnormalities in IBD, altered levels of Hsp90 have been

found in peripheral blood mononuclear cells from individuals with steroid-resistant forms of asthma^[74], multiple sclerosis^[75], and idiopathic nephrotic syndrome^[76]. Kojika *et al.*^[77] have shown that alteration in Hsp90 and Hsp70 is associated with decreased sensitivity to GCs in human leukemia cells. However, no relationship has been found between Hsp90 mRNA and resistance to GCs in spare bone marrow or peripheral blood samples taken from ALL patients at diagnosis^[78]. SNPs in the Hsp90 genes (HSPCA encoding hsp90-1 α , HSPCB encoding hsp90-1 β) have been recently described; however, in an adult asthmatic population, no correlation was found between SNPs in the HSPCA (3'-UTR+307, rs3736807, rs4906178, rs3809386, promoter -32) or HSPCB (rs504697 and rs3757286) genes and response to treatment^[79].

Generally, steroid receptors display functional instability when deprived of chaperones. FKBP51, coded by the FKBP5 gene, is a negative regulator of GC action and reduces GR binding affinity^[80]. However, when GCs binds to the GR, the receptor complex is activated and FKBP51 is replaced by FKBP52 (coded by FKBP4 gene), a positive regulator of GR signaling^[81,82]. The relative levels of FKBP51 and FKBP52 have been shown to be important determinants of GC cellular sensitivity in various systems. One recent study has investigated the role of FKBP5 genetic variants in the response to GCs in asthmatic patients^[79], however the studied polymorphisms (rs3800373, rs9394309, rs938525, rs9470080, rs9368878 and rs3798346) were not correlated with response. In this study, genetic variations in the *STIP1* gene, which codes for the co-chaperone Hsp70/Hsp90 organizing protein, on the contrary, seemed to have a role in identifying asthmatic subjects who were more responsive to GC therapy^[79].

Nuclear transport factors: Importins represent important players in GC pharmacology, as they mediate nuclear translocation through nuclear pore complexes. Importin 13 (IPO13) has been functionally characterized as a primary regulator of GC-bound GR across the nuclear membrane^[23]. IPO13 was first discovered as a GC-inducible gene that is important in lung development^[83], therefore, its functional characterization has been performed in airway epithelial cells and lung-derived transformed cell lines^[84]. Inhibition of lung epithelial cell IPO13 production reduces the nuclear translocation of GR from the cytoplasm, and subsequent GC-mediated silencing of inflammatory cytokine production^[84], which suggests that the normal anti-inflammatory response induced by GCs is dependent on normal IPO13 expression levels or activity. Therefore, irregular GC-GR signaling, ascribable to IPO13 variation, might affect the therapeutic responsiveness to GCs. IPO13 is expressed in other tissues as well, such as fetal brain, heart, kidneys and intestine^[83,85], therefore, it is feasible to hypothesize that dysregulation of IPO13-mediated processes might account for the variable response to GCs also in other diseases, such as IBD.

Importins are interesting candidates for pharmacogenomic studies, although little is known about their genetic variants. Recently, the association of 10 IPO13 polymorphisms with responsiveness to inhaled GCs, measured by

change in methacoline dose required for a 20% drop in FEV1, has been investigated in children with mild to moderate asthma^[86]. Unexpectedly, the genetic effects conferred by IPO13 variants were clinically significant in subjects who were randomized to placebo and nedocromil treatment (control group), rather than those treated with the inhaled GC budesonide, either in single SNP or in haplotype analysis. No other study on IPO13 genetic variants is available to date, therefore, these results require confirmation and further investigations are needed to shed light on the putative role of IPO13 mutants in GC-resistant or GC-hyper-responsive cases in other chronic inflammatory diseases.

Transcription machinery: In eukaryotic cells, gene transcription is inhibited by condensed chromatin structure, which prevents the interaction between gene-specific transcription factors and their DNA recognition sequences, thus blocking the access of the transcriptional machinery to DNA^[87]. Dynamic chromatin remodeling is therefore a fundamental mechanism in mediating genomic effects, and a large family of protein complexes that promote chromatin restructuring in an ATP-dependent manner, by disrupting histone-DNA contacts, has been described^[88-90]. Among these, the highly conserved mammalian SWI/SNF chromatin remodeling complex is the one recruited during GC-dependent gene activation^[91-93]. The complex is composed of several subunits^[94,95], including a catalytic ATPase subunit (either SMARCA4/BRG1 or SMARCA2/BRM) and Brahma-related gene 1 (BRG1)-associated proteins^[96], such as the SWI/SNF-related, matrix-associated, actin-dependent regulators of chromatin (SMARCC1, SMARCC2, SMARCD1-3, SMARCE1, SMARCB1 and ACTL6-A-B^[94,95]).

Alterations in any component of the SWI/SNF complex might be responsible for GC resistance, if access of GC-bound GR to DNA is compromised because of an impaired or suboptimal chromatin remodeling and nucleosome disruption. Using a genome-wide approach in patients with newly diagnosed childhood B-lineage ALL, differential expression of a relatively small number of genes has been shown to be associated with drug resistance and treatment outcome^[97]. Lower expression of SMARCB1 is related to resistant leukemia cells and, vice versa, higher levels are associated with GC-sensitive ALL^[97]. Decreased expression of other core subunits of the SWI/SNF complex, such as SMARCA4 and ARID1A, is also associated with GC resistance in primary ALL cells^[98].

To date, only a few studies have addressed the functional effects of SMARC polymorphisms. By using the human CEPH (Centre d'Etude du Polymorphisme Humain) cell lines from 90 individuals and sequencing the SMARCB1 promoter region, a regulatory SNP (-228G>T) has been discovered: the TT genotype has been functionally associated with higher SMARCB1 expression at both mRNA and protein levels^[99], and a positive association has been found between the SMARCB1 mRNA level and prednisolone sensitivity, as evaluated by MTT assay. In addition, knockdown of SMARCB1 in human ALL cell lines has confirmed that reduced SMARCB1 expression induces GC resistance^[99].

Pro-inflammatory mediators in the downstream signaling pathway of the GC-GR complex

Inflammation can be seen as a physiological homeostatic process elicited by the body in response to injurious agents, to protect tissues and to help in recovery. However, inflammation itself can potentially lead to tissue damage, if the organism does not properly control the process. Endogenous GCs are involved in the regulation of many physiological functions and assist the innate and adaptive immunity^[100-102] by balancing pro- and anti-inflammatory mediators, thus preventing overwhelming inflammation^[103].

According to gene expression analysis of human peripheral blood mononuclear cells from healthy donors, approximately 20% of genes, particularly those involved in the immune response, are regulated either positively or negatively in response to DEX treatment^[104]. GCs downregulate the expression of pro-inflammatory cytokines [such as IL-1 α , IL-1 β , IL-8, interferon (IFN)- α and IFN- β ^[104,105]], chemokines^[106,107], adhesion molecules, inflammatory enzymes and receptors. At the same time, GCs upregulate the expression of other cytokines that suppress the production of inflammatory mediators (such as transforming growth factor- β 3 and IL-10), thus boosting the anti-inflammatory effects.

Pro-inflammatory cytokines are involved in the pathogenesis of several chronic inflammatory diseases such as rheumatoid arthritis, osteoarthritis, asthma and IBD^[108,109]. Their excessive expression is generally efficiently counteracted by GCs^[110]. Individuals with steroid-non-responsive forms often show higher levels of local and/or systemic pro-inflammatory cytokines^[111-113].

Research of the cytokine profile in relation to GC resistance has been mainly performed in steroid-resistant asthma, and only a few studies have involved patients with IBD. Several *in vitro* data suggest that cytokines modify GC effects by interference with the GR signaling^[114]. IL-1 α has been reported to inhibit DEX-induced GR translocation in mouse fibroblasts^[115] and to downregulate the GR in a rat hepatoma cell line^[116], whereas IL-1 β inhibits GR function in colonic epithelial cells^[117]. Tumor necrosis factor (TNF)- α decreases corticoid sensitivity in monocytes by downregulation of GR^[118], and, in patients with UC, mucosal levels of this cytokine, as well as of IL-6 and IL-8 are higher in steroid-resistant patients^[119]. In a recent study, a large panel of cytokines was studied and their expression was correlated with steroid response. In particular, high IL-10 expression significantly enhanced steroid action, while IL-2 appeared to have the greatest antagonistic effect on the antiproliferative activity of steroids^[19]. This cytokine has been also related to increased GR β expression^[120], decreased translocation of the GR-GC complex to the nucleus^[121], and increased AP-1 levels, with abnormal interaction with the GR^[122]. IL-2 and IL-4 reduce GR affinity and T-cell response to GCs *in vitro*^[43], by a mechanism that involves p38 mitogen activated protein kinase (MAPK) activation^[123]. GCs inhibit the MAPK signaling pathway, through the induction of MAPK phosphatase 1 (MKP1), and this could result in inhibition of expression of various inflammatory genes^[124]. In

conclusion, a complex circular interplay between GCs and cytokines takes place, with GCs downregulating pro-inflammatory cytokines and cytokines limiting GC action.

Basal cytokine expression levels are fine-tuned by genetic profile. Polymorphisms in the cytokine regulatory regions determine a “lower/higher cytokine producers” phenotype that might in part be responsible of inter-individual variations, in terms of severity of inflammation and therapy responses. Higher cytokine producers might become GC-resistant or they might be less responsive at standard doses, therefore requiring dose adjustment to overcome the inflammation; however, only a few studies have focused on the effect of these genetic polymorphisms on GC response.

IL-1 β : Among the major inflammatory cytokines, IL-1 has a pivotal role. IL-1 is constituted by two distinct polypeptides, IL-1 α and IL-1 β . IL-1 β can promote the production of matrix metalloproteinases and the synthesis of prostaglandins^[110,125], as well as the production of other inflammatory mediators such as IL-6, IL-8 and TNF- α , thus amplifying the inflammation cascade^[126]. IL-1 β is therefore a key player in prompting and maintaining inflammation^[119,127] and polymorphisms in the *IL-1 β* gene might be of primary relevance in the modulation of GC response.

A cluster of genes encoding for IL-1 α , IL-1 β and for the natural receptor antagonist IL-1Ra has been mapped on chromosome 2q13^[128,129]. Polymorphisms in this gene cluster have been associated with a large variety of human diseases^[130] and with altered levels of IL-1^[131-134]. So far, the dbSNP build 130 database of NCBI reports 158 submissions for human IL-1, among which, several SNPs are described^[131,135]. Two SNPs in the IL-1 β promoter region (C-511T and T-31C) exhibit almost complete linkage disequilibrium. The C-511T SNP (rs16944) results in the loss of AP-2 binding site, while the T-31C (rs1143627) results in the loss of the first T in TATA box. The latter SNP appears to cause a paradoxical increase in IL-1 β in the presence of steroids^[156], which could be relevant to the occurrence of GC resistance. Carriers of the haplotype composed of IL-1 β -31C allele and -511T allele showed higher plasmatic concentrations of the cytokine, compared to subjects with IL-1 β wild-type genotype in Caucasians^[132,137], but decreased mRNA and protein levels in Japanese subjects^[138]. A recent report from this laboratory has investigated the role of the C-511T polymorphism in the response to GCs in 154 young IBD patients, but no relation with GC resistance (14 patients) or dependence (54 patients) was found^[72].

IL-1 β is released as an inactive precursor (pro IL-1 β , p35) by monocytes and macrophages in response to inflammatory stimuli, and is cleaved to the active mature form (p17) by caspase-1^[139,140]. Caspase-1 is part of multiprotein cytoplasmic complexes, called NACHT leucine-rich-repeat protein 1 (NALP1) and NALP3 inflammasomes. Jin *et al.*^[141,142] have recently shown that variants of NALP1 are associated with several autoimmune diseases, and have suggested that mutations in NALP1 gene may result in deregulated secretion of IL-1 β . The rs12150220

non-synonymous polymorphism, previously reported to confer susceptibility to autoimmune and autoinflammatory diseases^[143] results in the Leu > His amino acid variation in position 155, between the N-terminal pyrin and NACHT domains of the human NALP1 protein. This region has been highly conserved through primate evolution, which suggests a critical role in protein function^[142]. Data from our laboratory have shown that pediatric IBD patients, carriers of the NALP1 homozygote rs12150220 variant genotype, exhibit a higher probability of non-response to GC therapy^[72].

TNF- α : TNF- α is a potent pro-inflammatory cytokine released by cells of the immune system upon stimulation, and is almost not detectable in resting conditions^[144]. The gene encoding TNF- α is located in the class III region of the major histocompatibility complex within the human leukocyte antigen (HLA) on chromosome 6p21.3^[145]. This part of the genome is one of the most polymorphic in humans and contains many genes that encode proteins involved in inflammatory and immune responses^[146].

The G-308A (rs1800629) is one of the best documented polymorphisms of the TNF- α gene^[147]. This SNP lies in a binding site for the transcription factor AP-1 and the A allele has been shown to have higher transcriptional activity than the G allele, increasing TNF- α production *in vitro*^[148]. The A allele carriers show an enhanced susceptibility to several autoimmune and inflammatory disorders, such as systemic lupus erythematosus, celiac disease^[149], Alzheimer disease^[150,151], IBD^[152], asthma^[153] and rheumatoid arthritis^[154].

The polymorphism has been correlated also with steroid response in several diseases. In a cohort of 386 pediatric IBD patients, the mutated allele was significantly associated with steroid resistance and requirement for surgery in the subset of 200 CD patients^[152]. In addition, previous evidence in a large population of CD patients has shown that this polymorphism is more frequent in steroid-dependent subjects; possibly as a consequence of a more intense TNF- α -driven inflammatory reaction at the mucosal level^[155]. The AA genotype has been associated with reduced response to steroids also in other diseases, such as idiopathic nephrotic syndrome^[156], rejection episodes in HLA-DR mismatched transplant patients^[157] and solid and lymphoid malignancies^[158,159].

IL-10: IL-10, known as human cytokine synthesis inhibitory factor, is a cytokine that is produced primarily by monocytes and to a lesser extent by lymphocytes. IL-10 has pleiotropic effects in immunoregulation and inflammation^[160-162]. It inhibits the production of inflammatory mediators, and can be considered as a natural immunosuppressant of TNF^[163]. GCs upregulate the expression of IL-10^[104], and conversely, IL-10 acts synergistically with GCs, improving the ability of DEX to reduce IL-6 secretion in whole-blood cell cultures. In addition, the cytokine increases the concentration of DEX-binding sites in these cells, with no effect on the binding affinity^[118]. The human IL-10 gene is located on chromosome 1q31-q32. Previous studies have demonstrated that an A>G polymorphism at

nucleotide position -1082 within the IL-10 gene promoter region (rs1800896) influences the cytokine plasma levels, which are significantly higher in patients homozygous for the G allele^[159]. No data exist on the role of IL-10 polymorphisms in GC response in IBD, however, the mutated genotype is related to a positive prednisone response in childhood ALL^[159]. In accordance, Marino and colleagues^[63] have found a better response to GC remission induction therapy in Italian pediatric ALL patients with the mutated allele. In patients affected by rheumatoid arthritis, the high IL-10 producer genotype (-1082GG) is also associated with a favorable outcome, specifically to prednisone therapy^[164].

The multidrug resistance gene and other proteins involved in the pharmacokinetics of GCs

Cellular extruding pumps and metabolizing enzymes are the two key pathways involved in the elimination of many drugs. P-gp is one of the major transporters that extrude xenobiotics and drugs out of the cells. The cytochrome P450 (CYP) enzyme superfamily, that catalyzes phase I reactions, is active in the metabolism of many exogenous and endogenous compounds. P-gp and CYP3A are expressed in the intestinal epithelial cells, in lymphocytes and in the liver and have been reported to be involved in the transport and metabolism of GCs.

P-gp: P-gp is a 170-kDa transport membrane glycoprotein, which is responsible for resistance to a number of structurally and functionally unrelated drugs in clinical use. Human P-gp is a phosphorylated and glycosylated protein that consists of 1280 amino acids and two homologous and symmetric sequences, each containing six transmembrane domains and an ATP-binding motif. ATP hydrolysis provides the energy for active drug transport against a steep concentration gradient^[165]. The protein plays an important role in the absorption, distribution, and elimination of drugs that are its substrates, among which GCs, and P-gp inhibitors reduce cortisol efflux from human intestinal epithelial cells and T cells^[166]. The protein is highly expressed in circulating lymphocytes and epithelial cells from CD and UC patients with GC-resistant IBD^[167], however a relationship between GC administration and P-gp expression has been described in monocytes from IBD patients^[168]. It remains therefore to be clarified if the increased expression of P-gp reflects a primary phenomenon in IBD or a secondary one, influenced by GC therapy.

P-gp is encoded by the ABCB1 (MDR1) gene, located on human chromosome 7q21.12^[169], and several studies have demonstrated that genetic polymorphisms in this gene lead to functional alterations and phenotypic variations in P-gp expression^[170,171]. The first systematic screening for ABCB1 polymorphisms was performed in 2000^[170]: a synonymous SNP in exon 26 (C3435T) was the first variation to be associated with altered protein expression. P-gp expression in the duodenum of individuals with the homozygous variant T allele was decreased when compared with individuals with the C allele (wild-type). Other studies have shown that SNPs at exons 12 (C1236T), 21 (G2677T/A) and 1b (T-129C) may also be associated with altered

transport function or expression^[172]. A weak association between GC refractory CD and MDR1 polymorphisms in introns 13 and 16 has been initially described^[173], however, subsequent studies have not confirmed this observation. In 2007, Cucchiara and colleagues studied the C3435T MDR1 polymorphism in 200 pediatric Italian patients with CD and 186 patients with UC treated with GCs, and demonstrated that this SNP was not associated with response to medical therapy^[152]. In confirmation of these results, a large study performed on an adult Italian IBD population did not find any association between the polymorphisms of the MDR1 gene (C3435T and G2667T/A) and clinical response to GC therapy^[174]. Further studies are therefore needed to clarify if MDR1 polymorphisms play a role in steroid resistance in IBD.

CYP3A: CYP3A is the primary CYP subfamily in humans and is responsible for the phase I metabolism of > 50% of drugs currently in use^[175], including GCs^[176]. Many drug substrates of CYP3A4 are also substrates of P-gp, and the overlap between CYP3A4 and P-gp is also emphasized by the genomic proximity of these genes (7q22.1 and 7q21.1 for CYP3A4 and MDR1, respectively)^[172]. The CYP3A activity of the adult human liver is the sum activity of all subfamily members, including CYP3A5, which is highly polymorphic in Caucasians^[177], and genetic variants may play an important role in inter-individual differences in the pharmacokinetics of drugs metabolized by CYP3A5.

The most frequent and functionally important SNP in the *CYP3A5* gene consists of an A6986G transition within intron 3 (*CYP3A5*3*)^[175]: this mutation creates an alternative splice site in the pre-mRNA and results in production of an aberrant mRNA (SV1-mRNA) that contains 131 bp of intron 3 sequence (exon 3B) inserted between exons 3 and 4. The exon 3B insertion turns out in a frameshift and predicted truncation of the translated protein at amino acid 102. Additional intronic or exonic mutations (*CYP3A5*5*, *6, and *7) may alter splicing and result in premature stop codons or exon deletion^[178,179].

No report is present in the literature about the role of CYP3A5 polymorphisms in GC resistance in IBD, but plasma prednisolone concentrations, measured by HPLC in 95 renal transplant recipients treated with repeated doses of triple therapy immunosuppression, consisting of prednisolone, tacrolimus and mycophenolate mofetil, have been recently studied^[180]. The AUC₀₋₂₄ of prednisolone in recipients having both MDR1 3435CC and *CYP3A5*3*/**3* genotypes tends to be higher than the MDR1 3435TT plus *CYP3A5*3*/**3* genotype. The *CYP3A5*3* polymorphism has also been included in a study to identify pharmacogenomic predictors of outcome in 70 pediatric heart transplant patients followed for at least 1 year post-transplantation, but in this population, no correlation of the *CYP3A5*3* SNP with steroid response after transplantation was observed^[181].

CONCLUSION

GCs are potent anti-inflammatory drugs and, despite con-

siderable adverse effects, still remain the first-line therapy for inducing a rapid remission in moderate to severe active CD and UC. In addition, high inter-individual variability is observed when these agents are administered to patients with IBD and other chronic inflammatory diseases. A main goal in this area of medicine is therefore to improve the efficacy and safety of these agents and, when possible, to reduce steroid exposure and to employ a non-steroid option. This is particularly important in patients that do not respond, who will suffer considerable steroid-dependent morbidity without any clinical gain.

Pharmacogenomics is a relatively novel branch of investigation and represents an innovative frontier of medicine. Its ambitious goal is to identify genetic determinants that will help physicians in diagnostic decisions, and supply reliable genetic tools to adjust treatment *a priori*. A knowledge of genetic profiles with an impact on drug response would improve cure rates, avoid inadequate regimens or time wasting, and reduce overall health-care costs.

Pharmacogenetic research in IBD has witnessed only modest success; in particular, because treatment response in this disease is influenced by many factors, such as disease duration, behavior and severity, and at present, despite intensive investigation, none of the potential pharmacogenetic markers is strong enough to be used in clinical practice. Reported genetic associations have not yet shown consistent or robust results, and for most of the considered SNPs, results are controversial. More studies with larger sample size and well-characterized patient cohorts, uniformly treated and systematically evaluated, are therefore needed. These studies should support findings with greater statistical confidence that should be hopefully translated into clinical practice in the near future.

Abstract

Until the late 1980s, gastroenterology (GE) was considered a subspecialty of Internal Medicine. Today, GE also incorporates Hepatology. However, Digestive Oncology training is poorly defined in the Hepatogastroenterology (HGE)-curriculum. Therefore, a Digestive Oncology curriculum should be developed and this document might be a starting point for such a curriculum. HGE-specialists are increasingly resisting the paradigm in which they play only a diagnostic and technical role in the management of digestive tumors. We suggest minimum endpoints in the standard HGE-curriculum for oncology, and recommend a focus year in the Netherlands for Digestive Oncology in the HGE-curriculum. To produce well-trained digestive oncologists, an advanced Digestive Oncology training program with specific qualifications in Digestive Oncology (2 years) has been developed. The schedule in Belgium includes a period of at least 6 mo to be spent in a medical oncology department. The goal of

these programs remains the production of well-trained digestive oncologists. HGE specialists are part of the multidisciplinary oncological teams, and some have been administering chemotherapy in their countries for years. In this article, we provide a road map for the organization of a proper training in Digestive Oncology. We hope that the World Gastroenterology Organisation and other (inter)national societies will support the necessary certifications for this specific training in the HGE-curriculum.

Digestive oncologist in the gastroenterology training curriculum. *World J Gastroenterol* 2011; 17(9): 1109-1115 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1109.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1109>

INTRODUCTION

Until the late 1980s, gastroenterology (GE) was considered a subspecialty of Internal Medicine. However, since then, GE has become more complex, in both endoscopy and drug therapy, and the speciality now also incorporates Hepatology. We now train Hepatogastroenterologists (HGE-specialists). It is a challenge to develop a training program that will produce HGE-specialists who are competent in all aspects of HGE by the end of their program^[1,2].

In 2002, the Dutch Board for Hepatogastroenterol-

ogy extended GE training to 4 years, with a Common Internal Medicine Trunk of 2 years^[3]. In the final year of training, a fellow subspecializes, if possible/desirable, in advanced endoscopy, neuromotility, hepatology, or (digestive) oncology. Training in hepatology has been well defined^[4,5]. Digestive Oncology training is currently poorly defined^[1]. The European Board for Gastroenterology and Hepatology has defined subspecialties in advanced endoscopy, hepatology, clinical nutrition, and, indeed, Digestive Oncology. However, a proper curriculum is lacking (<http://www.eubog.org>)^[6]. The World Gastroenterology Organisation (WGO) formulated a document outlining standards for HGE training^[5]. However, again Digestive Oncology was poorly defined. Therefore, a Digestive Oncology curriculum needs to be developed and subjected to regular revision. This document serves as a starting point for such a curriculum.

DIGESTIVE ONCOLOGY

Today, there are remarkable opportunities for those seeking a career in Digestive Oncology^[1,7]. The revolution in molecular biology, advances in interventional endoscopy and anti-cancer therapies, as well as the management of subsequent treatment-related side effects, have permanently changed the way we care for our patients with digestive tumors. HGE-specialists are increasingly resisting the paradigm in which they play only a diagnostic or technical role in the care of digestive tumors. They now perceive the empty space they need to fill with their knowledge. HGE-specialists are pre-eminently competent to organize supportive care around the Digestive Oncology patient. They recognize the caveats in the poor nutritional condition of the patient and are able to immediately take supporting measures that are necessary for completion of the patient's treatment. This also holds true for situations in which patients experience toxicity induced by different anti-cancer treatments. A new generation seeks to assume this more central role in the multidisciplinary care of our patients. With proper training, we see no reason why future generations of gastroenterologists should be barred from the delivery of anti-cancer therapies, because some might term it "chemotherapy".

Minimally invasive laparoscopic approaches have been developed for almost all digestive tumors, and image-guided intervention is providing an innovative therapeutic option for early cancers^[8]. Modern evidence-based "outcomes research" provides an objective tool for assessing clinical results. Patient-completed questionnaires and standardized assessment of individual preferences have helped us to understand survivorship issues among Digestive Oncology patients, including the long-term effects of treatment on quality of life^[9,10].

The HGE-specialist has the immense advantage that he/she has can both recognizing malnutrition or obstructing symptoms threatening the patient's condition in an early state, can subsequently visualize this endoscopically, and can then take the necessary measures to resolve

such devastating situations. Obviously, full insight into the possible treatment plan for this vulnerable patient group is warranted.

Surgical excellence remains critically important in the field of Digestive Oncology. Despite the development of modern anti-cancer drug therapy, (intra-operative) radiotherapy, and the combined use of these treatment modalities, the need for optimal surgery has not been eliminated. Rather, the pre-operative use of such therapies has challenged surgeons to develop the necessary skills to operate on highly pre-treated tumors, whilst simultaneously reducing the burden of surgical morbidity. Similarly induction chemo(radio)therapy for oesophageal and gastric cancers has also expanded the role of surgery, by allowing the resection of some cancers previously considered inoperable^[11,12]. Future leaders in Digestive Oncology must be skilled gastroenterologists and surgeons capable of advanced endoscopy, laparoscopic techniques, and image-guided therapy. They must also be scholars, well versed in the nuances of modern diagnostic and staging procedures, fully appreciative of the benefits and limitations of anti-cancer therapy (chemotherapy, immunological, and targeted therapy) and radiation therapy (including chemoradiation).

Comprehensive training also requires exposure to research, either in the basic sciences, translational research, and/or clinical trials. This will prepare future HGE-specialists to explore hypotheses about digestive tumors in an effort to improve patient care.

SOCIETIES FOR DIGESTIVE ONCOLOGY

The European Society of Digestive Oncology (ESDO) was founded in 2008 (<http://www.esdo.com>). Currently, more and more academic centres are offering fellowships in Digestive Oncology. According to the ESDO membership details, essential requirements of the digestive oncologist include: expertise in multidisciplinary care, the ability to perform and understand the limitations of complex tumor treatments, a clear understanding of the biology and science of digestive tumors, and the ability to collaborate in (translational) research. We suggest that active membership of ESDO should be encouraged for HGE-specialists who devote > 50% of their total professional activity to the field of digestive tumors, who have presented at least one oncology paper in a national meeting, are board certified by the European Board of Gastroenterology and Hepatology (<http://www.eubog.org>) or the respective equivalent in their country of origin, and have additional oncology experience following formal HGE training. The goal of advanced training in Digestive Oncology is to enhance knowledge and skills beyond the expertise obtained during a normal HGE residency program. The duration of advanced fellowship training might be 24 mo, with a minimum of 12 mo of clinical exposure during the formal 6 years of HGE training (focus year) and 12 mo of formal Digestive Oncology. If applicants have completed research in Diges-

tive Oncology, for example a PhD under the auspices of governing bodies such as ESDO (or equivalent in their country), they might apply to have the 6 mo research requirement waived during their 24 mo of advanced fellowship training in Digestive Oncology: this should be discussed.

PROGRAMS IN DEVELOPMENT

All training programs are required to provide a structured educational experience at an advanced level to ensure that trainees acquire the knowledge and skills necessary to gain expertise beyond that acquired in the standard HGE residency^[1]. Access to patient care and multidisciplinary team discussions with medical oncologists, radiation oncologists, surgeons, pathologists, and radiologists who have expertise in digestive tumors are an additional requirement for the trainees. Programs must provide structured clinical opportunities for trainees to develop advanced skills in interventional endoscopy. Each fellow on the advanced Digestive Oncology program should be involved in at least 100 major interventional procedures for the treatment of digestive tumors. Additionally, a research component should be discussed with structured supervision for at least 6 mo. If basic science laboratory training is offered, the necessary facilities must be available under the supervision of a trainer who has demonstrated at least a national reputation in research, as evidenced by publications in peer-reviewed journals, and membership of digestive oncological societies. As an example of one of the Dutch HGE-approved fellowships for a focus year in formal HGE training, the following section describes the suggested curriculum for Digestive Oncology.

DIGESTIVE ONCOLOGY IN THE DUTCH TRAINING OF HGE-SPECIALISTS (FOCUS YEAR)

In the Netherlands, during the last year of HGE training, it is possible to focus on Digestive Oncology^[3]. In this year, a minimum of six sessions per week must be spent on oncology-related activities in the context of the focus area. The content of the training within the professional body and the terms for the fellowship have been designed under the auspices of the National Board for Hepato-Gastroenterology.

END OF TRAINING COMPETENCIES

Knowledge

Knowledge of the duties/remit as described by the end of training competencies for general HGE-specialists, with particular emphasis on anti-cancer drug treatment and radiotherapy treatment possibilities; knowledge of primary and secondary prevention of digestive tumors; knowledge of hereditary cancer and polyposis syndromes

affecting the digestive tract; knowledge of the rarer digestive tumors, such as anal carcinomas, hepatocellular carcinomas, GI-lymphomas (MALT-lymphomas and Enteropathy Associated T-cell lymphomas), GIST tumors, neuro-endocrine tumors, cystic pancreas tumors; knowledge of advanced endoscopic techniques for diagnosis, staging, and treatment of pre-malignant disorders of the gastrointestinal tract, such as chromo-endoscopy, Endoscopic Ultrasonography (EUS), ablative techniques, and endoscopic mucosal resection; knowledge of palliative care for malignant digestive disorders and early recognition patients in need of nutritional support; and knowledge of side-effects of different anti-cancer treatment modalities.

Skills

Skill in procedures such as those described by the end of training general HGE-specialists; optional (overlap with focus year of advanced endoscopy); endoscopic treatment of malignant stenoses of the oesophagus, stomach, duodenum, and colon; recognition and identification of premalignant lesions; endoscopic treatment of anastomotic leakages after surgery; percutaneous endoscopic gastrostomy (PEG) placement; endoscopic ultrasound (EUS) and EUS-guided fine needle aspiration (FNA); endoscopic ablative treatment, such as Photo-Dynamic Therapy, electrocoagulation, argon plasma coagulation (APC), and intraluminal radiotherapy; and endoscopic mucosal resections in the oesophagus, stomach, duodenum, and colorectum.

Learning environment

A minimum of two HGE-specialists with an interest in oncology, one of whom is recognised as a mentor by the National Society in the focus area; weekly multidisciplinary oncology meetings; and practice within the department in EUS, including diagnostic biopsy, endoscopic ablative treatment methods, intraluminal radiotherapy, endoscopic treatment of malignant stenoses in the oesophagus, stomach, duodenum, and colorectum, and endoscopic mucosal resections. The department should be active in the development of newly targeted endoscopic diagnostic and therapeutic modalities for pre-malignant abnormalities. Within the hospital the personnel should include: registered medical oncologists (internist-oncologist), minimum two; registered surgical oncologists (surgeon-oncologist), minimum two; radiation oncologists, minimum two; and a clinical geneticist, possibly seconded or on a consultative basis.

Training

(Endoscopic) activities, based on the end of training targets; medical oncology, minimum 40 sessions; radiation oncology, minimum 10 sessions; attendance at oncological/surgical interventions (oesophageal resection, gastric resection, pylorus-preserving pancreatoduodenectomy (PPPD), liver resection, colon resection, total mesorectal excision (TME)-resection, only once); a minimum of 10

sessions of pathology; and a minimum of 10 sessions of clinical genetics.

Participation in discussions and structured consultations

At least weekly multidisciplinary oncology meetings with minimum participants to include an internist-oncologist, an oncological surgeon, a radiotherapist, a radiation oncologist, a pathologist, and a nuclear medicine specialist. At least one meeting per quarter should include a clinical geneticist.

Scientific activities

Conference attendance: minimum of one attendance at an international clinical oncology conference (ASCO, ESMO, ESDO) or an international interdisciplinary Digestive Oncology conference. The fellow should take an active part in a research project in the area of oncology, preferably in the context of a research degree. The fellow should write at least one scientific publication on an oncology-related subject and present at least one abstract concerning an oncology-related subject at a national or international conference.

Quality control

GI training and quality inspection at a regular interval of at least 5 years, organized and supervised by the national society for HGE.

Educational supervision

Trainers are required to provide appraisal during training and assessment that contributes to the evidence of competence of the fellow, who is recommended to provide a portfolio of assessed cases. Trainers must provide adequate on-site supervision for trainees at all times, as defined in the curriculum. Satisfactory assessments from trainers and completed log books that demonstrate that the fellow meets the criteria of competence are required for a fellow to be assessed as competent in Digestive Oncology (focus year).

Advanced Digestive Oncology training in Belgium (2 years)

The HGE-specialist of the future, or at least some of them, desire continuous care for their digestive tumor patients. To treat them, however, HGE-specialists should acquire skills. The necessary skills are currently beyond those taught during the HGE training in most countries. Since the beginning of 2010, there has been official recognition of HGE-specialists with a specific qualification in Digestive Oncology in Belgium^[13]. To obtain this qualification, the candidate has to do one oriented year (focus year) during the main training years for HGE and one additional year. Six months of this training period needs to be spent in a medical oncology department. The curriculum will be focused on: (1) the pathophysiology of the different types of gastrointestinal tumors; (2) diagnostic management; (3) development of a multidisciplinary treatment plan; (4) the correct administration of systemic treatments, including chemo- and immunothera-

py, biological and genetic treatments; (5) the management of side effects; (6) the management of tumor-related and iatrogenic complications; (7) cancer registration; (8) multidisciplinary approaches; (9) the evaluation and conception of clinical trials; and (10) active participation in palliation. To maintain their recognition, more than 50% of the specialist's working time has to focus on oncology.

Standards for safe administration of treatment

Chemotherapy ordering, preparation and administration; patient education and informed consent; staff education and training; assessing how patients respond to treatment; monitoring patient-related toxicity.

DIGESTIVE TUMORS

Risk factors in HGE-cancers; indicators for endoscopy in diagnosis; indicators for endoscopy in staging; indicators for nutritional support; combined modality therapy; role of palliative chemotherapy; chemoprevention; (family) screening; and genetic testing. The Curriculum of the European Society for Medical Oncology (ESMO) and the American Society of Clinical Oncology (ASCO) described in the Global Core Curriculum for training in Medical Oncology provides the main framework for the training for Digestive Oncology^[14].

FUTURE EUROPEAN BOARD PROGRAM DESCRIPTION

The goal of the future European HGE-Board fellowship program remains to produce, for the local countries, a framework of well-trained digestive oncologists who will be leaders in academic Digestive Oncology and be qualified to promote improvements in national care to reduce the incidence, morbidity, and mortality of digestive cancer, and improve quality of life^[6]. Disease management teams include specific cancer sites (oesophageal, gastric, colorectal cancer (CRC), pancreatic, liver, hepatobiliary, anal, neuroendocrine, and gastrointestinal stroma cell tumors) and comprise surgeons, (digestive) oncologists, radiation oncologists, palliative care physicians, dieticians, pathologists, radiologists, nuclear physicists, clinical geneticists, and laboratory researchers. In case of GI-lymphomas, such management teams should also include hematologists. Working in these disease management teams, fellows have an opportunity to participate in the development of multidisciplinary management plans for patients, as well as the design and pursuit research opportunities, including clinical trials. The role of these teams includes, for example, the enhancement and promotion of CRC-screening, early tumor detection, primary and secondary prevention, and management of pre-malignant or malignant HGE diseases, as well as the translation of research into the clinical setting.

CLINICAL EXPERIENCE

The future program of the European Board's curriculum

should be designed to provide the fellow with a practical knowledge of the most up-to-date diagnostic and therapeutic strategies for digestive tumors^[15]. The aim is to develop familiarity with, and stimulate interest in, clinical and laboratory studies designed to advance knowledge in the field. The responsibility for clinical care is shared by the faculty, fellows, residents, medical students, and nurse practitioners. Fellows are directly involved in the management of patients with digestive tumors. The volume and nature of the clinical experience is such that the fellow has an opportunity to participate in the management of patients with all types and stages of digestive tumors.

TRAINING CRITERIA

During the general HGE training, fellows should acquire better theoretical knowledge of the etiology, pathogenesis, natural history, clinical manifestation, work-up, and treatment of digestive tumors^[15]. Such knowledge should include nutrition, if necessary pre-operative, during treatment, and for palliative care. Knowledge of logistics, health care economics, and medical ethics seems mandatory^[16]. The fellow must have observed, and been responsible for, adequate numbers of patients with digestive tumors, both as inpatients and outpatients. Such patients include those with complications encountered during work-up, surgery, chemotherapy and radiotherapy. They should also include those in need of enteral and parenteral nutritional support, such as nasogastric feeding, PEG-/percutaneous endoscopic jejunostomy (PEJ)-feeding. Close cooperation with a hospital dietician should be part of this.

Clinical experience must be gained in paid positions, obtained by open and transparent competition. Teaching must be an integral part of this Digestive Oncology program. Supervision of clinical work should be defined locally.

DIDACTIC EDUCATION

The goal of the advanced 24-mo educational program of the European Board of HGE is to provide a broad view of all aspects of digestive tumours, and a familiarity with diagnostic and therapeutic approaches. Rotations in medical oncology for at least 4-8 mo are supplemented by lectures on systemic therapy. In an oncology setting, staff work in the presence of patients with cancer every day. The emotional impact of this work must be recognized, and fellows should be coached on this, not only to appreciate the impact of the cancers on the patients, but also on the impact of oncology care on non-licensed support staff^[17].

ONCOLOGY IN THE STANDARD HGE-CURRICULUM

The description of the end of training competency, learning environment, and the training are as indicated in

the Gastroenterology Consensus Document in the Netherlands dated 14 December 2004^[1,3].

With relation to oncology, we can quote from the current terms the following passages: (1) General end of training competency: medical aspects: prevention; knowledge of preventative medicine with emphasis on pre-malignant disorders of the digestive tract; and (2) specific syndromes: (a) the specialist is experienced in the area of malignant disorders of the digestive tract; and (b) during the training in HGE there should be sufficient attention and space for the following basic courses: (i) Clinical genetics; and (ii) Clinical epidemiology.

An important part of the workload of HGE-specialists involves oncology. Areas in which the HGE-specialist must have expertise and skills include: (1) prevention, screening and surveillance; (2) diagnosis and staging; (3) endoscopic therapy, both curative and palliative; (4) supportive treatment, for example in relation to nutrition; and (5) diagnosis and treatment of both short-term and long-term complications of oncological therapies, for example radiation damage and drug-induced treatment induced mucositis.

CRITERIA FOR THE END OF THE TRAINING COMPETENCY IS SPECIFIED AS FOLLOWS

Knowledge

Basic knowledge of epidemiology and pathogenesis of the frequently occurring digestive tumors; knowledge of symptomatology, diagnosis and staging of frequently occurring digestive tumors; basic knowledge of rare digestive tumors; basic knowledge of molecular tumor biology; knowledge of familial tumor syndromes, such as familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer (HNPCC), and MYH-associated polyposis (MAP), including surveillance advice and knowledge of indications for referral to clinical genetic centres; knowledge of surveillance (pro's and cons) of premalignant disorders, such as Barrett's oesophagus, intestinal metaplasia and atrophy in the stomach, adenomatous polyps, and ulcerative colitis; knowledge of policy with relation to the follow-up after anti-cancer treatment; knowledge of the screening of the general population for pre-malignant and malignant disorders of the digestive tract; knowledge of the current range of abdominal imaging techniques with relation to oncological diagnosis, and their indications; familiarity with microscopic pre-malignant and malignant disorders of the digestive tract; knowledge of endoscopic treatment possibilities with curative and palliative intent; basic knowledge of other treatment modalities, such as surgery, radiotherapy, and chemotherapy; basic knowledge with relation to the development of neo-adjuvant and adjuvant treatments of the different digestive tumors; knowledge of nutrition as an integral part of treatment and of the different ways that feeding can be administered; and knowledge of di-

gestive problems in patients with non-gastroenterological tumors, for example radiation enteritis and proctitis, and the metastasis and ingrowth of other tumors into the digestive tract (breast cancer, melanoma).

Skills

Conventional endoscopic diagnosis of tumors of the digestive tract; global assessment of current abdominal imaging techniques in the context of oncological diagnosis; endoscopic resection of colorectal and gastric polyps; treatment of mild to moderately severe radiation proctitis with the use of APC; PEG placement; drainage of malignant ascites; delivery of bad news and the counselling of patients and their family members.

Learning environment

Each HGE training clinic must have the necessary facilities to integrate oncological aspects of digestive medicine into general training. The HGE-specialist should participate in multidisciplinary oncological discussions concerning abdominal tumors.

Training

There is no reason to introduce a separate oncological training period into the general HGE training program. This is only required for those individuals choosing to specialize in Digestive Oncology (focus year). Through local, regional and national teaching courses, much of the knowledge that is not accumulated in daily practice can be acquired to fulfil the end of training competency.

Review

To develop anonymous national assessment tests. Test frequency of once every 2 years.

Monitoring

Through HGE trainer.

Quality control

HGE training and quality inspection.

HGE-TRAINING AROUND THE WORLD

Differences in HGE training between the USA/Europe, India/China and, for example Sub Saharan Africa, are magnified by the obvious resource gaps between Third and First World countries. Redesigning training programs more efficiently would be another goal based on a common trunk system for HGE^[18]. India and China, with a common trunk of Internal Medicine for 2-3 years, have incorporated private hospitals into their programs. Well-equipped private hospitals should be used during Digestive Oncology focus years in the East and West. In Eastern Europe, Ministers of Health recently suggested that training for HGE should be reduced to 4 years in total^[19]. Arguments about specialist training are getting louder as governments get poorer because the current credit crisis. However, a properly organized scheme for Digestive On-

cology is mandatory to give patients the best chance of benefiting from national resources.

CONCLUSION

In this article, we present the critical elements of multidisciplinary fellowship training for the digestive oncologist, and suggest minimal competencies for the standard HGE-curriculum. Digestive Oncology is substantially under-represented in the undergraduate and postgraduate curricula of present day HGE training programs. Cancer prevention and screening, in particular, have suffered from poor exposure in the past^[20,21].

At the present time, the HGE specialist organizes the work-up, endoscopic-intervention of early digestive tumors, nutritional support and palliation of HGE-oncological patients. Interestingly, HGE-tumors are diagnosed by endoscopists often at the tip of their scope. Chemotherapy (neo-adjuvant) should be included based on competence^[11,12,22]. HGE-specialists have an essential role in the treatment of complications of digestive cancer and cancer therapy, from the placement of stents to the relief of obstructions and feeding tubes/PEG's to help anorexia and malnutrition, to the management of radiotherapy-induced bowel disorders. Malnutrition increases complications and reduces tolerance to systemic treatment^[23]. The HGE-specialist has a critical role in primary and secondary prevention of digestive tumors. However, just preventing a polyp from becoming a tumor, just making a diagnosis, just staging a tumor by EUS, just making referrals, just treating early complications of the oncologist, radiotherapist or surgeons, just taking care of palliation are unlikely to be "only" roles of HGE-specialists nowadays. It is this idea of expansion of the scope of HGE-units that will necessitate advanced Digestive Oncology training for a minority of HGE-specialists. What about immunotherapy in cancer, such as is performed for IBD? What about chemotherapy, a red line for HGE-specialists? Subspecialization within medical oncology has occurred to provide the required expertise needed to provide optimal patient care. The field of Digestive Oncology is also rapidly evolving. It requires specialized knowledge and skills to appropriately and safely administer various anti-cancer drug agents, with subsequent management of their toxicities. Some HGE-specialists trained as sub-specialists of Internal Medicine already administer chemotherapy in their countries. Maintaining the continuity of patient care is certainly a worthwhile goal.

In our opinion, HGE-specialists with advanced oncology training should be part of the gastrointestinal oncology team and be able to administer anti-cancer therapy in the years to come. In this article we provide a road map to organize this training. The scope and personalization of the HGE-curriculum is our major challenge, and one that will change HGE once again in the coming years. The proper positioning of Digestive Oncology is an important part of this. We hope that the WGO, American Gastroenterology Association, the European Board of

Hepatogastroenterology, and other (inter)national societies will organize the necessary certification for this HGE-specialization.

Abstract

Inflammatory bowel diseases are an ideal indication for the laparoscopic surgical approach as they are basically benign diseases not requiring lymphadenectomy and extended mesenteric excision; well-established surgical procedures are available for the conventional approach. Inflammatory alterations and fragility of the bowel and mesentery, however, may demand a high level of laparoscopic experience. A broad spectrum of operations from the rather easy enterostomy formation for anal Crohn's disease (CD) to restorative proctocolectomies for ulcerative colitis (UC) may be managed laparoscopically. The current evidence base for the use of laparoscopic techniques in the surgical therapy of inflammatory bowel diseases is presented. CD limited to the terminal ileum has become a common indication for laparoscopic surgical therapy. In severe anal CD, laparoscopic stoma formation is a standard procedure with low morbidity and short operative time. Studies comparing conventional and laparoscopic bowel resections, have found shorter times to first postoperative bowel movements and shorter hospital stays as well as lower complication rates in favour of the laparoscopic approach. Even complicated cases with previous surgery, abscess formation and enteric fistulas may be op-

erated on laparoscopically with a low morbidity. In UC, restorative proctocolectomy is the standard procedure in elective surgery. The demanding laparoscopic approach is increasingly used, however, mainly in major centers; its feasibility has been proven in various studies. An increased body mass index and acute inflammation of the bowel may be relative contraindications. Short and long-term outcomes like quality of life seem to be equivalent for open and laparoscopic surgery. Multiple studies have proven that the laparoscopic approach to CD and UC is a safe and successful alternative for selected patients. The appropriate selection criteria are still under investigation. Technical considerations are playing an important role for the complexity of both diseases.

INTRODUCTION

Laparoscopic techniques have rapidly gained acceptance since their first introduction into surgery for cholecystolithiasis. Other pathologies of the gastrointestinal tract have become indications within a short period of time. First attempts in minimally invasive approaches to colorectal surgery date back to the early 1990s. Potential benefits are evident: smaller incision size, improved

cosmesis, less postoperative pain, earlier return of bowel movements and tolerance to diet. These factors may be translated into a faster recovery of the patient in general with reduced floor costs, and earlier return of the patient to normal activity^[1].

In inflammatory bowel diseases, Crohn's disease (CD) and ulcerative colitis (UC) have to be distinguished clearly regarding the introduction of laparoscopy as the operative procedures are varied. In CD, there is a wide range of potential procedures whereas in UC, restorative proctocolectomy is the standard operation in elective situations. Early reports about the introduction of laparoscopy to CD demonstrated the feasibility of laparoscopic surgery for the creation of stomas and for limited segmental bowel involvement. Rapidly, more complex procedures like ileocelectomies or subtotal colectomies were attempted successfully. First results of laparoscopic restorative proctocolectomy and ileal pouch-anal anastomosis (IPAA) for selected patients with UC or indeterminate colitis were not encouraging. Only around the year 2000, with newly-developed instruments, refined technique, and in specialized treatment centers, this comprehensive procedure was reappraised with improved results. Also, subtotal colectomies for acute inflammatory bowel diseases may be managed laparoscopically.

Complicated cases of CD may still be a special challenge, even for surgeons with excellent experience in operations for IBD and intensive laparoscopic training. Rates of conversion from laparoscopic to conventional surgery are comparatively high^[2,3]. There are high rates of unexpected findings like proximal strictures, stenoses, abscesses or phlegmons^[4]. In this article, an overview of the current status of the special surgical approach to CD and UC is provided.

CD

In CD, in general, surgery is normally reserved for patients who develop complications of the disease such as strictures and fistulas or who are unresponsive to or develop complications from aggressive medical therapy. The laparoscopic approach should be an ideal indication since it is a benign disease and the concerns related to laparoscopic cancer surgery do not apply. Additionally, it may provide an improved cosmetic result, which is an important factor in this mostly young patient population^[5]. Thickened bowel loops, thickened and friable mesentery, inflammatory phlegmons and masses, enteric fistulas, abscesses, and multiple adhesions from previous conventional surgeries have deterred surgeons from considering a laparoscopic approach. However, as most patients are aware of the fact that there is a high risk of further surgeries becoming necessary at some later point in their lives, they are motivated to prefer a type of surgery that offers them minimal scarring and faster recovery^[6,7]. Even cases with complications may be attempted and completed laparoscopically, depending on the individual situation and the surgeon's expertise.

Early postoperative results

The decision to perform a laparoscopic procedure in an individual case as well as the conversion rates during surgery are influenced by the expertise of the surgeon which also determines the immediate postoperative outcome. After a number of years of application of the new technique, several studies about short and long-term results have been published.

The purpose of a study at the University of Chicago^[8] was to compare short-term outcomes of laparoscopic colectomy (LC) *vs* open colectomy (OC) in patients with Crohn's colitis. Data on all patients undergoing colectomy for primary or recurrent CD confined to the colon during 6 years were collected. Patient and disease-specific characteristics and perioperative and short-term postoperative outcomes were prospectively collected and analyzed. A total of 125 patients underwent colectomy during the study period, 55 (44%) LC. There were six conversions (10.9%). Median operative time was shorter in the LC group ($P = 0.032$). Earlier return of bowel function was noted in the LC group (3 d *vs* 4 d, OC). Length of postoperative stay was shorter in the LC group ($P = 0.001$). There was one death in the OC group. Postoperative complications occurred in 8 (14.5%) LC patients *vs* 16 (22.9%) OC patients. Disease recurrence rate was 16%, 10.9% LC and 20% OC, respectively.

It was stated that LC was a safe and effective technique in the hands of experienced surgeons. Benefits of LC in CD included reduced operative blood loss, quicker return of bowel function, and shorter hospital length of stay. Very similar results were found in studies published by Soop *et al*^[9], Tanaka *et al*^[10] and Kroesen *et al*^[11] who investigated the results of laparoscopic proctocolectomies with an incisionless technique.

For a long time it has been known that there is a higher leak rate in bowel resections for CD than for other benign conditions. In order to investigate the safety of laparoscopic (Lap) colorectal surgery as reflected by the anastomotic bowel leak (ABL) rate compared with that seen in open surgery, the Cleveland Clinic Foundation has recently evaluated its data^[12]. Between 2000 and 2007, 1516 consecutive patients undergoing laparoscopic surgery with bowel anastomosis were covariate-adjusted to 3258 patients undergoing open surgery by pathology and site of anastomosis using the institutional review board-approved laparoscopic, diverticular, Crohn's, and colorectal cancer databases. Of these patients, 643 patients in each group were equally matched by pathology, site of anastomosis, date of surgery, age, gender, and body mass index (BMI). The clinical ABL rate was compared between the two groups by the location of bowel anastomosis and year of surgery. A total of 4774 patients (1516 laparoscopic, 3258 open; mean age, 55.8 ± 17.4 years; BMI, 27.8 ± 6.2 kg/m²) underwent colorectal resection with bowel anastomosis (cancer 45.3%, Crohn's 29.6%, diverticulitis 12.3%, other 12.8%). There were no differences in the overall clinical ABL rates between laparoscopic (2.6%) and open procedures (2.1%, $P = 0.5$), between laparo-

scopic right *vs* open right ($P = 0.6$), between laparoscopic left *vs* open left ($P = 0.8$), and between patients operated on during different time periods ($P = 0.4$). For the case-matched 643 patients, there were no differences in clinical ABL rates between laparoscopic *vs* open groups based on site of anastomosis, pathology, and year of surgery. A laparoscopic colorectal approach was not associated with a higher risk of clinical ABL.

The largest unicentric study published until now comes from the Mount Sinai Hospital in New York City^[13]. The authors reviewed their experience with 335 laparoscopic resections for CD over the past 15 years in a retrospective analysis of a prospective database. The mean age of the patients was 39 years, 54% of the patients were women. In most cases, the indication for surgery was intestinal obstruction (73%) or abdominal pain (16%). The most common operation was primary ileocolic resection, performed for 178 cases (49%). Secondary ileocolic resections were performed for 20% and small bowel resections for 11% of the cases. Of the 117 patients with enteric fistulas, 45% had multiple fistulas. There were 80 enteroenteric, 51 ileosigmoid, 33 enteroabdominal wall, and 22 ileovesical fistulas. Multiple resections were performed for 33 patients (9%). Eight conversions occurred (2%), primarily because of large inflammatory masses involving the intestinal mesentery. The mean length of hospital stay was 5 d, and the mean operative time was 177 min (range, 62-400 min). There were no mortalities. The complications were primarily bowel obstruction, anastomotic leak, and postoperative bleeding, resulting in a postoperative complication rate of 13%.

Long-term results

The question has been raised for a long time if in laparoscopic resection for CD occult segments of disease may be missed at surgery and if the long-term result may be impaired this way. There had also been concerns if less of an immune response may be induced by laparoscopic methods compared with conventional surgery.

Long-term results of laparoscopically assisted *vs* open ileocolic resection for CD were evaluated in a randomized trial by Eshuis *et al.*^[14]. Sixty patients who underwent ileocolic resection between 1999 and 2003 were followed prospectively. Primary outcomes were reoperation, re-admission and repeat resection rates for recurrent CD. Secondary outcomes were quality of life (QOL), body image and cosmesis. Median follow-up was 6.7 years (interquartile range, 5.7-7.9 years). Sixteen of 29 and 16 of 26 patients remained relapse free after ileocolic resection in the laparoscopic and open groups, respectively. Resection of recurrent CD was necessary in two of 29 *vs* three of 26 patients. Overall reoperation rates for recurrent CD, incisional hernia and adhesion-related problems were two of 29 *vs* six of 26. QOL was similar, whereas body image and cosmesis scores were significantly higher after laparoscopy ($P = 0.029$ and $P < 0.001$, respectively). It was concluded that laparoscopic assisted ileocolic resection resulted in better body image and cosmesis, whereas open surgery was more likely

to produce incisional hernia and obstruction.

Long-term results of a prospective randomized study previously conducted at the Cleveland Clinic Foundation comparing laparoscopic (LC) and open ileocelectomy (OC) for ileocolic CD were published by Stocchi *et al.*^[15]. The purpose was to analyze long-term recurrence rates and complications. Follow-up data were available on 56 of 60 patients. Demographic data, recurrence rates, need for additional surgery related to primary procedure, and medication uses were recorded. Mean follow-up for 56 patients (27 LC *vs* 29 OC) was 10.5 years and comparable between LC and OC (10.0 *vs* 11.0, respectively, $P = 0.64$). One patient died 8 years after OC of causes unrelated to CD. One patient underwent incisional hernia repair after LC (4%) *vs* 4 patients (14%) after OC ($P = 0.61$). Two patients in the LC group underwent adhesiolysis *vs* none after OC ($P = 0.23$). Incidences of anorectal disease, anorectal surgery, endoscopic or radiologic recurrence, and medication use were also similar between LC and OC. OC patients requiring operation during follow-up were significantly more likely than LC to require multiple operations ($P = 0.006$). As a conclusion, long-term data confirmed that LC is at least comparable to OC in the treatment of ileocolic CD.

Complex CD

Goyer *et al.*^[16] analyzed in a prospective study the feasibility of laparoscopic ileocolonic resection for complex CD, i.e. recurrence or complication from abscess and/or fistula, and compared postoperative outcomes in patients with and without complex CD. During 10 years, 124 laparoscopic ileocolonic resections were attempted for CD: 54 patients with complex CD (group I) and 70 patients without complex CD (group II). Indications for surgery in group I included fistula (43%), abscess (30%), and recurrent disease after ileocolonic resection (27%). Complex CD was significantly associated with increased mean operative time (214 min *vs* 191 min, $P < 0.05$), increased conversion rate to open procedure (37% *vs* 14%, $P < 0.01$), and increased use of temporary stoma (39% *vs* 9%, $P < 0.001$). No patients died. Overall postoperative morbidity was similar between both groups (17% *vs* 17%), including major surgical postoperative complications (7% *vs* 6%, $P = \text{NS}$). Mean hospital stay was not statistically different between both groups (8 d *vs* 7 d, $P = \text{NS}$). This large comparative study suggested that laparoscopic ileocolonic resection for complex CD was feasible and safe with good postoperative outcomes.

Recurrent disease

Laparoscopic surgery is increasingly performed for primary, especially ileocolic CD, but its application in patients with recurrent disease is less well described. The aim of a study of the Mayo Clinic^[17] was to assess the safety, feasibility and potential short-term benefits of a laparoscopic approach. Patients undergoing laparoscopic surgery for recurrent ileocolic disease were identified using a prospectively maintained database. Potential risk factors for con-

version to open surgery and overall patient outcomes were assessed with univariate analysis. Forty patients were identified, of which 30 (75%) were completed laparoscopically and 10 (25%) were converted to open surgery. The groups did not differ with respect to clinicopathological features. Converted patients were significantly more likely to require adhesiolysis (100% *vs* 67%, $P = 0.04$). The groups did not differ with respect to incidence of postoperative complications or frequency of readmission within 30 d. There was no mortality. Conversion increased the length of stay in the hospital. Similar results were found by other authors^[18-20].

Hand-assisted surgery

Hand-assisted laparoscopic surgery (HALS) has gained clinical acceptance as a practical alternative to purely laparoscopically assisted surgery (LAP) for the surgical treatment of complex colorectal diseases like in IBD. Its role in challenging operations for CD (subtotal or total colectomy) has yet to be established. A recent study of Nakajima *et al.*^[21] aimed to evaluate the feasibility, safety, and potential benefit of HALS subtotal and total colectomy for Crohn's colitis. Thirty-eight consecutive patients who underwent subtotal or total colectomy as their initial abdominal surgery for Crohn's extensive colitis (involvement of 3 or more colonic segments) were evaluated. The patients were divided into three groups (open, LAP, and HALS), and their background and postoperative data were retrospectively analyzed. The reviews included 14 open, 6 LAP, and 18 HALS cases. The groups were comparable in terms of age at surgery, gender, BMI, extent and type of disease, indications, and procedures. The median operative time was significantly longer for LAP (330 min; range, 154-540 min) than for HALS (251 min; range, 165-340 min) or open surgery (200 min; range, 172-315 min). The blood loss was significantly less with LAP (170 mL; range, 115-257 mL) and HALS (225 mL; range, 35-890 mL) than with open surgery (438 mL; range, 280-780 mL). No difference was seen in postoperative complications, and no mortality occurred in the series. The authors concluded that HALS subtotal and total colectomies were feasible and safe. The HALS procedure seemed potentially beneficial for patients with extensive Crohn's colitis by reducing the operative time for laparoscopic surgery while retaining its less invasive nature.

Laparoscopic resection and transcolonic specimen retrieval

Recently, in numerous surgical meetings, "natural-orifice transluminal endoscopic surgery" and "single-incision laparoscopic surgery" have moved into the focus of interest. Either no or maximally one abdominal port incision are necessary for this. It has been demonstrated that ileocolic resection for CD is feasible entirely laparoscopically. However, normally, an incision is needed for specimen extraction (minilaparotomy). Eshuis *et al.*^[22] recently reported an early observational study assessing the feasibility of endoscopic transcolonic specimen removal avoiding any type of minilaparotomy. Endoscopic specimen removal was attempted in a consecutive series of ten

patients scheduled for laparoscopic ileocolic resection. Primary outcomes were feasibility, operating time, reoperation rate, pain scores, morphine requirement and hospital stay. To assess applicability, outcomes were compared with previous data from patients who had laparoscopic assisted operations. Transcolonic removal was successful in eight of ten patients; it was considered not feasible in two patients because the inflammatory mass was too large (7-8 cm). Median operating time was 208 min and median postoperative hospital stay was 5 d. After surgery, two patients developed an intra-abdominal abscess, drained laparoscopically or percutaneously, and one patient had another site-specific infection. The operation took longer than conventional laparoscopy, with no benefits perceived by patients in terms of cosmesis or body image. The authors concluded that transcolonic removal of the specimen in ileocolic CD was feasible in the absence of a large inflammatory mass but infection might be a problem. It could not be stated that the technique offered any benefits compared with conventional laparoscopic surgery.

Influence of body weight

In obese patients, laparoscopic techniques may be impaired by difficulties in creating a sufficient pneumoperitoneum and by worse visualisation of the regular anatomy caused by masses of fatty tissue. At the Cleveland Clinic Florida^[23] a retrospective study of prospectively collected data was designed to evaluate the results of laparoscopic colorectal resections in normal weight patients compared with overweight and obese patients with IBD. All consecutive patients with IBD who underwent laparoscopy in 8 years were reviewed. BMI, age, gender, comorbidities, ASA classification, and surgical- and disease-related variables, including 60-d postoperative complications, were reviewed. A total of 213 patients were analyzed. Group I comprised 127 normal-weight patients (BMI, 18.5-24.9 kg/m²), and group II included 67 overweight patients (BMI, 25-29.9 kg/m²) and 19 obese patients (BMI ≥ 30 kg/m²). Procedures performed included ileocolic resection in 56% of patients in each group. Total colectomy with or without proctectomy was undertaken in 39.4% in group I and 40.7% in group II. The conversion rate was 18% for group I and 22.09% for group II ($P > 0.005$; not significant). The most common reason for conversion was failure to progress due to adhesions or phlegmon. There were no differences in major postoperative complication rates (wound infection, abscess, anastomotic leakage, or small-bowel obstruction) or mean hospital stay (6.7, 6.8, respectively), and there was no mortality. These results demonstrated that the benefits of laparoscopic bowel resection should not be denied to overweight or obese patients based strictly on their BMI.

Nationwide study

The fact that the laparoscopic approach to CD has demonstrated benefits in several small series was an incentive for Lesperance *et al.*^[24] to examine its use and outcomes on a national level in the United States. A variety of patient-

and system-related factors were identified to influence the utilization of laparoscopy in CD. All admissions with a diagnosis of CD requiring bowel resection were selected from the 2000-2004 Nationwide Inpatient Sample. Regression analyses were used to compare outcome measures and identify independent predictors of undergoing laparoscopy. Of 396 911 patients admitted for CD, 49 609 (12%) required surgical treatment. They were predominantly Caucasian (64%), female (54%), and with ileocolic disease (72%). Laparoscopic resection was performed in 2826 cases (6%) and was associated with lower complications (8% *vs* 16%), shorter length of stay (6 d *vs* 9 d), lower charges (\$27 575 *vs* \$38 713), and mortality (0.2% *vs* 0.9%, all $P < 0.01$). Open surgery was used more often for fistulas (8% *vs* 1%) and when ostomies were required (12% *vs* 7%). Independent predictors of laparoscopic resection were age < 35 [odds ratio (OR) = 2.4], female gender (OR = 1.4), admission to a teaching hospital (OR = 1.2), ileocecal location (OR = 1.5), and lower disease stage (OR = 1.1, all $P < 0.05$). Ethnic category, insurance status, and type of admission (elective *vs* non-elective) were not associated with operative method ($P > 0.05$). In conclusion, laparoscopic resection was associated with excellent short-term outcomes compared to open surgery.

Meta-analyses

Several meta-analyses about the impact of laparoscopic surgery in CD have been published^[25-29]. Tan's most recent study was designed to determine the safety and feasibility of laparoscopic surgery in CD. A search of published studies in English between January 1990 and February 2006 was performed by using the MEDLINE and PubMed databases and the Cochrane Central Register of Controlled Trials. The studies were reviewed by two independent assessors. The rate of conversion from laparoscopic to open surgery was 11.2%. Laparoscopic procedures took longer to perform compared with open procedures, with a weighted mean difference of 25.54 min ($P = 0.03$). Patients who underwent laparoscopic surgery had a more rapid recovery of bowel function, with a weighted mean difference of 0.75 d ($P = 0.02$) and were able to tolerate oral intake earlier, with a weighted mean difference of 1.43 d ($P = 0.0008$). The duration of hospitalization was shorter, with a weighted mean difference of 1.82 d ($P = 0.02$). Morbidity was lower for laparoscopic procedures compared with open procedures (OR = 0.57, 95% CI: 0.37-0.87, $P = 0.01$). The rate of disease recurrence was similar for both laparoscopic and open surgery.

In all meta-analyses published to date, laparoscopic surgery for CD took longer to perform, but significant short-term benefits to the patient were observed. The morbidity was lower and the rate of disease recurrence was similar. Therefore, laparoscopic surgery for CD proved to be safely feasible.

UC

Under elective conditions, today, restorative procto-

colectomy with ileal J-pouch formation is the standard of surgery. In the early 1990s, initial experiences with a laparoscopic management were reported. However, these first results did not seem very promising, the laparoscopic technique in these comprehensive operations appeared too difficult to apply, too time-consuming, and comorbidity was too high^[30-33]. In the meantime, multiple technical innovations which have been introduced and increased surgical experience have advanced the field of complex surgery. In recent studies, more favourable results have been stated. Earlier return of bowel movements and shorter hospital stays have been observed in patients undergoing laparoscopy^[34-37]. In other studies, even more benefits like reduced pain, decreased morbidity and hospital stay, improved nutrition, preservation of immune response and decreased short and long-term complications have been observed. Functional outcomes and quality-of-life measurements have been comparable^[38-40]. Long operative times and learning curves, however, are still delaying a universal application of laparoscopy in the surgical management of UC^[41]. Boller *et al.*^[42] suggested breaking down comprehensive operations like the IPAA procedure in a stepwise fashion to simplify their complexity and allow the young surgeon to effectively reproduce this operation. The approach becomes viable by outlining the single steps in a systematic manner.

Early postoperative results

Total proctocolectomy with Brooke ileostomy has remained the classical traditional operation, also as a reserve for cases where an ileal pouch is not feasible or advisable. However, hardly any studies describe outcomes after the minimally invasive approach. Holubar *et al.*^[43] analyzed the safety and feasibility of these procedures by examining short-term (30-d) outcomes. Using a prospective database at the Mayo Clinic, a cohort of patients who underwent laparoscopic total proctocolectomy with Brooke ileostomy during 8 years was identified. Forty-four patients were included. Colitis duration was 66 mo (24-240 mo), and 40% had prior surgery. The indication for surgery was refractory colitis (82%) and neoplasia (18%). Factors influencing choice of total proctocolectomy with permanent ileostomy were advanced age in 18 (41%), lifestyle in 13 (30%), medical comorbidities in 11 (25%), fecal incontinence in 10 (23%), oncologic reasons in 3 (6.8%), and obesity in 3 (6.8%). Twenty-three (52%) operations were hand-assisted laparoscopic surgeries, 13 (30%) were laparoscopic-assisted, and 8 (18%) were "laparoscopic-incisionless" with transanal specimen extraction. Two laparoscopic-assisted cases (4.6%) were converted. Operative time was 329 (272-402) min, and length of stay 5 (4-6) d. Major post-operative complications occurred in 4 (9%); there were no perioperative mortalities.

At the same institution, a study was designed to compare short-term outcomes after laparoscopic IPAA with those of open IPAA in patients with both sclerosing cholangitis and UC^[44]. Sixteen patients with sclerosing cholangitis and UC undergoing laparoscopic IPAA were

matched with 16 open ileal pouch control subjects by sex, American Society of Anesthesiologists' score, age, and BMI. Operative mortality was zero. Operative time was longer in the laparoscopic group. Thirty-day complications were not significantly different between groups, but length of stay was significantly shorter in the laparoscopic group. Average return of gastrointestinal function was 2.5 d in the laparoscopic group and 4.8 d in the open group ($P = 0.001$). Time to soft diet was 3 d in the laparoscopic group and 6 d in the open group ($P < 0.001$). All patients were alive and all pouches were intact at last follow-up.

Satisfying mid-term outcomes have been reported in a series by Berdah *et al*⁴⁵. His prospective study aimed to analyze the functional outcome after a two-stage laparoscopic total proctocolectomy with IPAA. Over 9 years, 68 consecutive two-stage laparoscopic total proctocolectomies with IPAA were performed (UC: $n = 61$; familial adenomatous polyposis: $n = 7$). A covering ileostomy was used in all patients. Forty patients whose covering ileostomy had been closed for a minimum of 2 years were included in this series. Conversion to laparotomy was necessary in 4 of 40 patients (10%). Thirteen postoperative complications occurred in 13 of 40 patients (30%). At a median follow-up of 38 mo (range, 26-90 mo), the median number of bowel movements was 4 per 24 h (range, 2-10); 15 patients (38%) had no nighttime bowel movements. None of the patients had fecal incontinence or urgency. Thirty-four of the 40 patients (85%) experienced no soiling. Seven patients (18%) took regular antidiarrheal medication. All patients were able to resume all activities practiced prior to illness onset, and 36 of 40 (90%) were satisfied with their overall QOL (very good or good).

Long-term results

In contrast to short term results, long-term outcomes after laparoscopic IPAA have not been evaluated thoroughly. In a study published by Fichera *et al*⁴⁶, short- and long-term results were compared prospectively. During 5 years, 73 laparoscopic and 106 open IPAA patients were enrolled. There were no differences in demographics, treatment, indication, duration of surgery, and diversion between groups. Laparoscopic patients had faster return of flatus ($P = 0.008$), faster resumption of a liquid diet ($P < 0.001$), and less blood loss ($P = 0.026$). While complications were similar, the incidence of incisional hernias was lower in the laparoscopic group ($P = 0.011$). Mean follow-up was 24.8 mo. The average number of bowel movements was 6.8 ± 2.8 per day for laparoscopy and 6.3 ± 1.7 for open ($P = 0.058$). Overall, 68.4% of patients were fully continent at 1 year, up to 83.7% long term without differences between groups. Other indicators of defecatory function and QOL remained similar over time.

Self-reported sexual function, body image and QOL after laparoscopic and open IPAA were compared and analyzed in a study by Larson *et al*⁴⁷. At the Mayo Clinic, between 1978 and 2004, 100 laparoscopic and 189 open operations were performed in patients who were identi-

fied from a previously published cohort. Patients were surveyed 1 year after operation to evaluate sexual function, body image, and QOL. A total of 125 of 289 patients (43%) returned completed surveys. There were no significant differences in terms of demographics, complications, or long-term functional outcomes between those who completed the surveys and those who did not. There were no clinical differences in results between laparoscopic and open patients using the three survey instruments. Orgasmic function scores were lower in men who underwent laparoscopic IPAA ($P < 0.05$) compared with open IPAA. Overall, sexual function scores were equal to or better than normal values for men but were lower in women. Finally, overall body image and QOL scores were above the means published for the United States.

Postoperative adhesions are an expected outcome for the majority of open abdominal operations. Adhesions are responsible for more than 75% of small bowel obstruction cases. Another study from the Mayo Clinic⁴⁸ was initiated to evaluate adhesions to the anterior abdominal wall and adnexal organs after laparoscopic IPAA. Patients who underwent laparoscopic IPAA for UC had laparoscopic evaluation of adhesions at loop ileostomy closure for assessment of adhesions to the anterior abdominal wall and for adhesions to the adnexae in the case of women. Adhesions to the adnexae were quantified using the American Fertility Society adhesion score. Data were maintained prospectively. In this study, 34 patients (21 women) ranging in age from 19 to 78 years (median, 36 years) underwent laparoscopic IPAA. Twenty-three patients (68%) had no adhesions to the anterior abdominal wall, and the remaining 11 patients had few adhesions (filmy, avascular). No patients had dense adhesions to the abdominal wall. Of the 21 women, 15 (71%) had no adnexal adhesions, 5 had filmy adhesions enclosing less than one-third one adnexa, and one had filmy adhesions enclosing one-third to two-thirds of one adnexa. No patient had adhesions affecting both adnexae. It was concluded that laparoscopic IPAA results in few adhesions to the anterior abdominal wall or to gynecologic organs. These adhesions were significantly fewer than previously reported for open operations with or without the use of a glycerol hyaluronate/carboxymethylcellulose bioresorbable adhesion barrier.

Hand-assisted surgery

The role of hand-assistance in laparoscopic restorative proctocolectomies has not yet been defined. In a few comparative and randomized studies, hand-assisted laparoscopic restorative proctocolectomy (HALS-RP) maintained the advantages of a minimally invasive approach with some potential benefits. The aim of a study by Tsuruta *et al*⁴⁹ from Keio University in Tokyo was to evaluate the effectiveness of HALS-RP compared with a conventional laparoscopic restorative proctocolectomy (LAP-RP) in patients with UC. A retrospective study was conducted using a prospectively maintained database to compare a consecutive series of 30 patients who underwent HALS-

RP during 3 years with 40 patients who underwent LAP-RP during 10 years. Both groups were well matched. The median operative time was significantly shorter for HALS-RP [356 min (range, 176-590 min)] than for LAP-RP [505 min (range, 360-785 min), $P < 0.001$]. The median length of incision was significantly longer for HALS-RP [8 cm (range, 7.5-8 cm)] than for LAP-RP [5.5 cm (range, 5-8 cm)]. The estimated blood loss and the length of hospital stay were similar between the two groups. The incidence of postoperative complications including anastomotic leakage did not differ between the both groups ($P = 0.437$).

Hand-assistance in emergency subtotal colectomies for cases of severe UC was analyzed by Watanabe *et al*^[50]. The medical records of 60 patients who underwent emergency subtotal colectomy with hand-assisted laparoscopic technique (30 cases) or open technique (30 cases) were reviewed. One patient in the laparoscopic group required conversion to open surgery. The median operative time was significantly longer in the laparoscopic group (242 min *vs* 191 min, $P < 0.001$). The rate of early postoperative complications in the laparoscopic group was significantly less than that in the open group (37% *vs* 63%, $P = 0.041$). In the open group, four patients required relaparotomy because of peritoneal abscess or strangulation ileus, whereas no patient required relaparotomy in the laparoscopic group ($P = 0.040$). HALS was found to be an acceptable alternative to conventional open surgery.

Fulminant colitis and emergency surgery

Several institutions have published their data about their experience with minimally-invasive procedures applied in emergency cases. At the Mayo Clinic, safety, feasibility, and short-term outcomes of three-stage minimally invasive surgery for fulminant UC were evaluated^[51]. All patients with UC who underwent minimally invasive surgery for both subtotal colectomy and subsequent IPAA from 2000 to 2007 were identified. Fifty patients underwent minimally invasive subtotal colectomy for fulminant UC; 50% were male, with a median age of 34 years. All patients had refractory colitis: 96% were taking steroids, 76% were recently hospitalized, 59% had ≥ 5 kg weight loss, 57% had anemia that required transfusions, 30% were on biologic-based therapy, and 96% had ≥ 1 severe Truelove and Witts' criteria. Of these 50 procedures, 72% were performed by using laparoscopic-assisted and 28% with hand-assisted techniques. The conversion rate was 6%. Subsequently, minimally invasive completion proctectomy with IPAA was performed in 42 patients with a 2.3% conversion rate. Median length of stay after each procedure was 4 d. There was one anastomotic leak and no mortality.

At Washington University in St. Louis, short-term outcomes of laparoscopic *vs* open total abdominal colectomy and end ileostomy for severe UC were investigated^[52]. The impact of the initial surgical approach on subsequent operations for three-stage restorative proctocolectomy was evaluated. Thirty-seven patients underwent laparoscopic, 41 open total abdominal colectomy at the initial stage of

a three-stage restorative proctocolectomy. Each stage was analyzed independently by using two-tailed *t*-tests and analysis of covariance. The laparoscopic total abdominal colectomy patients underwent subsequent restorative proctectomy 49 d sooner ($P = 0.0044$) and ileostomy closure 17 d sooner ($P = 0.00003$) than the open total abdominal colectomy patients. Laparoscopic abdominal colectomy for severe UC in selected patients was safe and associated with short-term benefits that may lead to faster recovery and progression to completion of restorative proctocolectomy.

In a very similar retrospective review of 90 patients at the Mount Sinai Hospital in New York City, laparoscopic subtotal colectomy was safely feasible and conferred the benefits of improved cosmesis, reduced intraoperative blood loss and shorter hospital stay^[53].

Comparing patients' outcome after laparoscopic IPAA with and without previous emergency subtotal colectomy, McAllister *et al*^[54] found the pouch procedure not only safely feasible in the virgin abdomen but also in patients with previous OC.

Several studies suggested that infliximab may increase postoperative complication rates for patients who later require a restorative proctocolectomy with IPAA. This question was investigated in a study by Coquet-Reinier *et al*^[55] aimed to assess the postoperative course of patients after laparoscopic IPAA, comparing those who had and those who had not received infliximab before surgery. No significant difference was found between patients treated with and those treated without infliximab for mean operative time (353 min *vs* 355 min), complication rate (23% *vs* 38%), and mean hospital stay (22 d *vs* 25 d). No adverse impact from previous infliximab therapy on the laparoscopic IPAA postoperative course was detected.

Meta-analysis and cochrane review

Wu *et al*^[56,57] published a meta-analysis comprising sixteen controlled trials. There was only one prospective randomized study among the studies selected. Outcome effects of laparoscopic and open surgery were pooled. A fixed effect model or random effect model was respectively used depending on the heterogeneity test of trials. Postoperative fasting time and postoperative hospital stay were shorter in laparoscopic surgery for UC [-1.37 (-2.15, -0.58), -3.22 (-4.20, -2.24), respectively, $P < 0.05$]. The overall complication rate was higher in open surgery, compared with laparoscopic surgery (54.8% *vs* 39.3%, $P = 0.004$). However, duration of laparoscopic surgery for UC was extended compared with open surgery (weighted mean difference 69.29 min, $P = 0.04$). As to recovery of bowel function, as indicated by peritoneal abscess, anastomotic leakage, postoperative bowel obstruction, wound infection, blood loss, and mortality, laparoscopic surgery did not show any superiority over open surgery. Re-operation rate was almost even (5.2% *vs* 7.3%). The whole conversion to open surgery was 4.2%.

The presumed benefits of the laparoscopic approach were analyzed systematically in a Cochrane review by

Table 1 Overview of most important study results dealing with laparoscopic and open surgical management of inflammatory bowel diseases

| Author | Yr | Patients | Findings |
|---|------|---|---|
| Crohn's disease | | | |
| Umanskiy <i>et al</i> ^[8] | 2010 | 55 lap colect 70 open colect | Early postop. results favourable for laparoscopy |
| El-Gazzaz <i>et al</i> ^[12] | 2010 | 643 matched cases open and laparosc | Anastomotic leak rates even for open and lap surgery |
| Nguyen <i>et al</i> ^[13] | 2009 | 335 laparoscopic | Postop compl. rate 13% (leaks, obstruction, bleeding) |
| Eshuis <i>et al</i> ^[14] | 2010 | 29 laparoscopic 26 open | Better cosmesis for laparoscopy, more hernias and obstructions in open surgery |
| Stocchi <i>et al</i> ^[15] | 2008 | Follow-up, randomized study 27 lap, 29 open | Open colectomy patients significantly more frequently requiring multiple reoperations, otherwise results similar |
| Goyer <i>et al</i> ^[16] | 2009 | 54, complex CD 70, uncomplicated | In complex disease, significantly longer OR time, conversion rate and stoma frequency |
| Holubar <i>et al</i> ^[17] | 2010 | 30 lap completed 10 converted | Significantly more adhesions and length of stay in conversion, complication rates even |
| Nakajima <i>et al</i> ^[21] | 2010 | 14 open 6 lap 18 hand-assisted | Significantly longer OR time in laparoscopic cases, significantly less blood loss in lap. and hand-assisted cases |
| Canedo <i>et al</i> ^[23] | 2010 | 127 BMI < 25 kg/m ² 67 BMI > 25 kg/m ² , < 30 kg/m ² 19 BMI > 30 kg/m ² | More conversions in obesity, no differences in postop. complications and hospital stays |
| Lesperance <i>et al</i> ^[24] | 2009 | Nationwide study 49.609 surg. cases 2.826 lap cases | Less complications, shorter hospital stays, lower charges and mortality in laparoscopy, applied mainly in younger female patients with ileocecal disease at lower stage |
| Tan <i>et al</i> ^[25] | 2007 | Metaanalysis 14 studies 881 patients | Conversion rate 11.2%, lap. surgery with significantly longer OR time, more rapid recovery, shorter hospital stay and lower morbidity, similar recurrence rates |
| Ulcerative colitis | | | |
| Holubar <i>et al</i> ^[43] | 2009 | Total proctocolect 23 hand-assisted 13 lap-assisted 8 lap-"incisionless" | Median OR time 329 min, hospital stay 5 d, major complications in 9%, no mortality |
| Berdah <i>et al</i> ^[45] | 2009 | 68 RPC + pouch | 30% complication rate, all patients resuming preop. grade of activity, 90% satisfaction "good/very good" |
| Fichera <i>et al</i> ^[46] | 2009 | RPC + pouch 73 lap, 106 open | In laparoscopy, faster resumption of bowel function, less blood loss and lower rate of hernias in follow-up |
| Larson <i>et al</i> ^[47] | 2008 | RPC + pouch 100 lap, 189 open | Long-term data, worse sexual functional results in lap. cases, better body image and quality of life |
| Indar <i>et al</i> ^[48] | 2008 | 34, RPC + pouch | Adhesion evaluation at ileostomy closure : 68% no and 32% few adhesions, lower than in open surgery |
| Tsuruta <i>et al</i> ^[49] | 2009 | 30, HALS-RPC 40, Lap-RPC | OR time significantly longer for lap-RPC, incision length significantly longer for HALS-RPC |
| Watanabe <i>et al</i> ^[50] | 2009 | Emergency colect 30 HALS, 30 open | For HALS, OR time significantly longer, postop. complication rate significantly lower |
| Holubar <i>et al</i> ^[51] | 2009 | Fulminant colitis, 36 lap-assist. colect | Conversion rate 6%, median lengths of stay 4 d in both 14 HALS colect. groups, subsequent completion proctectomy in 42 pat |
| Chung <i>et al</i> ^[52] | 2009 | Severe UC 37 lap., 41 open | Faster recovery and progression to completion of RPC in lap. colectomies patients |
| Wu <i>et al</i> ^[56,57] | 2008 | Metaanalysis | Overall complication rate higher in open surgery duration of lap surgery significantly extended |
| Ahmed Ali <i>et al</i> ^[58] | 2010 | 16 controlled trials | OR time significantly longer in lap. surgery, no differences in postop. course or recovery between lap. and open procedures |
| Ahmed Ali <i>et al</i> ^[58] | 2009 | Cochrane review 11 studies, 607 pat 253 laparoscopic | |

CD: Crohn's disease; UC: Ulcerative colitis; OR: Operation room; BMI: Body mass index; HALS: Hand-assisted laparoscopic surgery; RPC: Restorative proctocolectomy.

Ahmed Ali *et al*^[58]. The aim was to compare the beneficial and harmful effects of laparoscopic *vs* open IPAA for patients with UC and FAP. The authors searched The Cochrane IBD/FBD Group Specialized Trial Register (April 2007), The Cochrane Library (Issue 1, 2007), MEDLINE (1990 to April 2007), EMBASE (1990 to April 2007), ISI Web of Knowledge (1990 to April 2007) and the

web casts of the American Society of Colon and Rectal Surgeons (up to 2006) for all trials comparing open *vs* laparoscopic IPAA. All trials in patients with UC or FAP comparing any kind of laparoscopic IPAA *vs* open IPAA were included. No language limitations were applied. Two authors independently performed selection of trials and data extraction. The methodological quality of all included

trials was evaluated to assess bias risk. Analysis of randomized and non-randomized controlled trials was performed separately. Analyses were based on the intention-to-treat principle. Sensitivity and subgroup analyses were performed if appropriate. Eleven trials were identified which included 607 patients, of whom 253 (41%) were in the laparoscopic IPAA group. Only one of the included trials was a randomized controlled trial. There were no significant differences in mortality or complications between the two groups. Reoperation and readmission rates were not significantly different. Operative time was significantly longer in the laparoscopic group both in the randomized and meta-analysis of non-randomized controlled trials (weighted mean difference 91 min). There were no significant differences between the two groups regarding postoperative recovery parameters. Total incision length was significantly shorter in the laparoscopic group, while two trials evaluating cosmesis found significantly higher cosmesis scores in the laparoscopic group. Short-term advantages of the laparoscopic approach seemed to be limited and their clinical significance arguable.

Table 1 summarizes the most important study results dealing with laparoscopic and open surgical management of inflammatory bowel diseases.

CONCLUSION

Laparoscopic surgery for CD has been established in numerous major centers. A wide range of procedures may be performed laparoscopically from stoma formation to extended colon and small bowel resections. The minimally-invasive approach shows short-term advantages in complex cases with previous conventional operations, recurrences, enteric fistula and abscess formations. Only limited indications or contraindications may be seen in cases like ileus where no sufficient visualization is obtained during laparoscopy and in acute and fulminant cases demanding a quick and safe surgical solution of the emergency situation. The size of the specimen which needs to be removed may restrict any type of minimally-invasive approach in extended disease.

In UC, laparoscopic restorative proctocolectomy with IPAA is carried out in major surgical centers for elective surgery, but also in cancer and emergency cases. Short and long-term results are comparable to open surgery; in some studies shorter hospital stays and earlier postoperative recovery have been observed. Long operative times and the long learning curve are still factors restricting a broad use of the minimally-invasive approach. A considerable variety of individual laparoscopic techniques is still being observed among different institutions. An important task for future studies will be the analysis of which case selection has the best benefit from a laparoscopic approach in inflammatory bowel diseases.

Abstract

AIM: To investigate predilection sites of recurrence of pancreatic cancer by computed tomography (CT) in follow-up after surgery.

METHODS: Seventy seven patients with recurrence after pancreatic cancer surgery were retrospectively identified. The operative technique, R-status, T-stage and development of tumor markers were evaluated. Two radiologists analyzed CT scans with consensus readings. Location of local recurrence, lymph node recurrence and organ metastases were noted. Surgery and progression of findings on follow-up CT were con-

sidered as reference standard.

RESULTS: The mean follow-up interval was 3.9 ± 1.8 mo, with a mean relapse-free interval of 12.9 ± 10.4 mo. The predominant site of recurrence was local (65%), followed by lymph node (17%), liver metastasis (11%) and peritoneal carcinosis (7%). Local recurrence emerged at the superior mesenteric artery ($n = 28$), the hepatic artery ($n = 8$), in an area defined by the surrounding vessels: celiac trunk, portal vein, inferior vena cava ($n = 22$), and in a space limited by the mesenteric artery, portal vein and inferior vena cava ($n = 17$). Lymph node recurrence occurred in the mesenteric root and left lateral to the aorta. Recurrence was confirmed by surgery ($n = 22$) and follow-up CT ($n = 55$). Tumor markers [carbohydrate antigen 19-9 (CA19-9), carcinoembryonic antigen (CEA)] increased in accordance with signs of recurrence in most cases (86% CA19-9; 79.2% CEA).

CONCLUSION: Specific changes of local and lymph node recurrence can be found in the course of the cardinal peripancreatic vessels. The superior mesenteric artery is the leading structure for recurrence.

INTRODUCTION

Pancreatic cancer is a disease with a poor survival rate after curative surgical therapy^[1]. Local recurrence after resection with curative intent is frequently observed within 2 years for the majority of patients^[2]. The median survival in resectable pancreatic cancer is reported to range from 11 mo for surgery alone to 20 mo for surgery in combination with adjuvant chemotherapy^[3-6]. These data are reflected by a 5-year survival rate of 10%-25%^[7,8]. The mean disease-free period in imaging studies is 267 ± 158 d with negative surgical margins but 72 ± 47 d with positive margins^[9].

So far there have not been many imaging studies in the literature focusing on detection of pancreatic cancer recurrence. One reason may be that recurrence of pancreatic cancer was not treated, but in recent years radiochemotherapy and, in rare cases, surgery for local recurrence has been advocated^[10]. A major problem in patients with pancreatic cancer is that extensive postoperative changes with scar tissue formation as well as lymph node enlargement are present after surgical therapy that may be mistaken for disease recurrence^[11]. This study was conducted to investigate whether recurrence of pancreatic cancer shows a specific pattern of regrowth on regular follow-up computed tomography (CT) examinations after surgery. The goal was to identify predilection sites of recurrence on CT in the follow-up of pancreatic cancer surgery.

MATERIALS AND METHODS

This retrospective study was approved by the local ethics committee.

Patients

A total of 641 patients, who underwent surgery for a primary malignant tumor of the pancreas in a local surgical department from January 2002 to March 2007, were identified for this study. Of these, 245 had at least one follow-up CT in our department. In all patients with CT follow-up postoperative changes such as enlarged lymph nodes, and soft tissue formation in the resection area and along the cardinal mesenteric vessels were initially present. We excluded 168 patients because further consecutive follow-up CT imaging was not available. In 77 patients (47 male, 30 female; mean age: 67.8 years; range, 41-86 years) with a baseline CT examination 3-6 mo postoperatively, follow-up imaging revealed progression of soft tissue surrounding the peripancreatic vessels, progression of lymph nodes, or appearance of liver metastasis as an indication of tumor recurrence. All these patients also showed clinical signs of tumor recurrence with rising tumor marker levels and deterioration of their physical condition. Apart from 3 patients that

are alive to date, all other patients died in the course of further progression of tumor recurrence. Tumor and relevant surgical data including the operative technique, TNM stage, the R-status and the development of postoperative tumor markers were taken from the postoperative database of all pancreatic cancer patients (Table 1). If disease recurrence was detected on follow-up imaging, surgery was considered as standard of reference if performed. The surgical report as well as the histological workup was evaluated. If no surgery was performed the progression of findings on further follow-up imaging studies served as standard of reference.

Surgery for recurrence was performed in 22 cases confirming recurrence. In 55 cases no surgery was performed but further follow-up imaging by CT (*n* = 53) and by positron emission tomography (PET)-CT (*n* = 2) showed further progression of disease recurrence. In 9 patients a potential curative approach for surgery was pursued with 4 hemihepatectomies, 3 lymphadenectomies and 2 resections of the remnant pancreas. In 6 other patients a potential curative surgical approach was not feasible but intraoperative radiotherapy, and in one case a combination of radiochemotherapy with additional tumor reduction was performed. In all patients with a diagnosis of tumor recurrence, second line chemotherapy or radiation therapy was administered for disease control.

As tumor marker values during follow-up might have a great interindividual variability, the factor for the tumor marker increase over time was calculated from the value at the time of tumor recurrence divided by the initial postoperative (2-4 mo) value. In 48 cases tumor marker values for carcinoembryonic antigen (CEA) were measured during the initial postoperative period and the time of tumor recurrence; in 57 cases carbohydrate antigen 19-9 (CA19-9) levels were available.

Image evaluation

All image data were evaluated by two radiologists (with 5 and 10 years experience of pancreas imaging) on diagnostic workstations (Centricity PACS, GE, USA) with consensus readings. Disease recurrence was classified into local recurrence, lymph node recurrence, liver metastasis and peritoneal carcinosis. For each case, tumor recurrence could either appear as a singular finding, such as local recurrence, or as a combination, e.g. local recurrence and liver metastasis concurrently on follow-up imaging. The criteria for local disease recurrence were defined as a soft tissue formation that increased in size over time in the resection area or along the cardinal visceral vessels around the pancreatic bed. An increase in lymph node size over multiple follow-ups was classified as lymph node recurrence. Disease recurrence was classified as liver metastasis if the appearance of new liver lesions with specific image characteristics, e.g. irregular margins, hypodensity, was observed. Peritoneal carcinosis was considered as another possible form of disease recurrence if typical, e.g. nodal peritoneal, changes were present. The exact location of each form of disease recurrence was noted.

CT protocol

All patients were given 1-1.5 L of water orally prior to the examination. The standard hydro-pancreas protocol consists of an unenhanced (5 mm slice thickness/4 mm increment), arterial and venous phase (3 mm slice thickness/2 mm increment, axial and coronal reconstructions) imaging after injecting 130 mL contrast agent (Ultravist 370, Bayer-Schering, Berlin, Germany) at a flow rate of 5 mL/s via a cubital vein. Scanning was performed on different CT scanner generations with 4, 16, 64 slices (Volume Zoom, Sensation, Definition; Siemens, Forchheim, Germany).

Data analysis

All data are presented as absolute numbers and percentages. Statistical analysis was performed using the paired Student *t*-test and one-way analysis of variance test for tumor marker values with commercially available software (SPSS Statistics 17.0, SPSS Inc., Chicago, USA).

RESULTS

Patients

The mean follow-up time between CT examinations was

3.9 ± 1.8 mo (range, 2-12 mo). The mean relapse-free time interval was 12.9 ± 10.4 mo (range, 3-76 mo).

Tumor recurrence

In 55 cases a solitary presentation of tumor relapse was present and in 22 cases combinations of different types of tumor recurrence (*n* = 45) resulting in a total of 100 types of recurrence were present (Table 2). The predominant type of tumor recurrence was local recurrence in 65 cases (65%), with isolated manifestations in 43 cases and in combination with other types of tumor recurrence in 22 cases (Table 2). Lymph node recurrence (17%) was found in 6 cases as an isolated finding but in 11 cases in combination. Liver metastasis (11%) was commonly seen in combination with local recurrence and with isolated tumor presentation in 5 cases. Peritoneal carcinosis (7%) was, except for one case with an isolated manifestation, mainly associated with other forms of tumor recurrence. In cases where the initial resection status was R1, the most common tumor recurrence type was local recurrence in 8 cases, lymph node recurrence in one case, and in another case peritoneal carcinosis. The R2 status presented as local recurrence in all 5 cases.

Localization of tumor recurrence

Local recurrence was found most often along the superior mesenteric artery (SMA, *n* = 28), either as a localized tumor mass or as a diffuse cuff-like tissue formation (Figure 1). The second most common site for tumor recurrence (*n* = 22) was an area defined by the celiac trunk (cT) as the medial border, the portal vein (PV) as the anterior border and the inferior vena cava (IVC) as the dorsal border (Figure 2). This is followed by an area (*n* = 17) which is just caudal to the aforementioned space where the medial boundary is the SMA while the other limiting structures, the PV and IVC, remain the same. In 10 cases, tumor regrowth or a secondary tumor occurred at the resection margin of the residual pancreatic parenchyma. In 8 cases the tumor presented as a cuff-like tissue formation along the common or proper hepatic artery (HA). One case was identified with tumor recurrence in the very distal mesenteric root.

Lymph node recurrence was found in 12 cases in the mesenteric root mainly in close proximity to the superior mesenteric artery. In 5 cases, lymph node recurrence was found to the left of the aorta and in one case anterior to

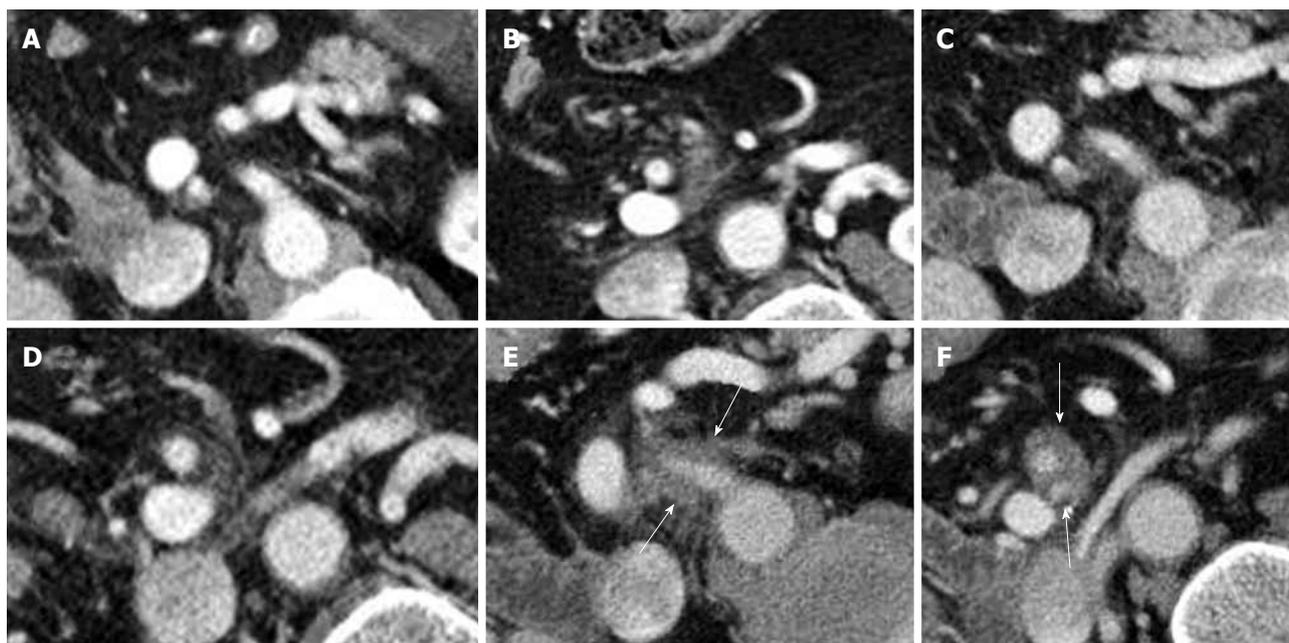

Figure 1 Computed tomography follow-up after Whipple's procedure for pancreatic cancer of the head in a 69-year-old patient (T3, N1). A, B: Follow-up imaging after 3 mo; C, D: 11 mo; E, F: 22 mo. Recurrence at the origin of the superior mesenteric artery (E) and more distally in the mesenteric root (F: white arrows).

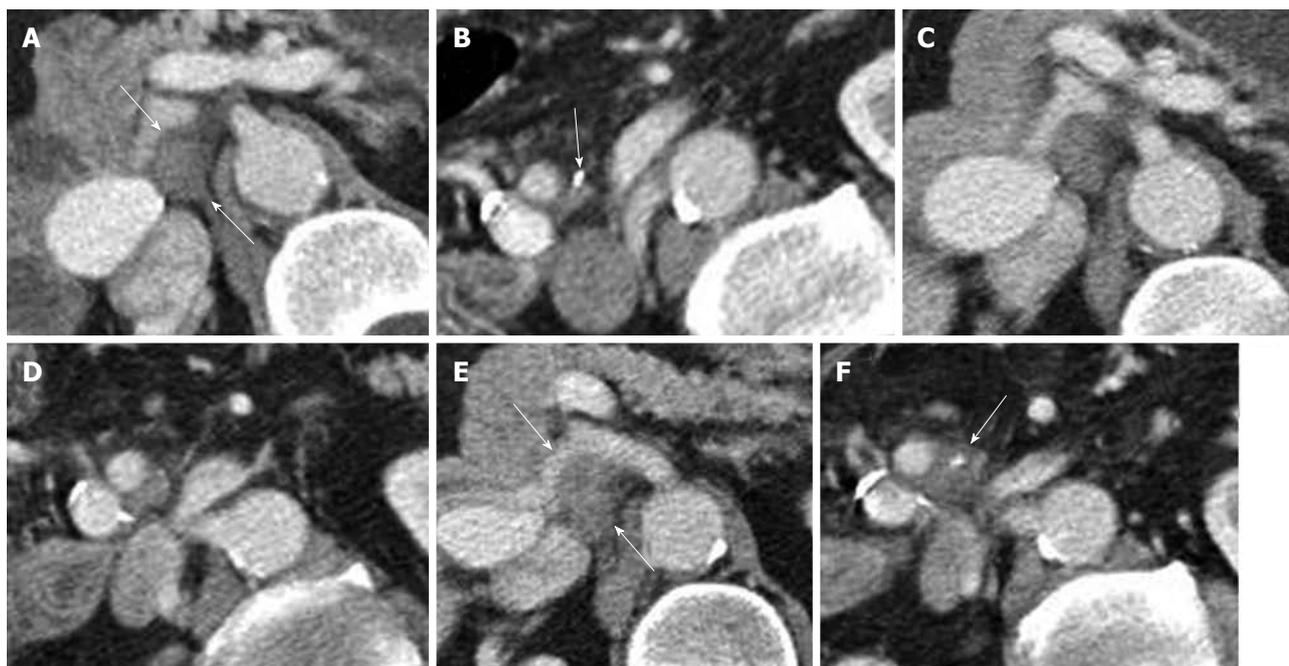

Figure 2 Sixty-eight-year-old patient after surgery for ductal adenocarcinoma of the pancreatic head (T3, N1). A, B: Follow-up imaging after 6 mo; C, D: 8 mo; E, F: 12 mo. Initial soft tissue formation (A, B: white arrows) with a carbohydrate antigen 19-9 (CA19-9) level of 9 U/mL increased (E, F: white arrows) with concurrent increase in CA 19-9 to 56 U/mL.

the aorta (Figure 3).

Tumor marker development

The mean initial postoperative tumor marker level for CEA was $3.12 \pm 2.7 \mu\text{g/L}$ and for CA19-9 was $66.98 \pm 501.2 \text{ U/mL}$. At the time of tumor recurrence, the mean value for CEA was $12.3 \pm 18.1 \mu\text{g/L}$ and for CA19-9 was $587.65 \pm 4475.4 \text{ U/mL}$. CEA tumor marker values at the time of tumor recurrence were significantly different

from the mean initial values ($P = 0.001$). The mean values of CA19-9 showed no significant differences in this comparison ($P = 0.067$). The mean factor for the tumor marker increase was 5.6 ± 1.6 for CEA and 51.5 ± 309.6 for CA19-9. There was no significant difference ($P > 0.05$) for mean tumor marker values of CEA and CA19-9 stratified by type of recurrence (Table 3), except for the level of CA19-9 in the case of an isolated appearance of liver metastasis compared with mean values in local recurrence

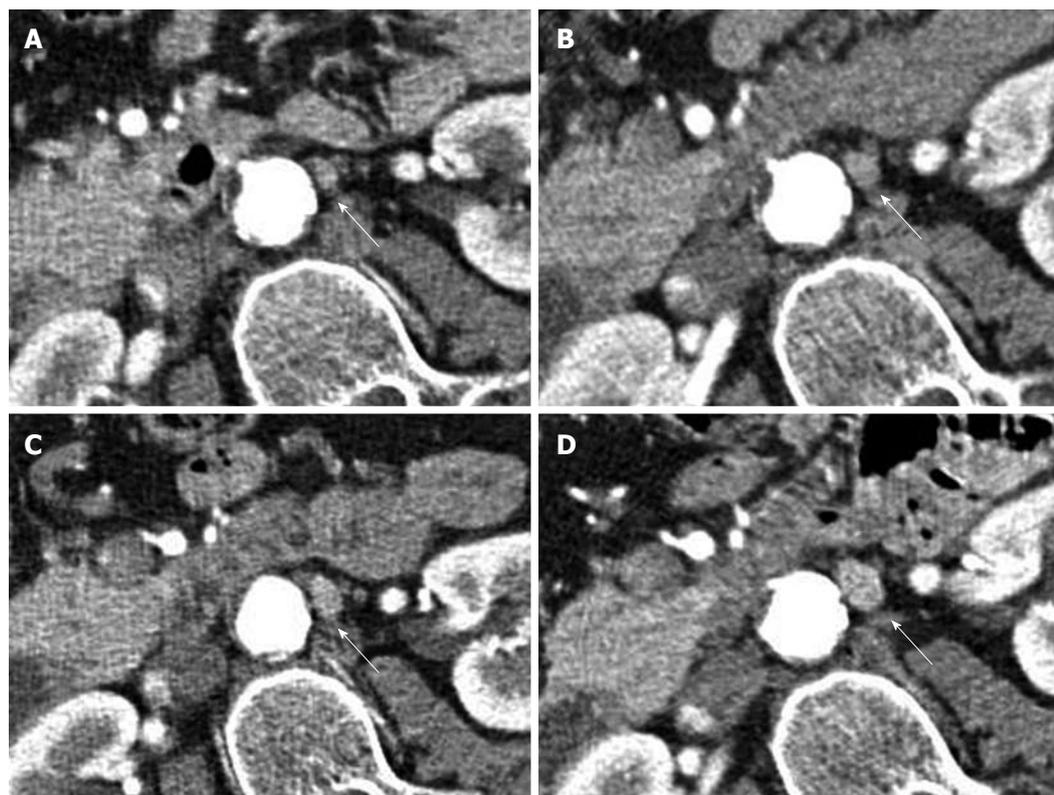

Figure 3 Sixty-year-old patient after resection of the pancreatic tail for a neuroendocrine carcinoma. Follow-up imaging after A : 4 mo; B: 7 mo; C: 9 mo; D: 12 mo. A normal size lymph node(white arrows) of 9 mm initially at the left of the aorta (A) increased to 16 mm (D) indicating lymph node recurrence.

Table 3 Mean tumor marker values at the time of recurrence stratified by type of recurrence

| Type of recurrence | Tumor marker | | | |
|-------------------------------|--------------|--------------------|----|---------------|
| | n | CA 19-9 (U/mL) | n | CEA (μg/L) |
| Local | 32 | 781.67 ± 2090.28 | 26 | 9.95 ± 15.57 |
| Lymph node | 5 | 244.02 ± 413.03 | 4 | 3.13 ± 2.35 |
| Liver metastasis | 5 | 6674.80 ± 14338.02 | 5 | 18.1 ± 18.26 |
| Local & lymph node | 7 | 399 ± 738.15 | 6 | 4.28 ± 4.03 |
| Local & liver metastasis | 5 | 1157.0 ± 1802.0 | 5 | 21.88 ± 26.76 |
| Local & peritoneal carcinosis | 3 | 351.0 ± 257.66 | 2 | 46.0 ± 39.6 |

No statistically significant differences in tumor markers between types of recurrence (one-way analysis of variance) except comparison of mean values of carbohydrate antigen 19-9 (CA19-9) for local recurrence and liver metastasis ($P = 0.025$, Student *t*-test). CEA: Carcinoembryonic antigen.

($P = 0.025$). The mean factor for the increase in CEA and CA19-9 values did not show any significant differences stratified by type of recurrence (Figure 4B and D). In a direct comparison of local recurrence with liver metastasis, there was a significant difference for both CEA and CA19-9 increase factors ($P < 0.05$). In 8 of 57 (14.0%) cases CA19-9 did not increase, and in 10 of 48 (20.8%) CEA values did not increase with detection of recurrence on CT scans.

DISCUSSION

This study indicated that a specific pattern of disease

recurrence in pancreatic cancer exists, especially of local recurrence, and that regular follow-up CT examinations are able to identify this pattern and detect recurrence in accordance with an increase in tumor markers (Figure 5).

To improve the prognosis of pancreatic cancer it is necessary to focus on the situation when tumor recurrence takes place. Second-line chemotherapy or radiotherapy in case of disease relapse seek to control tumor progression and improve the survival rate^[12]. In rare cases a potentially curative surgical approach for liver metastasis or local tumor recurrence was shown to be successful^[13-22].

It is essential to identify tumor recurrence early in order to offer patients further disease controlling measures or potentially curative options. Early intervention with chemotherapy in case of tumor recurrence has a higher chance of improving survival. The case for follow-up imaging is to identify tumor recurrence as early as possible in order to intervene appropriately. A major problem is that extensive postoperative changes, such as scar tissue formation, and enlarged and increased lymph nodes in the resection area are difficult to distinguish from real tumor relapse^[23].

Ruf *et al*^[24] compared ¹⁸F-fluorodeoxyglucose (FDG)-PET with CT/magnetic resonance imaging (MRI) in 25 patients with suspected disease recurrence and reported a 96% detection rate for FDG-PET in comparison to 39% with CT/MRI. Mortelé *et al*^[25] reported a diagnostic accuracy of 93.5% for CT in detecting recurrent pancreatic cancer, but pointed out that no predilection site for tumor recurrence was found in their series of 32 patients.

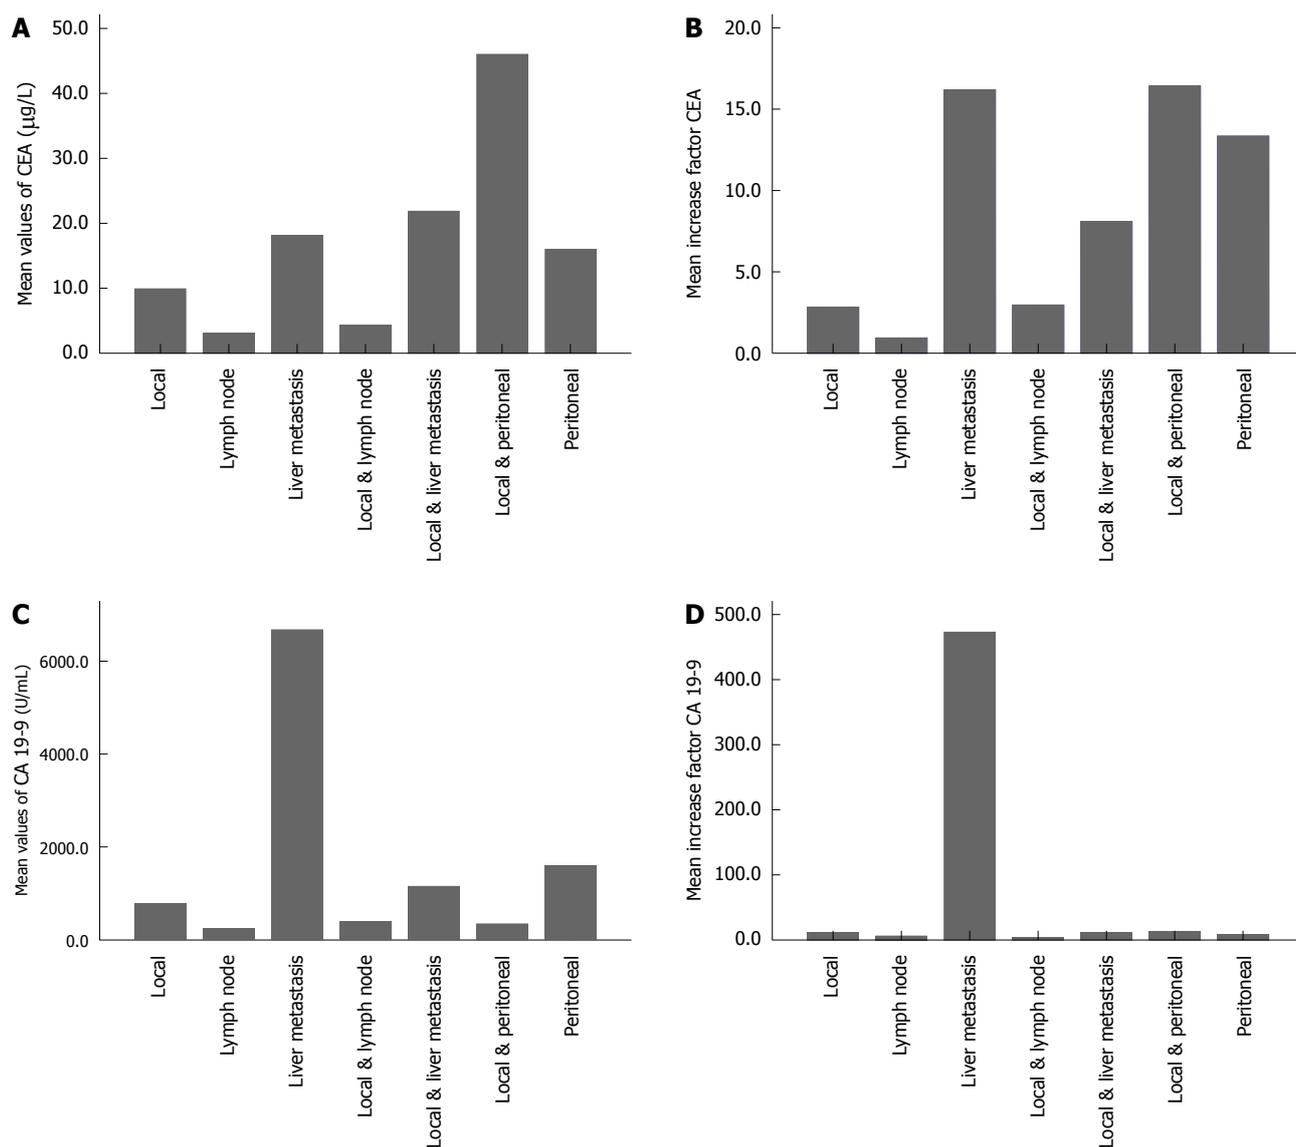

Figure 4 Bar graphs of mean values and mean increase factors for carcinoembryonic antigen and carbohydrate antigen 19-9 stratified by type of recurrence. A: Mean values of carcinoembryonic antigen (CEA) ($\mu\text{g/L}$) at the time of recurrence stratified by type of recurrence; B: Mean increase factor of CEA ($\mu\text{g/L}$) (values at the time of recurrence divided by initial values) stratified by type of recurrence; C: Mean values of carbohydrate antigen 19-9 (CA 19-9) (U/mL) at the time of recurrence stratified by type of recurrence; D: Mean increase factor of CA 19-9 (U/mL) (values at the time of recurrence divided by initial values) stratified by type of recurrence.

Coombs *et al*^[26] investigated 19 patients after pancreatoduodenectomy and detected tumor recurrence by follow-up CT in 12 patients. Larger studies on the diagnostic accuracy of follow-up imaging after surgical treatment for pancreatic cancer are lacking.

CT is a morphology-based imaging method and does not offer functional or metabolic information such as FDG-PET or PET-CT. Regular postoperative PET-CT imaging may be the optimal method to identify early tumor relapse but this modality is costly and not widely available. CT imaging does offer high resolution and artifact-free imaging which is widely available, safe and fast. In order to render CT the method of choice for follow-up of patients after surgery for pancreatic cancer there is a need to gather morphological information from follow-up studies to determine the pattern of disease recurrence.

Local pancreatic tumor re-growth spreads along the

cardinal visceral vessels, mainly the SMA and the HA, but can also present as a mass in specific spaces that are defined by the surrounding vasculature (SMA, HA, PV, IVC, cT). This behavior is consistent with the fact that pancreatic cancer is known to propagate along neurovascular structures on a histological level^[27]. Makino *et al*^[28] found a pattern of invasion into pancreatic and extrapancreatic nerve plexuses depending on the ventral or dorsal location of the tumor in the pancreatic head. Interestingly, in cases of invasion into the extrapancreatic nerve plexus of the SMA and HA, invasion to the adventitia of these vessels was a frequent finding. The distribution of local recurrence in the current study, which is primarily defined by the cardinal visceral vessels, may support speculations that tumor recurrence follows the same patterns of spread as the primary tumor. Noto *et al*^[29] investigated the SMA in 6 patients with *en bloc* resection of the pancreatic head

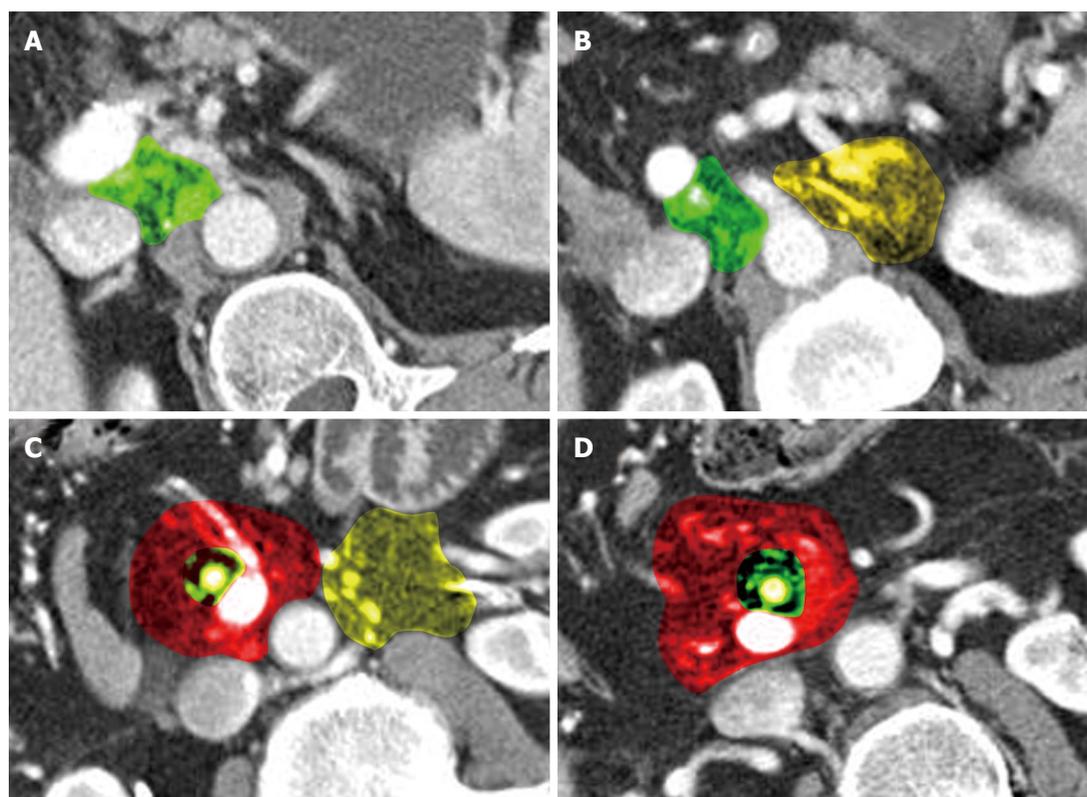

Figure 5 Schematic summary of localizations of local and lymph node recurrence patterns on contrast enhanced computed tomography at different levels of the upper abdomen. A: Offspring celiac trunk; B: Offspring superior mesenteric artery; C: Middle part of mesenteric root; D: Distal mesenteric root. Light green: Local recurrence in the area limited by cT (celiac trunk), (portal vein) PV, (inferior vena cava) IVC (top left); light green: Local recurrence in the area limited by superior mesenteric artery (SMA), PV, IVC (top right); yellow: Lymph node recurrence to the left of the aorta above/below the level of the renal vein; dark green: Local recurrence along the SMA; red: Lymph node recurrence in the mesenteric root close to the SMA.

for cancer, and found that the SMA was directly invaded in 3 cases and in 4 cases there was invasion to the perivascular nerve plexus. Furthermore invasion extended upwards along the SMA for the celiac nerve plexus. This corresponds with our results of the SMA being the most frequent site for tumor recurrence but also the space defined by the celiac trunk as the second most frequent site of recurrence. Additionally, Noto *et al*^[29], Kayahara *et al*^[30] found nodal metastasis around the SMA in all cases. Again this correlates with our findings that lymph node recurrence was mainly seen to the left of the aorta just superior or inferior to the left renal vein, as well as in the mesenteric root within a certain boundary of the SMA. Thus, for primary cancer of the pancreatic head, the SMA seems to serve as the main leading structure for disease propagation. As a hypothesis one could transfer these facts from initial tumor spread to tumor recurrence. This concept is even more convincing looking at recent discussions that the high rate of local tumor recurrence in pancreatic cancer is due to the fact that neurovascular tumor invasion may be left behind during the initial surgery. In other words, most pancreatic cancer resections are R1 (= microscopic residual tumor) resections, as recent studies with standardized pathological examinations have shown^[31,32]. According to recent articles there is no international consensus on the resection margins, and pathological reporting of pancreatic cancer specimens has resulted in a false low rate of R1 sta-

tus^[32]. Following Verbeke^[32], the critical resection margins for microscopic tumor residuals, the posterior margin but especially the medial margin, are very close to the SMA. In the case of R1 status, the remaining tumor cells would regrow along these vascular structures and coincide with the locations of macroscopic tumor relapse on follow-up imaging. The results of our study seem to support this thesis since all sites of recurrence are mainly defined by vascular structures and locations of extrapancreatic nerve plexuses. These results are supported by the work of Ishigami *et al*^[33] showing malignant perivascular soft tissue along the HA and SMA. However, it must be mentioned that most of the included patients were initially operated on before standardized pathological reporting was introduced at the local pathology institute, explaining the low rate of R1 resections^[31].

In our study, 9 patients underwent surgical resection of the recurrent tumor with potential curative intent. Three of these patients, with initial surgery performed in 2000, 2003 and 2004 and second-line surgery in 2004 and 2007, are alive to date and are seen for regular follow-up. In all patients with the diagnosis of recurrence, second-line chemotherapy was recommended. This strongly emphasizes that there are multiple therapy options for disease recurrence at hand. In the future it will be necessary to develop new multi-modal approaches to therapy for the scenario of disease recurrence in order to improve

survival even in cases with advanced disease presentations.

Tumor marker (CEA, CA19-9) measurement showed that the increase in levels were concordant with the detection of recurrence on CT in most cases. The mean values for CEA and CA19-9 increased from local and lymph node recurrence to liver metastasis and combinations of recurrence, indicating an association between tumor burden and tumor markers (Figure 4A-D). This gives an estimation of the type of recurrence but does underline the need for imaging at this point if an increase in tumor marker levels is detected. However, this deduction from the present data is limited since local recurrence is over-represented compared to other types of recurrence, and the variability of the tumor marker values is high.

Another limitation of this study is a possible selection bias as it was not possible for practical reasons to include all patients after surgery, e.g. follow-up at their local hospitals, *etc.* Therefore it cannot be concluded that the remaining 168 patients with initial CT imaging did not develop tumor recurrence at some point. Also pathologic proof was not obtained in all cases owing to the retrospective nature of the study and also for ethical and practical reasons. The deductions of this work reflect mainly experience with ductal adenocarcinoma of the pancreatic head after Whipple's procedure. However this is the natural distribution of pancreatic tumors.

CT is a valuable tool that allows identification of tumor recurrence in accordance with an increase in tumor marker level. If tumor marker levels do not increase, recurrence can only be detected by imaging studies. We suggest a protocol for postoperative follow-up for pancreatic cancer that includes regular CT imaging and tumor marker measurement as a cost-effective and secure way to monitor these patients. A baseline CT examination 3 mo post-operatively is a prerequisite for follow-up imaging. This baseline examination is the template for comparisons with follow-up studies to distinguish postoperative changes from local tumor growth. PET-CT should be performed in addition if clinical suspicion of tumor recurrence is high, tumor markers increase and CT findings are inconclusive or negative for disease recurrence.

In conclusion, specific changes in local and lymph node recurrence of pancreatic cancer after surgery are present along the path of the peripancreatic cardinal vessels. These findings may also help differentiate non-specific postoperative changes from actual recurrence. Local tumor regrowth spreads along the cardinal visceral vessels but can also present as a mass-like recurrence at specific spaces that are defined by the surrounding vasculature. This is consistent with the known behavior of pancreatic cancer propagating along neurovascular structures. The SMA plays a major role as a leading structure for tumor regrowth. CT follow-up examinations in combination with tumor marker measurement are crucial diagnostic tools to identify local recurrence and lymph node metastasis at an early stage, allowing as many patients as possible to have second, potentially curative, surgical therapy or second-line radio/chemotherapy.

COMMENTS

Background

Pancreatic cancer has a poor 5-year survival rate of 10%-25%. Local recurrence is observed within 2 years after surgery for the majority of patients. Detection of recurrence of pancreatic cancer by imaging is challenging since extensive postoperative changes are present in the resection area after pancreatic surgery. It is crucial to identify signs of recurrence early in order to provide second line chemotherapy or even reoperation.

Research frontiers

Detection of recurrence patterns by CT imaging of pancreatic cancer after surgery to facilitate differentiation of postoperative changes from true recurrence. Development of a follow-up imaging protocol for pancreatic cancer after surgery.

Innovations and breakthroughs

This study describes a recurrence pattern of pancreatic cancer on CT imaging that has not been identified so far. Detection of recurrence by imaging was concordant with significant rise in tumor markers. The pattern demonstrates that pancreatic cancer reoccurs mainly along the cardinal neurovascular structures such as the superior mesenteric artery and hepatic artery. This is the same propagation pattern as the primary pancreatic cancer exhibits during tumor extension. The high rate of tumor recurrence is thought to arise because of residual tumor at the medial resection margin which is very close to the superior mesenteric artery. Previous articles have shown that many tumor resections were R1 resections as there was no international consensus on the histopathological workup. As a consequence a standardized histopathological workup for pancreatic cancer was recently introduced. This study confirms the relationship between residual microscopic tumor after surgery and its presentation as macroscopic recurrence on CT imaging.

Applications

The results of this study, demonstrating a distinct pattern of tumor recurrence, can be applied to optimize the radiological follow-up of pancreatic cancer after surgery. A baseline CT imaging study 3 mo after surgery is recommended for further follow-up imaging. It remains to be determined if early detection of recurrence leads to new therapy options and ultimately an improved survival rate.

Peer review

This well written and well structured paper reports the results of a retrospective single-center study on the role of CT imaging after surgical resection of pancreatic cancer. Adjuvant treatment strategies as well as novel methods for the follow-up of patients with this high risk disease are currently topics of a high clinical and scientific interest.

Abstract

AIM: To evaluate the effect of chronic mild stress (CMS) on the emergence of gastric ulcers and possible modulation by octreotide, a synthetic somatostatin analogue.

METHODS: Adult male Wistar rats were subjected to nine different unpredictable random stress procedures for 21 d, a multifactorial interactional animal model for CMS. Octreotide was administered daily for 21 d at two dose levels (50 and 90 $\mu\text{g}/\text{kg}$) before exposure to stress procedure. Macro- and microscopical assessments were made, in addition to quantification of plasma corticosterone and gastric mucosal inflammatory, oxidative stress, and apoptotic biomarkers.

RESULTS: Exposure to CMS elevated plasma corticosterone ($28.3 \pm 0.6 \mu\text{g}/\text{dL}$, $P = 0.002$), an event that was accompanied by gastric lesions ($6.4 \pm 0.16 \text{ mm}$, $P = 0.01$) and confirmed histopathologically. Moreover, the insult elevated gastric mucosal lipid peroxides ($13 \pm 0.5 \text{ nmol}/\text{g}$ tissue, $P = 0.001$), tumor necrosis factor- α ($3008.6 \pm$

$78.18 \text{ pg}/\text{g}$ tissue, $P < 0.001$), prostaglandin E2 ($117.1 \pm 4.31 \text{ pg}/\text{g}$ tissue, $P = 0.002$), and caspase-3 activity ($2.4 \pm 0.14 \text{ OD}/\text{mg}$ protein, $P = 0.002$). Conversely, CMS mitigated interleukin-10 ($627.9 \pm 12.82 \text{ pg}/\text{g}$ tissue, $P = 0.001$). Furthermore, in animals exposed to CMS, octreotide restored plasma corticosterone (61% and 71% from CMS, $P = 0.002$) at both dose levels. These beneficial effects were associated with a remarkable suppression of gastric lesions (38% and 9% from CMS, $P = 0.01$) and reversal of derangements in gastric mucosa.

CONCLUSION: The current investigation provides evidence that exposure to CMS induces gastric ulceration, which was alleviated by administration of octreotide possibly possessing antioxidant, anti-inflammatory, and anti-apoptotic actions.

INTRODUCTION

Severe life stressors frequently antedate the onset of functional gastrointestinal disorders. The stomach, in particular, is extremely sensitive to various stress stimuli and peptic ulcer has often been described as a stress disease^[1].

Stress *per se*, alters the mechanisms of neurohormonal regulation, which results in lesions earliest found in the stomach, as a consequence of a general adaptation syndrome^[2]. Chronic mild stress (CMS) is a paradigm where animals are exposed to a combination of mild unpredictable stressors^[3]. Moreover, in the CMS model, several reports implicate important roles of reactive oxygen species (ROS)^[4-6], and enhanced production of inflammatory mediators, which are also prime events in acute stress models^[7,8]. Markedly, stress induces gastric ulceration *via* different factors, *viz.*: stimulation of brain gut axis, reduction of mucosal blood flow, and leukocyte infiltration^[7,9,10]. The latter contributes to free radical and pro-inflammatory cytokines formation, which further recruit more inflammatory cells, thus augmenting ROS production and maximizing mucosal damage^[7,8,11-13]. Imbalances in the production of interleukin (IL)-10 and tumor necrosis factor (TNF)- α play crucial roles in gastric ulceration^[7,14]. Furthermore, TNF- α activates extrinsic apoptotic pathway *via* caspase-3 induction, ultimately resulting in gastric injury^[15]. On the contrary, inhibition of TNF- α *via* the cytoprotective prostaglandin (PG) highlights its anti-inflammatory properties in the gastric mucosa^[13].

Somatostatin is secreted from D-cells in the stomach where it suppresses acid secretion directly from parietal cells and indirectly by inhibiting the release of histamine and gastrin^[16]. Furthermore, somatostatin inhibits pepsin secretion and reduces gastroduodenal mucosal blood flow, which are important entities in the pathophysiology of peptic ulcer bleeding^[17]. Conversely, gastric ulcers are linked to decreased levels of this hormone^[18,19]. The effectiveness of synthetic somatostatin analogues as gastro-protective agents is advocated by inhibition of leukocyte adhesion^[20] and antioxidant^[21] properties, beside their anti-secretory potential^[22].

The possibility that animals exposed to chronic stressors may develop gastric lesions has not been extensively investigated. Hence, the present study aimed to assess the potential modulatory effect of CMS on the stomach integrity assessed macro- and microscopically. In addition, the gastric mucosal redox status, as well as the inflammatory process that might accompany exposure to CMS were determined herein. Moreover, the study evaluated the effect of octreotide, a synthetic cyclic octapeptide somatostatin analogue, on CMS-induced gastric mucosal alterations.

MATERIALS AND METHODS

Animals

Adult male Wistar rats (175 \pm 15 g; National Research Center Laboratory, Cairo, Egypt) were kept in a controlled environment, at a constant temperature (23 \pm 2°C), humidity (60% \pm 10%), and light/dark (12/12 h) cycle, lights on at 5:00 am. Rats were singly housed and acclimatized for 1 wk before any experimental procedures and were allowed standard rat chow and tap water *ad libitum*. Experimental protocols were approved by the Research Ethical Committee of Faculty of Pharmacy Cairo University (Cairo, Egypt).

Induction of CMS, treatment, and experimental groups

Rats were randomly assigned to 6 groups ($n = 10-12$; each). Animals in group I received an ip injection of saline and served as control group, while groups II and III rats received octreotide (Novartis Pharmaceuticals, Basle, Switzerland) at two dose levels (50 and 90 μ g/kg, ip)^[23]. Group IV rats were exposed to CMS, as detailed below, while animals of groups V and VI were subjected to CMS during daily treatment with octreotide at the indicated doses. The somatostatin analogue was dissolved in saline and its administration started from the first day 2 h before exposure to stressors between 9:00 am and 12:00 pm. CMS was induced by exposure of animals to unpredictable repetitive random stress procedures for 21 d following the protocol described by Bekris *et al.*^[24]. Briefly, the stressors comprised high-speed agitation for 10 min; deprivation of either food and/or water for 24 h; either 45°C heat stimulus for 5 min or 4°C cold exposure for 1 h; immobilization for 2 h; interrupted noise for 3 h; continuous illumination for 24 h; and tilted cage for 12 h. On the other hand, unstressed control animals were housed undisturbed under constant conditions, without contact with the stressed animals.

Plasma corticosterone level measurement

At the beginning of the following dark cycle, blood was collected in chilled EDTA-tubes. Plasma corticosterone levels were determined using a commercially available radioimmunoassay kit (ICN Biomedicals, Costa Mesa, CA).

Measurement of ulcer index

Rats were euthanized and their stomachs were rapidly removed and opened along the greater curvature to assess the extent of gastric damage in a double blind fashion. The length of each lesion along its greatest diameter was measured and the sum of lengths was expressed as ulcer index (mm)^[8].

Biochemical determinations

Gastric mucosa was scraped and homogenized either in ice-cold saline for assessment of lipid peroxides, total antioxidant capacity (TAC), TNF- α , IL-10, and caspase-3 or in 0.1 mol/L phosphate (pH 7.4) buffer, containing 1 mmol/L EDTA and 0.1 μ mol/L indomethacin for PGE₂ measurement and frozen at -70°C until assayed.

Lipid peroxides and TAC

The thiobarbituric acid reaction of Mihara and Uchiyama^[25] was adopted for estimation of lipid peroxides level, using malondialdehyde (MDA) as a standard. The method for the assessment of TAC of gastric mucosa was based on that of Koracevic *et al.*^[26].

TNF- α , IL-10, PGE₂, and caspase-3 activity estimations

Gastric mucosal TNF- α , IL-10, and PGE₂ were measured by ELISA kits purchased from Invitrogen (California, USA), Bender MedSystems (Vienna, Austria), and Cayman

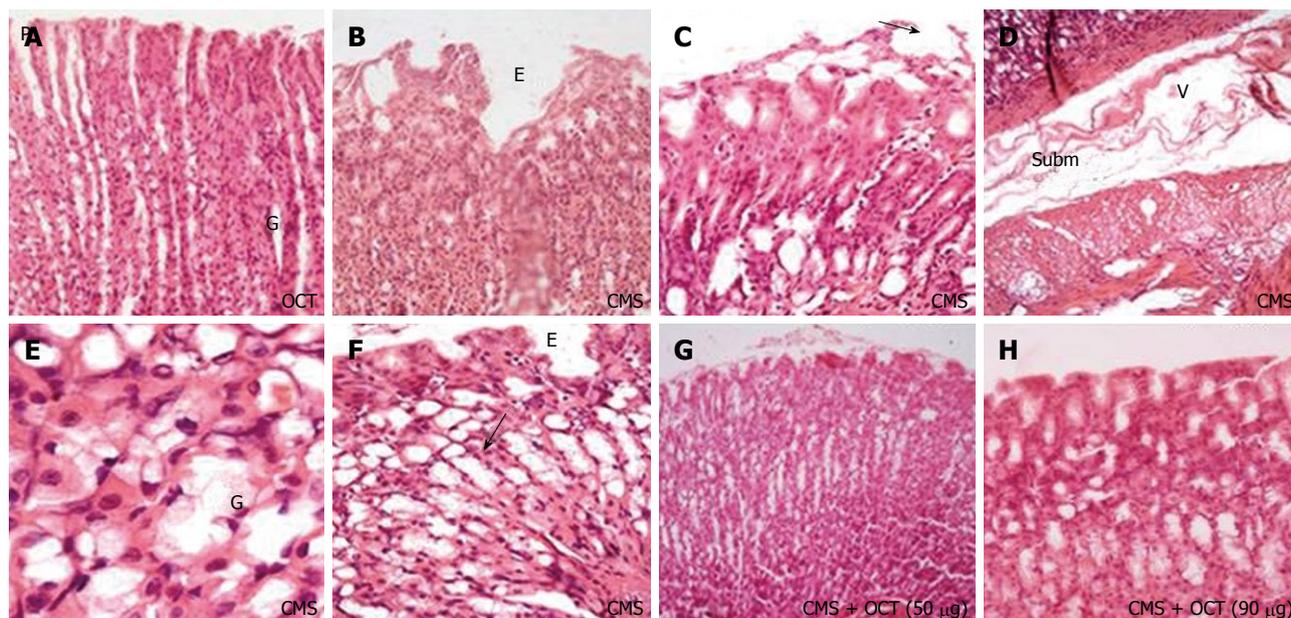

Figure 1 Representative photomicrographs of stomach fundus mucosa obtained at the beginning of the following dark cycle after last exposure to mild stressors with or in absence of octreotide (50 and 90 µg/kg, ip) treatment. A: Octreotide (OCT) administered to normal rats showing normal gastric architecture with gastric pits (P) and gastric glands (G); B: Chronic mild stress (CMS) sections showing mucosal erosion designated by letter E; C: CMS showing hydroptic degeneration with erosion and epithelial desquamation (arrow); D: CMS with submucosal edema (V) as represented by wide separation of connective tissue between mucosa and muscularis mucosa infiltrated macrophages and eosinophils (E); E: CMS showing goblet cell (G) metaplasia indicative of mucous secretion and increase in activity of mucous secretion due to fasting, irritation and stress; F: CMS showing surface erosions (E) and marked goblet cell metaplasia with inflammatory cell infiltration (arrow) in the deep mucosa; G and H: Improvement of epithelial lining as indication for surface regeneration with OCT at both dose levels in CMS rats (HE stain, × 40 and 100).

Table 1 Effect of octreotide on ulcer index and plasma corticosterone level in chronic mild stressed rats

| Groups | Parameters | |
|----------------------|---------------------------|-------------------------------|
| | Ulcer index (mm) | Plasma corticosterone (µg/dL) |
| Control | 0 ± 0 | 15.4 ± 1.0 |
| OCT (50 µg/kg) | 0 ± 0 | 17.3 ± 0.7 |
| OCT (90 µg/kg) | 0 ± 0 | 16.0 ± 1.2 |
| CMS | 6.4 ± 0.16 ^a | 28.4 ± 0.6 ^a |
| CMS + OCT (50 µg/kg) | 2.4 ± 0.06 ^{a,b} | 17.2 ± 0.7 ^b |
| CMS + OCT (90 µg/kg) | 0.6 ± 0.01 ^{a,b} | 20.4 ± 1.1 ^b |

Rats were subjected to mild stressors for 21 d; octreotide was given 2 h before the insults or to normal animals. Data are mean of 6-8 rats ± SE. ^{a,b}*P* < 0.05 compared to control and chronic mild stress (CMS) groups respectively. For comparisons among treatment groups, one-way ANOVA followed by Tukey-Kramer Multiple Comparisons Test was used. OCT: Octreotide.

Chemical (MI, USA), respectively. In addition, the activity of gastric mucosal caspase-3 was measured by using a colorimetric assay kit (Biosource International, California, USA). Briefly, the levels of the chromophore p-nitroanilide (pNA) released by caspase-3 activity in the tissue lysates were quantified spectrophotometrically at 405 nm. All the procedures of the used kits were performed following the manufacturer's instruction manual.

Stomach histopathological examination

The stomach was removed from representative animals (*n* = 4) in each group and immediately fixed in 10% phosphate buffered formaldehyde. Subsequently sections were

embedded in paraffin, and 5 µm sections were prepared. The sections were stained with haematoxylin and eosin (HE) and examined microscopically.

Statistical analysis

Data were expressed as mean of 6-8 experiments ± SE. The comparisons of data were carried out using one-way analysis of variance (ANOVA) followed by Tukey-Kramer Multiple Comparisons Test. All analysis utilized SPSS 16.0 statistical package for Windows (SPSS Inc., Chicago, IL, USA). A probability level of less than 0.05 was accepted as statistically significant.

RESULTS

Exposure of animals to CMS elevated plasma corticosterone (28 ± 0.6 µg/dL, *P* = 0.002, Table 1), an effect that was associated with erosion formation in the glandular region of the stomach, manifested by gross inspection (6.4 ± 0.16 mm, *P* = 0.01), as well as microscopically (Table 1 and Figure 1). Treatment with 50 and 90 µg/kg octreotide, on the contrary, restored plasma corticosterone level (61% and 71%, *P* = 0.002, respectively) and ameliorated gastric lesion formation (38%, *P* = 0.01, 50 µg/kg), which was more evident at the higher dose (9%, *P* = 0.01) in rats subjected to CMS.

Daily administration of octreotide at the indicated dose levels (50 and 90 µg/kg) for 3 wk to rats did not show any statistical difference from non-treated control animals except for a decrease in PGE₂ (64.9 ± 2.2 and 62.95 ± 3.57 pg/g tissue, *P* = 0.002, respectively) and in-

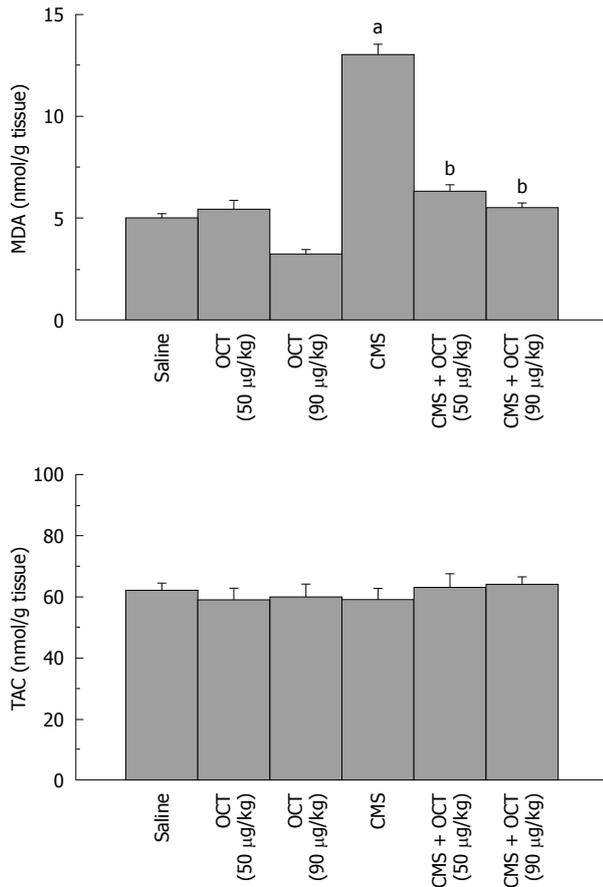

Figure 2 Effect of octreotide (50 and 90 µg/kg, ip) given 2 h prior to chronic mild stress exposure on mucosal malondialdehyde content (upper panel) and total antioxidant capacity (lower panel) in normal rats and those subjected to chronic mild stress. Values are mean ± SE, n = 6-8 each. ^{a,b}P < 0.05 vs control and chronic mild stress (CMS), respectively, using one-way ANOVA followed by Tukey-Kramer Multiple Comparisons Test. OCT: Octreotide; MDA: Malondialdehyde content; TAC: Total antioxidant capacity.

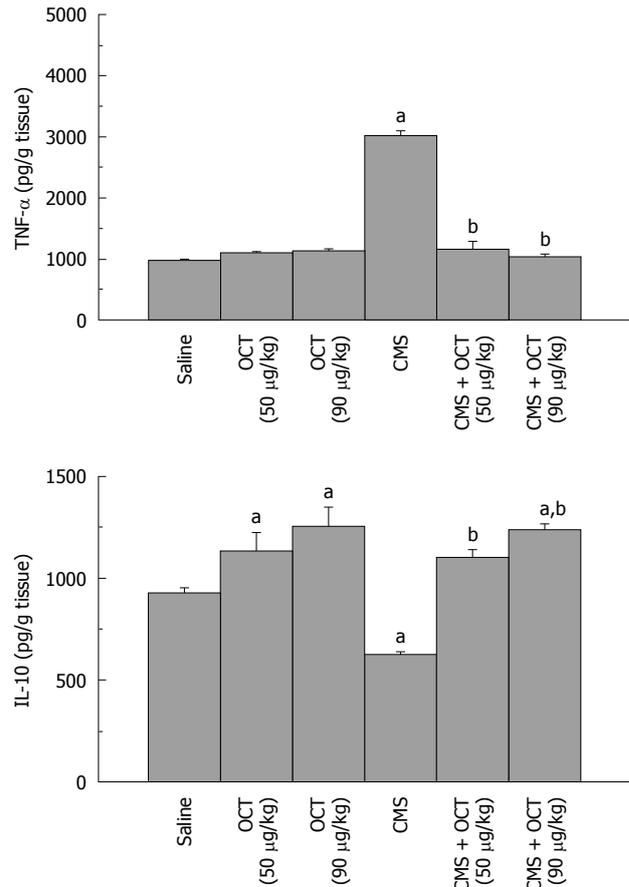

Figure 3 Effect of octreotide (50 and 90 µg/kg, ip) on gastric mucosal tumor necrosis factor-α (upper panel) and interleukin-10 (lower panel) content in normal rats and those subjected to chronic mild stress, where octreotide was administered 2 h before chronic mild stress exposure. Values are mean ± SE, n = 6-8 each. ^{a,b}P < 0.05 vs control and chronic mild stress (CMS), respectively, using one-way ANOVA followed by Tukey-Kramer Multiple Comparisons Test. OCT: Octreotide; TNF: Tumor necrosis factor; IL: Interleukin.

creased IL-10 (1128.5 ± 94.1 and 1250.53 ± 95.21 pg/g tissue, P = 0.001, respectively) levels (Figures 2-5).

CMS elevated gastric mucosal MDA (13 ± 0.5 nmol/g tissue, P = 0.001, Figure 2), TNF-α (3008.6 ± 78.18 pg/g tissue, P < 0.001, Figure 3), PGE₂ (117.1 ± 4.31 pg/g tissue, P = 0.002, Figure 4), and caspase-3 (2.4 ± 0.14 OD/mg protein, P = 0.002, Figure 5) as compared to control values. Furthermore, reduction in the level of IL-10 (627.9 ± 12.82 pg/g tissue, P = 0.001, Figure 3) in the gastric mucosa was detected, while TAC (P = 0.099) was not altered significantly (Figure 2). Octreotide at both dose levels (50 and 90 µg/kg) suppressed gastric mucosal MDA (58% and 50%, P = 0.001, respectively, Figure 2), TNF-α (39% and 34%, P < 0.001, respectively, Figure 3), PGE₂ (73% and 67%, P = 0.002, respectively, Figure 4) and caspase-3 activity (67% and 79%, P = 0.002, respectively, Figure 5), as compared to animals subjected to CMS. Furthermore, octreotide evoked an increment in gastric mucosal IL-10 (175% and 197%, P = 0.001, respectively, Figure 3), as compared to stressed rats; however TAC (P = 0.099, Figure 2) was unaltered.

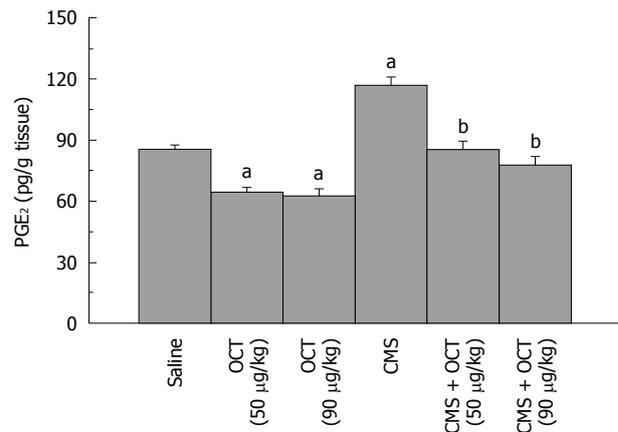

Figure 4 Effect of octreotide (50 and 90 µg/kg, ip) on gastric mucosal PGE₂ content in normal rats and those subjected to chronic mild stress (mean of 6-8 animals ± SE). Octreotide was administered 2 h before chronic mild stress (CMS) exposure. ^{a,b}P < 0.05 vs control and CMS, respectively, using one-way ANOVA followed by Tukey-Kramer Multiple Comparisons Test. OCT: Octreotide.

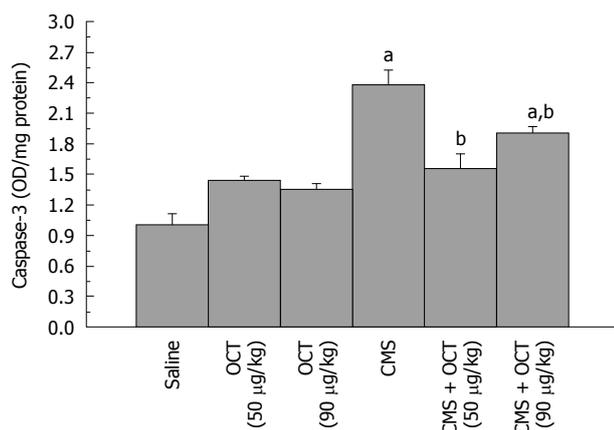

Figure 5 Effect of octreotide (50 and 90 µg/kg, ip) on gastric mucosal caspase-3 activity in normal rats and those subjected to chronic mild stress (mean of 6-8 animals ± SE). Octreotide was administered 2 h before chronic mild stress (CMS) exposure. ^{a,b}*P* < 0.05 vs control and CMS, respectively, using one-way ANOVA followed by Tukey-Kramer Multiple Comparisons Test. OCT: Octreotide.

DISCUSSION

Previous studies have implicated the influence of acute stress exposure in gastric induced ulcerations^[7,8,10]; however the effect of chronic exposure to mild environmental stressors on gastric mucosal integrity have not been fully delineated. The current investigation extends previous findings, using other stress procedures^[6,27,28], that CMS exposure induces gastric lesions as evidenced by macro- and microscopical besides mechanistic pathways. The most important findings of the current study demonstrate that CMS for 21 d (1) increased plasma corticosterone; (2) induces gastric mucosal erosions; (3) deranges mucosal oxidant status, as well as pro- and anti-inflammatory cytokines; (4) activates caspase-3 mediated apoptosis; and (5) surprisingly enhances PGE₂ production in the gastric mucosa. On the other hand, concomitant administration of octreotide reduced ulcer formation and efficiently reinstated most of the changes associated with CMS.

Stress, on one hand, causes the activation of the brain gut axis and stimulates the stomach both sympathetically and parasympathetically^[29]. The former produces arteriolar vasoconstriction, thus reducing blood flow to the stomach, while the latter enhances gastric motility and muscular contraction leading to vascular compression with consequent mucosal ischemia^[30]. Interestingly, in the present study we demonstrate hydropic degeneration with erosion and epithelial desquamation suggestive of ischemic outcome. Consequently, following the ischemic event, superoxide anion (O₂⁻) leakage from mitochondrial electron transport chain is triggered, which further augments hydroxyl radical (OH[•]) production, with subsequent oxidative damage of macromolecules^[31].

Stress ulcers, on the other hand, are linked to leukocyte infiltration, which further exacerbates free radicals production and TNF-α generation^[7,8,10]. This inflammatory cytokine further recruits more neutrophils resulting in a feed forward damaging cycle^[7]. Both effects were evidenced in

the current study by an increase in lipid peroxides, as well as TNF-α. The increment in lipid peroxides corroborates similar findings in other organs when exposed to CMS^[4,5] and several reports utilizing acute stress models^[18,31], as well as another chronic restraint stress ulcer model^[6]. Notably, lipid peroxides formation is an indicative marker of a vicious ROS cycle; however, there was no change in TAC levels from baseline. A plausible explanation for the latter is the adaptation of the gastric mucosa to CMS-induced ROS, where the presence of either decreased^[6,8,31] or increased^[31,32] levels of endogenous antioxidants, with a net unchanged concentration, was previously reported in ulcer models including acute stress. Meanwhile, we observed a decline in the level of the anti-inflammatory cytokine IL-10, which accounts for the overwhelming antagonistic effect of TNF-α as reported by Brossart *et al.*^[33], which may additionally aggravate gastric lesion formation. Recently, genetic IL-10 polymorphism has been found to predispose individuals to peptic ulcer^[34], thus lending further support to our findings.

Evidence exists that the synthetic somatostatin analogue, octreotide, possesses antiulcerogenic activity in other gastric lesions models^[20,21]. Notably, this protective effect may be attributed to maintaining of mucosal blood flow, an essential gastroprotective factor thus preserving tissue integrity. The gastroprotective effect was associated with reduction in MDA levels, which is in line with the reported findings utilizing octreotide in another model of gastric injury by Sener *et al.*^[21]. In addition, the study of Scheiman *et al.*^[20] provided evidence that octreotide affords gastroprotection by inhibition of neutrophil infiltration, which lends further support to the reduction in inflammatory cells recruitment in the gastric mucosa, more evident with the higher dose of octreotide in this study.

Octreotide also reinstated cytokine levels in the gastric mucosa of animals subjected to a combination of various stressors. Somatostatin analogues were shown to have significant anti-inflammatory effects *in vivo* associated with suppression of inflammatory cytokines as TNF-α^[35]. Meanwhile, a recent *in vitro* report of ter Veld *et al.*^[36] displayed that octreotide increased IL-10 dose-dependently, an effect that supports the current finding in animals treated with the somatostatin analogue.

Apoptosis is largely implicated in the pathogenesis of gastric ulcers^[37]. Increased TNF-α, as well as free radicals activate caspase-3, one of the effector caspases involved in apoptotic cell death^[38]. Caspases, in turn, elicit neutrophil activation through increased expression of chemoattractants^[10] thus a vicious cycle exists, which further aggravates gastric damage. Therefore, the enhanced caspase-3 activity by CMS is consistent with the noted increase in TNF-α content of the gastric mucosa and the disturbance in oxidants/antioxidants mucosal homeostasis. Moreover, Esplugues *et al.*^[39] depicted that stress itself inhibits gastric acid secretion through a central nervous reflex mechanism; however, the present study documents that atrophy and degeneration of gastric glands as shown in photomicrographs of gastric mucosa of rats subjected to CMC may also be a cause. Additionally, this event, as

well as sloughing of the gastric epithelial layer, may thus pin down the contribution of cell death in this study. Although somatostatin has been reported as an inducer of apoptosis^[40], evidence supports its ability to upregulate Bcl-2, a major inhibitor of apoptosis^[41].

Despite the fact that some studies supported an ulcerogenic action of the endogenous glucocorticoids^[42], other reports^[42,43] showed that these steroids are released as an adaptive response to stress rather than being a significant ulcerogenic component of the brain-gut axis. The present study supports this notion, where CMS was shown to increase corticosterone level. In agreement with the adaptive response to stress, the current investigation revealed that rats subjected to CMS surprisingly elevated PGE₂, an action that is similar to cold-restraint stress^[44]. Exposure to mild stressors is known to cause preconditioning, which contributes to gastroprotective effects against more severe stressors in several gastric ulcer models including exposure to stressful conditions^[45]. Under stress conditions, the enhanced resistance to subsequent challenges by other irritants is attributed, in part, to increased endothelial growth factor (EGF) expression and release, as well as gastric mucosal cell proliferation^[46]. Moreover, phospholipase A₂ is activated by mild stress, which releases arachidonic acid to be metabolized to PGs by both COX-1 and -2 activation^[28]. Hence, PGs formed by preconditioning stress may attenuate stress induced gastric injury^[47]. Such an action could thus account for the erosions seen in the histopathological study rather than deep ulcerations that invade the muscularis layer. PGE₂ is among the factors that regulate gastric blood flow^[47] and enhance mucus, as well as bicarbonate synthesis^[48], which are important gastric defensive factors. The current study shows dilated gastric pits, which reflect increased mucus production in the gastric mucosa of rats exposed to CMS. Such an effect may be a consequence of elevated PGE₂ levels, hence confirming the adaptation theory. Since an imbalance between protective and aggressive factors in the stomach accounts for peptic ulcer formation, the present diverse conditions may favor ulcer formation rather than gastroprotection. On the other hand, treatment with octreotide restored PGE₂ in the gastric mucosa, an effect that highlights its efficacy in intercepting preconditioning of the gastric mucosa to mild stressful procedures.

This study reveals that exposure to chronic mild stressors, such as those present in the environment, may increase susceptibility of the gastric mucosa to aggressive factors, resulting ultimately in gastric lesions. Hence, rats subjected to CMS could serve as a chronic model for stress-induced peptic ulceration that can be used for the evaluation of compounds possessing antiulcer activity. Gastroprotective mechanisms of octreotide are probably due to its antioxidant capacity with concomitant anti-inflammatory and anti-apoptotic effects.

nary Medicine, Cairo University, Egypt, for her valuable assistance with the histopathological testing and photomicrography interpretation.

COMMENTS

Background

Stress has been linked to the etiopathogenesis of various diseases, ranging from psychiatric disorders to several ailments of the gastrointestinal tract. Evidence exists that exposure to acute, as well as chronic, stressful conditions is linked to gastric injury. However, animal models for chronic induction of gastropathy are limited. Izgüt-Uysal *et al* showed that a chronic restrained model for 21 d induced gastric lesions. Moreover, Bhattacharya *et al* introduced another chronic mild stress (CMS) procedure using a rat footshock model as a modification of that adopted by Conti *et al* by adding the element of unpredictability. This model, as well as other stress procedures have been correlated to gastric injury. The current study aimed to evaluate the effect of random exposure to nine different unpredictable stress procedures for 21 d, a multifactorial interactional animal model for CMS, on the emergence of hemorrhagic gastric ulcers and the possible modulatory effects of octreotide, a synthetic somatostatin analogue.

Research frontiers

Gastric ulcer formation is attributed to an imbalance between aggressive and protective factors overweighing the effect of the former. Several hormones regulate gastric mucosal functions among which is somatostatin, a hormone secreted from D-cells in the stomach. Somatostatin suppresses acid secretion directly from parietal cells and indirectly by inhibiting the release of histamine and gastrin. It is used clinically in peptic ulcer bleeding due to its inhibitory effects on pepsin secretion and gastroduodenal mucosal blood flow. Conversely, gastric ulcers are linked to decreased levels of this hormone. However, somatostatin has a short half life, thus synthetic analogues are used efficiently. The effectiveness of synthetic somatostatin analogues as gastroprotective agents is advocated by inhibition of leukocyte adhesion and antioxidant properties, beside their antisecretory potential. Thus the current study utilized octreotide, a synthetic cyclic octapeptide somatostatin analogue, on a chronic model of mild stress exposures for its well documented gastroprotective effect.

Innovations and breakthroughs

A vast majority of acute models for stress-induced gastric ulcerations exists; however, workable models for chronicity and excessive exposure to stressors are limited. To further understand mechanistic pathways and identify new targets for ulcer treatments, the current study aimed to evaluate the effect of random exposure to nine different unpredictable stress procedures for 21 d, a multifactorial interactional animal model for CMS, on the emergence of hemorrhagic gastric ulcers and the possible modulatory effects of a somatostatin analogue, octreotide, utilizing two dose levels.

Applications

The introduction of a CMS gastric lesion model can give better insights for understanding the mechanisms involved in exposure to stressful stimuli in the environment on daily basis that produces gastric injury, as well to facilitate management of such hassle events.

Peer review

The authors presented data of some pathophysiological and morphologic alterations of gastric mucosa associated with experimental chronic stress in rats. They also tried to use a somatostatin analogue, octreotide, to protect the animals from stress-caused ulceration in gastric mucosa. The results appear to be very interesting. They may be helpful for fully understanding chronic stress and gastric lesions. It may indicate a possible therapeutic usage of similar chemicals in prevention of stress-associated gastric ulcer in high-risk individuals.

Abstract

AIM: To explore the role of prostaglandin F_{2α} (PGF_{2α}) on pacemaker activity in interstitial cells of Cajal (ICC) from mouse small intestine.

METHODS: In this study, effects of PGF_{2α} in the cultured ICC cells were investigated with patch clamp technology combined with Ca²⁺ image analysis.

RESULTS: Externally applied PGF_{2α} (10 μmol/L) produced membrane depolarization in current-clamp mode and increased tonic inward pacemaker currents in voltage-clamp mode. The application of flufenamic acid (a non-selective cation channel inhibitor) or niflumic acid (a

Cl⁻ channel inhibitor) abolished the generation of pacemaker currents but only flufenamic acid inhibited the PGF_{2α}-induced tonic inward currents. In addition, the tonic inward currents induced by PGF_{2α} were not inhibited by intracellular application of 5'-[thio]diphosphate trilithium salt. Pretreatment with Ca²⁺ free solution, U-73122, an active phospholipase C inhibitor, and thapsigargin, a Ca²⁺-ATPase inhibitor in endoplasmic reticulum, abolished the generation of pacemaker currents and suppressed the PGF_{2α}-induced tonic inward currents. However, chelerythrine or calphostin C, protein kinase C inhibitors, did not block the PGF_{2α}-induced effects on pacemaker currents. When recording intracellular Ca²⁺ ([Ca²⁺]_i) concentration using fluo-3/AM, PGF_{2α} broadly increased the spontaneous [Ca²⁺]_i oscillations.

CONCLUSION: These results suggest that PGF_{2α} can modulate pacemaker activity of ICC by acting non-selective action channels through phospholipase C-dependent pathway *via* [Ca²⁺]_i regulation

INTRODUCTION

Prostaglandins (PGs) of the E, F, and I series are widely

distributed in all body tissues, including the gastrointestinal (GI) tract and have been shown to affect water and electrolyte transport, mucous secretion and blood flow^[1-3]. Also, there is much evidence that PGs may be involved in the control of the contractions of intestinal smooth muscle. Inhibition of endogenous PG synthesis by indomethacin appears to enhance intestinal motility by inducing a fed-like pattern^[4-6]. These reports suggest that endogenous PGs may play an important role in the modulation of intestinal motility.

In general, PGE₂ is known to contract longitudinal muscle and to relax circular muscle, whereas PGF_{2α} induces contractions of both muscular layers^[6-9]. PGF_{2α} causes contractions of both colonic muscle layers in the guinea pig and in humans and rats^[10,11]. Endogenous PGF_{2α} is suggested to modify contractile activity of antral smooth muscle and intestinal muscle^[12,13]. Therefore, exogenous PGF_{2α} and PGF_{2α} synthesized in the intestinal smooth muscle cells may affect motor activities.

The interstitial cells of Cajal (ICC) have functions of pacemaker cells and neuromediator cells in the tunica muscularis of the GI tract^[14]. The ICC generate the rhythmic oscillations in membrane potential known as slow waves and this generation of slow waves is due to spontaneous inward currents called pacemaker currents^[15,16]. Although the exact mechanisms regarding these events are still unclear, many reports have suggested that the activation of non-selective cation channels, Cl⁻ channels, and spontaneous intracellular Ca²⁺ ([Ca²⁺]_i) activities in ICC are involved in the production of pacemaker activity^[15-17]. Also, it is well known that many endogenous agents such as neurotransmitters, hormones and paracrine substances modulate GI tract motility by influencing ICC.

There are many reports that PGF_{2α} has a role in GI motility by acting on smooth muscles but no studies have been performed to determine the effects of PGF_{2α} on electrical events in ICC. Therefore, the purpose of our study was to investigate the signal transduction effects of PGF_{2α} on pacemaker activity in cultured ICC.

MATERIALS AND METHODS

Ethics

All experiments were carried out according to the guiding principles for the care and use of animals approved by the ethics committee of Chosun University and the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Every effort was made to minimize both the number of animals used and their suffering.

Solutions and drugs

The cells were bathed in a solution containing: 5 mmol/L KCl, 135 mmol/L NaCl, 2 mmol/L CaCl₂, 10 mmol/L glucose, 1.2 mmol/L MgCl₂, and 10 mmol/L HEPES, adjusted to pH 7.2 with Tris. The pipette solution contained 140 mmol/L KCl, 5 mmol/L MgCl₂, 2.7 mmol/L K₂ATP, 0.1 mmol/L Na₂GTP, 2.5 mmol/L creatine phosphate disodium, 5 mmol/L HEPES, 0.1 mmol/L EGTA, adjusted to pH 7.2 with Tris.

Drugs used were: PGF_{2α}, guanosine 5'-[thio]diphosphate trilithium salt (GDP-β-S), U-73122, Calphostin C, Chelethrine, and Thapsigargin. All drugs were purchased from the Sigma Chemical Co (St. Louis, MO, USA). Flufenamic acid and niflumic acid were purchased from Calbiochem (San Diego, CA, USA).

All drugs were dissolved in DW or DMSO to prepare stock solutions (10 or 100 mmol/L), and were either added to the bath solution or applied to the whole-cell preparations by superfusion. The final concentration of DMSO was less than 0.05%.

Preparation of cells and tissues

Balb/C mice (3- to 7-d-old) of either sex were anesthetized with ether and sacrificed by cervical dislocation. The small intestines from 1 cm below the pyloric ring to the cecum were removed and opened along the mesenteric border. The luminal contents were washed away with Krebs-Ringer bicarbonate solution. The tissues were pinned to the base of a Sylgard dish and the mucosa removed by sharp dissection. Small strips of intestinal muscle were equilibrated in Ca²⁺-free Hank's solution for 30 min and the cells were dispersed with an enzyme solution containing collagenase (Worthington Biochemical Co, Lakewood, NJ, USA), 1.3 mg/mL; bovine serum albumin (Sigma Chemical Co., St. Louis, MO, USA), 2 mg/mL; trypsin inhibitor (Sigma), 2 mg/mL; and ATP, 0.27 mg/mL. Cells were plated onto sterile glass coverslips coated with murine collagen (2.5 μg/mL, Falcon/BD) in 35 mm culture dishes. The cells were then cultured at 37°C in a 95% O₂-5% CO₂ incubator in smooth muscle growth medium (SMGM, Clonetics Co., San Diego, CA, USA) supplemented with 2% antibiotics/antimycotics (Gibco, Grand Island, NY, USA) and murine stem cell factor (SCF, 5 ng/mL, Sigma). Interstitial cells of Cajal (ICC) were identified immunologically with a monoclonal antibody for Kit protein (ACK2) labeled with Alexa Fluor 488 (Molecular Probes, Eugene, OR, USA).

Patch clamp experiments

The whole-cell configuration of the patch-clamp technique was used to record membrane currents (voltage clamp) and membrane potentials (current clamp) from cultured ICC. Currents or potentials were amplified by use of an Axopatch 1-D (Axon Instruments, Foster, CA, USA). Command pulse was applied using an IBM-compatible personal computer and pClamp software (version 6.1; Axon Instruments). The data were filtered at 5 kHz and displayed on an oscilloscope, a computer monitor and a pen recorder (Gould 2200, Gould, Valley view, OH, USA).

Results were analyzed using pClamp and Sigma plot (version 9.0) software. All experiments were performed at 30°C.

Measurement of the [Ca²⁺]_i concentration

Changes in the [Ca²⁺]_i concentration were monitored by using fluo-3/AM, which was initially dissolved in dimethyl

sulfoxide and stored at -20°C. The cultured ICC on coverslips (25 mm) were rinsed twice with a bath solution (5 mmol/L KCl, 135 mmol/L NaCl, 2 mmol/L CaCl₂, 10 mmol/L glucose, 1.2 mmol/L MgCl₂ and 10 mmol/L HEPES, adjusted to pH 7.4 with Tris). The coverslips were then incubated in the bath solution containing 5 μmol/L fluo-3 with 5% CO₂ at 37°C for 5 min, rinsed two more times with the bath solution, mounted on a perfusion chamber, and scanned every 0.4 s with a Nikon Eclipse TE200 inverted microscope equipped with a Perkin-Elmer Ultraview confocal scanner and a Hamamatsu Orca ER 12-bit CCD camera (× 400). Fluorescence was determined with an excitation wavelength of 488 nm, and emitted light was observed at 515 nm. During scanning of the Ca²⁺ imaging, the temperature of the perfusion chamber containing the cultured ICC was kept at 30°C. The variations of [Ca²⁺]_i fluorescence emission intensity were expressed as F1/F0 where F0 is the intensity of the first imaging.

Statistical analysis

Data are expressed as the mean ± SE. Differences in the data were evaluated by Student's *t*-test. *P* < 0.05 was taken as a statistically significant difference. The *n* values reported in the text refer to the number of cells used in the patch-clamp experiments.

RESULTS

Effect of PGF_{2α} on pacemaker potentials and currents in cultured ICC

ICC, identified by Kit immunofluorescence, had a distinctive morphology that was easily recognized in cultures. We thus performed the electrophysiological recording from cultured ICC under current (*I* = 0) and voltage clamp mode. Under current clamp mode, ICC showed spontaneous pacemaker potentials. The resting membrane potential was -53 ± 4 mV and amplitude was 27 ± 2 mV. In the presence of PGF_{2α} (10 μmol/L), membrane potentials were depolarized to -29 ± 3.4 mV and the amplitude of pacemaker potentials was decreased to 3.9 ± 1.6 mV (*n* = 5, Figure 1A, bar graph not shown). These results are in agreement with previous studies showing that ICC have spontaneous pacemaker activity and we also found PGF_{2α} to have action on this electrical activity of ICC. Under a voltage clamp at a holding potential of -70 mV, the ICC generated spontaneous inward currents. Treatment with various concentrations of PGF_{2α} in cultured ICC produced tonic inward currents and decreased the frequency and the amplitude of pacemaker currents in a dose-dependent manner (Figure 1B-D). As shown in Figure 1E-G, the values of frequency, amplitude and resting currents with regard to pacemaker currents under control conditions were significantly different from those obtained in the presence of PGF_{2α}.

Effects of non-selective cation channel blocker or Cl⁻ channel blocker on PGF_{2α}-induced responses in cultured ICC

In order to characterize the tonic inward currents in-

duced by PGF_{2α}, we used flufenamic acid, a non-selective cation channel blocker, or niflumic acid, a Cl⁻ channel blocker. Figure 2A shows that treatment with flufenamic acid (10 μmol/L) abolished the generation of pacemaker currents and blocked the PGF_{2α}-induced tonic currents in ICC. The summarized bar graph (Figure 2B) indicates that the resting currents produced by PGF_{2α} were -21 ± 9 pA in the presence of flufenamic acid and that this value was significantly different when compared with control values obtained in the absence of flufenamic acid (*n* = 4). In the presence of niflumic acid (10 μmol/L), the pacemaker currents were abolished. Under this condition, PGF_{2α} still produced the tonic inward currents (Figure 2C). In the presence of niflumic acid, the resting currents produced by PGF_{2α} were -98 ± 12 pA; this value was not significantly different when compared with control values obtained in the absence of niflumic acid (*n* = 5, Figure 2D).

No involvement of G proteins in the PGF_{2α}-induced tonic inward currents in cultured ICC

The effects of GDP-β-S, a nonhydrolysable guanosine 5'-diphosphate analogue which permanently inactivates GTP binding proteins, were examined to determine whether the G-protein is involved in the effects of PGF_{2α} in ICC. When GDP-β-S (1 mmol/L) was in the pipette, PGF_{2α} (10 μmol/L) still showed the tonic inward currents (Figure 3A). In the presence of GDP-β-S in the pipette, the resting currents in the control were -23 ± 9 pA. The resting currents during treatment with PGF_{2α} in the presence of GDP-β-S were -159.9 ± 36 pA (*n* = 4, Figure 3B), which were not significantly different from those obtained by treatment with PGF_{2α} in the absence of GDP-β-S.

External Ca²⁺-free solution and Ca²⁺-ATPase inhibitor of endoplasmic reticulum suppress PGF_{2α} effects in cultured ICC

To investigate the role of external Ca²⁺ or internal Ca²⁺, PGF_{2α} was tested under external Ca²⁺-free conditions and in the presence of thapsigargin, a Ca²⁺-ATPase inhibitor of endoplasmic reticulum. The application of external Ca²⁺-free solution completely inhibited the pacemaker currents in voltage clamp mode at a holding potential of -70 mV and in this condition, PGF_{2α} (10 μmol/L)-induced effects on pacemaker currents were blocked (*n* = 5, Figure 4A). The value of resting currents with PGF_{2α} (10 μmol/L) in Ca²⁺-free solution was significantly different when compared with control values obtained in normal solution (Figure 4B). In addition, the treatment with thapsigargin (5 μmol/L) inhibited the pacemaker currents in ICC and blocked the PGF_{2α}-induced tonic inward currents (Figure 4C). In the presence of thapsigargin, the value of resting currents during treatment with PGF_{2α} was significantly different from those obtained by treatment with PGF_{2α} in the absence of thapsigargin (*n* = 6, Figure 4D).

Effects of phospholipase C inhibitor on the PGF_{2α}-induced tonic inward currents in cultured ICC

To investigate whether the PGF_{2α}-induced effects on

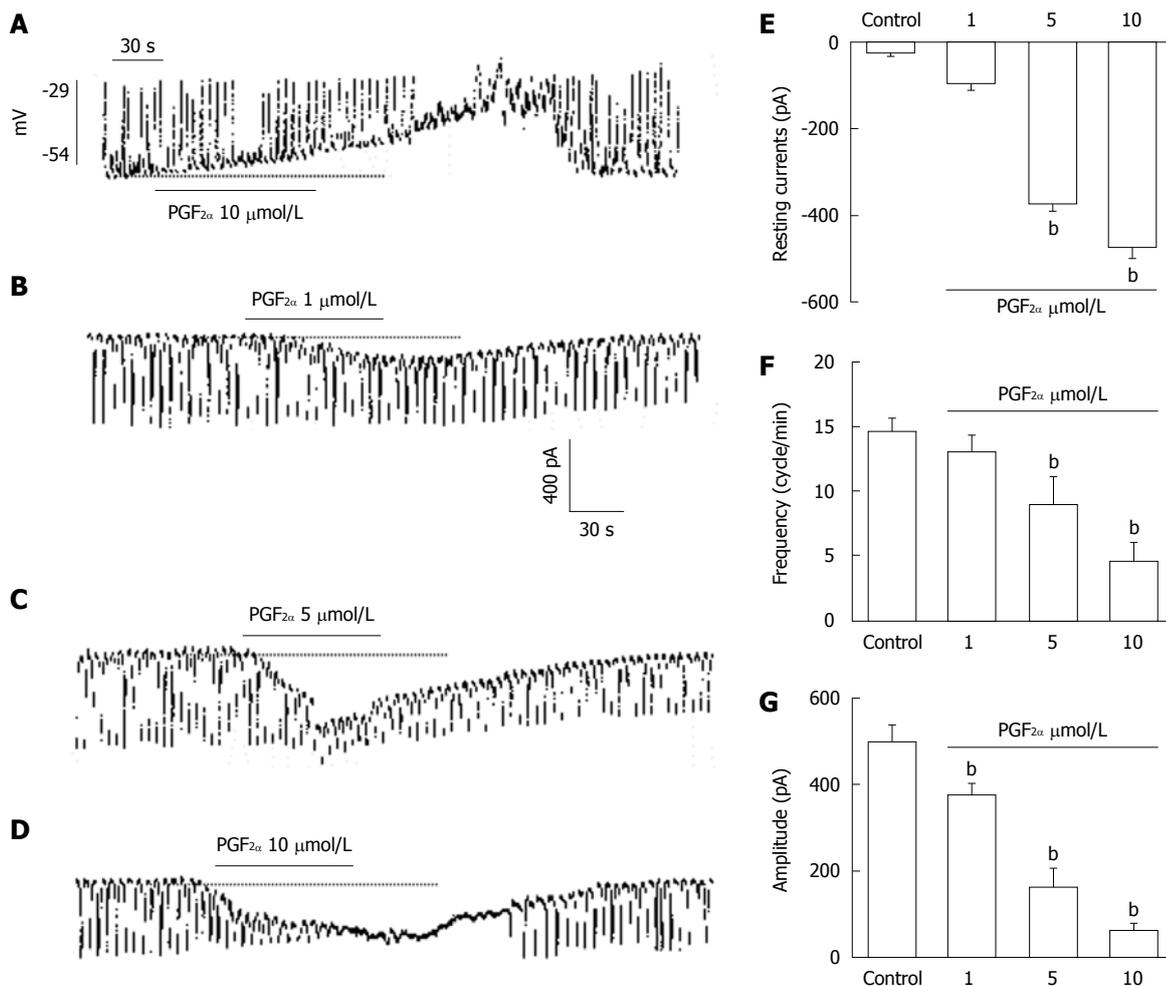

Figure 1 The effects of Prostaglandin F_{2α} on pacemaker potentials and pacemaker currents recorded in cultured interstitial cells of Cajal from mouse small intestine. A: Pacemaker potentials of interstitial cells of Cajal (ICC) exposed to Prostaglandin F_{2α} (PGF_{2α}) (10 μmol/L) in the current-clamping mode (*I* = 0). Vertical solid line scales denote amplitude of pacemaker potential and horizontal solid line scales denote duration of recording (s) pacemaker potentials; B-D: Pacemaker currents of ICC recorded at a holding potential of -70 mV exposed to various concentrations of PGF_{2α} (1, 5, and 10 μmol/L). The dotted lines indicate zero current levels. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker currents. The responses to PGF_{2α} are summarized in E-G. The bars represent mean ± SE. ^b*P* < 0.01 vs the untreated control.

pacemaker currents are mediated by the activation of phospholipase C (PLC), we treated the ICC with U-73122, a PLC inhibitor. U-73122 (5 μmol/L) abolished the generation of pacemaker currents and blocked the PGF_{2α}-induced tonic inward currents (Figure 5A). In the presence of U-73122, the tonic inward currents produced by PGF_{2α} (10 μmol/L) were -21 ± 11 pA. The value of resting currents induced by PGF_{2α} was significantly different from those obtained by treatment with PGF_{2α} in the absence of U-73122 (*n* = 5, Figure 5B). These results suggest that the PGF_{2α}-induced tonic inward currents may be a PLC-dependent mechanism.

Effects of protein kinase C inhibitor on PGF_{2α}-induced responses in cultured ICC

We tested the effects of chelerythrine or calphostin C, inhibitors of protein kinase C (PKC), to investigate whether PGF_{2α}-induced responses to pacemaker currents are mediated by the activation of PKC. Chelerythrine (1 μmol/L) or calphostin C (10 μmol/L) did not have an effect on

tonic inward currents induced by PGF_{2α} (10 μmol/L) (Figure 6A and C) and the value also was not significantly different when compared with the tonic inward currents induced by PGF_{2α} obtained in the absence of chelerythrine or calphostin C (*n* = 5, Figure 6B and D).

Increasing of [Ca²⁺]_i intensity by PGF_{2α}

Because many reports have suggested that [Ca²⁺]_i oscillations in ICC could be considered to be the primary mechanism for the pacemaker activity in GI activity, we examined the effect of PGF_{2α} on [Ca²⁺]_i oscillations in ICC. In this study, we measured spontaneous [Ca²⁺]_i oscillations of ICC which are connected with cell clusters. Spontaneous [Ca²⁺]_i oscillations observed in ICC which were loaded with fluo3-AM and the time series data show the spontaneous regular [Ca²⁺]_i oscillations. In the presence of PGF_{2α} (10 μmol/L), the basal points of [Ca²⁺]_i oscillations were increased but the peak points of [Ca²⁺]_i oscillations were slightly decreased (Figure 7A). The data of the time series are summarized in Figure 7B. These results suggest

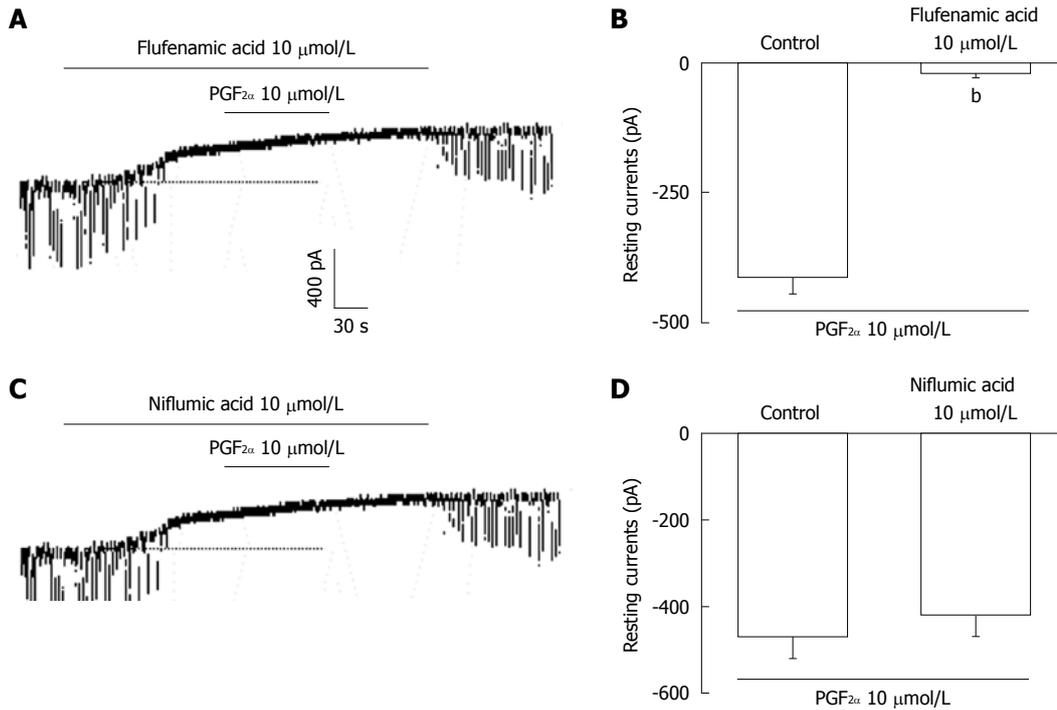

Figure 2 The effects of flufenamic acid or niflumic acid on prostaglandin F_{2α}-induced responses in pacemaker currents in cultured interstitial cells of Cajal from mouse small intestine. **A:** Application of flufenamic acid (10 μmol/L) abolished the generation of pacemaker currents. Under these conditions, the prostaglandin F_{2α} (PGF_{2α}) (10 μmol/L) did not produce tonic inward currents; **C:** Niflumic acid (10 μmol/L) also abolished the generation of pacemaker currents. However, niflumic acid did not block the PGF_{2α} (10 μmol/L)-induced tonic inward currents. The dotted lines indicate zero current levels. Responses to the PGF_{2α} in the presence of flufenamic acid or niflumic acid are summarized in **B** and **D**. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker currents. The bars represent mean ± SE. ^b*P* < 0.01 vs the untreated control.

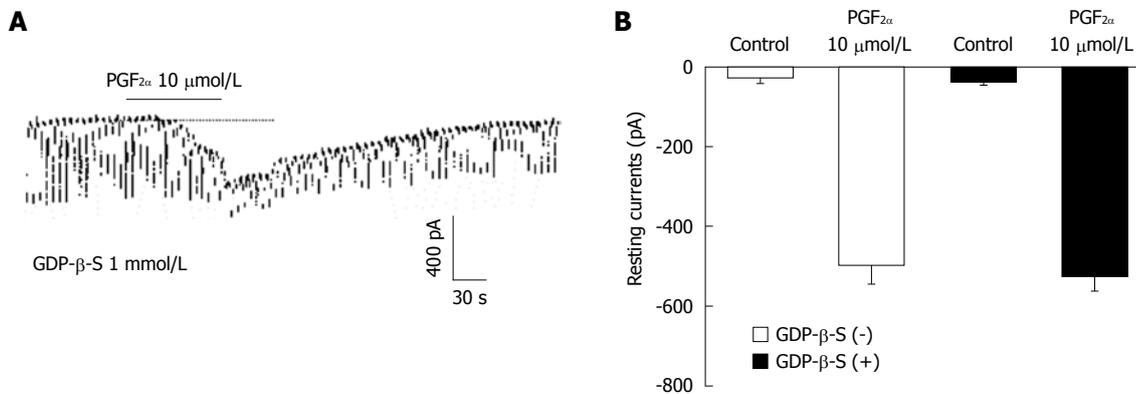

Figure 3 The effects of 5'-[thio]diphosphate trilithium salt on response to prostaglandin F_{2α}-induced pacemaker currents from interstitial cells of Cajal from mouse small intestine. **A:** Pacemaker currents from interstitial cells of Cajal exposed to prostaglandin F_{2α} (PGF_{2α}) (10 μmol/L) in the presence of 5'-[thio]diphosphate trilithium salt (GDP-β-S) (1 mmol/L) in the pipette. The tonic inward currents with suppressed amplitude and frequency induced by PGF_{2α} remained unchanged during internally applied GDP-β-S (1 mmol/L). The dotted lines indicate the zero current levels. The effects of PGF_{2α} in the presence of GDP-β-S are summarized in **B**. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker currents. Bars represent mean ± SE. The effects of GDP-β-S on PGF_{2α}-induced pacemaker currents were not significantly different from the PGF_{2α}-induced pacemaker currents in the absence of GDP-β-S.

that the action of PGF_{2α} on ICC may involve the regulation of spontaneous [Ca²⁺]_i oscillations.

DISCUSSION

Although the actions of PGF_{2α} have been demonstrated with regard to GI motility in tissue and smooth muscle cells, this is the first study in ICC in which an attempt has

been made to determine the effects of PGF_{2α} on electrical activity in the small intestine.

The results of the present study demonstrate that PGF_{2α} regulates intestinal motility by modulating the pacemaker currents of ICC and that this modulation is mediated *via* the action on non-selective cation channels and [Ca²⁺]_i mobilization in a PKC-independent manner.

Most regions of the GI tract generate spontaneous elec-

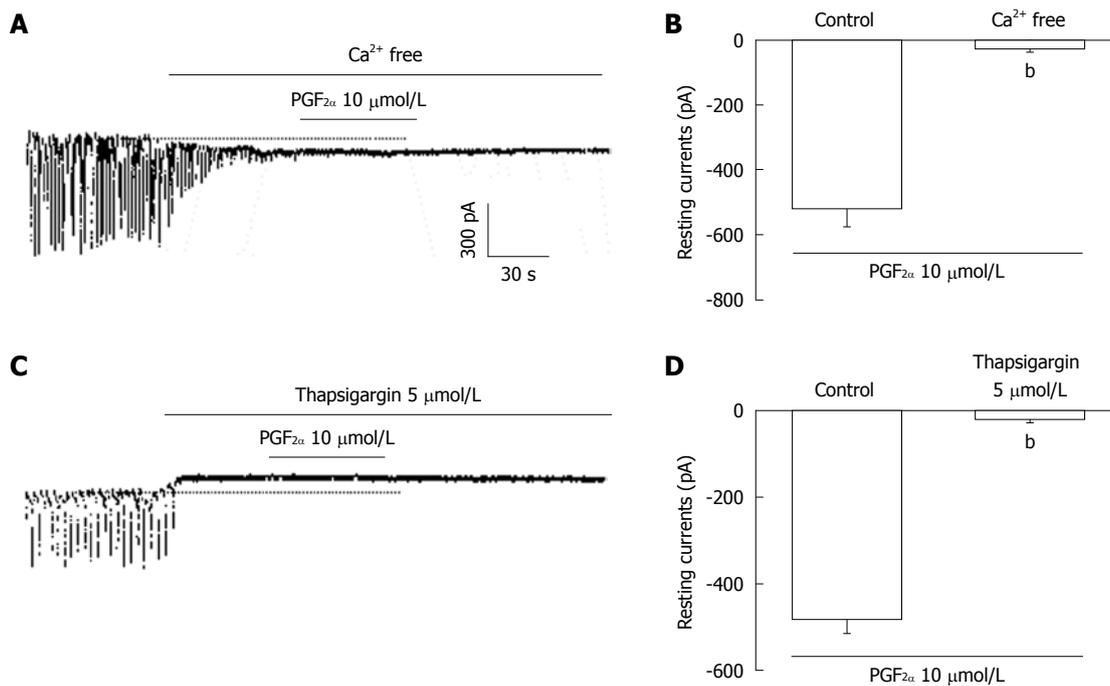

Figure 4 The effects of an external Ca²⁺-free solution or thapsigargin on the prostaglandin F_{2α}-induced response in pacemaker currents in cultured interstitial cells of Cajal from mouse small intestine. A: External Ca²⁺-free solution abolished the generation of pacemaker currents. Under these conditions, the prostaglandin F_{2α} (PGF_{2α}) (10 μmol/L)-induced tonic inward currents were blocked; C: Thapsigargin (5 μmol/L) abolished the generation of pacemaker currents. Thapsigargin also blocked the PGF_{2α} (10 μmol/L)-induced tonic inward currents. The dotted lines indicate the zero current levels. Responses to the PGF_{2α} in the external Ca²⁺-free solution and in the presence of thapsigargin are summarized in B and D. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker current. The bars represent mean ± SE. ^bP < 0.01 vs the untreated control.

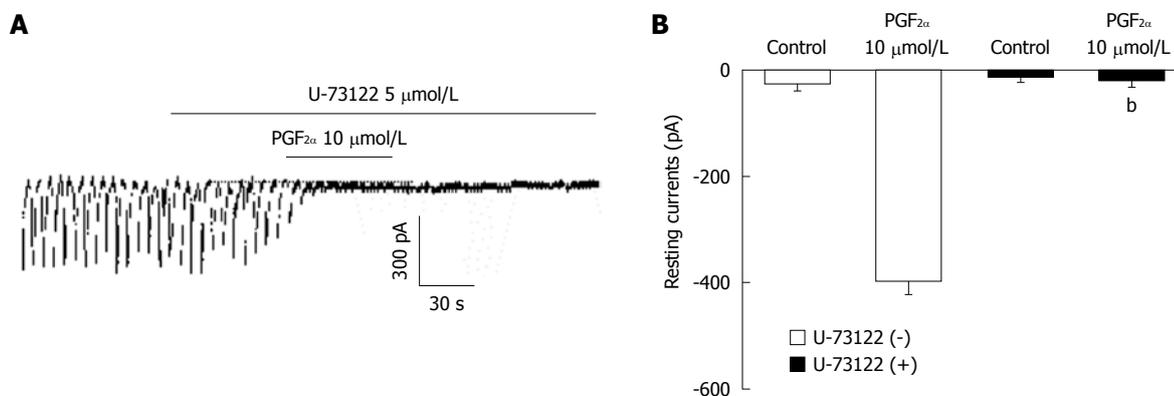

Figure 5 The effects of U-73122 on the prostaglandin F_{2α}-induced response in pacemaker currents of cultured interstitial cells of Cajal from mouse small intestine. A: U-73122 (5 μmol/L) abolished the generation of pacemaker currents. U-73122 also blocked the Prostaglandin F_{2α} (PGF_{2α}) (10 μmol/L)-induced tonic inward currents. The dotted lines indicate the zero current levels. Responses to the PGF_{2α} are summarized in B. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker current. The bars represent mean ± SE. The effect of U-73122 on PGF_{2α}-induced pacemaker currents was significantly different from the PGF_{2α}-induced pacemaker currents in the absence of U-73122 (^bP < 0.01).

trical and mechanical activity in the absence of stimulation. When electrical recordings are made from smooth muscle cells lying in the GI tract, a regular discharge of long lasting waves of depolarization, called slow waves, is detected. It has recently become apparent that slow waves are generated by a specialized population of smooth muscle cells, known as ICC^[18]. ICC generate spontaneous pacemaker inward currents that depolarize membrane, this spreads to smooth muscle *via* gap junctions resulting in depolarization of membrane in smooth muscle leading to contraction by

generating acting potentials through voltage-dependent Ca²⁺ channel activation^[18]. From previous studies, many reports suggested that PGF_{2α} usually showed contractile actions in *in vivo* and *in vitro* studies^[19,21]. These reports indicate the possibility that PGF_{2α} may have stimulatory functions on the electrical activity of ICC. In the present study we found that ICC produced spontaneous pacemaker inward currents under voltage clamp mode and that the application of PGF_{2α} evoked the tonic inward currents of pacemaker currents. This result offers the new suggestion that the

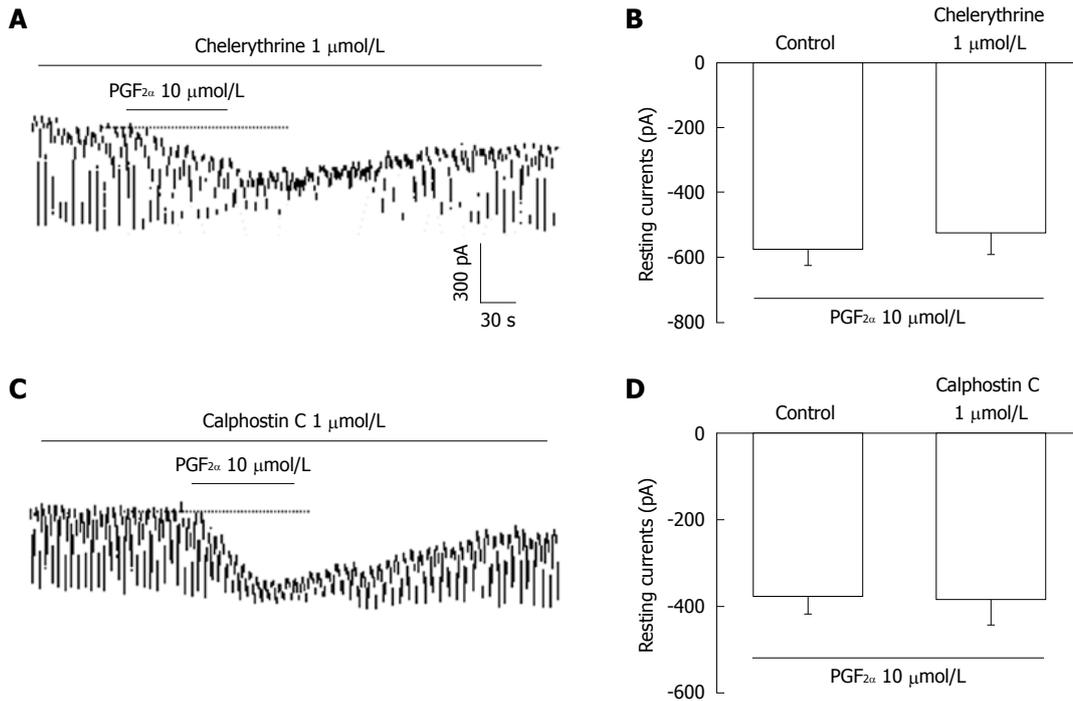

Figure 6 The effects of chelerythrine or calphostin C on the prostaglandin $\text{F}_{2\alpha}$ -induced response in pacemaker currents in cultured interstitial cells of Cajal from mouse small intestine. A and C: Pacemaker currents of interstitial cells of Cajal exposed to prostaglandin $\text{F}_{2\alpha}$ ($\text{PGF}_{2\alpha}$) (10 $\mu\text{mol/L}$) in the presence of chelerythrine (1 $\mu\text{mol/L}$) or calphostin C (1 $\mu\text{mol/L}$). Under these conditions, the $\text{PGF}_{2\alpha}$ caused tonic inward currents. The dotted lines indicate the zero current levels. Responses to the $\text{PGF}_{2\alpha}$ in the presence of chelerythrine or calphostin C are summarized in B and D. Vertical solid line scales denote amplitude of pacemaker current and horizontal solid line scales denote duration of recording (s) pacemaker current. The bars represent mean \pm SE. No significant difference from the untreated control.

regulation of electrical activity in ICC may be involved in the contractile effects of $\text{PGF}_{2\alpha}$ in the GI tract.

Until now, the exact mechanism of pacemaker activity generation has not been fully understood in ICC.

Two suggestions exist: that pacemaker currents of ICC are mediated by the activation of voltage-independent non-selective cation channels and that inwardly rectifying Cl⁻ channels can be generated by the rhythmic inward currents^[15-17]. For checking of these suggestions, we used the blockers of non-selective cation and inwardly rectifying Cl⁻ channels and we could find that flufenamic acid, a non-selective cation blocker, abolished pacemaker current generation and that PGF_{2α}-induced tonic inward currents were blocked by flufenamic acid. However, although niflumic acid, a Cl⁻ channel blocker, also abolished pacemaker generation, niflumic acid did not block the PGF_{2α}-induced tonic inward currents. Furthermore, we have already found that substance P and bradykinin may modulate intestinal motility acting on ICC through the activation of non-selective cation channels^[22,23]. Therefore, these data strongly provide support for the suggestion that, and it is likely that, both Cl⁻ channels and non-selective cation channels are essentially needed for the generation of the spontaneous pacemaker currents in ICC. However, the agent-induced tonic inward currents in ICC may modulate the pacemaker currents by regulating non-selective cation channels in ICC.

The effects of PGs are mediated by specific receptors, classified into basic types (DP, EP, FP, IP, and TP) according to the PG ligand that each binds with the greatest affinity. They have different cell- and tissue-specific functions, as determined by selective coupling to G proteins and by the expression of splicing isoforms. In the case of PGF_{2α}, PGF_{2α} induces inositol (1,4,5) trisphosphate (IP₃) production and increases Ca²⁺ levels *via* FP receptors, which are coupled to G proteins for functional action in various tissues. For example, PGF_{2α} induces phosphoinositol (PI) turnover in isolated luteal cells and the effect of PGF_{2α} in inducing Ca²⁺ mobilization in mouse fibroblasts occurs in conjunction with formation of IP₃, and is pertussis toxin-insensitive^[24,25]. These findings suggest that FP receptors can interact with a member of the G protein family to activate phospholipase C (PLC), leading ultimately to an IP₃-mediated mobilization of Ca²⁺ from intracellular pools. However, there also appears to be a secondary phase of Ca²⁺ release by PGF_{2α}-treated mouse fibroblasts that is likely due to extracellular Ca²⁺ entry. In this present study, when GDP-β-S was present in the pipette, the tonic inward pacemaker currents induced by PGF_{2α} were still present. This means that the effects of PGF_{2α} on electrical activity in ICC may be not related to G proteins. Additionally, since many proposals have been made that PGF_{2α} may have biological activity through mobilization of [Ca²⁺]_i and PLC activation, we used thapsigargin, a potent endoplasmic reticulum Ca²⁺-ATPase inhibitor and U-73122, an active PLC inhibitor, and found that these inhibitors suppressed the PGF_{2α}-induced tonic inward currents. These results strongly support the proposition that the release of Ca²⁺ from internal storage and PLC activation by PGF_{2α} are essential to produce tonic inward currents. Also, these findings have correlations with previous suggestions. In addition, it is well known

that the generation of pacemaker currents is dependent upon [Ca²⁺]_i oscillation and that the periodic release of Ca²⁺ from endoplasmic reticulum is essential for generating pacemaker currents. We believe that our experiments using thapsigargin and U-73122 underscore this information.

In many tissues, it is well known that the binding of PGF_{2α} to its receptor results in not only the activation of PLC (and PLC is the initial step of the PI cascade that generates diacylglycerol (DAG), IP₃, and Ca²⁺ release) but also in the activation of a PKC-dependent pathway. The increase in [Ca²⁺]_i not only promotes translocation of some PKC isozymes to the plasma membrane, but, in concert with DAG, is essential in activating the conventional isoforms of PKC^[22]. However, in the present study, chelerythrine or calphostin C, specific and potent PKC inhibitors, did not block PGF_{2α}-induced effects, suggesting that PKC is not involved in the actions of PGF_{2α} in ICC.

The periodic pacemaker activity of ICC is dependent on [Ca²⁺]_i oscillations. The pacemaker mechanism is initiated by release of Ca²⁺ from the endoplasmic reticulum and is followed by reuptake of Ca²⁺ into the mitochondria^[26]. In our results, we found spontaneous [Ca²⁺]_i oscillations in ICC and this means that the spontaneous pacemaker activity of ICC is closely involved with [Ca²⁺]_i oscillations in this experiment; the treatment with PGF_{2α} in ICC increased the basal point of [Ca²⁺]_i oscillation and decreased the peak point. However, the [Ca²⁺]_i intensity was broadly increased as the action of tonic inward currents reversed. Our previous report suggested that PGE₂ inhibited [Ca²⁺]_i oscillations by ATP-sensitive K⁺ channel activation in cultured ICC^[27]. The observed actions of PGE₂ on [Ca²⁺]_i oscillation in ICC support the suggestion that [Ca²⁺]_i oscillations are important actions of pacemaker activity. Namely, PGE₂ and PGF_{2α} have opposing actions in ICC. However, both PGE₂ and PGF_{2α} have the same target for modulating the pacemaker activity of ICC; that is, the [Ca²⁺]_i in ICC. Therefore, these results suggest that the spontaneous oscillation of [Ca²⁺]_i is essential for pacemaker activity of ICC and that the [Ca²⁺]_i can be the main regulatory target for various endogenous agents or neurotransmitters in ICC.

In the present study, externally applied PGF_{2α} depolarized ICC membranes and formed spike potentials which would result in muscle contraction. As the ICC are electrically coupled with nearby smooth muscles through the gap junctions, the resulting contraction propagates around and along the gut in a coordinated manner and ultimately regulates GI motility.

In conclusion, this study describes the effects of PGF_{2α} on ICC in the mouse small intestine. PGF_{2α} depolarized the membrane with increased tonic inward currents, which were activated by non-selective cation channels *via* external Ca²⁺ influx, PLC, and internal Ca²⁺ mobilization, in a PKC-independent manner. Thus, PGF_{2α} may play a very important role in regulating the rhythm and contraction of small intestinal smooth muscles by acting on ICC.

COMMENTS

Background

Prostaglandins (PGs) of the E, F, and I series are widely distributed in all body tissues, including the gastrointestinal (GI) tract. Many reports have suggested that PGF_{2α} plays an important role in the modulation of intestinal motility.

Research frontiers

There are many reports that PGF_{2α} has a function in GI motility by acting on smooth muscles but no studies have been performed to determine the effects of PGF_{2α} on electrical events in interstitial cells of Cajal (ICC). Therefore, the purpose of our study was to investigate the signal transduction effects of PGF_{2α} on pacemaker activity in cultured ICC.

Innovations and breakthroughs

This study showed the actions of PGF_{2α} on ICC in the mouse small intestine. PGF_{2α} depolarized the membrane with increased tonic inward currents, which were activated by non-selective cation channels via external Ca²⁺ influx, phospholipase C, and internal Ca²⁺ mobilization, in a protein kinase C-independent manner.

Applications

The role of PGF_{2α} in ICC may be one theory for understanding the excitatory action of PGF_{2α} in GI motility.

Terminology

ICC have functions of pacemaker cells and neuromediator cells in the tunica muscularis of the GI tract. The ICC generate rhythmic oscillations in membrane potential known as slow waves and this generation of slow waves is due to spontaneous inward currents called pacemaker currents.

Peer review

It is an interesting paper dealing with a demanding subject. They found that PGF_{2α} can regulate intestinal motility through the modulation of ICC pacemaker activities.

Abstract

AIM: To investigate the biological features of hepatitis B virus (HBV)-transfected HepG2.2.15 cells.

METHODS: The cell ultrastructure, cell cycle and apoptosis, and the abilities of proliferation and invasion of HBV-transfected HepG2.2.15 and the parent HepG2 cells were examined by electron microscopy, flow cytometry, 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide and trans-well assay. Oncogenicity of the two cell lines was compared *via* subcutaneous injection and orthotopic injection or implantation in nude mice,

and the pathological analysis of tumor formation was performed. Two cytoskeletal proteins were detected by Western blotting.

RESULTS: Compared with HepG2 cells, HepG2.2.15 cells showed organelle degeneration and filopodia disappearance under electron microscope. HepG2.2.15 cells proliferated and migrated slowly *in vitro*, and hardly formed tumor and lung metastasis in nude mice. Flow cytometry showed that the majority of HepG2.2.15 cells were arrested in G1 phase, and apoptosis was minor in both cell lines. Furthermore, the levels of cytoskeletal proteins F-actin and Ezrin were decreased in HepG2.2.15 cells.

CONCLUSION: HepG2.2.15 cells demonstrated a lower proliferation and invasion ability than the HepG2 cells due to HBV transfection.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the primary malignancy of the liver. It is the third leading cause of cancer

death in the world, and the second in China^[1,2]. It is generally accepted that hepatitis B virus (HBV) plays a major causative role in the development of HCC^[3,4]. To investigate the pathogenesis of HBV in HCC, several HBV expressing cell lines have been established by viral DNA transfection^[5,6]. Most of them are derived from HepG2 and HuH7^[7,8].

HepG2.2.15 cells are derived from the human hepatoblastoma cell line HepG2 and are characterized by having stable HBV expression and replication in the culture system^[9]. As a cell source that can produce HBV, HepG2.2.15 has been frequently used in studies of HBV infection.

In this study, to clarify the cellular and biological features associated with HBV transfection, we examined HBV-producing HepG2.2.15 and parental HepG2 cells in a variety of biological processes including cell proliferation, cell invasion, tumor development and metastasis. We also explored the underlying mechanism accounting for the different features between the two cell lines.

MATERIALS AND METHODS

Cell lines and culture

HepG2.2.15 and HepG2 cells were cultured in DMEM medium (Hyclone, Logan, UT, USA), supplemented with 10% fetal bovine serum (Invitrogen, Carlsbad, CA, USA), in 5% CO₂ at 37°C. A final concentration of 380 mg/L G418 (Invitrogen) was added into the medium for the maintenance of HepG2.2.15 cells.

Enzyme-linked immunosorbent assay

To detect the expression and replication of HBV in HepG2.2.15 cells, hepatitis B surface antigen (HBsAg) and hepatitis B envelope antigen (HBeAg) levels in the medium at 24 h, 48 h and 72 h were determined semi-quantitatively using enzyme-linked immunosorbent assay (ELISA) kits (Sino-American Biotechnology Company, Shanghai, China) according to the manufacturer's instructions. All experiments were performed in triplicate.

Electron microscopy

HepG2.2.15 and HepG2 cells were collected and fixed in 2.5% glutaraldehyde (GA) overnight, dehydrated in a graded series of ethanol and embedded in Quetol-812. The ultrathin sections were cut and stained with lead citrate. The grids were examined under a JEM-1220 electron microscope.

3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay

HepG2.2.15 and HepG2 cells were seeded in triplicate into 96-well plates at 4×10^3 cells per well. Twenty microliters 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (5 mg/mL) was added to the medium and cultured for another 4 h. DMSO (150 μ L) was added and the absorbance of each well was read using a Bio-Rad model 550 microplate reader at a wavelength of 490 nm. It was tested for 5 d and the data were expressed as mean \pm SD.

Flow cytometry

Cell cycle assay was monitored using propidium iodide (PI) staining of the nuclei. The cells were fixed in 75% cold alcohol overnight, resuspended in 300 μ L PBS and stained with 500 μ L PI (250 μ g/mL) for 30 min in the dark. Annexin V/PI double staining was used for apoptosis assay. Annexin V and PI were added for incubation for 15 min at 4°C. The cells were analyzed by flow cytometry (BD BioSciences, San Jose, CA, USA).

Trans-well assay

The invasive abilities of HepG2.2.15 and HepG2 cells were determined using matrigel (BD) coated 24-well trans-well chambers (Corning Costar, NY, USA) as described previously^[10]. In brief, trans-well was coated with 10 μ L matrigel and dried in the air; and 5×10^4 cells in serum-free DMEM were seeded into the upper chamber, with the lower chamber supplemented with DMEM containing 10% FBS. The trans-well was incubated at 37°C in 5% CO₂. Incubation time was different due to different invasive abilities of the two cell lines. The cells that had penetrated through the pores were fixed, stained with hematoxylin and eosin (HE) and photographed under light microscope. The experiments were conducted in triplicate.

Western blotting analysis

Total protein extracts of cultured cells were performed routinely. Twelve-microgram samples were size fractionated by SDS-PAGE and electrophoretically transferred to nitrocellulose membranes. The membranes were incubated with F-actin or Ezrin antibodies (Bioss, Beijing, China), and detected using Western blue (Promega, Madison, WI, USA). GAPDH (Calbiochem, Gibbstown, NJ, USA) was used as internal control.

Animals

Four-week-old female BALB/c nude mice were maintained in the laboratory for animal experiments under specific pathogen-free conditions. The experiments were conducted in accordance with the Guideline for Animal Experiments of the National Cancer Center of China.

Tumor formation assay via subcutaneous injection

HepG2.2.15 and HepG2 cells were harvested and resuspended to 2×10^7 /mL with PBS, and 300 μ L was injected subcutaneously into the left flank of each of eight nude mice. The tumor volume was calculated according to the formula: $V = \text{mean diameter}^3 \times \pi/6$ ^[11] and measured and recorded every 2 d.

Tumor development and metastasis assay via orthotopic implantation

Once the subcutaneous tumor reached 1 cm in diameter, it was removed and cut into 1 mm \times 1 mm \times 1 mm cubes freshly at 4°C. Another group of mice were anesthetized with an intra-peritoneal injection of pentobarbital at a dose of 60 mg/kg. Tumor cubes were implanted into the liver as described previously^[12]. The mice were

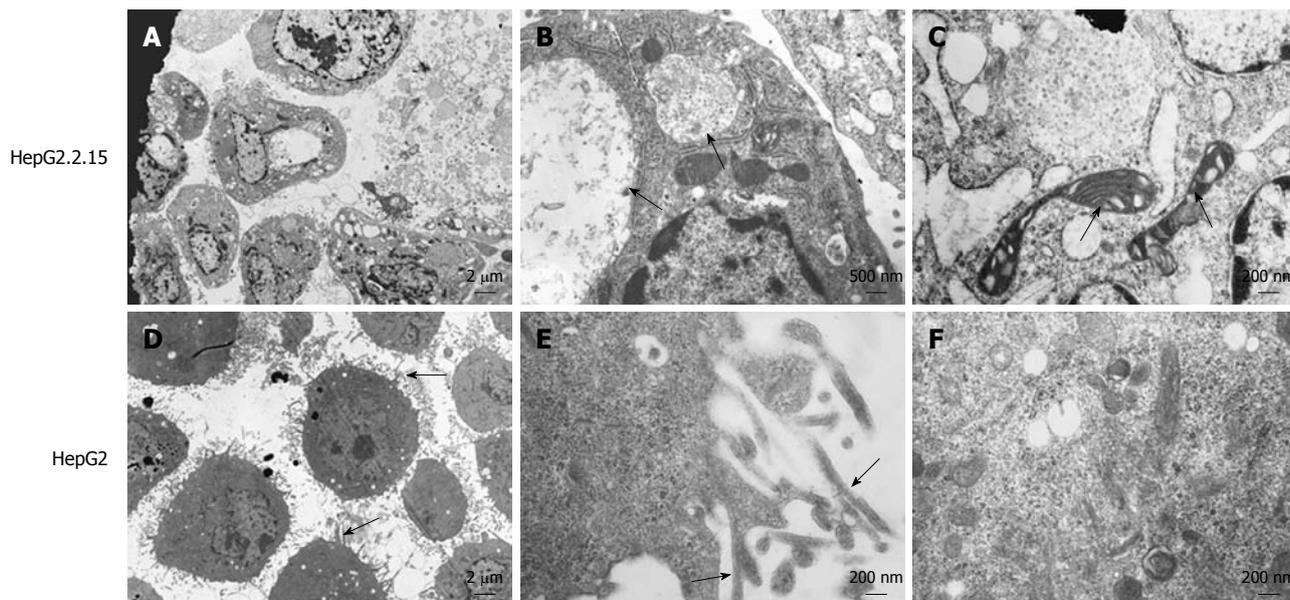

Figure 1 Ultrastructure of HepG2.2.15 and HepG2 cells. A: Filopodia disappearance in HepG2.2.15 cells (EM × 2500); B: Viral inclusion bodies in the cytoplasm of HepG2.2.15 cells. Arrows indicate the viral inclusion bodies (EM × 15000); C: Arrows indicate degenerated mitochondria (EM × 25000); D: Plentiful filopodia around HepG2 cells. Arrows indicate filopodia (EM × 2500); E: Microfilament appearance in filopodia in HepG2 cells in high power field. Arrows indicate microfilament (EM × 25000); F: Abundant organelles in the cytoplasm of HepG2 cells (EM × 25000).

killed 60 d after implantation to harvest the liver and lung. The volume of tumor was determined according to the method described by Janik *et al.*^[13]. The liver and lung were removed and fixed in 4% formalin for standard pathological studies.

Tumor development and metastasis assay via liver injection

HepG2.2.15 and HepG2 cells (1.5×10^6 cells/150 μ L) were prepared in PBS at 4°C for injection. The mice were anesthetized and the liver was exposed as mentioned above. The cells were injected into the left lobe of liver of ten nude mice. The mice were observed for 60 d. Liver and lung were sampled for standard pathological studies as described above.

Statistical analysis

Data were expressed as percentage, mean \pm SD. Comparisons between two groups were analyzed by the χ^2 and Student *t* test. Mann-Whitney *U*-test was employed for analysis of subcutaneous tumor growth. $P < 0.05$ was considered statistically significant.

RESULTS

Ultrastructure of HepG2.2.15 cells

Ultrastructural analysis demonstrated that HepG2.2.15 cells had obviously decreased filopodia (Figure 1A) compared with HepG2 cells (Figure 1D). Plentiful filopodia formed around HepG2 cells and higher amplification showed microfilaments in the filopodia (Figure 1E). Moreover, viral inclusion bodies existed in the cytoplasm of HepG2.2.15 cells (Figure 1B), and many organelles, such as mitochon-

dria, ribosome and endoplasmic reticulum, were found to be degenerated in HepG2.2.15 cells (Figure 1C). In contrast, HepG2 cells contained normal and abundant organelles including ribosome, glycogen, microfilament and microtubule (Figure 1F).

Lower proliferation ability of HepG2.2.15 cells

HBsAg and HBeAg were detected in the culture supernatant of HepG2.2.15 cells by ELISA. While the HBsAg level increased in a time-dependent manner, HBeAg level peaked at around 24 h and remained largely unchanged until 72 h (Figure 2A). As shown in Figure 2B, HepG2 cells had a significantly higher proliferation rate than HepG2.2.15 cells from Day 2 ($P < 0.01$), especially on Day 4 and Day 5 ($P < 0.001$).

Cell cycle G1/S arrest in HepG2.2.15 cells

To further investigate the reduced proliferation of HepG2.2.15, we tested cell cycle and apoptosis by flow cytometry. The results indicated that the percentage of the G1 phase of HepG2 was significantly lower than that of HepG2.2.15 ($P < 0.01$), but the HepG2 cells in S phase were increased significantly ($P < 0.001$) (Figure 2C), indicating cell cycle arrest at the G1/S phase in HepG2.2.15 cells. The apoptosis analysis showed no significant difference in apoptosis between HepG2.2.15 and HepG2 cells (Figure 2D).

Lower invasion ability of HepG2.2.15 cells in vitro

Trans-well analysis demonstrated that HepG2.2.15 and HepG2 cells were significantly different in invasion ability *in vitro*. HepG2 cells on the lower part of the membrane were detected as early as 2 h after incubation, with an in-

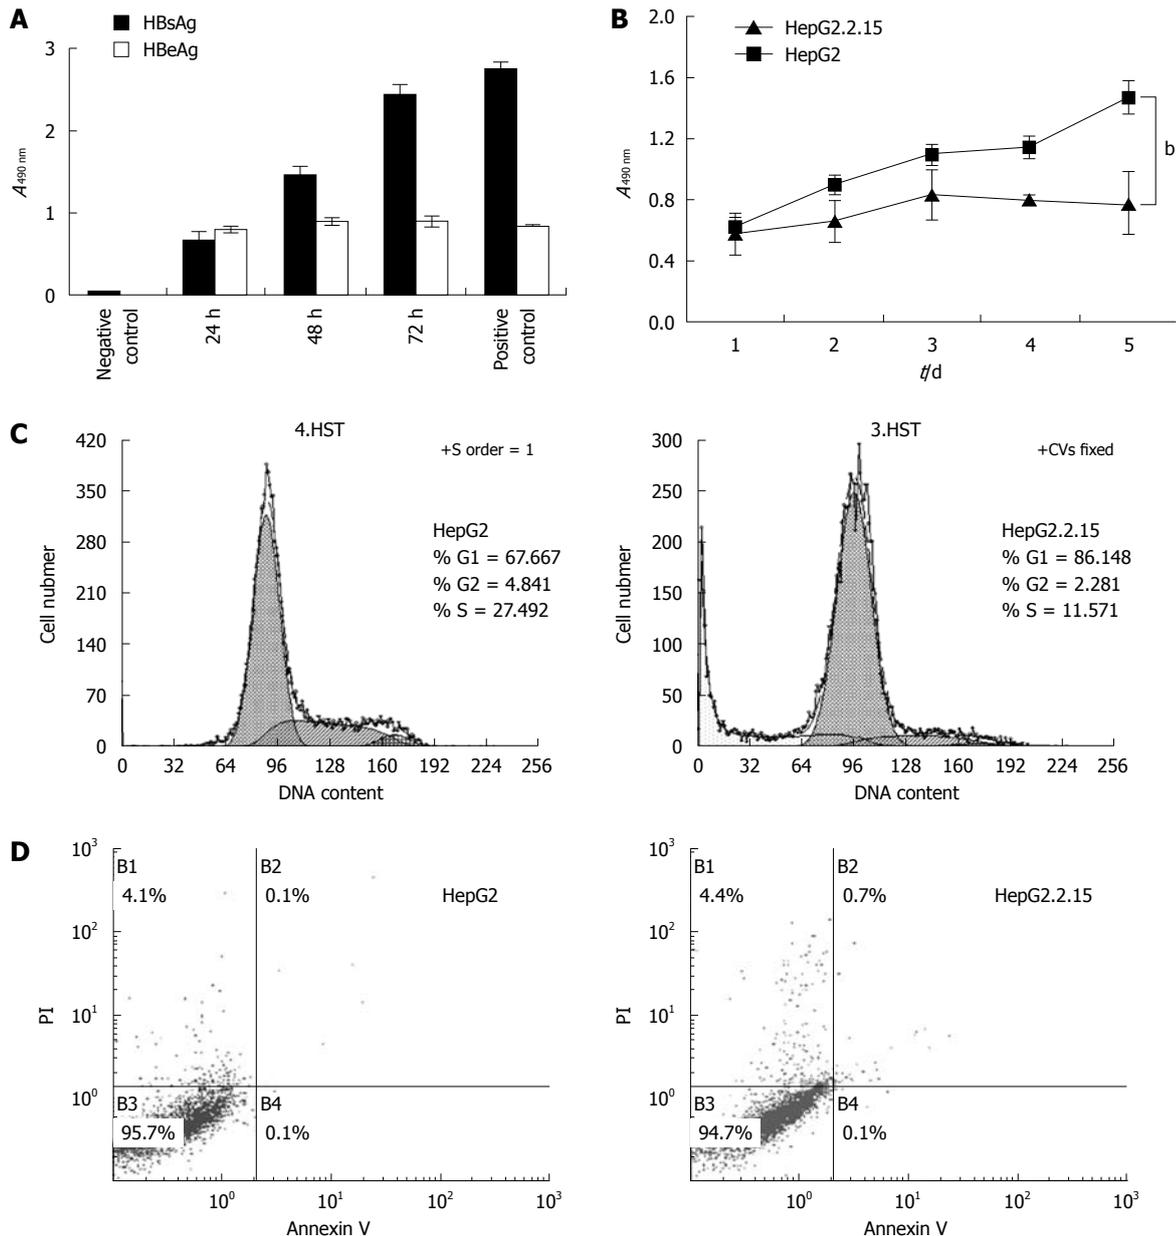

Figure 2 Cell proliferation and apoptosis flow cytometry. A: The levels of hepatitis B surface antigen (HBsAg) and hepatitis B envelope antigen (HBeAg) in HepG2.2.15 cell supernatant. The supernatant was collected every 24 h and tested by enzyme-linked immunosorbent assay; B: 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay of cell proliferation. The absorbencies of test wells were read every 24 h and the data represent the mean \pm SD ($^*P < 0.001$); C: Flow cytometry of cell cycle; D: Apoptosis percentages in B1, B2 and B4 areas. All experiments were repeated three times with similar results.

creasing number of cells invading through the membrane at 4 h, 6 h and 12 h (Figure 3A). In contrast, the invasion of HepG2.2.15 cells into the lower chamber was detected at 24 h, 36 h, 48 h and 60 h, respectively (Figure 3B). These results suggested that HepG2.2.15 cells had lower invasion ability and took longer time to go through the membrane.

Decreased expression levels of F-actin and Ezrin in HepG2.2.15 cells

To elucidate the mechanism accounting for the difference in cell invasion between HepG2.2.15 and HepG2 cells, we examined the expression of F-actin and Ezrin, which are both cytoskeleton proteins that play crucial roles in

maintaining cell shape and promoting cell invasion. Western blotting analysis showed a 0.7-fold decrease of F-actin level and a 3.8-fold decrease of Ezrin level in HepG2.2.15 cells compared with HepG2 cells (Figure 3C).

Lower tumorigenicity of HepG2.2.15 cells *in vivo*

To explore the biological features of HepG2.2.15 cells *in vivo*, we monitored subcutaneous tumor growth *in vivo*. Two days after injection of HepG2 cells, the nodules were visualized and the diameter reached 0.6 cm on Day 6, and 100% (8/8) mice formed tumors. In contrast, only 25% (2/8) mice injected with HepG2.2.15 cells formed tumors, significantly lower than that of HepG2 cells ($P < 0.01$), and tumor formation was slower than the mice injected

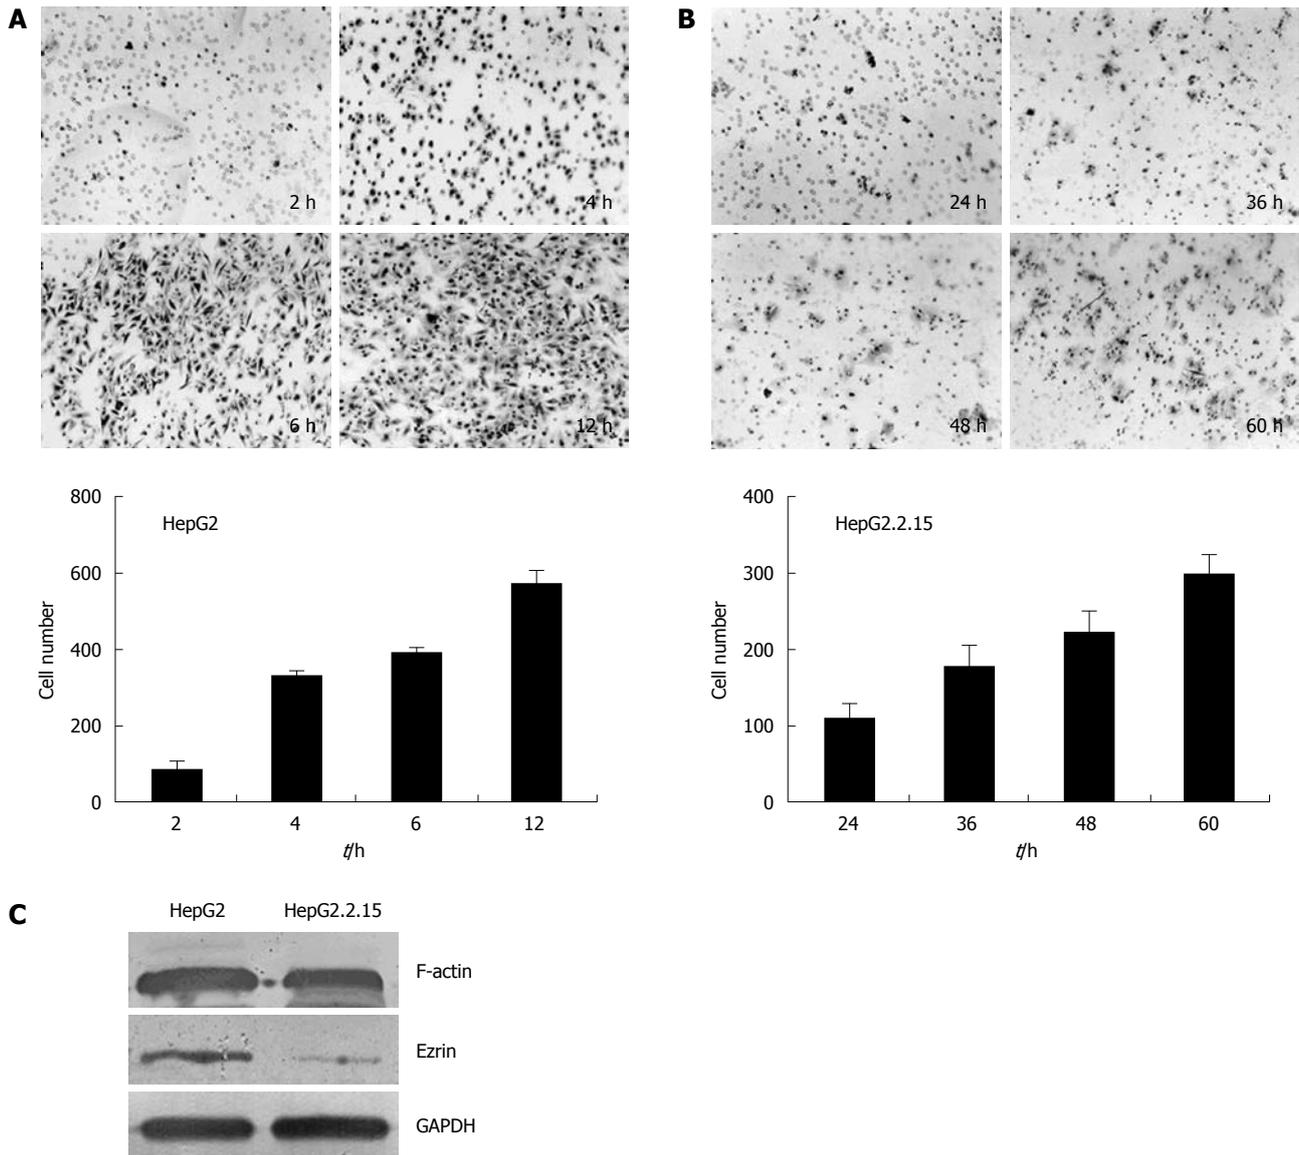

Figure 3 Invasion assays of HepG2 and HepG2.2.15 cells. The trans-well membranes were collected at different time points and the cells that went through the pores were stained with hematoxylin and eosin. The cell numbers were counted. A: HepG2 cells collected and stained at 2 h, 4 h, 6 h and 12 h after incubation; B: HepG2.2.15 cells collected and stained at 24 h, 36 h, 48 h and 60 h after incubation; C: Western blotting analysis of F-actin and Ezrin.

with HepG2 cells (Figure 4A). Notably, 100% (10/10) mice injected with HepG2 cells formed tumor in the liver 60 d after tumor cubes implantation, and the mean volume was $1.7 \pm 0.4 \text{ cm}^3$. Furthermore, all the mice (10/10) developed tumor in the liver after the injection of HepG2 cells and the mean volume of tumor was as big as $3.1 \pm 1.1 \text{ cm}^3$. Nevertheless, the incidence of tumor formation in HepG2.2.15 group (40%, 4/10) was significantly lower than the HepG2 group ($P < 0.05$). The mean volume was $2.3 \pm 0.3 \text{ cm}^3$ (Figure 4B). Only one case formed tumor (10%, 1/10) with a volume of 2.1 cm^3 (Figure 4B). The incidence of tumor formation in the liver was significantly higher in HepG2 implantation group ($P < 0.05$) and injection group ($P < 0.001$) when compared with HepG2.2.15 group. Taken together, these results indicated the low tumorigenicity of HepG2.2.15 cells *in vivo*, being consistent with their reduced cell proliferation and invasion *in vitro*.

Pathological analysis of tumor formation

Lung metastasis was observed under light microscope with a highest percentage of 50% (Figure 4E) in HepG2 group. The growth pattern (Figure 4C), invasion and changes in tumor and surrounding normal tissues were also analyzed in all the groups (Table 1). Most non-tumor livers showed obvious fatty changes in HepG2.2.15 groups (Figure 4D) and the invasion to surrounding organs occurred more frequently in HepG2 groups.

DISCUSSION

This study found that HepG2.2.15 cells had lower proliferation and invasion ability than the HepG2 cells. The majority of HepG2.2.15 cells were arrested at G1-S phase and the level of two important cytoskeletal proteins decreased.

Table 1 Pathological analysis *in vivo*

| Tumor behavior | HepG2 | | HepG2.2.15 | |
|---------------------------|---|--|--|--|
| | Cell injection (n = 10) | Tissue implantation (n = 10) | Cell injection (n = 10) | Tissue implantation (n = 10) |
| Formation (%) | 100 | 100 | 10 ^d | 40 ^a |
| Volume (cm ³) | 3.1 ± 1.1 | 1.7 ± 0.4 | 2.1 | 2.3 ± 0.3 |
| Growth | Expensive growth and central necrosis | Same | Same | Same |
| Surrounding tissue | Degeneration and necrosis | Same | Same | Same |
| Normal tissue | Spotty or piecemeal necrosis, scattered fat droplets and vacuolation, focal inflammatory infiltration | Spotty or piecemeal necrosis, diffuse fatty change 40% and focal inflammatory infiltration | Spotty or piecemeal necrosis, diffuse or scattered fatty change 50%, focal inflammatory infiltration and diffuse cytoplasmic swelling of liver cells | Spotty or piecemeal necrosis, diffuse fatty change 40%, focal inflammatory infiltration and mild cytoplasmic swelling of liver cells |
| Tumor invasion | Abdominal wall 100%; pancreas 37.5%; esophago 12.5% | Abdominal wall 50%; pancreas 12.5%; diaphragma/ribs 10% | Abdominal wall 10% | Diaphragma/ribs 10% |
| Metastasis | | | | |
| Intra-liver | 75% (6/8) | 30% (3/10) | 0 | 0 |
| Lung | 50% (4/8) | 0 | 10% (1/10) | 10% (1/10) |

^a*P* < 0.05 vs HepG2 tissue implantation group; ^d*P* < 0.001 vs HepG2 cell injected group, χ^2 test.

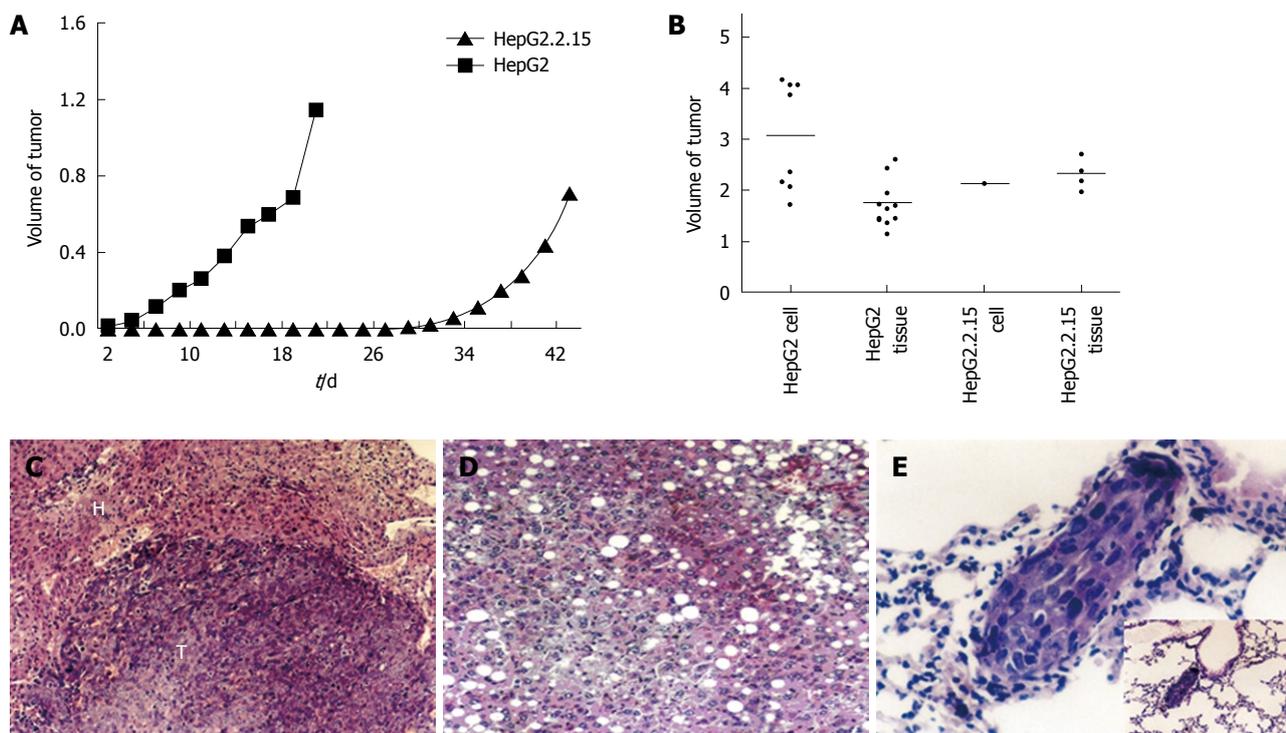

Figure 4 Tumor formation of HepG2 and HepG2.2.15 cells *in vivo*. A: The volume of subcutaneous tumors were measured and recorded every 2 d. The difference of tumor growth rate between HepG2 and HepG2.2.15 groups was significant (*P* < 0.01, Mann-Whitney *U* test); B: Tumor development in four groups *in vivo*; C: Expansive growth of tumor. The boundary of tumor and normal tissue is clear [hematoxylin and eosin (HE) stain, × 120]. T: Tumor; H: Liver tissue; D: Fatty changes in liver tissue of HepG2.2.15 groups (HE stain, × 120); E: Lung metastasis in HepG2 injected group (HE stain, × 460) and low power field.

HBV contains four open reading frames S, C, P, and X. Kanda *et al.*^[7] and Kim *et al.*^[14] showed that HBx transfection down-regulated cell viability and induced apoptosis. HBx suppressed tumor cell proliferation, induced apoptosis and caused cell cycle arrest at G1-S *in vitro*^[15]. These results are partly consistent with our findings in this study. It has been shown that HBV replication depends on the cell cycle and the decrease in S phase^[16], so HBV replica-

tion may affect cell cycle progression. This may partly explain the G1-S arrest in HepG2.2.15 cells. Proteome analysis of HepG2.2.15 and HepG2 cells displayed abundant differentially expressed proteins^[17]. In this study, we found that the expression level of Ezrin and F-actin was lower in HepG2.2.15 than in HepG2. F-actin is the major cytoskeletal element and Ezrin is a member of the ERM (ezrin-radixin-moesin) cytoskeleton-associated protein

family^[18]. Both of them have membrane-cytoskeleton linking functions^[19] and participate in cell migration, growth regulation^[20], filopodia formation^[21], and cancer metastasis^[22]. Therefore, reduced level of Ezrin and F-actin in HepG2.2.15 cells may contribute to the lower proliferation and invasion ability. Additionally, the lower expression of Ezrin was accompanied with reduced filopodia in HepG2.2.15 cells. The dysfunction of organelles and cytoskeleton in HepG2.2.15 cells may also contribute to the slower cell growth and invasion both *in vitro* and *in vivo*.

Notably, non-tumor liver tissues showed mild to severe hepatic fatty changes, necrosis and neutrophil infiltration in HepG2.2.15 groups. In the mice injected with HepG2.2.15 cells, the low rate of tumor formation was accompanied by severe degeneration and necrosis in liver tissues. Interestingly, similar results have been reported by other researchers. For example, overexpression of HBx caused negative accommodation of microsomal triglyceride transfer protein and accumulation of intracellular triglyceride and cholesterol in hepatocyte^[23]. Liver tissue from the HBx transgenic mice showed mild to severe hepatic necrosis, fatty changes, mild to moderate chronic hepatitis and cytoplasmic vacuolation^[24]. So, the correlations between HBV, hepatic degeneration and inflammation are striking and need to be further investigated.

In summary, HepG2.2.15 cells demonstrated decreased proliferation and invasion ability compared with its parental HepG2 cells due to HBV transfection. HBV-induced cell cycle arrest and cytoskeletal alteration might be implicated in the mechanism. Our findings will help better understand the cellular and biological features of HepG2.2.15 cells associated with HBV, and select the most suitable cell lines for research. These findings also shed new light on the interaction between HBV and host cells.

ACKNOWLEDGMENTS

We are grateful to Professor Yu-Mei Wen for providing us the cell lines.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the third leading cause of cancer death in the world, and the second in China. It is generally accepted that hepatitis B virus (HBV) plays a major causative role in the development of HCC. Although considerable studies have been conducted, the precise mechanism remains unclear.

Research frontiers

HBV infection is considered a high risk for the development of HCC. To investigate the pathogenesis of HBV in HCC, several HBV expressing cell lines have been established by viral DNA transfection. HepG2.2.15 cell line is one of the most common models for HBV-associated disease, but the cellular and biological features associated with HBV in HepG2.2.15 cells is seldom considered. Little is known about the effects of HBV on the biological features of host cells.

Innovations and breakthroughs

In this study, the authors demonstrated that HepG2.2.15 cells had lower proliferation and invasion ability than their parental HepG2 cells. HBV-induced cell cycle arrest and cytoskeletal alteration might be implicated in the mechanism.

Applications

The findings in this study will help us better understand the cellular and biological

features of HepG2.2.15 cells associated with HBV and select the most suitable cell lines for research. They also shed new light on the interaction between HBV and host cells.

Terminology

HepG2.2.15 cells are derived from HepG2 cells transfected with a full-length HBV plasmid. It is characterized by having stable HBV expression and replication in the culture system.

Peer review

The study is well conducted and the methodology is sound.

Abstract

AIM: To test the Genval recommendations and the usefulness of a short trial of proton pump inhibitor (PPI) in the initial management and maintenance treatment of gastroesophageal reflux disease (GERD) patients.

METHODS: Five hundred and seventy seven patients with heartburn were recruited. After completing a psychometric tool to assess quality of life (PGWBI) and a previously validated GERD symptom questionnaire (QUID), patients were grouped into those with esophagitis (EE, $n = 306$) or without mucosal damage (NERD, $n = 271$) according to endoscopy results. The study started with a 2-wk period of high dose omeprazole (omeprazole test); patients responding to this PPI test entered an acute phase (3 mo) of treatment with any PPI at the standard dose. Finally, those patients with a favorable response to the standard PPI dose were maintained on a half PPI dose for a further 3-mo period.

RESULTS: The test was positive in 519 (89.9%)

patients, with a greater response in EE patients (96.4%) compared with NERD patients (82.6%) ($P = 0.011$). Both the percentage of completely asymptomatic patients, at 3 and 6 mo, and the reduction in heartburn intensity were significantly higher in the EE compared with NERD patients ($P < 0.01$). Finally, the mean PGWBI score was significantly decreased before and increased after therapy in both subgroups when compared with the mean value in a reference Italian population.

CONCLUSION: Our study confirms the validity of the Genval guidelines in the management of GERD patients. In addition, we observed that the overall response to PPI therapy is lower in NERD compared to EE patients.

INTRODUCTION

In 1999 an international panel of experts involved in the

management of gastroesophageal reflux disease (GERD) convened in Genval, Belgium, for a workshop which aimed to review the existing evidence concerning the definition, pathogenesis and natural history, and impact of the disease on the patient, and clinical manifestations as well as diagnostic and therapeutic strategies. The results of this workshop were published as the “The Genval Workshop Report”^[1], and had a substantial impact both on the management strategies in GERD and in the development of further guidelines, as for example the Marrakech Workshop^[2] and the Montreal Global Definition^[3].

The Genval recommendations constitute a comprehensive body of knowledge relevant to good management. In 2002 we designed a multicenter study on GERD patients with the primary aim of testing “in the field” the Genval recommendations and to prospectively evaluate: (1) the usefulness of a short trial of proton pump inhibitor (PPI) in the initial management of GERD; and (2) the usefulness of a step-down PPI in the maintenance treatment of GERD patients.

As secondary aims we wanted to assess the ability of PPI maintenance therapy to restore the quality of life of our patients and to assess the ability in differentiating between erosive and non erosive disease by a new GERD questionnaire, the QUestionario Italiano Diagnostico (QUID), which has been created by application of artificial neural networks as reported elsewhere^[4]. The latter issue will be described in a separate paper.

MATERIALS AND METHODS

This study was a national multicenter collaborative investigation (the EMERGE project). The study was conducted on GERD patients with or without erosive esophagitis between June 2003 and June 2005. The study started with a 2-wk period of high dose omeprazole 20 mg *bid* (the so-called omeprazole test). Patients responding to this test entered an acute phase (3 mo) of treatment with any available PPI at a standard dose. Finally, those patients with a favorable response to the standard PPI dose were maintained on half the PPI dose for a further 3-mo period. Patients continued this regimen unless their symptoms relapsed: in this case, they could resume the previous dose. Patients requiring this change of therapy more than once were considered to have treatment failure and were excluded from the final analysis.

The study was conducted according to good clinical practices. All Ethics Committees of the participating centers granted authorization, and written informed consent was obtained from all patients.

Five hundred and seventy-seven adult outpatients (282 female, 295 male, mean age 43.5 ± 12.4 years), referred to the various centers in order to undergo upper GI endoscopy, were recruited by 60 gastroenterological Italian centers.

The demographic data and clinical characteristics of the whole patient sample are shown in Table 1, according to the endoscopic findings [erosive esophagitis (EE) vs nonerosive gastroesophageal reflux (NERD)].

Table 1 Proton pump inhibitor types and equivalent doses used for maintenance therapy *n* (%)

| PPI types and doses | Acute phase | Maintenance phase |
|---------------------|-------------|-------------------|
| Esomeprazole 40 mg | 149 (26.94) | 10 (2.16) |
| Esomeprazole 20 mg | 20 (3.62) | 141 (30.45) |
| Omeprazole 20 mg | 314 (56.78) | 33 (7.13) |
| Omeprazole 10 mg | 1 (0.18) | 211 (45.57) |
| Lansoprazole 30 mg | 13 (2.35) | 4 (0.86) |
| Lansoprazole 15 mg | 1 (0.18) | 14 (3.02) |
| Pantoprazole 40 mg | 39 (7.05) | 1 (0.22) |
| Pantoprazole 20 mg | 1 (0.18) | 35 (7.56) |
| Rabeprazole 20 mg | 15 (2.71) | 1 (0.22) |
| Rabeprazole 10 mg | | 13 (2.81) |

Inclusion criteria

Patients were included provided that, before endoscopic examination, the following criteria were fulfilled: (1) Age between 18 and 65 years; (2) Presence of heartburn symptoms for at least 15 d, at least once a day; (3) Referral by treating physician to a tertiary centre to undergo upper gastrointestinal (GI) endoscopy; (4) Ability to read and write Italian, > 5 years of schooling; and (5) Consent to voluntary participation with signature on the Informed Consent form before study screening.

Exclusion criteria

Patients who had one or more of these criteria at baseline were excluded from the study: (1) Treatment with PPI in the month preceding endoscopy; (2) Diagnosis of esophagitis established during the past 12 mo; (3) Pregnancy and/or lactation; and (4) Concomitant severe disease during the 4 wk preceding the study, requiring any pharmacological treatment.

Study design

Before undergoing endoscopy, patients were given a psychometric tool to assess quality of life (PGWBI-Psychological General Well Being Index) and the previously validated GERD symptom assessment questionnaire (QUID)^[4].

The PGWBI is a 22-item self-administered questionnaire designed to measure perception of general wellbeing through 6 domains: anxiety (5 items), depression (3 items), feeling of wellbeing (4 items), vitality (4 items), general health (3 items) and self-control (3 items). All the items were rated on a 6-point scale (0-5). The highest possible score (110) represented the best possible wellbeing^[5].

QUID is a 41-item questionnaire which investigates typical and atypical symptoms of GERD and relevant life habits for GERD. It was developed in a previous study^[4] and is partially derived from an Italian validated version of GERQ (Gastroesophageal Reflux Questionnaire by Mayo Clinic^[6]), in which the most relevant items were selected by means of artificial neural networks^[4].

Upper GI endoscopy was performed according to the standard protocol of each participating center, and biopsy samples for diagnosis of *Helicobacter pylori* infection were

not universally taken, nor was there any requirement to give eradication therapy.

Esophagitis was diagnosed and graded according to the Savary Miller classification as follows^[7]: Grade I -single or multiple erosions on a single fold; Grade II -multiple erosions on multiple folds; Grade III -multiple circumferential erosions; Grade IV -ulcer, stricture, and esophageal shortening.

Only omeprazole 20 mg *bid* was used for the initial PPI test, since the majority of studies existing in the literature at the time of study design were conducted with this drug^[8-14]. The choice of therapy following the PPI test, in accordance with Genval Guidelines^[2], was any available PPI at the standard dose. The same drug was subsequently used at half dose as maintenance treatment, again in accordance with Genval recommendations. In Table 1 the various PPIs used are shown with relative doses, according to the study phase. Only those patients who had a positive PPI test, defined as a reduction in heartburn severity greater than 50% at the end of the 15-d period of the test, continued the study^[8,9,14]. In the case of worsening of symptoms after any reduction of dose, the participating physicians were free to resume the previous therapy. The patient could resume the treatment schedule only once during the period of the trial. Additional therapeutic step-ups were considered failure of treatment and required withdrawal from the study. Patients taking concomitant medications for medical problems other than GERD could continue therapy, and this was recorded. Patients in the study were not allowed to take any other antisecretory or prokinetic drug. Over-the-counter (OTC) antacids were allowed, if needed because of insufficient symptom control and their use was recorded.

Daily diary

During the 15 d of the PPI test the patient had to report daily in a diary the characteristics of heartburn in terms of intensity and frequency: intensity was scored in a 5-point scale, ranging from 0 = absent to 4 = unbearable and intolerable, with 1 = mild, 2 = moderate, 3 = severe. Daily average frequency was expressed simply by giving the number of daily heartburn attack. This allowed a composite heartburn score to be constructed, by multiplying the daily average frequency by the intensity.

Heartburn intensity and frequency were also assessed at the end of the acute phase (3 mo after completion of the PPI test) and after 6 mo, at the end of the study. The entire bulk of symptoms, from regurgitation to extra-esophageal concomitant manifestations were assessed by means of the QUID questionnaire only, at baseline and at the end of study, at 6 mo.

RESULTS

The details of the study according to the various phases are shown in Figure 1.

Demographic and clinical features

Of the 577 patients recruited, 306 (53%) were diagnosed

Table 2 Study population demographics and features according to endoscopic results *n* (%)

| | EE (306/577, 53%) | NERD (271/577, 47%) | <i>P</i> |

| Male | 194 (63.4) | 101 (37.3) | < 0.05 |
| Female | 112 (36.6) | 170 (62.7) | < 0.05 |
| Age (yr), mean (± SD) | 43.6 (± 12.22) | 43.42 (± 12.56) | NS |
| Height (cm), mean (± SD) | 169.86 (± 8.63) | 166.84 (± 8.14) | NS |
| Weight (kg), mean (± SD) | 75.33 (± 15.40) | 68.49 (± 12.41) | NS |
| Smoking | 164 (48.1) | 115 (39.2) | NS |
| Esophagitis severity (Savary-Miller classification) | | | |
| Grade 1 | 237 (77.5) | - | NS |
| Grade 2 | 52 (16.9) | - | NS |
| Grade 3 | 9 (2.9) | - | NS |
| Grade 4 | 8 (2.6) | - | NS |
| <i>H. pylori</i> presence | 51 (14.9) | 37 (12.6) | NS |
| Heartburn intensity | | | |
| 1 = mild | 28 (9.2) | 33 (12.1) | NS |
| 2 = moderate | 181 (59.1) | 166 (61.2) | NS |
| 3 = severe | 88 (28.7) | 64 (23.6) | NS |
| 4 = unbearable | 9 (2.9) | 8 (2.9) | NS |
| Regurgitation | 248 (81) | 227 (83.7) | NS |
| Chest pain | 146 (47.7) | 120 (44.3) | NS |
| Dysphagia | 99 (32.3) | 95 (35) | NS |
| Belching | 198 (64.7) | 181 (66.7) | NS |
| Chronic cough | 102 (33) | 85 (31.4) | NS |
| Hoarseness | 89 (29) | 102 (37.6) | NS |

EE: Erosive esophagitis; NERD: Non erosive reflux disease; NS: Not significant.

with esophagitis while the remaining 271 (47%) showed no esophageal mucosal damage (Table 2). Two hundred and seventy-nine patients were smokers, 164 with EE and 115 with NERD, while 526 (289 with EE and 237 with NERD) were coffee drinkers. *H. pylori* status was investigated in a major subsample (454/577, 78.6%): *H. pylori* was found to be present in 88 patients (19.4%) and absent in 366 patients (80.6%). Eradication therapy was given in only 31 patients (16 with NERD and 15 with EE).

The severity of esophagitis, assessed by the Savary-Miller classification, was as follows: grade 1 = 237 (77.5%), grade 2 = 52 (16.9%), grade 3 = 9 (2.9%), and grade 4 = 8 (2.6%).

For various reasons, as shown in Table 2, 179 patients (31%) left the study early: of these, 87 had EE and 92 had NERD. Thus 398 patients (69%) completed the entire study period (Figure 1).

Symptoms, other than heartburn, which were evaluated by QUID questionnaire at baseline and at study completion, such as regurgitation, chest pain, dysphagia and belching, were present at baseline in percentages ranging from 83.1% for regurgitation to 33.3% for dysphagia (Table 2). Chest pain, chronic cough and hoarseness, were reported in 46.7% (296/634), 31.2% (202/634) and 33.1% (210/634) patients, respectively (Table 3).

PPI test

During the 2-wk PPI test phase, 24 patients dropped out (Figure 1) and, of 553 (95.8%) patients completing the

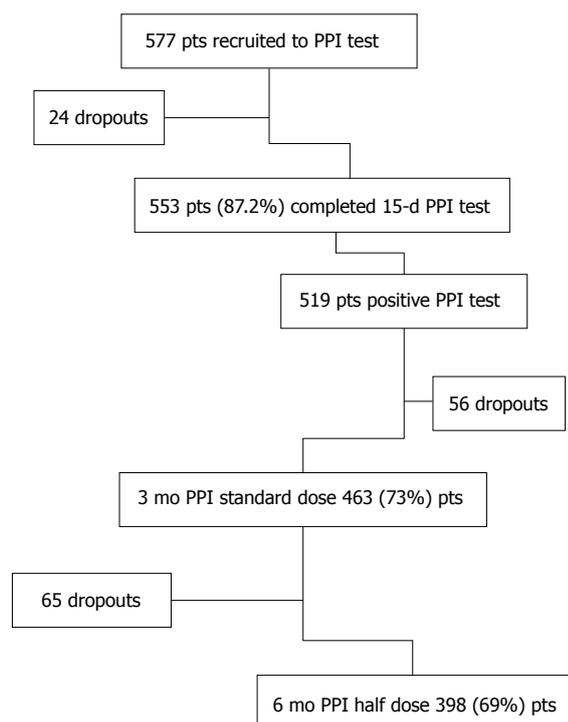

Figure 1 Study design (the percentages refer to recruited patients). PPI: Proton pump inhibitor. Pts: Patients.

Table 3 Dropout causes

| Dropout cause | n (%) |
|----------------------------------|-----------|
| Personal reasons | 12 (6.7) |
| Therapy failure | 1 (0.6) |
| Patient fails to follow-up visit | 46 (25.7) |
| Prolonged time to visit | 60 (33.5) |
| Adverse reaction | 2 (1.1) |
| Other | 58 (32.4) |
| Total | 179 (100) |

PPI test, 519 (89.9%) had a positive test, defined as a reduction in heartburn severity greater than 50% at the end of the 15-d period, and entered the acute study phase. The PPI test was positive in 224/271 (82.6%) of patients with NERD and in 295/306 (96.4%) of those with EE. The heartburn score at day 1 of the PPI test was 7.2 ± 16.09 (standard deviation) for the entire GERD population, while it was 5.94 ± 13.29 for EE patients and 8.8 ± 18.97 for NERD patients; the score was 1.37 ± 8.64 , 0.86 ± 6.50 and 1.99 ± 10.67 for the entire GERD population, EE patients and NERD patients, respectively, at day 16 (trend $P < 0.001$). The intensity of heartburn decreased over 16 d similarly in EE (mean delta variation 0.07 ± 0.1) and NERD (mean delta variation 0.08 ± 0.09) patients.

Acute and maintenance therapy

Five hundred and nineteen patients started the acute treatment period of 3 mo, with the standard PPI dose. After 3 mo, 463 (80.2%) patients were satisfactorily

treated and were admitted to the last 3-mo phase with half the PPI dose. Of these, 398 (69%) completed the full 6 mo of the study protocol (Figure 1). Corresponding figures for patients with EE after 3 mo and 6 mo were 261/577 (45.2%) and 219/577 (38%), respectively, and 202/577 (35%) and 179/577 (31%) respectively, for patients with NERD.

After 3 mo of acute therapy, 32/261 (12.3%) with EE and 40/202 (19.8%) NERD patients still complained of heartburn ($P = 0.02$), whereas after 6 mo, with half dose PPI therapy, the proportion was 27/219 (12.3%) and 45/179 (25.1%) for EE and NERD patients, respectively ($P < 0.001$). In other words, the percentage of completely asymptomatic patients, both at 3 and 6 mo, was significantly higher in the EE compared with NERD patients (Figure 2). The distribution of heartburn intensity among the 2 subgroups at 3 and 6 mo is shown in Figure 2.

Similarly the intensity of heartburn decreased with time differently in patients with EE and with NERD, the reduction of intensity being significantly greater in patients with EE (mean delta reduction 2.08 ± 0.77) compared with NERD patients (mean delta reduction 1.77 ± 0.83 , $P < 0.01$).

The other GERD symptoms, such as regurgitation, chest pain, dysphagia and belching, showed a consistent and significant decrease from baseline to the final visit (Figure 3), and the same happened with the 2 most frequently reported possible extraesophageal manifestations, chronic cough and hoarseness. None of these symptoms showed a different response in NERD as compared to EE patients.

PGWBI

Before therapy the mean PGWBI score of our GERD population was 72.4 ± 15.62 and it rose to 84.3 ± 14.27 after the 6 mo of therapy. When compared with the mean value of a reference Italian population^[15], which was 78 ± 17.89 , these values were significantly different before and after therapy, and both for EE and NERD patients. In other words, the quality of life was significantly worsened by GERD symptoms before therapy and it was fully restored, even above the reference values, by the therapy. If the effect size (ES) of this change is considered, i.e. the mean change found in a given variable divided by the standard deviation (where a positive value means improvement and a negative means worsening), we found a difference in ES of -0.31 between baseline GERD and the general population before therapy, and of 0.35 between study end and the general population, without significant differences between NERD and EE patients. Among the 6 domains of PGWBI for both NERD and EE patients, it appears that anxiety and general health showed the most important variation before and after therapy. Finally, in both NERD and EE subgroups, it was apparent that the decrease in anxiety was directly related to the improvement in symptoms, in particular heartburn and nausea (data not shown).

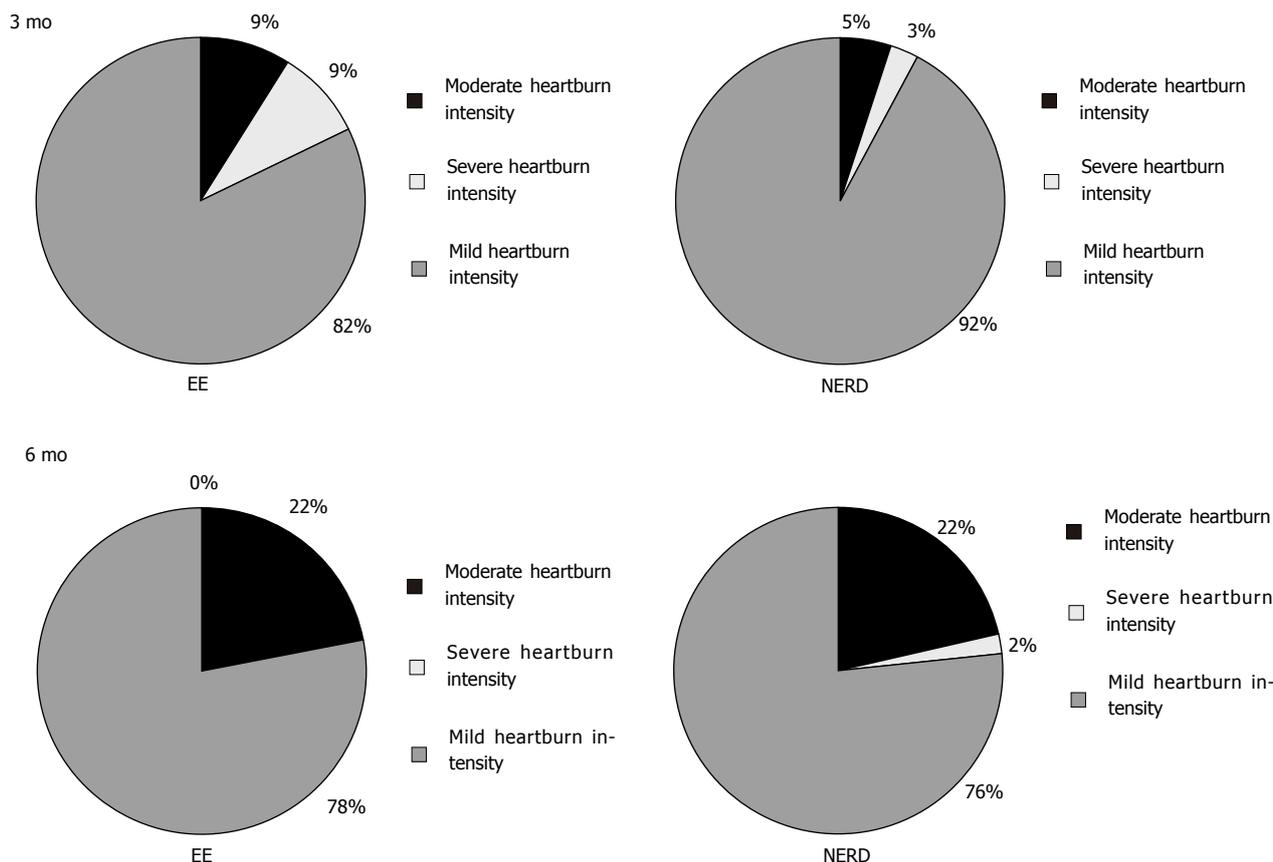

Figure 2 Distribution of heartburn intensity at 3 mo (top panels) and 6 mo (bottom panels) therapy in erosive esophagitis (left panels) and non erosive reflux disease patients (right panels). EE: Erosive esophagitis; NERD: Non erosive reflux disease.

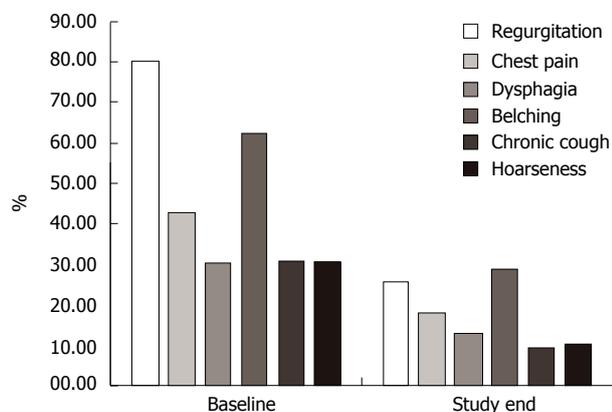

Figure 3 Additional symptoms assessed at baseline and at study end by QUESIONARIO ITALIANO DIAGNOSTICO questionnaire (data are presented for the 398 patients completing the study). Baseline vs study end, for all symptoms, $P < 0.001$.

DISCUSSION

Our study was specifically designed with the aim of assessing the validity of the Genval guidelines on GERD management in a population of patients referred for upper GI endoscopy in 60 Italian centers. In particular, we were interested in establishing, in patients with mild-to-moderate esophagitis or with NERD: (1) the symptomatic response to a brief, high dose PPI treat-

ment as initial management; (2) whether the step-down therapeutic approach is useful to optimally balance drug cost and symptom response. As far as the first aim was concerned, the omeprazole test was used for diagnostic purposes in NERD patients only, whereas we decided to use it as a therapeutic start-up also in the EE group in order to have comparable treatments in both groups. We observed a “positive” PPI test, as defined by a reduction in heartburn severity greater than 50% at the end of the 15-d period, in 96.4% of EE patients and in 82.6% of NERD patients. The latter patients were, according to the Genval guidelines, subjects with “clinically significant impairment in quality of life due to reflux-related symptoms”, and therefore could be diagnosed as GERD patients not only in accordance with Genval^[1], but also with Montreal^[3] guidelines, without any need to proceed with a PPI or other diagnostic test. However, it turned out that as many as 17.4% of our NERD patients did not respond to the PPI test and for the purpose of our study were not further treated with a PPI. We do not know how many of these “non responders” could in fact still be diagnosed as GERD patients by means of esophageal pH-metry or pH-impedance monitoring, since we did not apply such tests. On the other hand, by excluding those patients with presumably non acid-related problems, we selected in a very simple way those who could better respond to PPI treatment. The figure of about 80% of patients responding to PPI, and hence

categorizable as GERD patients, is in keeping with Genval statement 13, which states “When heartburn is a major or sole symptom, gastroesophageal reflux is the cause in at least 75% of individuals”. The Genval guidelines suggest, for non endoscoped patients, endoscopy-negative patients or Los Angeles grade A or B esophagitis patients, starting treatment with high dose PPI for 2-4 wk, which corresponds to our omeprazole test, and to check the symptomatic response thereafter^[1]. In studies conducted on NERD patients, the PPI test has been found to have a high sensitivity but a very low diagnostic specificity^[16], in particular when compared with objective measures of GERD, such as pH-metry, or with symptom questionnaires^[17]. Since our NERD population was recruited on the basis of clinical diagnostic criteria (e.g. the Genval criteria) and a positive response to the PPI test, the enrolled sample may not quite be representative of the NERD population at large. On the other hand, it is more homogeneous, because it includes only the acid-related segment of the NERD spectrum, and therefore by definition excludes patients with functional heartburn (cf the Rome criteria for functional heartburn)^[18]. As for the duration of the PPI test, we believe that our study proves that in GERD patients with typical symptoms, the suggestion to empirically treat with 2-4 wk of high dose PPIs^[1] could be temporally limited to 1 or 2 wk, since the reduction of heartburn was already near to the maximum after the first week of high dose omeprazole administration (Figure 2).

The Genval guidelines^[1] have been subsequently updated by the Marrakech recommendations^[2], which however do not differ much with regard to the indications and doses of PPI therapy, and the so called PPI test, in the management of GERD patients. On the contrary, the Montreal Workshop^[3] was only focused on developing a global definition and classification of GERD, but did not specifically address the issue of management.

Due to the particular design of our study, we had the opportunity to compare the subjective response to short term high dose PPI in the 2 populations of NERD and EE patients. We found an overall better response in the latter; this is, to our knowledge, a new observation, and is in keeping with the already established concept that NERD patients as a group responds less well to PPI compared with EE patients^[19]. We further extended this observation by showing that NERD patients with typical symptoms, on average, show a smaller decrease in heartburn intensity also during 3-6 mo maintenance therapy with PPI compared with EE patients. We want to emphasize the point that the relatively lower symptom response rate to PPI treatment in NERD patients was not due in our study, as pointed out in the study by Dean *et al*^[19], to the “contamination” of the NERD group by patients with functional heartburn, since our study design avoided this bias. Thus, it appears that the overall therapeutic efficacy of PPI is truly decreased in NERD as opposed to EE patients.

As far as the second aim is concerned, we have

observed that the great majority of patients can be maintained symptom-free by halving the PPI dose after 15 d and 3 mo, respectively: 229/261 (87.7%) of EE and 162/202 (80.2%) of NERD patients were heartburn-free after 3 mo, respectively and 192/219 (87.7%) of EE and 134/179 (74.9%) of NERD patients after 6 mo. Again, it seems that the symptomatic response to PPI treatment is lower in NERD patients as compared to EE also during a maintenance regimen. On the other hand, this finding implies that the step-down therapy could be successfully proposed for the majority of both EE patients and NERD patients following a positive PPI test, even after a short (3-mo) period.

Finally, our study clearly confirms previous data that suggest that quality of life is greatly reduced by GERD symptoms (compared to the general population) independently of the presence or absence of esophagitis^[20]. Interestingly enough, even the relatively short treatment period with PPIs in the present study (6.5 mo) was able to completely restore the quality of life in our patients, or even to improve it to levels above those showed by the general population.

In conclusion, this study is to our knowledge the first one to prospectively address relevant issues in the management of GERD outside a frame of therapeutic randomized, controlled trials. In patients with NERD or erosive esophagitis, a short period of high dose PPI (the so-called PPI test) is a valuable tool for diagnosing suspected GERD symptoms as being acid-related, and thus for selecting those patients who will benefit from PPI therapy. In the further management of these patients, 2 consecutive reductions in PPI dose are able to keep the vast majority of patients asymptomatic and to fully restore their quality of life. The overall response to PPI therapy is lower in NERD patients than in EE patients.

COMMENTS

Background

“The Genval Workshop Report” reviewed the existing evidence concerning gastroesophageal reflux disease (GERD). The study aimed to test these recommendations and to assess the usefulness of a short trial of proton pump inhibitor (PPI) in the initial management and maintenance treatment on GERD patients.

Research frontiers

The PPI test consists of measuring the symptomatic response to a high dose PPI treatment administered for 1 to 2 wk in patients with GERD symptoms and with erosive esophagitis (EE) or without it (so-called NERD). The rationale for using short-term, high dose PPI administration as a diagnostic tool is based on the strong effect of PPIs in inhibiting gastric acid secretion, healing EE and improving GERD symptoms.

Innovations and breakthroughs

This study is, to our knowledge, the first to prospectively address relevant issues in the management of GERD outside a frame of therapeutic randomized, controlled trials. In patients with NERD or EE, the PPI test is a valuable tool for diagnosing suspected GERD symptoms as being acid-related and thus for selecting those patients who will benefit from PPI therapy. In the further management of these patients, 2 consecutive reductions of PPI dose are able to keep the vast majority asymptomatic and to fully restore their quality of life. The overall response to PPI therapy is lower in NERD patients than in EE patients.

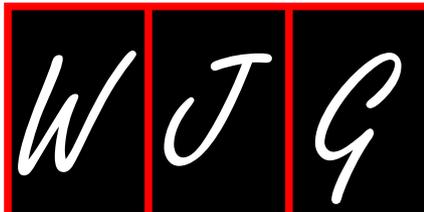

Peer review

The study is one of the first trying to prospectively address relevant issues in the management of GERD outside a frame of therapeutic RCTs.

Abstract

AIM: To assess the significance of interleukin (IL)-24 and vascular endothelial growth factor (VEGF) expression in lymph-node-positive rectal cancer.

METHODS: Between 1998 and 2005, 90 rectal adenocarcinoma patients with lymph node involvement were enrolled. All patients received radical surgery and postoperative pelvic chemoradiotherapy of 50.4-54.0 Gy. Chemotherapy of 5-fluorouracil and leucovorin or levamisole was given intravenously during the first and last week of radiotherapy, and then monthly for about 6 mo. Expression of IL-24 and VEGF was evaluated by immunohistochemical staining of surgical specimens, and their relations with patient characteristics and survival were analyzed. The median follow-up of surviving patients was 73 mo (range: 52-122 mo).

RESULTS: IL-24 expression was found in 81 out of 90 patients; 31 showed weak intensity and 50 showed

strong intensity. VEGF expression was found in 64 out of 90 patients. Negative and weak intensities of IL-24 expression were classified as negative expression for analysis. IL-24 expression was significantly reduced in poorly differentiated tumors in comparison with well or moderately differentiated tumors ($P = 0.004$), N2b to earlier N stages ($P = 0.016$), and stage IIIc to stage III a or III b ($P = 0.028$). The number of involved lymph nodes was also significantly reduced in IL-24-positive patients in comparison with IL-24-negative ones. There was no correlation between VEGF expression and patient characteristics. Expression of IL-24 and VEGF was not correlated with survival, but N stage and stages were significantly correlated with survival.

CONCLUSION: IL-24 expression was significantly correlated with histological differentiation, and inversely correlated with the degree of lymph node involvement in stage III rectal cancer.

INTRODUCTION

Treatment outcomes of rectal cancer have been improved with the use of adequate combination therapies

and the identification of effective targets, but relapses are still frequent in advanced-stage patients. The survival rate of patients whose tumors are confined to the rectal wall at diagnosis (stage I and II) is > 75%, but those rates are reduced to 30%-60% in higher-stage patients, according to the degree of penetration into the wall, and lymph node involvement^[1,2]. In order to yield more credibility and power to a study, we analyzed stage III patients for the identification of new therapeutic targets.

The melanoma differentiation associated gene-7, later renamed as interleukin (IL)-24, was identified by subtraction hybridization from human melanoma cells stimulated with interferon- β and mezerein^[3]. The expression of IL-24 is inversely related to human melanoma progression. That is, it is highest in melanocytes and lowest in metastatic melanomas^[3,4]. Transfection of IL-24 into melanoma cells reduces growth without a similar effect on normal cells^[3], and this antiproliferative activity of IL-24 has also been detected in a variety of cancer cells, such as breast, prostate, cervix, colorectal, lung, and nasopharynx carcinomas, as well as glioblastoma^[5-11]. In addition to the antiproliferative effect in cancer cell lines, favorable survival has been marginally identified in high-IL-24-expressing non small cell lung cancer (NSCLC) patients^[12]. From a subset analysis, high IL-24 expression has been revealed as a significant prognostic factor in adenocarcinoma patients. Whether high IL-24 expression also has a significant impact on the survival of patients with types of cancers other than NSCLC is unknown.

Multiple anticancer mechanisms of IL-24 have been reported, including cancer-specific apoptosis induction, cell cycle regulation, an ability to inhibit angiogenesis, potent bystander antitumor activity, and a capacity to enhance the sensitivity of tumor cells to radiation and chemotherapy^[13]. Among them, new vessel formation is required for tumor growth and metastasis^[14]. Vascular endothelial growth factor (VEGF) is one of the most important angiogenic factors^[15]. Expression of VEGF is proportional to the degree of carcinogenesis of the colorectum, ranging from 0% in dysplastic adenomas, to 62% in mucosal carcinomas, and 100% in submucosal carcinomas^[16]. However, the prognostic significance of VEGF expression in rectal cancers has been inconclusive so far^[17-21]. Therefore, we also analyzed VEGF expression in rectal cancer patients.

We carried out the first analysis of the correlation between IL-24 expression and prognostic features in rectal cancer patients. To resolve the unanswered question of the effect of VEGF expression on the survival of rectal cancer patients, while limiting biases related to treatment methods and patient heterogeneity, we restricted the analysis to rectal cancer patients with lymph node metastasis who were treated at a single institution.

MATERIALS AND METHODS

Patients

In this retrospective study, we reviewed 96 rectal adenocarcinoma patients with pathologic lymph node involvement,

who had consecutively undergone radical surgery and post-operative chemoradiotherapy at Dong-a University Hospital, Busan, South Korea between 1998 and 2005. The analysis of these patients was approved by the Institutional Review Board. Ninety patients were included for analysis, while six patients were excluded; two for lack of surgical specimens, and four due to liver metastasis at diagnosis, familial adenomatous polyposis, adenosquamous cell carcinoma, and mucinous adenocarcinoma, respectively (Table 1).

Thirty-three patients underwent abdominoperineal resection, and 57 underwent low anterior resection. Patients received postoperative chemoradiotherapy from the fourth to sixth week after radical surgery. Patients were positioned in a prone position on a belly board for radiotherapy. Tumor beds were boosted up to 50.4-54 Gy (1.8 Gy, once daily) after 45 Gy pelvic irradiation with 15 MV X-ray using a three-field technique. Two cycles of 5-fluorouracil with levamisole or leucovorin were concurrently given for radiotherapy, and maintenance chemotherapy was done thereafter for about 6 mo. Patients were followed up at 3-mo intervals for 2 years, 4-mo intervals for the next 2 years, and then every 6 mo. The median follow-up period of the surviving patients was 73 mo (range: 52-122 mo). The seventh edition of the American Joint Committee on Cancer TNM staging system (2010) was used for patient analysis.

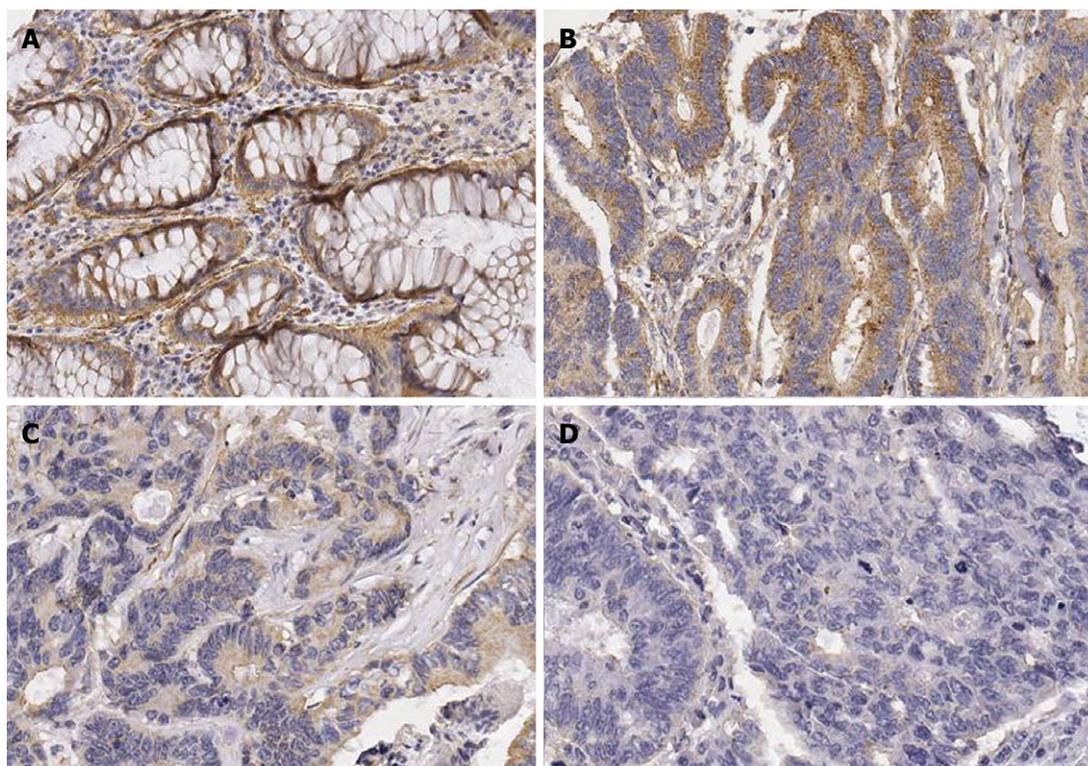

Figure 1 Immunohistochemical staining of interleukin-24 in rectal tissue (200 \times). A: In the normal rectal mucosa tissue, the non-neoplastic glandular epithelial cells were strongly positive for IL-24; B: In rectal cancer, a well-differentiated adenocarcinoma showed strong positive expression of IL-24; C: A moderately differentiated adenocarcinoma showed weak positive expression of IL-24; D: A poorly differentiated adenocarcinoma showed negative expression of IL-24. IL-24: Interleukin-24.

Immunohistochemical staining

The immunohistochemical studies for IL-24 and VEGF were performed on formalin-fixed, paraffin-embedded, 4- μ m-thick tissue sections, using the avidin-biotin-peroxidase complex method. The primary antibodies were a goat polyclonal antibody against IL-24 (Santa Cruz Biotechnology, Santa Cruz, CA, USA) used at 1:200 dilution and a rabbit polyclonal antibody against VEGF, which recognized the 121, 165 and 189 isoform (Santa Cruz Biotechnology) at a 1:100 dilution. Deparaffinization of all sections was performed through a series of xylene baths, and rehydration was performed with a series of graded alcohol solutions. To enhance the immunoreactivity, microwave antigen retrieval was performed at 750 W for 30 min in Tris EDTA (pH 9.0). After the endogenous peroxidase activity was blocked with 5% hydrogen peroxidase for 10 min, incubation with the primary antibody was performed for 1 h at room temperature. An Envision™ Chem™ Detection Kit (DakoCytomation, Carpinteria, CA, USA) was used for the secondary antibody at room temperature for 30 min. After the tissue samples were washed in Tris-buffered saline for 10 min, 3, 3'-diaminobenzidine was used as a chromogen, and then Mayer's hematoxylin counterstain was applied.

Evaluation of IL-24 expression: IL-24-positive samples were defined as those showing a cytoplasmic staining pattern of the lesional tissue. The staining intensity of IL-24 was graded as follows: 0, negative; 1, weak; 2, strong staining comparable to that seen in a positive control (adjacent

normal glands of colonic mucosa) (Figure 1). The negative intensity stood for no stained cells. Weak intensity was allotted when the staining intensity was weaker than that of adjacent normal mucosa or < 5% of cells were stained, and strong intensity when the staining intensity was stronger than that of normal mucosa.

Evaluation of VEGF expression: Immunostaining of VEGF was considered to be positive if unequivocal staining of the membrane or cytoplasm was seen in > 10% of the tumor cells on the slides of the largest section of the tumor.

Statistical analysis

Survival was calculated from the date of surgery for rectal adenocarcinoma. The Kaplan-Meier method was used for survival analysis, and a log rank test was used for survival difference analysis. Correlation between patient characteristics and IL-24 or VEGF expression was evaluated by Fisher's exact test. The number of involved lymph nodes according to IL-24 intensity or expression states was analyzed by one-way ANOVA and *t* test, respectively. Differences were considered significant at $P < 0.05$. Statistical analyses were carried out with SPSS version 18 (Chicago, IL, USA).

RESULTS

Expression of IL-24 and VEGF

IL-24 expression was found in 81 out of 90 patients: nine

| III c | 15 (65.2) | 8 (34.8) | 0.028 (III a, III b <i>vs</i> III c) | 8 (34.8) | 15 (65.2) | |

¹Negative (*n* = 9) and weak (*n* = 31) intensities were classified as negative expression, and strong intensity (*n* = 50) as positive one. IL: Interleukin; VEGF: Vascular endothelial growth factor.

negative, 31 weak intensity, and 50 strong intensity. Most cancer cells belonged to the strong intensity group were stained diffusely, so the proportion of immunoreactions was not analyzed. VEGF expression was observed in 64 out of 90 patients. The staining intensity of VEGF was strong in most stained cells, so the difference in terms of intensity of immunoreaction was not assessed.

Correlation between IL-24 or VEGF expression and clinicopathological factors

IL-24 expression was weaker in poorly differentiated tumors compared to well or moderately differentiated tumors. When the negative and weak intensities of IL-24 expression were categorized as negative expression for analysis (Table 2), IL-24 expression was significantly reduced in poorly differentiated tumors compared to well or moderately differentiated tumors, N2b to earlier N stages, and stage III c to stage III a or III b. These significant findings were maintained when another cut-off value of IL-24 was used for analysis (data not shown). There was no significant association between VEGF expression and patients' characteristics. This non-significance was sustained when other cut-off values of VEGF positivity were applied (data not shown).

Correlation between IL-24 expression and number of involved lymph nodes

IL-24 expression was inversely proportional to the N stages, so we compared the IL-24 expression status with the number of lymph nodes. The mean numbers of involved lymph nodes in the patients with negative, weak, and strong intensities of IL-24 expression were 12.11 ± 13.878 , 5.48 ± 5.253 , and 3.70 ± 3.346 , respectively ($P < 0.05$) (Table 3, Figure 2). The numbers of involved lymph nodes in patients with weak and strong intensities were not different after a multiple comparison test using the Tukey B method.

Table 3 Correlation of interleukin-24 expressions with the number of lymph nodes in the node positive rectal cancer patients

| | <i>n</i> | No. of lymph nodes | <i>P</i> value |
|--------------------------------------|----------|--------------------|----------------|
| Intensity of IL-24 expression | | | 0.001 |
| Negative | 9 | 12.11 ± 13.878 | |
| Weak | 31 | 5.48 ± 5.253 | |
| Strong | 50 | 3.70 ± 3.346 | |
| IL-24 expression | | | 0.012 |
| Negative (negative & weak intensity) | 40 | 6.98 ± 8.282 | |
| Positive | 50 | 3.70 ± 3.346 | |
| IL-24 expression | | | 0.000 |
| Negative | 9 | 12.11 ± 13.878 | |
| Positive (weak & strong intensity) | 81 | 4.38 ± 4.238 | |

IL: Interleukin.

Survival analysis

There were significant differences in disease-specific survival (DSS), disease-free survival (DFS), local-recurrence-free survival (LRFS), and distant-metastasis-free survival (DMFS) with regard to N stages (Table 4). DSS, DFS and DMFS were different according to stages. A significant difference in LRFS was found according to histological differentiation. The expressions of IL-24 and VEGF had no effect on survival.

DISCUSSION

The stage has been known as the most important prognostic factor in colorectal cancer patients until now. The seventh AJCC TNM classification (2010) subdivides N stages according to the number of involved lymph nodes^[22]. N1a is metastasis in one regional node, N1b in two or three, N2a in four to six, and N2b in seven or more. In this study, patients were distributed throughout

VEGF: Vascular endothelial growth factor; IL-24: Interleukin-24.

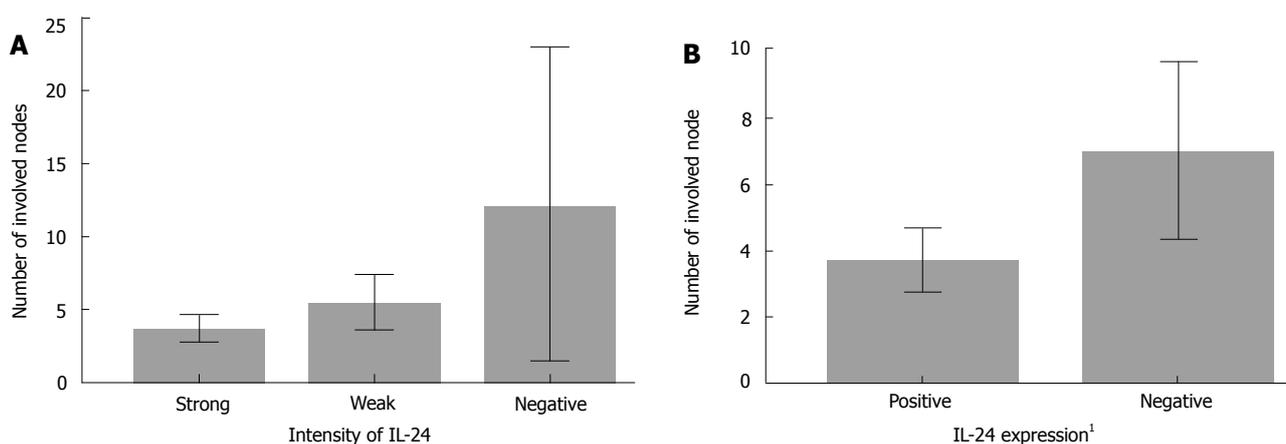

Figure 2 The number of involved lymph nodes according to interleukin-24 intensity (A) and expression status (B) in node-positive rectal cancer patients. ¹Negative (*n* = 9) and weak (*n* = 31) intensities were classified as negative expression, and strong intensity (*n* = 50) as positive. IL: Interleukin.

the N stages. That is, the proportions of the patient study group with cancer in the N1a, N1b, N2a and N2b stages were 26%, 29%, 18% and 26%, respectively. However, patients were not distributed evenly in terms of T stages: 79% were in stage T3. Therefore, to gain reasonable results from the T stage analysis was not possible, unlike the N stage analysis. The higher stages correlated significantly with poorer outcomes in terms of DSS, DFS, LRFS and

DMFS ($P < 0.05$). In addition, higher N stages also had poorer survival rates compared to lower ones. The N stages and stages from the seventh AJCC staging system seem to be applicable, although the subgroup patient numbers were not large in our analysis.

IL-24 promotes growth suppression and induces apoptosis in a broad array of human cancers, after forced expression by means of a plasmid or a replication-competent

adenovirus, but it does not induce growth suppressive or toxic effects in normal cells^[23]. To the best of our knowledge, the clinical significance of IL-24 expression in rectal cancer patients has not been assessed. This is believed to be the first study to analyze the association between IL-24 expression and patient prognostic features in lymph-node-involved rectal cancer patients.

IL-24 expression was weaker in the poorly differentiated tumors, N2b stage, and stage IIIc compared to well or moderately differentiated tumors, N1 or N2a stage, and stage IIIa or IIIb, respectively (Table 2). Moreover, the number of involved lymph nodes was significantly lower in patients with IL-24 expression compared to those without (Table 3). Even though IL-24 expression showed a significant correlation with these prognostic features, the status of IL-24 expression did not affect survival. This discrepancy may in part be explained by an inadequate patient number in the poor prognostic subgroups, and undetermined appropriate cut-off values for IL-24 positivity. Therefore, further studies with larger numbers of patients are necessary in order to develop an adequate grading system of IL-24 expression, and to verify whether IL-24 expression has a prognostic value.

The clinical significance of VEGF expression in rectal cancer is still open to debate. Several studies have insisted that increased VEGF expression is associated with poor prognosis, but some studies have shown that VEGF expression is not related to survival. Casinu *et al*^[21] have claimed from their analysis of lymph-node-positive rectal cancer patients that patients with VEGF-positive tumors have lower event-free survival rates and more frequent distant metastases. However, Bertolini *et al*^[18] have found from their study of locally advanced rectal cancer patients that VEGF expression obtained from pretreatment and post-chemoradiotherapy specimens does not show any significant correlation with DFS and overall survival (OS). In the study of Soumaoro *et al*^[24], OS was worse in colorectal cancer patients with VEGF expression, but this prognostic independence disappeared after multivariate analysis. Our study used unhampered surgical specimens without exposure to any chemoradiotherapy for immunohistochemical staining. VEGF expression was found in 64 out of 90 lymph-node-involved rectal cancer patients. There was no significant survival difference in the rectal cancer patients with regard to VEGF expression in spite of applying several cut-off values for VEGF expression. To verify the influence of VEGF expression on survival in advanced rectal cancer patients, further studies with large numbers of patients are required.

VEGF expression has been reported to be significantly correlated with tumor size, lymph node metastasis, lymphatic invasion, and TNM stage in colorectal cancer patients^[24,25]. It is also significantly associated with lymph node involvement in patients with locally advanced rectal cancer^[26]. However, these associations with VEGF expression were not found in present study.

In addition to the VEGF analysis with tumor tissues, soluble VEGF in the serum or plasma of patients has also been investigated. Werther *et al*^[27] have reported that

preoperative soluble VEGF is of independent prognostic value in patients with colon cancer, but not in those with rectal cancer. Tsai *et al*^[28] have found that patients with plasma VEGF elevation have worse DFS than those without plasma VEGF elevation in lymph-node negative colorectal cancer, but not in lymph-node-positive patients. Therefore, further studies are necessary to assess the role of soluble VEGF in rectal cancer patients.

In conclusion, we observed that IL-24 expression had a significant inverse relationship with N stage, overall stage, and the number of involved lymph nodes, but the status of IL-24 expression did not affect survival. Therefore, further studies with larger numbers of patients are needed in order to verify whether IL-24 expression has a prognostic value.

COMMENTS

Background

The survival rate of rectal cancer patients has been improved with the addition of chemoradiotherapy to surgery. However, that is still inadequate in stage III patients. Therefore, much endeavor is needed to increase the outcome of those through identification of new therapeutic targets. Anticancer activity of interleukin (IL)-24 has been reported in various cancer cells, but it is not known whether IL-24 has clinical importance in rectal cancer patients. In addition, vascular endothelial growth factor (VEGF) is considered to be essential in tumorigenesis, but its prognostic significance is still inconclusive in rectal cancer patients.

Research frontiers

Favorable survival is marginally identified in high-IL-24-expressing non-small cell lung cancer (NSCLC) patients. From a subset analysis, high IL-24 expression has been revealed as a significant prognostic factor in adenocarcinoma patients. However, whether high IL-24 expression has a significant impact on the survival of patients with types of cancers other than NSCLC is unknown.

Innovations and breakthroughs

Selective anticancer effects of IL-24 have been reported *in vitro* and *in vivo* without significant toxic effects on normal cells. These interesting properties may make IL-24 a candidate therapeutic target.

Applications

From this study, correlation of IL-24 expression with histological differentiation and the degree of lymph node involvement in rectal cancer patients was found, but IL-24 expression was not significantly correlated with survival. Therefore, further studies with larger numbers of patients are required in order to assess the prognostic value of IL-24 expression in rectal cancer patients.

Terminology

The melanoma differentiation associated gene-7 was identified by subtraction hybridization from human melanoma cells stimulated with interferon- β and mezerein, and was renamed later as IL-24. Multiple anticancer properties have been identified in a variety of cancer cells without injury to normal cells. Therefore, IL-24 has been emerging as an interesting candidate treatment target in many cancers.

Peer review

Choi *et al* studied immunohistochemically the clinicopathological significance of IL-24 expression in rectal carcinoma. The experiments were conducted appropriately and the results were reasonable.

Abstract

AIM: To assess the long-term efficacy of seton drainage with infliximab maintenance therapy in treatment of stricture for perianal Crohn's disease (CD).

METHODS: Sixty-two patients with perianal CD who required surgical treatment with or without infliximab between September 2000 and April 2010 were identified from our clinic's database. The activities of the perianal lesions were evaluated using the modified perianal CD activity index (mPDAI) score. The primary endpoint was a clinical response at 12-15 wk after surgery as a short-term efficacy. Secondary endpoints were recurrence as reflected in the mPDAI score, defined as increased points in every major element. The clinical responses were classified as completely healed (mPDAI = 0),

partially improved (mPDAI score decreased more than 4 points), and failure or recurrence (mPDAI score increased or decreased less than 3 points).

RESULTS: There were 43 males and 19 females, of whom 26 were consecutively treated with infliximab after surgery as maintenance therapy. Complete healing was not seen. Failure was seen in 10/36 (27.8%) patients without infliximab and 4/26 (15.4%) patients with infliximab ($P = 0.25$). Partial improvement was seen in 26/36 (72.2%) patients without infliximab and 22/26 (88.5%) patients with infliximab ($P = 0.25$). Short-term improvement was achieved in 48/62 (77.4%) patients. Although the mPDAI score improved significantly with surgery regardless of infliximab, it decreased more from baseline in patients with infliximab (50.0%) than in those without infliximab (28.6%), ($P = 0.003$). In the long-term, recurrence rates were low regardless of infliximab in patients without anorectal stricture. In patients with anorectal stricture, cumulative recurrence incidences increased gradually and exceeded 40% at 5 years regardless of infliximab. No efficacy of infliximab treatment was found ($P = 0.97$). Although the cumulative rate of ostomy creation was also low in patients without stricture and high in patients with stricture, no protective efficacy was found with infliximab treatment ($P = 0.6$ without stricture, $P = 0.22$ with stricture).

CONCLUSION: Infliximab treatment was demonstrated to have short-term efficacy for perianal lesions. Long-term benefit with infliximab was not proven, at least in patients with anorectal stricture.

Long-term efficacy of infliximab maintenance therapy for perianal Crohn's disease. *World J Gastroenterol* 2011; 17(9): 1174-1179 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1174.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1174>

INTRODUCTION

In recent years, infliximab (IFX), an IgG1 murine-human chimeric monoclonal antibody against tumor necrosis factor- α , has been recognized to be an effective treatment for active perianal fistula with Crohn's disease (CD)^[1]. However, in the ACCENT II trial, the closure of fistulas after the initial three IFX infusions occurred in 63% of patients at week 14, but decreased to 36% at week 54 with every 8 wk maintenance therapy and a high abscess formation rate (15%) was also seen^[2].

The placement of setons and drains prior to IFX therapy is generally recognized as the best combination therapy, and it allows for control of fistula healing and prevention of abscess formation^[3]. However, the efficacy of IFX with surgical treatment in perianal CD is controversial, and mainly short-term efficacy has been suggested^[4,5]. Moreover, most lesions of perianal CD are complicated by anorectal stricture that could affect the high recurrence rate and the risk for further ostomy creation. Although a further, large and long-term prospective study is needed for proper evaluation, the aim of this study was to assess the short and long-term efficacy of seton drainage in relation to IFX maintenance therapy with or without anorectal stricture for perianal CD retrospectively in advance of a longer duration prospective study.

MATERIALS AND METHODS

Patients

The clinical records of 131 patients with a perianal CD lesion who required surgical treatment between September 1995 and April 2010 were reviewed retrospectively. The surgical indications for all patients were limited to only a perianal lesion. Of these, 62 patients were identified from our out patients clinical records that were appreciable in detail of symptoms for assigning a modified perianal CD activity index (mPDAI) score, and these demographics and relevant medical details were recorded retrospectively^[6].

Patients on concomitant therapy that included corticosteroid and immunosuppressive agents were excluded from this study. Patients who did not use these agents postoperatively or used them after recurrence were included. Most patients were treated with oral antibiotics, including metronidazole, ciprofloxacin, or cefcapene pivoxil hydrochloride hydrate, before surgery as conservative treatment and after surgery as combination therapy. All patients were given a second-generation cefem intraoperatively.

Surgical procedure

Fistulas were classified by the method described by Parks *et al.*^[7]. At surgery, fistula tracts were thoroughly curetted, the abscess cavities were sufficiently drained and rubbed with a surgical spoon. Soft silastic or Teflon-coated vessel tape was inserted along the fistula tracts and tied loosely to facilitate drainage where appropriate as seton drainage. Anal dilation with the index finger was also performed in patients with stricture at surgery. Setons were removed in the outpatient clinic if the infection resolved on MRI findings and left in place if there were continuing signs of infection. The patients with incidental lesions as superficial fistulas were treated with conventional fistulotomy and excluded from this study.

Infliximab maintenance therapy

Initial IFX infusions (5 mg/kg) were administered within 2 wk from seton drainage (0 wk), and consecutive infusions were administered 2 wk and 6 wk later. This was continued as maintenance therapy every 8 wk. The patients who were given episodic infusions or could not be maintained on consecutive infusions due to adverse effects were not included in this study. Anal dilatation was performed in all patients with anorectal stricture preceding initial IFX infusion.

Assessments

The activities of perianal lesions were evaluated using the perianal CD activity index (PDAI)^[6]. The PDAI score is a 5-point index that detects changes in perianal status. The five major elements were the degrees of discharge, pain or restriction of living activity, restriction of sexual activity, type of perianal disease, and induration. Scores ranged from 0 to 20, with higher scores indicating more severe disease activity. Since the mPDAIs were reviewed from clinical records retrospectively in this study, the element of sexual function was not included, and the score ranged from 0 to 16.

The primary endpoint was a clinical response at 12-15 wk after surgery. The effective response was defined as at least a one point or greater reduction in every major element from baseline at week 12 as a short-term efficacy (a decrease of more than 4 points on the mPDAI score). Secondary endpoints were recurrence as reflected in the mPDAI score, defined as increased points in every major element (an increase of more than 4 points). The clinical responses were classified as completely healed (mPDAI = 0), partially improved (mPDAI score decreased more than 4 points), and failure (mPDAI score increased or decreased less than 3 points). Anorectal stricture was defined as the forefinger could not pass through during digital examination due to fibrotic changes.

Statistical analysis

Unless otherwise indicated, all numerical data are expressed as the median and range. Differences in patient's characteristics and mPDAI improvement rates with or without IFX were analyzed using the χ^2 test or the Mann-Whitney *U*-test. Evaluation of the change in mPDAI score

Table 1 Patients' characteristics *n* (%)

| | Surgery + infliximab (<i>n</i> = 26) | Surgery alone (<i>n</i> = 36) | <i>P</i> value |
|--|---------------------------------------|--------------------------------|----------------|
| Male:Female | 16:10 | 27:9 | 0.26 |
| Age at initial surgery (median years and range) | 27.5 (16-55) | 27.5 (16-41) | 0.73 |
| Duration from onset of perianal lesion (median month and range) | 45 (2.5-275.5) | 120 (26.5-339.5) | < 0.01 |
| Duration from initial surgery for perianal lesion (median month and range) | 28.2 (0.57-62.4) | 74.5 (7.4-218.9) | < 0.01 |
| Types of fistula | | | |
| Intrasphincteric | 7 (26.9) | 4 (11.1) | 0.11 |
| Transsphincteric | 12 (46.2) | 16 (44.4) | 0.89 |
| Suprasphincteric | 4 (15.4) | 8 (22.2) | 0.5 |
| Extrasphincteric | 3 (11.5) | 8 (22.2) | 0.28 |
| Anorectal stricture | 19 (73.1) | 21 (58.3) | 0.23 |

Data are numbers with percentage in parentheses unless otherwise indicated.

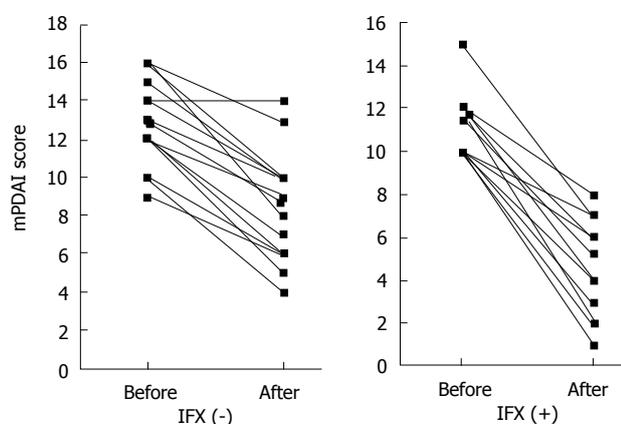

Figure 1 Individual modified perianal Crohn's disease activity index scores in patients before surgery and 12-15 wk after surgery with or without infliximab. The modified perianal Crohn's disease activity index (mPDAI) scores improved significantly with surgery regardless of infliximab (IFX) treatment: from 13.5 (9-16) before surgery to 9.5 (4-14) after surgery without IFX; from 11 (8-15) before surgery to 6 (1-10) with IFX ($P < 0.01$).

was analyzed using Wilcoxon's signed rank test. The cumulative maintained response rates or ostomy creation rates were compared using a log-rank test with Kaplan-Meier analysis. All statistical analyses were performed with SPSS for Windows, version 11.0.1. Two-tailed *P* values less than 0.05 were considered to indicate statistically significant differences.

RESULTS

Patients demographics

Sixty-two patients who underwent surgery for perianal CD could be followed up at our outpatient clinic consecutively. There were 43 males and 19 females, and their median age at surgery was 27.0 (12-58) years. Of these, 26 patients were treated with IFX after surgery as maintenance therapy from April 2004. Patients' characteristics are shown in Table 1. There was a high frequency of patients with anorectal stricture with or without IFX. Adverse events occurred in 7 patients, with infusion reactions as minor events. No major events related to IFX were seen in this series.

Short-term efficacies

Complete healing was not seen in any patients. Failure was seen in 10/36 (27.8%) patients without IFX and 4/26 (15.4%) patients with IFX ($P = 0.25$). Partial improvement was seen in 26/36 (72.2%) patients without IFX and 22/26 (88.5%) patients with IFX ($P = 0.25$). Short-term improvement was achieved in 48/62 (77.4%) patients. The mPDAI scores improved significantly with surgery regardless of IFX treatment: from 13.5 (9-16) before surgery to 9.5 (4-14) after surgery without IFX; from 11 (8-15) before surgery to 6 (1-10) with IFX ($P < 0.01$) (Figure 1). The rates of improving mPDAI score from baseline were greater in patients with IFX - 50.0% (0-90%) - than in those without IFX -28.6% (0%-60%); ($P = 0.003$) (Figure 2).

Long-term efficacies

In the long-term, recurrences were low regardless of IFX in patients without anorectal stricture (not significant, $P = 0.4$) (Figure 3). However, in patients with stricture, cumulative recurrence incidences increased gradually and exceeded 40% at 5 years in both groups (Figure 4). IFX treatment was not found to be effective ($P = 0.97$). Although the cumulative rate of ostomy creation was also low in patients without stricture and high in patients with stricture, no protective efficacy was found with IFX treatment ($P = 0.6$ without stricture, $P = 0.22$ with stricture) (Figures 5 and 6). The patients' present statuses are shown in Table 2. Of these, 12 patients required abdominoperineal resection (APR), and 14 patients required Hartmann's procedure. There were no significant differences in rates and duration from initial surgery to ostomy creation with or without IFX treatment.

Two patients without IFX treatment were diagnosed as having carcinoma in anorectal fistula and required APR. They had an 8.1- and 10.2-year history of perianal CD, respectively. Both cases demonstrated highly advanced disease and recurred within 2 years after APR.

DISCUSSION

CD is a chronic inflammatory bowel disease of unknown etiology, characterized by fissuring ulcers and segmental

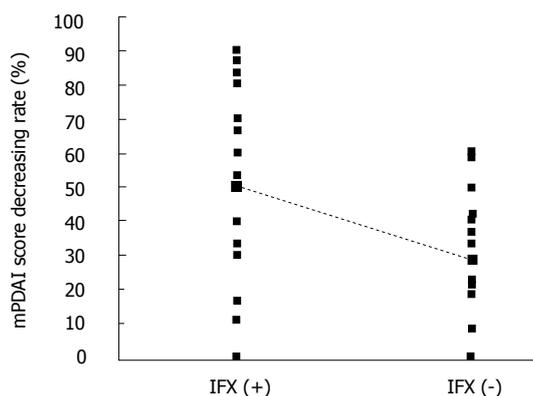

Figure 2 Decreasing rate of the modified perianal Crohn's disease activity index score after surgery in regards to infliximab. The squares represent the median value and the circles represent range plots. The rate of reduction in modified perianal Crohn's disease activity index (mPDAI) score from baseline was significantly greater in patients with infliximab (IFX) -50.0% (0%-90%) - than in those without IFX -28.6% (0%-60%); ($P = 0.003$).

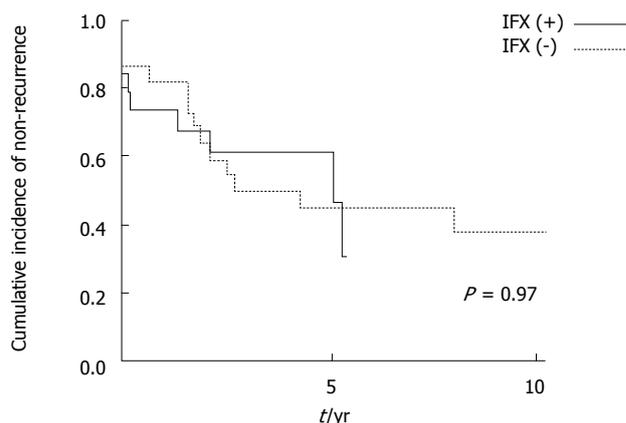

Figure 4 Cumulative incidence of maintaining non-recurrent status in patients with anorectal stricture. The cumulative incidence of fistula recurrence was 53.9%/5 years with infliximab (IFX) ($n = 19$) and 55.0%/5 years and 62.5%/10 years without IFX ($n = 21$), respectively.

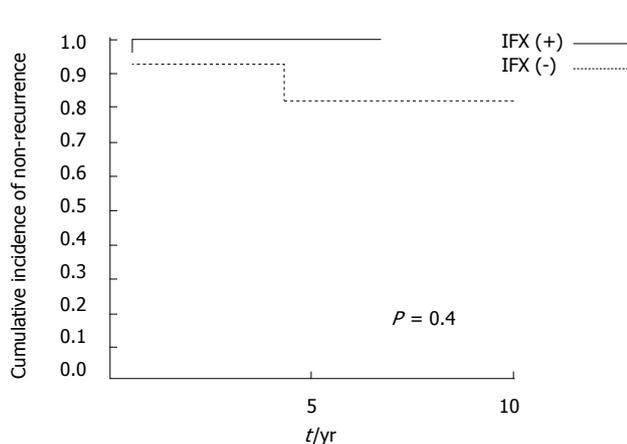

Figure 3 Cumulative incidence of maintaining non-recurrent status in patients without anorectal stricture. The cumulative incidence of fistula recurrence was 0%/5 years with infliximab (IFX) ($n = 7$) and 17.5%/10 years without IFX ($n = 15$), respectively.

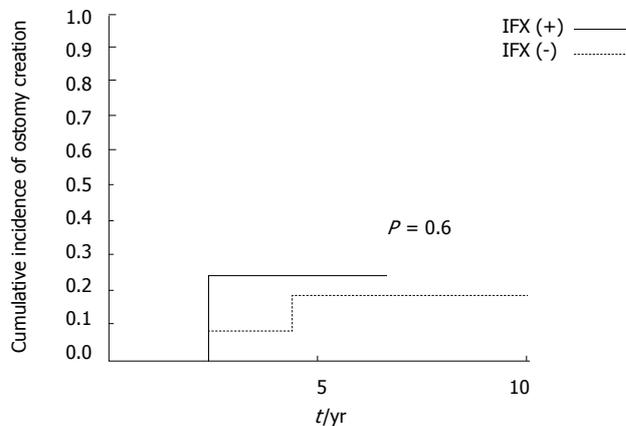

Figure 5 Cumulative incidence of ostomy creation in patients without anorectal stricture. The cumulative incidence of ostomy creation was 25.0%/5 years with infliximab (IFX) ($n = 7$) and 18.5%/5 years without IFX ($n = 15$), respectively.

APR: Abdominoperineal resection; IFX : Infliximab.

transmural inflammation of the gastrointestinal tract. Perianal fistulas are a frequent manifestation of CD, and the prevalence ranges from 20% to 50%^[8]. Medical approaches, with metronidazole, ciprofloxacin, azathioprine, or 6-mercaptopurine, and surgical approaches have been involved in combination therapy^[9-11]. These therapies have been suggested to have a short-term benefit. Furthermore, management with loose setons,

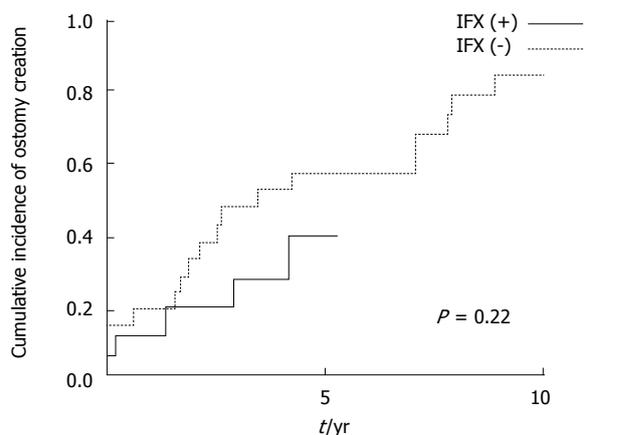

Figure 6 Cumulative incidence of ostomy creation in patients with anorectal stricture. The cumulative incidence of ostomy creation was 38.9%/5 years with infliximab (IFX) ($n = 19$) and 56.5%/5 years and 83.7%/10 years without IFX ($n = 21$), respectively.

advancement flaps, fibrin glue, or collagen plugs has been reported to have a short-term benefit^[12]. Though

the conventional fistulotomy is generally avoided for recurrence and fecal incontinence, surgical treatment with loose setons has shown good results^[13,14]. However, although the ideal goal for treatment of perianal CD lesion is fistula closure and prevention of recurrence, diversion with ostomy creation or APR might often be necessary in patients with refractory lesions.

Recently, IFX treatment has become well established. However, its efficacy for perianal CD has been controversial. Gaertner *et al*^[4] reported that surgery for perianal CD resulted in complete healing in approximately 60% of patients regardless of the use of IFX. However, the time to healing was shorter and the healing rate was improved with surgery plus IFX. Hyder *et al*^[5] also showed the efficacy of IFX in combination with surgery in 85% of cases as measured by PDAI. Although both studies evaluated the short-term efficacy of IFX plus surgery, the medium- or long-term results are less impressive. Also in Japan, IFX in combination with surgery has been recognized as the one of the main treatments for perianal CD, although the results are controversial. Although there are many variables and confounding factors that were not controlled in this retrospective study such as concomitant antibiotics administration, surgery plus IFX treatment was demonstrated to have a short-term benefit compared to surgery alone in improving the rate of PDAI. It is considered that IFX has additional effects which include a greater decrease in the degree of discharge and a reduced healing period though the pain, restriction of living activity and indurations could be improved a little with surgery alone. However, a long-term benefit with maintenance IFX was not proven, at least in patients with anorectal stricture who were excluded from the ACCENT II study, even with the anal dilatation in this series^[2]. Though the surgery with IFX treatment had no efficacy for preventing the recurrence and the comparison of ostomy creation was not significant, the *p* value was 0.08 in regard to ostomy creation in this study. The efficacies of avoidance or time extension for further ostomy creation should be considered in a further long-term and large prospective randomized trial.

On the other hand, prolonged inflammation in a perianal fistula will cause another problem. Although the causative relationship between anorectal fistula and CD has yet to be determined, the epithelial regeneration and hyperplasia are predisposed to malignant changes, and perianal fistula might lead to carcinogenesis due to constant regeneration^[15]. The carcinomas complicating CD have strikingly similar clinicopathologic features to ulcerative colitis with chronic inflammation. The increased risk of carcinoma in areas of prolonged inflammation, such as perianal lesions, has generally been recognized, and surveillance colonoscopy has been recommended for carcinoma screening in CD^[16,17]. However, such surveillance would be difficult for patients with severe pain and stricture of the anorectal CD lesion. In general, sudden changes in clinical symptoms, such as increased discharge, severe pain, or progressive stricture, could raise the suspicion of malignancies. Unfortunately, these malignancies are almost all advanced carcinomas when these symptoms change. Lad *et al*^[18] sug-

gested that contrast-enhanced MRI would be helpful for the diagnosis of carcinoma, but subsequent biopsy would be necessary. Finally, examination under anesthesia may be needed for accurate and early diagnosis, though there is a possibility of missing the diagnosis of occult carcinoma.

In Japan, the incidence of prolonged perianal CD has increased and the condition is associated with a risk of carcinogenesis due to long-standing inflammation^[19]. While the numbers of CD patients with carcinomas are increasing, and the establishment of an effective surveillance protocol is desired, it will be difficult to develop for the above reasons. Furthermore, Sjö Dahl *et al*^[20] suggested that the rectal remnant should be considered a risk factor for carcinogenesis. Prophylactic proctectomy may be justified in patients with persistent or recurrent perianal CD. Even if the long-term efficacy of IFX maintenance therapy is proven, it will be necessary to consider whether the prolonged anorectal CD lesion increases carcinogenesis.

In conclusion, surgery with IFX treatment was demonstrated to have short-term efficacy. However, a long-term benefit with maintenance IFX was not proven, at least in patients with anorectal stricture. Maintenance IFX therapy for patients with anorectal stricture may be contraindicated, even if anal dilatation is performed. Although a long-term prospective randomized trial is needed, surgery with IFX treatment had less efficacy for decreasing the recurrence rate and prophylactic proctectomy may be justified in patients with persistent or recurrent perianal CD, especially in patients with anorectal stricture, for early resolution of occult carcinogenesis.

COMMENTS

Background

In recent years, infliximab (IFX), an IgG1 murine-human chimeric monoclonal antibody against tumor necrosis factor- α , has been recognized to be an effective treatment for active perianal fistula with Crohn's disease (CD).

Research frontiers

In the ACCENT II trial, the closure of fistulas after the initial three IFX infusions occurred in 63% of patients at week 14, but closure decreased to 36% at week 54 with every 8 wk maintenance therapy and there was a high abscess formation rate (15%). The placement of setons and drains prior to IFX therapy is generally recognized as the best combination therapy, and it allows for control of fistula healing and prevention of abscess formation. However, the efficacy of IFX with surgical treatment in perianal CD is controversial, and mainly short-term efficacy has been suggested. Perianal lesions with stricture are recognized to have high recurrence potential, and this is thought to be a contraindication for combination therapy. The aim of this study was to assess the short and long-term efficacy of seton drainage in relation to IFX maintenance therapy with or without anorectal stricture for perianal CD.

Innovations and breakthroughs

The management with loose setons, advancement flaps, fibrin glue, or collagen plugs for perianal CD has been reported to have a short-term benefit. Though the conventional fistulotomy is generally avoided for recurrence and fecal incontinence, surgical treatment with loose setons has shown good results. However, although the ideal goal for treatment of perianal CD lesion is fistula closure and prevention of recurrence, diversion with ostomy creation or abdominoperineal resection may often be necessary in patients with refractory lesions. This study was designed to access data on the long-term efficacy of combination therapy. Although a further, large and long-term prospective study is needed for proper evaluation, the aim of this study was to assess retrospectively the short and long-term efficacy of seton drainage in relation to IFX combination therapy in advance of a prospective study that might take place over a longer period.

Applications

Sixty-two patients were identified from our out patients clinical records that were appreciable in detail of symptoms for assigning a modified perianal CD activity index (mPDAI) score, and the demographics and relevant medical details were recorded retrospectively. To evaluate the efficacies of combination therapy, the authors reviewed the clinical records in regard to anorectal stricture.

Terminology

The activities of perianal lesions were evaluated using the perianal CD activity index (PDAI). The PDAI score is a 5-point index that detects changes in perianal status. The five major elements were the degrees of discharge, pain or restriction of living activity, restriction of sexual activity, type of perianal disease, and induration. Scores ranged from 0 to 20, with higher scores indicating more severe disease activity. Since the mPDAIs were reviewed retrospectively from clinical records in this study, the element of sexual function was not included, and the score ranged from 0 to 16.

Peer review

Surgery with IFX treatment was demonstrated to have short-term efficacy. However, a long-term benefit with maintenance IFX was not proven, at least in patients with anorectal stricture. Maintenance IFX therapy for patient with anorectal stricture may have to be contraindicated, even if anal dilatation is performed. Prophylactic proctectomy may be justified in patients with persistent or recurrent perianal CD. Even if the long-term efficacy of IFX maintenance therapy is proven, it will be necessary to consider whether the prolonged anorectal CD lesion increases carcinogenesis.

Abstract

AIM: To investigate the prognostic factors of T4 gastric cancer patients without distant metastasis who could undergo potentially curative resection.

METHODS: We retrospectively analyzed the clinical data of 71 consecutive patients diagnosed with T4 gastric cancer and who underwent curative gastrectomy at our institutions. The clinicopathological factors that could be associated with overall survival were evaluated. The cumulative survival was determined by the Kaplan-Meier method, and univariate comparisons between the groups were performed using the log-rank test. Multivariate analysis was performed using the Cox proportional hazard model and a step-wise procedure.

RESULTS: The study patients comprised 53 men (74.6%) and 18 women (25.4%) aged 39-89 years (mean, 68.9 years). Nineteen patients (26.8%) had postoperative morbidity: pancreatic fistula developed in 6 patients (8.5%) and was the most frequent complication, followed by anastomosis stricture in 5 patients (7.0%). During the follow-up period, 28 patients (39.4%)

died because of gastric cancer recurrence, and 3 (4.2%) died because of another disease or accident. For all patients, the estimated overall survival was 34.1% at 5 years. Univariate analyses identified the following statistically significant prognostic factors in T4 gastric cancer patients who underwent potentially curative resection: peritoneal washing cytology ($P < 0.01$), number of metastatic lymph nodes ($P < 0.05$), and venous invasion ($P < 0.05$). In multivariate analyses, only peritoneal washing cytology was identified as an independent prognostic factor (HR = 3.62, 95% CI = 1.37-9.57) for long-term survival.

CONCLUSION: Positive peritoneal washing cytology was the only independent poor prognostic factor for T4 gastric cancer patients who could be treated with potentially curative resection.

INTRODUCTION

Although the incidence of gastric cancer has declined worldwide, this disease remains the second leading cause of cancer death because patients with an advanced form of gastric carcinoma still have a poor prognosis^[1,2]. Depth of invasion, lymph node metastasis, or tumor di-

iameter are believed to be independent prognostic factors of gastric carcinoma^[3,4]. Locally advanced gastric cancer defined as T4 in which the tumor perforates serosa (T4a) or invades adjacent structures (T4b)^[5] often has a poor prognosis due to simultaneous distant metastasis such as peritoneal seeding, liver metastasis, and/or distant lymph node involvement. Even though distant metastasis is not apparent in T4 gastric cancer, curative surgery cannot always be performed because such cases sometimes show marked invasion to adjacent structures. Moreover, curative gastrectomy with combined resection of invaded adjacent organs has a reportedly high incidence of post-operative morbidity and mortality^[6,7]. In fact, the overall survival rate for locally advanced gastric cancer patients is under 20% and is approximately 30% for those who can undergo surgical resection^[8].

Nevertheless, a certain number of patients with locally advanced gastric carcinoma could survive curative gastrectomy and progress satisfactorily without tumor recurrence. In this study, we retrospectively studied surgical outcomes and prognostic factors for T4 advanced gastric carcinoma treated with potentially curative resection.

MATERIALS AND METHODS

From 2001 to 2009, 452 gastric cancer patients underwent surgical treatment at our institutions. Of these, 71 patients (15.7%) diagnosed with histological T4^[5] gastric carcinoma and treated with potentially curative resection were selected for this study. All patients underwent D2gastrectomy. Surgery was considered potentially curative [tumor-nodes-metastases (TNM)-R0] or to be resection with curative intent when there was no gross residual tumor after surgery and the resection margins were histologically free from cancer cells. Patients with metastatic disease who had undergone palliative resection were excluded. The study patients comprised 53 men (74.6%) and 18 women (25.4%) aged 39-89 years (mean, 68.9 years). Sixty patients were included in the stage T4a group and 11 cases in the stage T4b group, according to TNM classification^[5]. On histological examination, it was found that T4b gastric carcinomas exhibited invasions to the transverse colon in 5 patients, the pancreas in 3 patients, the diaphragm in 2 patients, and the liver in 1 patient. Of the 71 patients, 7 had tumors located in the upper third of the stomach, 28 had tumors in the middle third of the stomach, 21 had tumors in the lower third of the stomach, and 15 had tumors occupying the entire stomach. The tumor diameter ranged from 20 to 205 mm (mean, 84 mm). Proximal gastrectomy, distal gastrectomy, and total gastrectomy were performed in 3 patients (4.2%), 35 patients (49.3%), and 33 patients (46.5%), respectively. All the surgical procedures were based on the policy of curative resection, which meant complete removal of cancer tissue regardless of combined multi-organ resection with no residual tumor macroscopically.

Data regarding the patients' clinicopathological features, surgical outcomes including morbidity and mortality, and follow-up data were obtained from a clinical database. Histological classification and staging were principally

based on the seventh edition of the International Union Against Cancer (UICC) TNM classification^[5]. We evaluated clinicopathological factors of T4 gastric cancer patients that could be associated with overall survival. These parameters were age, gender, tumor diameter, histological type, lymph node metastasis, metastatic lymph node ratio (MLR), lymphatic invasion (ly), venous invasion (v), and peritoneal washing cytology (CY). For statistical analysis, the patients were grouped into 2 categories with respect to age [≤ 68 years or > 68 years (mean value)], tumor diameter [≤ 84 mm or > 84 mm (mean value)], histological type (differentiated or undifferentiated), number of metastatic lymph nodes (N0 or N1 *vs* N2 or N3)^[5], MLR [≤ 0.27 or > 0.27 (mean value)], and peritoneal washing cytology (CY0 or CY1)^[5]. Similarly, the patients were divided into 2 groups with respect to lymphatic invasion (ly0 or ly1 *vs* ly2 or ly3) and venous invasion (v0 or v1 *vs* v2 or v3) according to the Japanese Gastric Cancer Association (JGCA) system^[9]. Post-operative morbidity and mortality were defined as operation-related complications or death that occurred within 30 days after surgery.

The observation period ended on July 31, 2010. The median follow-up duration from the date of surgery was 24 mo (range, 1-89 mo). Fifty patients (70.5%) were given post-operative adjuvant chemotherapy using S-1 for 29 patients, UFT for 7 patients, paclitaxel for 7 patients, and others for 7 patients. The cumulative survival was determined by the Kaplan-Meier method, and univariate comparisons between the groups were performed using the log-rank test. Multivariate analysis was performed using the Cox proportional hazard model and a step-wise procedure. *P* value differences less than 0.05 were considered significant.

RESULTS

Sixty-one patients (85.9%) had lymph node metastasis, 9 (12.7%) had N1, 18 (25.4%) had N2, and 34 (47.9%) had N3 disease. Differentiated tumors were histologically revealed in 31 patients and undifferentiated tumors were seen in 40 patients. The degree of lymphatic invasion according to the JGCA system^[9] were 0.0%, 23.9%, 45.1%, and 31.0% for ly0, ly1, ly2, and ly3, respectively. The degree of venous invasion according to the JGCA system^[9] were 32.4%, 42.3%, 23.9%, and 1.4% for v0, v1, v2, and v3, respectively. Twenty-seven patients (38.0%) were positive for peritoneal washing cytology. Patient characteristics are presented in Table 1. Nineteen patients (26.8%) had postoperative morbidity. Pancreatic fistula occurred in 6 patients (8.5%) and was the most frequent complication, followed by anastomosis stenosis in 5 patients (7.0%). Three patients (4.2%) died of post-operative complications: 2 were due to multi-organ failure associated with pancreatic fistula, and 1 was due to acute gangrenous cholecystitis combined with peritonitis. These complications are listed in Table 2. Thirty-one patients (43.7%) died during the follow-up period. Of these, 28 were related to recurrence of gastric cancer, and 3 were due to another disease or accident. CI: Confidence interval.

ing cytology was 15.2%, which was significantly decreased compared to patients with negative peritoneal washing cytology (47.6%). The 5-year overall survival rate of patients with N2 or N3 was 23.8%, which was significantly poorer than patients with N0 or N1 (67.4%). Similarly, the 5-year overall survival rate of patients with v2 or v3 was 9.7 %, which was significantly decreased compared to patients with v0 or v1 (45.7%). The tumor diameter, degree of lymphatic invasion, and histological classification were not significant prognostic factors according to the results of the univariate analysis. In multivariate analysis, only peritoneal washing cytology was identified as an independent prognostic factor (HR = 3.62, 95% CI = 1.37-9.57) for long-term survival (Table 4).

DISCUSSION

Owing to the progression of surgical techniques and the

standardization of curative R0 resection, the prognosis of the patients with gastric cancer has been improved in recent years. Nevertheless, patients with advanced gastric carcinoma, especially serosa invading locally advanced tumor diagnosed as T4 in TNM classification^[5], still have a poor prognosis^[10]. The poor prognosis associated with T4 advanced gastric cancer may result from the presence of incurable factors including distant lymph node involvement, peritoneal metastasis, and hematogenous metastasis such as liver metastasis^[11]. If a patient with T4 gastric carcinoma does not have the incurable factors mentioned above, a relatively better survival can be expected when curative surgery regardless of en-block multi-organ resection is achieved. Various T4 gastric carcinoma prognostic factors have been reported in the literature. Kunisaki *et al*^[4] reported that tumor diameter (> 100 mm) and lymph node metastases (more than 7) are poor prognostic factors in T4 gastric cancer patients and concluded that curative surgery with multi-organ resection is indicated for patients with few metastatic lymph nodes (6 or less) and a relatively small tumor diameter (\leq 100 mm). Similarly, several reports suggested that tumor size in gastric cancer is a significant prognostic factor, and large gastric cancers with a diameter > 80 mm have more aggressive behavior and frequent peritoneal recurrences^[12,13]. However, our study revealed that the tumor size was not a significant prognostic factor in T4 gastric carcinoma patients who could undergo potentially curative resection. The divergent conclusions of these reports^[4,12,13] with ours might be explained by different patient populations.

Our study was limited to patients with T4 gastric carcinoma without distant metastasis and who were treated with potentially curative resection, whereas other studies^[4,12,13] included patients with distant metastasis. Therefore, tumor size may not be a significant prognostic factor in T4 gastric carcinoma, if the patient does not have distant metastasis and can be treated with curative resection.

Lymph node metastasis is a commonly reported prognostic factor for poor outcome in patients with T4 gastric carcinoma^[4,11,14]. Saito *et al*^[14] reported that infiltrative type and lymph node metastasis were independent poor prognostic factors in curatively resected patients with T4 gastric carcinoma, and stated that multi-organ resection does not seem to be effective even when curative resection is performed in infiltrating tumors with lymph node metastasis. Jeong *et al*^[11] revealed that lymph node metastasis (greater than pN3) was an independent poor prognostic factor for patients with T4 gastric carcinoma who underwent curative surgery, and concluded that curative resection does not seem to be effective in patients with extensive lymph node metastasis (more than N3). In our study, although patients with more extensive lymph node metastasis (N2 or N3) had a significantly poorer prognosis compared to patients in whom lymph node metastasis was limited (N0 or N1) according to the results of univariate analysis, multivariate analysis revealed that lymph node metastasis was not an independent prognostic factor for T4 gastric cancer patients who underwent potentially curative resection. Although the degree of lymph node metastasis influences surgical

outcomes in patients with T4 gastric carcinoma, a relatively good prognosis can be expected with curative R0 resection followed by adjuvant chemotherapy even if the patient has extensive lymph node metastasis (N2 or N3).

In this study, positive peritoneal washing cytology was identified as the only independent prognostic factor for T4 gastric cancer patients who underwent potentially curative resection. Several reports^[15-21] have emphasized the prognostic significance of intra-peritoneal free cancer cells for potentially curable serosa-invaded gastric carcinoma. Intra-peritoneal free cancer cells which may be exfoliated mainly from the serosal surface of the stomach penetrated by the primary tumor, are closely related to peritoneal dissemination^[18]. Therefore, detection of intra-peritoneal free cancer cells that might have already seeded at the time of operation but cannot be found macroscopically is a key point for influencing the prognosis of T4 gastric cancer patients and for adjuvant treatment planning for those patients. Euanorasetr *et al*^[17] reported that all patients with positive peritoneal washing cytology developed peritoneal recurrence, with no patient surviving more than 5 years, and that the sensitivity of peritoneal washing cytology in predicting peritoneal recurrence was only 61% regardless of its high specificity (100%). In addition, the sensitivity of peritoneal washing cytology was previously reported as relatively low, ranging from 14% to 70%^[16,22-25]. The relatively high false-negative rate might arise from technical flaws such as incomplete sampling during the lavage process^[17]. Recently, the real-time quantitative polymerase chain reaction (PCR) technique has made it possible to detect the presence of only a few cancer cells in the abdominal cavity and this technique is more sensitive than traditional peritoneal lavage cytology^[26,27]. Katsuragi *et al*^[18] reported that the prognosis of patients with isolated tumor cells in the peritoneal lavage fluid detected by PCR-based identification was significantly poorer than the prognosis for PCR-negative patients in T4 gastric cancer. Therefore, detection of intra-peritoneal free cancer cells should be the most important and useful way to infer surgical outcome and prognosis of T4 gastric cancer patients. According to the results, T4 gastric cancer patients with positive peritoneal washing cytology might be treated in the same way as for the patients with peritoneal metastasis. More aggressive adjuvant chemotherapy such as S-1 plus cisplatin^[28] or DCF^[29] should be indicated for patients with T4 gastric cancer with positive peritoneal washing cytology that could undergo potentially curative resection to improve prognosis.

COMMENTS

Background

Although the incidence of gastric cancer has declined particularly in Western countries, the disease remains the fourth most common cancer and continues to be the second leading cause of cancer death worldwide. The therapeutic strategy for advanced gastric carcinoma, such as T4 locally advanced gastric carcinoma, is to improve the prognosis of all gastric cancer patients, since surgical results for early stage gastric carcinoma are satisfactory.

Innovations and breakthroughs

In this study, patients included were limited to T4 advanced gastric carcinoma without distant metastasis who could be treated with potentially curative resec-

tion. Various clinicopathological factors including peritoneal washing cytology that could be associated with overall survival of T4 gastric cancer patient were evaluated on univariate analysis using the Kaplan-Meier method and on multivariate analysis using a Cox proportional hazard model and a step-wise procedure.

Applications

Aggressive adjuvant chemotherapy should be indicated for the patients with T4 gastric carcinoma with positive peritoneal washing cytology to improve the prognosis, even if the tumor can be resected without no residual tumor macroscopically. Thus, identification of effective adjuvant chemotherapy for advanced gastric carcinoma with positive peritoneal cytology for patients who could undergo potentially curative resection will be the problem in the near future.

Peer review

This is an interesting work that underlines the prognostic value of peritoneal cytology in curatively resected T4 gastric carcinomas. The text is well-organized and the key points are clearly described.

(CMV) antigenemia assay for the diagnosis of CMV gastrointestinal disease (GID).

METHODS: One hundred and thirty immunocompromised patients were enrolled in this study. Patients with a history of anti-CMV treatment and who had not undergone examination using the antigenemia assay were excluded. CMV-GID was defined as the detection of large cells with intranuclear inclusions alone or associated with granular cytoplasmic inclusions by biopsy. Biopsy sections were stained with hematoxylin and eosin and immunohistochemically stained with anti-CMV. We evaluated the association between CMV-GID and patient characteristics (symptoms, underlying disease, medication, leukocyte counts, and antigenemia assay). All patients were checked with an human immunodeficiency virus (HIV) antibody test before endoscopic examination. White blood cell (WBC) counts were obtained from medical records within 1 wk of endoscopy. Leukopenia was defined as a total WBC count < 5000 cells/mm³. For HIV patients, we also checked CD4+ counts from medical records.

RESULTS: A total of 99 patients were retrospectively selected for analysis. Of the immunocompromised patients, 19 had malignant disease, 18 had autoimmune disease, 19 had disorders of biochemical homeostasis, three had undergone transplantation, and 45 had HIV infection. A total of 50 patients had received immunosuppressive therapy. No patients had inflammatory bowel disease. Fifty-five patients were diagnosed as having CMV-GID. Univariate analysis indicated an association between HIV infection, leukopenia, and positive antigenemia and CMV-GID ($P < 0.05$). Multivariate analysis using logistic regression revealed that HIV infection and positive antigenemia were the only independent factors related to CMV-GID ($P < 0.01$). The sensitivity, specificity, positive predictive value, and negative predictive value of antigenemia for CMV-GID were 65.4%, 93.6%, 91.9%, and 71.0%, respectively. In a subgroup analy-

Abstract

AIM: To investigate the utility of the cytomegalovirus

sis, patients with leukopenia displayed low sensitivity and high specificity. Minimal differences in accuracy were seen among patients with or without leukopenia. HIV-infected patients displayed low sensitivity and high specificity. Accuracy barely differed between HIV-positive and -negative patients. In HIV-infected patients, CD4 count < 50 cells/ μ L resulted in low sensitivity and high specificity. Differences in accuracy among patients were minor, regardless of CD4 count. In patients who had undergone both quantitative real-time polymerase chain reaction (PCR) and antigenemia assay, real-time PCR was slightly more accurate in terms of sensitivity than the antigenemia assay; however, this difference was not statistically significant ($P = 0.312$).

CONCLUSION: If the antigenemia test is positive, endoscopic lesions are acceptable for the diagnosis of CMV-GID without biopsy. The accuracy is not affected by HIV infection and leukopenia. Either PCR or the antigenemia assay are valid.

INTRODUCTION

As the number of patients with immune deficiency has been increasing dramatically in recent years, the number of patients with cytomegalovirus (CMV) disease has also been increasing. CMV gastrointestinal disease (CMV-GID) frequently occurs in immunocompromised patients, particularly among those with human immunodeficiency virus (HIV) infection, transplantation, autoimmune diseases, or secondary immunodeficiency^[1-8]. CMV-GID has also been described following the use of steroids, immunosuppressants, or cancer chemotherapy^[1,2]. In immunocompromised patients, CMV-GID in the absence of therapy is a major cause of morbidity and mortality due to events such as massive bleeding or perforation. Therefore, diagnosis at an early stage is essential^[1,2,9-12]. However, diagnosis of this infection is difficult because of wide variations in symptoms and endoscopic features depending on the infected organs^[1,2].

Although the utility of various diagnostic tests for

CMV-GID has been reported, the best approach is to conform the presence of CMV by histological analysis, including immunological staining by endoscopy^[1-3,5,13,14]. Endoscopic examination is generally tolerated, but tissue biopsy can possibly lead to hemorrhage or perforation after endoscopic examination^[10,11,15]. Endoscopists therefore hesitate to perform biopsy when deep, large, and bleeding ulcerous lesions are encountered. Patients receiving anti-thrombotic drugs or with thrombocytopenia also require careful consideration before biopsy.

On many occasions in recent years, noninvasive methods such as the CMV blood antigenemia assay have been applied instead of biopsy to avoid adverse effects^[3,16-22]. However, few reports have examined the diagnostic value of the CMV antigenemia assay for CMV-GID, and the clinical utility of this method in immunodeficiency remains unclear^[3,20-22]. Moreover, the CMV antigenemia assay requires sufficient granulocytes, and leukopenia and low CD4+ counts in patients with HIV infection could thus be expected to influence assay accuracy^[3]. However, no reports have yet clarified this issue.

The aims of this study were to clarify the utility of the CMV antigenemia assay for diagnosing suspected CMV-GID, and to evaluate the accuracy of this assay under different clinical settings.

MATERIALS AND METHODS

Patient selection

One hundred and thirty immunocompromised patients with endoscopic findings who had undergone biopsy were enrolled in this study at the National Center for Global Health and Medicine (NCGM) from January 2002 to September 2009. Patients with a history of treatment with anti-CMV therapy were excluded, as were cases not examined using the CMV antigenemia assay test within 1 wk of endoscopy. Written informed consent was obtained from all patients prior to endoscopy and biopsy. All study protocols were approved by the ethics committee of NCGM.

Immunocompromised patients

Immunocompromised patients are associated with secondary immune deficiency, particularly HIV infection, hematopoietic stem cell transplantation, autoimmune diseases, malignancy, disorders of biochemical homeostasis, and use of steroids, immunosuppressants, or cancer chemotherapy.

Underlying autoimmune diseases included Rheumatoid arthritis, Systemic lupus erythematosus, Still's disease, Behcet's disease, Polymyositis, and Dermatomyositis. Diabetes mellitus, renal insufficiency/dialysis, and hepatic cirrhosis were included among the disorders of biochemical homeostasis. All patients were checked with an HIV antibody test before endoscopic examination.

Clinical manifestations

Gastrointestinal symptoms were collected from medical records written by the doctor who interviewed each per-

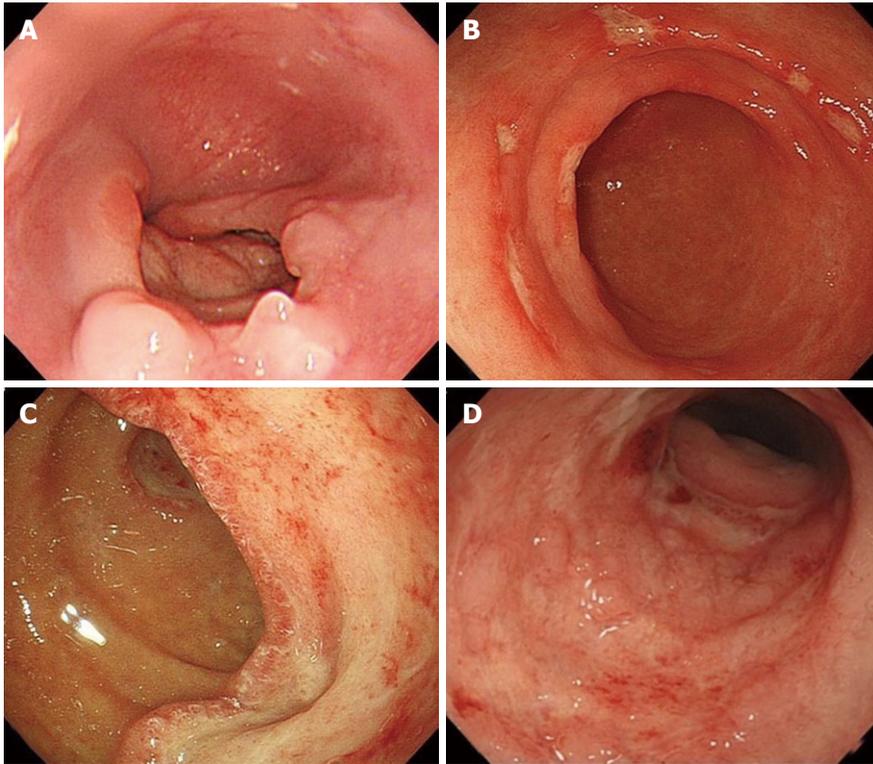

Figure 1 Endoscopic features in cytomegalovirus gastrointestinal disease. A: Deep, punched-out ulcer in the esophagus; B: Multiple, shallow ulcers in the gastric antrum; C: Large, deep ulcer in the duodenum; D: Multiple erosions and edematous mucosa with ulcer in the sigmoid colon.

son face-to-face before endoscopy. Those without records were treated as symptom free. Gastrointestinal symptoms included compromised odynophagia, epigastralgia, nausea, lower abdominal pain, diarrhea, and hematochezia. White blood cell (WBC) counts were obtained from medical records within 1 wk of endoscopy. Leukopenia was defined as a total WBC count < 5000 cells/ mm^3 . For HIV patients, we also checked CD4+ counts from medical records.

Antigenemia assay and quantitative real-time polymerase chain reaction

Antigenemia assay using C10/C11 monoclonal antibodies (Mitsubishi Chemical Medience, Tokyo, Japan) was performed as previously reported^[16,19,20]. A positive result for the CMV antigenemia assay was defined as ≥ 1 CMV-positive cell per 150 000 granulocytes applied.

A total of 47 patients underwent additional examination with real-time polymerase chain reaction (PCR), performed basically as previously reported^[3,23,24]. The minimum detection level was 200 copies/mL of plasma. A positive result for real-time CMV PCR was defined as > 200 copies/mL.

Diagnosis of CMV-GID

CMV-GID was suspected based on endoscopic findings, such as patchy erythema, edematous mucosa, multiple erosions, and ulcers (Figure 1)^[25,26]. Biopsy was therefore performed when such endoscopic findings were encountered. CMV-GID was defined as the detection of large

cells with intranuclear inclusions alone or associated with granular cytoplasmic inclusions by histological testing of biopsy specimens^[1]. Biopsy sections were stained with hematoxylin and eosin, and immunohistochemically stained with anti-CMV (Figure 2). The results were considered positive when the above-mentioned cells showed marked brown coloration in both nuclei and cytoplasm.

Statistical analysis

We divided patients into two groups based on the presence or absence of CMV-GID. Patient characteristics and clinical findings were then compared between groups. Fisher's exact test was used to compare frequencies for patient characteristics and clinical findings, and Mann-Whitney *U* test was used for comparing age and CD4 counts. To identify clinical factors independently associated with a diagnosis of CMV-GID, stepwise logistic regression modeling was used. Sensitivity, specificity, and positive and negative predictive values of CMV antigenemia for diagnosing CMV-GID were calculated. The difference in accuracy between CMV real-time PCR and CMV antigenemia assay was compared according to the area under the curve (AUC). Values of $P < 0.05$ were considered significant. All statistical analyses were performed using Stata software (version 10, Stata Co., USA).

RESULTS

Clinical features

We excluded 10 patients who had received anti-CMV

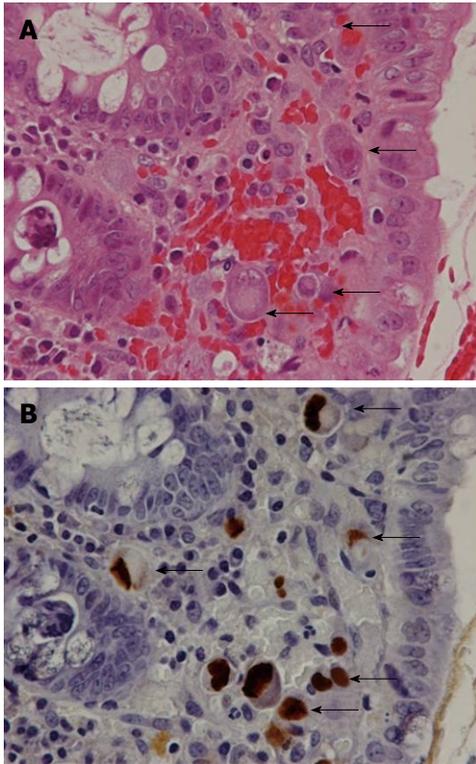

Figure 2 Pathological features in cytomegalovirus gastrointestinal disease. HIV: Human immunodeficiency virus; CMV: Cytomegalovirus; GID: Gastrointestinal disease.

patients had inflammatory bowel disease (IBD). Fifty-five patients were histologically diagnosed with CMV-GID. Univariate analysis (Table 1) identified HIV infection ($P < 0.001$), leukopenia ($P = 0.023$), and positive CMV antigenemia assay ($P < 0.001$) as being associated with CMV-GID. Multivariate analysis revealed HIV infection [odds ratio (OR), 6.57; 95% CI: 2.1-20.2, $P = 0.001$] and positive CMV antigenemia assay (OR, 33.3; 95% CI: 8.1-136.2, $P < 0.001$) as the only factors independently correlated with CMV-GID.

HIV-infected patients included 44 men (97.8%) and their mean age was 42.1 years (range, 25-74 years). Median CD4 count was 57 (interquartile range, 17-111). Patients with CMV-GID showed significantly lower CD4 counts than those without CMV-GID (median CD4 count; CMV-GID *vs* non-CMV-GID: 24 *vs* 150, $P < 0.001$).

Accuracy of CMV antigenemia assay for diagnosing CMV-GID

A positive CMV antigenemia assay showed low sensitivity and high specificity (Table 2). In a subgroup analysis, patients with leukopenia displayed low sensitivity and high specificity. Minimal differences in accuracy were seen among patients with or without leukopenia. HIV-infected patients displayed low sensitivity and high specificity. Accuracy barely differed between HIV-positive and -negative patients. In HIV-infected patients, CD4 count < 50 cells/ μ L resulted in low sensitivity and high specificity. Differences in accuracy among patients were minor, regardless of CD4 count.

In patients who had undergone both quantitative real-

time PCR and antigenemia assay (Table 3), real-time PCR was slightly more accurate in terms of sensitivity than the antigenemia assay; however, this difference was not statistically significant ($P = 0.312$).

DISCUSSION

CMV-GID is a major cause of morbidity and mortality in immunocompromised patients; therefore, diagnosis at an early stage is essential^[1,2,5,8,9]. However, clinical diagnosis of this disease can be difficult, as physicians need to consider various underlying diseases and clinical presentations. Patients at high risk of CMV-GID have been reported as those with HIV infection or undergoing steroid therapy or cancer therapy^[1]. The present study identified HIV infection as one of the independent factors in secondary immunodeficiency diseases. This is because the number of eligible subjects was small and included immunocompromised patients while excluding immunocompetent patients.

Among the various clinical manifestations, a positive CMV antigenemia assay was found to be a useful factor for diagnosing CMV-GID. The CMV antigenemia assay is one of the most widely used methods for detecting reactivation of CMV infection, but few studies have examined the diagnostic value for CMV-GID^[3,21,22]. Our findings demonstrated 65% sensitivity and 94% specificity of the CMV antigenemia assay for diagnosing CMV-GID. Mori *et al.*^[3] reported that only four of 19 patients (21%) developed a positive CMV antigenemia assay before developing CMV-GID; however, all 19 patients subsequently tested positive for CMV antigenemia after diagnosis of CMV-GID. There is a possibility that patients with CMV-GID will develop a positive CMV antigenemia assay at follow-up, but our study did not assess this process after diagnosis of CMV-GID. Fica *et al.*^[21] also reported that the CMV antigenemia assay result was positive for 18 of 31

patients (58%) with CMV end-organ disease, with CMV-GID (71%) as the most frequent cause. However, these studies were limited in that the number of subjects was small and the specificity of the CMV antigenemia assay was unknown. Jang *et al.*^[22] recently reported that the sensitivity and specificity of the CMV antigenemia assay for diagnosing CMV-GID were 54% and 88%, respectively, in patients with secondary immunodeficiency disease. The reports mentioned above showed that the CMV antigenemia assay has low sensitivity for the diagnosis of CMV-GID, which is consistent with our results.

It has been reported that sufficient granulocytes are essential in evaluating CMV using the antigenemia assay. Previous studies using the antigenemia assay to diagnose CMV-GID have reported that most of the patients were transplant recipients and were mostly HIV-negative^[3,21,22]. No studies have compared the assay among groups of HIV-positive/-negative patients and among groups with or without leukopenia. In patients with HIV infection, most cases of CMV-GID have known to occur with CD4 counts < 50 cells/ μL ^[2,4]. However, whether the accuracy of the antigenemia assay is affected by the immunosuppressed state has not been elucidated. We suspected that such different groups would show differences in the accuracy of CMV antigenemia assay, but found little difference. This suggests that our results are applicable to these different groups in clinical practice.

Besides the CMV antigenemia assay, quantitative real-time PCR is also used for detecting reactivation of CMV infection, and is considered more useful for predicting CMV disease than the CMV antigenemia assay^[23,24]. In our study, quantitative real-time PCR and CMV antigenemia assay were performed simultaneously on 47 patients. The PCR method showed a tendency toward slightly higher sensitivity, but no significant differences were evident. In Japan, the CMV PCR method has not been widely used in

clinical practice because of the higher costs compared to the antigenemia assay. We thus do not recommend use of PCR methods in the sub-diagnosis of CMV-GID, as the antigenemia assay is just as valid.

One limitation of this study was the single-center, retrospective nature of the investigation. A significant difference might not have been confirmed among independent factors due to the small number of patients. Further studies of more patients are needed. Another limitation is the verification bias, which is dependent on the physician's decision to perform the antigenemia assay.

The diagnosis of CMV-GID is considered as the gold standard for identifying CMV cells in tissue samples from endoscopic biopsy^[1,2,13]. Various endoscopic findings are present in CMV-GID, such as ulcer and mucosal inflammation^[25,26]; however, physicians may not perform a biopsy in cases only showing mucosal inflammation without ulcer. Even in cases of severe ulceration that is deep or bleeding, physicians may hesitate to perform a biopsy. In such cases, a diagnosis of CMV-GID may not be reached. Our results suggest that the CMV antigenemia assay is useful for the sub-diagnosis of CMV-GID in immunocompromised patients with endoscopic findings. Considering the high specificity of the test, the use of this method before endoscopy could potentially avoid complications due to biopsy. Positive antigenemia is also useful for evaluating improvements in CMV-GID after anti-CMV treatment. However, the low sensitivity means that if the antigenemia assay yields negative results, biopsy and immunohistochemical staining of specimens with anti-CMV will be required for diagnosis. Negative antigenemia assay results may require a repeat examination at a different time^[3]. Moreover, the use of different non-invasive methods such as quantitative PCR should be considered.

In conclusion, the CMV antigenemia assay is highly useful for diagnosing CMV-GID. If the antigenemia assay provides positive results, the presence of endoscopic lesions should allow diagnosis of CMV-GID without biopsy. The accuracy of the test is unaffected by the presence of HIV infection or leukopenia.

ACKNOWLEDGMENTS

We acknowledge Mr. Takashi Kurihara (Department, Mitsubishi Chemical Medience Corporation) for advice to this study on the antigenemia assay evaluation. We also acknowledge Shizuka Tanaka and Toshio Kitazawa for help with the pathological evaluation.

COMMENTS

Background

Cytomegalovirus (CMV) gastrointestinal disease (GID) is a major cause of morbidity and mortality in immunocompromised patients; therefore, diagnosis at an early stage is essential. However, clinical diagnosis of this disease can be difficult, as physicians need to consider various underlying diseases and clinical presentations.

Research frontiers

The diagnosis of CMV-GID requires an endoscopic biopsy, which is invasive and may lead to complications. While the CMV antigenemia assay is one of the

most widely used methods for detecting reactivation of CMV infection, few studies have examined its diagnostic value for CMV-GID. In this study, the authors demonstrate that the CMV antigenemia assay was highly useful for diagnosing CMV-GID.

Innovations and breakthroughs

There were no studies of diagnosis on CMV-GID related factors using multivariate analysis. In this study, among the various clinical manifestations, human immunodeficiency virus (HIV) infection and positive CMV antigenemia assay were found to be a useful factors for diagnosing CMV-GID by multivariate analysis. As for accuracy of CMV antigenemia for diagnosing CMV-GID, recent reports have highlighted that the sensitivity and specificity were 54% and 88%, respectively, in patients with secondary immunodeficiency disease. However, no studies have compared the assay among groups of HIV-positive/negative patients and among groups with or without leukopenia. In this study, the sensitivity, specificity, positive predictive value, and negative predictive value of antigenemia for CMV-GID were 65.4%, 93.6%, 91.9%, and 71.0%, respectively. In addition, its accuracy was not affected by the presence of HIV infection and leukopenia. These results are very useful for diagnosing CMV-GID by clinical physicians.

Applications

Considering the high specificity of the test, use of this method before endoscopy could potentially avoid complications due to biopsy. However, the low sensitivity means that if the antigenemia assay yields negative results, biopsy and immunohistochemical staining of specimens with anti-CMV will be required for diagnosis. Negative antigenemia assay results may require repeat examination at a different time. Moreover, the use of different non-invasive methods such as quantitative polymerase chain reaction should be considered.

Abstract

AIM: To determine the role of CD133 in cholangiocarcinoma progression.

METHODS: CD133 protein expression was evaluated by immunohistochemistry in 34 cholangiocarcinoma specimens. In addition, proliferation, chemoresistance and invasive properties of CD133-enriched (CD133⁺) and CD133-depleted (CD133⁻) RMCCA1 cholangiocarcinoma cells were studied and compared.

RESULTS: Strong CD133 expression was observed in 67.6% (23/34) of the cholangiocarcinoma specimens. Strong expression of CD133 was significantly associated with nodal metastasis ($P = 0.009$) and positive surgical margin status ($P = 0.011$). In the *in vitro* study, both the CD133⁺ and CD133⁻ cells had similar proliferation abilities and resistance to chemotherapeutic drugs.

INTRODUCTION

Cholangiocarcinoma is known as one of the most aggressive malignant tumors associated with local invasiveness and a high rate of metastasis. It is also known to be one of the most common causes of cancer death in Thailand^[1]. Three-year survival rates of 35% to 50% are achieved only in a subset of patients who have negative histological margins at the time of surgery^[2-4]. Palliative therapeutic approaches, consisting of percutaneous and endoscopic biliary drainage, have usually been used for these patients because there is no effective chemo-

therapeutic treatment for this type of cancer. Therefore, identification of the molecules involved in cholangiocarcinoma cell progression is crucial for the development of novel drug treatments for this disease.

CD133, a human homologue of a mouse Prominin-1, is a 5-transmembrane cell-surface glycoprotein^[5]. It has been detected in an enrichment of hematopoietic stem cells derived from fetal liver or bone marrow neuroepithelial cells, embryonic epithelial cells and adult immature epithelial cells^[5]. Furthermore, CD133 has been successfully used for the identification of cancer stem cell (CSC) niches in glioblastoma^[6], colon cancer^[7] and other solid carcinomas^[8]. Recently, CD133 was identified in many kinds of cancer specimens, including hepatocellular carcinoma^[9] and colon cancer^[10], and was associated with poor prognoses. To understand the roles of CD133 in cholangiocarcinoma cells, the characteristics of CD133⁺ and CD133⁻ cholangiocarcinoma cells must be investigated; such studies have not been carried out with CD133⁺ cholangiocarcinoma cells. In the present study, we investigated the clinicopathological significance of CD133 expression in human cholangiocarcinoma specimens. In addition, we studied the cell proliferation, chemoresistance and invasiveness of CD133⁺ and CD133⁻ cholangiocarcinoma cells from the RMCCA1 cholangiocarcinoma cell line.

MATERIALS AND METHODS

Human cholangiocarcinoma tissue samples

The cholangiocarcinoma tissue samples analyzed in this study were obtained from cholangiocarcinoma patients who underwent a surgical resection at Rajavithi Hospital in Bangkok, Thailand from 2008 to 2010. The study was approved by the ethics committee of Rajavithi Hospital.

Immunohistochemical staining

Paraffin wax sections of cholangiocarcinoma specimens were dewaxed in xylene, and transferred to alcohol. Endogenous peroxidase activity was blocked with 0.5% hydrogen peroxide in methanol, and the sections were boiled in 10 mmol/L citrate buffer (pH 6.0) in a microwave oven (750 W) for antigen retrieval. Nonspecific binding was blocked by incubating with 3% normal horse serum for 20 min. Sections were incubated overnight at 4°C with a 1/1000 dilution of mouse monoclonal antibody for CD133. Biotinylated rabbit anti-mouse IgM (Dako, Glostrup, Denmark) was applied to the sections, followed by an avidin-biotin-peroxidase conjugate (ABC Elite; Vector Laboratories, Burlingame, California, USA) for 30 min at room temperature. The immunohistochemical reaction was developed with freshly prepared reagents from a Histofine streptavidin-biotin complex peroxidase (SAB-PO) kit (Nichirei Inc., Tokyo, Japan). The immunohistochemical reactions were then visualized under high power magnification ($\times 400$) using an Olympus BH2 microscope (field width, 0.5 mm) and scored into 3 categories based on the percentage of positively stained cells, as follows: (1) negative, $< 5\%$; (2) weak, $5\% - 50\%$; and (3) strong $> 50\%$.

Cell culture and materials

The human cholangiocarcinoma RMCCA1 cells^[11] were routinely grown in Ham's F12 medium supplemented with 10% fetal bovine serum (FBS) (Gibco, Grand Island, NY, USA) at 37°C in a 5% CO₂ humidified atmosphere. For experiments, cells were grown in Ham's F12 medium supplemented with 1% FBS.

Enrichment of CD133⁺ cholangiocarcinoma cells

Cells were harvested by treatment with 0.25% trypsin (Gibco, LA, USA) in the logarithmic phase of growth followed by centrifugation at 300 *g* for 5 min. The cells were resuspended in 100 μ L buffer (phosphate-buffered saline (PBS), pH 7.2, 0.5% bovine serum albumin, 2 mmol/L ethylenediaminetetraacetic acid). Single cells were magnetically labeled with anti-CD133 MicroBeads (Miltenyi Biotec, Bergisch Gladbach, Germany) in the dark at 4°C for 30 min and applied to a prepared MS Column (Miltenyi Biotec, Bergisch Gladbach, Germany). CD133⁻ cells were collected in the flow-through of the column; CD133⁺ cells bound to the beads were flushed out by applying the plunger supplied with the column. The percentage of CD133-expressing cells in the original cell populations, the flow-through and the flushed-out fractions was analyzed by fluorescence-activated cell sorting (FACS) with fluorescein isothiocyanate (FITC)-conjugated anti-CD133 antibody (Miltenyi Biotec, Bergisch Gladbach, Germany). Cells were stained at a concentration of 1×10^6 cells per 90 μ L buffer and 10 μ L antibody at 4°C for 25 min before FACS analysis.

Cell proliferation assay

For proliferation assays, cells were seeded into 96-well culture plates at a density of 10000 cells per well. For cancer chemoresistance studies, cells were treated with vehicle (PBS) or 5-50 μ mol/L cisplatin. Cells were then incubated for 48 hours before applying the water soluble tetrazolium salts (WST)-1 cell proliferation assay reagent (Roche Diagnostics, Laval, Quebec, Canada) according to the manufacturer's recommendations. The degree of cell proliferation was assessed by determining the $A_{450\text{ nm}}$ of the cell culture medium after addition of WST-1 for 2 h. Results are reported as the percentage of inhibition of cell proliferation, where the optical density measured for vehicle-treated cells was considered to represent 100% proliferation.

Cell invasion assay

The invasiveness of cholangiocarcinoma cells was assayed in a 24-well Biocoat Matrigel invasion chamber (8 μ m; Becton Dickinson, Bioscience, Bedford, MA, USA). There were 50000 cells seeded in the upper chamber. The bottom chamber contained 10% FBS. After 24 h of incubation, the invading cells at the lower surface of the Matrigel-coated membrane were fixed with 70% ethanol, stained with crystal violet and counted in 5 random 200 \times power fields under a light microscope.

Statistical analysis

Statistical analysis of the association between clinicopatho-

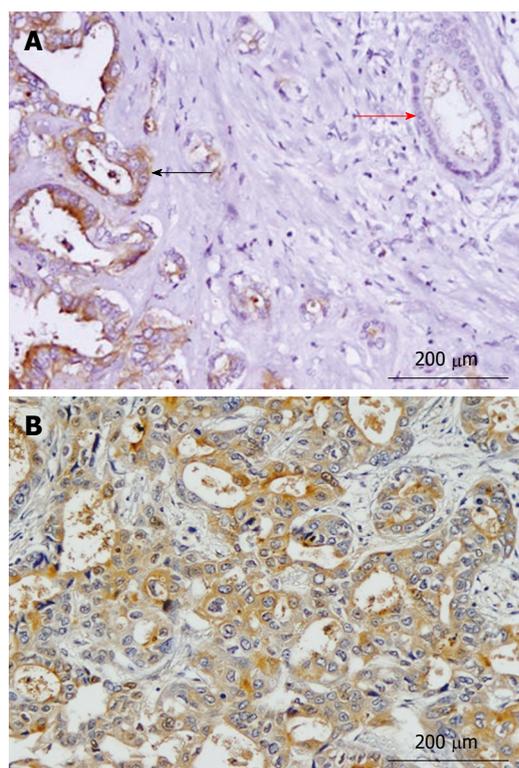

Figure 1 Representative immunohistochemical staining for CD133 in cholangiocarcinoma specimens. A: Normal bile duct cells (red arrow) demonstrated negative staining, whereas cholangiocarcinoma cells had strong cytoplasmic staining (black arrow); B: Moderately differentiated cholangiocarcinoma with overexpression of CD133. Positive staining was observed in the cytoplasm of cholangiocarcinoma cells (200 × magnification).

logical findings and the expression of CD133 was performed by means of the χ^2 test or Fisher’s exact test. The Kaplan-Meier method was used to estimate survival as a function of time, and the survival differences were analyzed by log-rank test. The Cox regression model was used for multivariate analysis of prognostic factors. The experiments in the cell proliferation and invasiveness assays were all performed in triplicate, and each result is reported as the mean with standard deviation. Data were compared using the Student *t*-test. A *P*-value < 0.05 was considered statistically significant.

RESULTS

Expression of CD133 in paraffin-embedded cholangiocarcinoma samples

Among the 34 cholangiocarcinoma specimens, 17 specimens were derived from the patients who received extended right hepatectomy, 7 specimens were derived from the patients who received left hepatectomy and 10 specimens were derived from the tissue biopsy of unresectable cholangiocarcinoma patients. Expression of CD133 was detected by immunohistochemistry in these 34 paraffin-embedded cholangiocarcinoma specimens. In non-cancerous bile duct tissues, the immunohistochemical signal for CD133 was negative. In cancerous tissues, specific CD133 signals were localized mainly in the cell membrane and cy-

toplasm of cholangiocarcinoma cells (Figure 1). We found that all cholangiocarcinoma specimens (34/34) exhibited signals indicating CD133 expression (> 5% of cell staining). Applying the criteria for intensity of immunohistochemical staining for CD133, strong expression (> 50% of cell staining) of CD133 was noted in 67.6% (23/34) of cholangiocarcinoma specimens. In addition, we demonstrated that 75% (9/12) of perihilar and 63.6% (14/22) of intrahepatic cholangiocarcinoma samples strongly expressed CD133.

When comparing clinicopathological variables, nodal metastasis (*P* = 0.009) and positive surgical margin status (*P* = 0.011) were more frequent in the CD133 strong expression group compared with the CD133 weak expression group (Table 1).

CD133 expression and patient survival

Univariate analysis revealed that the median survival time was 11 mo in patients with strong CD133 expression and 14 mo in patients with weak expression (*P* = 0.23). We also found that the median survival time in patients with a negative surgical margin was significantly better than in patients with a positive surgical margin (15 mo *vs* 8 mo, *P* = 0.009) (Figure 2). In a multivariate Cox regression analysis, only surgical margin status was indicated as an independent risk factor for survival (*P* = 0.04, Table 2).

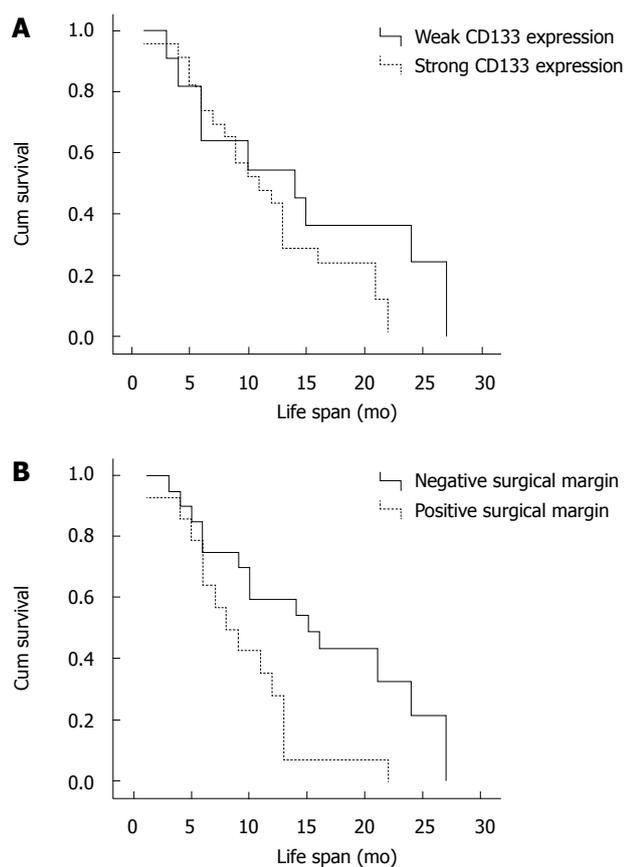

Figure 2 Kaplan-Meier cumulative overall survival curves. A: Survival curves of patients with strong and weak CD133 expression ($P = 0.23$); B: Survival curves of patients with positive and negative surgical margin status ($P = 0.009$).

Enrichment of CD133⁺ cholangiocarcinoma cells

To study the characteristics of CD133⁺ cholangiocarcinoma cells, we enriched the CD133⁺ and CD133⁻ cells from RMCCA1 cholangiocarcinoma cell lines using magnetic cell sorting technology. The percentage of CD133⁺ cells in CD133-enriched cells was 91.9%, and the percentage of CD133⁺ cells in the CD133-depleted cells was 11.2% (Figure 3A). As revealed by morphological studies, no cell morphology differences were observed between CD133⁺ and CD133⁻ RMCCA1 cells (Figure 3B).

Proliferation of CD133⁺ and CD133⁻ cholangiocarcinoma cells

Because previous reports demonstrated that CD133⁺ cells have higher proliferative potential than CD133⁻ cells^[12], we investigated the rate of cell proliferation in CD133⁺ and CD133⁻ RMCCA1 cells cultured for 3 days. The results showed that there was no statistically significant difference in cell proliferation between CD133⁺ and CD133⁻ RMCCA1 cells (Figure 4A).

Chemoresistance of CD133⁺ cholangiocarcinoma cells

Previous studies have proposed that CD133⁺ enrichment of cancer cells is a source of chemotherapy resistance^[13]. Therefore, we investigated the role of CD133 in cholangiocarcinoma cell resistance to chemotherapeutic drugs. CD133⁺ and CD133⁻ RMCCA1 cells were treated with

0-50 $\mu\text{mol/L}$ cisplatin for 2 d before cell proliferation assays were performed. The percentage of cell proliferation was set to 100% when cells were treated with vehicle (PBS). Both CD133⁺ and CD133⁻ cells displayed similar degrees of resistance to chemotherapeutic drugs. There was no statistically significant difference in cell proliferation between CD133⁺ and CD133⁻ RMCCA1 cells (Figure 4B).

Cell invasiveness of CD133⁺ cholangiocarcinoma cells

Because the expression of CD133 in cholangiocarcinoma specimens is significantly correlated with the lymph node metastatic status, we performed an *in vitro* invasion assay. When the percentage of CD133⁺ RMCCA1 cell invasion was set at 100%, the percentage of CD133⁻ RMCCA1 cell invasion was $58.3\% \pm 19.91\%$. CD133⁺ RMCCA1 cells showed significantly higher invasive ability than CD133⁻ RMCCA1 cells ($P < 0.001$, Figure 5).

DISCUSSION

In this study, we performed immunohistochemical staining to detect the expression of CD133 in cholangiocarcinoma specimens. We demonstrated that all of the cholangiocarcinoma specimens expressed CD133, and 67.6% of the cholangiocarcinoma specimens demonstrated strong expression of CD133. In addition, strong expression of CD133 was significantly associated with lymph node metastasis and surgical margin status. It is well known that lymph node metastasis and surgical margin status are the major prognostic factors for cholangiocarcinoma^[3,4]. These findings are consistent with a previous study, which demonstrated that cholangiocarcinoma that highly expressed CD133 tended to be related to higher incidences of metastasis and to worse prognoses^[14]. In this study, the multivariate Cox regression analysis demonstrated that surgical margin status is an independent prognostic predictor in our patients. Although we found that patients with high expression of CD133 had a lower median survival time than patients with low expression of CD133 in cholangiocarcinoma specimens, this did not reach the statistical difference. We suggest that this could be attributable to the small sample size of our study. A further study which includes a larger cohort of cholangiocarcinoma patients should be performed before using CD133 as a

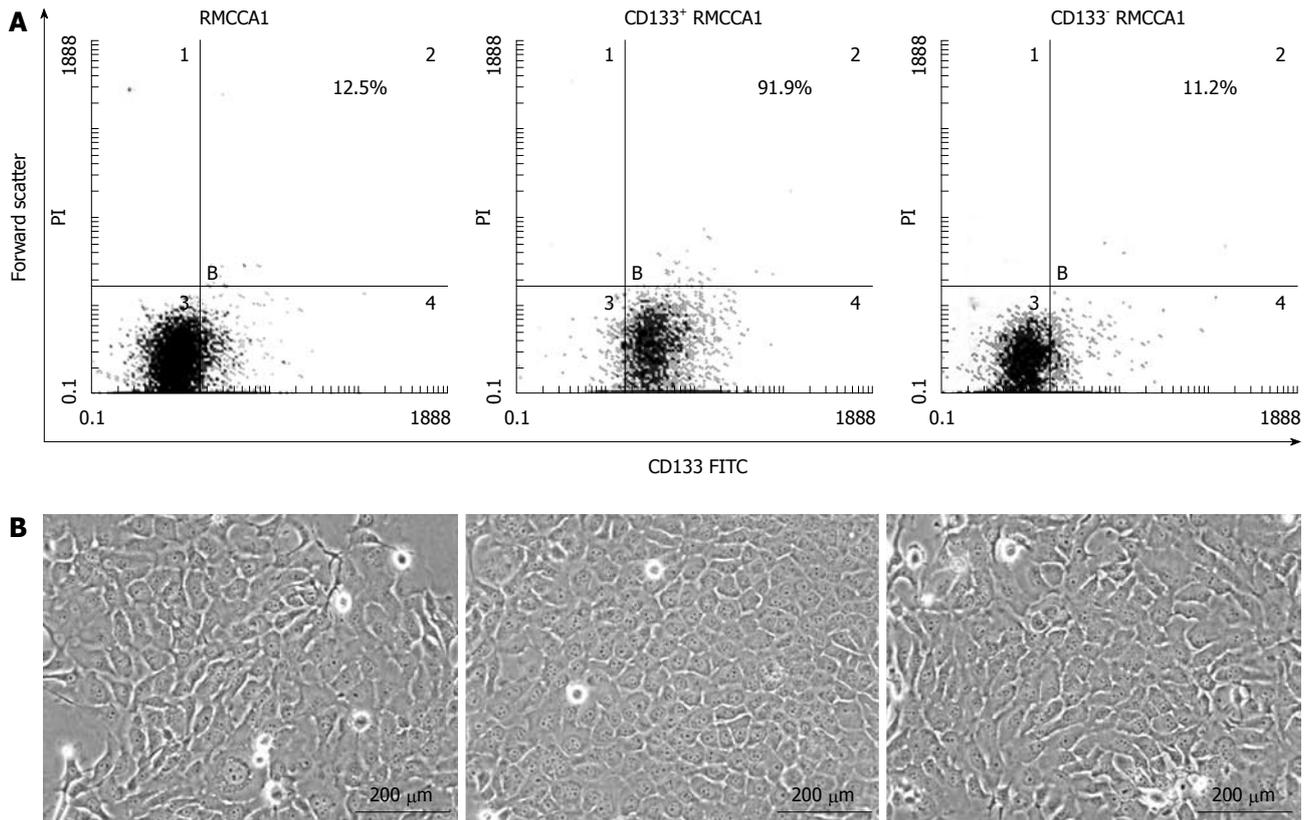

Figure 3 Isolation of CD133⁺ and CD133⁻ cholangiocarcinoma cells. A: The percentage of CD133⁺ cells in the original RMCCA1 cell populations, the flushed-out fractions (CD133⁺ RMCCA1 cells) and the flow-through (CD133⁻ RMCCA1 cells) were analyzed by fluorescence-activated cell sorting; B: The morphology of original, CD133⁺ and CD133⁻ RMCCA1 cells is demonstrated under a phase contrast microscope at 200 × magnification. FITC: Fluorescein isothiocyanate.

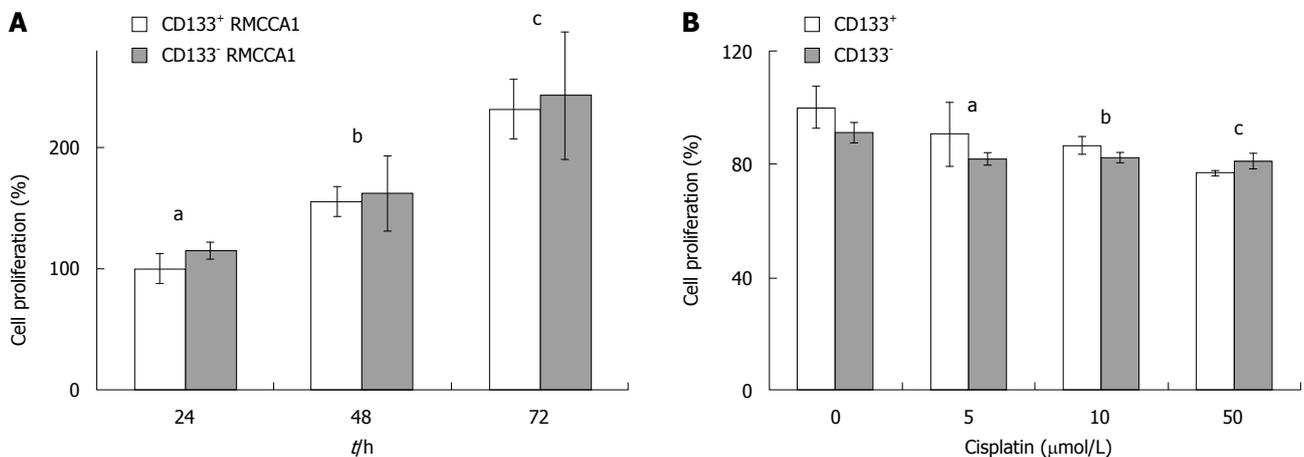

Figure 4 Cell proliferation assays of CD133⁺ and CD133⁻ RMCCA1 cells. A: The proliferation rates of CD133⁺ and CD133⁻ cholangiocarcinoma cells. CD133⁺ and CD133⁻ RMCCA1 cells were cultured for 24-72 h. A cell proliferation assay was performed using WST-1. Results are reported as a percentage of cell proliferation, where the optical density values from CD133⁺ cells cultured for 24 h are set as 100% of proliferation. Data is represented as the mean ± SD of 3 independent experiments. (^a*P* = 0.095, ^b*P* = 0.578, ^c*P* = 0.544 vs the same time of culturing); B: Effect of cisplatin on cholangiocarcinoma cells. CD133⁺ and CD133⁻ RMCCA1 cells were treated with cisplatin at various concentrations (0, 5, 10 and 50 μmol/L) for 2 d. Effects on cell proliferation were measured by WST-1. Results are reported as percentage of cell proliferation, where the optical density values from vehicle-treated cells (0 μmol/L cisplatin) are set as 100% proliferation. Data is presented as the mean ± SD of 3 independent experiments. (^a*P* = 0.060, ^b*P* = 0.056, ^c*P* = 0.053 vs the same concentration of cisplatin). WST: Water soluble tetrazolium salts.

prognostic marker for cholangiocarcinoma.

Previous studies have demonstrated that CD133⁺ cells exhibit more aggressive behavior, including increased cell proliferation^[12] and invasive abilities^[15,16]. Here, we studied the characteristics of CD133 in cholangiocarcinoma cell lines using cell proliferation and invasion assays. Our

results suggest that CD133⁺ RMCCA1 cells have higher invasive activity than CD133⁻ RMCCA1 cells. A previous study indicated that C-X-C chemokine receptor type 4 (CXCR4) is markedly expressed in CD133⁺ pancreatic cancer cells and may be responsible for the increased invasive ability of cells cocultured with pancreatic stromal

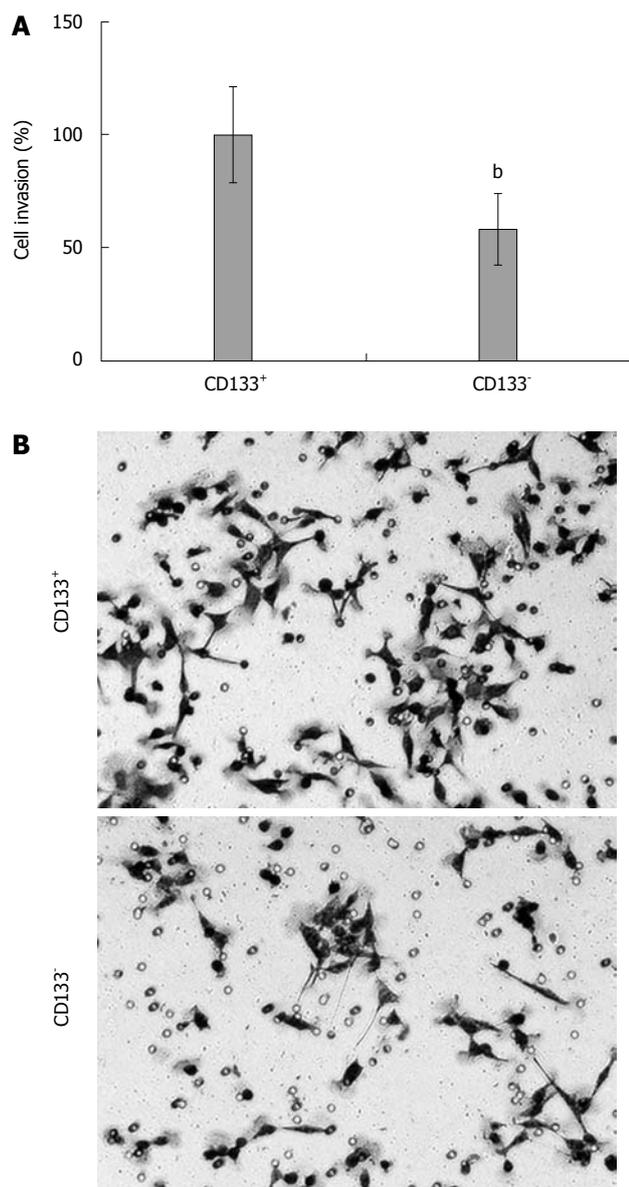

Figure 5 Invasion assays of CD133⁺ and CD133⁻ RMCCA1 cells. A: Invasion assays of CD133⁺ and CD133⁻ RMCCA1 cells were performed using the Biocoat Matrigel invasion chamber. Results are reported as the percentage of cell invasion, where the number of cell invasion from CD133⁺ RMCCA1 cells is set as 100% cell invasion. Data is represented as the mean \pm SD of three independent experiments ($^*P < 0.001$); B: The morphology of CD133⁺ and CD133⁻ RMCCA1 cell invasion is demonstrated under a phase contrast microscope at 200 \times magnification.

cells, which express stromal derived factor-1 (CXCL12), the ligand for CXCR4^[15]. Further studies focusing on the molecular mechanisms that enhance CD133⁺ cholangiocarcinoma cell invasiveness should be performed in the future.

A previous study indicated that enriched CD133⁺ lung cancer cells were resistant to cisplatin treatment^[13]. In contrast, Meng *et al*^[17] demonstrated that both CD133⁺ and CD133⁻ A549 lung cancer cells exhibited similar degrees of resistance to chemotherapeutic drugs. Our data are consistent with those of Meng *et al*^[17]: CD133⁺ and CD133⁻ cells exhibited similar cell proliferation abilities and resistance to chemotherapeutic drugs^[18]. We previous-

ly demonstrated that activation of the phosphatidylinositol 3-kinase (PI3K) pathway in cholangiocarcinoma cells protects the cells from cytotoxicity induced by platinum-based chemotherapy. In addition, we also found that there was no difference between Akt and mTOR (mammalian target of rapamycin) activation in CD133⁺ and CD133⁻ cholangiocarcinoma cells (data not shown). These results indicate that the proliferative ability and resistance to chemotherapeutic drugs in cholangiocarcinoma cells are not unique to CD133⁺ cells.

In conclusion, our findings indicate that CD133⁺ cells have higher invasive abilities than CD133⁻ cells. CD133 expression can be found in cholangiocarcinoma, and it significantly correlates with lymph node metastasis and surgical margin status. CD133 may be a potential prognostic factor of cholangiocarcinoma.

COMMENTS

Background

Cholangiocarcinoma is a malignancy arising from the biliary tract. Cholangiocarcinoma is one of the most common causes of cancer death in Thailand. A recent study suggested that expression of CD133 in cholangiocarcinoma specimens is associated with the severity of this disease.

Research frontiers

CD133⁺ cholangiocarcinoma cells have a high ability to invade through Matrigel. In addition, expression of CD133 in cholangiocarcinoma specimens is associated with cholangiocarcinoma progression.

Innovations and breakthroughs

This is believed to be the first report to show that, in cholangiocarcinoma cell lines with high CD133 expression, the neoplastic behavior is more aggressive than in CD133⁻ cells.

Applications

Strong CD133 expression was observed in 67.6% of the cholangiocarcinoma specimens and was significantly associated with nodal metastasis and positive surgical margin status. Therefore, the authors suggest that CD133⁺ cells play an important role in the invasiveness and progression of cholangiocarcinoma. Targeting of the CD133⁺ cholangiocarcinoma cells may be a useful approach to improve therapies directed against cholangiocarcinoma.

Terminology

CD133, a human homologue of a mouse prominin-1, is a 5-transmembrane cell-surface glycoprotein. It has been detected in an enrichment of hematopoietic stem cells derived from fetal liver or bone marrow neuroepithelial cells, embryonic epithelial cells and adult immature epithelial cells.

Peer review

This study provides evidence that high CD133 expression in cholangiocarcinoma cells may be used as a marker for targeted cancer therapy. This was a well performed and clearly presented study.

Abstract

AIM: To investigate the prevalence and risk factors of asymptomatic peptic ulcer disease (PUD) in a general Taiwanese population.

METHODS: From January to August 2008, consecutive asymptomatic subjects undergoing a routine health check-up were evaluated by upper gastrointestinal endoscopy. Gastroduodenal mucosal breaks were carefully assessed, and a complete medical history and demographic data were obtained from each patient. Logistic regression analysis was conducted to identify indepen-

dent risk factors for asymptomatic PUD.

RESULTS: Of the 572 asymptomatic subjects, 54 (9.4%) were diagnosed as having PUD. The prevalence of gastric ulcer, duodenal ulcer and both gastric and duodenal ulcers were 4.7%, 3.9%, and 0.9%, respectively. Multivariate analysis revealed that prior history of PUD [odds ratio (OR), 2.0, 95% CI: 1.3-2.9], high body mass index [body mass index (BMI) 25-30: OR, 1.5, 95% CI: 1.0-2.2; BMI > 30 kg/m²: OR, 3.6, 95% CI: 1.5-8.7] and current smoker (OR, 2.6, 95% CI: 1.6-4.4) were independent predictors of asymptomatic PUD. In contrast, high education level was a negative predictor of PUD (years of education 10-12: OR, 0.5, 95% CI: 0.3-0.8; years of education > 12: OR, 0.6, 95% CI: 0.3-0.9).

CONCLUSION: The prevalence of PUD in asymptomatic subjects is 9.4% in Taiwan. Prior history of PUD, low education level, a high BMI and current smoker are independent risk factors for developing asymptomatic PUD.

Wang FW, Tu MS, Mar GY, Chuang HY, Yu HC, Cheng LC, Hsu PI. Prevalence and risk factors of asymptomatic peptic ulcer disease in Taiwan. *World J Gastroenterol* 2011; 17(9): 1199-1203 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1199.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1199>

INTRODUCTION

Peptic ulcer disease (PUD) is a common disease of the

digestive system^[1]. The self-reported PUD prevalence among people aged 18 years and older in the United States was 10.3% in 1989^[2], compared with 14% among people aged 20 to 81 years in Hong Kong^[3].

The pathogenesis of symptom development in PUD is unclear. A few studies have revealed that several factors, such as acid, inflammation, or muscle spasm, may be related to the pathogenesis of ulcer pain^[4,5]. A study in Taiwan revealed that 67% of PUD patients had no remarkable symptoms^[6]. Some patients with PUD are asymptomatic until life-threatening complications (e.g. hemorrhage, perforation) develop^[7]. Previous studies found that the majority of patients who died from PUD usually had no ulcer symptoms until the final fatal illness^[8]. Therefore, non-symptom producing ulcers remain a clinical challenge.

Currently, the long-term consequences of silent PUD remain unclear, however, hemorrhage, perforation, and stricture are well known complications of PUD^[9,10]. Therefore, identification and follow up of these asymptomatic patients is essential. Nonetheless, the risk factors for asymptomatic PUD still remain unclear. The aims of this study were to investigate the prevalence and risk factors of asymptomatic PUD in Taiwan.

MATERIALS AND METHODS

Subjects

From January to August 2008, consecutive asymptomatic subjects undergoing a routine endoscopy during a health check-up were invited to participate in this study. The eligible subjects were free of reflux and dyspeptic symptoms such as heartburn, regurgitation, dysphagia, epigastric pain, epigastric fullness, nausea and vomiting in the previous month. Exclusion criteria were (1) use of proton pump inhibitors, histamine-2 receptor antagonists, sucralfate, prostaglandin analogs and antacids within the previous month; (2) use of prokinetic or anticholinergic agents; and (3) serious medical illness.

Study design

A complete history and physical examination were performed for every subject undergoing a health check-up. All subjects were carefully interviewed regarding the presence of reflux or dyspeptic symptoms in the previous month, and subjects who responded negatively were classified as asymptomatic subjects and enrolled in this study. Endoscopies were performed by three experienced endoscopists (Hsu PI, Cheng LC, and Yu HC) using an Olympus GIF XV10 and GIF XQ200 (Olympus Corp., Tokyo, Japan) after the subjects had fasted overnight. The endoscopists were blinded as to whether the patients they were examining were symptomatic or asymptomatic. The patients were carefully examined for gastroduodenal mucosal breaks, and the length of these breaks was measured by opening a pair of biopsy forceps of known span in front of the breaks. Peptic ulcer disease was defined as a circumscribed mucosal break 5 mm or more in diameter, with a well defined ulcer crater^[11].

To assess the relationships between clinical charac-

teristics and asymptomatic PUD, the following data were recorded for each subject: age; gender; educational status; prior history of PUD; consumption of tobacco, alcohol, coffee, tea, spicy foods or betel nut, and use of non-steroidal anti-inflammatory drugs (NSAIDs) within 4 wk of endoscopy. All variables were categorized for data analyses.

Statistical analysis

The χ^2 test or Fisher's exact test was employed to investigate the relationships between the rate of PUD and clinical characteristics. These variables included the following: gender; age (< 45, 45-60, or > 60 years); educational status (< 10, 10-12, or > 12 years); body mass index [body mass index (BMI): < 25, 25-30, or > 30 kg/m²]; NSAID use (yes or no); history of PUD (yes or no); smoking status (no, former smoker, current smoker); consumption of alcohol, coffee, tea or spicy foods (no, \leq 3 times per week, or > 3 times per week); betel nut habit (yes or no). A *P* value less than 0.05 was considered significant. Significant variables revealed by univariate analysis were subsequently assessed by a stepwise logistic regression method to identify independent clinical factors predicting the presence of PUD in asymptomatic subjects.

RESULTS

Patient demographics and endoscopic characteristics

From January to August 2008, 572 asymptomatic subjects (mean age, 51.5 ± 12.9 years; age range, 18-87 years; male/female, 372/200) were recruited into this study. Of these patients, 54 (9.4%) had PUD (Table 1). The cases of PUD consisted of 27 gastric ulcer (4.7%), 22 duodenal ulcer (3.9%) and 5 had both gastric ulcer and duodenal ulcer (0.9%).

Comparison of socio-demographic and lifestyle factors in subjects with and without peptic ulcer disease

istics and the presence of PUD. The subjects with PUD were less educated than those without ulcer. Additionally, male gender, prior history of PUD, current smoker, and betel nut chewing were significantly higher in the PUD group than in the non-PUD group ($P < 0.001$, < 0.005 , < 0.001 , 0.016 , respectively). Furthermore, the PUD group had higher BMI than the non-PUD group. However, the two groups had similar age, alcohol, coffee, tea, and spicy food consumption and NSAID use.

Independent factors influencing the presence of peptic ulcer disease in asymptomatic subjects

OR: Odds ratio; BMI: Body mass index, indicating weight in kg divided by body surface area. ¹Analysis for sex, education level, BMI, peptic ulcer history, smoking and betel nut consumption; CI: Confidence interval.

showed that history of PUD [odds ratio (OR), 1.99; 95% CI: 1.34-2.93], low education level (years of education 10-12: OR, 0.49; 95% CI: 0.31-0.80; years of education > 12: OR, 0.57; 95% CI: 0.34-0.96), high BMI (BMI 25-30 kg/m²: OR, 1.49; 95% CI: 1.01-2.23; BMI > 30 kg/m²: OR, 3.64; 95% CI: 1.53-8.68) and current smoker (OR, 2.61; 95% CI: 1.56-4.38) were independent factors predicting the development of PUD (Table 3).

DISCUSSION

The clinical presentation of peptic ulcer patients is variable. Some patients with PUD are asymptomatic until life-threatening complications develop. This study demonstrated that the prevalence of asymptomatic PUD in Taiwan was 9.4%. Further analysis showed that prior history of PUD, high BMI, low education level and current smoker were independent predictors for developing asymptomatic PUD.

This study revealed a strong positive association between BMI and asymptomatic PUD. These associations remained robust even after adjusting for several important potential factors, including age, gender and lifestyle. Furthermore, a significant dose-response relationship between BMI and PUD was noted. The odds ratio of BMI 25-30 kg/m² (overweight) and BMI > 30 kg/m² (obesity) were 1.5 and 3.6, respectively. Previous studies indicated that higher BMI, considered as overweight or obese, revealed associations with more severe symptoms of reflux esophagitis^[12,13] and PPI treatment response to achieve sustained symptomatic response in reflux esophagitis^[14]. Little data exist on the association between obesity and PUD. The mechanism by which obesity increases the risk of asymptomatic PUD is unknown. Possible explanations include the increased intra-abdominal pressure and higher acid secretion rates in obese subjects^[15]. Wisén *et al* reported that obese (nondiabetic) patients were found to have higher gastric acid secretion than non-obese patients using the gastric acid secretion test after modified sham feeding^[16]. Moreover, obese subjects appear to be more sensitive to acid in the upper gastrointestinal tract than non-obese subjects^[17]. In addition, studies have demonstrated that obese rats and humans have higher "somatic" pain thresholds because obese patients have a higher plasma

level of endorphins^[18,19].

The present study also demonstrated that subjects with low education level have a higher risk of asymptomatic PUD. It has been well documented that PUD is associated with low socioeconomic status^[20]. That association may be explained by a higher risk of *Helicobacter pylori* (*H. pylori*) infection among less educated groups, probably due to poor standards of hygiene^[21]. Psychological stress, risk lifestyle behaviors, and hard physical work may be other important risk factors for PUD in low education populations^[22].

NSAIDs are known to be associated with gastrointestinal injury, including erosions, ulceration and hemorrhage. During long-term administration, 60%-94% of NSAIDs users have been reported to show mucosal damage and 15%-31% to have evidence of frank gastric ulcer^[23,24]. In this study, NSAID use was not identified as a risk factor for the development of asymptomatic peptic ulcer. The reasons for the lack of association between NSAIDs and asymptomatic peptic ulcer could be due to short-term use of NSAIDs in our patients, the use of selective cyclooxygenase-2 inhibitors in some subjects or a small number of cases (type II error).

Certain lifestyle factors such as consumption of tobacco, alcohol, tea, coffee, betel nut and spicy foods are believed to stimulate gastric acid secretion, however, the findings of previous cross-sectional epidemiological studies have been inconsistent^[25,26]. The current cross-sectional study revealed that only current smoking independently predicted the development of PUD in asymptomatic subjects. A Japanese study of men aged 45 years and older revealed that current smokers were at higher risk of both gastric (OR, 3.4, 95% CI: 2.4- 4.7) and duodenal ulcers (OR, 3.0, 95% CI: 1.9- 4.7), compared with nonsmokers^[27]. However, another study failed to confirm these findings for PUD risk in smokers compared with nonsmokers^[28]. Recent studies have suggested that tobacco smoking causes peptic ulcer only if *H. pylori* infection is present^[29]. A prospective cohort study in Denmark showed that tobacco smoking remained an independent risk factor for PUD despite controlling for *H. pylori* infection status^[30]. Hence, we believe that ulcer patients should be advised to cease smoking. In this study, the specific aim was to investigate the prevalence and risk factors of asymptomatic PUD in Taiwan. It is necessary to further examine the risk factors for peptic ulcer in symptomatic subjects and to investigate the differences in risk factors for PUD between symptomatic and asymptomatic subjects in the future.

Despite its contributions, this study had certain limitations. First, self-selection bias of the population in this trial was possible, because all enrolled subjects had undergone self-paid health examinations and likely had a better economic status than the general population. Second, the studied subjects may differ from subjects in a primary care hospital because our hospital is a tertiary care center. Third, the status of *H. pylori* infection was not routinely examined. Its prevalence might differ between the non-peptic ulcer group and the peptic ulcer group. Nevertheless, most asymptomatic subjects had not received an ex-

amination for *H. pylori* infection before their routine upper gastrointestinal endoscopy and did not know their *H. pylori* status. The major aim of this study was to identify the clinical factors predicting peptic ulcer development prior to endoscopic examination. The findings may be useful for identifying asymptomatic subjects at high risk for the development of peptic ulcer.

In conclusion, the prevalence of PUD in asymptomatic subjects is 9.4% in Taiwan. Prior history of PUD, low education level, a high BMI and current smoker are independent risk factors for developing asymptomatic peptic ulcer.

The authors appreciate colleagues in the Kaohsiung Medical University Hospital and Kaohsiung Veterans General Hospital. We also appreciate the cooperation of the subjects undergoing a health checkup. The authors declare they have no competing financial interest.

COMMENTS

Background

Peptic ulcer disease (PUD) is a common disease of the digestive system and the pathogenesis of symptom development in PUD is unclear. Some patients with PUD are asymptomatic until life-threatening complications (e.g. hemorrhage, perforation) develop. The aims of this study were to investigate the prevalence and risk factors of asymptomatic PUD in Taiwan.

Research frontiers

Currently, the long-term consequences of silent PUD remain unclear, however, hemorrhage, perforation, and stricture are well known complications of PUD. Therefore, identification and follow up of these asymptomatic patients is essential. Nonetheless, the risk factors for asymptomatic PUD still remain unclear.

Innovations and breakthroughs

Helicobacter pylori (*H. pylori*) infection, smoking and non-steroidal anti-inflammatory drugs use are known risk factors of symptomatic PUD but few studies to date have reported the risk factors for asymptomatic PUD. In this study, the authors observed that prior history of PUD, low education level, a high body mass index and current smoker are independent risk factors for developing asymptomatic PUD.

Applications

The status of *H. pylori* infection was not routinely examined and the prevalence of *H. pylori* status might differ between the non-peptic ulcer group and the peptic ulcer group. Nevertheless, the major aim of this study was to identify the clinical factors predicting peptic ulcer development prior to endoscopic examination, and most of the asymptomatic subjects did not receive any tests for *H. pylori* infection.

Terminology

PUD was defined as a circumscribed mucosal break 5 mm or more in diameter, with a well defined ulcer crater. All subjects were carefully interviewed regarding the presence of reflux or dyspeptic symptoms in the previous month, and subjects who responded negatively were classified as asymptomatic subjects and enrolled in this study.

Peer review

The study was well performed and very interesting. However, it contains some serious problems which have to be answered by the authors. The reviewer considered that the comparisons should be also required between the asymptomatic peptic ulcer disease group and the symptomatic peptic ulcer disease group to investigate risk factors of asymptomatic peptic ulcer disease.

Abstract

AIM: To quantitatively assess the relationship between coffee consumption and incidence of pancreatic cancer in a meta-analysis of cohort studies.

METHODS: We searched MEDLINE, EMBASE, Science Citation Index Expanded and bibliographies of retrieved articles. Studies were included if they reported relative risks (RRs) and corresponding 95% CIs of pancreatic cancer with respect to frequency of coffee intake. We performed random-effects meta-analyses and meta-regressions of study-specific incremental estimates to determine the risk of pancreatic cancer associated with a 1 cup/d increment in coffee consumption.

RESULTS: Fourteen studies met the inclusion criteria, which included 671080 individuals (1496 cancer events) with an average follow-up of 14.9 years. Compared with individuals who did not drink or seldom drank coffee per day, the pooled RR of pancreatic cancer was 0.82 (95% CI: 0.69-0.95) for regular coffee drinkers, 0.86 (0.76-0.96) for low to moderate coffee drinkers, and 0.68 (0.51-0.84) for high drinkers. In subgroup analyses, we noted that, coffee drinking was associated with

a reduced risk of pancreatic cancer in men, while this association was not seen in women. These associations were also similar in studies from North America, Europe, and the Asia-Pacific region.

CONCLUSION: Findings from this meta-analysis suggest that there is an inverse relationship between coffee drinking and risk of pancreatic cancer.

INTRODUCTION

Coffee is one of the most widely consumed beverages in the world, with a yearly world average consumption of 1.1 kg per capita, which reaches 4.5 kg in industrialized countries^[1]. More recently, coffee consumption has been associated with a reduction in the risk of several chronic diseases, including type 2 diabetes mellitus, Parkinson's disease and liver disease^[2-4]. Of these associations, the relationship between coffee drinking and cancer risk is of great interest.

Coffee consumption may exert an anticarcinogenic effect in some organs. For example, a reduction in cholesterol, bile acid, and neutral sterol secretion in the colon is a

direct effect of coffee consumption as is increased colonic motility, which can reduce exposure of epithelium to carcinogens^[5]. The components of coffee which have received attention are caffeine (a purine alkaloid), cafestol (a diterpene), kahweol (another diterpene), and chlorogenic acid (a dietary phenol). Cafestol and kahweol, which are active ingredients in the coffee oil, decrease mutagenesis and tumorigenesis in animal models. Diterpenes, found in coffee, reduce genotoxicity of carcinogens and lower DNA adduct formation. Caffeic acid and chlorogenic acid are antioxidants and have been reported to decrease DNA methylation^[6]. More subtly, caffeine itself appears to be protective-affecting cell cycle, proliferation, and apoptosis^[7,8].

Pancreatic cancer is one of the most aggressive and treatment-refractory malignancies in humans. Given that there is no screening test for the early detection of this cancer and no effective treatment to prolong survival time, primary prevention appears to be the most important way of reducing pancreatic cancer mortality. Over the last 4 decades, a number of epidemiologic studies have estimated the association between coffee consumption and pancreatic cancer occurrence. However, the results of these studies were inconsistent. Data from case-control studies may be subject to recall bias with respect to coffee consumption and selection bias with respect to the control group. Additional prospective cohort studies excluding those biases would be more useful for assessing coffee-cancer associations. We, therefore, systematically reviewed and performed a meta-analysis of prospective cohort studies to quantitatively assess the association between coffee intake and pancreatic cancer risk in humans. Because of the high consumption of coffee, even small effects on pancreatic cancer occurrence could have a large impact on public health.

MATERIALS AND METHODS

Literature search

We searched the electronic databases MEDLINE (1966 to August 2010), EMBASE (1985 to August 2010), and Science Citation Index Expanded (1945 to August 2010), using the Medical Subject Heading (MeSH) term coffee combined with pancreatic cancer or pancreatic neoplasm or pancreatic carcinoma. Furthermore, we reviewed reference lists of retrieved articles to search for more studies. Articles published in any language were included.

Inclusion and exclusion criteria

For inclusion, studies had to fulfill the following criteria: have a prospective cohort design; report relative risks (RRs) or hazard ratios and their corresponding 95% CIs (or data to calculate them) of pancreatic cancer relating to every category of coffee intake; and provide the frequency of coffee consumption. Studies were excluded if: case-control design was used; mixed beverage was reported, in which the effect of coffee could not be separated; only surrogate nutrients of coffee were reported; no categories of coffee intake were reported that could not allow for adequate

classification of intake. If multiple published reports from the same study cohort were available, we included only the one with the most detailed information for both outcome and coffee consumption.

Data extraction

Data were extracted independently by two investigators (Yu and Dong) according to the meta-analysis of observation studies in epidemiology guidelines^[9], and discrepancies were resolved by discussion with a third investigator (Zou). For each study, the following information was extracted: first author's last name; year of publication; country of origin; follow-up period; number of subjects and cases; age at baseline; category amounts of coffee intake; outcome assessment; RRs or hazard ratios of pancreatic cancer and corresponding 95% CIs for every category of coffee intake; and covariates adjusted in the statistical analysis.

Statistical analysis

The measures of interest were the RR and the corresponding 95% CIs for included cohort studies. When RRs were not available in the published article, they were computed from the exposure distributions. Because various studies used different measurement units for coffee consumption, we converted these into cups per day as a standard measure. If coffee consumption was indicated by milliliter, we assumed 125 mL as approximately equivalent to 1 cup.

We computed the summary RR for coffee drinkers *vs* nondrinkers and for different levels of consumption by giving each study-specific RR a weight that was proportional to its precision (i.e. the inverse of the variance derived, when necessary, from the reported 95% CIs). To estimate the summary RR for various levels of coffee consumption, we first calculated the study-specific estimate separately for low to moderate consumption and high consumption.

Statistical heterogeneity among studies was estimated using Q and I^2 statistics. For the Q statistic, heterogeneity was considered present when $P < 0.1$. We pooled the study-specific estimates using both the fixed effect model and the random effect model proposed by DerSimonian and Laird; when a significant heterogeneity was found, the random effect model results were presented. A sensitivity analysis was also conducted, in which one study at a time was removed and the rest analyzed to estimate whether the results could have been affected markedly by a single study.

For dose-response analysis, we used the method proposed by Greenland *et al.*^[10] to estimate study-specific slopes from the correlated natural logarithm of the RR across categories of coffee consumption, assigning to each class the dose corresponding to the midpoint of upper and lower boundaries. The highest, open-ended category was assumed to have the same amplitude of consumption as the preceding category^[11]. Then the summary RR for pancreatic cancer risk with a 1 cup/d increment in

coffee consumption was obtained by pooling the study-specific slopes, using the inverse of the corresponding variances as weights.

Finally, publication bias was evaluated through funnel plot visual analysis and with the Begg's and Egger's tests. $P < 0.05$ was considered statistically significant. All statistical analyses were performed with STATA (version 9.0; Stata Co., College Station, TX, USA).

RESULTS

Using the predefined search strategy, we identified 14 prospective cohort studies (Figure 1), including 671 080 participants and 1496 incident cases of pancreatic cancer with an average follow-up of 14.9 years, which were eligible for inclusion in the meta-analysis^[12-25]. The characteristics of the included studies are summarized in Table 1. Initial agreement between the two reviewers on whether a study was eligible for inclusion occurred in 48/50 manuscripts (96%; $\kappa = 0.92$). Of the 14 cohorts included in the meta-analysis, 4 were conducted in Europe (Norway, Sweden and Finland), 6 in North America (the United States), and 4 in Asia (Japan).

Figure 2A shows the estimated RRs for coffee drinkers *vs* non/lowest drinkers from the cohort studies. The summary RR of pancreatic cancer from all combined studies was 0.82 (95% CI: 0.69-0.95). There was significant heterogeneity across the studies ($Q = 21.88$, $P = 0.057$, $I^2 = 40.6\%$). Figure 2B and C give the RRs according to low to moderate and high coffee consumption from various studies. The summary RR was 0.86 (95% CI: 0.76-0.96) for low to moderate coffee consumption, with no heterogeneity between studies ($Q = 16.12$, $P = 0.186$, $I^2 = 25.6\%$). The summary RR for high consumption of coffee was 0.68 (95% CI: 0.51-0.84), also with no heterogeneity between studies ($Q = 7.82$, $P = 0.729$, $I^2 = 0\%$). The summary RR for an increment of 1 cup of coffee per day was 0.96 (95% CI: 0.90-1.02) for all studies combined, but was statistically insignificant.

Various sources of heterogeneity likely exist due to international differences in coffee consumption (e.g. coffee type, serving size, or brewing method) in this analysis. To examine the magnitude of the combined RR in each stratum and its respective test of heterogeneity, we conducted subgroup analyses by gender and geographic regions. The summary RR was 0.73 (95% CI: 0.63-0.84) for men and 0.82 (95% CI: 0.52-1.11) for women when combining all studies. There was no heterogeneity for men ($Q = 9.01$, $P = 0.252$, $I^2 = 22.3\%$) and a significant heterogeneity for women ($Q = 12.42$, $P = 0.029$, $I^2 = 59.7\%$).

Associations were also similar in studies from North America, Europe and the Asia-Pacific region. The RR was 0.81 (95% CI: 0.67-0.95) when considering the 6 studies conducted in North America, 0.86 (95% CI: 0.50-1.22) for the 4 studies from Europe, and 0.76 (95% CI: 0.52-0.99) for the 4 Asian studies. No significant differences by sex were found.

There was no indication of publication bias from either

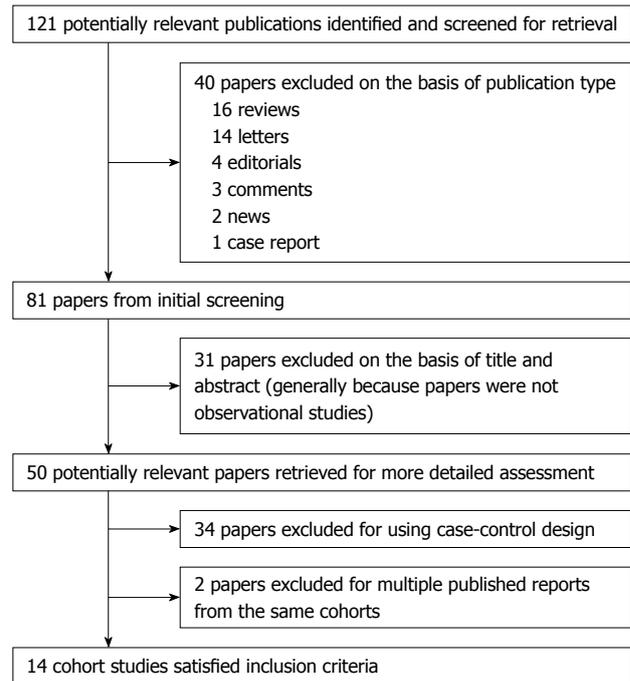

Figure 1 Flow diagram of search strategy and study selection.

visualization of the funnel plot or Egger's ($P = 0.735$) and Begg's ($P = 0.381$) (Figure 3) tests. A sensitivity analysis, in which one study was removed at a time, was performed to evaluate the stability of the results. This analysis confirmed the stability of our results.

DISCUSSION

Coffee consumption, as a major and frequent dietary exposure in diverse cultures around the globe, has been shown to be associated with pancreatic cancer in epidemiological studies. However, there is no comprehensive, up-to-date overview of the entirety of the substantial body of epidemiologic evidence. To address this need, we quantitatively assessed the relationship between coffee intake and incidence of pancreatic cancer in a meta-analysis of cohort studies.

Coffee can potentially impact the etiology of cancer of various sites along multiple pathways, ranging from carcinogenesis to cellular apoptosis. A number of *in vitro* studies suggest that caffeine can influence carcinogenesis through inhibition of DNA repair, and induction of mitotic events before DNA replication is completed^[26-28]. Porta *et al*^[29] argues that in exocrine pancreatic cancer, caffeine, other coffee compounds, or other correlates of coffee drinking could modulate Ki-ras activation by interfering with DNA repair, cell-cycle checkpoints, and apoptosis. However, for most cancer sites, there is a significant amount of evidence to show that there is no detrimental effect following the consumption of up to 6 cups of coffee per day in relation to cancer occurrence. Through the meta-analysis of cohort studies, we found that compared with individuals who did not drink or seldom drank

Table 1 Summary characteristics of studies included in the meta-analysis

| Study | Country | Follow-up period | Study subjects | No. of cases | Coffee consumption | Relative risk (95% CI) | Adjustments |
|--|---------------|------------------------|--|-----------------------|---|--|--|
| Snowdon <i>et al</i> ^[12] 1984 | United States | 1960-1980 | 23912 Aged ≥ 30 yr | 71 | < 1 cup/d 1 cup/d ≥ 2 cups/d | 1.00 (reference) 1.7 (0.9-3.3) 0.8 (0.4-1.6) | Age, sex |

coffee per day, the pooled RR of pancreatic cancer was 0.82 (95% CI: 0.69-0.95) for regular coffee drinkers, 0.86

(0.76-0.96) for low to moderate coffee drinkers, and 0.68 (0.51-0.84) for high drinkers. Overall, an increase in con-

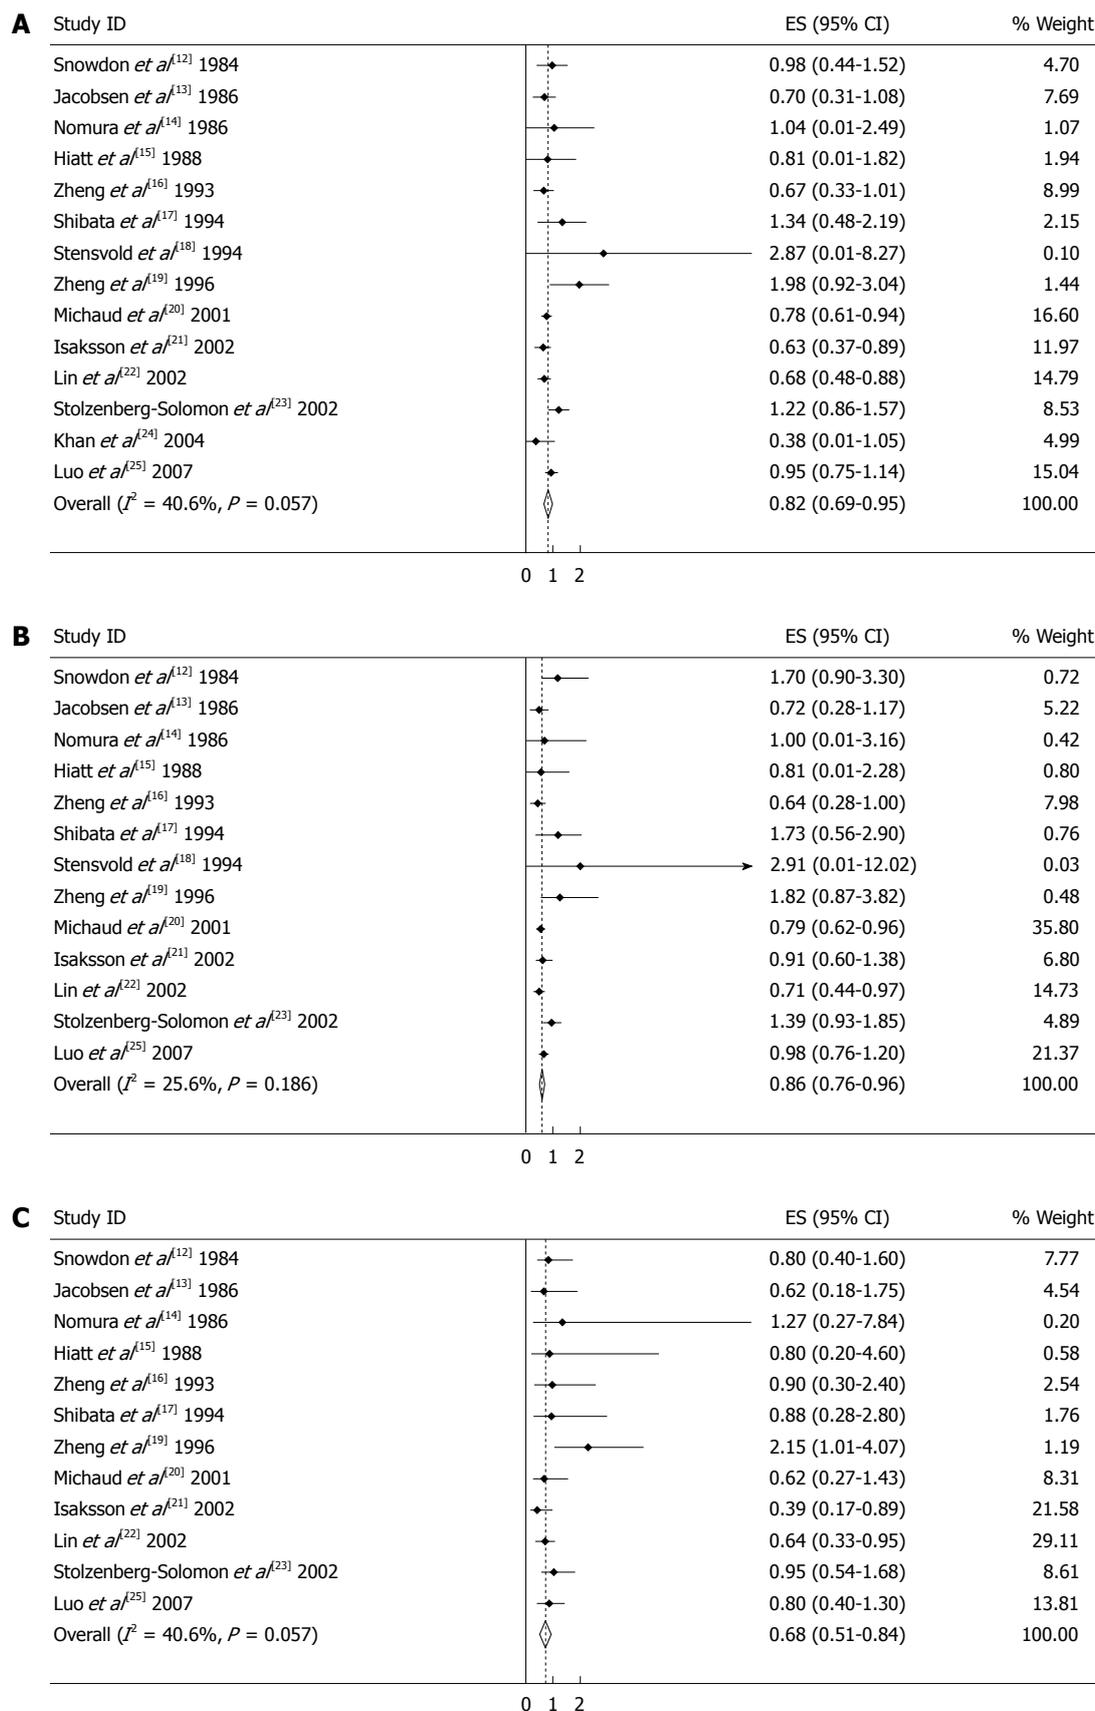

Figure 2 Summary relative risks of pancreatic cancer for coffee drinkers vs non/lowest drinkers from included studies (A), low to moderate coffee drinkers vs non/lowest drinkers from included studies (B) and high coffee drinkers vs non/lowest drinkers from included studies (C). Weights are from random effect analysis. Squares represent study-specific relative risk estimates (size of the square reflects the study-specific statistical weight, that is, the inverse of the variance); horizontal lines represent 95% CIs; diamonds represent summary relative risk estimates with corresponding 95% CIs.

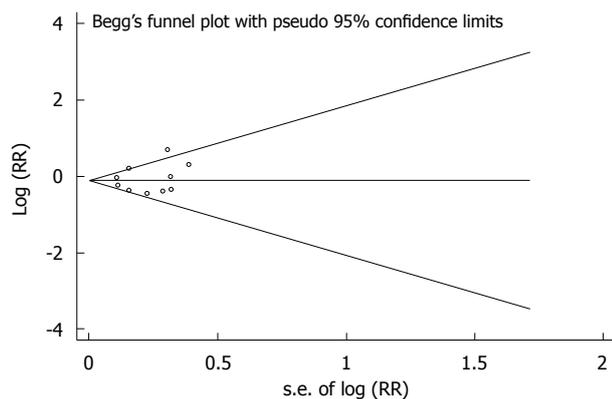

Figure 3 Publication bias in the studies. Begg's funnel plot indicating no publication bias in the studies included in this meta-analysis. No indication of publication bias was noted from both visualization of funnel plot and Egger's test. RR: Relative risk.

sumption of 1 cup of coffee per day was associated with a 4% reduced risk of pancreatic cancer (RR, 0.96; 95% CI: 0.90-1.02). Thus, the evidence presented above suggests that coffee intake might prevent pancreatic cancer occurrence in humans.

Over the past two decades, many studies have been carried out on coffee and pancreatic cancer following the early warning in the early 1980s that coffee consumption was related to pancreatic cancer risk. Some ecological^[30], case-control^[31], and cohort^[20,22] studies carried out in the USA, Canada, Europe and Asia investigated the relationship between coffee consumption and the risk of pancreatic cancer. In general, these investigations yielded inconsistent results, with a meta-analysis on 25 case-control studies giving a summary effect estimate of 1.04 (95% CI: 1.00-1.07) and a summary RR of 1.00 (0.94-1.07) per 1 cup/d for 10 cohort studies^[5]. Since the WCRF report, Luo *et al.*^[25] studied the association between drinking coffee and the risk of pancreatic cancer in a large population-based cohort study in Japan. Among 102137 participants followed for an average of 11 years in which 233 incident cases of pancreatic cancer were identified, there was no increased risk of pancreatic cancer with coffee intake. A reduced risk was apparent among men who drank at least 3 cups of coffee per day compared with those who did not drink any or only rarely drank coffee. After a pooled analysis of 14 cohort studies, we found that there was a reverse association between coffee consumption and the risk of pancreatic cancer.

Some limitations of this meta-analysis should be acknowledged. First, as in all observational studies of diet and disease, the possibility of bias and confounding can not be excluded. However, cohort studies, which are less susceptible to bias because of the prospective design, also showed an inverse association between coffee consumption and risk of pancreatic cancer, suggesting that the finding is not likely attributable to recall and selection bias. Individual studies may have failed to adjust for potential known or unknown confounders. Second, our results are likely to be affected by the misclassification of

coffee consumption. Coffee exposure is mostly assessed in relation to the number of cups of coffee consumed daily, weekly or monthly. However, most of the studies included in our meta-analysis did not provide information on coffee type, serving size, or brewing method. Serving sizes and brewing methods for coffee can vary substantially within and between countries. Standard coffee cups are larger in the United States than in Europe or Japan, and the difference in the strength of the coffee brewed may compensate for the different serving size between countries^[32]. Third, we extracted the risk estimates that reflected the greatest degree of the control potential confounders, because it was hard to obtain raw data from each study to conduct standardized adjustments. Therefore, it is probable that the results based on the adjustment for different confounders were different from those based on standardized adjustments. Finally, only published studies were included in our meta-analysis. Therefore, publication bias may have occurred although no publication bias was indicated from both visualization of the funnel plot and Egger's test.

In summary, there is substantial evidence from both laboratory and animal studies on the favorable influence of coffee on the risk of pancreatic cancer. Although well designed studies, in particular randomized clinical studies among high risk populations, are needed to provide valuable insights into coffee consumption and the risk of pancreatic cancer, our meta-analysis which included 14 prospective cohort studies confirmed that coffee consumption is inversely associated with the risk of pancreatic cancer.

ACKNOWLEDGMENTS

We thank the authors who kindly provided the data necessary for our meta-analysis.

COMMENTS

Background

Coffee consumption, as a major and frequent dietary exposure in diverse cultures around the globe, has been shown to be associated with pancreatic cancer in epidemiological studies. However, there is no comprehensive, up-to-date overview of the entirety of the substantial body of epidemiologic evidence.

Research frontiers

Over the past two decades, many studies have been carried out on coffee and pancreatic cancer. Some ecological, case-control, and cohort studies carried out in the USA, Canada, Europe and Asia investigated the relationship between coffee consumption and the risk of pancreatic cancer. However, these investigations yielded inconsistent results, with a meta-analysis on 25 case-control studies giving a summary effect estimate of 1.04 and a summary relative risk (RR) of 1.00 per 1 cup/d for 10 cohort studies.

Innovations and breakthroughs

Findings from this meta-analysis suggested that, compared with individuals who did not drink or seldom drank coffee per day, the pooled RR of pancreatic cancer was 0.82 for regular coffee drinkers, 0.86 for low to moderate coffee drinkers, and 0.68 for high drinkers. Coffee drinking was associated with a reduced risk of pancreatic cancer for men, while this association was not seen in women.

Applications

Coffee consumption may reduce pancreatic cancer incidence and it has a

consistent preventive effect on some type of cancers. These epidemiological observations should provide information for the exploration of biological mechanisms involved in the inverse relationship between coffee drinking and risk of pancreatic cancer.

Terminology

Roasted coffee is a complex mixture of more than one thousand chemicals. Many of these constituents could potentially alter cancer risk through several biological mechanisms. The anticarcinogenic components in coffee which have received attention are caffeine, cafestol, kahweol, polyphenols, caffeic acid and chlorogenic acid.

Peer review

Dr. Dong *et al* showed that coffee consumption may reduce the pancreatic cancer incidence, using meta-analysis. The results are very interesting.

Abstract

AIM: To evaluate the association between p53 codon 72 polymorphism and liver cancer risk by means of meta-analysis.

METHODS: Two investigators independently searched the Medline, Embase and Chinese Biomedicine databases. Summary odds ratios and 95% CI for p53 codon 72 polymorphism and liver cancer were calculated in fixed-effects model (Mantel-Haenszel method) and random-effects model (DerSimonian and Laird method) when appropriate.

RESULTS: This meta-analysis included 1115 liver cancer cases and 1778 controls. The combined results based on all studies showed that there was a statistically significant link between Pro/Pro genotype and liver cancer, but not between Arg/Arg or Pro/Arg genotype and liver cancer. When stratifying for race, similar results were obtained, i.e. patients with liver cancer had a significantly higher frequency of Pro/Pro genotype than non-cancer patients among Asians. After stratifying the

various studies by control source, gender, family history of liver cancer and chronic hepatitis virus infection, we found that (1) patients among hospital-based studies had a significantly higher frequency of Pro/Pro and a significantly lower frequency of Arg/Arg genotype than individuals without cancer; (2) female patients with liver cancer had a significantly lower frequency of Arg/Arg and a higher frequency of Pro/Arg+Pro/Pro genotypes than female individuals without cancer; (3) subgroup analyses for family history of liver cancer did not reveal any significant association between p53 codon 72 polymorphism and liver cancer development; and (4) patients with negative hepatitis virus infection had a significantly higher frequency of Pro/Pro and a significantly lower frequency of Arg/Arg genotype than individuals without cancer.

CONCLUSION: This meta-analysis suggests that the p53 codon 72 polymorphism may be associated with liver cancer among Asians.

INTRODUCTION

Primary liver cancer is the sixth most common cancer in

the world and the third most common cause of cancer mortality^[1]. A 2005 analysis of the worldwide incidence of and mortality from cancer showed that 626 000 cases of liver cancer occurred in 2002, 82% of which are from developing countries and that 598 000 patients die annually of this disease^[1]. China alone accounts for 55% liver cancer death worldwide. Moreover, the 5-year survival rate was 8% in the United States during 1988-2001^[2], 9% in Europe during 1995-1999^[3], and 5% in developing countries in 2002^[1]. The major etiologies of hepatocellular carcinoma (HCC) include infection with hepatitis B virus (HBV) and hepatitis C virus (HCV), cigarette smoking, alcohol drinking and aflatoxin B1 (AFB₁) exposure^[4-9]. However, not all individuals with exposure to the risk factors develop cancer even after a long-term follow-up. The pathogenesis of human HCC is a multistage process with the involvement of a series of genes, including oncogenes and tumor suppressor genes.

The p53 tumor suppressor gene, located on chromosome 17p13, is of critical importance for the regulation of cell cycle and maintenance of genomic integrity. Loss of p53 function has been suggested to be a critical step in multistage hepatocarcinogenesis^[10]. A specific p53 mutation at codon 249 in exon 7 was associated with AFB₁-induced HCC in certain areas of high AFB₁ contamination^[11]. The wild-type p53 gene exhibits a polymorphism at codon 72 in exon 4, with a single nucleotide change that causes a substitution of proline for arginine (Arg72Pro)^[12]. The polymorphism occurs in the proline-rich domain of p53 protein, which is necessary for the protein to fully induce apoptosis. It is found that in cell lines containing inducible versions of alleles encoding the Pro and Arg variants, the Arg variant induces apoptosis more markedly than the Pro variant^[13]. In other words, the two polymorphic variants of p53 are functionally distinct, and these differences may influence cancer risk. The polymorphism consists of a single base pair change of either arginine or proline which creates 3 distinct genotypes: homozygous for arginine (Arg/Arg), homozygous for proline (Pro/Pro) and a heterozygote (Pro/Arg)^[14]. p53 codon 72 polymorphisms have been reported to be associated with cancers of the lung^[15], esophagus^[16], stomach^[17], colorectum^[18], breast^[19], bladder^[20] and cervix^[21].

In recent years, a number of case-control studies were conducted to investigate the association between p53 codon 72 polymorphism and liver cancer susceptibility in humans. But these studies reported conflicting results. No quantitative summary of the evidence has ever been performed. The purpose of this meta-analysis was to quantitatively summarize the evidence for such a relationship.

MATERIALS AND METHODS

Literature search strategy

Search was applied to the following electronic databases: Medline (from 1966 to September 2010), Embase (from 1950 to September 2010) and Chinese Biomedicine databases (from 1979 to September 2010). The following

key words were used: “p53” or “codon 72”, “liver” or “hepatocellular”, “carcinoma” or “cancer” or “tumor”. The search was without restriction in language, but with restriction in the studies conducted in human subjects. The reference lists of reviews and retrieved articles were hand searched at the same time. We did not include abstracts or unpublished reports. If more than one article was published by the same author using the same case series, we selected the study with the largest series.

Inclusion and exclusion criteria

We reviewed abstracts of all citations and retrieved studies. The following criteria were used to include published studies: (1) evaluating the association between p53 codon 72 polymorphism and liver cancer; (2) case-control study; and (3) sufficient genotype data were presented to calculate the odds ratio (OR) with confidence interval (CI). Major reasons for exclusion of studies were: (1) no control; (2) duplicate; and (3) no usable data reported.

Data extraction

All data were extracted independently by two reviewers (Chen X and Liu F) according to the prespecified selection criteria. Disagreement was resolved by discussion. The following data were extracted: the last name of the first author, study design, publication year, statistical methods, ethnicity of the population, genotyping methods, number of liver cancer cases and controls studied and results of studies.

Statistical analysis

The statistical analysis was conducted using STATA 8.2 (Stata Corp LP, College Station, TX, USA), $P < 0.05$ was considered statistically significant. Dichotomous data were presented as OR with 95% CI. Statistical heterogeneity was measured using the Q statistic test ($P < 0.10$ was considered statistically significant heterogeneity)^[22]. Either a random-effects model (DerSimonian-Laird method^[23]) or fixed-effects model (Mantel-Haenszel method^[24]) was used to calculate pooled effect estimates in the presence or absence of heterogeneity, respectively. To establish the effect of clinical heterogeneity among the studies on the conclusions of this meta-analysis, subgroup analyses were conducted based on race, study design, gender, chronic hepatitis virus status and family history of liver cancer patients. Several methods were used to assess the potential for publication bias. Visual inspection of funnel plot asymmetry was conducted. The Begg's rank correlation method^[25] and the Egger's weighted regression method^[26] were used to statistically assess publication bias. $P < 0.05$ was considered statistically significant.

the entire article, 12 cohort studies were identified^[27-38]. Six of them were excluded (four studies reported duplicate data^[31-34] and three are not related to liver cancer^[27,28,37]). As a result, six studies^[29-31,35,36,38] were selected, including 1115 liver cancer cases and 1778 controls. These studies were carried out in China, Spain, Italy, Morocco and Korea. Characteristics of the studies included in the meta-analysis are presented in Table 1.

Quantitative data synthesis

The combined results based on all studies showed that there was a statistically significant link between Pro/Pro genotype and liver cancer (OR = 1.38, 95% CI: 1.11-1.72, $P = 0.004$), but not between Arg/Arg or Pro/Arg and liver cancer (Arg/Arg, OR = 0.85, 95% CI: 0.72-1.00; Pro/Arg, OR = 0.99, 95% CI: 0.85-1.16). When stratifying for race, similar results were obtained, i.e. patients with liver cancer had a significantly higher frequency of Pro/Pro (OR = 1.35, 95% CI: 1.06-1.71, $P = 0.014$) genotype than non-cancer patients among Asians (Figure 1).

When stratifying by control source, we found that patients among hospital-based studies had a significantly higher frequency of Pro/Pro (OR = 1.34, 95%

CI: 1.06-1.70, $P = 0.014$) and a significantly lower frequency of Arg/Arg (OR = 0.80, 95% CI: 0.67-0.96, $P = 0.018$) genotype than patients without cancer, but not in population-based studies. When stratifying for gender, we found that female patients with liver cancer had a significantly lower frequency of Arg/Arg (OR = 0.49, 95% CI: 0.26-0.94, $P = 0.031$) and a higher frequency of Pro/Arg+Pro/Pro (OR = 2.03, 95% CI: 1.07-3.85, $P = 0.031$) genotypes than female individuals without cancer. When we stratified the various studies by family history of liver cancer, no statistically significant results were observed for all the analyses. When stratifying by chronic hepatitis virus status, we found that patients with negative hepatitis virus infection had a significantly higher frequency of Pro/Pro (OR = 2.07, 95% CI: 1.29-3.30, $P = 0.002$) and a significantly lower frequency of Arg/Arg (OR = 0.55, 95% CI: 0.32-0.94, $P = 0.028$) genotype than individuals without cancer, but not in patients with positive hepatitis virus infection (Table 2).

Heterogeneity and publication bias

No statistically significant heterogeneity was observed among trials for all the analyses with the *Q* statistic (Arg/

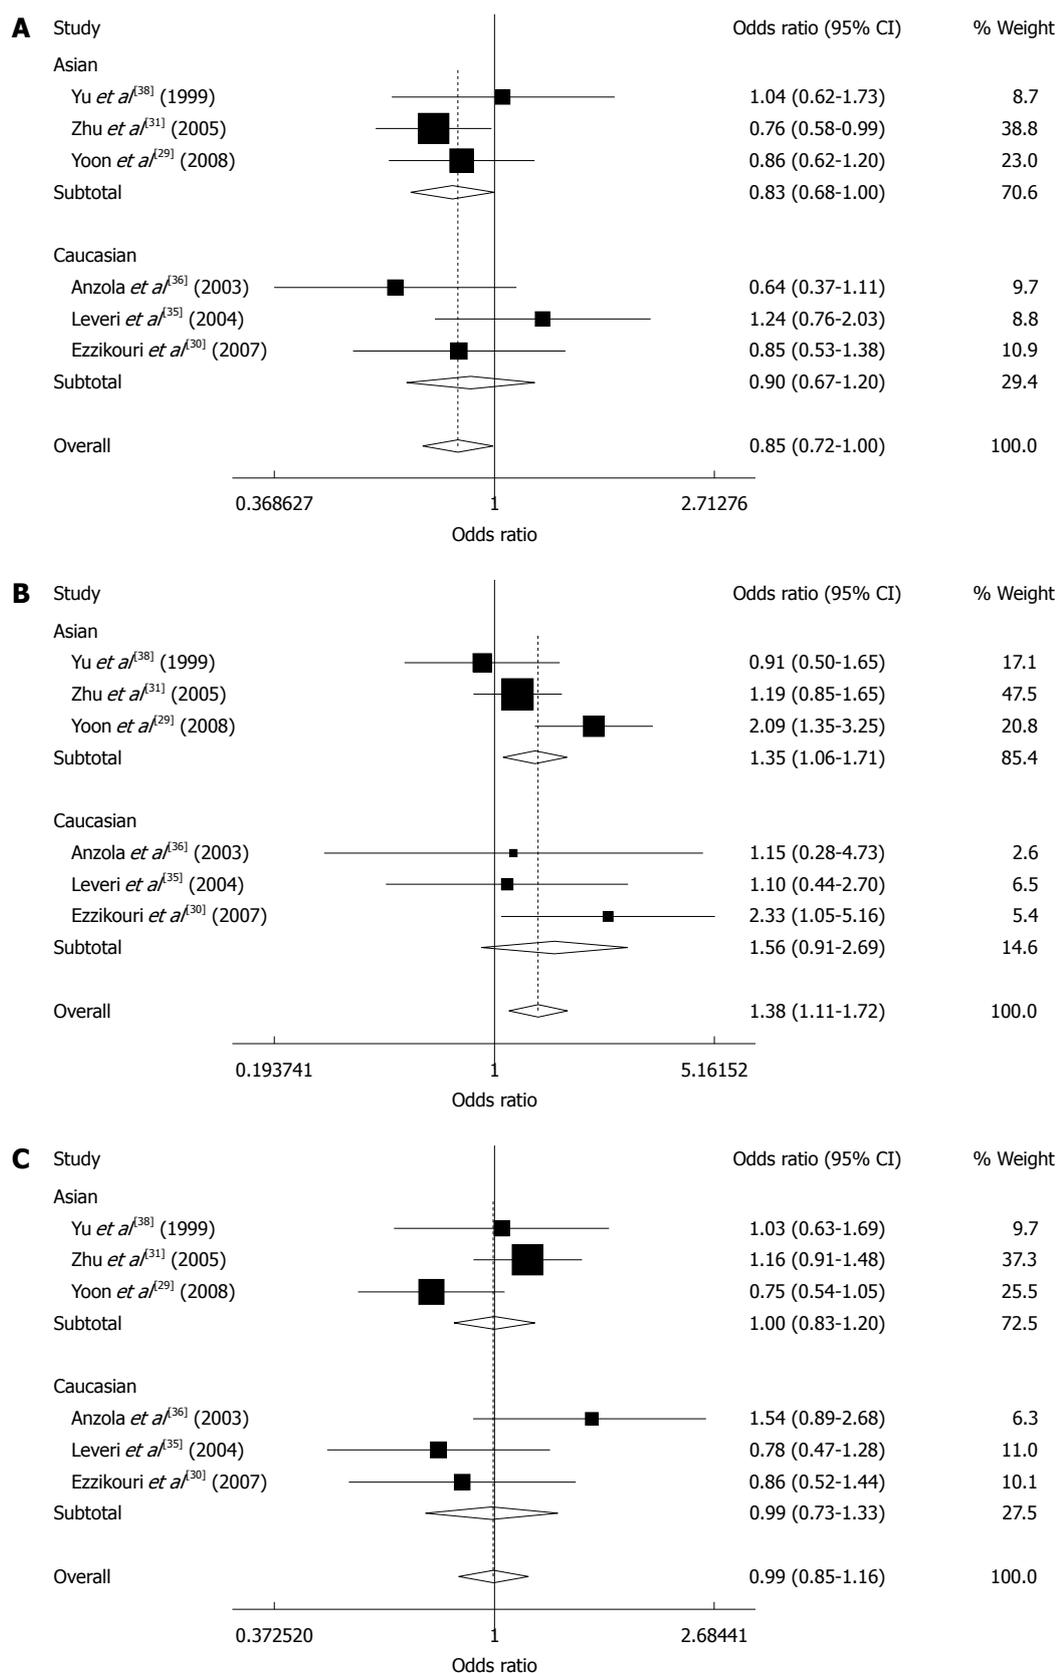

Figure 1 Meta-analysis of p53 codon 72 Arg/Arg (A), Pro/Pro (B) and Pro/Arg (C) and liver cancer risk.

Arg $P = 0.458$; Pro/Pro $P = 0.152$; Pro/Arg $P = 0.161$). In addition, L'Abbe plots did not show evidence of heterogeneity (Figure 2A). Review of funnel plots could

not rule out the potential for publication bias for all the analyses. Publication bias was not evident when the Begg rank correlation method (Arg/Arg $P = 1.00$; Pro/Pro P

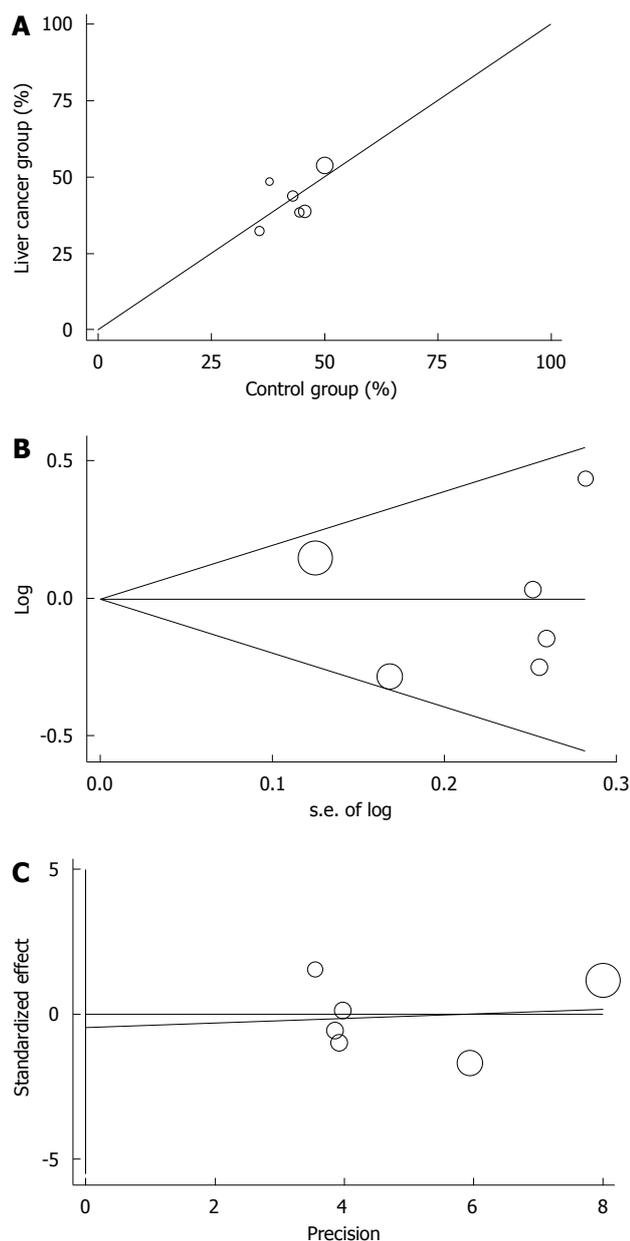

Figure 2 L'Abbe plots (A), Begg's funnel plot (B) and Egger's publication bias plot (C) of p53 codon 72 polymorphism and liver cancer risk.

= 1.00; Pro/Arg $P = 0.707$) and the Egger weighted regression method (Arg/Arg $P = 0.440$; Pro/Pro $P = 0.995$; Pro/Arg $P = 0.818$) were used (Figure 2B and C).

DISCUSSION

Although many environmental factors are found to correlate with the tumorigenesis of liver cancer^[4-9], the risk factors still need to be further elucidated. It has been recognized that the most important risk factor for the development of HCC is cirrhosis^[39]. Chronic infections with HBV and HCV are the most frequent causes of cirrhosis worldwide. A large number of cohort and case-control studies have shown that alcohol consumption causes liver cirrhosis and is an independent risk factor for primary

liver cancer^[6,40,41]. Epidemiological studies reported elevated HCC risks associated with exposure to aflatoxins after adjustment for HBV exposure^[42]. Cigarette smoking has been causally associated with the risk of HCC^[6,43]. However, there are a portion of patients without known risk factors who eventually developed liver cancer^[44]. Previous studies had shown an interaction of environmental factors and genetic predisposition in the development of liver cancer^[31,38]. Therefore, genetic predisposition may contribute to the process of tumorigenesis.

A genetic predisposition to liver cancer has been suggested by many studies^[45-47]. Recent studies suggest that single nucleotide polymorphism may be related to the tumorigenesis of liver cancer^[48,49]. The p53 gene and its encoded protein controls cell cycle, cell growth and apoptosis, which has a common polymorphism at codon 72 of exon 4 that encodes either Pro or Arg. Until recently, a number of studies have been conducted to find the relationship between p53 codon 72 polymorphism and liver cancer risk. Most of these studies were based on small sample sizes. Moreover, there are still some conflicting results. As a powerful statistical method, meta-analysis can provide a quantitative approach for pooling the results of different researches on the same topic, and for estimating and explaining their diversity^[50,51].

We found that Pro/Pro genotype had a 1.38-fold statistically significant increased risk of liver cancer in this meta-analysis. When stratifying for race, patients with liver cancer had a significantly higher frequency of Pro/Pro genotype than individuals without cancer among Asians. When stratifying the various studies by control source, gender, family history of liver cancer and chronic hepatitis virus infection, we found that (1) patients in hospital-based studies had a significantly higher frequency of Pro/Pro and a significantly lower frequency of Arg/Arg genotype than patients without cancer; (2) female patients with liver cancer had a significantly lower frequency of Arg/Arg and a higher frequency of Pro/Arg+Pro/Pro genotypes than female individuals without cancer; (3) subgroup analyses for family history of liver cancer did not reveal any significant association between p53 codon 72 polymorphism and liver cancer development; and (4) patients with negative hepatitis virus infection had a significantly higher frequency of Pro/Pro and a significantly lower frequency of Arg/Arg genotype than individuals without cancer.

A number of studies have shown significant differences in the biochemical properties of the p53 protein, depending on the particular polymorphic form. It has been shown that the Arg/Arg and Pro/Pro variants differ in binding activity, transcriptional activation, apoptosis induction and cell cycle arrest^[13,52]. The p53 Arg variant induces apoptosis faster and more efficiently than the p53 Pro variant^[13]. One explanation of such higher apoptotic potential is the greater ability of the Arg variant to localize to the mitochondria; this localization is accompanied by the proapoptotic release of cytochrome C into the cytosol^[13]. In addition, p53 Arg72 is more active

than p53 Pro72 in the induction of apoptosis through a transcription-dependant pathway. Pim *et al.*^[53] also found that the Arg72 form of p53 is significantly more efficient than the Pro72 form in inducing apoptosis. In contrast, the Pro72 form appears to induce a higher level of G1 arrest than the Arg72 form. These data indicate that the two polymorphic variants of p53 are functionally distinct, and these differences may influence cancer risk. From our meta-analyses, we found that patients with liver cancer had a significantly higher frequency of Pro/Pro than non-cancer patients ($P = 0.004$), which can be explained by the points of view mentioned above.

Another major finding of this study was the different associations of p53 codon 72 gene polymorphism with the risk of liver cancer based on race. In fact, race-specific variation in the distribution of genotypes in the p53 codon 72 polymorphism has been demonstrated^[54]. Because race may be related to the disease, either through common risk factors or other genes in linkage disequilibrium with p53, confounding by race, or population stratification, may lead to result bias in studies conducted on ethnically diverse populations that did not account for possible confounding^[55]. In this subgroup analysis, the frequency of Pro/Pro genotype showed distinct differences among Asians and Caucasians. The pooled OR associated with p53 codon 72 gene polymorphism was statistically significant among Asians, but not in Caucasians. The discrepancy might be due to genetic background and/or environmental exposure differences.

Results of meta-analyses often depend on control selection procedures^[56]. Arg/Arg and Pro/Pro genotype frequency might be different between the two control sources (hospital-based and population-based) (Table 1). In subgroup analysis stratified by the different study designs, the hospital-based controls resulted in a significantly stronger association between p53 Arg72 Pro polymorphism and development of liver cancer than population-based controls.

It is widely accepted that family history of liver cancer and chronic hepatitis virus infection are obvious risk factors for development of liver cancer. By pooling the available data that evaluated associations and interaction between p53 Arg72 Pro genotype and family history of liver cancer risk, the p53 Arg72 Pro genotype was not found to be associated with increased risk of liver cancer in those either with or without family history of liver cancer. Interestingly, we found that patients with negative hepatitis virus infection were at higher risk for liver cancer than patients with positive hepatitis virus infection. One explanation for the preferentially increased liver cancer risk of the p53 Arg72Pro polymorphism among hepatitis virus-negative but not hepatitis virus-positive subjects, is that the effect of the Pro allele may be concealed by chronic HBV infection since the relative risk of HCC among chronic HBV carriers is 10-200-folds higher than among non-carriers^[57,58]. Moreover, we demonstrated that there is an association between p53 Arg72Pro and enhanced risk of liver cancer in female patients. Such differences between

men and women have already been reported in colorectal cancer, which were explained by exogenous hormones intake^[18]. However, because of the limited study sample size, these results should be interpreted with caution.

However, there are still some limitations in this meta-analysis: (1) only published studies were included in the meta-analysis; therefore, publication bias may have occurred, even though the use of a statistical test did not show it; (2) these results should be interpreted with caution because the population from five countries and controls were not uniform; (3) the number of cases and controls in the included studies was low; and (4) meta-analysis is a retrospective research that is subject to the methodological limitations. In order to minimize the bias, we developed a detailed protocol before initiating the study, and performed a meticulous search for published studies using explicit methods for study selection, data extraction and data analysis. Nevertheless, our results still should be interpreted with caution.

In conclusion, this meta-analysis suggests that the p53 codon 72 polymorphism may be associated with liver cancer, and that difference in genotype distribution may be associated with race, gender and chronic hepatitis virus status of patients. Due to limited number of cases in this analysis, it is critical that larger and well-designed multicenter studies based on the same ethnic group are needed to confirm our results.

COMMENTS

Background

The wild-type p53 gene exhibits a polymorphism at codon 72 in exon 4, with a single nucleotide change that causes a substitution of proline for arginine (Arg72Pro). This change has been implicated as a risk factor for liver cancer, but individual studies have been inconclusive or controversial. The aim of this meta-analysis was to clarify the effect of p53 Arg72Pro polymorphism on the risk of liver cancer.

Research frontiers

There have been many studies on the association between p53 genetic polymorphism Arg72Pro and liver cancer risk, but no meta-analysis has been conducted.

Innovations and breakthroughs

To the best of our knowledge, this is the first systematic review that has investigated the association between p53 codon 72 polymorphisms and liver cancer. This meta-analysis revealed that the p53 codon 72 polymorphism may be associated with liver cancer among Asians.

Applications

It can be seen from this paper that p53 polymorphism Arg72Pro could alter the susceptibility to liver cancer. It suggests that, even a common variant in the functional region of a definitively meaningful gene had an effect on human diseases, such as cancer.

Terminology

Meta-analysis is a means of increasing the effective sample size under investigation through the pooling of data from individual association studies, thus enhancing the statistical power of the analysis.

Peer review

The authors analyzed the association between p53 codon 72 polymorphism and liver cancer susceptibility in humans through this meta-analysis, and quantitatively summarized the evidence for such a relationship. They found that patients with liver cancer had a significantly higher frequency of Pro/Pro than non-cancer patients among Asians. Female patients with liver cancer had a significantly lower frequency of Arg/Arg and a higher frequency of Pro/Arg+Pro/Pro than female individuals without cancer.

Abstract

AIM: To study the correlation between high metastasis-associated protein 1 (MTA1) expression and lymphangiogenesis in colorectal cancer (CRC) and its role in production of vascular endothelial growth factor-C (VEGF-C).

METHODS: Impact of high MTA1 and VEGF-C expression levels on disease progression and lymphovascular

density (LVD, D2-40-immunolabeled) in 81 cases of human CRC was evaluated by immunohistochemistry. VEGF-C mRNA and protein expressions in human LoVo and HCT116 cell lines were detected by real-time polymerase chain reaction and Western blotting, respectively, with a stable expression vector or siRNA.

RESULTS: The elevated MTA1 and VEGF-C expression levels were correlated with lymph node metastasis and Dukes stages ($P < 0.05$). Additionally, high MTA1 expression level was correlated with a large tumor size ($P < 0.05$). A significant correlation was found between MTA1 and VEGF-C protein expressions in tumor cells ($r = 0.371$, $P < 0.05$). Similar to the VEGF-C expression level, high MTA1 expression level was correlated with high LVD in CRC ($P < 0.05$). Furthermore, over-expression of MTA1 significantly enhanced the VEGF-C mRNA and protein expression levels, whereas siRNAs - knocked down MTA1 decreased the VEGF-C expression level.

CONCLUSION: MTA1, as a regulator of tumor-associated lymphangiogenesis, promotes lymphangiogenesis in CRC by mediating the VEGF-C expression.

Metastasis-associated protein 1 induces VEGF-C and facilitates lymphangiogenesis in colorectal cancer. *World J Gastroenterol* 2011; 17(9): 1219-1226 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1219.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1219>

INTRODUCTION

Lymphatic metastasis is one of the most important metastatic routes of epithelial cancer including colorectal cancer (CRC)^[1]. Excessive formation of new lymphatics (lymphangiogenesis) in CRC is a key process for lymphatic metastasis, and lymphatic vessel density (LVD) is an indicator for lymphangiogenesis^[1-3]. Metastasis-associated protein 1 (MTA1) is expressed in a wide range of epithelial cancers and plays a crucial role in tumor metastasis^[4]. MTA1 has been established as the only single gene showing consistently increased in lymph node metastases of head and neck squamous cell carcinoma^[5]. A large number of clinicopathological studies show that elevated MTA1 is correlated with lymph node metastasis of epithelial cancer^[4,6-9]. These data indicate that MTA1 is involved in lymphatic metastasis of epithelial cancer. However, whether the pro-metastatic effects of MTA1 are mediated by promoting lymphangiogenesis remains unknown.

MTA1, as a part of the nucleosome remodeling and deacetylation complex (NuRD), promotes metastasis of cancer by regulating many tumor-associated genes^[4,9]. For example, MTA1 physically binds to hypoxia-inducible factor-1 α (HIF-1 α) and increases its transcriptional activity, leading to enhanced expression of vascular endothelial growth factor (VEGF)-A which is associated with metastasis^[10,11]. VEGF-C is another member of the VEGF family and the major regulatory factor for tumor lymphangiogenesis^[1,2]. Similar to VEGF-A, VEGF-C is also directly induced by HIF-1 α ^[12-14], and therefore, is a potential target molecule of MTA1. Thus, whether MTA1 can promote lymphangiogenesis by up-regulating the expression of VEGF-C in CRC is unknown and worthy of further study.

In this study, the expression of MTA1 was correlated with VEGF-C in CRC specimens. MTA1 was related with high LVD, indicating that MTA1 promotes lymphangiogenesis and thus induces metastasis of tumor. Furthermore, MTA1 mediated VEGF-C expression, suggesting MTA1 can promote lymphangiogenesis by increasing the VEGF-C expression level in CRC.

MATERIALS AND METHODS

Colorectal cancer samples

Eighty-one CRC tissue specimens, provided by Department of Pathology, First Affiliated Hospital of Jinan University, were fixed in 10% buffered formalin for 24-48 h, embedded in paraffin wax, and then cut into sections which were stained with hematoxylin and eosin and reviewed twice by two experienced pathologists to verify the diagnosis, histological grade and type, based on the system of the Union for International Cancer Control (UICC). A synopsis of the clinicopathological parameters is provided in Table 1.

Immunohistochemical staining

The sections of CRC tissue specimen were stained with immunohistochemistry (IHC) using a streptavidin-peroxidase

MTA1: Metastasis-associated protein 1; VEGF-C: Vascular endothelial growth factor-C.

technique (Beijing Zhong Shan Golden Bridge Biological Technology Co., Ltd., China). Briefly, the sections were incubated in methanol/H₂O₂ for 30 min to inhibit the endogenous peroxidase activity, washed with PBS for 5 min and blocked with normal goat serum for 20 min at room temperature. The sections were incubated with antibodies against MTA1 (sc-9446; Santa Cruz Biotechnology Inc., CA, USA) or VEGF-C (sc-7133; Santa Cruz Biotechnology Inc., CA, USA) overnight at 4°C, then with biotinylated secondary antibody for 1 h at room temperature and avidin-conjugated peroxidase for 45 min at room temperature. The sections were washed three times with PBS between each step. Peroxidase was stained with diaminobenzidine (1 mg/mL) and H₂O₂ for 5 min and washed with tap water for 10 min. The sections were counterstained with hematoxylin for 1 min. PBS was used as a negative control instead of primary antibody.

Evaluation of immunostaining

Two investigators who were blinded to the patient outcomes and all clinicopathological findings examined the stainings independently. Positive expression of MTA1 and VEGF-C was detected by estimating the staining intensity and the percentage of tumor cells showing specific immunoreactivity. Samples with 10% tumor cells were defined as positive. The intensity score was defined as 0 (no staining), 1 (weak staining), 2 (moderate staining), and 3 (strong

staining), respectively, as previously described^[15,16]. Tumors with a score > 2 (moderate and strong expression) showed a high expression level of MTA1 and VEGF-C^[15,16].

Assessment of LVD

LVD in CRC tissue sections that were single-stained for D2-40 was quantitatively analyzed as previously described^[3,17]. Tumoral LVD located at the periphery of tissue, within 2 mm of the tumor and adjacent to the invasive front was assessed. Five areas with most lymphatic regions ("hot spots") were chosen by light microscopy at 40 × magnification. LVD was assessed by counting all stained vessels at 200 × magnification. The assessed mean number of lymphatics was determined and expressed as LVD^[17,18]. The LVD was scored and counted by two investigators independently who were blinded to clinical information about the patients.

Cell culture

Human CRC cell lines, HCT116 and LoVo, purchased from Center of Experimental Animals, Sun Yat-Sen University (Guangzhou, China), were cultured in Dulbecco's modified Eagle's medium (Life Technologies Corporation, CA, USA) containing 100 IU/mL penicillin, 100 µg/mL streptomycin, and 10% heat-inactivated fetal bovine serum in a humidified atmosphere containing 5 mL CO₂ at 37°C.

RNA interference

Two 21-nucleotide MTA1 siRNAs (si-MTA1#1 and si-MTA1#2) were designed to target the sequences 5'-GGAGAAUCGAGGAGCUACA-3' and 5'-GCAUCAUUGAGUACUACUACA-3' of MTA1 mRNA (NCBI accession number: NM_004689.3). BLAST searches indicated that the targeted regions had no significant homology with any other genes. A non-targeting siRNA was used as a negative control (NC, 5'-UUCUCCGAACGU-GUCACGUTT-3') in all siRNA transfection experiments. All siRNAs, purchased from Shanghai GenePharma Co., Ltd (Shanghai, China) were transfected twice at 24-h intervals with Oligofectamine reagent (Life Technologies Corporation, CA, USA) according to its manufacturer's protocol^[19].

Plasmid and transfection

Plasmid MTA1-EGFP-C1 (a gift from Professor Chen Anman at Huazhong University of Science and Technology, China)^[20] and plasmid EGFP-C1 vector (as a blank control) was transfected into LoVo cells with Oligofectamine reagent (Life Technologies Corporation, CA, USA) according to its manufacturer's protocol. Medium was supplemented with 400-800 µg/mL G418 (Life Technologies Corporation, CA, USA) to screen for positive cells, then with 400 µg/mL G418 after two weeks. Positive cell clones were isolated by ring chining and further expanded for genetic and functional characterization. Expression of MTA1 was detected by real-time polymerase chain reaction (PCR) and Western blotting, respectively.

Real-time PCR

MTA1 and VEGF-C mRNA was analyzed by real-time PCR as previously described^[19]. Briefly, total RNA was extracted from cells using TRIzol (Life Technologies Corporation, CA, USA). First strand cDNA was synthesized from mRNA using a Primescript™ RT reagent kit (TaKaRa, Tokyo, Japan). Real-time PCR was carried out using the SYBR Premix ExTaq™ (TaKaRa, Tokyo, Japan) according to its manufacturer's instructions. The input was normalized by GAPDH mRNA. Gene-specific primers are as follows: 5'-AGCTACGAGCAGCACAACGGGGT-3' (forward primer for mta1) and 5'-CACGCTTGGTTTCCGAGGAT-3' (reverse primer, 289 bp), 5'-AACCTC-CATGTGTGTCCGTC-3' (forward primer for vegf-c) and 5'-TGGCAAACTGATTGTTACTGG-3' (reverse primer, 156 bp), 5'-ACAGTCCATGCCATCACTGCC-3' (forward primer for GAPDH) and 5'-GCCTGCTTCAC-CACCTTCTTG-3' (reverse primer, 266 bp). Experiments were performed in triplicate, with the results represented as mean ± SE.

Western blotting

MTA1 and VEGF-C protein expression was detected by Western blotting as previously described^[21]. Briefly, the cells were lysed in a RIPA buffer (1% NP-40, 150 mM NaCl, 0.05% DOC, 1% SDS, and 50 mM TrisCl, pH = 7.5) containing protease inhibitors. After separated by SDS-PAGE, the proteins were transferred to polyvinylidene difluoride membranes and subjected to immunoblotting with antibodies against MTA1 (Santa Cruz Biochemistry, CA, USA), VEGF-C (Santa Cruz Biochemistry, CA, USA) and tubulin (Sigma-Aldrich, Inc., MI, USA) at 4°C overnight. After washed, the membranes were incubated with horseradish peroxidase-conjugated secondary antibodies and visualized using the ECL chemiluminescence system (Thermo Fisher Scientific Inc., MA, USA).

Statistical analysis

Statistical analysis was carried out using the SPSS 13.0 for Windows. Pearson's χ^2 test was used to examine the relation between immunostaining scores of two different markers within different clinicopathological subgroups. Spearman's rank-order correlation was used to test immunostaining scores of the significant association between MTA1 and VEGF-C. Student's *t*-test was used to determine differences in two data sets, including the effect of LVD and siRNA treatment or gene transfection on gene expression. All tests were two-tailed and *P* < 0.05 was considered statistically significant.

RESULTS

Immunohistochemistry for MTA1 and VEGF-C expression in CRC tissue specimens

The expression of MTA1 and VEGF-C protein was detected in CRC tissue samples with IHC staining and the correlation between their expression and clinicopathological parameters was further analyzed. The MTA1 immu-

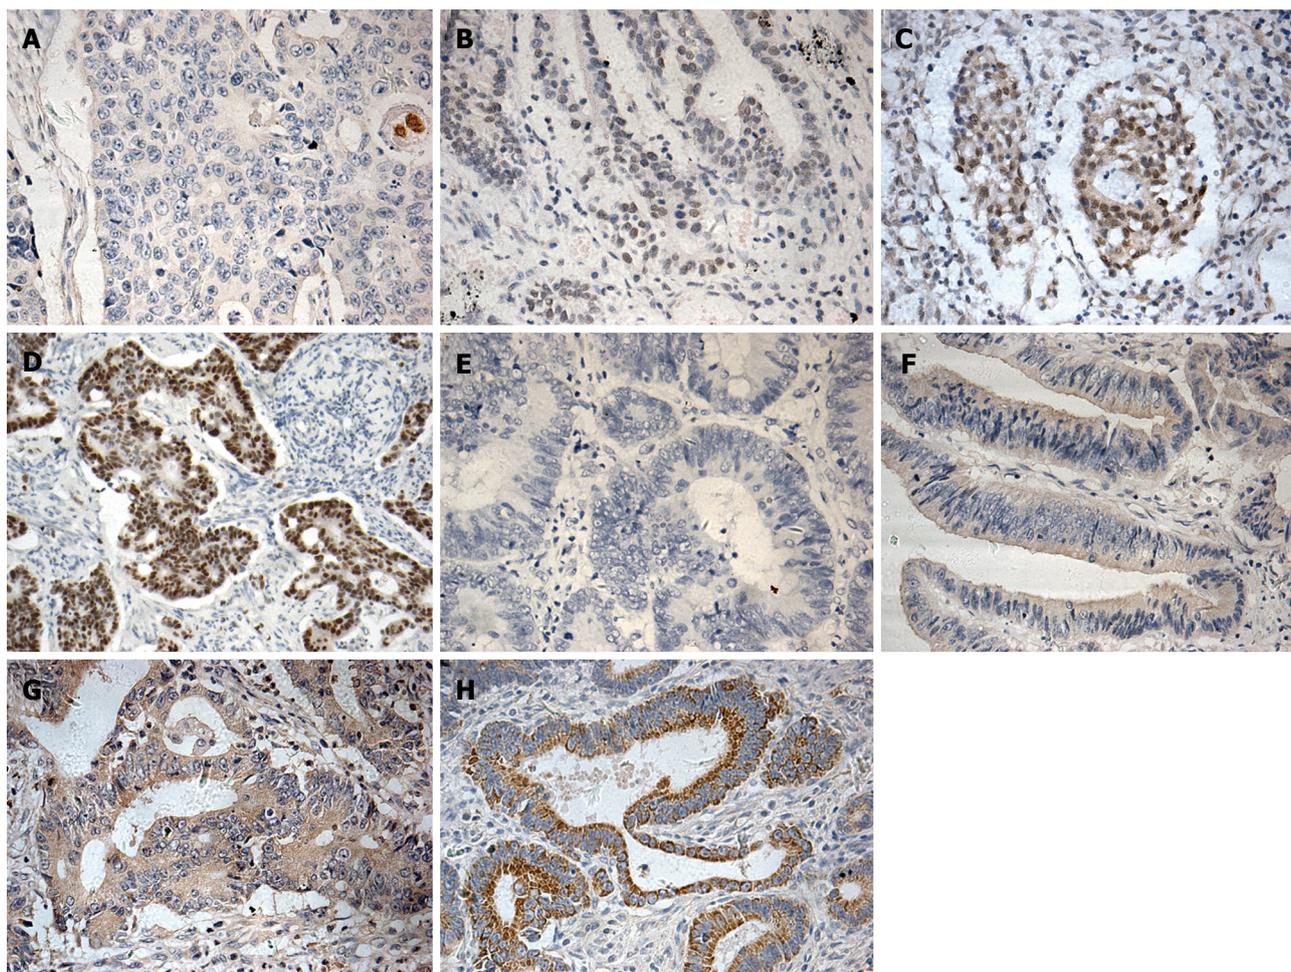

Figure 1 Immunohistochemical labeling for metastasis-associated protein 1, vascular endothelial growth factor-C in colorectal cancer. Metastasis-associated protein 1 (MTA1) (A-D) and VEGF-C (E-H) expressions are indicated as score 0 (A and E), score 1 (B and F), score 2 (C and G), and score 3 (D and H), respectively. MTA1 showing extremely weak staining of cytoplasm and intense staining of nuclei, while VEGF-C showing staining of cytoplasm of tumor cells ($\times 200$).

noreactivity was detected primarily in nuclei and weakly in cytoplasm of tumor cells with with IHC staining (Figure 1A-D), whereas positive VEGF-C staining was observed in cytoplasm (Figure 1E-H). However, faint staining of VEGF-C was occasionally observed in normal epithelial cells and stromal components showed, particularly in adjacent stromal endothelial cells, which is consistent with the reported findings^[16,22,23].

The correlation between the MTA1 and VEGF-C expression and the clinicopathologic parameters is shown in Table 1. High MTA1 expression level was observed in 25 (30.8%) of the 81 tumor tissue samples, while high VEGF-C expression level was found in 35 (43.2%) of the 81 tumor tissue samples. The MTA1 and VEGF-C expressions were correlated with lymph node metastasis and Dukes stages ($P < 0.05$). Additionally, the high MTA1 expression level was correlated with a large tumor size ($P < 0.05$). Neither MTA1 nor VEGF-C was correlated with tumor location, differentiation, infiltration, and sex or age of the patients.

A significant correlation was found between MTA1 and VEGF-C protein expressions in tumor cells ($r = 0.371$, $P < 0.05$, Table 2), indicating that the high MTA1 expression level can facilitate lymphatic metastasis of CRC.

Table 2 Correlation between expression levels of metastasis-associated protein 1 and vascular endothelial growth factor-C in human colorectal cancer

^a $P = 0.001$, $r = 0.371$, Spearman's coefficient of correlation. ¹Number of cases. MTA1: Metastasis-associated protein 1; VEGF-C: Vascular endothelial growth factor-C.

Correlation between high MTA1 and VEGF-C expression level and LVD in CRC

It has been reported that high peritumoral LVD is an independent risk factor for lymphangiogenesis^[3,24]. Immunostaining of D2-40 is a specific marker for evaluation of lymphatic invasion and lymphatic microvessel density in human cancers^[3,24,25]. To further determine whether MTA1 plays a role in lymphangiogenesis, the correlation between the

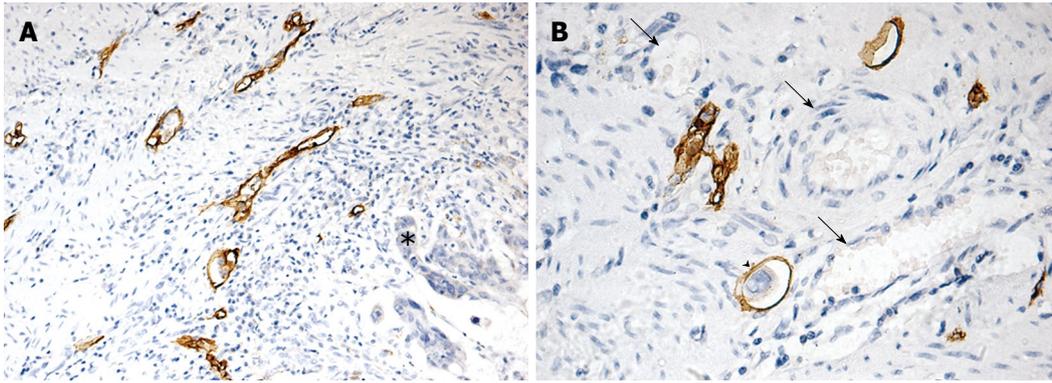

Figure 2 Morphological features of D2-40 positive lymphatic vessels in colorectal cancer. A: Positive D2-40 stained lymphatic vessels with thin walls and irregular shapes in peritumoral area (asterisk, $\times 100$); B: Positive D2-40 stained lymphatic vessel containing tumor emboli within tumor mass (arrow head) and D2-40-negative erythrocytes (black arrows, $\times 200$).

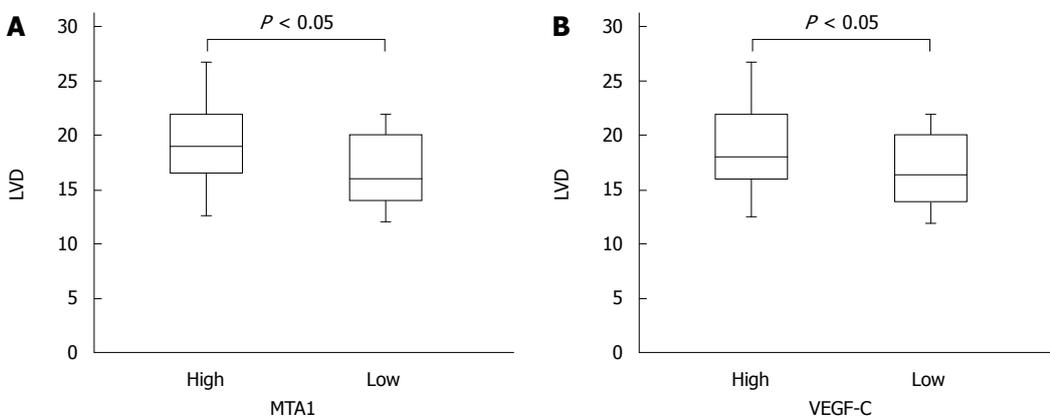

Figure 3 Correlation between metastasis-associated protein 1 or vascular endothelial growth factor-C expression and lymphovascular density. Analysis of subgroups with low and high metastasis-associated protein 1 (MTA1) and VEGF-C are presented by box bars. Tumors with higher MTA1 and VEGF-C expression showed significantly higher microvessel density than tumors with lower expression. LVD: Lymphovascular density. VEGF-C: Vascular endothelial growth factor-C.

expression of MTA1 and the quantity of D2-40 positive lymphatic vessels was analyzed in this study. The lymphatic vessels were lined with a single layer of D2-40 positive endothelial cells, while the adjacent blood vessels containing erythrocytes showed negative staining. Lymphatic vessels were distributed unevenly throughout the sections, and mostly located in the peritumoral area (Figure 2).

The LVD was 9- 31 with a mean of 17.76. The mean LVD was 19.92 and 19.60, respectively, in patients with a high MTA-1 and VEGF-C expression level, and 16.37 and 16.80, respectively, in those with a low, MTA-1 and VEGF-C expression level ($P < 0.05$), indicating that MTA1 also promotes lymphangiogenesis of CRC as VEGF-C. The correlation between MTA1 and VEGF-C expression and LVD is shown in Figure 3.

MTA1 regulates the expression of VEGF-C in CRC cell lines

After a positive relation was established between MTA1 and VEGF-C expressions in CRC tissue specimens, whether MTA1 mediates VEGF-C expression in CRC cell lines was studied. HCT-116 cells with a high MTA1 level and LoVo cells with a low MTA1 level were used in our next experiments as previously described^[26,27]. The

expression of MTA1 and VEGF-C was detected in these two cell lines by real-time PCR and Western blotting, respectively. The MTA1 and VEGF-C mRNA and protein expression levels were significantly higher in HCT-116 cells than in LoVo cells (Figure 4A).

To determine whether MTA1 is responsible for the expression of VEGF-C, the MTA1 stable expression vector was used to mimic the MTA1 protein expression in LoVo cells, showing that the MTA1 stable expression vector significantly increased the MTA1 protein expression, while the VEGF-C protein expression level was remarkably up-regulated by the MTA1 stable expression vector compared to the mock and control vector (Figure 4B, left panel). Furthermore, over-expression of the MTA1 stable vector enhanced the VEGF-C mRNA expression level compared to the mock and control vector (Figure 4B, right panel), suggesting that MTA1 is required for VEGF-C expression.

To further specifically confirm the regulation of VEGF-C by MTA1, siRNA-mediated knockdown of MTA1 was employed. HCT116 cells were transfected with two siRNAs specific for MTA1. MTA1-targeted siRNAs specifically suppressed the MTA1 protein expression, while the level of an unrelated gene (like Tubulin) was unaffected.

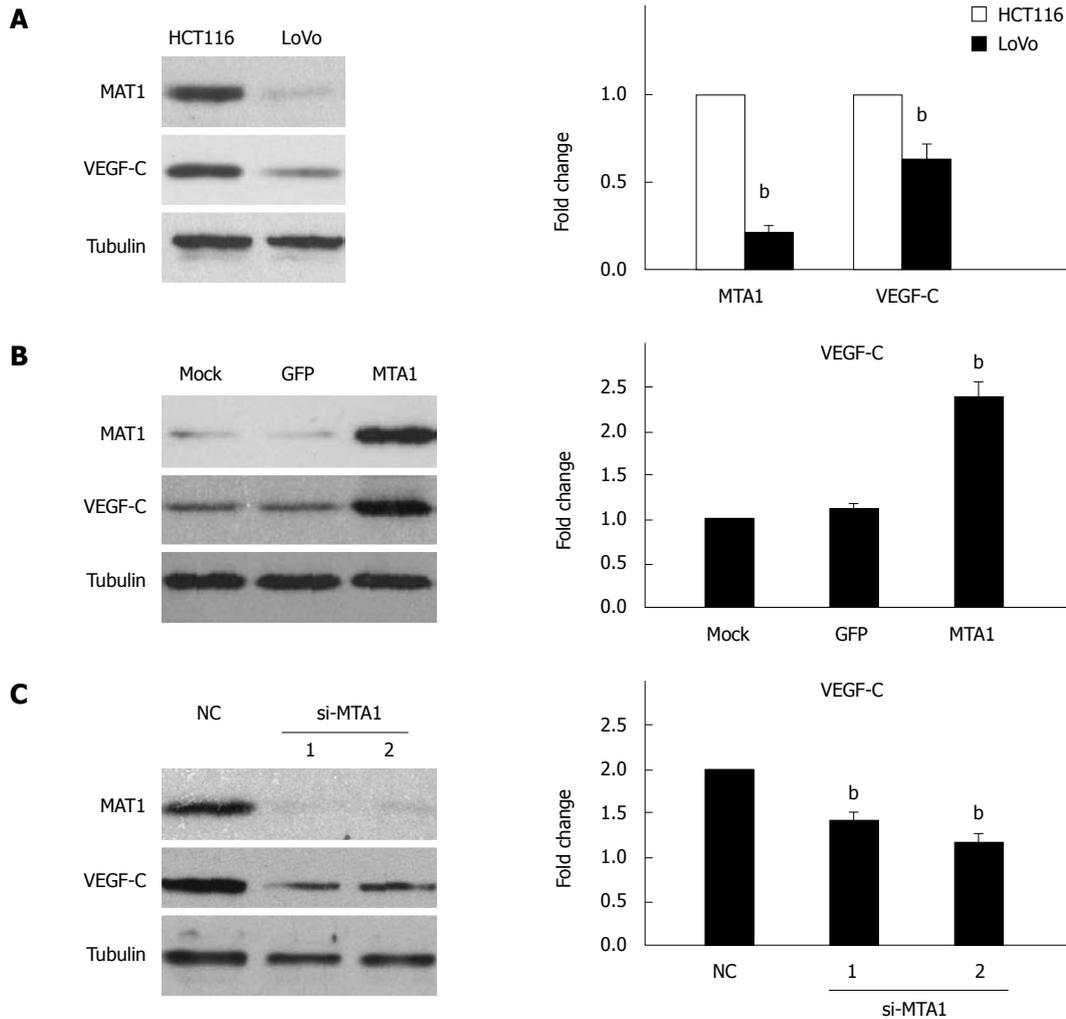

Figure 4 Metastasis-associated protein 1 regulates the expression of vascular endothelial growth factor-C in colorectal cancer cell lines. Western blotting (left panel) and real-time PCR (right panel) showing different expressions of metastasis-associated protein 1 (MTA1) and VEGF-C in HCT116 and LoVo cell lines (A), increased VEGF-C expression in LoVo cells due to overexpression of MTA1 (B), and decreased VEGF-C expression in HCT116 cells due to knocked down MTA1 (C). 1 and 2 indicate two different si-MTA1 oligonucleotide as showed in "Materials and Methods". All data represent three independent experiments \pm SE, with $n = 3$ and $^bP < 0.01$. VEGF-C: Vascular endothelial growth factor-C.

ed, verifying that the siRNAs have a high selectivity and efficacy (Figure 4C, left panel). Furthermore, the silencing of MTA1 endogenous expression significantly decreased the VEGF-C protein expression, whereas the RNA interference technique had no significant effect on the VEGF-C expression as revealed by the negative control siRNA (NC), (Figure 4C, left panel), indicating that MTA1 is necessary for VEGF-C expression. Furthermore, knockdown of MTA1 expression decreased the VEGF-C mRNA expression level (Figure 4C, right panel), suggesting that MTA1 mediates VEGF-C expression in CRC cell lines.

DISCUSSION

This study investigated whether the expression of VEGF-C regulated by MTA1 affects the lymphangiogenesis of colon cancer. IHC studies in CRC specimens and mechanistic studies with genetic manipulation in colon cancer cell lines, demonstrated that MTA1-mediated expression of VEGF-C

could facilitate the lymphangiogenesis of colon cancer.

MTA1 is associated with progression to the metastatic state in many epithelial cancers, including carcinomas of breast^[6,28], prostate^[22], and esophagus^[7], as well as head and neck squamous cell carcinoma^[5]. However, the relation between MTA1 and CRC metastasis is not clear. It has been showed that the expression of MTA1 mRNA in CRC is significantly correlated to the depth of invasion and lymph node metastasis^[29]. It was reported that the expression level of MTA1 mRNA is higher in colorectal cancer tissue than in its adjacent normal tissue^[30]. In this study, the MTA1 protein expression in CRC tissue specimens was evaluated with IHC staining, showing that the MTA1 expression level was significantly higher in primary CRC tumors with lymph node metastases than in those without lymph node metastases, which is consistent with the reported data^[29,30].

Hematogenous and lymphatic metastases are the two main forms of tumor metastasis to distant organs. Jang *et al.*^[31] examined MTA1 protein expression and microves-

sel density (MVD) in breast cancer tissue specimens and showed that MTA1 overexpression is significantly correlated with high MVD. The proangiogenic effects of MTA1 have also been observed in hepatocellular carcinoma^[32] and prostate cancer^[22]. In this study, the over-expression of MTA1 was significantly associated with the increased tumor LVD, indicating that MTA1 facilitates tumor metastasis by up-regulating angiogenesis and lymphangiogenesis.

The presence of VEGF-C, an independent predictor of poor survival, is associated with lymphangiogenesis^[17,23]. In this study, the expression of VEGF-C was correlated with lymphatic metastases and greater LVD in CRC, which is consistent with the reported findings^[1,23,27]. More importantly, the lymphangiogenesis up-regulated by MTA1 was related to the induction of VEGF-C, the expression of MTA1 in CRC tissue specimens was associated with that of VEGF-C, over-expression of MTA1 increased the expression level of VEGF-C, and knock-down of MTA1 reduced it in CRC cell lines, indicating that MTA1 mediates the induction of VEGF-C during lymphangiogenesis of CRC.

Although we demonstrated MTA1 could mediate VEGF-C expression, its precise mechanism remains to be defined. MTA1 regulates the expression of target genes by inhibiting or promoting their transcriptional activity. For example, MTA1 has a strong transcription repressing activity on estrogen receptor- α ^[33] and BRCA1^[34] (breast cancer type 1 susceptibility protein) by forming a complex with NuRD. However, other studies demonstrate that MTA1 stimulates the transcriptional activity of several gene promoters by interacting with RNA polymerase II^[35,36]. Moreover, the expression of MTA1 can be strongly induced under hypoxic conditions in breast cancer cell lines, and MTA1 over-expression increases the transcriptional activity and stability of HIF-1 α protein^[10,11]. Hypoxia is one of the most powerful inducers of lymphangiogenesis, and VEGF-C is a target molecule of HIF-1 α ^[13,14,37,38]. Therefore, MTA1 can promote VEGF-C expression through the HIF-1 α pathways. The precise mechanism involved in MTA1 targeting of VEGF-C should be further studied.

In conclusion, MTA1 plays a role in lymphangiogenesis of human CRC by up-regulating VEGF-C, a key regulator of lymphangiogenic factors, thus providing a novel mechanism underlying the relation between the high MTA1 level, cancer metastasis and poor outcome. Therefore, MTA1 is a potentially novel target for the treatment of lymphatic metastasis of human CRC.

COMMENTS

Background

Excessive formation of new lymphatics (lymphangiogenesis) in colorectal cancer (CRC) facilitates metastasis of cancer cells to lymph nodes and distant organs. Metastasis-associated protein 1 (MTA1) is expressed in a wide range of epithelial cancers including CRC, and plays a crucial role in their metastasis. Vascular endothelial growth factor-C (VEGF-C) is the major regulatory factor for CRC lymphangiogenesis.

Research frontiers

MTA1 is involved in regulation of VEGF family during metastasis. Whether MTA1 promotes lymphangiogenesis by up-regulating the expression of VEGF-C

in CRC needs to be further studied.

Innovations and breakthroughs

This is the first study to demonstrate that MTA1 plays a role in lymphangiogenesis by up-regulating VEGF-C, thus providing a novel mechanism of MTA1 underlying the promotion of CRC metastasis.

Applications

The findings in this study are of value in explanation of the mechanism of CRC lymphangiogenesis. MTA1 may be used as a new potential target for the treatment of lymphatic metastasis of human CRC, although further animal experiments are required to confirm its activity in promoting lymphangiogenesis of CRC.

Peer review

It is a well written manuscript with promising results that may be the basis of forthcoming new research in CRC biology and therapy. The correlation between MTA1 and VEGF-C is of great clinical importance, as new therapeutic targets may be identified based on the results of this study.

genotypes for Arg/Arg + Arg/Pro vs Pro/Pro (OR = 0.73, 95% CI: 0.57-0.94, $P = 0.014$). Subgroup analyses according to the source of controls and the specimens used for determining TP53 Arg72Pro genotypes or sample size showed that significantly reduced risk was observed only in studies which have population-based controls (Arg/Arg vs Pro/Pro: OR = 0.56, 95% CI: 0.47-0.66, $P < 0.001$), and use white blood cells or normal tissue to assess TP53 genotypes of cases (Arg/Arg vs Pro/Pro: OR = 0.56, 95% CI: 0.47-0.65, $P < 0.001$) or include at least 200 subjects (Arg/Arg vs Pro/Pro: OR = 0.56, 95% CI: 0.47-0.65, $P < 0.001$). Analysis restricted to well-designed studies also supported the significantly decreased risk of EC (Arg/Arg vs Pro/Pro: OR = 0.54, 95% CI: 0.46-0.64, $P < 0.001$).

CONCLUSION: TP53 Arg72 carriers are significantly associated with decreased EC risk. Nevertheless, more well-designed studies are needed to confirm our findings.

TP53 Arg72Pro polymorphism is associated with esophageal cancer risk: A meta-analysis. *World J Gastroenterol* 2011; 17(9): 1227-1233 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i9/1227.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i9.1227>

Abstract

AIM: To investigate the association between TP53 Arg72Pro polymorphism and esophageal cancer (EC) risk using meta-analysis.

METHODS: All eligible studies published before March 1, 2010 were selected by searching PubMed using keywords "p53" or "TP53", "polymorphism" or "variation", "esophageal" and "cancer" or "carcinoma". Crude odds ratios (ORs) with 95% confidence intervals (CIs) were assessed for EC risk associated with TP53 Arg72Pro polymorphism using fixed- and random-effects models.

RESULTS: Nine case-control studies involving 5545 subjects were included in this meta-analysis. Significantly reduced risk of EC was associated with TP53

INTRODUCTION

Esophageal cancer (EC) is the eighth most common can-

cer and sixth most deadly cancer worldwide. China and southern and eastern Africa are the relatively high risk areas^[1,2]. There are two main forms of EC histologically: esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EA). ESCC constitutes the majority (over 90%) of EC, but the incidence rates of EA have sharply increased in many Western countries recently^[3-5]. The development of EC is a multifactorial process associated with a variety of risk factors. The two major risk factors of EC are tobacco smoking and alcohol drinking^[6-8]. Inherited predisposition may also explain the high rates of EC^[9].

TP53 is a major regulator of the cell response to stress and serves as a tumor suppressor by inducing cell cycle arrest or apoptosis^[10]. Inactivation of the TP53 signaling pathway has been seen in most human cancers^[11]. Previously, polymorphisms of TP53 have been reported to be the possible risk factors for some kinds of tumors^[12]. The most common polymorphism of TP53 is at the 72nd amino acid residue, with an arginine (Arg) to proline (Pro) change because of a G→C transverse^[13]. Differences in the biochemical or biological characteristics of these wild-type TP53 variants have been reported^[14]. The Arg72 variant can better induce apoptosis than the Pro72 variant, indicating that the two polymorphic variants of TP53 are functionally distinct, which may influence the cancer risk or treatment^[15].

A number of studies have reported the role of TP53 Arg72Pro polymorphism in cancers such as cervical cancer^[16], lung cancer^[17], breast cancer^[18], and gastric cancer^[19], but little is known about the association of TP53 polymorphism with EC. In recent years, several studies focused on the association between TP53 Arg72Pro polymorphism and EC susceptibility, with inconsistent results^[20-29]. Hence, we performed a meta-analysis of all eligible studies to estimate the association between TP53 polymorphism and the risk of EC.

MATERIALS AND METHODS

Publication search

We searched the articles using the terms “p53” or “TP53”, “polymorphism” or “variation”, “esophageal” and “cancer” or “carcinoma” in Medline database utilizing the PubMed engine, and all eligible studies were published before March 1, 2010. We evaluated all associated publications to retrieve the most eligible literatures. Their reference lists were hand-searched to find other relevant publications. Articles were limited to English language papers.

Inclusion and exclusion criteria

The following inclusion criteria were used to select literatures for the meta-analysis: (1) published in peer-reviewed journals; (2) articles about TP53 Arg72Pro polymorphism and risk of EC; and (3) containing useful genotype frequencies. The exclusion criteria were: (1) none-case-control studies; (2) control population including malignant tumor patients; (3) the genotype frequen-

cies of control group departing from Hardy-Weinberg equilibrium (HWE); and (4) duplicated publications.

Data extraction

Two investigators (Jiang and Yao) reviewed and extracted information from all eligible publications independently, according to the inclusion and exclusion criteria listed above. An agreement was reached by discussion between the two reviewers whenever there was a conflict. The following items were collected from each study: first author's surname, year of publication, country of origin, ethnicity, source of controls, specimens used for assessment of TP53 Arg72Pro genotypes, total number of cases and controls as well as numbers of cases and controls with Arg/Arg, Arg/Pro and Pro/Pro genotypes, respectively.

Statistic analysis

Crude odds ratios (ORs) with 95% confidence intervals (CIs) were used to assess the association between TP53 Arg72Pro polymorphism and EC risk. The pooled ORs were performed for homozygote comparison (Arg/Arg *vs* Pro/Pro), dominant model (Arg/Arg + Arg/Pro *vs* Pro/Pro), and recessive model (Arg/Arg *vs* Arg/Pro + Pro/Pro), respectively. Stratified analyses were performed based on the source of controls, the specimens used for determining TP53 Arg72Pro genotypes and sample size (cases and controls in total). A Chi-square-based *Q*-test was performed to check the heterogeneity^[30]. If $P \geq 0.1$ was obtained in the heterogeneity test, ORs were pooled according to the fixed-effects model (the Mantel-Haenszel model)^[31], otherwise the random-effects model (the DerSimonian and Laird model) was used^[32]. One-way sensitivity analyses were performed to evaluate the stability of the meta-analysis results^[33]. The potential publication bias was estimated using Egger's linear regression test by visual inspection of the Funnel plot. $P < 0.05$ was considered statistically significant in publication bias^[34]. If publication bias existed, the Duval and Tweedie non-parametric “trim and fill” method was used to adjust for it^[35]. All statistical tests were performed with the software STATA version 10.0 (Stata Corporation, College station, TX).

RESULTS

Study characteristics

Eighteen studies were identified through literature search and selection based on the inclusion criteria. By the extraction of data, seven articles which are not case-control studies and one review article were excluded. Among the remaining 10 studies, one study^[29] was excluded due to the genotype frequencies of controls deviated from HWE. In one study^[24], two groups of controls (a high risk population and a low risk population) were used. However, the genotype frequencies of the low-risk population controls deviated from HWE. Therefore, only the high-risk population controls of this study were included in the final analysis.

The characteristics of nine eligible case-control studies are summarized in Table 1. The sample size of the 9

Arg: Arginine; Pro: Proline.

studies ranged from 89 to 2178. In total, 2114 EC cases and 3431 controls were included in the meta-analysis. Distribution of *TP53* genotype frequencies among EC cases and controls of the nine studies are shown in Table 2. The frequencies of heterozygote genotype among the cases of the studies using the specimens of exfoliated esophageal cells^[21] or tumor tissues^[23] were obviously lower than those of other studies. In studies with at least 200 samples, there was not a wide variation of Arg72 and Pro72 allele frequencies among controls, with the Arg72 allele frequencies ranging from 53% to 60%^[20,22,24,26-28]. But in studies with less than 200 samples, the control groups represented diverse frequencies of the Arg72 allele, which were 37%^[21], 48%^[23] and 59%^[25], respectively.

Meta-analysis results

When all the eligible studies were pooled into the meta-analysis, evidence was found in an association between significantly decreased EC risk and the variant genotypes of *TP53* in the dominant model (OR = 0.73, 95% CI: 0.57-0.94, *P* = 0.014, Table 3). However, significant inter-study heterogeneity existed in all genetic models (Table 3). In order to figure out the main reasons of the heterogeneity among studies and obtain exact consequence on the relationship between *TP53* Arg72Pro polymorphism and EC susceptibility, stratified analyses were then performed.

In stratified analysis according to the source of controls, significant association between reduced EC risk and *TP53* genotypes was found solely in subgroup of studies

with population-based controls in all genetic models (homozygote comparison: OR = 0.56, 95% CI: 0.47-0.66, *P* < 0.001; dominant model: OR = 0.57, 95% CI: 0.50-0.66, *P* < 0.001; recessive model: OR = 0.80, 95% CI: 0.70-0.92, *P* = 0.001; Table 3). Significantly increased EC risk, however, was observed in the subgroup of a study with different source of controls selected from population and blood donors in homozygote comparison (OR = 2.33, 95% CI: 1.03-5.24, *P* = 0.041) and recessive model (OR = 2.71, 95% CI: 1.42-5.02, *P* = 0.003, Table 3). No evidence of association was observed in studies without clear presentation of hospital-based controls or the source of controls (Table 3).

We divided the included studies into four subgroups according to the specimens used. As a result, significantly reduced EC risk was found only in subgroups where white blood cells or normal tissue were used to determine *TP53* genotypes in different genetic models (homozygote comparison: OR = 0.56, 95% CI: 0.47-0.65, *P* < 0.001; dominant model: OR = 0.58, 95% CI: 0.51-0.67, *P* < 0.001; recessive model: OR = 0.78, 95% CI: 0.68-0.88, *P* < 0.001; Table 3). Nevertheless, significantly excessive risk of EC was observed in the subgroup of a study using tumor tissue to extract genomic DNA for genotyping *TP53* by homozygote comparison and recessive model (Table 3). This study also has different sources of controls. No significant association was observed in the studies using mixed specimens of white blood cells and tumor tissues or exfoliated esophageal cells to assess *TP53* genotypes (Table 3).

We also stratified the included studies into two sub-

groups by sample size. One included studies with at least 200 participants, and the other included studies with less than 200 participants. Interestingly, studies in the former subgroup also used white blood cells or normal tissue as the specimens to assess TP53 genotypes, and significant association between reduced EC risk and TP53 genotypes was observed in all genetic models (Table 3). However, in the latter subgroup, significantly increased EC risk was found in homozygote comparison (OR = 2.21, 95% CI: 1.24-3.93, P = 0.007) and recessive model (OR = 1.73, 95% CI: 1.15-2.61, P = 0.009).

We performed the analysis only in well-designed studies with population-based controls with at least 200 participants using white blood cells or normal tissue to determine TP53 genotypes. Significantly decreased risk of EC was found in all genetic models (homozygote comparison: OR = 0.54, 95% CI: 0.46-0.64, P < 0.001; dominant model: OR = 0.56, 95% CI: 0.49-0.65, P < 0.001; recessive model: OR = 0.79, 95% CI: 0.69-0.91, P = 0.001; Figure 1).

Sensitivity analysis

A single study involved in the meta-analysis was deleted each time to reflect the effects of individual data-set on the pooled ORs, and most of the corresponding pooled ORs were not materially altered (data not shown).

Publication bias

Both Begg’s funnel plot and Egger’s test were performed to assess the publication bias of literatures. Begg’s funnel plots did not reveal any evidence of obvious asymmetry except for heterozygote comparison and dominant model in the overall meta-analysis (figures not shown). The Egger’s test results suggested that publication bias was evident in heterozygote comparison (P = 0.003) and dominant model (P = 0.004), but not evident in homozygote comparison (P = 0.058) and recessive model (P = 0.389). The Duval and Tweedie non-parametric “trim and fill” method was used to adjust for publication bias. Meta-analysis with

and without using “trim and fill” method did not draw different conclusions (data not shown), indicating that our results were statistically robust.

DISCUSSION

Since the identification of TP53 Arg72Pro polymorphism^[13], a number of studies^[20-29] have investigated the genetic effect of this polymorphism on EC susceptibility, but the results are inconclusive. This led us to undertake the present meta-analysis, which could quantify all the available data and might help us to distinguish the true from the false, to explore a more robust estimate of the effect of this polymorphism on EC risk. The main finding of our meta-analysis with 9 published studies including 2114 cases and 3431 controls is that TP53 Arg72 carriers are significantly associated with decreased EC risk, and the results of increased risk or no effect of this polymorphism on EC may be due to methodological errors such as selection bias, inappropriate specimens used for genotype assessment, or limited statistical power.

We found that the distribution of TP53 Arg72Pro genotypes in controls deviated from HWE in the study by Yang *et al*^[29], although it has a relatively large sample size including 435 cases and 550 controls. Yang *et al*^[29] reported that TP53 Arg/Arg genotype was associated with significantly increased EC risk (OR = 6.48, 95% CI: 4.65-9.03), which is contrary to our results of meta-analysis. It is well known that deviation from HWE may be due to genetic reasons including non-random mating, or the alleles reflecting recent mutations that have not reached equilibrium, as well as methodological reasons including biased selection of subjects from the population, or genotyping errors^[36,37]. In despite of the reasons of disequilibrium, the results of genetic association studies might be spurious if the controls were not in HWE^[38,39]. In order to guarantee the criteria for the eligible studies, only studies with controls in HWE were included in this meta-analysis.

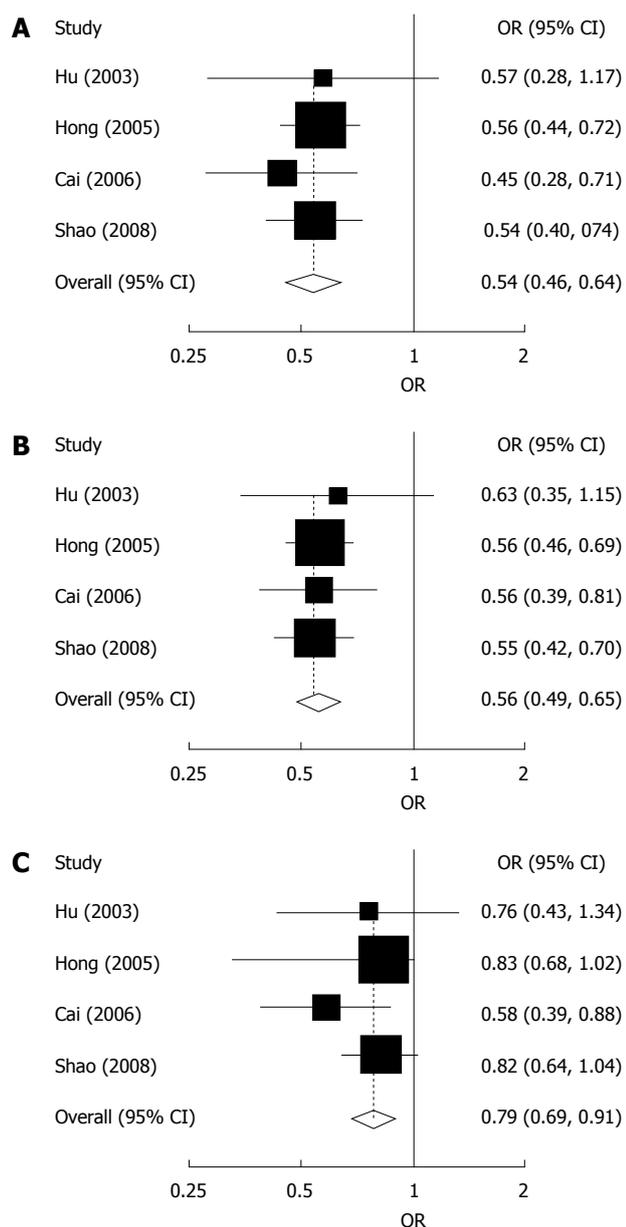

Figure 1 Forest plots for the relationship between *TP53* Arg72Pro polymorphism and esophageal cancer risk in studies with population-based controls with at least 200 participants, using white blood cells or normal tissues to determine *TP53* genotypes. A: Homozygote comparison; B: Dominant model; C: Recessive model. The first authors' surname and year of publication are given in the left part of the figure. The size of the black square corresponding to each study is proportional to the sample size. The centre of each square represents the odds ratio (OR) and the horizontal line shows the corresponding 95% CI. The pooled OR was obtained using fixed-effects model and is represented by hollow diamond, where its centre indicates the OR and its ends correspond to the 95% CI. Arg: Arginine; Pro: Proline.

In the present study, statistically significant inter-study heterogeneity of genotype effect was detected in different genetic models when all the eligible studies were pooled into the meta-analysis. Pooling despite the presence of heterogeneity may yield the mean of varying effect sizes, but the biological interpretation of such a mean and its clinical application would be very difficult^[40,41]. Therefore, it is important to explore the source of heterogeneity rather than obtaining a potentially meaningless pooled

summary measure^[42]. In order to identify the source of heterogeneity and ascertain the exact genetic effect of *TP53* Arg72Pro polymorphism on EC risk, we stratified the studies according to the source of controls, the specimens used for assessment of *TP53* genotypes and sample size. We found that the heterogeneity was remarkably decreased when the studies were divided according to the specimens used and sample size, indicating that the two factors may contribute to the observed heterogeneity.

In two of the nine included studies where the specimens used for assessment of *TP53* genotype were exfoliated esophageal cells^[21] or tumor tissues^[23], the frequencies of heterozygote genotype were obviously lower than those of other studies. This indicates that loss of heterozygosity (LOH) may exist and the distribution of *TP53* genotypes in these cases may not be the same as that in normal tissue or cells. Generally, spurious results may be obtained from genetic association studies with inappropriate material for determining genotypes^[16]. In our meta-analysis, significant association between *TP53* Arg72Pro polymorphism and reduced EC risk was not observed in subgroups using inappropriate material to determine *TP53* genotypes but only in the subgroups using white blood cells or normal tissues. Consequently, in genetic association studies, DNA from white blood cells or normal tissues should be used for determining genetic polymorphism, but not tumor tissue or exfoliated cells, in which LOH is a frequent event^[43,44].

Lacking sufficient statistical power is an unnegligible problem in genetic association studies detecting the possible risk for the polymorphism^[45]. It is likely that most genetic polymorphisms represent modest effects on disease susceptibility. An adequately powered study to detect single genetic associations would typically require a relatively large sample size, depending on the prevalence of the implicated polymorphism and the exact OR. Some of the eligible studies for our meta-analysis had a very small sample size and may have limited statistical power to detect a slight effect or may have generated a fluctuated risk estimate^[46,47]. Carefully conducted meta-analysis of these data is essential to clarify whether these associations are true or not. Through stratified analysis, we found significantly increased EC risk associated with *TP53* genotypes in subgroups of the studies with less than 200 participants, which was contrary to the results in subgroup of the studies with at least 200 participants. Given that all of the studies with a sample size of less than 200 used inappropriate specimens for determining *TP53* genotypes, the results may be unreliable.

Some limitations of this meta-analysis should be addressed. Firstly, publication bias was detected for heterozygote comparison and dominant model in overall meta-analysis. The potential reason may be that results from small studies were more likely to be published if there was positive data reported. Therefore, well-designed studies with large sample size are required. Secondly, in the subgroup analyses by ethnicity, the included studies involved only Asians and Africans. Data concerning other ethnicities such as Caucasians were not found. For Africans, only

one study was conducted, with a small sample size of 73 cases and 115 controls, which has not enough statistical power to find the real association. Thus, additional studies are warranted to evaluate the effect of this functional polymorphism on EC risk in different ethnicities, especially in Africans and Caucasians. Thirdly, lack of original data, including data of genotypes and environmental risk factors, of the included studies limited our further evaluation of potential gene-environment interaction, especially the interaction between human papillomavirus (HPV) infection and TP53 Arg72Pro polymorphism, which was investigated in several studies^[25,48-50]. However, unlike HPV infection in cervical carcinoma, the role of HPV in the etiology of EC remains controversial^[8]. A more precise analysis should be conducted if individual data are available.

Despite some limitations, the results of this meta-analysis still suggest that TP53 Arg72 allele is a protective factor for EC. The significantly reduced EC risk was found only in subgroup analyses of well-designed studies. Therefore, it is necessary to conduct large-sample studies using appropriate materials for assessment of genotypes, as well as homogeneous EC patients and unbiased selected controls. Such studies taking these factors into account may eventually lead to a better and comprehensive understanding of the association between TP53 Arg72pro polymorphism and EC risk.

COMMENTS

Background

Esophageal cancer (EC) is the eighth most common cancer and sixth most deadly cancer worldwide. A common polymorphism of TP53 at the 72nd amino acid residue, with an arginine (Arg) to proline (Pro) change because of a G→C transverse has been implicated as a risk factor for EC, but individual studies have been inconclusive or controversial.

Research frontiers

A number of studies have reported the role of TP53 Arg72Pro polymorphism in cancers such as cervical cancer, lung cancer, breast cancer, and gastric cancer, but the association of TP53 polymorphism with EC is not fully understood.

Innovations and breakthroughs

The present study demonstrated that TP53 Arg72 carriers are significantly associated with decreased EC risk, and suggested that increased risk or no effect of Arg72 variant on EC reported may be due to methodological errors such as selection bias, inappropriate specimens used for genotype assessment, or limited statistical power.

Applications

In this report, the association between TP53 Arg72Pro polymorphism and EC risk was observed, and the Arg72 allele decreased the EC risk, which is meaningful to early diagnosis, prevention and individual-based treatment of EC. Therefore, Arg72Pro polymorphism of the TP53 gene might be a potential therapeutic target for EC.

Terminology

TP53 is a major regulator of the cellular response to stress and serves as a tumor suppressor by inducing cell cycle arrest or apoptosis. Inactivation of the TP53 signaling pathway has been seen in most human cancers and polymorphisms of TP53 have also been reported to be the possible risk factors for some kinds of tumors.

Peer review

This study is an interesting meta-analysis on the association of TP53 ArgPro polymorphism with EC risk. Out of the 9 studies that survived the selection criteria, they found that TP53 Arg72 carriers were significantly associated with decreased EC risk. The authors concluded that previous reports of increased risk or no effect of this polymorphism on EC may be due to methodological er-

rors such as selection bias, inappropriate specimen or limited statistical power and they give guidelines on how to avoid these pitfalls.

As well as immunohistochemical detection. The cells with eosinophilic inclusions stained positive for CD138, CD79a, and κ and lambda light chains, which confirmed plasma cell origin. In particular, κ and lambda light chains showed a polyclonal origin and the patient was negative for immunological dyscrasia. The histological observations were confirmed by ultrastructural examination. The cases reported in the literature associated with *H. pylori* infection have shown regression of plasma cells after eradication of *H. pylori*. Nothing is known about the progression of *H. pylori*-negative cases. The unusual morphological appearance of this type of chronic gastritis should not be misinterpreted during routine examination, and it should be distinguished from other common forms of chronic gastritis. It is mandatory to exclude neoplastic diseases such as gastric carcinoma, lymphoma and plasmacytoma by immunohistochemistry and electron microscopy, which can help with differential diagnosis. The long-term effects of plasma cells hyperactivation are still unknown, because cases of gastric tumor that originated in patients affected by Russell body gastritis have not been described in the literature. We are of the opinion that these patients should be scheduled for endoscopic surveillance.

INTRODUCTION

Russell body gastritis is an unusual form of chronic gastritis. Its distinctive histological feature is permeation of the lamina propria by plasma cells (called Mott cells) that contain eosinophilic cytoplasmic inclusions (Russell bodies), which displace the nuclei to the periphery of the cell^[1]. Patients generally present with non-specific symptoms, such as epigastric pain, dyspepsia and nausea, which suggests the presence of gastric inflammation. In the majority of the reported cases, concomitant infection with *Helicobacter pylori* (*H. pylori*) has been documented, which suggests plasma cell infiltration as the natural consequence of the infection and antigenic stimulation^[2-6], or immunosuppression as in HIV infection^[7,8] and Epstein-Barr virus-associated carcinoma^[9].

We report a case of Russell body gastritis not associated with *H. pylori* infection as rarely observed previously^[7,10].

CASE REPORT

A 78-year-old female patient was admitted to the Gastroenterology Unit of the Fondazione IRCCS Cà-Granda Ospedale Maggiore Policlinico to undergo esophagogastroduodenoscopy (EGDS) for epigastric pain. EGDS showed a hyperemic gastric mucosa, and biopsies were taken from the antral region and the esophagogastric junction. Histological examination showed moderate chronic gastritis in the antral region with no polymorphonuclear neutrophil activity, glandular atrophy of the gastric mucosa, or intestinal metaplasia, according to Sydney classification system^[11].

The lamina propria of the gastroesophageal junction mucosa showed the presence of cells with hyaline pink bodies that were periodic acid-Schiff (PAS)-positive and PAS-diastase-resistant (Figure 1A and B). No mitotic activity or atypia was observed. Giemsa staining for *H. pylori* infection in the antral and cardiac regions was negative, as was immunohistochemical detection.

The cells with eosinophilic inclusions stained positive for CD138 (Figure 1C), CD79a, and κ and lambda light chains, and negative for cytokeratin pool and leukocyte common antigen. κ and lambda light chains showed a polyclonal origin of plasma cells. Evaluation for immunological dyscrasia was negative. Ultrastructural examination showed the presence of plasma cells with an abundance of round and electron-dense material, up to 5 μ m in diameter, in the rough endoplasmic reticulum (RER) (Figure 1D). These findings were suggestive of a diagnosis of Russell body gastritis.

The patient performed a 13C urea breath test (UBT), which gave a negative result; as did abdominal ultrasonographic examination, chest X-ray, electrocardiographic study and routine biochemical analysis. In the absence of confirmed *H. pylori* infection, the patient was treated with proton pump inhibitors, which led to resolution of epigastric pain, and long-term clinical endoscopic follow-up was scheduled.

DISCUSSION

The first case of Russell body gastritis was described in 1998, when Tazawa and Tsutsumi reported a localized accumulation of plasma cells with Russell bodies in the gastric mucosa, in association with *H. pylori* infection^[3].

Many authors have suggested that chronic antigenic stimulation caused by *H. pylori* infection can result in overproduction of immunoglobulins by plasma cells. In contrast with the majority of case reports that have been positive for *H. pylori*^[1-3,5,6,8], our patient, at the time of examination, was negative by histology and UBT. Although we could not exclude a precedent infection, it is possible to hypothesize a different etiology for Russell body gastritis, as in the case described by Erbersdobler *et al*^[10], which was associated with ethanol and analgesic abuse and a history of fungal esophagitis. Recently, vacA and cagA *H. pylori* genotypes, which are characterized by increased pathogenicity, have been associated with the development of Russell bodies and Mott cells in the antral mucosa^[12]. However, we think that a direct link between *H. pylori* infection and Mott cells in the gastric mucosa has yet to be demonstrated because the high frequency of *H. pylori* infection in western countries is not associated with an increase in Russell body gastritis, which is still a rare event.

As in our patient, subjects affected by Russell body gastritis are generally women, from 47 to 80 years old (median: 60 years), with non-specific symptoms (abdominal and epigastric pain, dyspepsia and/or nausea) that overlap with those of irritable bowel syndrome, and without specific endoscopic markers. These could be the reasons for the rare diagnosis of Russell body gastritis, which is probably underestimated.

Russell body gastritis must be clearly differentiated from neoplastic diseases, such as signet ring carcinoma, MALTooma and plasmacytoma^[3]. Most often, the differential diagnosis is with monoclonal gammopathy of undetermined significance, which develops after chronic antigen stimulation (in the present case, *H. pylori* antigens) in subjects with a genetic predisposition. Immunohistochemistry is essential to exclude a monoclonal origin of these plasma cells^[4]. Absence of nuclear atypia and mitosis, lack of lymphoepithelial lesions, and a polyclonal pattern of the plasma cells are factors that favor diagnosis of Russell body gastritis when negative staining for cytokeratins rules out carcinoma.

The cases reported in literature associated with *H. pylori* infection show that eradication of *H. pylori* leads to regression of the activated plasma cells, with the disappearance of Russell bodies and Mott cells^[6]. Nothing is known about the progression of *H. pylori*-negative cases.

Russell body gastritis is an unusual and rare form of chronic gastritis; it can be associated with *H. pylori* infection, and it can be misinterpreted during ordinary routine examination.

The peculiar presence of Mott cells in the lamina propria of the gastric mucosa needs to be distinguished from other common forms of chronic gastritis, and it is

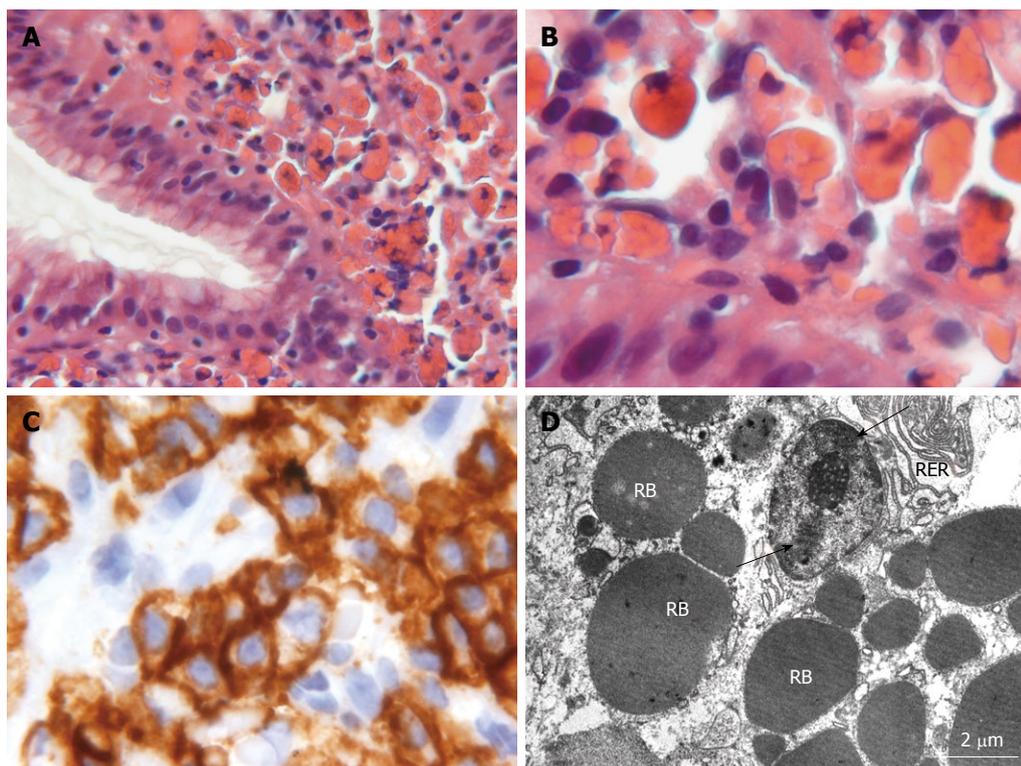

Figure 1 Histological, immunohistochemical and ultrastructural features of Russell body gastritis. A: Gastroesophageal junction sample showing monomorphous cells with eosinophilic inclusions: Russell bodies; B: Higher magnification of plasma cells with crystalline inclusions; C: Immunohistochemical reactivity of plasma cells for CD138 antibody; D: Electron micrograph of a plasma cell with typical condensation pattern of nuclear chromatin (arrows) and well-developed rough endoplasmic reticulum (RER). Several Russell bodies (RB) with 1-5 μ m diameter are present in dilated RER cisternae.

mandatory to exclude neoplastic diseases such as gastric carcinoma, lymphoma and plasmocytoma by means of immunohistochemistry and electron microscopy, which can help in the differential diagnosis.

The long-term effects of plasma cell hyperactivation are still unknown. Gastric tumors that originate in patients with Russell body gastritis are not described in the literature; however, since the etiopathogenesis of this entity is not completely understood, we are of the opinion that these patients should be scheduled for endoscopic surveillance.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^{1,2b}". If references are cited directly in the text, they should be put together within the text, for example, "From references^{19,22-24}, we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make com-

ments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

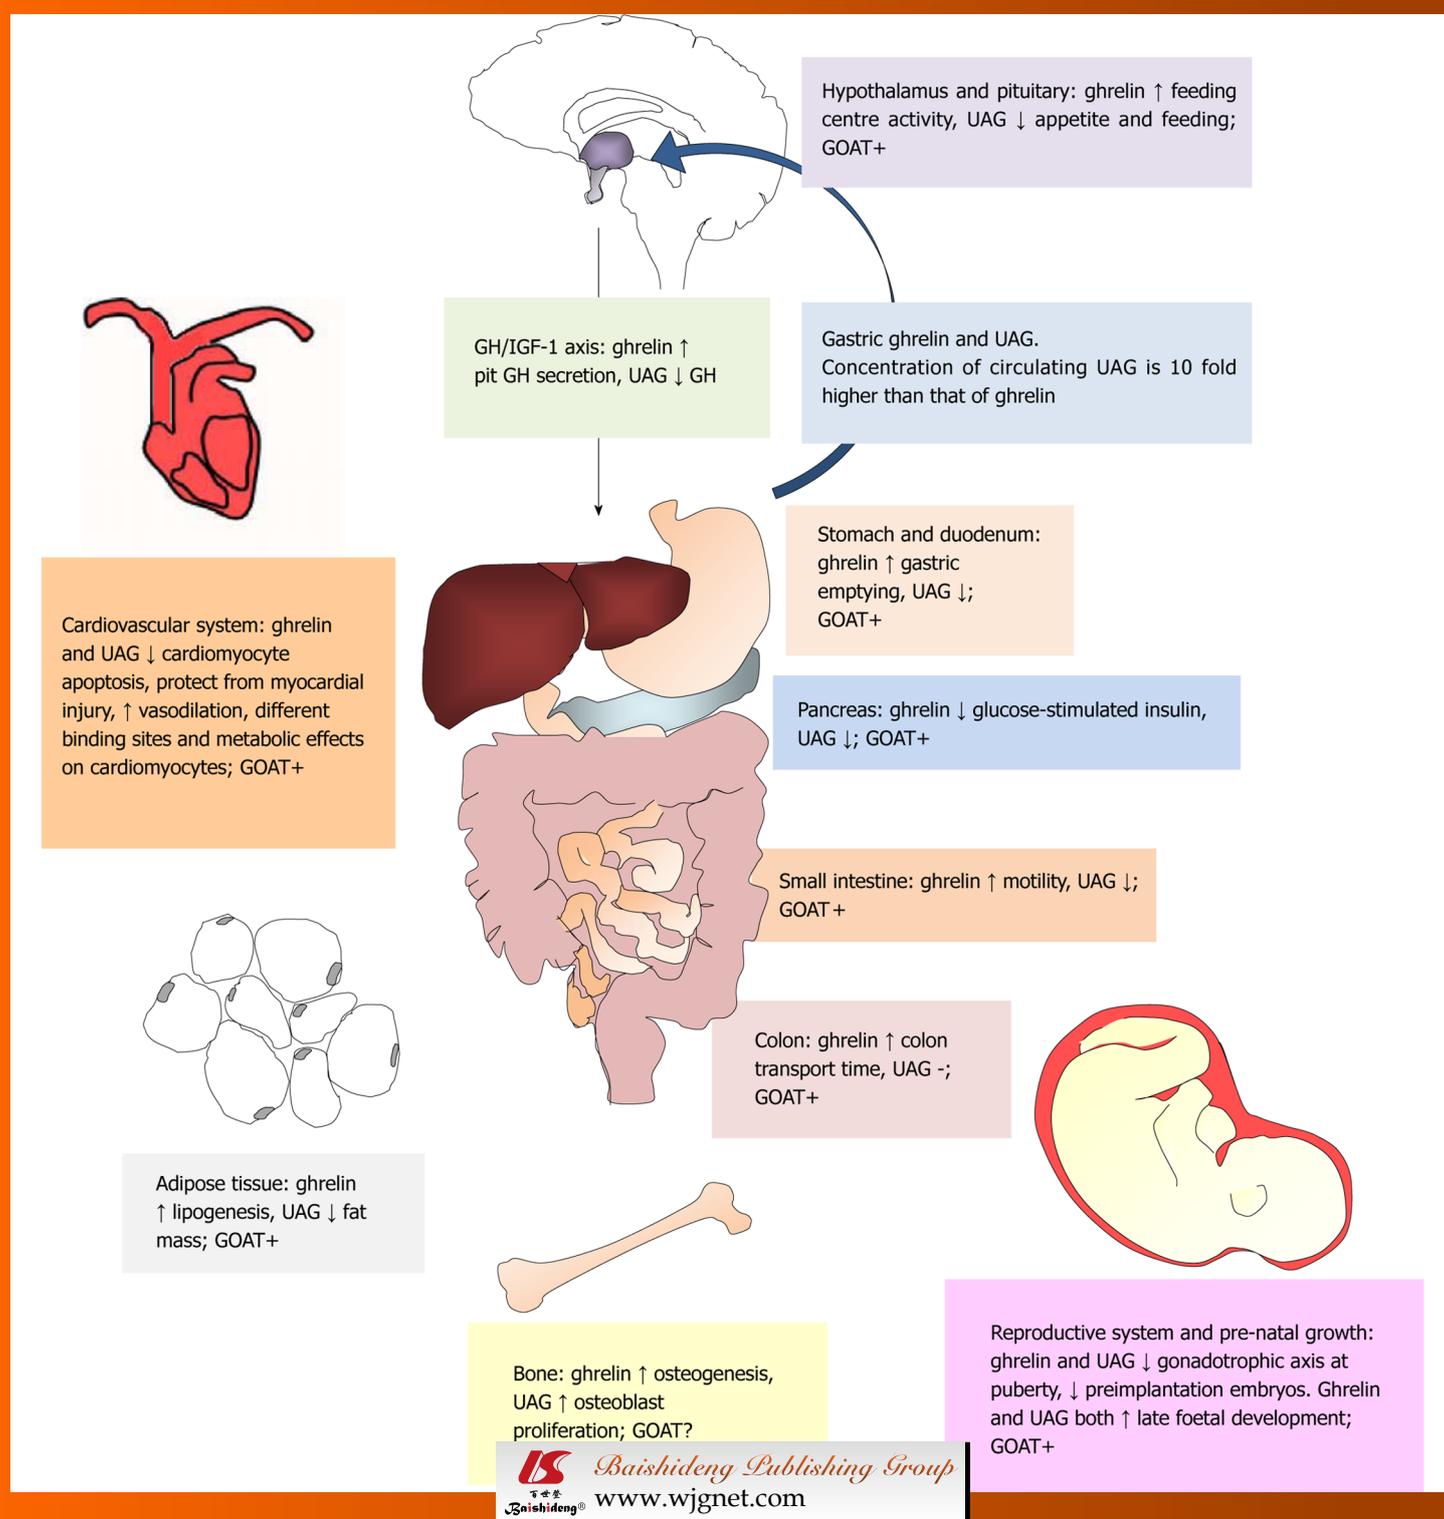

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Ascites is one of the major complications of liver cirrhosis and is associated with a poor prognosis. It is important to distinguish noncirrhotic from cirrhotic causes of ascites to guide therapy in patients with noncirrhotic ascites. Mild to moderate ascites is treated by salt restriction and diuretic therapy. The diuretic of choice is spironolactone. A combination treatment with furosemide might be necessary in patients who do not respond to spironolactone alone. Tense ascites is treated by paracentesis, followed by albumin infusion and diuretic therapy. Treatment options for refractory ascites include repeated paracentesis and transjugular intrahepatic portosystemic shunt placement in patients with a preserved liver function. Potential complications of ascites are spontaneous bacterial peritonitis (SBP) and hepatorenal syndrome (HRS). SBP is diagnosed by an ascitic neutrophil count > 250 cells/mm³ and is treated with antibiotics. Patients who survive a first episode of SBP or with a low protein concentration in the ascitic fluid require an antibiotic prophylaxis. The prognosis of untreated HRS type 1 is grave. Treatment consists of a combination of terlipressin and albumin. Hemodialysis might serve in selected patients as a bridging therapy to liver transplantation. Liver transplantation should be considered in all patients with ascites and liver cirrhosis.

INTRODUCTION

Ascites is one of the major complications of liver cirrhosis and portal hypertension. Within 10 years of the diagnosis of cirrhosis, more than 50% of patients develop ascites^[1]. The development of ascites is associated with a poor prognosis, with a mortality of 15% at one-year and 44% at five-year follow-up, respectively^[2]. Therefore, patients with ascites should be considered for liver transplantation, preferably before the development of renal dysfunction^[1]. This article will give a concise overview of the diagnosis and treatment of patients with ascites in liver cirrhosis and the management of the most common complications of ascites.

EVALUATION AND DIAGNOSIS

Since 15% of patients with liver cirrhosis develop ascites of non-hepatic origin, the cause of new-onset ascites has to be evaluated in all patients^[3]. The most important diagnostic measure is diagnostic abdominal paracentesis. Paracentesis is considered a safe procedure even in patients with an abnormal prothrombin time, with an overall complication rate of not more than 1%^[4]. More serious complications such as bowel perforation or bleeding into the abdominal cavity occur in less than one in 1000 paracenteses^[5]. Data supporting cut-off values for

coagulation parameters are not available^[6]. One study which included 1100 large-volume paracenteses did not show hemorrhagic complications despite platelet counts as low as 19 g/L and international normalized ratios as high as 8.7^[7]. The routine prophylactic use of fresh frozen plasma or platelets before paracentesis is therefore not recommended^[6].

Ascitic fluid analysis should include total protein concentration, a neutrophil count and inoculation of ascites into blood culture bottles at the bedside. Determination of ascitic protein concentration is necessary to identify patients who are at increased risk for the development of spontaneous bacterial peritonitis (SBP), since a protein concentration below 1.5 g/dL is a risk factor for the development of SBP^[8]. Spontaneous bacterial peritonitis is defined as an ascitic neutrophil count of more than 0.25 g/L (see "treatment of SBP") and inoculation of ascitic fluid in blood culture flasks at the bedside helps to detect bacteria in the ascitic fluid^[9]. Additional tests are only necessary in patients in whom other causes of ascites are in the differential diagnosis^[10].

In patients in whom a cause of ascites different from liver cirrhosis is suspected, the determination of the serum-ascites-albumin gradient (SAAG) is useful. The SAAG is ≥ 1.1 g/dL in ascites due to portal hypertension with an accuracy of 97%^[11].

MANAGEMENT OF UNCOMPLICATED ASCITES

Uncomplicated ascites is defined as the absence of complications including refractory ascites, SBP, marked hyponatremia or hepatorenal syndrome (HRS)^[10].

There are no defined criteria as to when treatment of ascites should be initiated. Patients with clinically inapparent ascites usually do not require a specific therapy. It is recommended that patients with clinically evident and symptomatic ascites should be treated.

In patients with alcoholic liver cirrhosis, the most important measure is alcohol abstinence. In the majority of patients with alcoholic liver disease, alcohol abstinence results in an improvement of liver function and ascites^[12]. Also, decompensated cirrhosis due to chronic hepatitis B infection or autoimmune hepatitis often shows a marked improvement in response to antiviral or immunosuppressive treatment, respectively^[13].

Patients with uncomplicated mild or moderate ascites do not require hospitalization and can be treated as outpatients. Patients with ascites have a positive sodium balance, i.e. sodium excretion is low relative to sodium intake. Hence, the mainstay of ascites therapy is sodium restriction and diuretic therapy. Sodium intake should be restricted to 5-6 g/d (83-100 mmol/d NaCl)^[14-16]. A more stringent restriction is not recommended since this diet is distasteful and may worsen the malnutrition that is often present in patients with liver cirrhosis^[16]. A French study showed that a more stringent sodium restriction of 21 mmol/d led to a faster mobilization of ascites in the first 14 d, but revealed

no difference after 90 d^[17]. Another study found no benefit in patients treated with a strict sodium restriction of 50 mmol/d compared to patients with a moderate sodium restriction of 120 mmol/d^[18].

Theoretically, upright posture aggravates sodium retention by an increase of plasma renin activity and has led to the recommendation of bed rest. However, there are no clinical studies that provide evidence that bed rest actually improves ascites^[6].

Therapy of ascites that is based solely on sodium restriction is only applicable in patients with a 24 h sodium excretion of more than 80 mmol (90 mmol dietary intake - 10 mmol loss by sweat and feces) since an adequate sodium excretion is the requirement for a negative sodium balance. Patients with a 24 h sodium excretion less than 80 mmol/24 h need diuretic therapy.

Hyponatremia is a common finding in patients with ascites and liver cirrhosis, but a study including 997 patients with liver cirrhosis found severe hyponatremia (≤ 125 mmol/L) in only 6.9% of patients^[19]. Another study, including 753 patients evaluated for liver transplantation, found hyponatremia of less than 130 mmol/L in 8% of patients and an increase in the risk of death as sodium decreased to between 135 and 120 mmol/L^[20]. Since the total body sodium is not decreased in patients with ascites and hyponatremia (dilution hyponatremia), rapid correction of serum sodium is not indicated but has the risk of severe complications^[21]. Fluid restriction is recommended in patients with severe hyponatremia (120-125 mmol/L)^[6], but clinical studies that have evaluated the efficacy of fluid restriction, or the extent of hyponatremia when fluid restriction should be initiated, are lacking.

MEDICAL THERAPY

The activation of the renin-aldosterone-angiotensin-system in patients with liver cirrhosis causes hyperaldosteronism and increased reabsorption of sodium along the distal tubule^[22]. Therefore, aldosterone antagonists like spironolactone or its active metabolite potassium canrenoate are considered the diuretics of choice^[23]. Patients with mild to moderate ascites are treated with a monotherapy of spironolactone. The starting dose is 100-200 mg/d^[24]. A monotherapy with a loop diuretic like furosemide is less effective compared to spironolactone and is not recommended^[23]. If the response to 200 mg spironolactone within the first two weeks is not sufficient, furosemide with an initial dose of 20-40 mg/d is added. If necessary, the spironolactone dose is increased stepwise up to 400 mg/d and the furosemide dose is increased up to 160 mg/d^[22,23,25].

The daily weight loss in patients with or without peripheral edema should not exceed 1000 g or 500 g, respectively^[26]. A sufficient diuretic effect is achieved when only small amounts of ascites are left and peripheral edema has completely resolved.

It is generally recommended to apply furosemide orally, since intravenous administration bears the risk of azotemia^[27,28]. A combination therapy of spironolactone and

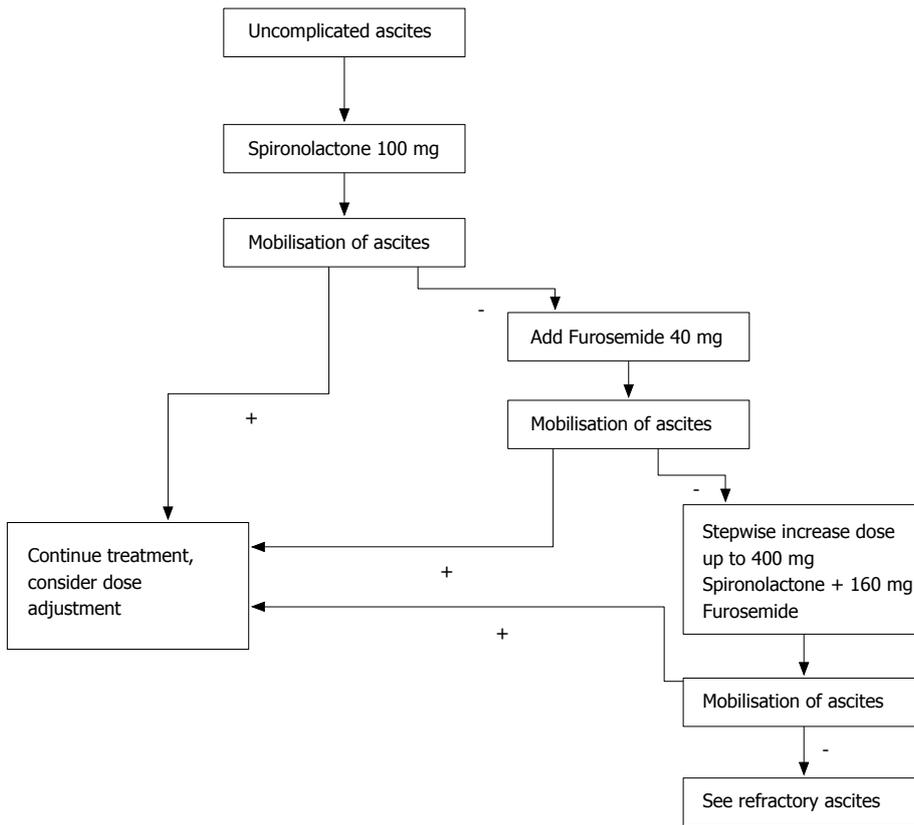

Figure 1 Treatment algorithm for the diuretic treatment of patients with uncomplicated ascites.

furosemide shortens the response time to diuretic therapy and minimizes adverse effects such as hyperkalemia^[29]. Angeli and co-workers compared the sequential therapy with potassium canrenoate and furosemide with the initial combination therapy of these two drugs^[30]. Patients receiving the sequential therapy were treated with an initial dose of 200 mg potassium canrenoate that was increased to 400 mg/d. Non-responders to the initial therapy were treated with 400 mg/d of potassium canrenoate and furosemide at an initial dose of 50 mg/d that was increased to 150 mg/d. Patients receiving the combination therapy were treated with an initial dose of 200 mg/d potassium canrenoate and 50 mg of furosemide that was increased to 400 mg/d and 150 mg/d, respectively. A sufficient treatment response was achieved in both treatment groups. However, there were more adverse effects of diuretic treatment (e.g. hyperkalemia) in the patients receiving the sequential therapy. In contrast to this study, another study found no difference comparing sequential and combination therapy^[31]. Possible explanations for these conflicting results are the different patient populations included in the studies. Angeli *et al.*^[30] included patients with recidivant ascites and reduction in the glomerular filtration rate whereas in the study of Santos *et al.*^[31], the majority of patients had newly diagnosed ascites.

An established scheme for an initial combination therapy is 100 mg spironolactone and 40 mg furosemide per day given in the morning^[32]. If this dosage is not sufficient, a stepwise increase keeping the spironolactone/fu-

rosemid ratio (e.g. 200 mg spironolactone/80 mg furosemide) is possible. The combination of spironolactone and furosemide lowers the risk of a spironolactone-induced hyperkalemia.

The combination of sodium restriction, spironolactone and furosemide achieves a sufficient therapy of ascites in patients with liver cirrhosis in 90% of cases^[18,23,25]. Figure 1 shows an algorithm for the diuretic treatment of patients with uncomplicated ascites.

Several studies have evaluated the newer loop-diuretic torasemide in patients with liver cirrhosis and ascites^[33-35]. Torasemide was shown to be at least as effective and safe as furosemide and is considered an alternative in the treatment of ascites^[33-35].

Amiloride is an alternative to spironolactone in patients with painful gynecomastia. Amiloride is given in a dose of 10-40 mg/d but is less effective than potassium canrenoate^[36].

Complications of diuretic therapy include hepatic encephalopathy, renal failure, gynecomastia, electrolyte disturbances such as hyponatremia, hypo- or hyperkalemia, as well as muscle cramps^[22,23,30,31,36]. To minimize these complications, it is generally advised to reduce the dosage of diuretic drugs after the mobilization of ascites. Complications of diuretic therapy are most frequent in the first weeks after initiation of therapy^[30].

A common complication of diuretic therapy is hyponatremia. The level of hyponatremia at which diuretic treatment should be stopped is a subject of discussion. It

is generally agreed that diuretics should be paused when the serum sodium is less than 120-125 mmol/L^[6].

THErapy OF REFRACTORY ASCITES

Refractory ascites is defined as ascites that does not respond to sodium restriction and high-dose diuretic treatment (400 mg/d spironolactone and 160 mg/d furosemide) or that reoccurs rapidly after therapeutic paracentesis^[3]. About 10% of patients with cirrhosis and ascites are considered to have refractory ascites^[6]. The median survival of patients with ascites refractory to medical treatment is approximately six months^[3,37-39].

Possible treatment options for refractory ascites include large volume paracentesis (LVP), transjugular intrahepatic portosystemic shunt (TIPS) and liver transplantation.

Large volume paracentesis

Large volume paracentesis is the treatment of choice for patients with tense ascites. It is considered a safe procedure^[40] and complication rates are not higher than in diagnostic paracentesis^[4,7]. The risk of bleeding is generally low and a relationship between the degree of coagulopathy and the risk of bleeding is not evident^[40]. Hence, there are no data that support the prophylactic administration of pooled platelets and/or fresh frozen plasma prior to paracentesis. Nevertheless, in patients with severe coagulopathy, paracentesis should be performed with caution. Paracentesis is performed under sterile conditions. If ultrasound is available, it should be used to localize the best puncture site to minimize the risk of bowel perforation.

The most important complication following LVP is paracentesis-induced circulatory dysfunction (PICD)^[41-43]. This is caused by a depletion of the effective central blood volume leading to a further stimulation of vasoconstrictor systems. Post-paracentesis circulatory dysfunction is characterized by a deterioration of renal function that can ultimately culminate in hepatorenal syndrome in up to 20% of patients^[42]. A rapid re-accumulation of ascites^[44], hyponatremia, as well as an increase in portal pressure^[45], are additional consequences. PICD is associated with an increase in mortality^[41].

Paracentesis of not more than 5 L can safely be conducted without post-paracentesis colloid infusions and the risk of PICD^[46]. If a paracentesis of more than 5 L is performed, the administration of albumin is advisable^[47]. However, it has to be kept in mind that albumin is costly, and that studies that are large enough to demonstrate decreased survival in patients who are given no plasma expander compared to patients given albumin are lacking^[41]. There are no studies that have evaluated the appropriate dose of albumin after paracentesis. In the available studies, 5 to 10 g of albumin per litre of removed ascites have been given^[41,42,47,48]. Hence, a dose of 6-8 g albumin per litre of removed ascites seems appropriate^[6]. Dextran-70 and polygeline as alternative plasma expanders have been compared to albumin for the prevention of PICD after LVP but have been shown to be less effective^[41]. However,

a benefit in survival in favor of albumin over dextran-70, polygeline and saline was not shown in three trials^[41,49,50]. Albumin should be administered slowly after the completion of paracentesis to reduce the risk of a volume overload.

Large volume paracentesis *per se* does not positively influence renal sodium and water retention. To prevent the re-accumulation of ascites after LVP, sodium restriction and diuretic treatment are necessary^[51].

TIPS

TIPS provides a side-to-side porto-caval shunt. It is usually placed under local anesthesia by transhepatic puncture of the (usually) right main branch of the portal vein using an approach from a hepatic vein. After the connection between the hepatic and portal vein is established, the tract is dilated and a stent is placed^[52].

Contraindications for TIPS in the therapy of recurrent ascites include advanced liver disease (bilirubin > 5 mg/dL), episodic or persistent hepatic encephalopathy, cardiac or respiratory failure and hepatocellular carcinoma^[53-57].

TIPS insertion causes an increase in right atrial and pulmonary artery pressure as well as an increase in cardiac output, a reduction of systemic vascular resistance, a reduction of effective arterial blood volume and, most importantly, a reduction of portal pressure^[52,58-67]. Whereas the effect on renal function (increased sodium excretion and increased glomerular filtration rate) persists, the increase in cardiac output tends to return to pre-TIPS levels^[59-63,67].

Compared to repeated LVP, TIPS is more effective in the therapy of ascites^[53,55,68], but the effect on mortality is less clear. Whereas two studies showed no difference in mortality comparing paracentesis and TIPS^[53,57], another two studies revealed decreased mortality in patients receiving TIPS^[55,56]. A meta-analysis based on individual patient data from four randomized trials showed that TIPS in patients with refractory ascites improved transplant-free survival^[68].

A frequent complication after TIPS insertion is hepatic encephalopathy, which occurs in 30%-50% of patients^[69,70], but seems to be less frequent in carefully selected patients with preserved liver function. Other complications are shunt thrombosis and shunt stenosis^[69,71]. Shunt thrombosis and shunt stenosis were shown to be less frequent in polytetrafluoroethylene (e-PTFE) coated stents compared to non-coated stents in one study^[72]. A retrospective multicenter study showed that the use of e-PTFE covered stents is associated with a higher 2-year survival compared to non-covered stents^[73].

Figure 2 shows an algorithm for the treatment of refractory ascites.

HEPATORENAL SYNDROME

The occurrence of renal failure in patients with advanced liver disease in the absence of an identifiable cause of renal failure is defined as hepatorenal syndrome^[3]. Therefore, it is essential to rule out other possible causes of renal fail-

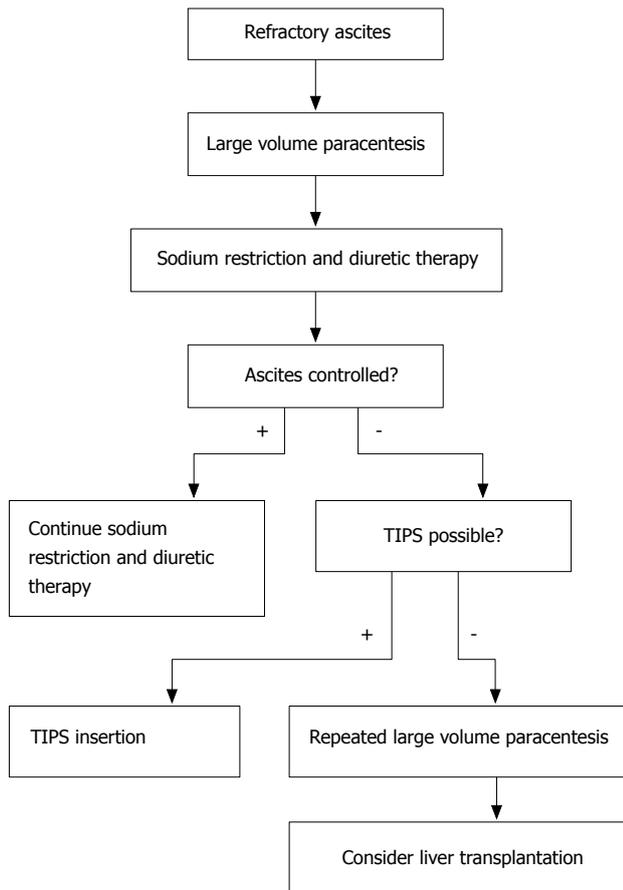

Figure 2 Treatment algorithm for the treatment of patients with refractory ascites. TIPS: Transjugular intrahepatic portosystemic shunt.

ure before the diagnosis of hepatorenal syndrome (HRS) is made. In 1994, the International Ascites Club defined criteria for the diagnosis of hepatorenal syndrome^[3] that were modified in 2007^[74]. The modified criteria include: (1) cirrhotic liver disease with ascites; (2) a serum creatinine > 1.5 mg/dL; (3) no improvement of serum creatinine (decrease to \leq 1.5 mg/dL) after at least 2 d with diuretic withdrawal and volume expansion with albumin (1 g/kg body weight/d up to 100 g/d); (4) absence of shock; (5) no current or recent treatment with nephrotoxic drugs; and (6) absence of parenchymal kidney disease^[74]. According to the progression of renal failure, two types of HRS are defined: type 1 is rapidly progressive with a doubling of the initial serum creatinine to > 2.5 mg/dL or a 50% reduction of the initial 24-h creatinine clearance to < 20 mL/min in less than 2 wk. Patients with HRS type 2 do not have a rapidly progressive course^[74].

HRS type 1 often develops in temporal relationship with a precipitating factor like infection (e.g. spontaneous bacterial peritonitis)^[75,81] or severe alcoholic hepatitis in patients with advanced cirrhosis. The prognosis of all patients with HRS is poor with a median survival of approximately three months^[79,80]. The prognosis of patients with untreated HRS type 1 is even worse, with a median survival of only one month^[81].

Treatment should be initiated immediately after the diagnosis is made to prevent further deterioration of renal

function. Several treatment options of HRS are available: drug therapy, hemodialysis, TIPS and liver transplantation.

Drug therapy of HRS consists of the application of vasopressors in combination with albumin.

One randomized, controlled study compared the effect of noradrenalin as a continuous intravenous infusion in combination with albumin *vs* terlipressin and albumin in 40 patients with HRS type 1^[82]. The study did not reveal a significant difference in short-term survival between the two groups. Two studies demonstrated that treatment with octreotide alone is not successful^[83,84] but that a combination with the vasopressor midodrine is required. Two other studies investigated the effect of octreotide and midodrine in combination with albumin^[85,86]. One small study compared octreotide 200 μ g subcutaneously three times a day, midodrine up to 12.5 mg/d orally and albumin 10-20 g/d with dopamine plus albumin^[85]. The results in the octreotide/midodrine group were superior to those in the dopamine group. A larger, retrospective study compared a combination treatment with octreotide/midodrine and albumin with a treatment with albumin only^[86]. The mortality rate of the patients treated with the combination of octreotide, midodrine and albumin was lower than the mortality rate of the patients treated with albumin alone (43% *vs* 71%, respectively). More data are available with regard to the vasoconstrictor terlipressin in the treatment of HRS type 1. Treatment with terlipressin is started with an initial dose of 1 mg 4-6 times a day and is given in combination with albumin (1 g/kg body weight on day 1, followed by 40 g/d)^[87]. If a reduction of serum creatinine of at least 25% is not achieved after three days of therapy, the dose is increased to a maximum of 2 mg 4-6 times a day. The treatment is continued until a reduction of serum creatinine below 1.5 mg/dL is achieved. The median response time is around two weeks^[88]. Patients with a better liver function and an early increase in arterial pressure after initiation of treatment have a higher probability of treatment response^[88]. Treatment with terlipressin is successful in 40%-50% of patients^[89,90]. Cardiovascular or ischemic complications are the most important adverse effects of terlipressin treatment^[80,89]. A meta-analysis of randomized trials regarding terlipressin and other vasoactive drugs showed an improved short-term survival for the patients treated with terlipressin^[90].

Two small studies evaluated the effect of terlipressin in patients with HRS type 2^[91,92]. Both studies showed an improvement of renal function with terlipressin treatment^[91,92].

TIPS has been shown to improve renal function in HRS type 1 patients in two studies^[60,93]. However, the results of these studies might be biased since only patients with a maintained liver function underwent TIPS insertion. In addition, TIPS insertion is beneficial in patients with HRS type 2^[53].

Few data are available on the role of hemodialysis in patients with HRS type 1^[94,95]. Hemodialysis seems to be effective, but studies comparing hemodialysis with medical treatment or TIPS are lacking. Hence, hemodialysis remains a therapy option in selected patients with electrolyte

disturbances, severe acidosis or volume overload and as a bridging therapy in patients awaiting liver transplantation.

The treatment option of choice for patients with HRS type 1 and HRS type 2 is liver transplantation^[96]. However, the survival rate of 65% is low compared to other cirrhotic patients who have undergone liver transplantation. In addition, the mortality rate on the waiting list for liver transplantation of patients with HRS is higher than for patients with cirrhosis without HRS. Combined liver-kidney transplantation is usually not necessary. Only patients who have been on hemodialysis for more than 12 wk might be considered for combined liver-kidney transplantation as renal function might irreversibly deteriorate in patients with HRS and long-term hemodialysis^[97,98].

SPONTANEOUS BACTERIAL PERITONITIS

Spontaneous bacterial peritonitis (SBP) is a bacterial infection of the peritoneal cavity in patients with cirrhosis and ascites^[99-101]. All patients with cirrhosis and ascites are at risk of developing SBP. Symptoms are often unspecific and include signs of peritonitis, clinical and laboratory signs of inflammation, deterioration of liver function, gastrointestinal bleeding and hepatic encephalopathy^[102-104]. The prevalence in hospitalized patients is approximately 10% and higher than in outpatients (1.5%-3.5%)^[102,103].

The diagnosis of SBP is based on a positive ascitic fluid bacterial culture and an elevated ascitic fluid neutrophil count in patients without an evident source of infection^[105]. Ascitic bacterial culture is negative in more than 50% of patients with suspected SBP and an elevated neutrophil count^[8,100,101,106]. If bacteria are found in the culture, the most common bacteria include *E. coli* as well as streptococcus species and enterococci^[99-101,106].

A neutrophil count of more than 250 cells/mm³ (0.25 × 10⁹/L) is considered diagnostic of SBP^[107]. An ascitic neutrophil count ≥ 250 cells/mm³ but with negative cultures is termed as culture-negative neutrocytic ascites. Several studies were undertaken to investigate the use of reagent strips ("dipstick testing") designed for the use in urine in the diagnosis of SBP. However, a review of studies comparing different types of reagent strips with cyto-bacteriological methods revealed a high rate of false negative results for the reagent strips^[108].

Patients with an ascitic fluid neutrophil count ≥ 250 cells/mm³ and clinical signs of SBP should receive antibiotic treatment. Also, cirrhotic patients with ascites and signs or symptoms of infection or unexplained clinical deterioration should receive treatment regardless of a neutrophil count below 250 cells/mm³, since it is known that bactericides (positive ascitic fluid culture with a neutrophil count below 250 cells/mm³) might precede the neutrophil response^[109].

Treatment should be initiated with a broad-spectrum antibiotic as long as results of bacterial culture are not available. The treatment of choice is a third-generation cephalosporin. Most data are available for cefotaxime. Cefotaxime covers 95% of the causative bacteria including the most common isolates *E. coli*, *Klebsiella pneumoniae*

and pneumococci^[110]. In addition, it reaches high concentrations in the ascitic fluid^[110,111]. In most patients, 5 d of treatment is as effective as 10 d of treatment^[112]. Ceftriaxone was also shown to be effective in the treatment of SBP and is an alternative to cefotaxime^[113]. Amoxicillin/clavulanic acid, given as a sequential intravenous/oral therapy was shown to be as effective as cefotaxime in a small study^[114]. Intravenous ciprofloxacin is similarly effective with respect to survival and SBP resolution rate as treatment with cefotaxime, but costs are higher^[115]. In uncomplicated SBP, oral ofloxacin was shown to be as effective as cefotaxime^[116]. Since patients who have received quinolone prophylaxis against SBP may have developed a quinolone resistant flora, quinolones should not be used in these patients^[6].

Failure of the initial antibiotic treatment should be considered in patients in whom the initial neutrophil count does not decrease below 25% of the pre-treatment value after two days of treatment^[117]. Treatment failure might be due to bacteria resistant to the initial treatment or secondary peritonitis. Under these circumstances, treatment has to be modified according to susceptibility testing (if available) or on an empiric basis.

The addition of intravenous albumin to cefotaxime in the treatment of SBP has been shown to be effective in two studies^[76,118]. One controlled randomized trial compared patients with SBP receiving cefotaxime alone vs patients with cefotaxime plus albumin 1.5 g/kg body weight at diagnosis, followed by 1 g/kg albumin on day 3. The study revealed a decrease in mortality from 29% in the cefotaxime group to 10% in the cefotaxime/albumin group^[76]. The study by Sigal *et al*^[118] found that combination treatment with albumin is particularly effective in patients with an impaired liver and kidney function (bilirubin > 4 mg/dL and creatinine > 1 mg/dL, respectively) but that combination treatment with albumin is not necessary in patients who do not fulfil these criteria.

In patients who promptly respond to antibiotic treatment, a follow-up paracentesis and ascitic fluid analysis is not necessary^[6]. In patients who do not respond to treatment or show a delayed response, a follow-up ascitic fluid analysis is mandatory for further evaluation^[119].

Several subgroups of patients at high risk for the development of SBP have been identified in the past. Risk factors for SBP are ascitic fluid protein concentration < 1.0 g/dL, variceal hemorrhage and a prior episode of SBP^[6]. Several randomized controlled trials have shown a benefit of prophylactic antibiotic treatment in these patients^[120-126].

Variceal bleeding is a major risk factor for the development of SBP, especially in patients with advanced cirrhosis and severe bleeding^[120,126-134]. Antibiotic prophylaxis in patients with variceal hemorrhage has been shown to not only decrease the rate of SBP^[8,101,106] but also decrease the risk for rebleeding^[135] and hospital mortality^[128].

Norfloxacin (400 mg twice daily) for 7 d has been widely used for selective intestinal decontamination in cirrhotic patients with variceal bleeding^[8,101,126]. In patients with gastrointestinal bleeding and advanced cirrhosis,

intravenous ceftriaxone (1 g/d for 7 d) has been shown to be superior to norfloxacin^[121].

Low ascitic fluid protein concentration (< 1.0 g/dL) is a risk factor for the development of SBP^[123,136-138] and prophylactic antibiotic treatment is advisable in these patients. Most data are available for prophylaxis of SBP using norfloxacin^[125,139-142]. One randomized trial in which patients with low ascitic fluid protein concentration (< 1.0 g/dL) or a bilirubin > 2.5 mg/dL were treated with continuous norfloxacin or inpatient-only norfloxacin showed that the incidence of SBP was lower in the continuous treatment group at the expense of more resistant flora when they did develop infection^[141]. These findings were substantiated by another randomized trial comparing daily norfloxacin (400 mg for twelve months) with placebo in patients with low ascitic fluid protein concentration (< 1.5 g/dL) and an impaired liver or kidney function^[139]. The patients in the verum group had a lower incidence of SBP and hepatorenal syndrome as well as a survival advantage (after three months but not after one year) compared to the patients receiving placebo^[139].

Another randomized, double blind, placebo-controlled trial compared ciprofloxacin 500 mg/d for twelve months with placebo in patients with ascitic fluid protein concentration less than 1.5 g/dL and impaired liver function (Child-Pugh score 8.3 ± 1.3 and 8.5 ± 1.5 , in the placebo and ciprofloxacin group, respectively)^[142]. The study revealed a trend towards a lower incidence of SBP in the ciprofloxacin group but the result was not significant. Nevertheless, the 1-year survival was higher in the patients in the ciprofloxacin group^[142]. This might be attributed to the fact that the probability of remaining free of bacterial infections was higher in the ciprofloxacin group^[142].

The overall recurrence rate of SBP in patients surviving the first episode of SBP is approximately 70% in the first year^[106] and survival rates are 30%-50% and 25%-30% in the first and second year after SBP, respectively. Norfloxacin is effective in the secondary prophylaxis of SBP. One randomized, double blind, placebo-controlled multicenter study revealed that prophylactic treatment with 400 mg/d norfloxacin reduced the recurrence rate of SBP from 68% to 20%^[122]. Another trial compared norfloxacin 400 mg/d with rifloxacin 400 mg/wk and did not find a significant difference in the SBP recurrence rate between the two treatment groups^[143]. The effects of trimethoprim-sulfamethoxazole, ciprofloxacin and norfloxacin were assessed in three more studies^[124,125,144]. All three studies revealed a reduced occurrence of SBP in the patients receiving prophylactic treatment. However, the significance of the studies in the setting of secondary prophylaxis is limited since the studies included patients with and without prior episodes of SBP. There are no trials available that have studied for how long secondary prophylaxis should be given.

Abstract

Ghrelin is predominantly produced by the gastric enteroendocrine cell compartment and is octanoylated by the recently discovered ghrelin *o*-acyltransferase (GOAT) before secretion into the bloodstream. This octanoylation is essential for many of the biological properties of ghrelin including appetite stimulation and anti-inflammatory properties as only the acylated form of ghrelin binds to the ghrelin receptor, the growth hormone secretagogue receptor (GHS-R). Given the gastric location of ghrelin production, it is perhaps not surprising that insult to the gastric mucosa affects circulating ghrelin levels in humans. *Helicobacter pylori* (*H. pylori*) infects more than fifty percent of the world's population and once established within the gastric mucosa, can persist for life. Infection is associated with chronic gastritis, gastric atrophy and ulceration, reduced appetite and a lower body mass index (BMI). The large majority of studies investigating levels of circulating ghrelin and ghrelin expression in the stomach in patients with *H. pylori* infection

indicate that the bacterium has a negative impact on ghrelin production and/or secretion. Eradication of infection restores ghrelin, improves appetite and increases BMI in some studies, however, a causative relationship between *H. pylori*-associated serum ghrelin decline and food intake and obesity has not been established. Most studies measure total ghrelin in the circulation although the measurement of the ratio of acyl/total ghrelin gives a clearer indication that the ghrelin acylation process is altered during infection and atrophy. GOAT is essential for the production of biologically-active, acyl ghrelin and the impact of *H. pylori* on GOAT expression and activity will be highly informative in the future.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection of the gastric mucosa in humans has been shown to alter the normal gastric physiology. Ghrelin is a 28 amino acid peptide hormone, primarily produced in, and secreted from, the gastric mucosa, that has been demonstrated to be involved in appetite, food intake and energy homeostasis. *H. pylori* colonization has been negatively associated with circulating ghrelin levels although this finding is the subject

of much controversy. The following review seeks to address differences in the published studies regarding the impact of *H. pylori* infection on ghrelin and introduces a putative role for the newly-discovered ghrelin acylating enzyme, ghrelin *o*-acyltransferase (GOAT).

THE GUT AS AN ENDOCRINE ORGAN

In addition to classical endocrine tissues such as the pituitary, thyroid and adrenal glands, peripheral organs are a rich source of hormones, some of which act in an intracrine/autocrine/paracrine manner. Amongst these organs, the gut is the largest and most diffuse endocrine organ producing an array of peptide hormones important for both enteric and non-enteric physiology. Enteroendocrine cells are distributed throughout the gastrointestinal tract, however, a significant proportion of endocrine hormones involved in appetite regulation are produced and secreted by the gastric mucosa.

The gastric mucosa

In the stomach, the surface epithelium is connected *via* the foveolae and neck region to the deeper gastric glands (Figure 1). Undifferentiated stem cells are located in the neck region and migrate outwards along the foveolar axis differentiating into mucous cells, and inwards differentiating into mucous, parietal, chief and endocrine cells^[1]. Histologically, the stomach is divided into three different regions - cardia, corpus/fundus and antrum/pylorus (Figure 1). The cardia comprises the proximal 0.5-2 cm of the stomach, and is mainly composed of mucus-producing cells and scattered parietal cells. In the corpus and fundus, most cells in the upper part of the glands are acid-secreting parietal cells, whereas the lower half of the glands is dominated by chief (peptic) cells that secrete digestive enzymes (pepsinogen and lipase). Most of the endocrine cells are found in the lower third of the glands. The antrum/pylorus occupies the distal quarter of the stomach, is mainly composed of mucus producing cells, with sparse parietal and endocrine cells located in the connecting neck region, and the endocrine cells are dominated by gastrin-producing (G) cells^[2]. Maintenance of gastric secretory functions is achieved through endocrine and paracrine mediators. Acid secretion is induced by a variety of stimuli and governed by the endocrine cells of the stomach. Gastrin is released from the G cells of the antral mucosa and travels through the blood stream to the corpus where the enterochromaffin-like cells are stimulated to secrete histamine which, in turn, stimulates the parietal cells to secrete acid^[2]. In contrast, somatostatin and prostaglandins, inhibit acid secretion^[2].

The gut-brain axis and ghrelin

Gut-derived regulatory peptide hormones are typically considered to be important in the control of basic enteric physiology including gastric acid secretion, digestion, gut motility and blood flow. Additional gastric hormones have been identified which point to further critical roles for the stomach in controlling appetite and satiety. *Via* interaction with their cognate receptors in the brain, these hormones

form part of an important signalling network often referred to as the gut-brain axis which co-ordinates many of the functions of the gut, including appetite modulation. The most potent orexigenic hormone and the only circulating orexigen described thus far is ghrelin.

Ghrelin is a peptide hormone consisting of 28 amino acids with a hydrophobic octanoyl moiety (or to a lesser extent decanoic acid) esterified to the third residue, serine^[3]. Ghrelin was discovered by “reverse pharmacology” using the endogenous growth hormone secretagogue receptor (GHS-R) which had been considered an orphan G protein-coupled receptor prior to discovery of ghrelin, but is now accepted as the major ghrelin receptor^[4]. Initially characterised as a new component of the growth hormone (GH)/insulin-like growth factor axis, ghrelin was shown to be a potent stimulator of GH secretion from mammalian somatotroph cells after activation of the GHS-R. This activity is reliant upon a complex interaction of signalling pathways incorporating the phospholipase C, cAMP and nitric oxide/cGMP systems^[5].

Human ghrelin is produced predominantly by the P/D₁ enteroendocrine cells of the gastric fundus (known as X/A-like cells in rodents) and the octanoylated mature hormone is secreted into the general circulation *via* the capillary networks of the gastric lamina propria^[6]. Interestingly, whilst ghrelin expression and secretion is greatest in the gastric mucosa, the GHS-R is present at its highest level in the pituitary^[7] and hypothalamic nuclei^[4], leading to speculation that ghrelin and its receptor have evolved to provide a link between peripheral energy homeostasis and GH secretion^[8].

The mechanisms underlying the co- and post-translational modifications of ghrelin have only recently begun to be deciphered. Hydrophobicity conferred by acylation may allow for the bidirectional transport of ghrelin across the blood-brain barrier^[9]. This modification also facilitates the binding of ghrelin to the GHS-R and is essential for GHS-R-mediated ghrelin activity. GOAT is a lipid transferase from the membrane bound *o*-acyl transferase (MBOAT) family of acyl transferases that specifically acylates proghrelin^[10]. Expression of murine GOAT is highest in the stomach, followed by pancreas, small intestine and colon^[11], although in human tissues the pancreas may be the major site of expression^[10]. As anticipated, GOAT expression is enriched in the ghrelin-producing gastric enteroendocrine cells of mice although a small subset of ghrelin immunopositive cells appear to be devoid of GOAT^[12], supporting the hypothesis that unacylated ghrelin has independent biological functions. Furthermore, it is tempting to speculate that unacylated ghrelin secreted from the stomach could be acylated by paracrine GOAT-expressing cells. Mice with genetic disruption of GOAT completely lack circulating acylated ghrelin but display supraphysiological levels of serum unacylated ghrelin, suggesting that GOAT may play a role in the translational control of ghrelin synthesis and/or secretion and activity^[13] or that ghrelin feedback mechanisms are disrupted in the absence of GOAT.

Plasma ghrelin secretion is episodic and concentrations

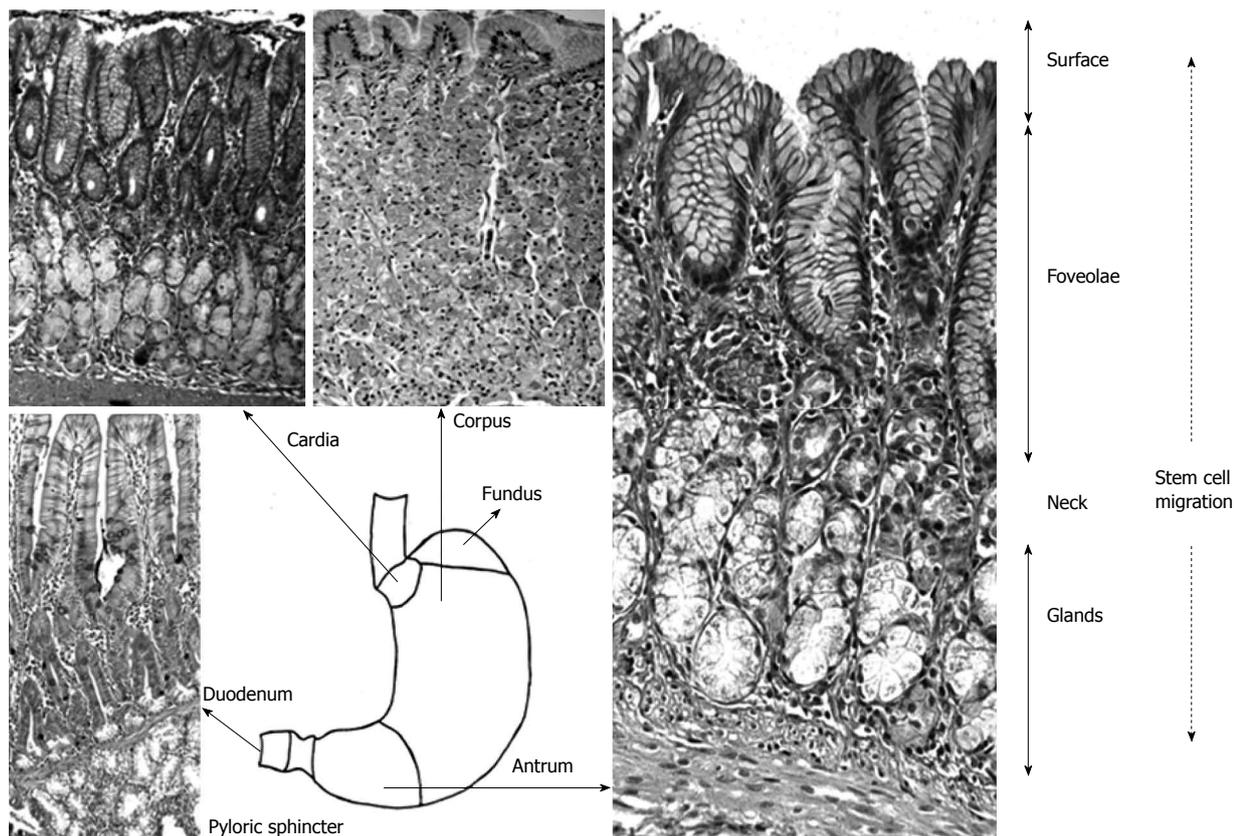

Figure 1 The regions of the stomach. In the stomach, undifferentiated stem cells located in the neck region migrate outwards or inwards specializing into mucous, parietal, chief and endocrine cells. In this figure, the antrum is shown at a three-fold larger magnification than the other images of the stomach. Ghrelin expression has been detected throughout the human gastric mucosa with strongest expression in the oxyntic mucosa.

in adults of healthy body mass index (BMI) are reported to range from 100-200 fmol/mL^[3] with healthy women having higher levels of acyl and total ghrelin than healthy men^[14]. Short-term fasting stimulates ghrelin secretion which may then initiate feeding in humans and rodents; post-prandial ghrelin serum levels are then reduced dramatically^[15]. In obesity, plasma ghrelin is decreased compared to normal counterparts^[16]. This phenomenon has previously been thought to be due to the reduced need for production and secretion of orexigenic ghrelin during periods of caloric excess. Ghrelin targets central nervous system appetite networks on multiple levels with a complex interplay occurring between it and other appetite-modulating peptides including neuropeptide Y, agouti-related protein, pro-opiomelanocortin and leptin^[17]. Whilst it is well established that pharmacological doses of ghrelin profoundly influence food intake, recent studies dissecting the mechanisms of the ghrelin acylation process have challenged the traditional dogma surrounding the endogenous ghrelin/GHS-R system and its role in appetite modulation that has existed since its discovery over ten years ago. Using GOAT transgenic knockout mouse models, Kirchner *et al.*^[13], have proposed that ghrelin and GOAT are primarily lipid-sensing molecules that are highly sensitive to changes in dietary fatty acid intake, specifically medium chain fatty acids and that acyl ghrelin signals to the brain that energy-dense food is available. In this regard, diets rich in octanoate (found in breast milk, coconut milk and

commercial infant formula) will result in an increase in the fatty acid substrate for GOAT and, therefore, a theoretical increase in circulating, acylated ghrelin. Experimental studies have shown that ghrelin influences metabolic substrate utilization in rodents^[18]. Additionally, it appears that GOAT plays a crucial role in this facet of ghrelin activity because the GOAT knockout mouse displays increased fat oxidation and is leaner than wild-type mice when given a high fat diet^[13]. Taken together, these studies advocate a role for ghrelin/GOAT and the GHS-R in sensing and reversing states of energy deficiency and reducing fat utilisation, suggesting that during times of nutrient excess, inhibition of ghrelin activity may reduce hyperphagia, obesity and type 2 diabetes. During prolonged caloric restriction, however, ghrelin activity is essential for maintaining blood glucose levels and preventing death in mice and this protective effect is mediated *via* increased GH secretion^[19].

ACYLATED GHRELIN IS NOT THE ONLY GHRELIN

The ghrelin/GHS-R axis may be expanded to incorporate several ghrelin isoforms that have been identified, including the splice variant des-Gln14-ghrelin and the non-modified des-octanoyl or unacylated ghrelin^[20]. Despite being the most predominant species of ghrelin in serum, unacylated ghrelin cannot bind to and, therefore,

does not activate the GHS-R. Initially thought to be a by-product of bioactive ghrelin degradation, unacylated ghrelin now appears to be an important hormone with an array of biological activities, particularly in the cardiovascular system, bone physiology, reproductive axes and prenatal growth^[20]. Many actions of unacylated ghrelin oppose those of acylated ghrelin. For example, the GH/IGF-1 axis is downregulated in transgenic mice overexpressing the non-modified isoform of ghrelin, resulting in a smaller than normal phenotype^[21], and food intake and gastric emptying are suppressed in mice administered unacylated ghrelin^[22]. It seems likely that these apparently inverse biological properties are the result of alternative receptor activation, and support the notion of the existence of undiscovered non-GHS-R ghrelin receptor(s). The differences and similarities between the isoforms in regards to function in gastrointestinal and selected peripheral tissues is summarised in Figure 2.

Interactions of ghrelin with the anorectic, pro-inflammatory adipokine leptin

It is well documented that ghrelin and the adipokine leptin exert mutually antagonistic regulatory effects on energy balance and appetite at the hypothalamic level. Whereas ghrelin stimulates NPY neurons in the arcuate nucleus, leptin inhibits these neurons and stimulates proopiomelanocortin (POMC) neurons, thereby suppressing food intake. The stomach contributes, in part, to plasma leptin levels, although the majority of leptin production occurs in adipose tissue. Stomach-derived leptin is expressed in the lower half of the gastric fundic glands in an endocrine cell type distinct from ghrelin-producing cells^[23]. The gastric co-expression of these two antagonistic hormones involved in appetite modulation, generation of satiety signals and energy homeostasis again highlights the importance of the stomach as an endocrine organ.

Ghrelin suppresses inflammation in rodent models of disease and in humans

Ghrelin and GHS-R are expressed in immune cells, and manipulation of ghrelin/GHS-R expression and activity affects T cell function. In immune cells, as in the hypothalamus, ghrelin again antagonises leptin. Human T cells stimulated by leptin increase their production of the pro-inflammatory, anorectic cytokines IL-1 β , IL-6 and TNF α as well as displaying increased GHS-R1a expression. Co-treatment with ghrelin inhibits leptin-induced cytokine levels in a dose-dependent manner^[24]. Knockdown of ghrelin in primary human T cells increases Th1 cytokine production and IL-17 secretion suggesting a role for autocrine/paracrine ghrelin in the endogenous restraint of pro-inflammatory cytokine production and release^[25]. Studies demonstrating an *in vivo* anti-inflammatory role for ghrelin are rapidly increasing in number and include mouse models of pancreatitis and colitis^[26]. The therapeutic effect of ghrelin has been attributed to the down-regulation of pro-inflammatory cytokines (including IL-12, IFN- γ , and TNF- α), recruitment of inflammation-suppressing regulatory T cells and increased levels of the

anti-inflammatory cytokine IL-10^[26]. Recently, ghrelin has also been shown to inhibit secretion of pro-inflammatory high-mobility group box 1 (HMGB1; a DNA-binding cytokine that is a critical late mediator of inflammation) from activated macrophages, and treatment with ghrelin reduces serum HMGB1 levels in rodent models of sepsis^[27]. Pro-inflammatory cytokine production in the resident macrophages of the brain and spinal cord (microglia) is also reduced by ghrelin treatment, thereby reducing the severity of experimental autoimmune encephalomyelitis, a model of multiple sclerosis^[28]. In clinical trials, ghrelin has been used with success as an anti-inflammatory agent in cachexic patients with chronic respiratory infection and inflammation. In these patients, ghrelin treatment increased body weight and significantly suppressed inflammation in the lungs by decreasing neutrophil infiltration/accumulation and reducing serum TNF- α ^[29].

Exogenous ghrelin is gastroprotective and prokinetic

Gastric mucosal injury is attenuated by central and peripheral administration of ghrelin in rodent models of gastric and duodenal disease. Ghrelin also accelerates healing in these ulcerogen models by increasing mucosal healing, proliferation and blood flow,^[30] and these factors have been shown to be dependent on an intact GH/IGF axis, endogenous nitric oxide activity and vagal and sensory nerve integrity^[31,32]. Ghrelin protects gastric mucosal cells from apoptosis induced by *H. pylori* LPS by increasing constitutive nitric oxide synthase activity, reducing caspase-3 and inducible nitric oxide synthase^[33]. Unsurprisingly, given its structural similarity to the classical prokinetic peptide motilin, ghrelin also has a prokinetic effect on gut motility in many species including humans^[34] and the benefits of this are being evaluated in clinical trials in patients with gastrointestinal motility disorders.

Non-infectious gastric disorders disturb ghrelin expression

Non-infectious gastric disorders are known to impact ghrelin secretion from the stomach and subsequent circulating ghrelin levels. Ghrelin-producing endocrine tumours of the stomach induce supra-physiological ghrelin levels^[35] which may result in desensitization of the GHS-R. Recently, methyl donor deficiency (MDD) in pregnant rats was shown to result in reduced circulating ghrelin but not ghrelin gene transcription in the offspring^[36]. The altered polarity of the gastric fundic glands due to the nutritional deficiency in these rats may be responsible for a reversal in normal ghrelin secretion; that is, ghrelin may be secreted into the gastric lumen instead of the normal secretion pattern into the blood. The authors speculated that the reduction in ghrelin could be the cause of the significant intrauterine and post-natal growth restriction associated with MDD.

Autoimmune atrophic gastritis has also been shown to decrease ghrelin production and secretion^[37] and acylation of proghrelin may be disrupted - it is tempting to speculate that this may be due to the effects of inflammation on the activity and or expression of the more recently discovered GOAT.

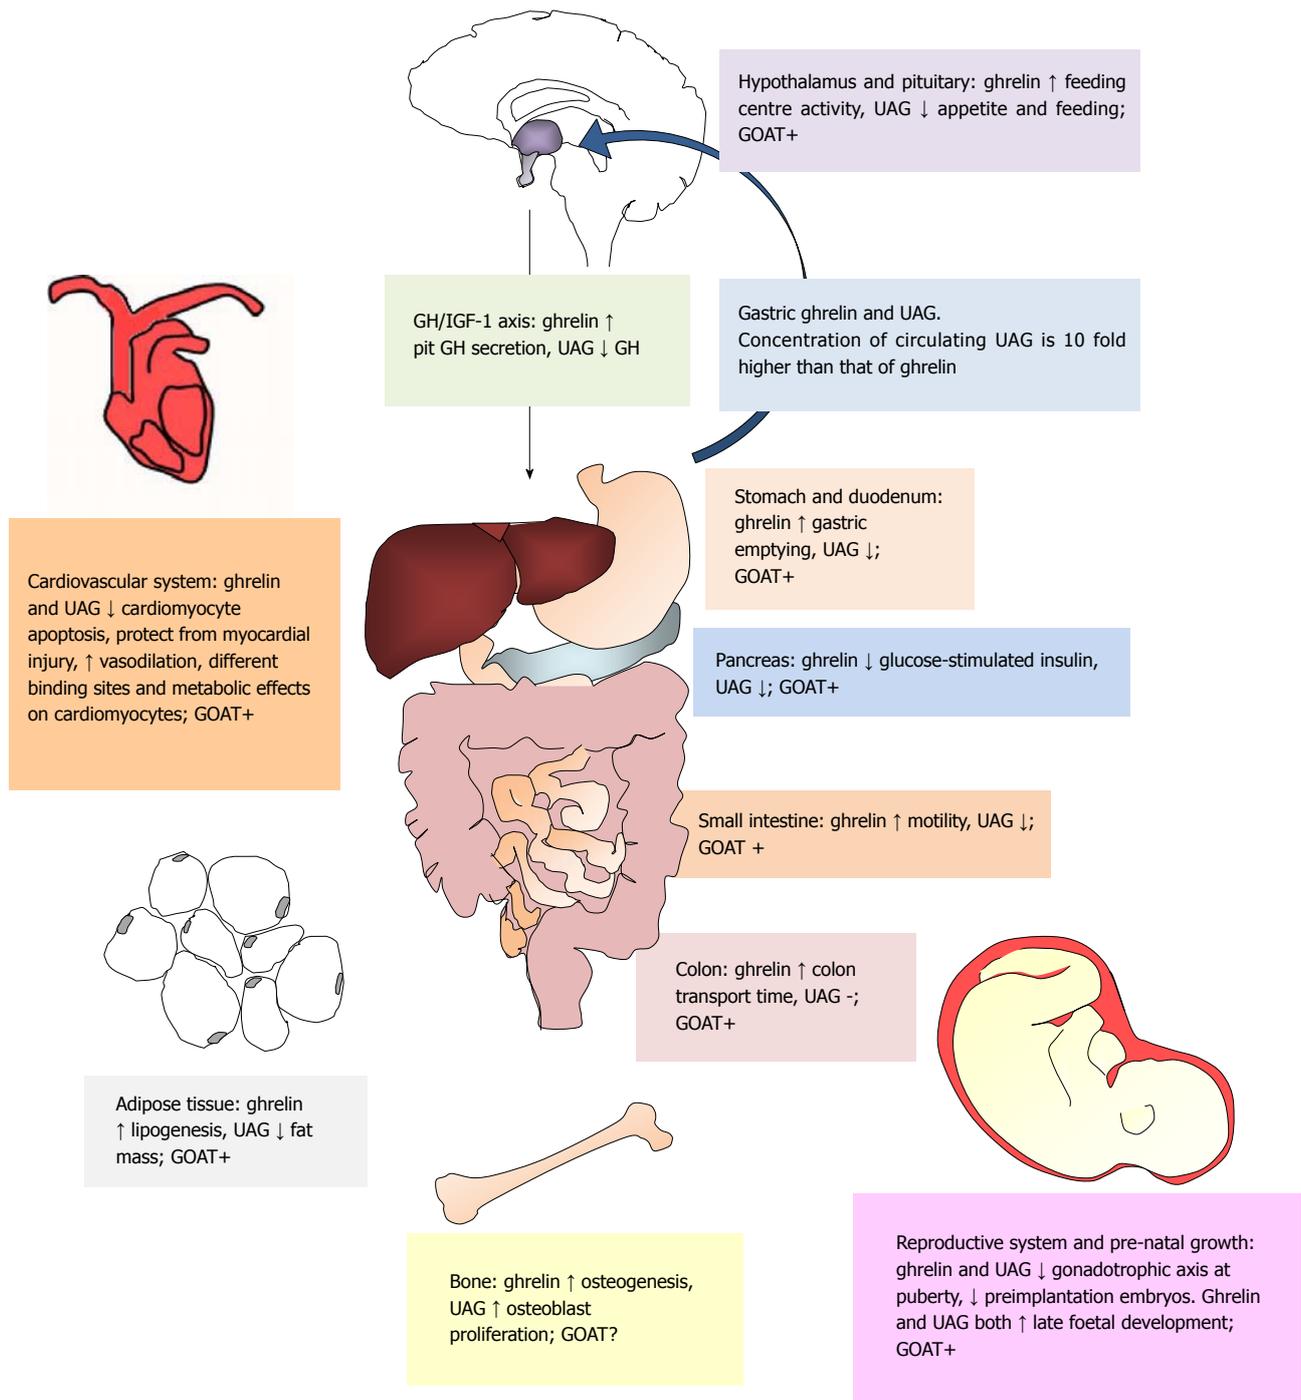

Figure 2 Diagram summarising the similarities and diversities of ghrelin and unacylated ghrelin activities in gastrointestinal and selected peripheral tissues/systems. The expression of ghrelin *o*-acyltransferase (GOAT) in most peripheral tissues suggests that acylation of locally-produced unacylated ghrelin (UAG) is possible. GOAT + indicates tissues that have been found to express mRNA for GOAT. GOAT? indicates that GOAT expression status is unknown. Pit: Pituitary; ↑: Increases or stimulates; ↓: Decreases; -: Effect unknown.

Atrophic gastritis is also associated with chronic *H. pylori* infection in a subset of patients. Of the infectious agents causing gastric pathogenicity, *H. pylori* is the most common one, however, other *Helicobacter* species can cause milder forms of gastritis^[38].

H. PYLORI INFECTION

H. pylori is a Gram-negative, rod/spiral-shaped micro-aer-

ophilic bacterium that causes life long infection. *H. pylori* has strategies that allows its survival and persistence in the inhospitable environment of the stomach. Adherence of *H. pylori* to the mucosal surface supports gain of nutrients and also facilitates entry into epithelial cells and the underlying mucosal tissue as shown *in vivo*^[39,40] and *in vitro*^[41]. Adherence of *H. pylori* is dependent on expression of bacterial attachment proteins (adhesins) and the cognate host oligosaccharides (glycans), displayed by glycoproteins

and glycosphingolipids in gastric epithelium and also by mucins in the gastric mucus layer^[42-44]. The microbe is well adapted to the gastric mucus niche, having long whip-like flagella facilitating locomotion through the mucus layer. In addition, surface-bound urease that catalyzes the hydrolysis of urea to ammonia and carbon dioxide allows the microbe to “neutralize” its microenvironment. Flagella, urease, adhesins, and genes encoding proteins with a predicted function in chemotaxis are essential for *H. pylori* colonization of laboratory animals^[45].

The majority of *H. pylori* infected individuals remain asymptomatic, but 10%-15% develop peptic ulcers, and 3% gastric non-cardia adenocarcinoma^[46]. Since most infected individuals show no clinical symptoms, the pathological process must be influenced by host/environmental factors in addition to the genotype of the infecting strain. Inter-individual factors, such as the type of host structures that *H. pylori* can bind to (blood group dependent), account for some of the variance of pathology as a consequence of infection^[47]. Stress is another factor that may work in conjunction with *H. pylori* or cause ulcers through alternative pathways, as people exposed to disasters as well as prisoners of war have increased occurrence of ulcers, and wound healing is slower in stressed individuals^[48]. The intense humoral and cellular immune responses associated with gastric colonization are usually unable to eradicate *H. pylori* and may play a major role in the morbidity of the disease.

H. pylori infection is one of the most common bacterial infections in the world, colonizing approximately half the population^[49]. Colonization usually occurs before the age of ten^[49], and once established within the gastric mucosa, the bacterium can persist for life, although transient infection occurs in a few individuals^[50].

The classification of *H. pylori* as a human carcinogen is mainly based on results from prospective epidemiological studies showing a relationship between infection with *H. pylori* and subsequent development of gastric carcinoma. Eradication of *H. pylori* has also resulted in reversal of pre-neoplastic conditions^[51], and *H. pylori* eradication in gastric ulcer patients reduces the risk of developing gastric cancer^[52], further supporting an association between *H. pylori* infection and cancer development.

Effect of *H. pylori* infection on the gastric endocrine system

In the majority of infected individuals, *H. pylori* infection is antrum predominant, and acid production by the largely unaffected corpus is enhanced leading to an increased risk of duodenal ulcers. In a minority, infection is corpus predominant, and infection is associated with progressive gastric atrophy and intestinal metaplasia, subsequent hypochlorhydria and an increased risk of gastric cancer^[53,54]. Possibly, the initial infection starts in the antrum, and in individuals with a lower basic acid production, the infection spreads to the corpus, as supported by the observations that relatives of gastric cancer patients have a lower basic acid production than the general population^[55], and that patients with antral predominant *H. pylori* infection

and gastritis developed corpus predominant infection and gastritis after treatment with acid suppressive therapy^[56]. Hypochlorhydria permits infection with other bacteria that may enhance the production of carcinogenic (e.g. *N*-nitroso) compounds. Thus, impaired control of gastric juice secretion is observed in chronic gastritis due to *H. pylori* infection, but the site/type of infection determines what effect *H. pylori* has on the endocrine system, or the downstream results of the endocrine system such as acid production. Further differences can be attributed to the development of intestinal metaplasia in a subset of individuals with chronic gastritis, and the endocrine-cell population present in the intestinal metaplasia resembles that found in the cryptal region of the normal small intestine^[57]. The literature is biased towards the antrum predominant infection, as these represent the majority of infections, and the effects of corpus predominant infection may therefore be disguised in many studies.

Effects of *H. pylori* on endocrine cells

Colonization of *H. pylori* in the human stomach results in release of chemoattractants such as IL-8, IL1 β and TNF α , which stimulate G cells, and the gastrin cell count is increased in *H. pylori* infected gastric mucosa^[58]. The number of D cells producing somatostatin decreases simultaneously^[59]. Similarly, some species of swine *Helicobacter* alter the number of endocrine cells in gastric mucosa. Some of these alterations, for example an increase in the number of G cells, decrease in the number of D cells and especially an increase in the ratio of G to D cells can be responsible for the development of gastroesophageal ulcers in swine^[60].

The impact of *H. pylori* on circulating plasma ghrelin levels highlights the importance of GOAT

Due to the gastric location of ghrelin-producing cells it is intuitive that ghrelin production, acylation and/or secretion might be compromised by chronic gastritis and atrophy and that this in turn will affect appetite, weight and BMI.

There have been contradictory reports in the literature in regards to the effect of *H. pylori* infection on circulating ghrelin levels and some of these discrepancies may be due to differences in populations (age, race, geography, gender, diet and overall health), extent of disease (for example whether atrophy is present or not) and *H. pylori* strain differences. This is also complicated by the use of different immunoassays to measure ghrelin and by the fact that acylated ghrelin is highly unstable and degrades rapidly to unacylated ghrelin^[61]. The optimum method of plasma ghrelin measurement is a contentious issue - a number of researchers maintain that measurement of total ghrelin is reflective of active ghrelin levels and is an adequate approach. Most studies examining the impact of *H. pylori* have examined total ghrelin levels only and the majority of these studies determined that infection decreases plasma ghrelin levels (Table 1). However, an important theme that emerges from these studies is that plasma total

Table 1 Original studies measuring total ghrelin only (in chronological order)

| Subjects | Nationality | Tissue | Total ghrelin in <i>H. pylori</i> infection (or cure) | Ref. |
|-------------------------------|-------------|--------|---|------|
| 39 Adults F | Turkish | G | - | [78] |
| 10 Adults F + M | UK | P | ↑ after <i>H. pylori</i> cure | [79] |
| 68 Adults F + M | Japanese | P | ↓ | [80] |
| 160 Adults F + M | Japanese | G + P | ↓ more so as atrophy increases | [81] |
| 89 Adults F + M | Japanese | P | ↓ but did not recover after cure | [82] |
| 225 Adults F + M | Japanese | P | ↓ in chronic gastritis | [83] |
| 61 Adults F + M | Japanese | G + P | ↓ and associated with virulence strain | [84] |
| 132 Adults F + M | Japanese | P | ↓ | [85] |
| 100 Adults F + M | Polish | P | ↓ | [86] |
| 56 Adults F + M | Japanese | P | ↓ | [87] |
| 146 Children F + M | Polish | P | ↓ | [88] |
| 134 Adults F + M | Japanese | G + P | ↑ or ↓ after cure, depending on BMI. Ghrl mRNA ↑ | [89] |
| 62 Adults (> 75 yr) F + M | French | G + P | ↓ | [90] |
| 120 Adults, 60 children F + M | Polish | P | ↓ | [91] |
| 63 Adults F + M | Korean | G + P | - no healthy control group | [92] |
| 50 Adults F + M | Turkish | P | - in absence of atrophic gastritis | [93] |
| 85 Prepubertal children F + M | Italian | P | ↓ related to severity of gastritis | [69] |
| 256 Adults M | American | G + P | - | [94] |
| 100 Adults F + M | Chinese | P | ↓ | [95] |
| 22 Adults F + M | Korean | G + P | ↑ ghrl mRNA after cure | [96] |
| 341 Adults F + M | Chinese | P | ↓ in males only | [97] |

F: Female; M: Male; G: Gastric tissue; P: Plasma; Ghrl: Ghrelin; ↑: Increased; ↓: Decreased.

Table 2 Original studies measuring the effect of *H. pylori* infection on plasma acyl and unacylated ghrelin levels

| Subjects | Nationality | Tissue | Acyl and total ghrelin in <i>H. pylori</i> infection (or cure) | Ref. |
|------------------|-------------|--------|--|------|
| 69 Adults F + M | Japanese | P | ↓ acyl ghrl in atrophy only | [98] |
| 50 Adults F + M | Italian | P | ↑ acyl ghrl and acyl/total ratio in atrophy cf. healthy controls | [63] |
| 220 Adults F + M | Japanese | P | ↓ acyl ghrl associated with atrophy and ↑ after cure | [62] |

F: Female; M: Male; P: Plasma; Ghrl: Ghrelin; ↑: Increased; ↓: Decreased.

ghrelin is reduced only in the presence of gastric atrophy and that in a subset of these studies, plasma ghrelin levels are negatively correlated with the severity of atrophy^[62,63].

The potentially different, even perhaps inverse, biological roles of acyl- and unacylated ghrelin suggest that the ratio of modified to unmodified ghrelin is highly important. In the context of *H. pylori* infection, few studies have taken this into account and in those that have, the findings are again contradictory (Table 2). In Japanese adults^[62], the acylated ghrelin/total ghrelin ratio as well as plasma acyl ghrelin levels are reduced, whereas in a study conducted on Western males^[63], there was a significant increase in acyl ghrelin and indeed the ratio of acylated ghrelin/total ghrelin which the authors speculate may be due to an endogenous, compensatory increase in the acylation process in response to a loss of total ghrelin secretion. A logical extension of this work would be to assess the level of expression and activity of GOAT during *H. pylori* infection and chronic gastritis and gastric atrophy.

The substrates for GOAT are the prohormone proghrelin and dietary medium chain free fatty acids which are used directly by GOAT. GOAT preferentially acylates proghrelin with octanoic acid, however, other species of acyl ghrelin (including C10:0 ghrelin) are present in the circulation at low levels and even unnatural forms of ghrelin

(C7:0 ghrelin) can be synthesised in mice when they are fed a diet rich in n-heptanoic acid or glyceryl triheptanoate^[13]. This new research suggests another potential reason for the effect of *H. pylori* infection on acyl ghrelin levels in addition to ghrelin endocrine cell destruction by gastric atrophy and or inflammatory cell destruction. Given that infection has been associated with malabsorption due to hypochlorhydria, vomiting, dyspepsia and with increased susceptibility to other enteric pathogens, especially in children^[64], it is tempting to speculate that altered dietary intake or dysregulated absorption of fatty acid substrate for GOAT could alter the ratio of acyl to total ghrelin during *H. pylori* infection. In this regard, a proportion of medium chain triglycerides are absorbed directly in the stomach as well as the small intestine^[65], and chronic gastritis leading to gastric atrophy may impair this absorption and reduce the ability of GOAT to acylate ghrelin. GOAT expressed in the small intestine of humans most likely contributes to systemic acyl ghrelin levels, and duodenal ulceration due to *H. pylori* infection may disrupt acyl production and secretion in this region of the gut. The development of techniques to assess human GOAT expression and function and the use of GOAT transgenic and knockout animal models for *H. pylori* infection experiments will allow researchers to explore this empirically in the near future.

***H. pylori*, malnutrition and growth failure**

Children with chronic gastrointestinal disease, including Crohn's disease, are known to have a higher incidence of growth retardation and pubertal delay when compared to their healthy counterparts^[66]. In a significant proportion of *H. pylori*-positive children, growth impairment, as indicated by a reduced mean height to below the 25th percentile, is evident and may be linked to *H. pylori* associated factors including, but not limited to, dyspepsia, diarrhoea, malnutrition and iron deficiency anaemia^[67]. Due to its potent stimulation of GH release, ghrelin may contribute to postnatal growth in humans. Ghrelin is synthesised and acylated by the placenta and is detected in foetal circulation from week 20-23, indicating that it may also play an important role in pre-natal growth^[68]. In support of this is a study showing that ghrelin deficiency in rat pups due to MDD contributes to severe intrauterine growth retardation^[36]. Whether there is a causative relationship between reduced circulating ghrelin during *H. pylori* infection and growth retardation/delay in infected children has not been adequately tested. Successful early eradication of *H. pylori* in a small study of infected children was associated with increased BMI and lean and fat mass, but not ghrelin, which was actually decreased^[69]. This may suggest that changes in ghrelin levels after *H. pylori* cure are epiphenomenal, however, only total ghrelin was measured in this study and the determination of the ratio of acyl to total ghrelin in cured children would have been more informative.

In contrast to the Pacifico *et al* study in which paediatric subjects cured of *H. pylori* have decreased plasma ghrelin, most studies report an increase in gastric ghrelin expression and secretion into the circulation after *H. pylori* cure in adults^[70,71]. However, in agreement with Pacifico *et al*, a study by Choe *et al*^[70] showed no increase in plasma or tissue ghrelin levels in children post *H. pylori* eradication and indeed no difference in ghrelin expression between *H. pylori* positive and negative children before treatment. It may be that the gastropathology of infected children differs from infected adults resulting in no significant impact on ghrelin-producing cells. Neutrophilic activity is associated with decreased density of ghrelin-producing cells^[71] and the neutrophilic infiltration of the mucosa is less in infected children than it is in adults^[72]. Gastric atrophy, which typically takes more than 10 years of chronic infection to develop, is rarer in children from Western developed countries, although the incidence of *H. pylori* associated atrophy is significantly higher in the Japanese paediatric population^[73]. Even in adults, specific measurement of acyl ghrelin in patients with varying severity of atrophic gastritis showed that atrophy is the defining factor for changes in plasma acyl ghrelin, irrespective of *H. pylori* status^[62].

IS OBESITY A POTENTIAL CONSEQUENCE OF *H. PYLORI* ERADICATION AND DOES GHRELIN HAVE A ROLE?

Human populations have evolved with very high rates of

chronic *H. pylori* infection. Therefore, it is likely that our metabolic rheostats have evolved to work in the context of chronic gastric infection. Indirect evidence such as the lower BMI and adiposity in *H. pylori* infected compared to uninfected populations, coinciding with lower levels of circulating ghrelin in infected individuals that can be increased after eradication, hints at a role for *H. pylori* as an obesity preventing agent. Whether there is a causative relationship between the falling prevalence of *H. pylori* infection and rising obesity rates in developed countries, where fewer children are becoming colonized, is a highly controversial topic. In a large study with 6724 adult patients who comprised a probability sample of the USA population, *H. pylori* seropositivity (either CagA-positive or -negative strains) was not associated with BMI or serum leptin levels, and ghrelin levels were not measured^[74]. Serological methods used in this study may not be as accurate at measuring *H. pylori* activity as other techniques. Nonetheless, there is no strong data to support a protective role of *H. pylori* in the prevention of obesity in developed countries. However, this lack of evidence may be due to the fact that both dietary habits associated with obesity and *H. pylori* infection are more prevalent in groups with low socioeconomic status^[75-77]. Eradication can restore a normal BMI in adults and growth velocity in children, however, this occurs particularly in developing countries and in Japan, where severity of atrophic gastritis is more pronounced. Whether ghrelin and other appetite-regulating peptides have a physiological role in this process is yet to be determined.

CONCLUSION

H. pylori infection affects the gut-brain axis due to its direct effects on gastric mucosa and on the enteroendocrine cell population including ghrelin-producing cells. Ghrelin is anti-inflammatory, anti-apoptotic and wound healing in gastritis, therefore, loss of ghrelin acylation during gastritis may impair healing. The relationships between *H. pylori*, ghrelin and BMI, adiposity and appetite remain speculative, but a greater understanding may give important insights into the pathophysiological processes underlying obesity in Western populations (Figure 3). By measuring gastric GOAT during infection in the future, we can shed more light on the effect of inflammation and infection on acyl ghrelin levels as opposed to the less illuminating total ghrelin levels.

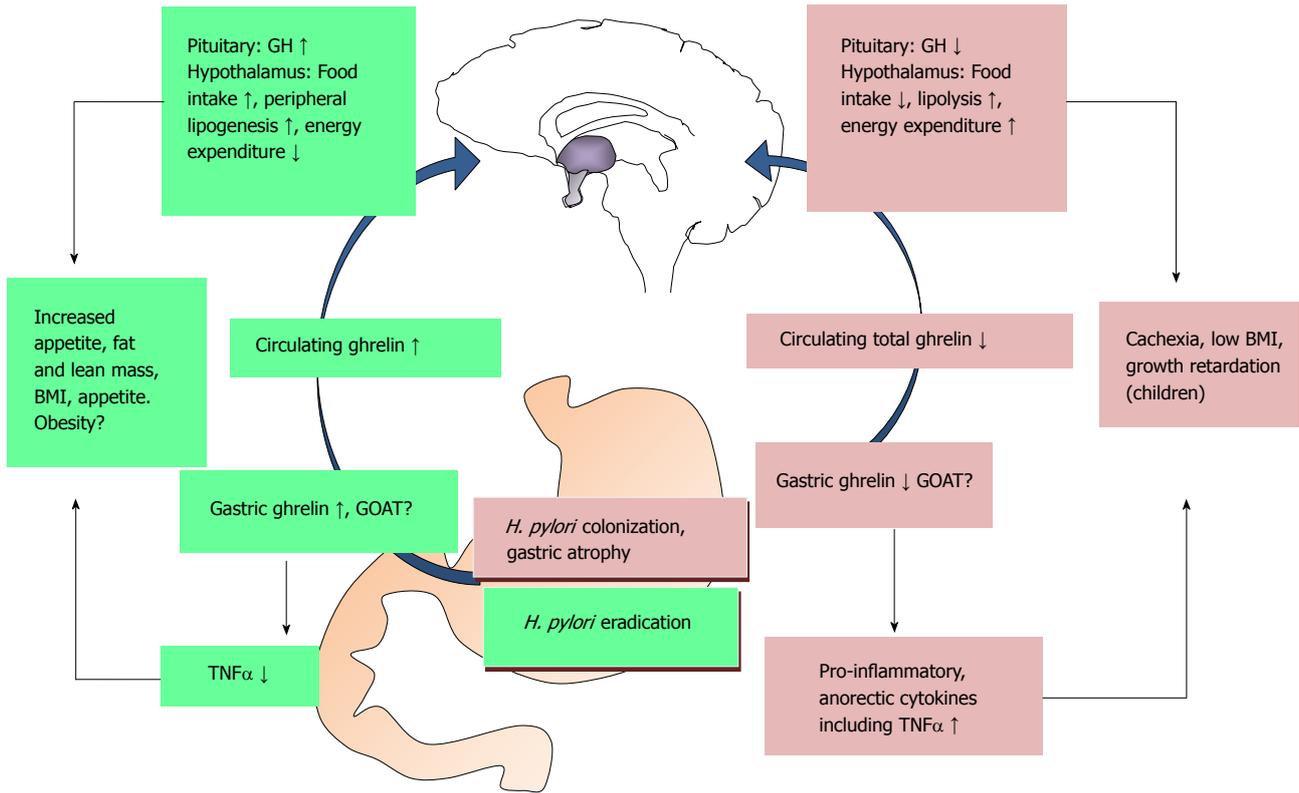

Figure 3 Potential pathways leading to reduced appetite, weight loss and pro-inflammatory state in chronic *Helicobacter pylori* infection, implicating the ghrelin axis. The majority of studies identify reduced gastric and circulating ghrelin in patients with chronic infection and gastric atrophy which may in turn lead to decreased growth hormone (GH) secretion and somatic growth in children. Reduction in ghrelin signalling in the hypothalamic feeding centres during chronic infection may be responsible for the observed reduced body mass index (BMI) in patients; *Helicobacter pylori* (*H. pylori*) eradication and subsequent restoration of ghrelin may reverse this situation. It is speculated that this in turn can contribute to obesity. GOAT? indicates that the effect of *H. pylori* status on GOAT expression is unknown. ↑: Increase; ↓: Decrease. Abstract

Glial cells in the gut represent the morphological and functional equivalent of astrocytes and microglia in the central nervous system (CNS). In recent years, the role of enteric glial cells (EGCs) has extended from that of simple nutritive support for enteric neurons to that of being pivotal participants in the regulation of inflammatory events in the gut. Similar to the CNS astrocytes, the EGCs physiologically express the S100B protein that exerts either trophic or toxic effects depending on its concentration in the extracellular milieu. In the CNS, S100B overexpression is responsible for the initiation of a gliotic reaction by the release of pro-inflammatory mediators, which may have a deleterious effect on neighboring cells. S100B-mediated pro-inflammatory effects are not limited to the brain: S100B overexpression is associated with the onset and maintenance of inflammation in the human gut too. In this review we describe

INTRODUCTION

Intestinal tissues are innervated by a complex and extensive component known as the enteric nervous system (ENS)^[1]. The ENS is characterized by the presence of neurons and enteric glial cells (EGCs) which are arranged into interconnected ganglia distributed between 2 major plexuses, and they control several gut functions^[2,3]. During the course of time, the traditional view of EGCs has changed from being a mere mechanical support for surrounding neurons to that of a more articulate and complex nature, since they are actively involved in the regulation of homeostasis, motility and inflammatory processes within the gut^[4,5].

Similar to the astrocytes in the central nervous system (CNS), the EGCs release several signaling molecules^[4,5]. Among these, great importance has been given to the better comprehension of the specific glial-derived S100B protein^[6-8]. This protein is a small, diffusible neurotrophin that is situated in the cytoplasm and/or the nucleus of both

nervous and non-nervous tissues^[9,10]. In the brain, S100B has been considered a “Janus face” neurotrophin^[11,12] because it exerts opposite actions depending on its concentration in the extracellular milieu: it has a pro-proliferative and neurogenic effect on astroglia and on serotonergic neurons at nanomolar concentrations, as well as a neurodegenerative function^[12] at micromolar concentrations, determining dysregulated glial cell proliferation and amplifying neuroinflammation. Similar to the brain, recent studies have suggested the involvement of S100B in inflammatory processes occurring in the gut, highlighting the importance of EGCs as key regulators of gut homeostasis^[13-15].

In this review, we will focus on the role of EGCs and the S100B protein and we will take them into consideration by looking at both experimental animal models and some human diseases for which evidence exists, and in particular their involvement in inflammatory conditions of the human gut where the role of S100B appears to be prominent.

ENTERIC NERVOUS SYSTEM

The gut is characterized by a sequence, starting from the serosa, as follows: subserosa, longitudinal muscle, myenteric plexus, circular muscle, submucosal plexus, muscularis mucosae and mucosa^[2]. The myenteric and submucosal plexuses are characterized by the presence of ganglia which, in turn, contain enteric neurons and EGCs in a ratio of 1:7^[16]. In the ENS, the enteric ganglia are involved in basic gut functions, such as the regulation of peristalsis, secretion and blood flow and the modulation of the immune/inflammatory processes^[17-19]. Several neurotransmitters are involved in the control of all these intestinal functions, such as vasoactive intestinal peptide and nitric oxide (NO)^[20,21]. In particular, NO is produced by the biosynthetic enzyme neuronal NO synthase (NOS), which is expressed in myenteric neurons, and by the inducible form of NOS (iNOS), which is expressed in EGCs^[15].

EGCs: both protective and destructive cells in the gut

EGCs are small cells with a “star-like” appearance^[16] containing intracellular arrays of 10 nm filaments made up of glial fibrillary acidic protein (GFAP)^[16,22-24]. This cell population was first described by Dogiel^[25] using methylene blue staining on full thickness preparations. At present, the S100B protein and GFAP are commonly used as specific markers in order to identify EGCs^[22,26]. More recently, other markers have been proposed for the identification of glial cells in the human gut, especially in whole-mount preparations: Sox8/9/10, a specific nuclear marker^[16]. EGCs release a wide range of factors accounting for the development, survival and differentiation of peripheral neurons^[27]. Traditionally, EGCs have been considered as a mechanical support for enteric neurons, but, in recent years, this restrictive view has changed to one of a more articulate and complex nature, since it has been described that EGCs are involved in the maintenance of intestinal homeostasis^[28-30]. Indeed, EGCs control intestinal epithelial barrier (IEB)

functions, as demonstrated in animal studies in which the ablation of enteroglial network enhances intestinal vascular permeability together with an increase in IEB paracellular permeability^[31-34]. Furthermore, *in vitro* data has shown that EGCs partially decrease IEB permeability *via* the release of S-nitrosoglutathione and the regulation of zonulin-1 and occludin expression^[35,36]. Although the function of glial mediators still have to be identified, it is conceivable that they could be actively involved in the EGCs-mediated effects on barrier functions.

Besides the well documented ‘protective role’, EGCs are activated by means of inflammatory insults and they may directly contribute to an inflammatory condition working as an antigen presenting cell-type promoting a variegated release of cytokine synthesis^[13-15,35-37] in the gut milieu. Therefore, EGCs may act as “receptors” for cytokines and they themselves produce interleukin-6 (IL-6) and IL-1b^[38,39]. Moreover, EGCs express iNOS and L-arginine, the machinery for the time-delayed and micromolar release of NO, one of the most important signaling molecules involved in host-immune defense against viruses and bacteria as well as a well-known pro-inflammatory mediator^[15,40,41].

EGC-SELECTIVELY EXPRESSED PROTEINS

GFAP

Mature EGCs are rich in the intermediate filament protein, GFAP^[42,43]. Its expression is modulated by glial cell differentiation, inflammation and injury^[42], indicating that the level of GFAP accords with the functional state of glial cells.

In animals, two classes of glial cells can be distinguished, namely the GFAP positive (+) and GFAP negative (-) groups, as demonstrated by von Boyen *et al*^[8]. In the same study, it was suggested that pro-inflammatory cytokines control GFAP+ enteric glia, which, in turn, are involved in the modulation of the integrity of the bowel during inflammation^[8].

In humans, GFAP expression is altered in the mucosa of patients with inflammatory bowel diseases (IBD), as well as ulcerative colitis (UC) and Crohn’s disease^[33].

S100B protein

S100B belongs to the S100 protein family that includes more than 20 EF-hand Ca²⁺-Zn²⁺ binding proteins^[9,10,44-47]. S100B is the homodimer of β subunit^[48]. In the brain, S100B in nanomolar concentrations promotes neuronal survival, neurite outgrowth^[49] and it stimulates astrocytic proliferation^[50], increasing the intracellular free Ca²⁺ levels *in vitro*^[51]. On the other hand, micromolar amounts of S100B protein have been observed in several neuropathologies such as Alzheimer’s disease and Down’s syndrome^[52,53].

In the human gut, among S100 proteins, only the S100B protein is specifically and physiologically expressed

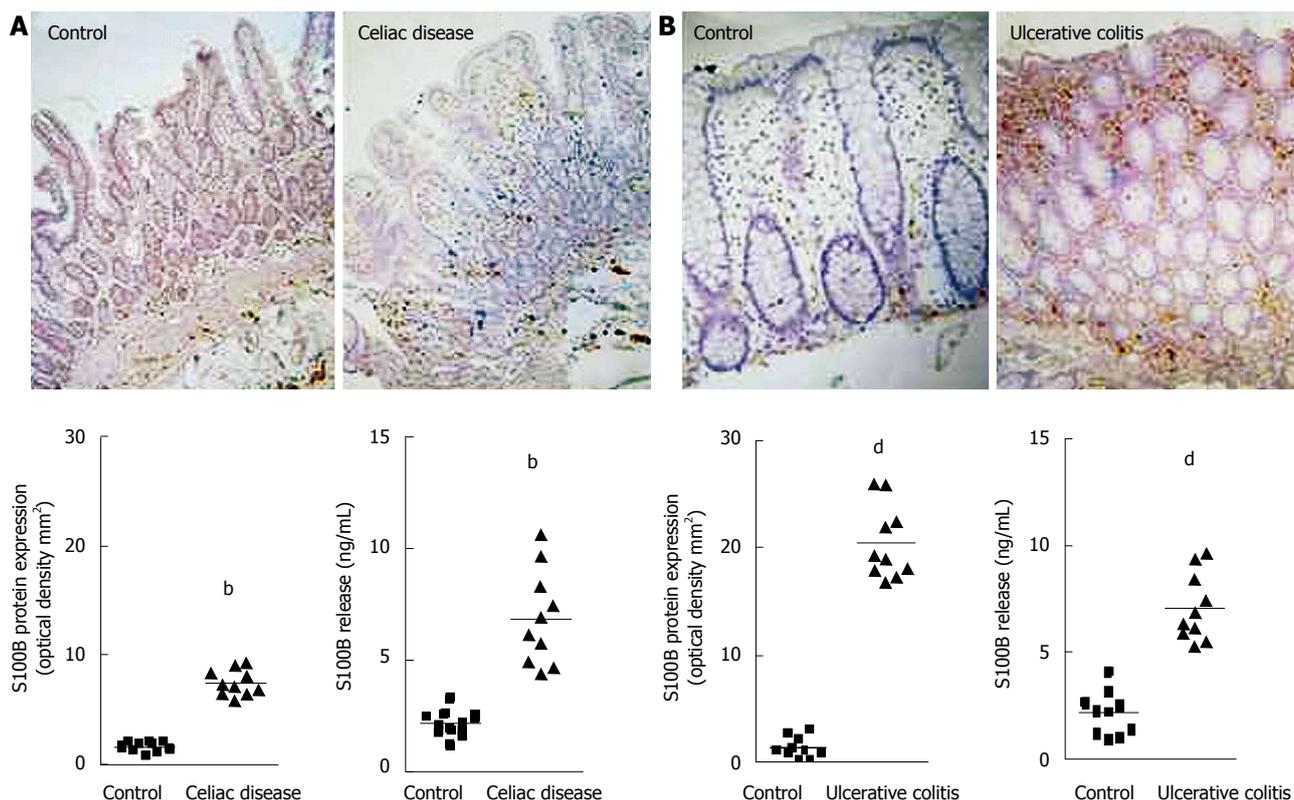

Figure 1 Changes in S100B protein expression during intestinal inflammation. A: Celiac disease^[13]. Immunohistochemistry shows stronger S100B immunopositivity in the duodenal mucosa of patients affected by celiac disease, compared with healthy controls (original magnification, × 100). The graphs represent S100B protein expression (left) and release (right) in healthy controls and patients with celiac disease (^b*P* < 0.01); B: Ulcerative colitis^[14]. Immunohistochemistry shows stronger S100B immunopositivity in the rectal submucosa of patients with ulcerative colitis, compared with healthy controls (original magnification, × 100). The graphs represent S100B protein expression (left) and release (right) in healthy controls and patients with ulcerative colitis (^d*P* < 0.01).

by EGCs^[13-15], while other members, such as S100A8, S100A9 and S100A12 are found in phagocytes and in intestinal epithelial cells in patients affected by IBD^[54,55].

Recent findings have demonstrated that aberrant expression and the release of S100B correlate with the gut inflammatory status^[13,14]. Interestingly, the search for a specific S100B signaling receptor has demonstrated that this protein may accumulate at the RAGE (receptor for advanced glycation end products) site only in micromolar concentrations^[14,56-59]. Such interaction leads to mitogen-activated protein kinase (MAPK) phosphorylation and consequent nuclear factor-κB (NF-κB) activation^[13] which, in turn, leads to the transcription of different cytokines and iNOS protein. Thus, S100B can be considered as an easily diffusible pro-inflammatory cytokine which gains access to the extracellular space especially at immune-inflammatory reaction sites in the gut^[13-15,60,61].

EGCs AND S100B IN GUT INFLAMMATION

In humans, recent and increasing data has demonstrated that EGCs and S100B protein are directly involved in gut inflammatory diseases^[13,14,33]. Previous investigations described abnormalities of the enteroglia network in patients with Crohn's disease and UC^[33]. More recently, glial abnor-

malities have been confirmed by 2 separate studies carried out by our group^[13,14]. In particular, we demonstrated that, in patients with celiac disease (CD)^[13] and UC^[14], EGCs participate in the modulation of mucosal NO production *via* S100B overexpression and release. Indeed, in patients with CD, we demonstrated that S100B plays an active role in NO-dependent inflammation^[13]. In particular, increased S100B protein expression and release were observed in the duodenal mucosa of patients with untreated CD, compared to healthy controls (Figure 1A)^[13]. Very interestingly, S100B upregulation was accompanied by enhanced iNOS protein expression and consequent NO release, both representing crucial features in CD^[62].

The relationship between S100B and NO production was confirmed by the demonstration that the administration of exogenous S100B protein to non-inflamed duodenal biopsy specimens from healthy controls, resulted in both iNOS protein expression and NO release, indicating that micromolar concentrations of this protein are able to participate in the inflammatory response of even "healthy duodenum"^[13]. Besides NO production, exogenous S100B mediates a significant increase in lipid peroxidation associated with a marked increase in phosphorylated-p38 MAPK protein expression and with the activation of NF-κB, in accordance with the previously mentioned studies^[13].

Taken together, these observations represented the

first data in humans suggesting that *via* S100B upregulation, EGCs directly participate in NO-dependent inflammation occurring in CD, and they paved the way by supposing that EGCs are part of complex immunoregulatory effectors since they establish a strategic first defense line against foreign antigens. By means of EGC proliferation, changes in enteroglia architecture have been reported also in patients with IBD^[33,63]. Several studies have shown that EGC markers are differentially altered in Crohn's disease and UC with a decrease in EGC density in Crohn's disease and a gliosis-like phenomenon in UC^[33,63].

In support of these observations, it has recently been confirmed that EGCs directly participate in the chronic mucosal inflammation of patients with UC^[14]. In fact, S100B immunoreactivity significantly increased in the rectal mucosa of these patients when compared to the mucosal S100B expression in healthy controls (Figure 1B)^[14]. This upregulation was associated with the specific stimulation of iNOS and consequent abnormal mucosal NO production, both representing characteristic features of UC^[64,65].

In addition, *via* iNOS expression, exogenous S100B induces a significant and concentration-dependent increase in NO production in the human rectal mucosa of healthy controls *via* RAGE interaction^[14], confirming the ability of EGCs to modulate NO production and the specificity of S100B protein-mediated responses in the human gut.

Further confirming that EGCs are part of the complex system of immunoregulatory effectors in the gut, it has been shown that the addition of pro-inflammatory stimuli to rectal mucosal tissue led to EGC activation, again *via* RAGE involvement^[14] as demonstrated by both S100B upregulation and enhanced NO production. These findings indicate that EGCs are able to recognize inflammatory stimuli and that once activated, they produce and release S100B up to micromolar concentrations, thereby contributing to NO production in the human gut.

CONCLUSION

EGCs as a target for new drugs aimed at inflammatory gut disorder management

In summary, emerging evidence now indicates that EGCs actively participate in the modulation of inflammatory responses in the human gut. Targeting their hyperactivation in the gut in inflammatory disorders may represent a novel approach to diminish tissue damage and to counteract the lack of long-term effectiveness of classical immunosuppressant agents.

Additional studies investigating the relationship between EGCs and immune cells are warranted in order to carry out an in-depth examination of the role of glial cells and glia-derived factors in the modulation of immune/inflammatory responses in the human gut. Preliminary data indicates that EGCs-derived S100B is able to affect peripheral blood and intestinal mucosal immune cell responses *via* RAGE^[66].

The application of this approach may help the future evaluation of the relationships between EGCs and im-

mune cells in order to better understand the pathophysiology of intestinal inflammation and to establish new therapeutic approaches towards the treatment of gut inflammatory disorders.

Abstract

AIM: To evaluate the effect of portal vein thrombosis and arterioportal shunts on local tumor response in advanced cases of unresectable hepatocellular carcinoma treated by transarterial chemoembolization.

METHODS: A retrospective study included 39 patients (mean age: 66.4 years, range: 45-79 years, SD: 7) with unresectable hepatocellular carcinoma (HCC) who were treated with repetitive transarterial chemoembolization (TACE) in the period between March 2006 and October 2009. The effect of portal vein thrombosis (PVT) (in 19 out of 39 patients), the presence of arterioportal shunt (APS) (in 7 out of 39), the underlying liver pathology,

Child-Pugh score, initial tumor volume, number of tumors and tumor margin definition on imaging were correlated with the local tumor response after TACE. The initial and end therapy local tumor responses were evaluated according to the response evaluation criteria in solid tumors (RECIST) and magnetic resonance imaging volumetric measurements.

RESULTS: The treatment protocols were well tolerated by all patients with no major complications. Local tumor response for all patients according to RECIST criteria were partial response in one patient (2.6%), stable disease in 34 patients (87.1%), and progressive disease in 4 patients (10.2%). The MR volumetric measurements showed that the PVT, APS, underlying liver pathology and tumor margin definition were statistically significant prognostic factors for the local tumor response ($P = 0.018$, $P = 0.008$, $P = 0.034$ and $P = 0.001$, respectively). The overall 6-, 12- and 18-mo survival rates from the initial TACE were 79.5%, 37.5% and 21%, respectively.

CONCLUSION: TACE may be exploited safely for palliative tumor control in patients with advanced unresectable HCC; however, tumor response is significantly affected by the presence or absence of PVT and APS.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common neoplasms in the world and its incidence is increasing worldwide. It is associated with liver cirrhosis in 80% of cases and it is the leading cause of death among cirrhotic patients^[1]. Liver resection and liver transplantation are curative therapeutic options^[2]. Likewise, percutaneous ablative treatments such as percutaneous ethanol injection (PEI)^[3], radiofrequency ablation^[4], microwave ablation^[5] or MR-guided laser-induced thermotherapy (LITT)^[6] can also be applied as therapeutic options with curative potential. However, curative treatments are applicable in only 30%-40% of cases due to the presence of multifocal tumors or limited hepatic reserve at the time of diagnosis^[7,8]. Transarterial chemoembolization (TACE) was introduced as a palliative local therapeutic option for the treatment of unresectable HCC. The goal of palliation is to control symptoms, improve life quality and prolong survival^[8,9]. Different studies have investigated the predictors of survival after TACE and concluded that the prognosis is multifactorial, including the extent of the tumor at diagnosis and also the extent of liver injury^[8,10,11].

The purpose of this study was to evaluate retrospectively the role of TACE in local tumor control of unresectable HCC and the effect of portal vein thrombosis (PVT) and arterioportal shunts (APS), as well as other associated pathological factors, on the local tumor response in advanced cases.

MATERIALS AND METHODS

Approval of this study was obtained from the institutional review board, and informed consent was obtained from all patients including approval of the protocol of treatment and the anonymous use of the data for research purposes.

Patients

The medical records of all patients who had unresectable hepatocellular carcinoma and who were treated with TACE between March 2006 and October 2009 were retrospectively evaluated. A total of 39 patients (33 males and 6 females) ranging in age from 45-79 years (mean: 66.4 years, SD: 7) with unresectable HCC were treated with repetitive TACE. The total number of sessions was 219, range: 1-17, mean: 5.6 sessions, SD: 3.7. Patient demographics, lesion pathology, treatment, and outcome data, including all histopathology reports and imaging studies, were collected from the electronic medical record archiving system and were subsequently analyzed. Special emphasis was placed on the stage of disease at the time of first embolization. The number, location and size of liver tumors were obtained by reevaluating the original CT

and magnetic resonance imaging (MRI) scans. The patient and tumor characteristics are summarized in Table 1.

Inclusion and exclusion criteria

All patients involved in the study were not eligible for surgical or local ablative therapies. The inclusion criteria of the study were: (1) Tumors of any size associated with portal vein thrombosis, either partial thrombosis of the main portal vein or segmental portal vein branch thrombosis; (2) Tumors associated with APS with or without PVT; (3) Large solitary tumors of more than 5 cm in maximal diameter, multinodular or bilobar tumors; and (4) Patients with Child-Pugh Scores between A and B.

The exclusion criteria were: (1) Patients with poor performance status (Karnofsky index < 50%); (2) Nutritional impairment; (3) Presence of ascites; (4) Encephalopathy; (5) High serum total bilirubin level (> 3 mg/dL); (6) Serum albumin level < 2.0 mg/dL; (7) Renal failure (serum creatinine level > 2 mg/dL); (8) Cardiovascular or respiratory failure; (9) Florid infection; (10) Main PV complete thrombosis; and (11) Extrahepatic tumor manifestation.

Management protocol of the patients

The protocol for management was decided by a multidisciplinary team composed of hepatic surgeons, interventional radiologists, hepatologists and medical oncologists. The end point of TACE therapy was defined as stable disease for two successive sessions or disease progression.

TACE technique

TACE was performed with a treatment interval of 4-6 wk. For patients with bilobar disease, the treatment was

performed to control disease in the lobe with higher tumor burden as seen on MRI performed immediately before the procedure; the second lobe was treated in another session. All angiographies were performed on an Axiom Multistar system (Siemens; Erlangen). After the introduction of a 5 French sheath into a femoral artery, an angiographic survey of the abdominal vessels was performed using a 5 F pigtail catheter in the first TACE course. After exclusion of the presence of a right hepatic artery by selective catheterization of the mesenteric artery, indirect portography followed, outlining the portal circulation in the venous phase. Afterwards, a 5 French Cobra catheter was placed in the coeliac trunk and advanced beyond the gastroduodenal artery. If possible, the tip of the catheter was advanced further into segmental arteries adjacent to the tumor.

The embolization suspension, containing 5-10 mg/m² mitomycin C as a chemotherapeutic agent and 1-10 mL Lipiodol, an iodized oil, was administered, followed by injection of 60-180 mg degradable starch microspheres (EmboCept, PharmaCept) for vascular occlusion. The embolization material was injected slowly with fluoroscopic control until stasis of blood flow was observed. Devascularization after embolization was confirmed by an additional angiographic study of the hepatic artery.

Follow up after TACE

TACE procedure was performed on an outpatient basis. After the procedure, patients were observed for 10-12 h to ensure adequate hydration and symptomatic treatment of pain and vomiting. After the observation time, patients who had remained symptom-free were discharged to the care of the referring oncologist. If complications developed, patients were to be readmitted immediately. Complications were evaluated adopting the Society of Interventional Radiology (SIR) criteria^[12]. Major complications were defined as any event that resulted in additional treatment including an increased level of care, hospital stay beyond observation status (including readmission after initial discharge, substantial morbidity and disability and death. All other complications were classified as minor.

Local tumor response

The local tumor response to the treatment protocol was evaluated using the response evaluation criteria in solid tumors (RECIST) and MRI volumetric assessment.

According to RECIST criteria, complete response was defined as the complete disappearance of all recognizable tumor in the liver confirmed at 4 wk after the procedure. Partial response was defined as a reduction of at least 30% in the sum of the longest diameter of the lesions, taking as reference the baseline study, and was confirmed at 4 wk. Stable disease was defined when neither partial response nor progressive disease criteria were met, taking as reference the smallest sum of the longest diameter recorded since treatment started. Progressive disease was defined as the appearance of new lesions or as an increase of at least 20% in the sum of the longest diameter of the lesions, taking as reference the smallest-sum longest diameter recorded since treatment started^[13].

To evaluate the local tumor response using volumetric MRI measurements, tumor volumes were calculated before treatment, one month after the first TACE session and after the last TACE session. Tumor volumes were calculated with the ellipsoidal volume formula: Volume = (length × width × height × 0.523). For assessment of multicentric tumors; in patients with up to 3 focal lesions, the sum of all tumor volumes was calculated. For patients with more than 3 tumors, the sum of the largest 3 tumors was calculated.

The percentage of volume changes before and after treatment was then calculated. The local tumor response was considered as progressive if there was increase in the post-treatment volume (after the last TACE session) compared to the pretreatment volume, and as regressive if there was reduction in the post-treatment volume compared to the initial volume.

Imaging technique

The morphologic tumor response (number, size and volume) was evaluated on MRI in consensus by two senior radiologists. For initial treatment planning, unenhanced and contrast-enhanced [application of 0.1 mmol of gadopentate dimeglumine (Magnevist, Schering, Berlin, Germany) per kilogram body weight] T1-weighted gradient-echo sequences (FLASH-2D) with transversal and sagittal slice orientation (TR/TE:135/6 ms; FA 80°; FOV 350 mm; matrix 134 × 256; slice thickness 8 mm) MRI studies were carried out for all patients with a conventional 1.5-T system (Magnetom Symphony; Siemens, Erlangen, Germany). Additional non-enhanced T2-weighted turbo-spin-echo (TSE) sequences (TR/TE: 3 800/92 ms; FA 150°; FOV 350 mm; matrix 115 × 256; slice thickness 8 mm) and contrast-enhanced dynamic VIBE sequences (TR/TE: 4.5/1.8 ms; FA 15°; FOV 350 mm; matrix 128 × 256; slice thickness 8 mm) were used for the differentiation of the lesions.

Lipiodol retention in the tumor and the liver parenchyma was verified with non-enhanced CT examinations. In addition, CT allows optimal comparison between results on follow-up images in the subsequent sessions and can efficiently exclude major post-procedure complications such as pancreatitis, hepatic infarction, mesenteric ischemia, and ascites or ectopic embolization. CT was performed 24 h after TACE using the spiral technique (slice thickness, 8 mm) on fourth-generation scanners (Somatom plus or Somatom plus 4, Siemens, Erlangen, Germany).

Statistical evaluation

For assessment of different risk factors, patients were divided into two groups according to the following: (1) Presence or absence of PVT; (2) Presence or absence of APS; (3) Child-Pugh scores (A or B); (4) Number of focal lesions (solitary or multiple); and (5) Definition of the focal lesions (well defined or ill defined margin). Patients were further divided into groups according to the underlying liver pathology (HCV, HBV, alcoholic, toxic and cryptogenic cirrhosis). Data were statistically described in terms of range, mean ± SD, frequencies (number of

cases) and relative frequencies (percentages) when appropriate. Comparison of quantitative variables between different groups was done using Wilcoxon Mann Whitney *U* test for independent samples. Comparison of quantitative variables over the study period was done using Wilcoxon matched-pairs test comparisons. A probability value (*P* value) less than 0.05 was considered statistically significant. The influence of variables on prognosis was evaluated by univariate analysis. When the result was statistically significant, multivariate regression analysis was used to analyze the factors influencing the prognosis to avoid any confounding interaction between them.

Survival times were calculated beginning with the dates of the first TACE treatment using the Kaplan-Meier method. The log-rank test was used to determine the significance of the difference between patient survival rates in different patient groups.

RESULTS

The treatment protocols were well tolerated by all patients, with only minor side effects and no major complications. Post-embolization syndrome in the form of nausea and vomiting occurred in 9 patients (23%) and a dull aching upper abdominal pain persisting for 24 h in 11 patients (28.2%). There was no mortality within 30 d from the time of TACE.

Local tumor response using RECIST criteria

Local tumor morphologic evaluations according to RECIST criteria were as follows: no patient achieved complete response, partial response in one patient (2.6%), stable disease in 34 patients (87.1%) and progressive disease in 4 patients (10.3%). The comparisons of the local tumor response according to RECIST criteria in different patient groups are summarized in Table 2.

Local tumor response using volumetric MR imaging assessment

The local tumor response using MR volumetric measurements revealed the following results: tumor volume reduction in 17 patients (43.6%) and tumor volume progression in 22 patients (56.4%). The changes of the tumor volumes after TACE and the local tumor response are summarized in Tables 3 and 4.

The local tumor response evaluated using the percentage of volume changes between the pre- and post-treat-

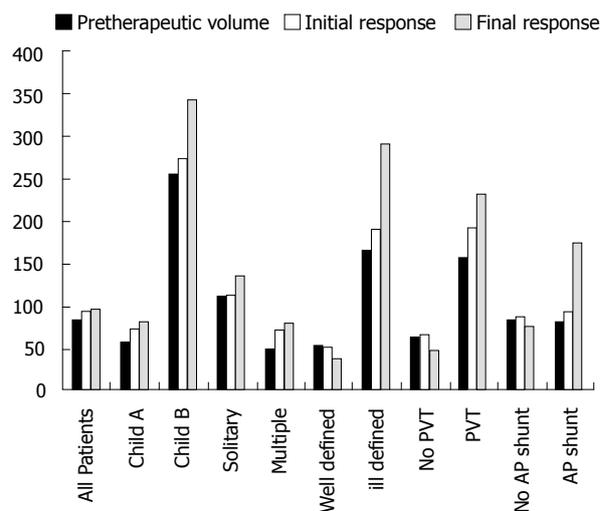

Figure 1 Magnetic resonance imaging volumetric changes of the median tumor volume (mL) in different patient groups. PVT: Portal vein thrombosis; AP: Arterioportal.

ment volumes was statistically significant and influenced by the following factors: the presence or absence of PVT, presence or absence of APS and tumor margin definition ($P = 0.018, 0.008$ and 0.001 , respectively) (using Mann-Whitney-*U*-test), as tumor volume regression was detected more in the absence of PVT and APS and in tumors with well defined margins (Figure 1). Multivariate analysis (using multiple regression test) showed that the tumor margin definition seems a more significant factor compared to the presence of PVT or AP shunts ($P = 0.002$).

The local tumor response was insignificantly affected by the number of focal lesions and Child-Pugh score of the patient ($P = 0.478$ and 0.893 , respectively). Correlation between the underlying liver pathology and the percentage of volume changes between the pre- and post-treatment volumes was statistically significant ($P = 0.034$) (using Kruskal Wallis-test). However, correlation between the different patient groups failed to prove statistical significance (using Conover-Iman-Test). The changes of the median tumor volumes are illustrated in Figure 2. The correlation between the pre- and post-treatment tumor volumes for all patients is illustrated in a scatter gram (Figure 3).

Survival analysis

The overall survival rates calculated from the time of first TACE sessions for all patients at 6, 12 and 18 mo were

79.5%, 37.5% and 21%, respectively (Figure 4). The median survival time was 10 mo. There was an insignificant difference in the survival rates between different patient groups on analysis by log-rank test (PVT: $P = 0.653$, APS: $P = 0.822$, number of lesions: $P = 0.26$, margin definition of lesion: $P = 0.155$ and Child-Pugh score: $P = 0.09$) (Figure 4).

DISCUSSION

Despite the remarkable advancement and availability of novel curative options, a great proportion of HCCs are still not eligible for curative treatment due to advanced tumor stage or poor hepatic functional reserve^[7]. There is no evidenced-based knowledge regarding a standard systemic chemotherapy protocol that improves the overall survival in advanced HCC patients^[14]. Combination chemotherapy using different mixtures of doxorubicin, 5-FU, mitomycin C, bleomycin, cisplatin, interferon (PIAF), gemcitabine and mitoxantrone has been employed in the treatment of advanced HCC. Although some of the combination regimes have shown improved tumor control in phase II studies, most of them fail to demonstrate any survival advantage in randomized phase III studies^[15].

New research trials utilizing sorafenib have demonstrated survival extension in two phase III trials in North America, Europe and in the Asia-Pacific area, which respectively reported a median survival after treatment of 10.7 and 6.5 mo^[16]. However, drug-related adverse effects including diarrhea, hand-foot skin reaction, anorexia, alopecia, weight loss, dry skin, abdominal pain and voice changes have been reported^[17].

Attention has been focused on locoregional approaches for the palliative treatment of HCC in recent years. Although TACE is widely used in the palliative treatment of unresectable HCC, its role remains controversial^[18-20]. It has been shown to provide reasonable survival advantages in two randomized control trials and a meta-analysis^[21].

Different reports have investigated the predictors of survival after TACE for unresectable HCC. These predictors may be related to the tumor burden (number of focal lesions, size of the tumor, tumor/liver volume ratio and PVT), the liver function (Child-Pugh score), health status (constitutional syndrome and Karnofsky index) or may be related to the treatment protocol^[8,10,20,22,23]. In a large scale study of 8510 patients who underwent TACE, multivariate analyses revealed the following variables to be independent predictors of patient prognosis: degree of liver

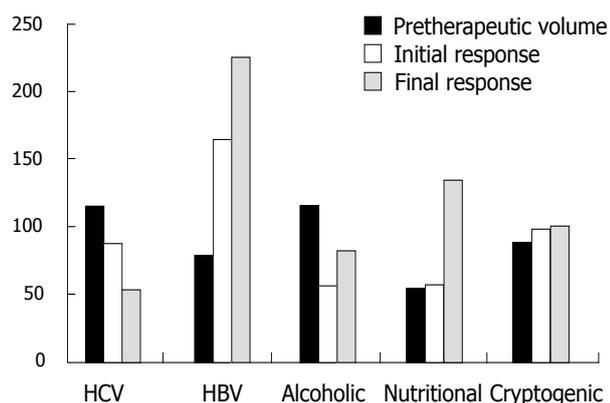

Figure 2 Magnetic resonance imaging volumetric changes of the median tumor volume (mL) according to the underlying liver pathology. HBV: Hepatitis B virus; HCV: Hepatitis C virus.

damage, maximum tumor size, number of lesion(s) and portal vein invasion^[8]. Portal vein invasion showed much higher risks than the other variables.

The endpoint in cancer research is overall survival. Nonetheless, other potential endpoints, such as response rate and time to progression, are currently used. In this study, the predictors of local tumor response after TACE were evaluated, as well as the role of TACE in local tumor control for unresectable advanced HCC. Since volumetric quantification can lead to a different assessment result compared with uni- and bi-dimensional measurement techniques^[24], the local tumor response to the TACE treatment was evaluated using both RECIST criteria and MRI volumetric measurements. According to RECIST criteria, tumor stability was achieved in 34/39 patients (87.1%), and partial response in 1 patient (2.6 %), while progression occurred in 4 patients (10.3%) and, by volumetric measurements, reduction of the tumor volume occurred in 17 patients (43.6%) and progression in (56.4%), taking into consideration the inclusion of advanced pretreatment tumor stage regarding the size, number and portal vein invasion. This may emphasize the role of TACE in local tumor control even in the advanced stages of HCC. Univariate analysis revealed the following 4 variables as significant prognostic factors: PVT, APS, tumor margin definition and underlying liver pathology (Figures 5 and 6). The clinical significance of the presence of PVT, APS and tumor margin ill definition is clearly demonstrated by the progressive increase in the corresponding median tumor volumes at the end of TACE treatment (Figure 1). Multivariate analysis showed that the tumor margin ill definition affects the local tumor response more significantly compared to the presence of PVT or AP shunts.

TACE has been limited in palliative treatment of cases associated with major portal vein (PV) invasion due to the possibility of liver failure following embolization and that it may predispose to hepatic infarction. Transcatheter arterial chemo infusion (TACI) has been an option in such cases^[25]. However, recent studies have shown that TACE using less aggressive embolization can be performed

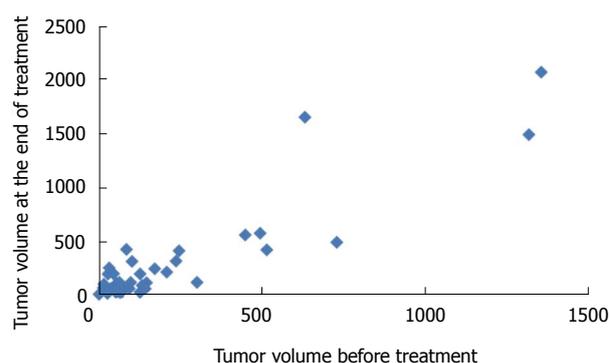

Figure 3 Scatter gram. Correlation between the pre- and post-treatment volume.

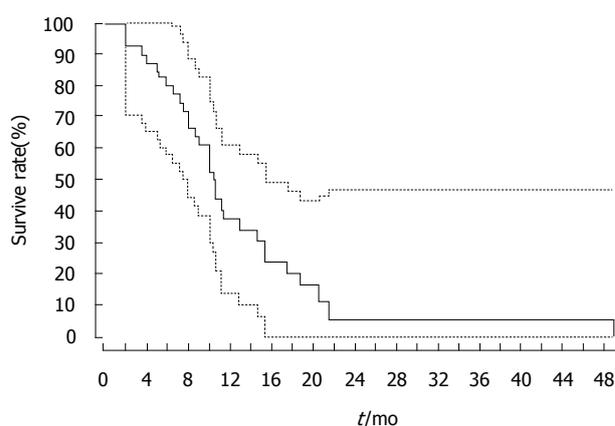

Figure 4 Kaplan-Meier survival curve for all patients showing the overall survival rates calculated from the time of first transarterial chemoembolization sessions. The estimated survival rates at 6, 12 and 18 mo were 79.5%, 37.5% and 21%, respectively, with a median survival time of 10 mo. Kaplan-Meier with confidence $P = 0.95$.

safely in patients with major PV thrombosis with no increase in morbidity or mortality^[26-28]. The current study included patients with partial thrombosis of the main PV or thrombosis of one of its lobar branches or segmental branches. The procedure was tolerated by all patients and none of the patients developed major complications that required prolonged hospitalization. Chung *et al*^[29] explained the prognostic significance of PVT by suggesting that the presence of tumor thrombi in the PV results in extensive tumor spread throughout the liver.

Arterioportal shunts associated with HCC have been reported in about 28.8% to 63.2% of HCCs. Ngan *et al*^[30] explained the poor prognostic clinical significance by suggesting that the shunt flow to the portal vein aggravates the portal venous pressure, which induces life-threatening conditions such as esophageal varix, ascites and hepatic encephalopathy. In this present study 7/39 patients (17.9%) had associated APS, six of these cases were associated with ill defined tumor margin and four cases were associated with PVT. The MR volumetric measurements revealed progression of the tumor in the 7 patients (100%) and the percentage of volume changes between both groups (APS and no APS) were statistically significant. Huang *et al*^[31] explained poor response to TACE by the fact that during

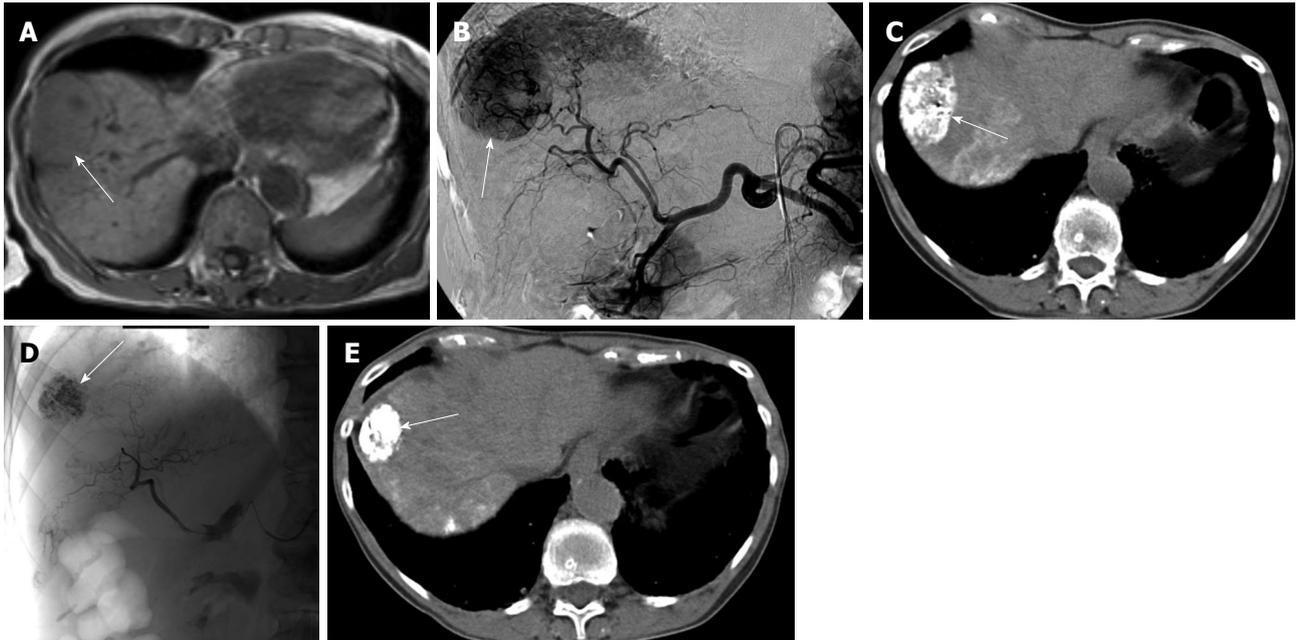

Figure 5 A 76-year-old female patient, hepatitis C virus liver cirrhosis. Note enhancement of the portal vein (black arrow) in the arterial phase (black arrow head at the aorta) denoting an underlying arterioportal shunt; B: Digital subtraction angiography showing opacified portal vein (white arrows) during the arterial phase (APS) (white arrows); C: Digital subtraction angiography during the last (6th) transarterial chemoembolization (TACE) showing the APS with markedly dilated and partially thrombosed portal vein (white arrows); D, E: Axial MRI T1 post contrast after the last TACE showing tumor infiltration of the dilated main portal vein (white arrow in Figure 6D) and progression of the tumor size (> 20%) by MRI volumetry (white arrows in Figure 6E) (white arrows).

TACE, oil emulsion may be diverted into the portal vein branches and delivered to non-tumor hepatic tissue instead of being deposited intratumorally. Although the univariate analysis revealed a statistical significance between the un-

derlying liver pathology and the local tumor response, the multivariate analysis failed to prove the clinical significance, probably because of the sample size and the registered data which are located out of the overlapping area statistically.

Limitations of this study are the retrospective design and the heterogeneous population. However, this study at least illustrates the role of TACE in local tumor control of unresectable HCC, even in advanced cases, and the prognostic factors affecting the tumor response.

In conclusion, TACE may be applied in the palliative treatment of patients with unresectable advanced HCC for local tumor control. The local tumor response to TACE is significantly affected by the presence or absence of portal vein thrombosis, arteriportal shunt, tumor margin definition and the underlying liver pathology.

COMMENTS

Background

To date, there is no evidence-based knowledge regarding a standard systemic chemotherapy protocol that improves the overall survival in advanced hepatic cancer (HCC). Attention has been focused on regional liver approaches for the palliative treatment of HCC in recent years, including transarterial hepatic chemoembolization (TACE). This therapy been shown to provide reasonable survival advantages in two randomized control trials and a meta-analysis. However, the factors that determine tumor response under the effect of local chemotherapy are still under research and evaluation.

Research frontiers

This research focused on the vascular factors that may affect the tumor response and patient survival in patients undergoing TACE therapy in advanced HCC. Both portal vein thrombosis (PVT) and arteriportal shunts (APS) were found to be statistically significant factors influencing reduced tumor responsiveness to TACE therapy. Other pathological factors which may determine the tumor end response are the underlying liver pathology, Child-Pugh status and tumor margin definition.

Innovations and breakthroughs

The study concludes that TACE may be exploited safely for palliative tumor control in patients with advanced unresectable HCC; however tumor response is significantly affected by the presence or absence of PVT and APS.

Terminology

Transarterial Chemoembolization is a minimally invasive therapeutic procedure which consists of: catheterization of the hepatic artery to inject the chemotherapeutic medications selectively in the feeding vessels of the liver tumor. The therapeutic medications consist of chemotherapeutic agent (which inhibits tumor cell proliferation) in a mixture with occlusive material (to block the feeding vessels of the tumor). Both agents work together to suppress tumor activity and kill tumor cells. Portal vein thrombosis: thrombosis of the major blood vessel of the liver that carries the nutritive materials from the gastrointestinal tract to be metabolized in the liver. The hepatic portal vein is responsible for 75% of blood supply to the liver. Arteriportal shunt: This is an abnormal communication between the hepatic artery and portal vein tributaries.

Abstract

AIM: To isolate and identify the biological characteristics of human colon cancer stem cells (SW1116 cells) and further study their proteome.

METHODS: SW1116 cells were isolated and cultured with a serum-free medium (SFM). Sphere formation was assayed to observe the formation of colon cancer stem cell spheres. SW1116 cells were inoculated into a serum-containing medium for observing their differentiation characteristics. Proliferation curve and cross-resistance of SW1116 cells to different drugs were detected by MTT. Percentage of SP cells in SW1116 cells was detected with Hoechst33342 staining. Telomerase activity in SW1116 cells was checked by polymerase chain reaction (PCR)-enzyme linked immunosorbent assay. Expressions of stem cell relevant genes and proteins were detected by reverse transcription-PCR and Western blot, respectively. Total protein was isolated from SW1116 cells by two-dimensional gel electrophoresis (2-DE) and

differentially expressed proteins were identified by tandem mass spectrometry (MALDI-TOF/TOF).

RESULTS: The isolated SW1116 cells presented as spheroid and suspension growths in SFM with a strong self-renewal, proliferation, differentiation and drug-resistance ability. The percentage of SP cells in SW1116 cells was 38.9%. The SW1116 cells co-expressed the CD133 and CD29 proteins. The telomerase activity in SW1116 cells was increased. The expressions of different stem cell relevant genes and proteins were detected. The proteomic analysis showed that the 26 protein spots were differently expressed in SW1116 cells and 10 protein spots were identified as ubiquitin fusion-degradation 1-like protein, nuclear chloride channel protein, tubulin β , Raichu404X, stratifin, F-actin capping protein α -1 subunit, eukaryotic translation elongation factor 1 delta isoform 2, hypothetical protein, glyceraldehyde-3-phosphate dehydrogenase and guanine nucleotide binding protein β polypeptide 2-like 1, respectively.

CONCLUSION: SW1116 cells are biologically characterized by self-renewal, proliferation and differentiation, and the differently expressed proteins in SW1116 cells may be essential for isolating cancer stem cells.

INTRODUCTION

Colon cancer is the leading cause of cancer-related death in developed countries^[1]. Although its incidence has significantly reduced in most Asian countries, the incidence of colorectal cancer in Japan is increasing due to westernized diets. More information on factors influencing the increase, progression, and metastasis of colon cancer will lead to the development of its novel diagnostic and treatment methods. One of these factors is stem cells, but their function in the early stage of cancer is not completely understood.

Stem cells are defined as cells able to perpetuate themselves through self-renewal and to generate mature cells of a particular tissue through differentiation. They play an important role in the maintenance of organ homeostasis and may be responsible for tumorigenesis and contribute to resistance to cancer therapy^[2]. Since the identification and characterization of cancer stem cells (CSC) in hematological malignancies, an increasing number of studies have described CSC in solid tumors such as ovarian tumor^[3], colon tumor^[4], lung tumor^[5], breast tumor^[6], liver tumor^[7], melanoma^[8] and pancreatic tumor^[9], raising that the cancer stem cell hypothesis can be applied to all neoplastic systems. CSC are more important than other tumor cells because they are capable of self-renewing, differentiating, and maintaining tumor growth and heterogeneity, thus playing an important role in both tumorigenesis and therapeutics. However, research has been hampered by the lack of distinct molecular markers for CSC.

The most recent research findings have extended the criteria for CSC to human colon cancers, suggesting that colon carcinoma is organized in a hierarchical fashion, where only a CD133⁺ small subset of cells with self-renewal properties are able to recapitulate the bulk tumor population^[3,10]. CD133⁺ cells within colon carcinoma can be propagated *in vitro* as spheroid culture retains the tumorigenic capacity under these conditions. The high resistance of CD133⁺ cells to apoptosis induced by chemotherapeutic drugs is additionally consistent with the cancer stem cell hypothesis, whereas the number of CSC is particularly resistant to death-induced signals. In addition to CD133 based identification of colon cancer stem cells, Dalerba and co-workers^[11] have recently reported an alternative protocol for the isolation of human colon CSC by exploiting the surface phenotype EpCAM^{high}/CD44⁺/CD166⁺. In their study, EpCAM and CD44 antigens were selected on the basis of their previously described expression in human breast cancer stem cells. CD166 is known as a mesenchymal stem cell marker and its increased expression in colon cancer is associated with a poor clinical outcome^[12]. In this study, a comparative proteomic analysis of a human colon CSC line was performed to find more specific phenotypic markers for colon cancer.

MATERIALS AND METHODS

Reagents and cell line

Human colon cancer cells (SW1116 cells) were purchased

from Shanghai Institute of Life Science, Chinese Academy of Sciences. TeloTAGGG Telomerase polymerase chain reaction (PCR) ELISAPLUS kit was purchased from Roche Molecular Biochemicals (Basel, Switzerland). Chemiluminescent detection kit was from SuperArray Bioscience (Frederick, MD, USA). Bio-Rad protein assay kit and silver stain plusTM kit were from Bio-Rad (Hercules, CA, USA).

Isolation and culture of human SW1116 cells

Human SW1116 cells were maintained in RPMI-1640 medium (Invitrogen, Carlsbad, CA, USA) containing 10% fetal bovine serum (Gibco BRL, USA), 1×10^5 U/L penicillin G and 100 mg/L streptomycin in an atmosphere containing 5% CO₂ at 37°C. Adherent SW1116 cells were dissociated to single cell suspensions and seeded in serum-free medium (SFM). After spheres of SW1116 cells were formed, proliferation and differentiation potentials of SW1116 cells were observed. SW1116 cells were isolated and maintained in a SFM (DMEM/F12 medium) containing 20 µg/L human recombinant epidermal growth factor (EGF; Invitrogen, Carlsbad, CA, USA), 20 µg/L human recombinant basic fibroblast growth factor (bFGF; Invitrogen, Carlsbad, CA, USA), 2 mmol/L L-glutamine, 4 U/L insulin, 1×10^5 U/L penicillin G, and 100 mg/L streptomycin.

Sphere formation assay

Primary spheres of SW1116 cells were dissociated to single cell suspensions and inoculated in ultra-low attachment 96-well plates (Corning Life Sciences, Acton, MA) (100 cells per well) supplemented with 200 µL SFM. Then, 25 µL SFM per well was added every 2 d. The number of spheres of SW1116 cells in each well was evaluated 14 d after culture.

Differentiation assay of spheres

Two days after primary culture, SW1116 cells were plated in 24-well culture plates with 10% FBS and cultured with FBS-supplemented medium every two days. Differentiation potentials of SW1116 cells were observed under a microscope.

Cell proliferation assay

SW1116 cells were seeded onto 35 mm Petri dishes at a density of 1×10^4 . Cultured SW1116 cells were stained with trypan blue and counted in triplicate under a microscope for 6 wk.

Chemosensitivity test

SW1116 cells were seeded onto 96-well plates at a density of 5×10^3 per well. Twenty four hours after drugs were added at different concentrations, SW1116 cells were exposed to drugs for 2 d. Then MTT (5 mg/mL) was added and the plates were incubated at 37°C for 4 h before 100 µL 100% dimethyl sulfoxide was added to each well. The optical density of SW1116 cells in each well was detected with a microplate reader (Bio-Rad, Model 550) at a wavelength of 570 nm. The survival time

of SW1116 cells was calculated as OD value of OM- exerted cells/OD value of mocked-cells $\times 100\%$.

Fluorescence-activated cell sorting analysis

Stained SW1116 cells at a concentration of 1×10^6 cells per 100 μL buffer contained PBS at pH 7.2, 0.5% BSA, and 2 mmol/L EDTA. Antibodies against CD133 (anti-CD133-PE, BD Pharmingen, Franklin Lakes, USA) and CD29 (anti-CD29-FITC, Chemicon, Billerica, MA, USA) were used. Antibody was incubated at 4°C for 30 min. FACS analysis was done using a FACS calibur flow cytometer (Becton Dickinson).

Hoechst33342 staining

SW1116 cells were maintained in a SFM containing 5 mg/L Hoechst 33342, cultured in an atmosphere containing 5% CO_2 at 37°C for 90 min, harvested, trypsinized and fixed with 4% methanol for 20 min. SP cells were counted under a fluorescence microscope.

Telomerase assay

To quantitatively detect changes in telomerase activity, SW1116 cells were assayed with a telomerase PCR-enzyme linked immunosorbent assay (ELISA) kit according to its manufacturer's instructions. After PCR-ELISA, telomerase activity was detected using a microplate reader (Bio-Rad, Model 550) and recorded as the absorbance units. Relative telomerase activity (RTA) within different samples was obtained according to the following equation. $\text{RTA} = [(A_s - A_{so})/A_{s,IS}] / [(A_{TS8} - A_{TS8,0})/A_{TS8,IS}] \times 100$ Where A_s is the absorbance of sample, A_{so} is the absorbance of heat- or RNase-treated sample, $A_{s,IS}$ is the absorbance of internal standard (IS) of the sample, A_{TS8} is the absorbance of control template (TS8), $A_{TS8,0}$ is the absorbance of lysis buffer, and $A_{TS8,IS}$ is the absorbance of IS of the TS8.

Reverse transcription-PCR

Total RNA was isolated from SW1116 cells using Trizol reagent (Invitrogen, Carlsbad, CA, USA) following its manufacturer's instructions. First strand cDNA was synthesized using M-MLV for reverse transcription (RT-PCR) in a 24 μL solution containing 2 μL Oligo(dT)18 (500 $\mu\text{g}/\text{mL}$) (Sangon Co., Shanghai, China), 1 μg total RNA, 2 μL dNTP (10 mmol/L) (Sangon Co., Shanghai, China) and 7 μL DEPC water. Then, 5 μL 5 \times first-strand buffer, 6 μL DEPC water, 1 μL RNasin ribonuclease inhibitor (40 U/ μL) (Hua Mei Co., Guangzhou, China) were added and incubated at 42°C for 2 min. One μL M-MLV reverse transcriptase (Hua Mei Co., Guangzhou, China, 200 U) was added, the solution was placed into water bath at 42°C for 50 min and then at 70°C for 15 min. A 50 μL solution containing 1 μL Taq DNA polymerase (Hua Mei Co., Guangzhou, China), 5 μL 10 \times buffer, 1 μL dNTP (10 mmol/L), 2 μL primer (10 $\mu\text{mol}/\text{L}$) and 1 μL cDNA (0.1 $\mu\text{g}/\mu\text{L}$) was used for PCR. PCR amplification was performed in a thermal cycler (Perkin-Elmer Co., USA). The PCR products were analyzed and photographed with a gel documentation system (FR-200, Shanghai Fu Ri Bio Co., China). RT-

Table 1 Sequences of primers for RT-PCR and length of RT-PCR products

| Genes | Primer sequences | Products |
|-------|---|----------|

GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; Mus-1: Musashi-1.

PCR primers were designed and synthesized by Sangon Co, Shanghai, China (Table 1).

Western blotting

SW1116 cell extract was prepared using a lysing buffer containing 20 mmol/L Tris-HCl at pH 7.5, 0.1% Triton X, 0.5% sodium deoxycholate, 1 mmol/L phenylmethylsulfonyl fluoride, 10 $\mu\text{g}/\text{mL}$ aprotinin, and 10 $\mu\text{g}/\text{mL}$ leupeptin and centrifuged ($12000 \times g$) at 4°C . Total protein concentration was measured by BCA assay. Cellular extracts containing 50 μg total protein were subjected to 10% SDS-PAGE, and then transferred electrophoretically to polyvinylidene difluoride membranes (Invitrogen, Carlsbad, CA, USA). Blots were probed at 4°C overnight with primary antibodies in 5% milk/TBST. The antibodies used for Western blotting were CD133, CD29, Musashi-1, ABCG2, TERT and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Santa Cruz Biotechnology, Santa Cruz, CA).

Two-DE and silver-staining

Cultured SW1116 cells were harvested, washed with PBS, and lysed in a lysis buffer containing 8 mol/L urea, 4% CHAPS, 40 mmol/L Tris, 65 mmol/L DTT, 2% Bio-Lytes⁺ and centrifuged at $25000 \times g$ for 1 h at 4°C . Protein concentrations were measured by a modified Bradford assay. All samples were stored at -80°C for electrophoresis. Two-DE was performed using the PROTEAN IEF and PROTEAN xi II systems (Bio-Rad, Hercules, CA, USA). Total protein (80 mg) was run in an IEF system using a 17 cm pH 3 - 10 ReadyStrip (Bio-Rad, Hercules, CA, USA). The total Vh was 47000-52000. Following IEF separation, gel strips were equilibrated with buffer I containing 6 mol/L urea, 30% glycerol, 2% SDS, 1% DTT, followed by buffer II (DTT was replaced with 2.5% IAA), each for 15 min. The equilibrated gel strips were placed on top of a 12% T slab gel and

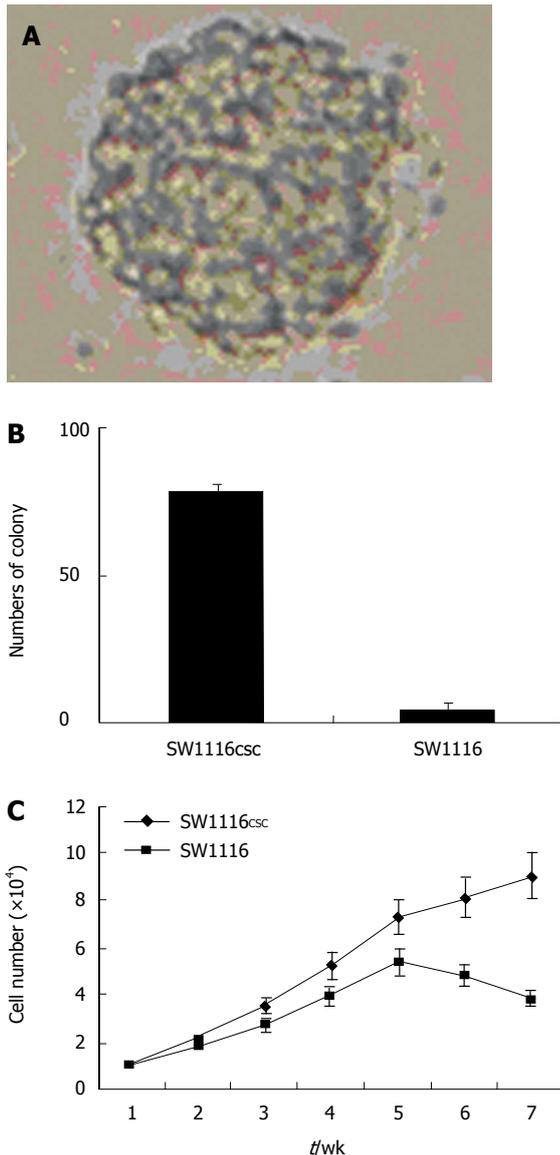

Figure 1 Spheres (A), sphere formation assay (B), and proliferation assay (C) of SW1116 cells.

sealed with 0.5% agarose. SDS-PAGE was performed for 30 min at a constant current of 10 mA and then at 25 mA until bromophenol blue reached the bottom of gels. The separated proteins were visualized with silver diamine-staining. For preparative 2-DE, 400 μ g of total proteins was separated as described above. The total Vh of IEF was 90000-120000. Proteins were detected with modified silver-staining compatible with MS analysis. Experiments (from cell culture to 2-DE) were performed in triplicate.

Image acquisition and statistical analysis

Silver-stained 2-DE gels were scanned at an optical resolution of 84.7 μ m perpixel using a GS-710 imaging densitometer (Bio-Rad, Hercules, CA, USA). Digitized images were analyzed with the PD Quest 7.1 software package (Bio-Rad, Hercules, CA, USA). Following spot detection, a matchset including the three batches of SW1116 cells was built. A reference gel was selected from one of the

SW1116 gels, and unmatched protein spots of the member gels were automatically added to the reference gel. The raw quantity of each spot in a member gel was divided by the total quantity of valid spots in the gel. Quantitative analysis of SW1116 gels was performed by Student's *t*-test.

Protein identification

Protein spots were excised from gels, destained and washed until the gels became clear. The spots were kept in 0.2 mol/L NH_4HCO_3 for 20 min, dried by lyophilization, and digested overnight in 12.5 ng/mL trypsin in 0.1 mol/L NH_4HCO_3 . Peptides were extracted three times with 50% ACN (Fisher, Fair Lawn, New Jersey, USA), 0.1% TFA (Merck, Schuchardt, Hohenbrunn, Germany) and dried in vacuum. The peptide mixture was dissolved in 0.1% TFA and desalted using a C18 ZipTip (Millipore, Bedford, MA). The eluted peptides in 0.1% TFA/50% ACN mixed with an equal volume of 0.1% TFA/30% ACN saturated with CHCA solution were applied onto the target, air-dried and analyzed by Ultraflex III matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF)/TOF mass spectrometry (MS; Bruker, Bremen, Germany). The extraction voltage was set at 20 kV and the cut-off mass value was set at 500. Tandem mass spectrometry (MS/MS) spectra were used to search protein identity from NCBI human database using Mascot search engine (www.matrixscience.com).

RESULTS

Isolation and growth characterization of SW1116 cells

Serum-free culture condition was used to isolate and maintain SW1116 cells. SFM could maintain an undifferentiated stem cell state, and addition of bFGF and EGF induced the proliferation of multipotent, self-renewing, and expandable colon stem cells. Within 24-48 h of primary culture, a minority fraction of SW1116 cells that demonstrated growth into clonally derived spheres was yielded (Figure 1A). Primary sphere formation assay showed that the frequency of SW1116 cells was $1.9\% \pm 0.3\%$. The majority of the remaining cancer SW1116 cells exhibited adherence, loss of proliferation, and subsequent differentiation, whereas tumor spheres remained non-adherent, continuous proliferation and expansion in tumor cell culture over time. When plated in a medium with 10% FBS, SW1116 cells exhibited adherent growth phenomena. After 72 h, no difference was observed in cellular volume or shape of SW1116 cells.

The self-renewing capacity of SW1116 cell spheres was assayed by dissociating primary tumor spheres, and plating SW1116 cells at serial dilutions down to 1 cell/well. Nearly all the dissociated primary tumor spheres were able to form secondary tumor spheres, exhibiting a self-renewing ability. SW1116 cells at a density of 100 cells/well generated a greater mean number of secondary tumor spheres (87.4 ± 5.1) than that (1.9 ± 0.3) of SW1116 cells (Figure 1B).

Difference was also detected in proliferation rate of SW1116 cells. The number of SW1116 cells was calcu-

Table 2 Chemosensitivity of SW1116csc and SW1116 cells to chemotherapeutic drugs (mean ± SD)

| Drugs | IC ₅₀ (mg/L) | | Times (fold) |
|--------------|-------------------------|--------------|--------------|
| | SW1116csc | SW1116 cells | |
| Paclitaxel | 23.4 ± 1.8 | 1.5 ± 0.2 | 15.6 |
| Adriamycin | 29.7 ± 2.1 | 4.4 ± 0.4 | 6.8 |
| Etoposide | 9.8 ± 0.3 | 2.1 ± 0.2 | 4.7 |
| Cytarabine | 34.2 ± 2.5 | 9.6 ± 0.7 | 3.6 |
| Fluorouracil | 57.7 ± 3.8 | 26.5 ± 1.5 | 2.2 |
| Cisplatin | 11.6 ± 0.9 | 7.3 ± 0.3 | 1.6 |
| Mitomycin | 0.67 ± 0.04 | 0.46 ± 0.03 | 1.5 |

IC₅₀: The half maximal inhibitory concentration.

lated during the first 7 wk after seeding. A difference was observed in growth rate of SW1116 cells (Figure 1C). SW1116 cells grew slowly and showed a growth inhibition after 5 wk.

Cross-resistance of SW1116 cells to chemotherapeutic drugs

Chemosensitivity of SW1116csc and SW1116 cells to chemotherapeutic drugs was detected by MTT, which showed that the resistance of SW1116 cells to paclitaxel, adriamycin, etoposide, cytarabine, fluorouracil, cisplatin and mitomycin was 15.6-fold, 6.8-fold, 4.7-fold, 3.6-fold, 2.2-fold, 1.6-fold and 1.5-fold higher than that of SW1116csc (Table 2), indicating that SW1116 cells are more sensitive than SW1116csc to therapeutic drugs.

Identification of CD133 and CD29 expression in SW1116 cells

FACS analysis showed that 65% and 36.8% of SW1116 cells were positive for CD133 and for CD29 protein, respectively. SW1116 cells (34%) co-expressed CD133 and CD29, suggesting that the in vitro propagated spheroid cells can express both markers (Figure 2A and B).

Side population cells in SW1116 cells

After cultured for 30 d, SW1116csc and SW1116 cells were stained with Hoechst 33342 to analyze differences in the SP proportion. The data showed that SW1116csc

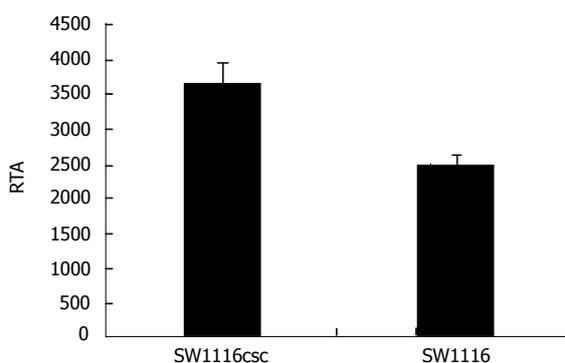

Figure 3 Telomerase activities in SW1116csc and SW1116 cells. RTA: Relative telomerase activities.

contained 38.9% ± 7.5% of Hoechst 33342-stained dull cells, while SW1116 cells contained only 1.2% ± 0.3% of Hoechst 33342-stained dull cells.

Telomerase activity of SW1116 cells

Telomerase reactivation is essential for stabilization of telomere length in attaining cellular immortality and telomerase is activated in human CSC. In this study, the RTA of SW1116csc and SW1116 cells was 3674 ± 287 and 2518 ± 140, respectively, indicating that the telomerase activity of SW1116csc is higher than that of SW1116 cells (Figure 3, P < 0.01).

Expressions of stem cell genes and proteins in SW1116 cells

RT-PCR showed that the expressions of CD133, CD29, Musashi-1, ABCG2, TERT genes increased significantly in SW1116 cells, while no change occurred in expressions of Oct-4 and Sca-1 gene in SW1116csc and SW1116 cells (Figure 4A). Western blot showed that the expressions of CD133, CD29, Musashi-1, ABCG2, and TERT proteins in SW1116csc and SW1116 cells were increased at transcriptional level (Figure 4B).

SW1116csc and SW1116 cells were presented. The protein spots detected in gels of total protein were 2115 ± 137 and 2133 ± 153 , respectively. One of the gels was selected as a reference gel. Student's t-test showed that the volume of 26 protein spots was significantly changed in gels (Figure 5A, $P < 0.05$). The expression levels were increased and decreased, respectively, in 15 and 11 out of the 26 protein spots of SW1116 cells (Figure 5B).

Identification of differentially expressed proteins in SW1116 cells

Ten out of the differentially expressed protein spots were chosen and identified as ubiquitin fusion-degradation 1 like protein, nuclear chloride channel protein, tubulin β , Raichu404X, stratifin, F-actin capping protein α -1 subunit, eukaryotic translation elongation factor 1 delta isoform 2, hypothetical protein, glyceraldehyde-3-phosphate dehydrogenase and guanine nucleotide binding protein β polypeptide 2-like 1, respectively, as detected by Western blotting (Table 3).

DISCUSSION

Cancer is composed of heterogeneous cells. A cancer

stem cell concept means that cancer cells exhibit a hierarchy and a small number of cancer cells are maintained as cancer stem cells able to renew and differentiate. Therefore, presumably all cancers come from stem cells and these cancer stem cells may be associated with metastasis, treatment resistance, and recurrence. Biologically distinct and relatively rare populations of tumor-initiating cells have been detected by several methods and markers in a variety of cancers. Putative breast cancer tumorigenic cells and $CD44^+ CD24^- / \text{low} \text{ESA}^+$ cells are able to drive tumor formation when a few hundred cells are injected into the mammary fat pad of NOD/SCID mice^[13]. In addition, different populations of cancer cells derived from primary head and neck squamous cell carcinomas display a tumorigenic potential. A minority number of $CD44^+$ cells give rise to new tumors *in vivo*^[14]. Pancreatic cancer cells with the $CD44^+ CD24^+ \text{ESA}^+$ phenotype have stem cell properties and exhibit a 100-fold higher tumorigenic potential than nontumorigenic cancer cells^[15]. In this study, colon CSC were found in the $CD133^+ CD29^+$ fraction and colon cancer stem cells with this phenotype were biologically characterized by self-renewal, proliferation and differentiation.

CD133 (prominin-1, PROM1) is a 5-transmembrane glycoprotein of 865 amino acids with a total molecular weight of 120 kDa. It has been shown that CD133 antigen is expressed in undifferentiated endothelial progenitor cells^[16], hematopoietic stem cells^[17], fetal brain stem cells^[18], embryonic epithelium^[19], prostatic epithelial stem cells^[20], and myogenic cells^[21]. CD133 has also been found on cancer stem or tumor-initiating cells in cancers such as retinoblastoma^[22], teratocarcinoma^[23], leukemia^[24], brain tumor^[25], hepatocellular carcinoma^[26], and colon cancer^[27]. It was reported that a small number of $CD133^+$ cells from primary colon cancer tissue have a tumorigenic potential in immunodeficient mice^[4], indicating that $CD133^+$ cells in colon cancer tissue have a high tumorigenic ability.

Integrin is a non-covalently-bound heterodimeric cell adhesion molecule that links ECM to cytoskeleton. $\beta 1$ integrin family ($\beta 1$ integrins, CD29), the largest group of integrins, is composed of a $\beta 1$ and one of the 12 α subunits and functions predominantly as cell-ECM adhesion. Both subunits have single hydrophobic transmembrane domains and transmit information from ECM context surrounding cells into outside-in signaling cells, while

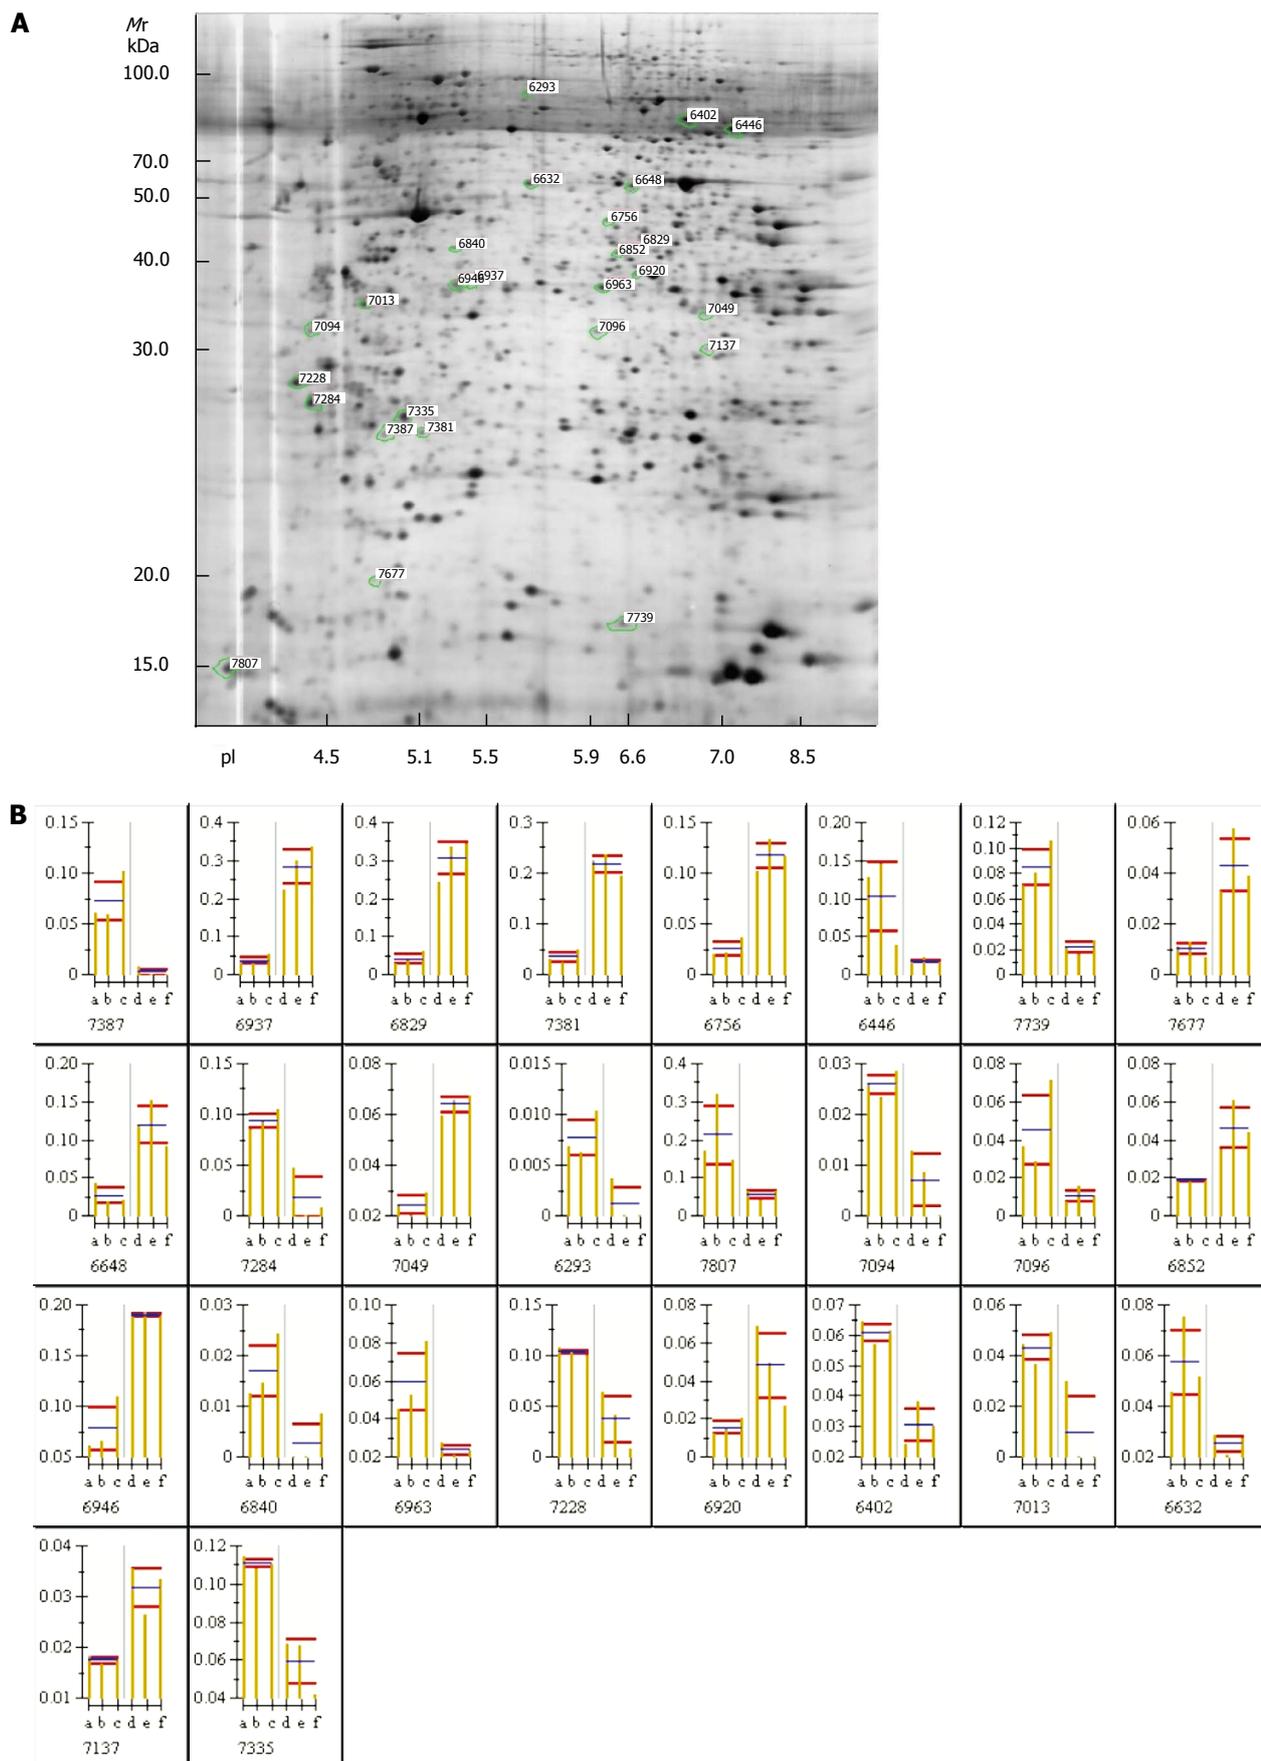

Figure 5 Two-dimensional gel electrophoresis profile (A) and histogram (B) showing expression levels of 26 protein spots in SW1116 cells and SW-1116csc.

the extracellular binding activity of integrin is regulated from the inside of cells (inside-out signaling). It was reported that integrins are involved in many biological processes such as cell growth, differentiation, migration, and death^[28], suggesting that CD29 ($\beta 1$ integrin) is a new stem cell marker for colon cancer.

In mouse small intestine and human colon, Musashi-1 (Mus-1), a mammalian RNA-binding protein associated with the maintenance of neural stem cell state and its differentiation, has been found only in the lower third crypt, with a distribution that is compared in terms of cell position with the theoretical distribution of potential stem cells in the intestinal epithelium^[29]. It has been shown that Mus-1 can activate the Notch signaling pathway by suppressing the translation of the Notch inhibitor m-Numb^[30]. The Numb protein is asymmetrically distributed in neural progenitor cells in *Drosophila* and a similar asymmetrical distribution can maintain the intestinal epithelium stem cell compartment. However, interaction of Mus-1 with Notch, Delta and Tcf-4 (which appears to be intimately involved in intestinal stem cell maintenance) together with the wide variety of stem cells that express Mus-1^[31,32], suggest that this protein plays a general role in regulation of stem cell maintenance and differentiation, thus representing distinct progenitor cells.

In this study, the expression of stem cell genes (Musashi-1, TERT, ABCG2, Oct-4, Sca-1) was detected by RT-PCR, which showed that the expression levels of Musashi-1, TERT, ABCG2 genes were significantly increased in SW1116 cells, indicating that the expression of these genes in SW1116 cells is up-regulated at transcriptional level and that SW1116 cells can express stem cell genes and proteins biologically characterized by self-renewal, proliferation and differentiation.

Telomerase is a ribonucleoprotein that extends the telomeric ends of chromosomes to counterbalance their natural shortening due to incomplete DNA replication in eukaryotic cells. It has been demonstrated that telomerase is activated in 90% of malignant tumors, but is stringently repressed in normal somatic cells^[33,34], displaying that telomerase reactivation is a critical step in carcinogenesis. In this study, the activity of telomerase was increased in SW1116 cells, which is essential for the stabilization of telomere length in attaining cellular immortality.

In this study, proteomics of SW1116 cells was used to identify more specific phenotypic markers of colon CSC and elucidate the mechanism underlying their self-renewal and differentiation^[26]. Differential protein spots were found and 10 proteins were identified. Among the differentially expressed proteins, some may be essential for isolation and identification of colon CSC.

Ubiquitin fusion degradation 1 L (UFD1L) is a human homologue of the yeast ubiquitin fusion degradation 1 (Ufd1) gene. In yeast, Ufd1 protein is involved in a degradation pathway for ubiquitin fused products (UFD pathway). The biochemical role of UFD1L protein in human cells is unknown. Velazquez-Fernandez D^[35] used microarray to study the expression profiling of adrenocortical

neoplasms, and found that UFD1L is a molecular signature of malignancy. In this study, the UFD1L protein was intensively expressed in SW1116csc and hardly expressed in SW1116 cells, indicating that the degradation pathway for ubiquitin fused products is active in colon CSC.

Stratifin is a member of 14-3-3 protein family, a highly conserved group of proteins consisting 7 isoforms involved in numerous crucial intracellular functions such as cell cycle and apoptosis, regulation of signal transduction pathways, cellular trafficking, cell proliferation and differentiation, cell survival, protein folding and processing. In eukaryotes, peptide chain elongation is mediated by elongation factors, EF-1 and EF-2. EF-1 is composed of a nucleotide-binding protein EF-1 α , and a nucleotide exchange protein complex EF-1 β gamma. Elongation factors are highly conserved among different species and may be involved in functions other than protein synthesis, such as organization of the mitotic apparatus, signal transduction, developmental regulation, ageing and transformation. Increased expression levels of stratifin and EF-1 delta in SW1116 cells may be related to cell proliferation and differentiation.

In this study, the expression of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was down-regulated in SW1116 cells. GAPDH, a multifunctional protein with defined functions in numerous subcellular processes, plays an integral role in glycolysis. New investigations are needed to establish the primary role of GAPDH in a variety of critical nuclear pathways apart from its already recognized role in apoptosis. The new roles of GAPDH include its requirement for transcriptional control of histone gene expression^[36], its essential function in nuclear membrane fusion, its necessity for recognition of fraudulently incorporated nucleotides in DNA, and its mandatory participation in maintenance of telomere structure. To undertake these new functions, GAPDH is recruited to the nuclei in S phase or its intracellular distribution is regulated as a function of drug exposure. Further study is needed to explore the functions of GAPDH in SW1116 cells.

In conclusion, SW1116 cells and CD133⁺/CD29⁺ fraction in human colon cancer cells are biologically characterized by self-renewal, proliferation and differentiation. SW1116csc is also more chemoresistant than SW1116 cells. CD133, CD29 and Mus-1 may be used in isolation and identification of colon cancer stem cells.

COMMENTS

Background

Cancer stem cell hypothesis is currently at the centre of a rapidly evolving field, involving a change of perspective in development and treatment of cancers. However, research has been hampered by the lack of distinct molecular markers of cancer stem cells.

Research frontiers

Since the identification and characterization of cancer stem cells (CSC) in hematological malignancies, an increasing number of studies have described CSC in solid tumors such as ovarian tumor, colon tumor, lung tumor, breast tumor, liver tumor, melanoma and pancreatic tumor, raising that the cancer stem cell hypothesis can be applied to all neoplastic systems.

Innovations and breakthroughs

In our study, human CSC were isolated, which presented as spheroid and suspension growths in serum-free medium, with a strong ability of self-renewal, proliferation, differentiation and drug-resistance. Proteomic analysis showed that 26 differentially expressed protein spots were detected and 10 protein spots were chosen and identified.

Applications

The results of this study have important implications for future cancer treatment. The CSC hypothesis infers that if the CSC were eliminated, the tumor would simply regress due to cell differentiation and death. It is possible to treat patients with aggressive, non-resectable tumors and prevent their metastasis by selectively targeting CSC.

Terminology

Cancer stem cells are a sub-population of cancer cells that possess characteristics associated with normal stem cells, such as self renewal and differentiation into multiple cell types. CSC are tumorigenic while the bulk of cancer cells are non-tumorigenic. CSC persist in tumors as a distinct population and cause relapse and metastasis by giving rise to new tumors.

Peer review

The authors identified the biological characteristics and proteome of human colon cancer stem cells. The results are interesting and may be essential for CSC isolation and characterization.

Abstract

AIM: To assess the efficacy and tolerability of thalidomide in pediatric Crohn's disease (CD).

METHODS: Six patients with refractory CD received thalidomide at an initial dose of 2 mg/kg per day for one month, then increased to 3 mg/kg per day or decreased to 1 mg/kg per day, and again further reduced to 0.5 mg/kg per day, according to the individual patient's response to the drug.

RESULTS: Remission was achieved within three months. Dramatic clinical improvement was demonstrated after thalidomide treatment. Endoscopic and pathological improvements were also observed after thalidomide treatment, which was well tolerated by all patients.

CONCLUSION: Thalidomide is a useful drug for pediatric refractory CD.

INTRODUCTION

Crohn's disease (CD) is a chronic transmural inflammatory bowel disease (IBD) that may involve any part of the alimentary tract from mouth to anus, especially the distal ileum and colon. It may also accompany various intra- and extra-intestinal complications during its clinical course^[1,2]. In addition to causing serious clinical symptoms and complications, its chronic nature can adversely affect the quality of life of patients^[3,4]. Despite an increasing number of treatment options, many patients with CD continue to pose a therapeutic challenge because they do not adequately respond to therapy, or because they experience serious side effects of standard medical interventions. This is particularly true for those patients with refractory CD or concomitant tuberculosis. There is an urgent need to develop new treatment modalities for refractory CD.

Thalidomide, originally used to treat morning sickness in the early 1960s, has been withdrawn from the market because it leads to serious congenital birth defects. In 1991, it was discovered that thalidomide can inhibit the synthesis of cytokine, a tumor necrosis factor- α (TNF- α), by accelerating the degradation of its mRNA^[5]. Interest in thalidomide has intensified in recent years since its immunomodulatory^[6,7] and anti-angiogenic^[8,9] properties were identified and clarified. A series of clinical trials have demonstrated the efficacy of thalidomide in treatment of several clinical conditions such as human immunodeficiency virus (HIV)-associated wasting syndrome^[10], hereditary hemorrhagic telangiectasia^[11], refractory cutaneous lesions of lupus erythematosus^[12], multiple myeloma^[13], and Behcet's disease^[14],

for which there are few or no alternative treatment options. Based on these observed clinical responses and the apparent anti-TNF- α properties of thalidomide, we used it in treatment of a 12-year-old boy with concomitant refractory CD and tuberculosis infection, and achieved a dramatic success. With this experience, we started to treat refractory CD with thalidomide. Following is a report of 6 children with a complete remission after treated with thalidomide.

MATERIALS AND METHODS

Ethics

This study was approved by the Institutional Ethics Committee of Children's Hospital of Fudan University and informed consent was obtained from all patients and their parents.

Clinical data

This is a retrospective study of 6 patients with refractory CD who visited the Children's Hospital of Fudan University in 2006-2010 (Table 1). Conventional therapy failed in these patients, and/or they could not receive steroid or immunosuppressive treatment because of concomitant tuberculosis infection.

Study design

Patients administered thalidomide in the evening at a starting dose of 2.0 mg/kg per day, which was increased to 2.5-3.0 mg/kg per day or decreased to 1.5 mg/kg per day, according to the individual patient's response to the drug. Patients were assessed at baseline, at weeks 2, 8 and 12, and then every three months for the following parameters, including physical examination, laboratory analyses and pediatric CD activity index (PCDAI) scoring. Endoscopies were repeated at six months after administration of thalidomide. Its side effects were intensely monitored during follow-up. CD was defined as refractory when standard induction therapy with high-dose intravenous steroids failed to induce remission either at diagnosis or during subsequent relapse. Efficacy was defined as thalidomide induced and maintained remission and mean time to achieve clinical remission (PCDAI^[15] < 7.5).

Statistical analysis

Results are expressed as mean \pm SD. Changes in interval PCDAI scores were evaluated by multivariate analysis of variance. $P < 0.05$ was considered statistically significant.

RESULTS

Patient A

Patient A was a 22-year-old boy with a 10-year history of CD. Steroids and 5-aminosalicylic acid (5-ASA) were administered for 4 years. However, abdominal pain, diarrhea and fever were still recurrent, and the patient remained seriously undergrown: 42.5 kg, below 10th percentile (< P10) weight-for-age and 162 cm (< P10 height-for-age). In 2006, an immunosuppressant, azathioprine, was started but could not be tolerated because of severe thrombocy-

topenia. He was then given thalidomide (2 mg/kg per day) in addition to prednisone (10 mg/d) and 5-ASA for four weeks, after which the dosage of steroid was reduced gradually while that of thalidomide was increased. After eight weeks of thalidomide treatment, abdominal pain and fever improved significantly, and the dosage of thalidomide was increased to 3 mg/kg per day while the dose of prednisone was reduced to 5 mg/d. After six months of treatment, this patient achieved complete clinical remission. The dose of thalidomide was reduced to 1.5 mg/kg per day and prednisone was withdrawn. Enteroscopic examination at this time showed that the mucosal ulceration and hyperplasia improved significantly. During thalidomide therapy, this patient experienced transient hepatic function abnormality which became normal after withdrawal of thalidomide. In August 2010, both thalidomide and prednisone were withdrawn and he was on 5-ASA for maintenance of remission without any clinical evidence for recurrence of the disease. His body weight was 67 kg (P75-P90, weight-for-age) and height was 168 cm (P10-P25, height-for-age).

Patient B

Patient B, a 13-year-old boy with a 5-year history of splenic tuberculosis, was diagnosed as CD 3 years ago. This patient also had a history of chronic diarrhea accompanying hematochezia, abdominal pain, weight loss, oral and perianal ulcers, anemia, fatigue, malnutrition and spiking fever up to 40°C. Symptoms did not improve upon anti-tuberculosis (TB) treatment with rifampin, isoniazid and pyrazinamide, and splenectomy was performed 3 years ago after which the symptoms persisted. In June 2009, double-balloon enteroscopy demonstrated segmental distribution of ulcers with different sizes and characteristics in the colon and ileum. Histological examination revealed acute and chronic mucosal inflammation and hyperplasia, with infiltration of a large number of neutrophils, plasma cells, macrophages and scanty eosinophils. Bone marrow culture identified *Mycobacterium*. Steroids, immunosuppressive agents and biologics such as infliximab could not be used due to concurrent tuberculosis infection, thalidomide was therefore chosen as the second-line therapy for his CD.

After he received thalidomide at a dose of 2 mg/kg per day for two weeks, his body temperature returned to normal, his abdominal pain and diarrhea were significantly alleviated, and his oral ulcers became more superficial and then completely disappeared. After one month of treatment, steroids were withdrawn. Six months later, thalidomide was reduced to 0.5 mg/kg per day. His body weight increased from 33 kg (< P10, weight-for-age) to 54 kg (P50-P75, weight-for-age). Endoscopic examination revealed that the intestine appeared almost normal, and laboratory data improved significantly with a normal erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). In August 2010, he was on thalidomide, 1.0 mg/kg per day, to maintain remission. No adverse effect was found throughout the treatment.

Patient C

Patient C was an 11-year-old boy who underwent two sur-

PCDAI: pediatric Crohn's disease activity index.

gical procedures for perianal abscess in September 2008 and February 2009 and had a positive history of close contact with a TB patient. TB-PPD test was strongly positive, but culture of intestinal mucosa for tuberculosis was negative. He had no response to 5-ASA and a limited response to immunosuppressive agents. In November 2009, colonoscopy identified several polyps and ulcers in the transverse and ascending colon. Because of suspected *Mycobacterium tuberculosis* infection, steroid was not used in this patient. Treatment with thalidomide at a dose of 2 mg/kg per day was started in November 2009. After two weeks of thalidomide treatment, his symptoms including fever, abdominal pain and diarrhea were significantly relieved. CRP and ESR became normal within two months after thalidomide treatment, and his body weight increased from 27 kg (< P10, weight-for-age) to 37.5 kg (P20-P50, weight-for-age). After six months of thalidomide treatment, the PCDAI was reduced to 7.5 from 70 before thalidomide treatment.

Patient D

Patient D, a 16-year-old girl with a 5-year history of CD, suffered from severe abdominal pain, chronic diarrhea and severe malnutrition. Growth failure was very marked in this patient. Her body weight was only 21 kg (< P10, weight-for-age) while her height was 130 cm (< P10, height-for-age) when she was 15 years old, and showed no secondary sexual characteristics. During the five years of treatment with steroids, immunosuppressive agents and 5-ASA, her clinical symptoms were relieved significantly, but her height or weight did not increase after the diagnosis of CD. In April 2010, thalidomide therapy was initiated. Three months after treatment, her appetite was significantly improved, her body weight increased from 21 to 33 kg (< P10, weight-for-age) and her height increased 1 cm.

Patient E

Patient E was a 9-year-old boy with a four-year history of CD accompanying recurrent fever, abdominal pain, diarrhea and poor weight gain. PPD test was regarded as positive when the induration was 18 mm × 18 mm. He was

diagnosed with intestinal tuberculosis and received anti-TB therapy for one year without any improvement in his symptoms. Because he was allergic to a variety of foods including egg, milk, soybean, peanut and wheat, his allergic colitis was treated by failed. During the last two years, he developed edema in lower limbs, ascites and pleural effusion attributable to serious malnutrition. In 2009, colonoscopy showed chronic granulomatous inflammation and segmental distribution of ulcers in the colon and terminal ileum, and CD was diagnosed. Infliximab was contraindicated in this patient because of the positive tuberculin test, thalidomide was therefore given to control his CD. After three months of treatment, the both CRP and ESR decreased significantly. His symptoms also improved quite remarkably.

Patient F

Patient F was a 13-year-old girl with a 2-year history of CD accompanying abdominal pain, chronic diarrhea and hematochezia. The patient received steroid treatment during the last two years and clinical symptoms were relieved significantly. However, when the dose of steroids was reduced gradually, her clinical symptoms appeared again. She became steroid-dependent with obvious cushingoid features developed last year. Based on the strong desire of the patient and her parents, thalidomide treatment was started at a dose of 2 mg/kg per day in April 2010. After three months of thalidomide treatment, steroids were withdrawn and her clinical symptoms improved significantly.

In conclusion, thalidomide is an effective treatment modality for refractory CD. However, its long-term efficacy and safety need to be further evaluated in a large-scale randomized controlled trial (Figures 1 and 2).

DISCUSSION

TNF- α , one of the most important immunologic mediators generated by cells of the monocyte-macrophage lineage, has a broad spectrum of biological functions and plays a crucial role in amplification of responses to infection, injury, and immune-mediated damage. As a cytokine, TNF- α can transmit signals between immune and other

cells, and is involved in apoptosis, metabolism, inflammation, thrombosis, and fibrinolysis^[16]. The importance of TNF- α and TNF- α signaling in response of the immune system to disease has become clearer as a result of a number of seminal studies^[17-19]. It was reported that mice lacking of TNF- α show a high susceptibility to infectious agents^[17] and also an impaired clearance of adenoviral vectors^[18]. In addition, gene knockout experiments (TNF- $\alpha^{-/-}$ mice) showed that TNF- α is necessary for adhesion molecule expression and recruitment of leukocytes to inflammatory sites^[19].

Although TNF- α has critical physiological functions, its overproduction plays a key role in physiopathology of a variety of diseases. Of relevance to IBD are the abilities of TNF- α to recruit circulating inflammatory cells to local tissue sites of inflammation, to induce edema, to activate coagulation cascade, and to initiate formation of granuloma^[20]. Clinical trials demonstrating symptomatic improvement and remission of CD by suppressing TNF- α have provided additional evidence of the role of TNF- α in pathogenesis of CD^[21-24].

Thalidomide was developed in the 1960s as a sedative but was subsequently withdrawn from widespread use because of teratogenicity. The drug has been banned for more than two decades when it was shown to inhibit TNF- α production^[5], thus leading to its revival in clinical settings. This property of thalidomide was first described in treatment of patients with systemic erythema nodosum leprosum^[25]. Such patients demonstrated an extremely high TNF- α level in their blood, which decreased significantly during thalidomide treatment, indicating that thalidomide therapy can reduce not only serum TNF- α level, but also clinical symptoms as well. Dermal infiltration of polymorphonuclear leukocytes and T cells are also diminished after treatment with thalidomide^[25]. Studies also demonstrated that thalidomide improves clinical symptoms in patients with HIV-associated wasting syndrome^[10], multiple myeloma^[13], Behcet's disease^[14] and CD^[26-30]. Suppression of TNF- α may be the mechanism underlying CD. It was reported that thalidomide treatment can restore the normal levels myeloperoxidase and TNF- α in a rat model of IBD^[27].

Tuberculosis is still quite common in China. Treatment of CD patients with simultaneous TB infection may be difficult. In this situation, administration of steroids or immunosuppressive agents may lead to reactivation of latent tuberculosis or its flare-up. In this study, thalidomide was a good choice for such patients, which not only improved the symptoms of CD, but also enhanced the response of the patients to anti-TB drugs.

Although thalidomide can more uniquely improve the symptoms of many diseases than other drugs, it may lead to significant problems due to its side-effects. The most serious side-effect is teratogenicity. Moreover, thalidomide often has other side-effects, including peripheral neuropathy. For these reasons, synthetic thalidomide analogues (IMiDs) with an increased TNF- α inhibitory activity and diminished side effects are desirable. Many analogues

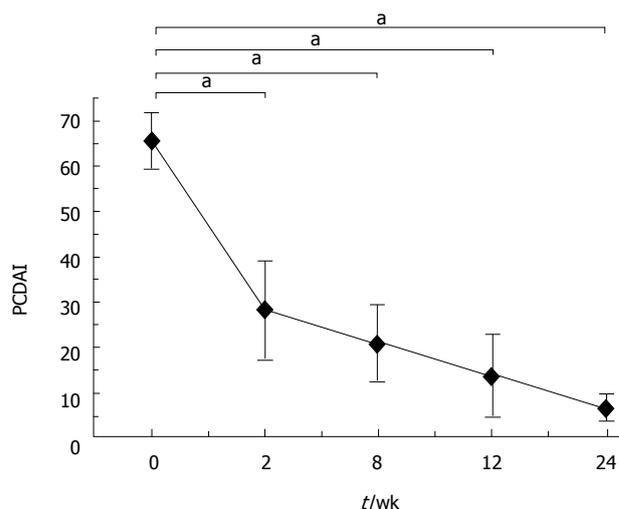

Figure 1 Mean pediatric Crohn's disease activity index during thalidomide treatment. ^a $P < 0.0005$. PCDAI: Pediatric Crohn's disease activity index.

exhibit a higher inhibition of TNF- α expression than thalidomide. In particular, the IMiDs, lenalidomide and pomalidomide (CC-4047), are respectively 2000- and 20000-fold more potent than thalidomide in inhibiting TNF- α and able to induce transcription and secretion of TGF- β and IL-10^[31]. The 4-amino analogues (in which an amino group is added to the fourth carbon of the phthaloyl ring of thalidomide) have been found to be up to 50000-fold more potent in inhibiting TNF- α than thalidomide *in vitro*^[32]. Several of these new compounds *in vivo* are able to reduce lipopolysaccharide-induced TNF- α levels in mice^[33] and inhibit development of adjuvant-induced arthritis in rats^[34]. Whether IMiDs have a greater therapeutic efficacy with fewer side-effects than thalidomide needs to be determined. It was reported that neuropathy may occur only after high cumulative doses of thalidomide are used^[26,29], indicating that thalidomide can be used as a maintenance modality.

COMMENTS

Background

Despite an increasing number of treatment options, treatment of Crohn's disease (CD) is still a challenge of physicians due to its poor response to therapy or serious side effects of standard medical interventions. This is particularly true for those with refractory Crohn's disease or concomitant tuberculosis infection. Thalidomide, a synthetic glutamic acid derivative, has anti-inflammatory, anti-angiogenic and immunomodulatory properties. Studies suggest that thalidomide can significantly inhibit the synthesis of a tumor necrosis factor- α (TNF- α) and plays a role in up-regulation of Th2-type immunity. Thalidomide may be a good choice for Crohn's disease patients.

Research frontiers

Treatment of CD patients with tuberculosis infection may be difficult. In this situation, administration of steroids or immunosuppressive agents may lead to

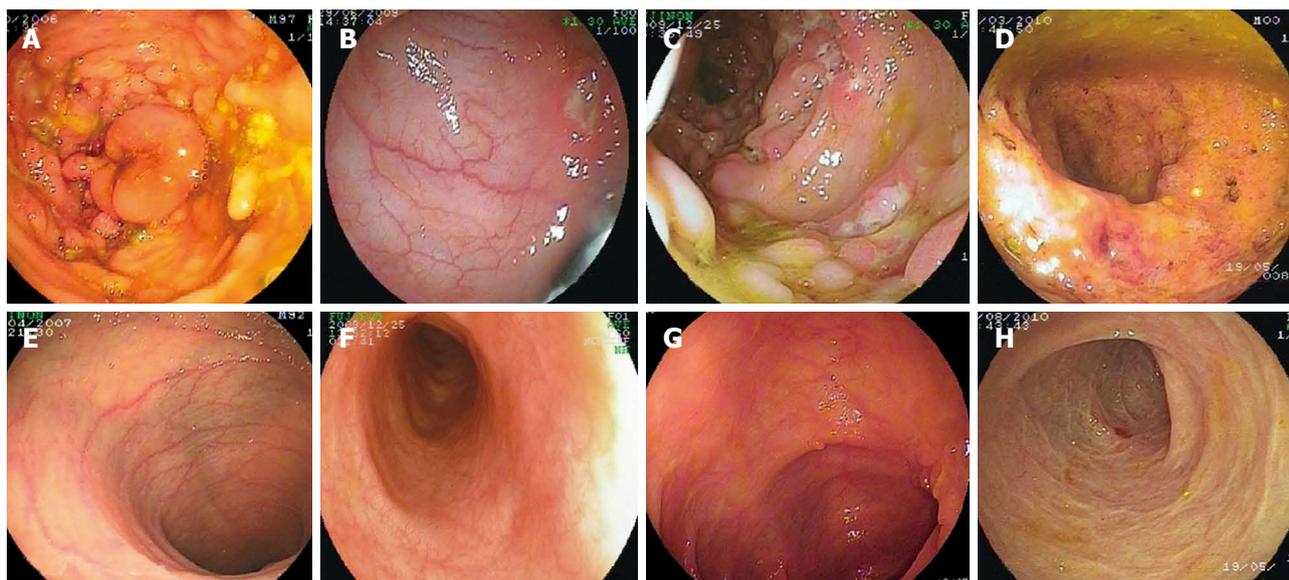

Figure 2 Endoscopy views of patients A, B, C, F before thalidomide treatment (A-D) and six months after thalidomide treatment (E-H).

reactivation of latent tuberculosis or tuberculosis infection flare-up, but tuberculosis infection is still quite common in some countries including China. It is therefore urgent to develop new treatment modalities for such patients.

Innovations and breakthroughs

Therapy for refractory Crohn's disease or concomitant tuberculosis infection is always a challenge. In the present study, thalidomide was a good choice for such patients, which can not only improve the symptoms of CD, but also enhance the response of the patients to anti-tuberculosis drugs. CD patients tolerate it quite well.

Applications

This study may offer a future strategy for therapeutic intervention of CD patients with a poor response to therapy or serious side effects of standard medical interventions.

Terminology

Refractory Crohn's disease refers to a condition in which standard induction therapy with high-dose intravenous steroids has failed to induce remission either at diagnosis or during subsequent relapse. Pediatric Crohn's disease activity index is a rating scale used to assess the severity of pediatric Crohn's disease and correlates well with disease activity.

Peer review

Although the number of patients investigated was small, the study was interesting, and well written. This manuscript is acceptable as a short article in *WJG*.

Abstract

AIM: To study the prognostic factors for intrahepatic cholangiocarcinoma (ICC) and evaluate the impact of chronic hepatitis B virus (HBV) infection on survival rate of ICC patients.

METHODS: A total of 155 ICC patients who underwent macroscopic curative resections (R0 and R1) were enrolled in this retrospective study and divided into group A with HBV infection and group B without HBV infection according to their chronic HBV infection, represented by positive hepatitis B surface antigen (HBsAg) in serum or in liver tissue. Clinicopathological characteristics and survival rate of the patients were evaluated.

RESULTS: All patients underwent anatomical resection. Their 1- and 3-year survival rates were 60.6% and 32.1%, respectively. Multivariate analyses revealed that HBV infection, hepatolithiasis, microscopic satellite

lesion, and lymphatic metastasis were the independent prognostic factors for the survival rate of ICC patients. The median disease-free survival time of the patients was 5.0 mo. The number of tumors, microscopic satellite lesion, and vascular invasion were the independent prognostic factors for the disease-free survival rate of the patients. The prognostic factors affecting the survival rate of ICC patients with HBV infection and those without HBV infection were not completely consistent. Alkaline phosphatase > 119 U/L, microscopic satellite lesion, vascular invasion, and lymphatic metastasis were the independent factors for the patients with HBV infection, while r-glutamyltransferase > 64 U/L, microscopic satellite lesion, and poor tumor differentiation were the independent factors for the patients without HBV infection.

CONCLUSION: HBV infection is a valuable clinical factor for predicting tumor invasiveness and clinical outcome of ICC patients. ICC patients with HBV infection should be distinguished from those without HBV infection because they have different clinicopathological characteristics, prognostic factors and outcomes after surgical resection.

INTRODUCTION

Cholangiocarcinoma originates from the extrahepatic bile duct, hilar bifurcation, and intrahepatic duct. Intrahepatic cholangiocarcinoma (ICC) is the second most common primary hepatic tumor after hepatocellular carcinoma (HCC). Primary sclerosing cholangitis (PSC)^[1,2], liver fluke infestation (particularly endemic *Opisthorcis viverrini*)^[3], and hepatolithiasis are the known risk factors for ICC^[4,5]. Recent evidence suggests that hepatitis B virus (HBV) or hepatitis C virus (HCV) infection is also an important risk factor for ICC^[5-10]. Our previous study also demonstrated that the incidence of HBV infection is significantly higher in ICC patients than in those without cancer (48.6% *vs* 6.6%) and chronic HBV infection is the most important independent risk factor for ICC in Chinese^[11].

The prognosis of ICC patients is poorer than that of HCC patients, mainly due to frequent lymphatic involvement, periductal invasion, poor encapsulation, or difficulty of early diagnosis. These characteristics are more prominent in ICC patients with seronegative hepatitis B surface antigen (HBsAg) than in those with seropositive HBsAg^[11], indicating that ICC patients with HBV infection have a more favorable prognosis than those without HBV infection. Given a higher incidence of microvascular invasion, poor tumor differentiation, and liver function in seropositive-HBsAg ICC patients compared with seronegative-HBsAg ICC patients, the real difference in prognosis is still unclear.

In the present study, the prognostic factors for ICC and the impact of chronic HBV infection on the survival rate of ICC patients were studied.

MATERIALS AND METHODS

Patients

A total of 209 patients underwent surgical dissection for ICC (the diagnosis of ICC was confirmed by pathology) at three departments of hepatobiliary surgery, Eastern Hepatobiliary Surgery Hospital, Second Military Medical University (Shanghai, China) in January 2005 - December 2007. Of the 209 patients, 195 underwent macroscopic curative resection (R0 and R1), 14 underwent only laparotomy and biopsy because of advanced lesions, such as peritoneal seeding. Of the 195 patients, there were 155 patients with information on survival and 40 lost their follow-up due to death, loss of contact, or other unknown reasons. Finally, 155 patients were included in the study. The prognostic factors influencing their survival rate and tumor recurrence were analyzed. The study was approved by the local ethics committee.

Clinicopathological investigations

Demographic and clinicopathological information was obtained from medical records of the patients including age, gender, alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), γ -glutamyltransferase (γ -GT), alkaline phosphatase (ALP), α -feto-

protein (AFP), carbohydrate antigen 19-9 (CA19-9), HBV infection, number of tumors, and tumor location, size, capsule formation, histologic type, differentiation and recurrence, as well as vascular invasion, microscopic satellite lesion, lymphatic and extrahepatic metastasis, surgical procedures, postoperative complications.

Statistical analysis

Patients were screened for carcinoembryonic antigen (CEA), AFP, CA19-9 and CT scan every 3-6 mo after operation. When recurrence was suspected, magnetic resonance imaging (MRI) or PET images were taken for confirmation. Disease-free survival was measured from the date of surgery to the date of recurrence. Survival was measured from the date of surgery. Follow-up of patients was continued until death or April 10, 2010.

Statistical analysis was performed using the SPSS, version 16.0 for Windows (SPSS Inc., Chicago, IL, USA). Overall and disease-free survival rates were calculated using the Kaplan-Meier method. Prognostic factors for the patients were evaluated using the univariate Kaplan-Meier method and compared with the log-rank test. Multivariate regression analysis was performed using the Cox proportional hazards model to identify the independent prognostic factors for the survival rate of patients and tumor recurrence. Variables to be entered into the multivariate analysis were selected on the basis of the results of univariate analysis ($P < 0.1$). χ^2 test was used for the comparison of categorical variables and t -test was employed for the comparison of discrete variables between the patients with HBV infection and those without HBV infection. $P < 0.05$ was considered statistically significant.

RESULTS

General characteristics of the patients and surgical procedures

One hundred and fifty-five ICC patients (102 men and 53 women with a male/female ratio of 1.92/1) were enrolled in this study. Their mean age was 54.97 ± 10.65 years (range, 27-76 years). Of the 87 patients with chronic HBV infection, 14 were positive for HBsAg in liver tissue, 29 were positive for HBsAg in serum, and 44 were positive for HBsAg both in serum and liver tissue. Of the 155 patients with anatomical *en bloc* resections, 111 (71.6%) underwent segmentectomy or bisegmentectomy or trisegmentectomy, 30 (19.4%) left hepatectomy, 2 (1.3%) left extended hemihepatectomy, and 14 (9.0%) right hemihepatectomy, 5 (3.2%) concomitant caudate segmentectomy, 6 (3.9%) common bile duct exploration for cholelithiasis or thrombus resection, and 3 (1.9%) Roux-en-Y cholangiojejunostomy. If the tumor invaded its adjacent organs grossly in the operative field, combined resection was performed to achieve complete removal of the tumor. An additional 21 combined resections of other organs were performed in 16 patients (10.3%) as shown in Table 1. Surgical complications occurred in 6 patients, including

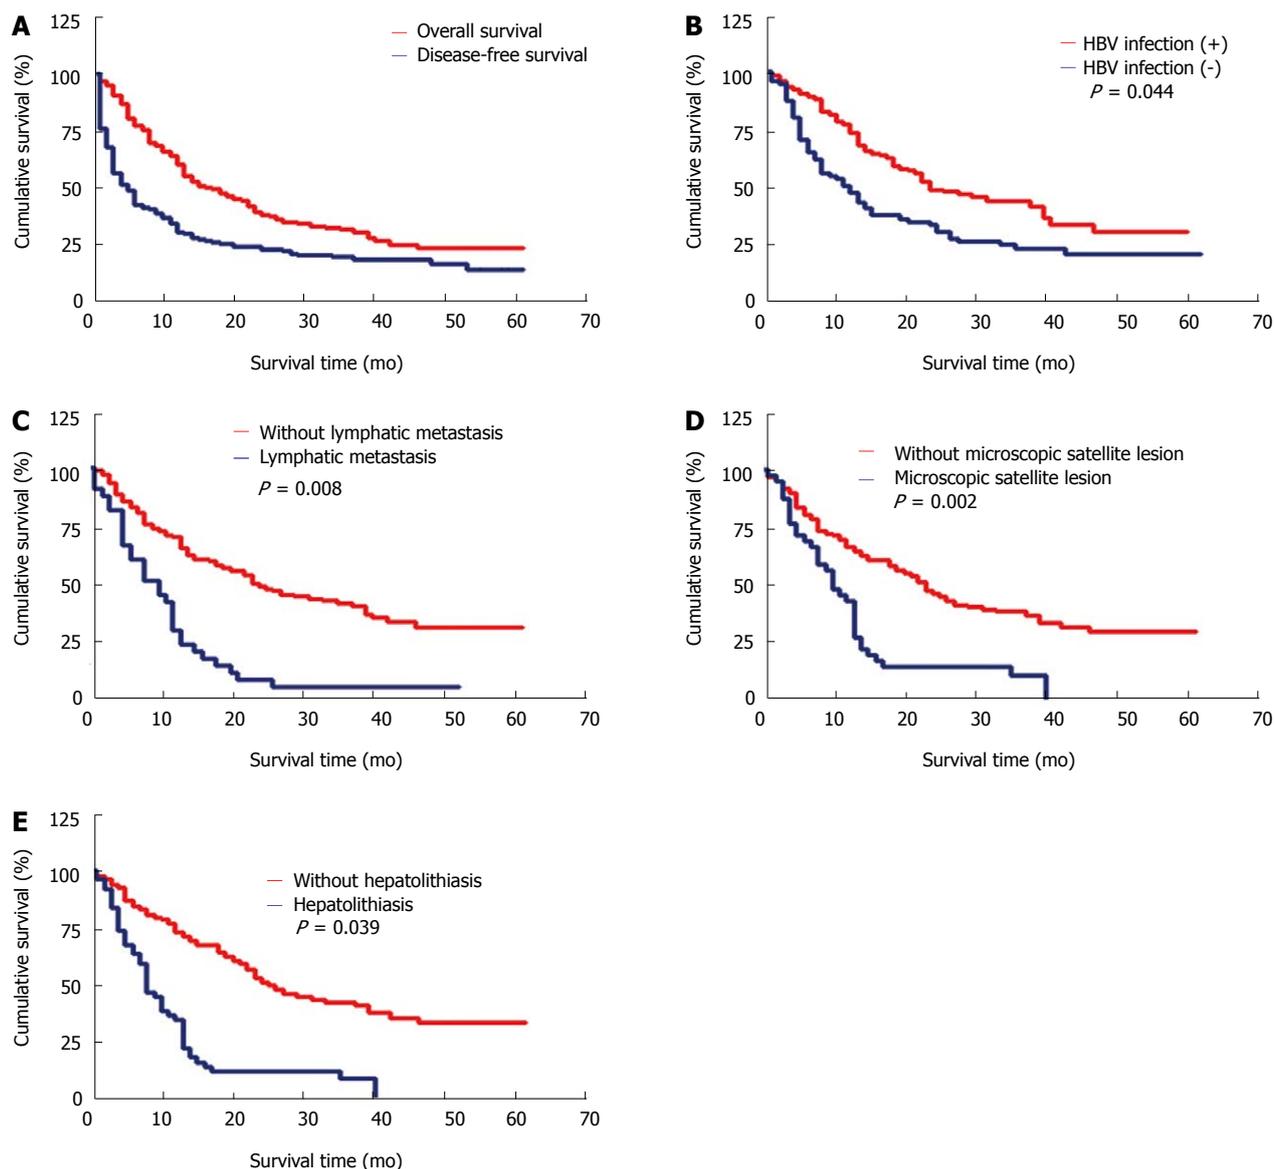

Figure 1 Overall and disease-free survival rates of patients with intrahepatic cholangiocarcinoma after surgical resection (A), higher survival rate of intrahepatic cholangiocarcinoma patients with hepatitis B virus infection than that of those without hepatitis B virus infection (B), significantly poorer survival rate of intrahepatic cholangiocarcinoma patients with lymphatic metastasis than that of those without lymphatic metastasis (C), significantly poorer survival rate of intrahepatic cholangiocarcinoma patients with microscopic satellite lesion than that of those without microscopic satellite lesion (D), and significantly poorer survival rate of intrahepatic cholangiocarcinoma patients with hepatolithiasis than that of those without hepatolithiasis (E).

biliary leakage in 2, subphrenic infection in 1, liver abscess in 2, and bleeding in 1, respectively.

Survival and recurrence

The cumulative 1- and 3-year survival rates were 60.6% and 32.1%, respectively, for the ICC patients (Figure 1). The median survival time was 17.0 mo and 35 patients survived more than 3 years. Univariate analysis demonstrated that absence of HBV infection, hepatolithiasis, γ -GT > 64 U/L, ALP > 119 U/L, CA19-9 > 37 U/mL, multiple tumors, tumor size \geq 5 cm and location, microscopic satellite lesion, lymphatic metastasis, and extrahepatic metastasis were the significant prognostic factors for the poor survival rates of ICC patients. Cox regression analyses revealed that HBV infection (hazard ratio: 4.075), hepatolithiasis (hazard ratio: 4.254), microscopic satel-

tumor differentiation, vascular invasion, and CK19 were not significantly correlated with the overall survival rate of ICC patients after hepatic resection (Table 2).

Tumor recurrence occurred in 108 patients. The disease-free survival rate was 31.1% and 20.3%, respectively, for the ICC patients 1 and 3 years after operation with a median disease-free survival time of 5.0 mo (Figure 1). Univariate analysis showed that hepatolithiasis, r-GT > 64 U/L, ALP > 119 U/L, CA19-9 > 37 U/mL, multiple tumors, microscopic satellite lesion, vascular invasion, lymph node metastasis, and positive CK19 were the significant risk factors for tumor recurrence in ICC patients. Multivariate analysis demonstrated that the number of tumors (95.0% CI = 1.194-3.863), microscopic satellite lesion (95.0% CI = 1.106-2.745), and vascular invasion (95.0% CI = 1.072-2.812) were the independent prognostic factors for disease-free survival rate of ICC patients (Table 3). The most common tumor recurrence sites were the remnant liver and regional lymph nodes. The treatment modalities for recurrent tumors included repeated operation (*n* = 9), transplantation (*n* = 2), radiation therapy (*n* = 7), radiofrequency ablation (*n* = 9), microwave coagulation (*n* = 3), percutaneous ethanol injection therapy (*n* = 23), and transarterial chemoembolization (*n* = 93).

Prognostic factors for ICC patients according to their HBV infection

The clinicopathological characteristics of ICC patients with HBV infection and those without HBV infection were compared to further interpret the influence of chronic HBV infection on their survival rate. Univariate analysis showed that the following variables were significantly different between the patients with HBV infection and those without HBV infection, including gender, AST, AFP, CA19-9, inflammation of liver tissue, cirrhosis, hepatolithiasis, tumor capsule formation, tumor differentiation, lymphatic metastasis, and positive immunohistochemical staining of CK19. Although perineural infiltration was not significantly different between them, it occurred more frequently in ICC patients without HBV infection than in those with HBV infection (Table 4).

The potential prognostic factors affecting the survival rate of the patients with HBV infection and those without HBV infection were compared to further clarify the difference in prognostic factors affecting their survival rate. The

¹Number of available data. HBV: Hepatitis B virus; M: Male; F: Female; TBIL: Total bilirubin; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; AFP: α -fetoprotein; ALP: Alkaline phosphatase; r-GT: R-glutamyltransferase; CA19-9: Carbohydrate antigen 19-9; CK: Cytokeratin.

prognostic factors for the patients with HBV infection and

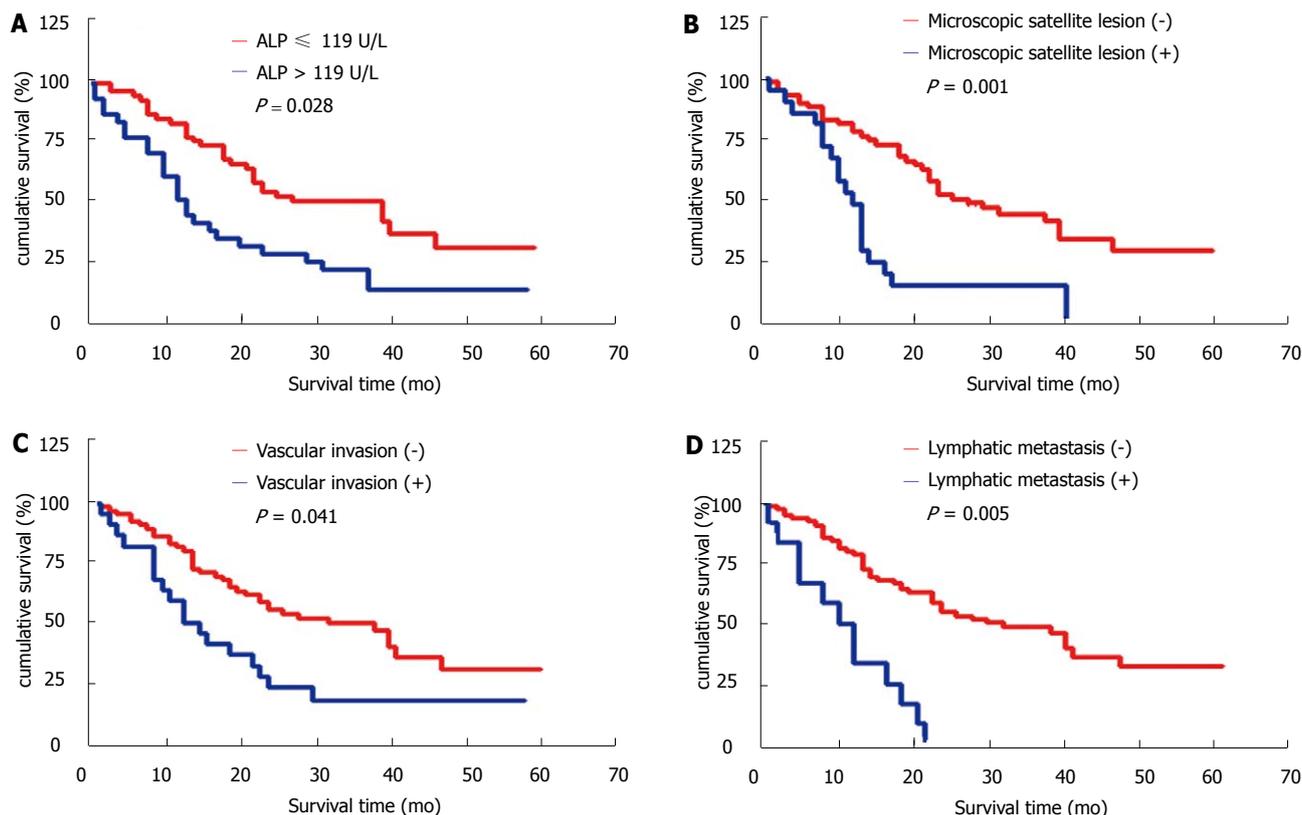

Figure 2 Adjusted survival curves according to the independent prognostic factors by multivariate analysis (Cox model) for intrahepatic cholangiocarcinoma with hepatitis B virus infection after resection. A: Alkaline phosphatase (ALP); B: Microscopic satellite lesion; C: Vascular invasion; D: Lymphatic metastasis.

those without HBV infection were not completely consistent (Tables 5 and Table 6). Univariate analysis demonstrated that ALP > 119 U/L, microscopic satellite lesion, tumor size ≥ 5 cm, lymphatic metastasis, and vascular invasion were the significant poor prognostic factors for the survival rate of patients with HBV infection (Table 5), while r-GT > 64 U/L, CA19-9 > 37 U/mL, hepatolithiasis, microscopic satellite lesion, lymphatic and extrahepatic metastasis were the significant poor prognostic factors for the survival rate of those without HBV infection (Table 6). Cox regression analysis demonstrated that ALP > 119 U/L (hazard ratio: 4.800), microscopic satellite lesion (hazard ratio: 12.066), lymphatic metastasis (hazard ratio: 7.887), and vascular invasion (hazard ratio: 4.167) were the independent poor prognostic factors for patients with HBV infection (Table 5, Figure 2), while r-GT > 64 U/L (hazard ratio: 4.157), microscopic satellite lesion (hazard ratio: 5.965), and poor tumor differentiation (hazard ratio: 5.844) were the independent poor prognostic factors for those with out HBV infection (Table 6, Figure 3).

DISCUSSION

Although a number studies are available on the correlation between chronic HBV infection and ICC^[5-11], the impact of HBV infection on the survival rate of ICC patients remains unclear. In the present study, HBV infection was found to be a favorable prognostic factor for the patients with ICC after resection, thus ICC patients with HBV in-

fection should be distinguished from those without HBV infection. First, ICC patients with HBV infection and those without HBV infection are different in their clinicopathological characteristics. It was reported that the number of male ICC patients with HBV infection is more, with a younger age, a higher abnormal liver function and a higher serum AFP level, a worse histological inflammation and cirrhosis, a poorer tumor differentiation and encapsulation, a lower serum CA19-9 level, and a lower frequency of lymphatic metastasis and positive CK19 than those of ICC patients without HBV infection^[11]. Second, ICC patients with HBV infection have a more favorable outcome after surgical resection than those without HBV infection. Third, the prognostic factors for the survival rate of ICC patients with and those without HBV infection are different.

Surgical resection remains the curable procedure for ICC. However, the prognosis of ICC after surgery is poor because of its high recurrence rate. The median survival time of ICC patients after operation is 11.0-37.4 mo^[12-18]. The overall 1- and 3-year survival rates of ICC patients after operation are 46.3%-73.3% and 23.0%-55.0%, respectively^[14,15,19-23], which are consistent with the findings in our study. It was reported that the preoperative CA19-9 level, vascular invasion, perineural invasion, lymph node metastasis, intrahepatic metastasis, the number and differentiation of tumors are the significant prognostic factors for the overall survival rate of ICC patients^[13,15-19]. In the present study, several clinicopathological factors that significantly influence the survival rate of ICC patients and

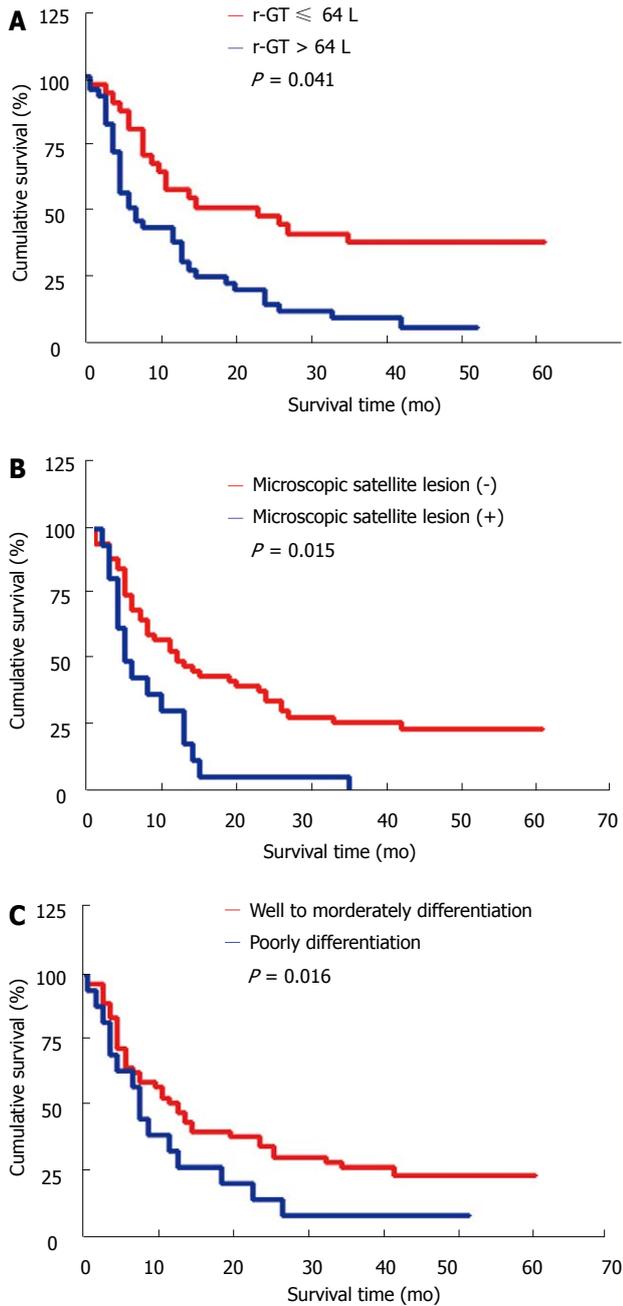

Figure 3 Adjusted survival curves according to the independent prognostic factors by multivariate analysis (Cox model) for intrahepatic cholangiocarcinoma without hepatitis B virus infection after resection. A: R-glutamyl-transferase (r-GT); B: Microscopic satellite lesion; C: Tumor differentiation.

tumor recurrence were investigated, and univariate analysis showed that absence of HBV infection, hepatolithiasis, high CA19-9 or ALP or r-GT level before operation, multiple tumors, tumor location, microscopic satellite lesion, lymphatic and extrahepatic metastasis, tumor size greater than 5 cm in diameter, were the significantly poor prognostic factors for the survival rate of ICC patients, Multivariate analysis revealed that the presence of HBV infection, hepatolithiasis, lymph node metastasis, microscopic satellite lesion were independent prognostic factor on survival. However, tumor differentiation, vascular invasion, tumor capsule formation were not found to be the

significant prognostic factors for the survival rate of ICC patients.

In Asia, intrahepatic duct stone (IHDS) is one of the factors highly related with ICC^[24]. Since Sanes and MacCallum^[25] reported two cases of hepatolithiasis-related cholangiocarcinoma discovered incidentally at autopsy for the first time in 1942, the correlation between IHDS with ICC has been reported in case series from all over the world^[4,5]. Our previous study also demonstrated that the incidence of IHDS is significantly higher in ICC patients than in non cancer patients (7.8% *vs* 1.1%), and IHDS is an independent risk factor for the development of ICC in Chinese (OR = 11.020, 95%CI = 4.238-28.657)^[11], which are consistent with the findings in the current study. IHDS was also found to be a negative prognostic factor affecting the survival rate of ICC patients in this study. Our explanation is that it is more difficult to diagnose early ICC with IHDS than to diagnose ICC without IHDS, and the recurrence of early ICC with IHDS is higher than that of ICC without IHDS.

It was reported that a high preoperative CA19-9 level ($>$ 37 U/mL) greatly influences the overall survival rate of ICC patients after hepatic resection^[26]. It has been demonstrated that the preoperative CA19-9 level is an indication of ICC in patients without primary sclerosing cholangitis, and the serum CA19-9 level is related to tumor burden^[27]. In our study, the median survival time of ICC patients with their preoperative CA19-9 level \leq 37 U/mL was significantly longer than that of those with their preoperative CA19-9 level $>$ 37 U/mL (23 mo *vs* 13 mo).

It has been shown that lymph node metastasis is a significant factor for the poor prognosis of ICC patients^[12,14,15,17,21]. The presence of lymph node metastasis is correlated with other poor prognosis factors, such as gross type of tumor, poorly or undifferentiated tumor, vascular invasion, and perineural invasion. In the current study, multivariate analysis showed that lymph node metastasis was correlated with both the overall and disease-free survival rates of ICC patients. The median survival time of ICC patients without lymph node metastasis was significantly longer than that of those with lymph metastasis (23 mo *vs* 8 mo).

CK19 belongs to type 1 cytokeratin with a molecular weight of 40-56 kDa^[28] and is normally expressed in ductal epithelium (bile ducts, pancreas, and renal collecting tubules) and in mucosa of the gastrointestinal (GI) tract^[29]. Most adenocarcinomas of the GI tract including cholangiocarcinoma are CK19 positive^[30]. It was reported that CK19, as a prognostic marker, plays a role in the pathogenesis of papillary thyroid carcinoma^[31], hepatocellular carcinoma^[32-33] and colorectal adenocarcinoma^[34]. For example, CK19 expressing HCCs had a higher rate of recurrence (hazard ratio 12.5) after transplantation^[35]. It has been shown that the expression level of CK19 in HCC patients increases with a worse prognosis of HCC patients and a faster recurrence of it after surgical treatment^[36-39], indicating that CK19 is a useful prognostic marker for HCC. However, the role of CK19 as a prognostic marker in ICC has not been explored. In the current study, CK19 was expressed more frequently in ICC patients in the

absence of HBV infection and the tumor disease-free survival rate of patients with CK19 expressing ICC was also lower after curative resection.

Recent studies showed that HBV infection is an important risk factor for the development of ICC^[5-11]. In the current study, 73 ICC patients (47.1%) were positive for serum HBsAg. Interestingly, 14 out of the 155 ICC patients were positive for HBsAg only in liver tissue, indicating that occult HBV infection is also a risk factor for the development of ICC as for HCC. In the current study, HBV infection was significantly correlated with some important clinicopathological factors, such as hepatolithiasis, high preoperative CA19-9 level, capsule formation, lymph node metastasis, perineural invasion, and positive CK19 (Table 4), which is consistent with the findings in our previous study^[11], indicating that the absence of HBV infection may be a predictor for the invasiveness of ICC and the poor survival rate of ICC patients. In the current study, the outcome of ICC patients with HBV infection was better than

that of those without HBV infection after curative resection. The median survival time of patients without HBV infection was significantly shorter than that of those with HBV infection (11 mo *vs* 23 mo), the prognostic factors affecting the survival rates of ICC patients with HBV infection and those without HBV infection were not completely consistent. Univariate analysis demonstrated that high preoperative ALP level, microscopic satellite lesion, tumor size greater than 5cm in diameter, lymph node metastasis, and vascular invasion were the poor prognostic factors for the survival rate of ICC patients with HBV infection (Table 5), while high preoperative r-GT or CA19-9 level, hepatolithiasis, microscopic satellite lesion, lymph node and extrahepatic metastasis were the poor prognostic factors for the survival rate of those without HBV infection (Table 6). Cox regression analysis demonstrated that high preoperative ALP level (hazard ratio: 4.800), microscopic satellite lesion (hazard ratio: 12.066), lymphatic metastasis (hazard ratio: 7.887), and vascular invasion (hazard ratio: 4.167)

NA: Not applicable; ALP: Alkaline phosphatase; r-GT: R-glutamyltransferase; CA 19-9: Carbohydrate antigen 19-9.

were the independent prognostic factors for ICC patients with HBV infection (Table 5), while high preoperative r-GT level (hazard ratio: 4.157), microscopic satellite lesion (hazard ratio: 5.965), and poor tumor differentiation (hazard ratio: 5.844) were the independent prognostic factors for those without HBV infection (Table 6), indicating that ICC patients with HBV infection should be distinguished from those without HBV infection.

It has been shown that vascular invasion or poor differentiation of tumor is a negative prognosis factor for ICC patients^[40], in this study, however, vascular invasion or differentiation of tumor was not a significant predictor for the overall survival rate of ICC patients. We hypothesize that compared ICC without HBV infection, ICC with HBV infection are associated with more vascular invasion and poor differentiation. While HBV infection is a favorable prognostic factor for survival, this may decrease the influence of vascular invasion or tumor differentiation on overall survival. Vascular invasion and poor differentiation were independent negative prognostic factors in ICC with HBV

infection and in ICC without HBV infection, respectively (Tables 5 and 6). The result may indirectly provide support for our hypothesis.

In conclusion, absence of HBV infection, hepatolithiasis, microscopic satellite lesion, and lymphatic metastasis are the independent predictors for a dismal prognosis of ICC patients. HBV infection is a valuable clinical factor for the invasiveness of tumor and the clinical outcome of ICC patients. ICC patients with HBV infection should be distinguished from those without HBV infection.

COMMENTS

Background

Although the correlation between chronic Hepatitis B virus (HBV) infection and intrahepatic cholangiocarcinoma (ICC) has been documented, the impact of HBV infection on the survival rate of ICC patients remains unclear.

Research frontiers

One hundred and fifty-five ICC patients who underwent macroscopic curative resections (R0 and R1) were classified according to their chronic HBV infection represented by positive hepatitis B surface antigen (HBsAg) in serum or in liver

tissue. The clinicopathological characteristics and survival rate of these patients were evaluated.

Innovations and breakthroughs

Multivariate analyses revealed that HBV infection, hepatolithiasis, microscopic satellite lesion, and lymphatic metastasis were the independent prognostic factors for the survival rate of ICC patients. The prognostic factors affecting the survival rate of ICC patients with HBV infection and those without HBV infection were not completely consistent. Alkaline phosphatase (ALP) > 119 U/L, microscopic satellite lesion, vascular invasion, and lymphatic metastasis were the poorer prognoses of ICC patients with HBV infection, and α -glutamyltransferase (α -GT) > 64 U/L, microscopic satellite lesion, and poor tumor differentiation were the poorer prognoses of ICC patients without HBV infection.

Applications

HBV infection in ICC patients is a valuable clinical factor for predicting the invasiveness of tumor and the clinical outcome of ICC patients. ICC patients with HBV infection should be distinguished from those without HBV infection because they have different clinicopathological characteristics, prognostic factors and favorable outcomes after surgical resection.

Terminology

ICC is a fatal cancer of the biliary epithelium, arising from the intrahepatic bile ducts. Globally, ICC is the most common primary hepatic malignancy, after hepatocellular carcinoma (HCC). The incidence of ICC varies greatly in different areas of the world, and is related to the distribution of risk factors. HBV or hepatitis C virus, primary sclerosing cholangitis, liver fluke infestation particularly the endemic *Opisthorcis viverrini*, and hepatolithiasis are the known risk factors for ICC.

Peer review

This study showed that HBV infection, hepatolithiasis, microscopic satellite lesion, and lymphatic metastasis were the independent prognostic factors for the survival rate of ICC patients. HBV infection was a valuable clinical factor for the invasiveness of tumor and the clinical outcome of ICC patients and ICC patients with HBV infection should be distinguished from those without HBV infection, thus providing certain accurate data for the diagnosis of ICC.

Abstract

AIM: To study a cohort of patients undergoing 48 h Bravo pH testing receiving deep sedation with propofol.

METHODS: We retrospectively reviewed the charts of 197 patients (81 male, 116 female) who underwent Bravo esophageal pH monitoring from July 2003 to January 2008. All patients underwent Bravo pH probe placement *via* esophagogastroduodenoscopy (EGD) and received propofol for sedation. Patients on a proton pump inhibitor (89 patients) were excluded. Acid reflux variables measured included the total, upright, and supine fractions of time at pH < 4 and DeMeester score, and were compared between day 1 and day 2.

RESULTS: Of the 108 patients that were included in the study, the most common indication for Bravo pH monitoring was heartburn, with chest pain being the second most common. A signed rank test revealed no

statistically significant difference between day 1 and day 2 reflux episodes.

CONCLUSION: Patients who received propofol for sedation for EGD with Bravo pH capsule placement did not experience any significant difference in reflux episodes from day 1 to day 2.

INTRODUCTION

Esophageal pH monitoring is widely used for the diagnosis of gastroesophageal reflux disease (GERD). Some indications for monitoring, as defined by expert panels, include refractory symptoms or continuation of atypical symptoms despite proton pump inhibitor (PPI) treatment, evaluation for anti-reflux surgery and recurrence of symptoms following anti-reflux surgery^[1-3].

Traditionally, the transnasal placement of a pH catheter probe was used to monitor esophageal pH. This technique often produced discomfort, inconvenience and often restricted activity and diet, thereby underestimating the amount of reflux^[4]. The limitations of the conventional catheter system (CCS) led to the development of a

catheter-less system (CLS) which utilizes a radiotelemetry pH-sensing capsule clipped to the esophageal wall. Compared to CCS, CLS is better tolerated by patients and permits increased duration of pH recording^[5].

Despite the wide use of the CLS, there have not been any standardized guidelines for the placement of the catheter. For example, the Bravo capsule may be clipped to the esophagus on the same day as esophagogastroduodenoscopy (EGD) with sedation or on a different day, with or without sedation.

Studies in the past on the CLS, have examined the differences in day 1 (d1) and day 2 (d2) with limited sample sizes and varied results. A few have suggested that a probable cause of increased reflux episodes on d1 may be the effect of sedation. Until now, there has been limited data examining the effect of deep sedation on d1 and d2 results.

MATERIALS AND METHODS

We retrospectively reviewed the charts of 197 patients who underwent 48-h Bravo pH monitoring (Medtronic) for suspected GERD over a 5-year period at Winthrop University Hospital. This study was approved by the Institutional Review Board of our institution. Eighty nine patients who were on anti-reflux medications at the time of the study were excluded.

All patients that were included in the study underwent EGD under deep sedation (propofol) with placement of the capsule at the time of the procedure. All patients underwent EGD with Bravo placement by the same endoscopist (KRK). The capsule was placed at 6 cm above the gastroesophageal junction. Following deployment of the capsule, accurate placement was confirmed with direct visualization. Following recovery from sedation, patients were instructed to keep the data recorder around their waist and were encouraged to resume their normal daily activities and usual diets. Patients were also instructed to keep a diary of daily activities (e.g. when they ate, periods of sleep), and occurrence of symptoms.

Patients returned 48 h later and turned in their receivers and diaries. The data was downloaded and analyzed by Medtronic software, which then generated a summary report, which was reviewed by one gastroenterologist (KRK). The summary report included percent of total time at pH < 4, percent of upright time at pH < 4, percent of supine time at pH < 4, total number of reflux episodes and the DeMeester score.

Statistical methods

All continuous variables were summarized using mean \pm SD. We calculated delta scores of our parameters, representing the difference from d1 to d2, i.e. to determine the effects of deep sedation. Since these difference scores were not normally distributed, we utilized the signed-rank test (instead of the paired *t*-test for normally distributed difference scores) to assess the statistical significance of these differences. All calculations were performed using SAS 9.1 for Windows (SAS Institute, Cary,

Table 1 Indication for Bravo monitoring

| Indication | Frequency | Percent (of <i>n</i> = 108) |
|---------------|-----------|-----------------------------|
| Heartburn | 63 | 58.30% |
| Chest pain | 32 | 29.60% |
| Chronic cough | 9 | 8.30% |
| Laryngitis | 23 | 21.30% |
| Bloating | 38 | 35.20% |

Total percentages exceed 100% since about half of the patients had two distinct indications.

NC, USA); results were considered significant when $P < 0.05$.

RESULTS

Our analysis included 108 patients (47 male, 61 female; mean age \pm SD, 54.74 \pm 14.67) after excluding 89 patients on anti-reflux medications. Table 1 shows the indications for Bravo pH monitoring. The most frequent indication was heartburn (58% of the patients) followed by chest pain. The total percentages in Table 1 exceed 100% since about half of the patients presented with two indications for the study.

Tables 2-5 indicate descriptive statistics for each of our parameters for d1, d2, and delta = d2-d1. None of the difference scores were significantly different from zero by the signed rank test, although one parameter (upright) showed a trend toward significance ($P = 0.0576$).

DISCUSSION

GERD is defined as symptoms or mucosal damage produced by the abnormal reflux of gastric contents into the esophagus^[3]. The typical clinical manifestations include heartburn and regurgitation; however an atypical presentation should be considered when chronic cough, non-cardiac chest pain, and otolaryngological (ENT) symptoms are present. It is appropriate to offer empiric therapy with a PPI to patients with symptoms consistent with GERD. However symptoms that are refractory to high-dose PPI would usually prompt the clinician to perform an endoscopy. The majority of symptomatic patients will have a normal endoscopy which does not necessarily indicate either less severe symptoms or a more easy to control form of GERD^[6].

Studies demonstrate that those GERD patients without esophagitis have symptoms that are just as difficult and at times more difficult to control^[7]. The diagnosis of GERD in the symptomatic patient without endoscopic findings requires prolonged ambulatory pH monitoring. This technique assesses the magnitude of esophageal acid exposure, and also allows one to assess whether a correlation exists between symptoms reported by the patient and acid reflux events^[8]. The only way to perform ambulatory pH monitoring, up until recently, has been by the transnasal placement of a pH catheter probe left in

Table 2 Time pH < 4 - upright (%)

| | Mean | Median | SD | Minimum | Maximum |
|---------------|-------|--------|------|---------|---------|
| Day 1 (d1) | 7.31 | 5.70 | 7.55 | 0 | 41.4 |
| Day 2 (d2) | 6.52 | 4.85 | 7.89 | 0 | 59.6 |
| Delta = d2-d1 | -0.79 | -0.50 | 5.81 | -19.9 | 24.8 |

Mean Delta (-0.79) not significantly different from zero ($P = 0.0576$) by signed rank test.

Table 4 Time pH < 4 - total (%)

| | Mean | Median | SD | Minimum | Maximum |
|---------------|-------|--------|------|---------|---------|
| Day 1 (d1) | 6.36 | 4.85 | 7.60 | 0.0 | 48.1 |
| Day 2 (d2) | 6.02 | 4.25 | 8.02 | 0.0 | 67.1 |
| Delta = d2-d1 | -0.34 | 0.00 | 6.13 | -22.5 | 29.6 |

Mean Delta (-0.34) not significantly different from zero ($P = 0.73$) by signed rank test.

place for 24 h. Patients often alter their daily physical and dietary activities, or do not complete the study, as they find a transnasally placed pH electrode conspicuous and uncomfortable. These changes result in “false negative” results if the activity and/or dietary limitations reduce esophageal acid exposure to within the normal limits^[4].

The Bravo pH monitoring system is a newer modality in which a pH-sensing capsule is endoscopically clipped to the esophageal wall, and transmits pH data to a recorder worn by the patient. Bravo esophageal pH monitoring is better tolerated by patients and permits increased duration of pH recording compared to the traditional catheter-based pH system^[9].

Many studies have been performed to investigate if a difference exists for gastroesophageal reflux as measured by the Bravo pH system between d1 and d2 of the study. The results have been somewhat conflicting. In a study performed by Bhat *et al*^[10], 217 patients underwent endoscopy and capsule placement. Of these, 56% were abnormal with 32.2% being abnormal on both days, and showed increased acid exposure on d1 compared to d2. The higher likelihood of abnormal results for d1 was associated with a significantly increased esophageal acid exposure during the first 6 h after capsule insertion on d1 compared with the corresponding time on d2 without differences in esophageal acidification during the remaining time or differences in recorded activity. The significantly higher likelihood of abnormal findings during the initial period of pH monitoring suggests an influence of endoscopy and associated sedation, typically performed prior to capsule insertion, which needs to be considered when pH data are analyzed^[10]. Bechtold *et al*^[11] performed a retrospective review on 27 consecutive adult patients who underwent Bravo pH monitoring with intravenous doses of midazolam and fentanyl. Their results demonstrated that people with moderate conscious sedation experience significantly more acid reflux on d1 than d2.

Other studies performed have reported no consistent differences. Pandolfino *et al*^[12] found no differences

Table 3 Time pH < 4 - supine (%)

| | Mean | Median | SD | Minimum | Maximum |
|---------------|------|--------|-------|---------|---------|
| Day 1 (d1) | 4.01 | 0.25 | 8.94 | 0.0 | 60.2 |
| Day 2 (d2) | 4.66 | 0.00 | 12.20 | 0.0 | 87.4 |
| Delta = d2-d1 | 0.65 | 0.00 | 11.80 | -33.1 | 63.3 |

Mean Delta (0.65) not significantly different from zero ($P = 0.56$) by signed rank test.

Table 5 DeMeester score

| | Mean | Median | SD | Minimum | Maximum |
|---------------|------|--------|------|---------|---------|
| Day 1 (d1) | 22.0 | 16.3 | 25.7 | 0.0 | 163.7 |
| Day 2 (d2) | 21.1 | 15.2 | 25.6 | 0.0 | 213.0 |
| Delta = d2-d1 | -0.9 | 0.0 | 21.0 | -100.5 | 82.2 |

Mean Delta (-0.9) not significantly different from zero ($P = 0.90$) by signed rank test.

between d1 and d2 in their patients who underwent same day EGD with 50 to 75 mg of meperidine and 1 to 5 mg of midazolam. Prakash *et al*^[13] evaluated patients who underwent endoscopic placement of a wireless capsule with conscious sedation, employing a variety of different medications at the time of Bravo placement, and found no differences in reflux variables between d1 and d2.

The limitations of our study include the fact that it was retrospective and that a variety of different anesthesiologists administered the anesthesia. However, all Bravo placements and interpretations were performed by the same gastroenterologist.

In conclusion, there is great variability in different studies between the number of reflux episodes from d1 to d2. However, this was not demonstrated in our study when looking at patients undergoing deep sedation with wireless ambulatory esophageal pH monitoring, thereby supporting deep sedation as the optimal method for patient comfort and accuracy of data. Future prospective studies looking at larger sample sizes are needed to substantiate our findings.

ACKNOWLEDGMENTS

The authors would like to acknowledge our biostatistician, Mr. Martin Feuerman for his contribution.

COMMENTS

Background

The prevalence of esophageal pH monitoring for the diagnosis of gastroesophageal reflux disease (GERD) has increased substantially. Despite its widespread use, there are no standard guidelines for the placement of the catheter.

Research frontiers

Some studies in the past have suggested that the effects of sedation used during placement of a 48 h catheter-less pH monitoring device may account for the difference in day 1 (d1) to day 2 (d2) data. In this study, the authors demonstrate that using deep sedation in the placement of a wireless pH monitoring device reduces the difference in d1 and d2 data.

Innovations and breakthroughs

Many studies have been performed to investigate if a difference exists for gastroesophageal reflux as measured by the Bravo pH system between d1 and d2 of the study. The results are conflicting. This study suggests that deep sedation may eliminate the variability in data from d1 to d2.

Applications

By using deep sedation during placement of a catheter-less pH monitoring device, the authors could limit the number of false positive results (i.e. acid reflux episodes) during d1.

Terminology

Bravo is a catheter-less pH monitoring device that is endoscopically clipped to the esophageal wall, and the data is transmitted to a recorder worn by the patient.

Peer review

This is an interesting study, delving into how to best use the Bravo capsule. Disadvantages include (as the authors state) that it is a retrospective study. Since there is no comparison group in the study either, it is difficult to generalize this study to other settings.

Abstract

AIM: To investigate the influence of remote ischemic preconditioning (RIPC) on anastomotic integrity.

METHODS: Sixty male Wistar rats were randomized to six groups. The control group ($n = 10$) had an end-to-end ileal anastomosis without RIPC. The preconditioned groups ($n = 34$) varied in time of ischemia and time of reperfusion. One group received the amino acid L-arginine before constructing the anastomosis ($n = 9$). On postoperative day 4, the rats were re-laparotomized, and bursting pressure, hydroxyproline concentration, intra-abdominal adhesions, and a histological score concerning the mucosal ischemic injury were collected. The data are given as median (range).

RESULTS: On postoperative day 4, median bursting pressure was 124 mmHg (60-146 mmHg) in the control group. The experimental groups did not show a statistically significant difference ($P > 0.05$). Regarding the hydroxyproline concentration, we did not find any significant variation in the experimental groups. We detected significantly less mucosal injury in the RIPC groups. Furthermore, we assessed more extensive intra-abdominal adhesions in the preconditioned groups than in the control group.

CONCLUSION: RIPC directly before performing small bowel anastomosis does not affect anastomotic stability in the early period, as seen in ischemic preconditioning.

INTRODUCTION

Wound healing in intestinal anastomoses is dependent on operative technique, the underlying medical condition, medical treatment, and individual, often unknown

factors^[1,2]. Primarily, the stability of an intestinal anastomosis is regulated by the suture holding capacity, due to a high activity of collagenases that peaks in the first 48-72 h. Over time, the suture holding capacity decreases, whereas the tissue strength increases because of upregulated collagen synthesis and remodeling^[3]. Despite optimal treatment, anastomotic insufficiency occurs, which causes significantly higher morbidity and mortality^[4-6]. The underlying medical condition and individual genetic factors are different in each case. Accordingly, investigational interest is focused on fundamentals in gastrointestinal wound healing^[1,2] and on innovative perioperative management to improve anastomotic healing, especially in patients at risk.

Ischemic preconditioning (IPC) in general was first described by Murry in 1986, when a delay in cell death in the myocardium after preconditioning was described^[7]. Concerning IPC in the intestine, Hotter *et al.*^[8] have found an increased NO level, which was the first report of such a feature. Several local and systemic effects of IPC have been described, including decreased bacterial translocation^[9], mucosal injury^[9], epithelial apoptosis^[10], and on the other hand, an improvement in microvascular perfusion and oxygenation^[11,12] after ischemia-reperfusion injury (IRI). Our group previously has shown that IPC of the superior mesenteric artery improves stability of intestinal anastomoses^[13].

Contrary to IPC, remote ischemic preconditioning (RIPC) is induced by temporary occlusion of different arteries, which are not responsible for direct blood supply of the organ of interest. Less is known about the influence of RIPC on the gastrointestinal tract, and especially on its impact on anastomotic healing in the small intestine. RIPC was first reported in the literature in 1993 when Przyklenk *et al.*^[14] discussed the effect of temporary coronary occlusion on virgin myocardium not affected by the artificial ischemia. Subsequent studies have all suggested an increased tolerance to IRI in different tissue types^[15-18]. To the best of our knowledge, Colak *et al.*^[19] are the only group that has investigated the effect of RIPC on intestinal anastomosis. They have performed an anastomosis in the descending colon after branching off the superior mesenteric artery in an IR setting. No beneficial effect was found concerning IRI-induced delay of anastomotic healing. Neither in IPC nor RIPC are the optimal IR intervals defined.

The aim of the present study was to investigate the effect of RIPC, directly before anastomotic construction, in the early period (postoperative day 4) when suture holding capacity has already decreased and tissue strength has gained more importance. We intentionally did not perform an IRI interval because we claim that an anastomosis itself is a temporary ischemic injury. Moreover, we were interested in the implication of L-arginine, as an NO progenitor and semi-essential proteinogenic amino acid, on intestinal wound healing because of its reported importance in this process^[20,21].

RIPC: Remote ischemic preconditioning

approved all animal experiments. Male Wistar rats (Charles River, Sulzfeld) weighing 219-350 g were used for all experiments. The animals were housed two per cage, fed standard chow and given water *ad libitum*. Twelve hours before anesthesia, rats were fasting but had free access to water. Postoperatively, rats also had free access to water but were fed stepwise following a specified increasing amount of chow to prevent postoperative ileus.

Experimental design

Randomization (closed envelopes) took place after a preoperative acclimatization under laboratory conditions of 5-7 d. Rats were assigned to one of the six groups. Each group consisted of at least nine (9-14) Wistar rats (Table 1): the RIPC 5/20 ($n = 9$) group was characterized by 5 min of intraoperative ischemia followed by 20 min of reperfusion, before constructing an anastomosis. This was compared with the RIPC 5/30 ($n = 11$), RIPC 10/20 ($n = 14$) and RIPC 10/30 ($n = 10$) groups. In the control group (CO) and the L-arginine group, the same anastomosis was created without preconditioning.

Operative procedure

Rats were operated upon by the same investigator under sterile laboratory conditions. After induction of anesthesia with isoflurane (4% isoflurane in 3 L/min oxygen) in an acrylic glass box, narcosis was maintained, after transferring the rats to an operating table, through a mask (1.5% isoflurane in 3 L/min oxygen). A 26 G silicon venous catheter was placed into the tail vein. A catheter was used for continuous infusion (9 mL/h per kg body weight) of an iso-osmolar electrolyte solution (Jonosteril; Fresenius, Bad Homburg, Germany: 137 mmol/L Na⁺, 4 mmol/L K⁺, 1.65 mmol/L Ca²⁺, 1.25 mmol/L Mg²⁺, 110 mmol/L Cl⁻, 18 mmol/L CHCOO⁻, pH 5.0-7.0; osmolarity 291 mosm/L). After anesthesia was established, the abdominal coat was shaved and disinfected with polyvidone (Betaisadonna; Mundipharma, Limburg, Germany). A 4-5-cm midline incision in the lower half of the abdomen was performed to accomplish optimal exposition.

In animals assigned to one of the four RIPC groups, the infrarenal aorta was prepared. Clamping off the infrarenal aorta directly above the bifurcation was achieved with an atraumatic microsurgical clamp (Medicon, Germany), following the different intervals of IR, as mentioned above. Intervals were similar to our previously published

paper on IPC. In the control group, the infrarenal aorta was prepared but not branched off. The arginine group received 200 µg/kg L-arginine (L-Arginin-Hydrochlorid; Fresenius) intraoperatively without preparing the abdominal aorta.

Afterwards, an approximately 1-cm segment, about 15 cm oral to the ileocecal valve was resected. Ileal continuity was restored by eight inverting interrupted sutures (Prolene 8/0; Ethicon, Germany). We used a silicon catheter (Heidelberger Verlängerung; Braun, Melsungen, Germany; diameter 5 mm) to standardize and simplify the suture technique. The silicon catheter was inserted into both lumina of the small intestine. At first, front-wall sutures were made, then we turned around the anastomosis to perform the back-wall sutures, removing the catheter just before the last two sutures. The distance between the single sutures and the stitches to the resection margin was 1-2 mm. The abdominal cavity was closed using a two-layer technique: musculoperitoneal layer (Monocryl 4/0 SHplus; Ethicon), and fasciocutaneous layer (Vicryl 4/0 SHplus; Ethicon).

On postoperative day 4, the rats were re-laparotomized and sacrificed by cardiac puncture with injection of a lethal dose of potassium. The abdomen was opened by a complete midline incision combined with a transverse incision to gain maximum exposure. Careful exploration was carried out to look for signs of inflammation, adhesions, anastomotic insufficiency, and abscesses. Without dissecting the directly adjacent tissue around the anastomosis, an approximately 4-6-cm segment bearing the anastomosis was harvested for further analysis.

Bursting pressure

The bowel segment was water-tight and connected to an infusion pump (Perfusor fm; Braun) filled with iso-osmolar saline solution (0.9% NaCl; Braun) via a 14 G silicon catheter (Vasofix Safety; Braun) and to a digital pressure transducer (Codman ICP Express; Ethicon). Intraluminal pressure was increased by an infusion rate of 60 mL/h. Monitoring included the bursting pressure recorded just before sudden loss of tension and the site of rupture (mesenterial vs anti-mesenterial). Subsequently, the bowel wall was released from all adhering tissue and the complete suture line was excised within a total length of the bowel of 1 cm. The anastomosis was opened at the mesenterial site and gently washed using a saline solution (0.9% NaCl, Braun). The anastomosis was divided at the anti-mesenterial site into two parts of the same length for paraffin embedding and measurement of hydroxyproline concentration. The former was achieved by immediately fixing the specimen in 4% phosphate-buffered formaldehyde (pH 7.3), and the latter by preservation of the anastomotic strip in an Eppendorf tube at -80°C until spectrophotometric measurement.

Hydroxyproline concentration

The specimens used for hydroxyproline concentration measurement were desiccated in an oven (Heraeus Elec-

Table 2 Mucosal injury scale from Chiu *et al*^[23]

| Grade | Definition |
|-------|--|
| 0 | Normal mucosal villi |
| 1 | Development of subepithelial Gruenhagen's space at the apex of the villus, often with capillary congestion |
| 2 | Extension of the subepithelial space with moderate lifting of the epithelial layer from the lamina propria |
| 3 | Massive epithelial lifting down the sides of villi, possibly with few denuded tips |
| 4 | Denuded villi with lamina propria and dilated capillaries exposed, possibly with increased cellularity of lamina propria |
| 5 | Digestion and disintegration of the lamina propria, hemorrhage and ulceration |

tronic UT5042EK, Germany) until a constant dry weight was achieved. Hydroxyproline concentration was determined by using the Chloramine-T spectrophotometric method as previously described by Reddy *et al*^[22]. The practice is based on alkaline hydrolysis of the tissue homogenate and the consecutive measurement of free hydroxyproline. Before measurement, Chloramine-T was used to oxidize the free hydroxyproline in a pyrrole. Adding Ehrlich's reagent resulted in a chromophore that could be recorded at 550 nm. Data finally were calculated to express the results as micrograms of hydroxyproline per gram dry weight of tissue.

Histological evaluation

After fixation in formalin and embedding in paraffin, histological sections were stained with hematoxylin-eosin. Mucosal injury, inflammation and hyperemia/hemorrhage were assessed and graded in a blinded manner by two pathologists. Pathologists used the injury scale (Table 2) as described by Chiu *et al*^[23].

Statistical analysis

All data are expressed as median and range. Overall significance was proved using the Kruskal-Wallis test. Subsequent comparison of subgroups was done using the Mann-Whitney U test; P < 0.05 was assumed to be significant. SPSS for Windows version 14.0.2 (Chicago, IL, USA) was used.

RESULTS

General observations

One rat died intraoperatively in the RIPC 10/20 group because of acute mesenterial bleeding. One anastomosis in the RIPC 10/20 group had to be redone because of a technical issue. Two rats in the RIPC group died on postoperative day 3: one had advanced peritonitis caused by bacterial translocation in ileus without anastomotic dehiscence; and the other had ileus without macroscopic signs of peritonitis.

The findings during planned re-laparotomy on postoperative day 4 are summarized in Table 1. There were three

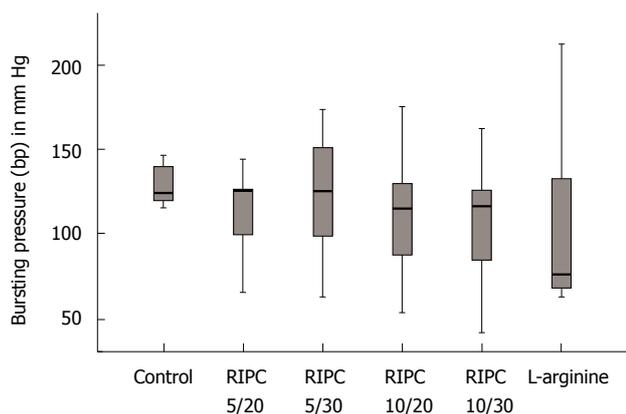

Figure 1 Bursting pressure after different remote ischemic preconditioning settings and after arginine application expressed as box plot. There was no significant overall difference between the groups ($P > 0.05$). RIPC: Remote ischemic preconditioning.

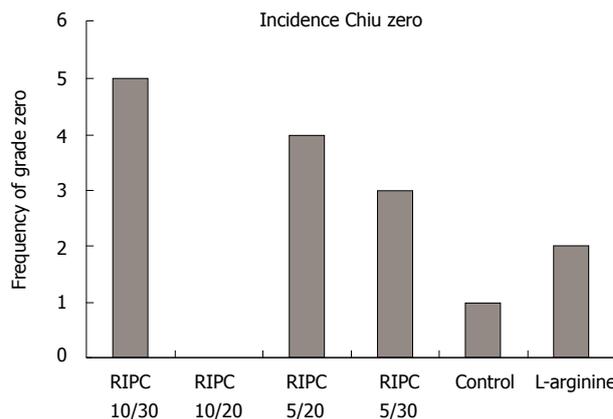

Figure 2 The histological mucosal damage score by Chiu^[23] showed significantly more low-grade alterations in the remote ischemic preconditioning groups (Remote ischemic preconditioning, 27% vs control, 10%). RIPC: Remote ischemic preconditioning.

insufficient anastomoses. Further observations were ileus, mesenterial hemorrhage, and three abscesses. Two of the three abscesses were adjacent to the anastomosis without macroscopic signs of insufficiency, whereas one was distant from the anastomosis. These nine rats were excluded from further examination (hydroxyproline concentration, bursting pressure and histology). We observed that intra-abdominal adhesions, especially near the anastomosis, were more pronounced in the RIPC groups than in the control or the arginine group.

Bursting pressure

Control vs RIPC groups: During bursting pressure measurement, the site of rupture was equally allocated to both the mesenterial and anti-mesenterial site along the suture line, and never occurred distant to the anastomosis. Median bursting pressure in the control group was 124 mm Hg (60-146 mmHg). Similar bursting pressure ($P > 0.05$) was documented in all of the RIPC groups: 125 mmHg (65-144 mmHg) in the RIPC 5/20 group; 125 mmHg (65-144 mmHg) in the RIPC 5/30 group; 130 mmHg (52-175 mmHg) in the RIPC 10/20; and 117 mmHg (41-162 mmHg) in the RIPC 10/30 group (Figure 1).

Control/RIPC vs arginine: The arginine group showed a median bursting pressure of 90 mmHg (65-212 mmHg) and was not different to the control and RIPC groups (Figure 1).

Hydroxyproline levels

Hydroxyproline was measured to establish a relationship with the collagen content in the anastomotic region. Median hydroxyproline concentration in the control group was 86 $\mu\text{g/g}$ dry weight (36-160 $\mu\text{g/g}$). Hydroxyproline concentration in the RIPC groups was not significantly different from the control group ($P > 0.05$): 58 $\mu\text{g/g}$ (30-158 $\mu\text{g/g}$) in the RIPC 5/20 group; 78 $\mu\text{g/g}$ (19-227 $\mu\text{g/g}$) in the RIPC 5/30 group; 99 $\mu\text{g/g}$ (40-250 $\mu\text{g/g}$) in the RIPC 10/20 group; and 108 $\mu\text{g/g}$ (57-198 $\mu\text{g/g}$) in

the RIPC 10/30 group. The arginine group also showed no significant disparity: 78 $\mu\text{g/g}$ (21-130 $\mu\text{g/g}$).

Histological examination

The above described histological score for mucosal damage according to Chiu *et al*^[23] was applied to evaluate the structural damage due to the creation of the anastomosis. Different grades of damage (0-3) were seen in all groups at the suture line. Maximum damage was seen up to grade 3, which means massive epithelial lifting down the sides of the villi, with possibly a few denuded tips. Mucosal damage was observed in the first few villi on both sides of the anastomotic line. Twelve rats (27%) in the RIPC groups did not show any mucosal damage (grade 0); and five in the RIPC 10/30 group, four in the RIPC 5/20 group, and three in the RIPC 5/30 group. The control group had only one rat (10%) with grade 0 damage (Figure 2).

DISCUSSION

Our research group has focused on fundamental aspects of gastrointestinal wound healing^[13,24,25], because anastomotic insufficiency still occurs and results in high morbidity and mortality^[4-6,26,27]. We previously have presented data on the influence of IPC on the stability of small intestine anastomoses. IPC has a beneficial effect on wound healing in the gastrointestinal tract^[13]. In the present study, we are the first to present experimental data on the effect of RIPC of the infrarenal aorta on anastomotic healing in the small bowel, with RIPC being performed directly before anastomotic construction.

RIPC has been shown to have consistently favorable effects in several other organs, such as heart, lungs, brain and kidney. Mostly, and contrary to our data, the effect has been measured by a reduction in IRI^[15-18,28-31]. However, in most publications, the best practice intervals for IR in IPC and RIPC are not clear. It may be that there are differences according to which organ is being studied. Colak *et al* have performed left colonic anastomoses after temporary clo-

sure of the superior mesenteric artery (SMA). Their experimental setting consisted of four groups: a control group without preconditioning and without IRI, a remote IRI group in which the anastomosis was executed after a temporary closure of the SMA for 40 min; a preconditioned IRI group with two cycles of preconditioning (5 min closure of SMA) before IRI; and a preconditioned group without IRI. IRI significantly impaired anastomotic healing in terms of a decreased bursting pressure in the non-preconditioned and preconditioned groups. Furthermore, they observed the lowest bursting pressure in the preconditioned group without IRI on postoperative day 7^[19]. The data are contrary to our findings because we worked out a non-inferiority of RIPC *vs* the control group. It could be that re-laparotomy on postoperative day 7, and the fact that they performed colonic anastomoses, are responsible for their findings, but on the other hand, there also could have been a delayed negative effect of remote preconditioning in general. Colonic anastomoses lose 70% of their initial strength and approach 75% of normal strength at 4 mo, whereas small intestine anastomoses primarily lose less strength and reach their original state at 4 wk^[32].

In our current experimental model, we could not demonstrate a superiority of RIPC over non-preconditioned rats, as expressed by bursting pressure and hydroxyproline concentration. Also, in our non-remote preconditioned model, hydroxyproline levels were not significantly higher than in the control group, whereas the bursting pressure was. In the literature, a positive but also a negative correlation between anastomotic stability and hydroxyproline concentration has been reported^[33,34]. Two of the studies have demonstrated the influence of pentoxifylline^[35] and doxycycline^[33] on intestinal anastomoses, thus indicating further factors that are involved in early anastomotic healing (e.g. other extracellular matrix molecules). Ahrendt *et al* have subdivided the total protein content of a tissue sample bearing an anastomosis into collagenase-digestible protein (CDP) and non-collagenous protein^[36]. Although they have primarily focused on the impact of sepsis on collagen synthesis, an alteration of non-collagenous protein synthesis after construction of an anastomosis is ascertainable^[36]. On the other hand, hydroxyproline concentration measurements do not distinguish between collagen subtypes (especially types I and III), which are known to influence wound stability in subject to their ratio^[36-41]. IPC may result in a higher collagen type I / III ratio or in a higher degree of crosslinking. Moreover, hydroxyproline measurement just reflects the total amount of collagen, but does not discern between pre-existing structural collagen and newly synthesized collagen^[36]. We suggest that anastomotic stability is not strictly correlated to the amount of collagen, but rather to the quality of collagen and other extracellular proteins that have not yet been identified to have an influence on anastomotic healing.

The physiological process of anastomotic healing is potentially disturbed by hypoperfusion, tension, hypovolemia, infection, drugs, malnutrition and immunodeficien-

cy^[42-48]. Tension resulting in hypoperfusion, or hypoperfusion itself at the region of the anastomosis, primarily has to be avoided by the surgeon *via* adequate mobilization of the oral and aboral segment, and foresighted transection to maintain sufficient perfusion. Jönsson *et al*^[3] have shown that collagen synthesis is dependent on tissue oxygenation, thus indicating disturbed anastomotic healing in cases of insufficient blood supply at the site of transection. Moreover, collagenase activity simultaneously is elevated in hypoxia^[43]. Against the background of the above-mentioned facts, any improvements in (micro)circulation could be beneficial to gastrointestinal wound healing in general. Although we did not find an impact on anastomotic stability in our RIPC model, the trend towards a lower grade of mucosal injury could be shown.

Even if significant improvements in bursting pressure and/or hydroxyproline concentration are not visible on postoperative day 4, a beneficial effect in the later phase cannot be excluded. The effects of preconditioning in general are subdivided into an early and a delayed response. Furthermore, subdivision into a humoral, neural and systemic pathway has been described previously^[15,49]. The early response leads to a release of trigger substances such as adenosine, bradykinin, norepinephrine, endocannabinoids, calcitonin gene-related peptide (CGRP), and opioids at the site of ischemia. Via membrane bound receptors and subsequent intracellular signaling, rapid protection in terms of avoiding necrosis and apoptosis is induced locally. Early protection lasts for 2-3 h but reappears approximately 24 h after preconditioning, and is dependent on *de novo* synthesis of molecules such as inducible NO synthase (iNOS), cyclooxygenase-2 (COX-2) and heat shock proteins (HSPs)^[15]. In RIPC, the early local protection is lacking because the site of preconditioning is distant to the region of interest. After the washout (reperfusion), mediators in an RIPC setup also reach the site of the anastomosis/IRI, but this secondary local effect seems to be attenuated compared with an IPC setting^[50]. The systemic effect of RIPC resulting in transcription of anti-apoptotic and anti-inflammatory proteins seems to be similar to IPC^[29,51]. Considering the attenuated local effect, it may be speculated that a positive effect of RIPC on intestinal wound healing becomes evident in a later phase due to newly synthesized molecules.

In our study, one group received 200 µg/kg L-arginine to test whether increased availability of an NO progenitor (L-arginine) and/or proteinogenic amino acid influenced the anastomotic stability. Compared to promising results after oral application^[20], we did not find any positive results compared to the control group. Whether a dose-dependent effect of arginine on anastomotic healing plays an important role remains to be proven. Thornton and colleagues have pointed out a possible dose-dependent effect of NO on collagen synthesis in sepsis^[52]. Stechmiller *et al*^[20] have summed up that NO is of paramount importance in the early phase (inflammation stage) of wound healing, but disturbs it in the pro-

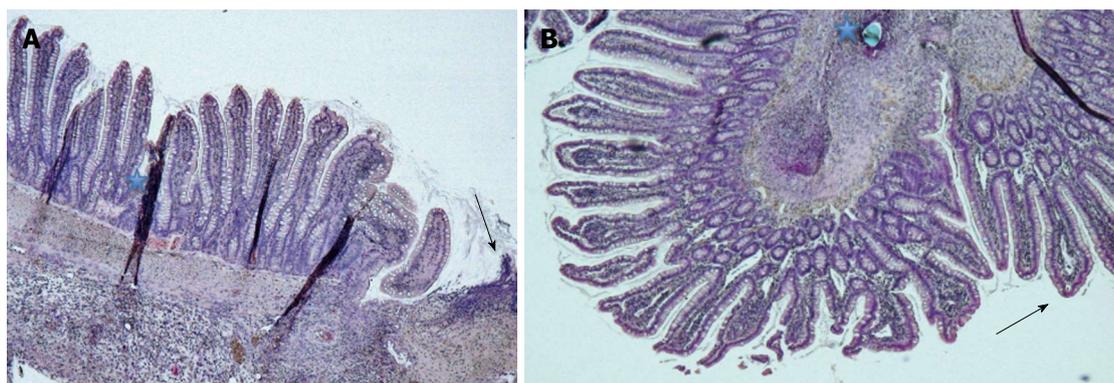

Figure 3 Histological view. A: Chiu grade 0 with intact epithelium and a few villi along one side of the anastomosis (HE staining; magnification 5 ×), Region of the anastomosis (arrow) and staining artefacts (*); B: Chiu grade 2 with a pronounced subepithelial space in the villi next to the inverted anastomosis (arrow) and a suture hole (*) (HE staining; magnification 5 ×).

liferation phase^[53]. Infusion of a substrate regarding the applied dose therefore is not as productive as mimicking preconditioning *via* direct mediators (pharmacological preconditioning)^[54]. In general, mimicking the effect of (remote) ischemic preconditioning could be promising because it could easily be implicated in clinical routine, and could avoid any harm to the site of preconditioning (e.g. vascular dissection in preconditioning)^[54].

The partly massive adhesions around the anastomosis, but also the whole abdominal cavity in the RIPC groups, are highly relevant for surgeons. Preparation on postoperative day 4 was significantly more difficult and technically demanding in the RIPC groups. There were two rats in the RIPC 10/20 group that died due to ileus. Although adhesions are not constant, re-laparotomy on postoperative day 4 could be problematic. Concerning these adhesions, re-laparotomy in the later phase (e.g. postoperative day 7, as mentioned above) in our experimental setting could shed light on the dynamics of these adhesions. Otherwise, it is known that the primary sealing of the anastomosis emanates from the serosal layer, therefore, the adhesions could imply better primary sealing of the anastomosis.

The most interesting issue is the tendency to a lower degree of mucosal injury in the RIPC groups. This could in part be a mark of improved microcirculation, at least at the mucosal level. Additionally, the mucosal injury index of Chiu^[23] (Table 2) is definitely affected by the stitching technique during surgery. Only strictly extramucosal stitches avoid partial mucosal necrosis; transmural stitches would have resulted in a higher degree of mucosal injury. In our highly standardized anastomotic technique, we paid attention to a strictly correct suture technique in a single surgical design. Figure 3 shows a sample of two different Chiu grades. Early or improved mucosal repair is important for the formation of an antimicrobial barrier, and furthermore, for untroubled anastomotic healing at a submucosal level. Mucosal integrity itself is definitely not responsible for anastomotic stability, but aseptic milieu at the submucosa accelerates wound healing and avoids disturbance caused by inflammation due to infection. This

could be useful for patients at risk (e.g. genetic alteration of collagen synthesis) in whom collagen synthesis and/or remodeling takes longer, or for patients suffering from an immunodeficiency who are susceptible to infection.

Given the fact that oxygenation at the site of anastomosis is of paramount importance, angiogenesis and especially drugs that boost or restrict the expression of pro-angiogenic proteins [e.g. vascular endothelial growth factor; (VEGF)] are of note. Ishii *et al.*^[55] have demonstrated an increased bursting pressure and hydroxyproline content on postoperative day 4 in colonic anastomosis. Another interesting approach is VEGF gene therapy, as reported by Enestvedt *et al.*^[56]. After esophagogastrectomy and gastric tube formation, a VEGF plasmid vector is injected at the site of anastomosis. Subjects treated with VEGF transfection resulted in an increased bursting pressure and neovascularization^[56]. They assumed a strong correlation between the number of microvessels and bursting pressure, which supports the enormous importance of oxygenation in anastomotic healing. In contrast, anti-angiogenic agents impair anastomotic integrity if applied shortly before surgery. It may be that (R)IPC can prevent the negative effect of agents such as bevacizumab^[57]. Pro-angiogenic agents could improve gastrointestinal wound healing in the absence of anti-angiogenic drugs, especially in patients with life-time steroid and/or combined immunosuppressive therapy.

The informative value of the current study could be influenced by the small groups and the wide data range, but the data are equally distributed within the range of each group. Therefore, it remains to be proven if larger groups would have led to distinctive findings. Moreover, the group size calculation was based on a presumed high difference in primary outcome measure between the groups indicating a potentially high clinical relevance. As mentioned above, we sacrificed the rats on postoperative day 4 to investigate early anastomotic healing and to match the results with our IPC study. Before postoperative day 4, anastomotic stability is more influenced by suture holding capacity than by tissue regeneration due to wound healing. Postoperative day 4 is a vulnerable phase in anastomotic healing because

suture holding capacity has already decreased and collagen synthesis increases and just overcomes collagenolysis. In fact, increasing the stability of anastomoses on postoperative day 4 would be of great clinical relevance. Given the fact that RIPC results in a commensurate effect, we cannot exclude a positive impact in a later phase of anastomotic healing. Optimum intervals of ischemia and reperfusion are not exactly established, therefore, we adopted the intervals from our previous study. It is not clear whether these are suitable or whether ideal intervals in RIPC differ from those in IPC, and moreover in different effector organs. Our current experiment is a highly mechanistic model, and it is not known whether it can be transferred into clinical routine, but it is easy to repeat and it is one small piece of experimental research on the fundamentals of gastrointestinal wound healing.

In conclusion, RIPC of the infrarenal aorta does not seem to have an influence on anastomotic stability, as was shown for IPC of the SMA. However, according to our previous results with IPC, mucosal injury seems to be less in the RIPC groups, thus indicating improved mucosal microcirculation at the anastomotic region. The observed relevant intra-abdominal adhesions around the anastomosis support the presumption of a gaugeable effect of RIPC on intestinal anastomoses. Further studies, especially in respect to the mucosal and submucosal microcirculation at the anastomotic region, will be of interest to verify the potential implementation of RIPC in intestinal wound healing.

COMMENTS

Background

Wound healing is a widely researched topic. Many experimental studies of wound healing, especially in the skin, have been published. The healing of an intestinal anastomosis in phases is similar to wound healing in the skin. The dehiscence of an anastomosis results in higher morbidity and mortality. To avoid anastomotic dehiscence, the best surgical technique is a prerequisite. Even though an optimal surgical technique for dehiscence is used, it is necessary to research the fundamentals of gastrointestinal wound healing to improve and innovate perioperative management for lowering the rate of anastomotic dehiscence.

Research frontiers

To study the fundamentals of gastrointestinal wound healing, ischemic preconditioning (IPC) and remote ischemic preconditioning (RIPC) were used. Other studies have investigated the effect of different volume regimens perioperatively, and the application of additive medication before or after installation of an anastomosis.

Innovations and breakthroughs

The Surgical Metabolic and Anastomotic Research Team has shown that IPC improves the stability of small-intestinal anastomoses. Other researchers who have used RIPC have not found an advantage in colonic anastomoses. Examination of mucosal injury in anastomoses is an innovation but its consequences are not clear.

Applications

Preconditioning in general could probably be transferred to clinical routine although there are risks, but RIPC has shown no benefit in terms of increasing anastomotic stability. The reduction of mucosal injury in this setting should be

confirmed by *in vivo* microscopy.

Terminology

In preconditioning, ischemia is induced by temporarily branching off an artery, followed by an interval of reperfusion in order to minimize the IR injury of subsequent prolonged ischemia. The ischemia following the preconditioning in our setting is the creation of an anastomosis. In (direct) IPC, the branched off artery supplies the region of interest, and in that case, it would be the later constructed anastomosis. In RIPC, the clamped artery does not supply the region of interest but other organs/regions.

Peer review

In this experimental work, the authors examined the effect of RIPC on small-intestinal anastomosis healing and the paper is interesting.

Abstract

AIM: To study the role of gram-positive and gram-negative bacteria in the pathogenesis of liver injury, specifically the activation of inflammatory mediators.

METHODS: Peripheral blood mononuclear cells of 20 out-patients were studied, 10 of them with cirrhosis.

Peripheral blood mononuclear cells were isolated and exposed to lipopolysaccharide or lipoteichoic acid. CD14, Toll-like receptor 2 and 4 expression was determined by flow cytometry, and tumor necrosis factor (TNF) α , interleukin (IL)-1 β , IL-6, IL-12 and IL-10 secretion in supernatants was determined by ELISA.

RESULTS: Higher CD14, Toll-like receptor 2 and 4 expression was observed in peripheral blood mononuclear cells from cirrhotic patients, ($P < 0.01$, $P < 0.006$, $P < 0.111$) respectively. Lipopolysaccharide and lipoteichoic acid induced a further increase in CD14 expression ($P < 0.111$ lipopolysaccharide, $P < 0.013$ lipoteichoic acid), and a decrease in Toll-like receptor 2 ($P < 0.008$ lipopolysaccharide, $P < 0.008$ lipoteichoic acid) and Toll-like receptor 4 ($P < 0.008$ lipopolysaccharide, $P < 0.028$ lipoteichoic acid) expression. With the exception of TNF α , absolute cytokine secretion of peripheral blood mononuclear cells was lower in cirrhotic patients under non-exposure conditions ($P < 0.070$ IL-6, $P < 0.009$ IL-1 β , $P < 0.022$ IL-12). Once exposed to lipopolysaccharide or lipoteichoic acid, absolute cytokine secretion of peripheral blood mononuclear cells was similar in cirrhotic and non-cirrhotic patients, determining a more vigorous response in the former ($P < 0.005$ TNF α , IL-1 β , IL-6, IL-2 and IL-10 lipopolysaccharide; $P < 0.037$ TNF α ; $P < 0.006$ IL-1 β ; $P < 0.005$ IL-6; $P < 0.007$ IL-12; $P < 0.014$ IL-10 lipoteichoic acid). Response of peripheral blood mononuclear cells was more intense after lipopolysaccharide than after lipoteichoic acid exposure.

CONCLUSION: Peripheral blood mononuclear cells of cirrhotic patients are able to respond to a sudden bacterial ligand exposure, particularly lipopolysaccharide, suggesting that immune regulation mechanisms are still present.

INTRODUCTION

Patients with cirrhosis frequently present with intestinal bacterial overgrowth of both gram-negative and gram-positive bacteria. Coexisting increased intestinal permeability facilitates bacterial translocation into the portal vein^[1]. The resulting bacteremia and endotoxemia can not be efficiently cleared by the injured liver^[2], leading to a rise of systemic proinflammatory cytokines^[3]. This is thought to aggravate the underlying liver damage. The role of gram-negative bacteria in the pathogenesis of liver injury has been extensively studied. As to gram-positive bacteria, a similar deleterious role has been proposed^[4], but still remains to be proven.

It is known that bacterial cell wall products, such as lipopolysaccharide (LPS), lipoteichoic acid (LTA) and peptidoglycan (PGN) fragments, trigger monocyte expression of many inflammatory cytokines. LPS, also known as endotoxin, a major constituent of the outer membrane of gram-negative bacteria, elicits an immune reaction which is responsible for many of the harmful effects seen in septic shock patients. LPS binds to the LPS-binding protein (LBP), a member of a binding and transport protein family. It requires either mCD14 or sCD14 receptors to be transferred to the toll-like receptor 4 (TLR4), a transmembrane signaling receptor, and translocated into the hydrophobic pocket of myeloid differentiation factor-2 (MD-2)^[5]. This signaling pathway activates a variety of transcription factors such as nuclear factor (NF)- κ B (p50/p65) and AP-1 (c-Fos/c-Jun), which induce the production of many inflammatory mediators^[6].

Nowadays, it has become clear that LPS can not reproduce all clinical features of sepsis. This emphasizes the participation of other contributing factors. Gram-positive bacteria, which lack LPS, are responsible today for a substantial part of sepsis incidence. The rapid transmission and acquisition of antibiotic-resistance genes among gram-positive bacteria, and their propensity to adhere and persist on vascular catheter surfaces and other implantable medical devices have contributed to an increasing incidence of gram-positive pathogens as a cause of sepsis^[7]. The major

Table 1 Biochemical characteristics of non-cirrhotic and cirrhotic patients

| | Non-Cirrhotic (n = 10) | Cirrhotic (n = 10) |
|-----------------------------|---------------------------|-----------------------|
| Bilirubin (mg/dL) | 0.8 (0.6-1.2) | 1.2 (0.5-28.5) |
| Albumin (g/dL) | 4.0 (1.8-4.2) | 3.3 (1.2-4.1) |
| PT (sec/ctl) | 11.8 (9.7-15.3) | 11.6 (10.2-18.4) |
| ALT (IU/L) | 23 (15-61) | 32.5 (19-57) |
| AST (IU/L) | 23 (17-48) | 43 (28-180) |
| Alkaline phosphatase (IU/L) | 78 (56-204) | 145.5 (56-479) |

Data are expressed as median (minimum -maximum) values. PT: Prothrombin time; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

wall components of gram-positive bacteria, LTA and PGN, are thought to contribute to the development of sepsis, septic shock^[8] and multiple organ dysfunction syndrome (MODS)^[9]. Like LPS, LTA can interact with CD14 to initiate signal transduction pathways that lead to NF- κ B activation^[10]. It has been observed recently, that LTA is recognized by TLR2, which heterodimerises with either TLR1 or TLR6^[11,12]. Activation of the TLR2/6 heterodimer is greatly facilitated by CD36 in a similar way as TLR4 by CD14^[13].

This study compares, in cirrhotic and non-cirrhotic patients, the ability to activate inflammatory pathways of both gram-negative and gram-positive bacteria ligands. We therefore assessed the response of peripheral blood mononuclear cells (PBMC) of cirrhotic and non-cirrhotic patients to LPS and LTA exposure in terms of receptor expression (CD14, TLR2 and TLR4) and cytokine secretion [tumor necrosis factor (TNF) α , interleukin (IL)-1 β , IL-6, IL-12 and IL-10].

MATERIALS AND METHODS

Patients

Twenty out-patients were studied, ten of them with cirrhosis. Diagnosis of cirrhosis was supported clinically, by laboratory tests and ultrasound. Cirrhosis was due to alcohol in 4 patients, cryptogenic in 5, and due to portal thrombosis in 1. Child-Pugh classification was A in 5 patients, B in 3, and C in 2. Male:female ratio was 1:1 and the median age was 56.5 (36-79) years. Coexisting disorders were diabetes in 2 patients, hypertension in 1 and systemic sclerosis in 1. Laboratory tests are summarized in Table 1. Non-cirrhotic controls were patients with dyslipidemia (4), peptic ulcer disease (3), hypothyroidism (2), major depression (1), diabetes (1), hypertension (1), and achalasia (1). Their male:female ratio was 1:4 and median age 54.5 (41-75) years. At the time of inclusion, subjects neither had a concurrent infectious disorder, nor were receiving antibiotic or immune-modulating therapy. They all signed an informed consent before entry. The protocol of the study was approved by the Human Biomedical Research Committee of the Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán.

Isolation and stimulation of PBMC

Peripheral blood mononuclear cells were used as experimental units, given that they represent well-suited low-cost proxy-measures of monocytic response^[14]. Peripheral venous blood was collected with heparinized sterile pyrogen-free disposable syringes (Becton Dickinson). PBMC were isolated from blood samples on a lymphoprep gradient (Axis Shield). After washing, PBMC were adjusted to 10^6 cells/mL in RPMI 1640 (Life Technologies, Invitrogen), and supplemented with 10% heat-inactivated fetal bovine serum (GIBCO, Invitrogen) and 1% penicillin-streptomycin 500 U/mL-500 µg/mL (GIBCO, Invitrogen). Then, 3×10^6 cells were plated on 2 mL media in 6-well round bottom tissue culture plates (NUNC). After stabilization at 37°C and 5% CO₂, cells were stimulated (duplicate experiments) with either 0.1 µg/mL ultra-purified *Escherichia coli* endotoxin (Sigma Chemical Co.) or 0.1 µg/mL *Streptococcus faecalis* lipoteichoic acid (Sigma Chemical Co.). In order to establish the optimal concentration of activation, PBMC from blood donors were cultured with LPS or LTA at different concentrations such as 0.01, 0.1, 1 and 10 µg/mL and 0.1, 1.0, 10 and 20 pg/mL, respectively. Cultures were incubated for 24 h before supernatant harvest and TNFα concentration measurement. TNFα levels were found highest with a concentration of 0.1 pg/mL. Also, to establish the optimal time of activation, normal PBMC were cultured with 0.1 pg/mL of LPS or LTA, and supernatants harvested after 6, 24 and 48 h. TNFα levels were highest after 24 h (data not shown). We therefore used 0.1 pg/mL of LPS or LTA for a 24-h exposure. Supernatants were harvested after 24 h and stored at -70°C until analysis.

CD14, TLR2 and TLR4 expression

5×10^5 freshly isolated or cultured PBMC were kept unexposed (NE), or were treated with LPS or LTA for 24 h. The expression of CD14, TLR2 or TLR4 was determined by flow cytometry. Briefly, treated PBMC were resuspended at 5×10^5 cells/mL in blocking buffer (PBS containing 2% FBS, 2% rabbit serum, 5 mM EDTA and 0.1% sodium azide) and incubated on ice for 30 min. Cell suspension was centrifuged and stained with fluorescein isothiocyanate (FITC)-conjugated anti-human CD14 (Santa Cruz Biotechnology), phycoerythrin (PE)-conjugated anti-human TLR2 (Santa Cruz Biotechnology), and PE-conjugated anti-human TLR4 (Santa Cruz Biotechnology). Isotype-matched nonbinding control goat antimouse IgG_{2a} (Santa Cruz Biotechnology) was used. The cells were incubated for 15 min in the dark, washed twice with FACS buffer (PBS containing 2% FBS, 5 mmol/L EDTA and 0.1% sodium azide) and fixed with 4% paraformaldehyde in PBS (pH 7.2) for 30 min and analyzed on an EPICS-ALTRA (Beckman-Coulter). A total of 20 000 events was obtained for each sample. Data were analyzed with WinMDI 2.8 software. CD14, TLR2 and TLR4 values were expressed as % fluorescence.

Cytokine assays

After activation, cell-free culture supernatants were harvested and concentrations of TNFα, IL-1β, IL-6, IL-12 and IL-10 were measured by enzyme-linked immunosorbent assay (ELISA) (OptEIA™, BD Pharmingen, San Diego, CA) according to the manufacturer's instructions. Detection limits for each assay were 4 pg/mL for TNFα, IL-1β, IL-6, and IL-10, and 15 pg/mL for IL-12. In each patient, every test was run in duplicate.

Data are summarized as median (minimum and maximum) values. Taking the NE condition as reference, absolute and relative (%) differences were determined for LPS or LTA exposed PBMC of cirrhotic and non-cirrhotic patients. The Mann-Whitney test was used to analyze differences between cirrhotic and non-cirrhotic groups, and the Wilcoxon sign-rank test to analyze differences between exposure and non-exposure to LPS or LTA. A *P* value < 0.05 was considered as statistically significant, and a *P* < 0.10 as tendency towards significance. The Stata v7 statistical package was used.

RESULTS

CD14, TLR2 and TLR4 expression

Expression of CD14, TLR2 and TLR4 by NE PBMC was higher in cirrhotic than non-cirrhotic patients. Median CD14 expression was 13.3% (8.9-34.6) *vs* 6.7% (3.5-27.5) (*P* < 0.01), median TLR2 expression was 9% (4.8-19.5) *vs* 4.8% (1.7-7.9) (*P* < 0.006), and median TLR4 expression was 26.9% (5.9-36.4) *vs* 8.5% (1.2-30) (*P* < 0.111), respectively. (Figure 1A-C) Non-exposure (NE), LPS or LTA exposure, bars represent median values.

After exposure to LPS, CD14 expression by PBMC of non-cirrhotic patients [5.6% (2-28.2)] was not significantly different from corresponding NE values [6.7% (3.5-27.5), NS], but TLR2 and TLR4 expressions were significantly lower [2% (1-6.5) *vs* 4.8% (1.7-7.9), *P* < 0.047, and 3.5% (0.9-26.1) *vs* 8.5% (1.2-30), *P* < 0.028]. PBMC of cirrhotic patients showed, after the same exposure, an increased CD14 expression [23.2% (3.2-48.5) *vs* 13.3% (8.9-34.6), *P* < 0.111], and significantly decreased TLR2 [4.9% (1.1-10.8) *vs* 9% (4.8-19.5), *P* < 0.008] and TLR4 [14.8% (1.2-32) *vs* 26.9% (5.9-36.4), *P* < 0.008] expression (Figure 1A-C). Taking the NE condition as 100% reference, the median relative difference in CD14 expression tended to be higher in cirrhotic than non-cirrhotic patients after LPS exposure (*P* < 0.096). As to TLR2 and TLR4 expression, LPS exposure induced a non-significant trend towards larger median relative differences in cirrhotic than non-cirrhotic patients (Table 2).

LTA exposure did not affect significantly CD14 expression in non-cirrhotic patients [6.5% (3.6-26.9)] when compared to NE conditions [6.7% (3.5-27.5), NS], neither did it affect TLR2 [2.1% (1-8.2) *vs* 4.8% (1.7-7.9), NS] expression. TLR4 expression was, however, significantly decreased [2.7% (0.7-28.8) *vs* 8.5% (1.2-30), *P* < 0.013]. LTA challenged PBMC of cirrhotic patients showed sig-

13.3% (8.9-34.6), $P < 0.013$], and decreased TLR2 [6.6% (1.2-13.4) *vs* 9% (4.8-19.5), $P < 0.008$] and TLR4 [19.4% (1.9-37) *vs* 26.9% (5.9-36.4), $P < 0.028$] expression (Figure 1A-C). LTA induced median relative differences in CD14, TLR2 and TLR4 expression were similar to those induced by LPS (Table 2).

TNF α , IL-1 β , IL-6, IL-12 and IL-10 secretion

NE PBMC of non-cirrhotic *vs* cirrhotic patients secreted similar amounts of TNF α [≤ 4 pg/mL ($\leq 4-143$) *vs* ≤ 4 pg/mL ($\leq 4-42$), NS] and IL-10 [26 pg/mL ($\leq 4-275$) *vs* 6 pg/mL ($\leq 4-72$), NS]. Secretion of IL-6 tended to be higher in non-cirrhotic [401 pg/mL (12-1530)] than cirrhotic [168 pg/mL (5-459)], patients ($P < 0.070$). Secretion of IL-1 β and IL-12 was significantly higher in non-cirrhotic [26 pg/mL ($\leq 4-159$) and 19 pg/mL ($\leq 15-959$)] than cirrhotic [≤ 4 pg/mL ($\leq 4-10$) and ≤ 15 pg/mL ($\leq 15-38$)] patients ($P < 0.009$ and < 0.022) (Figure 2A-E).

Taking NE values as reference [≤ 4 pg/mL ($\leq 4-143$) and ≤ 4 pg/mL ($\leq 4-42$)], LPS exposure triggered significant increases in TNF α secretion by both non-cirrhotic [443 pg/mL (52-658), $P < 0.005$] and cirrhotic [355 pg/mL (52-713), $P < 0.005$] PBMC. Similar increases were observed for IL-1 β , IL-6, IL-12 and IL-10 secretion. Specifically, IL-1 β PBMC secretion increased from NE values of 26 pg/mL ($\leq 4-159$) in non-cirrhotic and ≤ 4 pg/mL ($\leq 4-10$) in cirrhotic patients, to 61 pg/mL (8-192) and 51 pg/mL (17-286) after LPS exposure, respectively ($P < 0.028$ and < 0.005). As for IL-6, secre-

nificantly increased CD14 expression [25.7% (5-48.2) *vs*

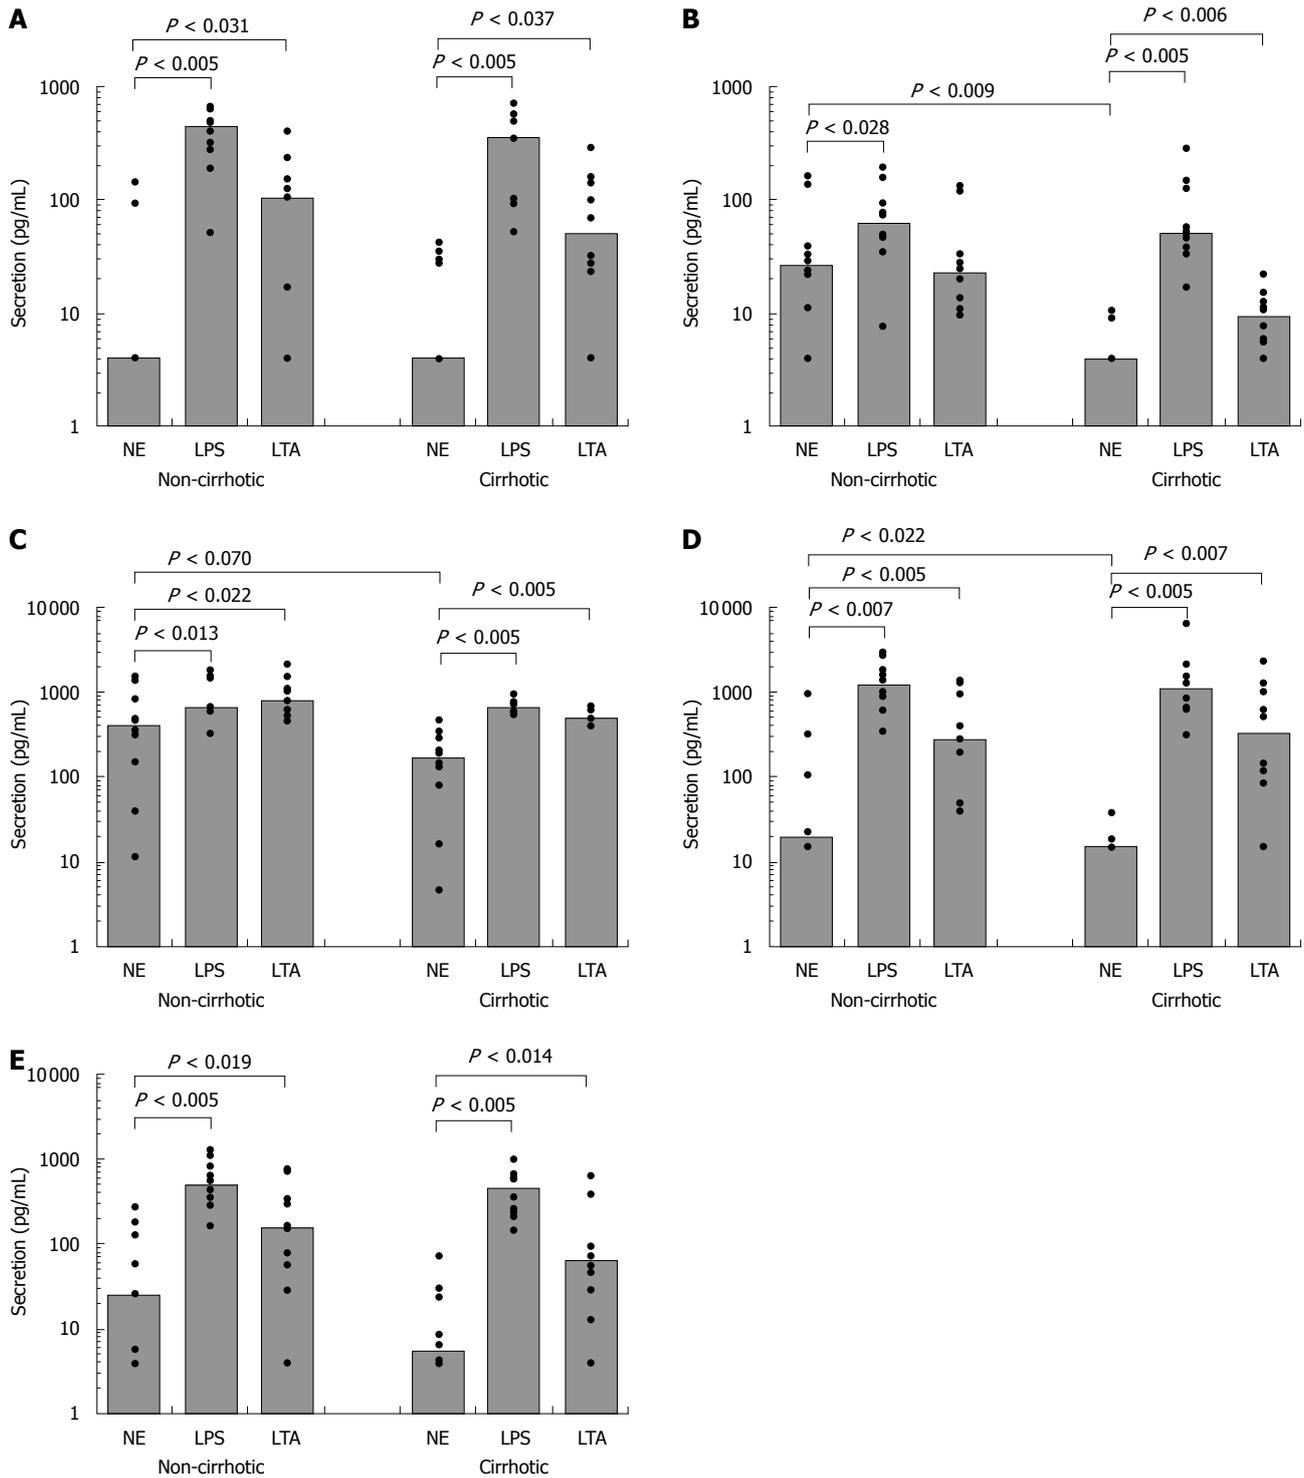

Figure 2 Cytokine secretion from peripheral blood mononuclear cells of non-cirrhotic and cirrhotic patients under conditions of non-exposure, lipopolysaccharide or lipoteichoic acid exposure for tumor necrosis factor α , interleukin-1 β , interleukin-6, interleukin-12 and interleukin-10 secretion. Bars represent median values. $P < 0.05$ denotes statistical significance and $P < 0.10$ denotes tendency to statistical significance. A: Tumor necrosis factor α secretion; B: Interleukin (IL)-1 β secretion; C: IL-6 secretion; D: IL-12 secretion; E: IL-10 secretion. NE: Non-exposure; LPS: Lipopolysaccharide; LTA: Lipoteichoic acid.

tion increased from NE values of 401 pg/mL (12-1530) and 168 pg/mL (5-459), to 645 pg/mL (325-1793) and 660 pg/mL (540-946), $P < 0.013$ and < 0.005 . IL-2 secretion showed an increase from 19 pg/mL (≤ 15 -959) and ≤ 15 pg/mL (≤ 15 -38), to 1201 pg/mL (15-2850) and 1074 pg/mL (317-6397), $P < 0.007$ and < 0.005 . IL-10

secretion was 26 pg/mL (≤ 4 -275) and 6 pg/mL (≤ 4 -72) under NE conditions, and 498 pg/mL (163-1292) and 464 pg/mL (146-1010) after LPS exposure, $P < 0.005$ and < 0.005 . Median relative difference in cytokine secretion between LPS exposure and NE tended to be higher in cirrhotic than non-cirrhotic patients, reaching statistical

significance in IL-1 β only ($P < 0.019$) (Table 2).

To a lesser degree than LPS, LTA exposure also induced increases in cytokine secretion. TNF α secreted by PBMC of non-cirrhotic and cirrhotic patients increased from NE values of ≤ 4 pg/mL ($\leq 4-143$) and ≤ 4 pg/mL ($\leq 4-42$), to 105 pg/mL (4-409) and 51 pg/mL (4-288), $P < 0.031$ and < 0.037 . IL-1 β secretion was 26 pg/mL ($\leq 4-159$) and ≤ 4 pg/mL ($\leq 4-10$) under NE conditions, and 23 pg/mL (10-133) and 9 pg/mL (4-22) after LTA exposure, NS and $P < 0.006$. IL-6 secretion increased from 401 pg/mL (12-1530) and 168 pg/mL (5-459), to 802 pg/mL (454-2155) and 509 pg/mL (397-705), $P < 0.022$ and < 0.005 . IL-12 secretion increased from 19 pg/mL ($\leq 15-959$) and ≤ 15 pg/mL ($\leq 15-38$), to 275 pg/mL (40-1385) and 334 pg/mL ($\leq 15-2339$), $P < 0.005$ and < 0.007 . IL-10 secretion increased from 26 pg/mL ($\leq 4-275$) and 6 pg/mL ($\leq 4-72$), to 157 pg/mL ($\leq 4-756$) and 64 pg/mL ($\leq 4-638$), $P < 0.019$ and < 0.014 (Figure 2A-E). Median LTA-induced relative differences in cytokine secretion tended to be more vigorous in cirrhotic than in non-cirrhotic patients, reaching statistical significance in IL-1 β only ($P < 0.049$) (Table 2).

DISCUSSION

In this study, higher PBMC CD14, TLR2 and TLR4 expression was observed in cirrhotic patients under NE and LPS/LTA exposure conditions. LPS and LTA exposure induced an increase in CD14 expression in cirrhotic patients, and a decrease in TLR2 and TLR4 expression in both non-cirrhotic and cirrhotic patients. With the exception of TNF α , PBMC absolute cytokine secretion was lower in cirrhotic patients under NE conditions. However, once exposed to LPS or LTA, cytokine secretion was similar in both non-cirrhotic and cirrhotic patients, determining a more vigorous response in the latter, as shown by the corresponding relative differences. As to LPS, and with the exception of IL-6 secretion, this bacterial ligand triggers a more vigorous cytokine response than LTA.

CD14, TLR2 and TLR4 expression

Higher PBMC CD14 expression in cirrhotic patients under NE conditions reflects a state of hyperactivation, conditioned probably by a long-standing exposure to intestinal microorganisms and their products. This hyperactivation leads to vigorous reactions with any further bacterial stimuli^[15]. It should be kept in mind that PBMC expression in our study is summarized as percentage of control baseline fluorescence conditions. In terms of the mean fluorescence intensity (MFI)^[16-18], no significant differences in CD14, TLR2 or TLR4 expression among cirrhotic and non-cirrhotic PBMC before and after exposure to LPS and LTA were observed (data not shown). This means that the herein reported differences in PBMC expression reflect differences in the number of activated cells, not in the amount of antibody bound per cell.

Chronic increase in circulating LPS, and the resulting state of PBMC hyperactivation has been associated

to low levels of high-density lipoprotein (HDL), a well-known complication of cirrhosis. HDL is able to bind LPS and neutralize its bioactivity. HDL can also down-regulate monocyte CD14 expression, and has other anti-inflammatory properties^[19]. Low HDL levels could explain the increased CD14 expression observed in PBMC of our cirrhotic patients under both NE and exposed conditions.

As to LTA, this ligand relies, at least in part, on CD14 to initiate signal transduction pathways^[10,20]. It has been shown recently, that CD14 expression enhances markedly LTA binding to plasma cell membranes^[21]. It seems, therefore, that increased CD14 expression in cirrhosis is due to high circulating levels of both LPS and LTA. Increased circulating levels of LPS and proinflammatory cytokines have been documented in patients with chronic liver disease, even in the absence of infection. However, no significant correlation between LPS and these inflammatory mediators has been shown, raising the possibility that other agents, besides LPS, may play a role. Recent studies on TLR expression in cirrhotic patients show that this might be in fact true. TLR4, in the presence of LPS, triggers the signal transduction that leads to TNF α production. When PGN and LTA are present, TLR2 is required for signaling and activation of the inflammatory cascade. Recently, PBMC expression of TLR2, but not TLR4 was shown to correlate significantly with circulating levels of both TNF α and anti-inflammatory soluble TNF receptors. These findings suggest that gram-positive microbial stimuli might be important in the proinflammatory state of chronic liver disease. If proven true, this would contraindicate the use of probiotic agents, such as gram-positive lactobacilli, in cirrhotic patients. Current evidence, however, shows that probiotic use is associated with a significant increase of fecal lactobacilli and a decrease of potentially pathogenic gram-positive and gram-negative bacterial species. Probiotics reverse bacterial overgrowth and improve minimal hepatic encephalopathy. They improve the Child-Pugh class at the expense of serum bilirubin, albumin and prothrombin. Also, serial ALT levels show a significantly reduced hepatic necro-inflammatory activity, suggesting that probiotics can protect against hepatocellular damage^[22].

In our study, PBMC of cirrhotic patients expressed more TLR2 and TLR4 under NE conditions than PBMC of non-cirrhotic patients. Exposure to LPS and LTA decreased expression of both receptors in all patients. (Figure 1B and C) A similar decrease in TLR2 expression was observed by Riordan *et al.* after exposing PBMC of cirrhotic patients to gram-positive bacteria products *in vitro*. However, *in vivo*, they observed an increased PBMC expression of TLR2, but not TLR4, in cirrhotic subjects^[4]. It has been shown recently, that monocyte expression of TLR4 is down-regulated in cirrhotic patients with Child-Pugh class C, whereas TLR2 expression is equivalent to controls. In our study, we included patients with Child-Pugh class A or B mainly, or patients with a reasonably preserved liver function and immune competence. TLR4 down-regulation in advanced cirrhosis is associated with

LPS tolerance, enhanced bacterial translocation and portal venous endotoxemia^[23]. In this context, endotoxin tolerance is viewed as a regulation mechanism that protects the cell from “over expression” or sustained activation. It is regarded as a protection mechanism that aims to limit tissue damage due to excessive immune response. Another explanatory mechanism of TLR down-regulation is receptor internalization, which has been shown for TLR2 and TLR4^[24].

After exposure to LPS, PBMC of both cirrhotic and non-cirrhotic patients showed a lower TLR2 and TLR4 expression. A similar but smaller decrease was observed after LTA exposure, suggesting that these two TLRs might not be completely specific. It is well documented that TLR2 recognizes LPS as well as LTA, while TLR4 recognizes LPS mainly^[5,25]. From our results, we can not exclude a cross-recognition of LPS and LTA that could lead to an “additive activation” of signaling pathways.

Differences and changes in CD14, TLR2 and TLR4 expression observed in our study support the so called hyperactivation state in cirrhotic patients which, compared to the non-cirrhotic patients, does not appear to be an uncontrolled response, but a process of cellular reprogramming or adaptation to bacteria or their products^[26]. We should point out that our non-cirrhotic controls had dyslipidemia, peptic ulcer disease, hypothyroidism, major depression, diabetes, hypertension, and/or achalasia. It is known that some of these entities compromise, up to certain degree, the immune response. In spite of this, PBMC response to bacterial stimuli among cirrhotic patients was significantly different to their non-cirrhotic counterpart.

TNF α , IL-1 β , IL-6, IL-12 and IL-10 secretion

Cytokines, chemokines, and growth factors such as TNF α , IL-1 β , IL-6, interferon- γ , IL-8, macrophage inflammatory protein-1, macrophage chemoattractant factor-1, and transforming growth factor, are all upregulated in patients with cirrhosis^[1]. This upregulation varies according to the degree of liver damage, or Child-Pugh score^[4,19]. *In vitro*, PBMC exposure to bacterial and viral ligands results in an elevated production of inflammatory cytokines, particularly IL-1 β , IL-6, IL-8, and TNF α , β ^[16]. In our study, PBMC exposure to LPS or LTA triggered a significant TNF α , IL-1 β , IL-6, IL-12 and IL-10 secretion in both cirrhotic and non-cirrhotic patients. Due to sample size restrictions, no correlation with the Child-Pugh score was observed.

LPS elicited a more vigorous cytokine secretion than LTA, irrespective of the presence or absence of cirrhosis. This “attenuated” response to LTA has been observed by other investigators and attributed, *in vivo*, to serum components such as lipoproteins and LBP^[19,27]. *In vitro*, to get a proinflammatory response in monocytes and hepatic stellate cells, the minimal active concentration of PGN or LTA needs to be 100 times higher than that of LPS^[1]. We used 0.1 μ g/mL of LTA and LPS based on dose-response experiments. With this exposure dosage, the highest TNF α secretion was obtained, which was quantitatively

lower for LTA than LPS.

As to IL-6, a higher secretion was observed after LTA than after LPS exposure. This cytokine plays a pivotal role in the acute response to bacterial products. Wang *et al.* reported that whole human blood is a potent source of IL-6 production after stimulation with *S. aureus* LTA^[28]. However, other investigators failed to induce IL-6 release from monocyte cultures^[29]. This discrepant IL-6 secretion has been attributed to non-monocytic cells present in the whole blood, not well characterized paracrine factors absent in monocyte cultures^[28], variable LTA exposure dosage^[29], and inter- and intra-species LTA variations^[29].

We should consider that, in cirrhosis, the innate immunity hyper-responsiveness observed in this and other studies do not occur in isolation to alterations in adaptive immunity. It is known that cirrhotic patients are prone to get frequent bacterial infections due to an immunosuppressed state. Contrary to the expected, their T lymphocytes are activated. The proportion of CD4+ T cells expressing CD25 and CD122 antigens is increased significantly, and so is the proportion of memory CD4+ and CD8+ T cells with characteristics of senescent cells. It is thought that repeated cycles of inflammation and damage lead to a continuous recruitment of effector leucocytes within the liver and amplify effector responses exerted by T cells, macrophages, natural killer cells or neutrophils^[30]. The contribution of these immune derangements, separately and as a whole, to chronic liver injury remains to be documented.

PBMC of cirrhotic patients show a hyperactivation state in terms of CD14, TLR2 and TLR4 expression. Exposure to LPS or LTA decreases this expression in both cirrhotic and non-cirrhotic PBMC, suggesting that control mechanisms are still present in chronic liver disease. Given that PBMC receptor expression changed after exposure to both LPS and LTA, our data suggest a non-specific cross-activation. Decreased CD14, TLR2 and TLR4 expression is accompanied by an increased TNF α , IL-1 β , IL-6, IL-12 and IL-10 secretion. This secretion is relatively higher in cirrhotic than non-cirrhotic patients. How this systemic hyperactivation relates to the progression of liver injury is still speculative. Both LPS and LTA elicit a PBMC response, but to a different degree. The impact of this differential response needs to be evaluated, particularly when potentially beneficial gram-positive bacteria (probiotics) are involved.

COMMENTS

Background

Liver diseases figure as the fifth cause of death in Mexico. They are the third cause of death in subjects between 35-44 years, and the fourth cause of death in subjects aged 45-64 years. Patients with advanced chronic liver disease or cirrhosis frequently present with intestinal bacterial overgrowth of both gram-negative and gram-positive bacteria. This leads to infectious complications such as spontaneous bacterial peritonitis or sepsis, and to a chronic proinflammatory state.

Research frontiers

The role of gram-negative bacteria in the pathogenesis of liver injury has been extensively studied. It involves intestinal bacterial translocation and decreased

liver clearance, leading to inflammation, tissue injury and, eventually, cirrhosis. As to gram-positive bacteria, a similar damaging role has been proposed, but still remains to be proven.

Innovations and breakthroughs

It became clear that lipopolysaccharide, a gram-negative bacterial cell wall product, cannot reproduce all the clinical features observed in sepsis. This emphasizes the participation of other contributing factors. Gram-positive bacteria, which lack lipopolysaccharide, are responsible today for a substantial part of sepsis incidence. Peripheral blood mononuclear cells of cirrhotic patients are able to respond to a sudden bacterial ligand exposure, particularly lipopolysaccharide, in terms of a decreased expression of CD14, Toll-like receptor 2 and 4, and an increased tumor necrosis factor α , interleukin (IL)-1 β , IL-6, IL-12 and IL-10 secretion. The authors suggest that immune regulation mechanisms persist in chronic liver disease, at least in Child-Pugh A and B stages.

Applications

Both lipopolysaccharide and lipoteichoic acid elicit a peripheral blood mononuclear cells response, but to a different degree, suggesting that gram-positive microbial stimuli might be important in the proinflammatory state of chronic liver disease. The impact of this differential response needs to be evaluated, particularly when potentially beneficial gram-positive bacteria (probiotics) are involved. Current evidence shows that probiotic use is associated with a significant increase of fecal lactobacilli and a decrease of potentially pathogenic gram-positive and gram-negative bacterial species.

Terminology

Intestinal bacterial overgrowth is a major promoting factor of bacterial translocation in cirrhosis. It is defined as bacterial migration from the intestinal lumen to the mesenteric lymph nodes or other extra-intestinal sites. Sepsis is a common cause of death in cirrhotic patients. Toll-like receptors are transmembrane receptor proteins that play a critical role in the induction of innate immunity to microbial pathogens via recognition of conserved molecular patterns.

Peer review

The paper is very scientific, has copious data and is well written.

Abstract

AIM: To characterize the effects of age on the mechanisms underlying the common condition of esophageal dysphagia in older patients, using detailed manometric analysis.

METHODS: A retrospective case-control audit was performed on 19 patients aged ≥ 80 years (mean age 85 ± 0.7 year) who underwent a manometric study for dysphagia (2004-2009). Data were compared with 19 younger dysphagic patients (32 ± 1.7 years). Detailed manometric analysis performed prospectively included

basal lower esophageal sphincter pressure (BLESP), pre-swallow and nadir LESP, esophageal body pressures and peristaltic duration, during water swallows (5 mL) in right lateral (RL) and upright (UR) postures and with solids. Data are mean \pm SE; a P -value < 0.05 was considered significant.

RESULTS: Elderly dysphagic patients had higher BLESP than younger patients (23.4 ± 3.8 vs 14.9 ± 1.2 mmHg; $P < 0.05$). Pre-swallow LESP was elevated in the elderly in both postures (RL: 1 and 4 s $P = 0.019$ and $P = 0.05$; UR: $P < 0.05$ and $P = 0.05$) and solids ($P < 0.01$). In older patients, LES nadir pressure was higher with liquids (RL: 2.3 ± 0.6 mmHg vs 0.7 ± 0.6 mmHg, $P < 0.05$; UR: 3.5 ± 0.9 mmHg vs 1.6 ± 0.5 mmHg, $P = 0.01$) with shorter relaxation after solids (7.9 ± 1.5 s vs 9.7 ± 0.4 s, $P = 0.05$). No age-related differences were seen in esophageal body pressures or peristalsis duration.

CONCLUSION: Basal LES pressure is elevated and swallow-induced relaxation impaired in elderly dysphagic patients. Its contribution to dysphagia and the effects of healthy ageing require further investigation.

INTRODUCTION

Dysphagia is common in older individuals, with mealtime difficulties being reported in 87% of residential care clients who are predominantly elderly^[1]. This condition is associated with significant morbidity (anxiety and depression) and, in some cases, increased mortality from malnutrition and aspiration pneumonia^[2]. People aged over 65 years constitute more than 15% of the South Australian population and this proportion is predicted to increase substantially over the next 10 years^[3]. Moreover, this demographic trend is consistently noted across the developed world. There is thus the need for a greater understanding of the pathophysiology of dysphagia in older individuals.

An increase in esophageal motor abnormalities has been reported with advancing age^[4]. Studies in patients with gastroesophageal reflux disease suggest that only 62% of swallows are normal in subjects aged over 64 years, compared with 95% of younger patients^[5]. Despite the magnitude of this clinical problem in the elderly, no studies have detected significant differences in the mechanism of esophageal dysphagia between age groups, although older patients tend to find dysphagia more clinically troublesome^[6].

In the absence of a structural esophageal lesion, more than 50% of all patients with dysphagia have abnormal motility on manometry^[7]. However, the most common diagnosis made after investigation is non-specific esophageal motility disorder (NSMD). This is a “default position” when esophageal motor function is abnormal, but does not satisfy the diagnostic features of classic motility disorders, such as diffuse esophageal spasm or achalasia. Advances in high resolution manometry have improved the ability to identify the specific motility changes underlying such conditions^[8], which has significantly improved treatment and patient outcomes^[8,9]. However, the absence of a clearly understood pathogenic mechanism for dysphagia in older adults currently limits the provision of specific therapeutic recommendations for these patients.

Much of our current understanding of the effects of aging on esophageal physiology is based on data from healthy older individuals without dysphagia. These studies have shown age-related esophageal motility changes that include decreased upper esophageal sphincter pressure with reduced duration of relaxation^[10], low amplitude peristalsis and increased stiffness of the esophageal body^[11]. Changes in lower esophageal sphincter function, however, have been harder to identify in healthy ageing^[12] and studies are rarely performed in adults above the age of 80 years. Alterations that may occur with extreme age are increasingly relevant as the proportion of the population surviving into their ninth decade increases.

The few studies looking specifically at esophageal motor function in symptomatic older patients have yielded conflicting results, but do not appear to support an earlier concept of “presbyesophagus”. This refers to a cluster of dysfunctions, including decreased contractile activity, polyphasic waves in the esophageal body and incomplete

relaxation with esophageal dilatation^[13]. Although no differences in broad diagnostic category have been demonstrated between older and younger dysphagic patients^[6,14], we hypothesize that older individuals may comprise a distinct subgroup of NSMD. The pathophysiologic abnormalities in these patients may involve more subtle motor sequencing problems that are not readily detected using standard manometry. Recognition of such abnormal motor patterns would improve understanding of the effects of ageing on the esophagus, as well as potentially provide a more targeted approach to treatment for the increasing number of older individuals with dysphagia.

The aim of the current study, therefore, was to compare esophageal motility between older (> 80 years) and younger adults with dysphagia, using analysis of high resolution manometric data.

MATERIALS AND METHODS

Subject selection

Subjects were identified from a prospectively collected database at the Repatriation General Hospital, Daw Park, a tertiary referral centre providing an esophageal manometry service to an ageing predominantly veteran population along with younger public hospital patients. Esophageal manometric studies were performed on patients presenting with a variety of symptoms suggestive of disease, including dysphagia, atypical chest pain, heartburn and cough. Of these, the database was audited to identify all patients aged ≥ 80 years investigated for dysphagia (as their primary symptom) between January 2004 and November 2009. These were gender-matched to a group of younger dysphagic patients. Exclusion criteria included (1) incomplete manometric data; (2) diagnosis of achalasia; (3) previous fundoplication; and (4) diabetes mellitus.

The standard manometric diagnoses as provided to the referring physician, and symptoms of older and younger dysphagic patients from this database have previously been reported in a clinical audit^[6]. The current study, however, provides a more specific evaluation of the possible motor mechanisms underlying dysphagia, with a detailed re-analysis of the previous manometric data.

The manometry database of this laboratory was approved by the Human Research Ethics Committee of the Repatriation General Hospital. All subjects provided written informed consent prior to the inclusion of their results in the database.

While all patients included in the study described dysphagia, each patient was asked to report whether it was present with solids, liquids or both and whether it was at the level of upper, mid or lower esophagus. These data were recorded prior to performing their esophageal manometry investigation.

Manometric technique

Esophageal pressures were measured using high resolution manometry (HRM). This technique allows visualization of esophageal contractility as a continuum of pressure and

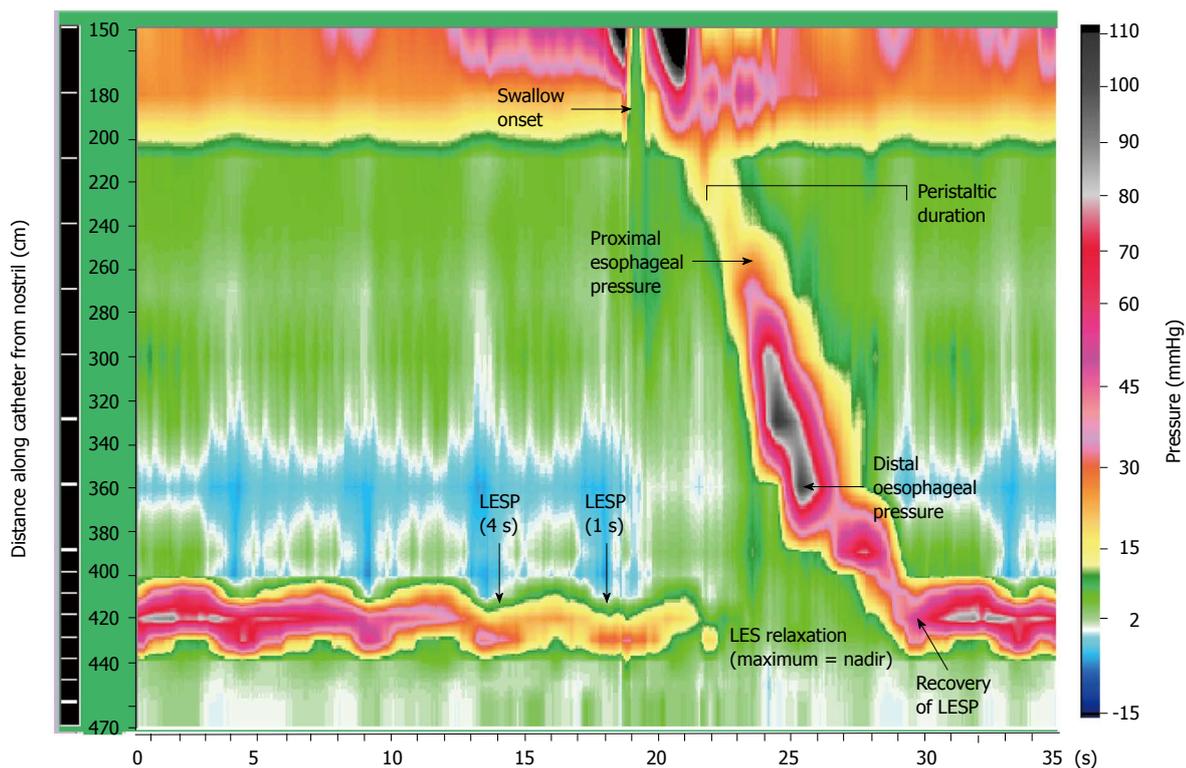

Figure 1 Example of swallow pressure topography spanning from the pharynx (15–20 cm) to stomach (44–47 cm), in a young patient with normal peristalsis and lower esophageal sphincter relaxation. Pressure data (amplitudes shown by colour gradient) are displayed with time on the x-axis and location of sensors on the y-axis. Points of measurement for motility parameters are indicated with arrows. Pressure sensors located in the region of the lower esophageal sphincter (LES) are spaced 1 cm apart, spanning a 6 cm segment. LESP: Lower esophageal sphincter pressure.

time (Figure 1) using a colour display. To achieve this, pressure sensors were spaced at close intervals (1–3 cm apart) and at multiple recording sites, enabling extrapolation of pressure values between sensors without loss of accuracy. Compared to conventional manometry, HRM has several technical advantages that include greater efficiency, higher quality recordings and more objective interpretation. Intraluminal pressures were measured using a 16 channel silicone-rubber manometric assembly (Dentsleeve International, Toronto, Canada). The 9 most proximal side-holes (channels 1–9) were spaced 3 cm apart and spanned the pharynx and esophageal body (24 cm). The remaining 7 side-holes (channels 10–16) were spaced at 1 cm intervals and positioned astride the LES, with the most distal channel in the proximal stomach. All lumina were perfused with degassed distilled water at a rate of 0.15 mL/min using a low compliance perfusion pump (Dentsleeve International, Ontario Canada). Data were recorded at 25Hz and analyzed using specialized software (Trace Version 1.2v, Hebbard, Melbourne, Australia). All pressures were referenced to the intra-gastric pressure and could be displayed as a spatio-temporal color plot or conventional line-plot.

Study protocol

All studies were performed after a minimum 4-h fast. The manometric assembly was passed transnasally into the stomach, *via* an anaesthetized nostril. Subjects were placed in the right lateral (RL) posture and allowed time to adapt to the assembly. A basal lower esophageal sphincter

pressure (BLESP) was recorded for 30 s. Ten 5 mL liquid (water) swallows were performed in the RL posture, and repeated seated upright (UR). Manometry was also recorded during 5 standardized solid boluses (1/8 sliced white bread with crust removed) in the UR position. Subjects were asked to chew the bread and indicate when they were ready to swallow. The presence or absence of dysphagia was recorded for each swallow.

Data analysis

The original clinical manometry recordings were re-analyzed manually by 2 observers (LB and CB), neither of whom was responsible for the initial report. Both observers were blinded to patient age, gender and initial manometric diagnosis. Detailed motility analysis was performed, comprising (1) BLESP at end-expiration; (2) LESP at 1 and 4 s before the onset of each swallow; (3) number of successful LES relaxations (defined as > 75% reduction in LESP); (4) nadir LESP (point of most complete LES relaxation) and time to nadir; (5) time to recovery of LES tone after swallow-induced relaxation; (6) amplitude of proximal and distal esophageal pressures (measured 6 cm below the upper esophageal sphincter and 4 cm above the LES, respectively); and (7) duration of peristalsis (time between peak amplitudes of channels 1–9). The sites at which esophageal pressure measurements were taken are shown in Figure 1. Subjects were excluded if more than 30% of their manometric data were missing, or more than 30% double swallows were encountered.

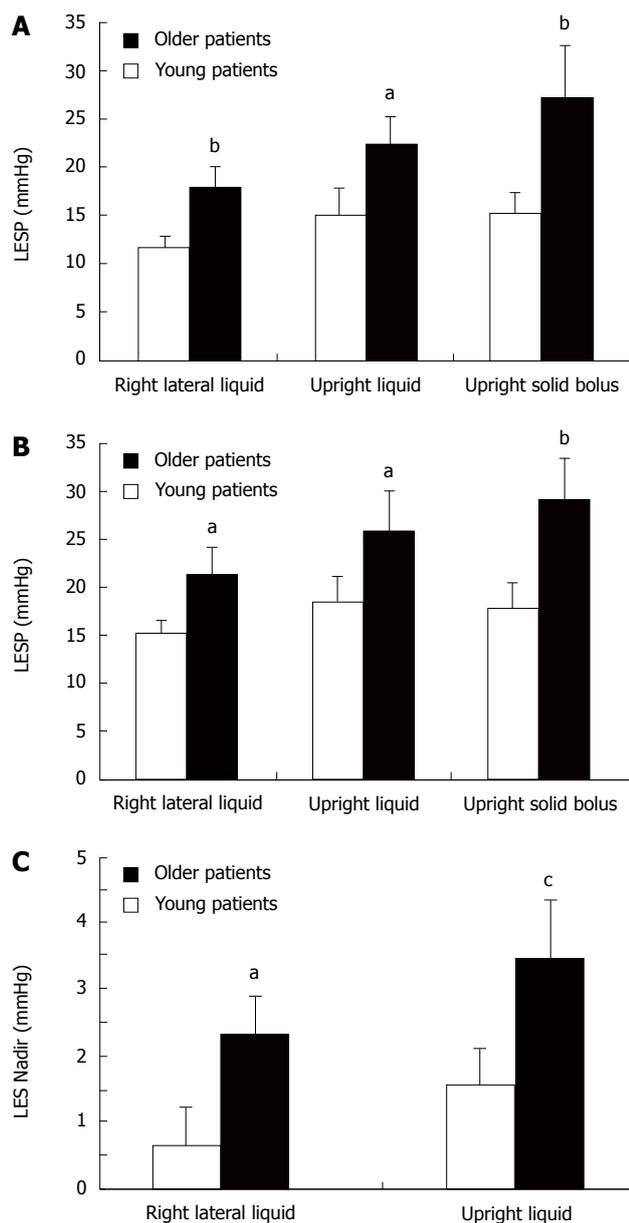

Figure 2 Lower esophageal sphincter pressure at 1 s (A) and 4 s (B) prior to swallow, and lower esophageal sphincter nadir pressure (C), in right lateral and upright postures with liquids and solids, in young ($n = 19$; 32 ± 1.7 years) and older ($n = 19$; 85 ± 0.7 year) patients with dysphagia. ^a $P < 0.05$; ^b $P < 0.01$; ^c $P = 0.01$ vs young. LES: Lower esophageal sphincter; LESP: Lower esophageal sphincter pressure.

Statistical analysis

All data are expressed as a mean \pm SE. Manometric parameters were compared between groups using Student unpaired *t*-test (two-tailed). A *P*-value < 0.05 was considered significant.

RESULTS

Nineteen patients aged older than 80 years (9 male, 10 female; mean age 85 ± 0.7 year) were included. The pattern of dysphagia was characterised as upper (21%), mid (42%) or lower (37%) esophagus, present with solids (47%), liquids (6%) or both (47%). Data were compared

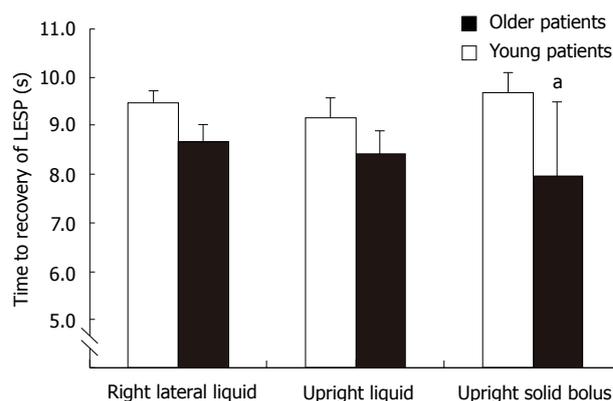

Figure 3 Time to recovery of lower esophageal sphincter tone after relaxation in right lateral and upright postures and with solids, in young and older patients with dysphagia. ^a $P = 0.05$ vs young. LESP: Lower esophageal sphincter pressure.

Table 1 Proximal and distal esophageal peristaltic amplitudes (mmHg) in older and young patients with dysphagia (mean \pm SE)

| | Right Lateral water | Upright water | Upright solids |
|----------|---------------------|-----------------|-----------------|
| Older | | | |
| Proximal | 39.1 \pm 7.3 | 41.4 \pm 5.7 | 45.2 \pm 7.5 |
| Distal | 53.8 \pm 7.8 | 67.3 \pm 16.4 | 61.7 \pm 14.8 |
| Young | | | |
| Proximal | 27.9 \pm 3.0 | 29.6 \pm 3.9 | 35.7 \pm 3.1 |
| Distal | 62.3 \pm 6.0 | 55.5 \pm 6.8 | 57.9 \pm 8.1 |

to 19 younger patients (9 male, 10 female; mean age 32 ± 1.7 years) with esophageal dysphagia in the upper (48%), mid (26%) or lower (26%) esophagus, with solids (79%), liquids (10%) or both (11%).

Mean basal LESP was higher in the older patients (23.4 ± 3.8 mmHg) compared to younger dysphagic patients (14.9 ± 1.2 mmHg) ($P < 0.05$).

Pre-swallow LESP was higher in older dysphagic patients in both RL (elderly *vs* young; 1 s: 17.8 ± 2.2 mmHg *vs* 11.6 ± 1.2 mmHg, $P = 0.019$; and 4 s: 21.3 ± 2.8 mmHg *vs* 15.3 ± 1.3 mmHg, $P = 0.05$) and UR (1 s: 22.3 ± 2.9 mmHg *vs* 14.9 ± 2.9 mmHg, $P < 0.05$; and 4 s: 25.9 ± 4.2 mmHg *vs* 18.3 ± 2.7 mmHg, $P = 0.05$) postures, and with solid boluses (1 s: 27.3 ± 5.5 mmHg *vs* 15.2 ± 2.2 mmHg, and 4 s: 29.1 ± 4.2 mmHg *vs* 17.7 ± 2.8 mmHg, $P < 0.01$ for both) (Figure 2A and B).

Mean nadir LESP was higher in older patients with liquid swallows in both RL (2.3 ± 0.6 mmHg *vs* 0.7 ± 0.6 mmHg, $P < 0.05$) and upright (3.5 ± 0.9 mmHg *vs* 1.6 ± 0.5 mmHg, $P = 0.01$) postures, when compared to younger patients (Figure 2C). There were no differences in nadir pressure with solids, time to nadir, or number of complete LES relaxations, between age groups.

Time to recovery of LES tone after swallow-induced relaxation was shorter in the older group after a solid bolus ($P = 0.05$), with a similar trend with liquid swallows in the RL posture ($P = 0.07$) (Figure 3).

There were no significant differences between age groups in mean amplitude of proximal or distal esophageal body contractions with liquids or solids (Table 1).

The duration of esophageal peristalsis was similar between age groups with liquid swallows in both postures (older *vs* young patients; RL 8.5 ± 0.5 s *vs* 8.6 ± 0.3 s; UR 8.9 ± 0.8 s *vs* 8.0 ± 0.3 s), and with solid boluses (9.4 ± 1.7 s *vs* 8.3 ± 0.5 s).

DISCUSSION

This study is the first to evaluate motility changes specific to dysphagia in the elderly. It demonstrates subtle differences in LES function between older and younger patients with dysphagia. In particular, increased age was associated with a higher resting pressure, incomplete relaxation and a shorter time to recovery of tone after swallowing. There were, however, no differences in esophageal body pressures or peristaltic duration between age groups. These findings of LES dysfunction provide new insights into the possible mechanisms underlying dysphagia in elderly patients.

Using standard clinical manometric analysis, previous studies reported no differences in the frequency of diagnostic categories between older and younger subjects with dysphagia^[6,14]. This suggests consistency amongst regular reporters of these clinical studies. However, the current study demonstrates specific motility differences between age groups using a more detailed approach to analysis. In agreement with Pandolfino *et al*^[15], these data suggest that standard manometric assessment may not be sufficiently sensitive to detect potentially relevant abnormalities.

Adequate LES relaxation is pivotal in allowing bolus transit across the gastroesophageal junction (GEJ); this is both intuitive and demonstrated in physiologic and mechanical studies of esophageal emptying^[16]. Studies in patients with achalasia^[17-19] or post-fundoplication^[20,21] confirm the functional consequence of inadequate LES relaxation. Therapeutic modalities aimed at reducing sphincter pressure and thus enhancing bolus clearance are known to reduce dysphagia in these patients^[22,23]. These findings support the concept that high LES nadir pressure and incomplete relaxation observed in elderly patients could impede bolus clearance, and may be directly relevant to the production of their dysphagia.

Increased basal LES pressure observed in our elderly patients did not meet current criteria used to define Hypertensive LES (HLES) syndrome (mean LESP > 45 mmHg)^[24]. However, we postulate that subtle increases in LESP, in combination with failure to relax adequately, may contribute to their dysphagia. Gockel *et al* demonstrated an association between elevated resting LESP and dysphagia in 100 patients with HLES (defined as BLES > 26 mmHg). Of these, 71% of subjects reported moderate dysphagia in the absence of any other motility disorder^[25]. There is, however, inconsistency in dysphagia rates between studies, and the pathophysiology and clinical significance of this are uncertain^[24,26,27]. It has also been reported in HLES patients that LES nadir pressure is higher than that seen in healthy subjects, with a shorter relaxation duration^[25,26]. Similar dynamics of the LES were observed in the elderly patients of the current study.

Disturbances in the activation of vagal pathways to the LES (in particular nitric oxide release) underlie impaired sphincter relaxation in motility disorders such as achalasia^[28]. A loss of vagal motor control of the LES has not yet been studied in older patients with dysphagia, however it is known that ageing is associated with degeneration of inhibitory ganglion cells in the intramural esophageal plexus^[29,30]. A significant reduction in the number of neurons innervating the LES leads to increased basal pressure and poor relaxation^[31]. If this age-associated neuronal loss occurs to a pathologic extent, it may produce dysphagia in a subset of older people. Another possibility may be decreased LES compliance, reflecting either changes in the characteristics of the circular muscle or adjacent anatomic structures. Specifically, this may include the crural fibres of the diaphragm and, in some patients, compression due to ectasia of the descending aorta; however further investigation is required.

Adequate propagation and strength of distal esophageal pressures are pivotal in efficient bolus clearance. Studies using impedance and fluoroscopic techniques have both confirmed that a minimum contractile amplitude of 30 mmHg in the distal esophagus is required for sufficient flow across the GEJ^[32,33]. In patients with hypertensive LES, Gockel *et al*^[25] showed that a quarter of subjects generated pressures in the distal esophagus above 180 mmHg, which is consistent with “nutcracker esophagus”. Previous data regarding the physiologic effect of ageing on esophageal body function, however, suggests an expected decrease in peristaltic amplitude in healthy older people. In the current study, distal esophageal amplitudes in elderly patients with dysphagia were similar to those of younger patients, despite a higher basal LES pressure and impaired LES relaxation. This failure to compensate for increased resistance at the GEJ may further contribute to their symptoms.

In conclusion, these data indicate that subtle impairment of LES relaxation, and thus increased resistance at the GEJ, is a potential contributor to dysphagia in elderly patients. This may reflect the normal ageing process or the pathogenesis of dysphagia, and warrants further study. As there are limited data on LES function in healthy asymptomatic elderly subjects, detailed examination of this area may be of benefit.

COMMENTS

Background

Esophageal dysphagia is common in older individuals and adversely affects both morbidity and mortality. Previous studies have shown changes in esophageal function with advancing age. However, data on the specific mechanisms underlying dysphagia in older patients have yielded conflicting results. A better understanding of the pathophysiology in this group would enable a more targeted approach to treatment.

Research frontiers

Much of our current understanding on esophageal motor abnormalities reported with advancing age is based on data from asymptomatic older individuals. In over 50% of patients with dysphagia, abnormal esophageal motility is seen on manometry. However, no specific differences in the mechanism underlying dysphagia in older patients have been identified. In this study, the authors demonstrate subtle differences in lower esophageal sphincter (LES) function in elderly dysphagic patients using a detailed manometric approach. These findings provide new insights into the possible mechanisms underlying dysphagia in this patient group.

Innovations and breakthroughs

The few studies examining esophageal motor function in older patients with dysphagia provide conflicting data. Recent studies do not support an earlier concept that age-related changes (presbyesophagus) are responsible for symptoms. Broad manometric diagnoses are similar between age-groups, although it is possible that elderly patients comprise a distinct sub-group of non-specific motility disorders. In the current study, LES basal pressure was elevated and relaxation impaired in elderly patients. A possible etiology may be degeneration of neurons innervating the LES, which has been described with ageing.

Applications

There is a need for a greater understanding of esophageal motor changes that are specific to older patients with dysphagia. The absence of a clearly understood pathogenic mechanism in this group currently limits the provision of specific therapeutic recommendations.

Terminology

High resolution manometry is a methodology that improves visualization of esophageal contractility. Intraluminal pressures are displayed as a colour plot over time, using multiple spaced pressure sensors (time on x-axis and location of sensors on y-axis). Pressure values between sensors are extrapolated and amplitudes displayed as different colours in the plot.

Peer review

In this manuscript, Besanko *et al* compared esophageal motility between older and younger adults with dysphagia using high resolution manometric data analysis. The trial is carefully performed and clinically important.

Abstract

AIM: To evaluate the prevalence and sociodemographics of gastroesophageal reflux disease (GERD) symptoms and to identify treatment patterns among GERD patients.

METHODS: A telephone survey of a representative sample of the adult Israeli population was conducted. The questionnaire included detailed sociodemographics, history of GERD symptoms and the various treatments used.

RESULTS: The survey included 2027 subjects. Twice weekly, once weekly and monthly GERD symptoms were reported by 8.4%, 12.5% and 21.5% of subjects, respectively. There was no difference in prevalence between men and woman; however, GERD symptoms were significantly more prevalent within the older age group and lower socioeconomic status. Among those reporting weekly symptoms, a quarter did not use any kind of therapy and another quarter used various

traditional remedies (e.g. soda, milk, almonds, *etc.*). Antacids were used by 35.1%, H₂ blockers by 13.2% and PPIs by 17.5%.

CONCLUSION: We found that 12.5% of the adult Israeli population experience weekly GERD symptoms. GERD prevalence and sociodemographics are similar to those described in other Western countries, and treatment is still suboptimal.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a highly prevalent gastrointestinal (GI) disorder and is one of the most common GI illnesses encountered in clinical practice^[1,2]. Heartburn and acid regurgitation are the most common symptoms reported by patients with GERD^[3,4]. The prevalence of GERD has been studied in many parts of the world and has been shown to be high in the Western population^[5]. In the United States, 44% of the adult population have reported experiencing heartburn at least once

a month, 14% have reported experiencing it weekly, and 7% have reported experiencing it daily^[6]. Previous studies have shown an association between GERD and several demographic and behavioral factors such as gender, age, educational level and socioeconomic status^[1,7]. However, inconsistent results have been reported for both GERD prevalence rates and possible associated risk factors in different countries. These inconsistencies may be the result of geographical variation, different lifestyle habits and methodological differences concerning the definition and evaluation of GERD symptoms^[8].

The aim of the present study was to define the prevalence of GERD in Israel, to assess the effect of sociodemographic factors on the occurrence of GERD and to evaluate treatment patterns and use of medications among GERD patients.

MATERIALS AND METHODS

Subjects

The study was conducted in late 2006. A total of 2033 individuals aged 18 years or more were included in the study.

Questionnaire

A telephone questionnaire designed for use in large, population-based studies to assess the prevalence of GERD was administered. The interview was performed by non-health related professional reviewers (Geocartography Group Information Strategy & Solutions, Israel). The interviewers were totally familiar with the questionnaire and were instructed to better explain any eventual question that might not have been fully understood by the interviewed individuals.

After disclosing their age and giving voluntary consent to participate in the study, the participants were asked if they had ever experienced heartburn or gastric content regurgitation. Heartburn was defined as burning feeling starting in the stomach and radiating towards the throat. The questionnaire included questions related to the following information: presence and characteristics of heartburn or regurgitation, frequency of symptoms and type of treatments that were used. The questionnaire also included demographic variables such as: age, gender, ethnic origin, education, monthly income and living conditions.

Statistical analysis

Categorical variables were summarized with number and percentage of patients. The χ^2 and Fisher exact tests were used to compare categorical variables whereas Kruskal-Wallis one-way analysis of variance was used to analyze the demographic data. A $P < 0.05$ was considered statistically significant. Data were analyzed using SPSS version 15.0 (SPSS Inc. Chicago, IL).

RESULTS

The study population consisted of 2027 subjects. There

jects who had significant GERD symptoms defined as having symptoms at least once a week.

Table 3 shows the pattern of anti-reflux medications that were used by the study population. Twenty-five percent of subjects with significant GERD (at least once a week GERD episode), and 38.5% of those with less frequent GERD, did not take any treatment. Natural and traditional remedies were used by 22%-25% of subjects and only 20% of subjects with significant GERD used proton pump inhibitors (PPI).

DISCUSSION

The results of the present study show that the prevalence of typical GERD defined by heartburn and/or acid regurgitation in the general adult population in Israel is close to 30%, and 12.5% of this population has suffered from at least one of these symptoms once weekly over the past year. These rates are similar to those reported in prior studies among Western populations, and recently in Israel^[1,3,6,9].

In our study, GERD symptom prevalence was strongly associated with increasing age (17.2% in the > 55 years age group and 12.2% in the 18-34 years age group). However, higher prevalence was observed only in the high frequency patient group (\geq once/wk) but not in the lower frequency group. The effect of increasing age on the prevalence of GERD symptoms has been reported by two European studies^[3,10], but was not seen in a study from Minnesota, USA^[6]. In the UK GP database study, the trend of increased GERD incidence with age was reversed at the age of 69 years^[11], while in the Georgia Medicaid study, the trend reversed earlier, at 55 years^[12]. In all of these studies, GERD was defined on a symptomatic basis which lacks the ability to evaluate whether objective aspects of GERD, such as reflux esophagitis, are more prevalent or severe in older individuals.

A recent study from Israel reported that GERD symptoms are more common and severe among men^[9]. However, our study, similar to several previous cross-sectional and longitudinal studies, did not find a significant association between gender and GERD^[3,6,7,10,12].

An interesting observation of the current study is the effect of low socioeconomic status on the prevalence of

GERD symptoms. Increased prevalence of GERD symptoms was reported in our study by subjects with lower income, lower level of education and by those of Oriental ethnic origin. Previous studies have found an increased GERD prevalence among subjects with lower educational level^[13,14]. Recently, Nocon *et al*^[15] from Germany reported similar results. A reasonable explanation for this observation is that people from a lower social class are more likely to have lifestyle-related risk factors, such as smoking or overweight. However, Nokon *et al*^[15] have found that even after adjusting for smoking and BMI, being in middle or lower social class nearly doubled the risk of severe GERD symptoms. The association of GERD and *Helicobacter pylori* (*H. pylori*) is controversial. While some argue for a preventive role of *H. pylori* in the pathogenesis of GERD by its ability to alter the nature of gastric refluxate, others find no link between the infection and GERD^[16]. The prevalence of *H. pylori* in Israel has been found to be similar to that of other Western countries.

Another important finding of the current study is that a third of the subjects suffering from GERD symptoms do not use any of the accepted medical treatments, such as antacids or antisecretory drugs. Self-medication is still very common, even in those who have reported frequent symptoms, and popular and traditional remedies (as well as antacids) are still widely used.

There are several limitations to this study, and interpretation of the results should be cautious. The questionnaire included only the major and most common GERD symptoms: heartburn and acid regurgitation, but not other symptoms. Extra-esophageal manifestations of GERD were not included. Moreover, symptoms were assessed only by using patient questionnaires and not by a physician. Indeed, in the absence of a gold standard for diagnosing GERD, patient questionnaires remain the common outcome in clinical or epidemiological studies. Finally, we also were unable to obtain data on body mass index, diet, smoking status, and alcohol intake, which may have been confounding factors. However, despite these limitations, our findings are in accordance with population-based studies from other Western countries and with a recent report from Israel.

In conclusion, we found that the prevalence of typical GERD symptoms in the general adult population in Israel

is close to 30%, and 12.5% of this population has suffered from at least one of these symptoms once weekly over the past year. These figures are similar to those found in other Western populations. There is an association between the frequency and severity of GERD symptoms and increased age, low income and low educational level. Antacids and traditional remedies are still widely used, and PPI treatment has not reached its full potential.

ACKNOWLEDGMENTS

The study was initiated by a pharmaceutical company (Dexcel Pharma) as part of launching an over-the-counter proton pump inhibitor.

COMMENTS

Background

Gastroesophageal reflux disease, commonly referred to as Gastroesophageal reflux disease (GERD), is defined as chronic symptoms or mucosal damage induced by abnormal regurgitation of fluids from the stomach into the esophagus. The most typical symptoms are heartburn and regurgitation. In most cases, this is a result of inappropriate lower esophageal sphincter (LES) function. Gastroesophageal refluxate contains a variety of noxious agents, mainly acid but also pepsin, bile salts and pancreatic enzymes, and the exposure of the esophageal mucosa to these agents may result in significant injuries to the esophageal mucosa. These injuries include: reflux esophagitis, esophageal stricture, Barrett's esophagus and esophageal adenocarcinoma. Over the past three decades, the incidence of GERD as well as esophageal adenocarcinoma has risen rapidly, especially in Western countries. Lifestyle modifications combined with proton pump inhibitors (PPI) are currently the first-line treatment for subjects with GERD. It is important, therefore, to identify populations at risk for GERD and to recognize those who are inappropriately or inadequately treated. The aim of the current study was to assess the prevalence and risk factors of GERD, presenting as heartburn or regurgitation, among the Israeli adult population and to identify treatment patterns exhibited by this population.

Research frontiers

In the current study the authors placed our emphasis on the importance of sociodemographic factors as risk factors for GERD. In addition, the authors examined to what extent subjects who suffer from GERD are treated appropriately according to current recommendations in the literature.

Innovations and breakthroughs

The authors have found an increased prevalence of GERD symptoms among subjects from lower socioeconomic status, defined as those with lower income, lower level of education and those of Oriental ethnic origin. The authors have also found that a significant proportion of GERD patients are not treated adequately.

Applications

More efforts are needed to identify subjects who are at risk for GERD, to promote lifestyle improving programs and to encourage adequate treatment for GERD in order to prevent complications, especially esophageal adenocarcinoma.

Peer review

In this manuscript, the authors described the prevalence of GERD and its related factors in an adult Israeli population. The study was uniquely performed and interesting.

Abstract

AIM: To evaluate the efficacy of non-sequential narrow band imaging (NBI) for a better recognition of gastric intestinal metaplasia (GIM).

METHODS: Previously diagnosed GIM patients underwent targeted biopsy from areas with and without GIM, as indicated by NBI, twice at an interval of 1 year. The authors compared the endoscopic criteria such as light blue crest (LBC), villous pattern (VP), and large long crest (LLC) with standard histology. The results from two surveillance endoscopies were compared with histology results for sensitivity, specificity, positive predic-

tive value (PPV), negative predictive value (NPV), and likelihood ratio of positive test (LR+). The number of early gastric cancer cases detected was also reported.

RESULTS: NBI targeted biopsy was performed in 38 and 26 patients during the first and second surveillance endoscopies, respectively. There were 2 early gastric cancers detected in the first endoscopy. No cancer was detected from the second study. Surgical and endoscopic resections were successfully performed in each patient. Sensitivity, specificity, PPV, NPV, and LR+ of all 3 endoscopic criteria during the first/second surveillances were 78.8%/91.3%, 82.5%/89.1%, 72.8%/77.8%, 86.8%/96.1, and 4.51/8.4, respectively. LBC provided the highest LR+ over VP and LLC.

CONCLUSION: Non-sequential NBI is useful for GIM targeted biopsy. LBC provides the most sensitive reading. However, the optimal duration between two surveillances requires further study.

INTRODUCTION

In Correa's gastric cancer cascade, gastric intestinal metaplasia (GIM) is an important precancerous lesion for the development of intestinal type gastric cancer^[1,2]. Although diffuse type gastric cancer can arise independently of GIM, in many cases GIM may be found nearby^[3]. The benefit of annual endoscopic surveillance in these high risk patients has been shown to improve survival by enhancing the detection of gastric cancer at the early stage^[4]. However, conventional white light endoscopy has a limitation in selection of the area for surveillance biopsy^[5]. Multiple random biopsies under white light endoscopy to detect GIM are quite cumbersome as they are time-consuming and have the possibility of missing a small lesion. Methylene blue chromoendoscopy is the only technique that provides a good validity score for GIM targeted biopsy^[6,7]. However, this technique still has a limitation because of the need for dye spraying. Moreover, it has been shown that DNA damage can occur in columnar cell-lined mucosa after chromoendoscopy with methylene blue, thus DNA damage to the GIM epithelium may also occur as it is also an intestinal type columnar cell^[8]. Magnifying narrow band imaging (NBI) has been introduced which negates the need for dye spray. This technique provides better details of the mucosa and vascular patterns of minute lesions, including early gastric adenocarcinoma and GIM^[9,10]. Uedo *et al.*^[11] reported on the excellent accuracy (91%) of the light blue crest (LBC) pattern detected by NBI in predicting the likelihood of GIM. Using a similar method but without magnification, a group from Missouri demonstrated that the ridge/villous pattern of the gastric mucosa detected by NBI was also useful for the diagnosis of GIM, with a sensitivity and specificity of 80% and 100%, respectively^[12]. However, these pioneer investigators used the sequential NBI system that is mainly available in Japan and South Korea. This system is not widely available for other commercial users. The slight differences in color spectrum of sequential and non-sequential NBI processors provide some differences in color images^[13]. Therefore the excellent results from the sequential system may not be replicable in the non-sequential system. To date there has been no study on the role of non-sequential NBI for the detection of precancerous gastric lesions. We therefore conducted a prospective endoscopic study to validate the feasibility of non-sequential NBI by using a combination of endoscopic criteria to determine the leading area for GIM biopsy.

MATERIALS AND METHODS

Non-sequential NBI

In the non-sequential NBI system, there is a rotating interference narrow band filter (R/G/B). The specific colors are transferred directly without alteration in R/G/B color pattern from the color charge-couple device (CCD) as a picture containing different mucosal depth patterns. This

incomplete image is further transformed with a matrix element, coefficient K, by a computer to a more complete image that provides a better contrast^[14]. The scope that we used in this study was a magnifying gastroscope (Olympus GIF Q160Z, Olympus, Tokyo, Japan) which is compatible with the non-sequential light source and processor EVIS Exera II (Olympus, Tokyo, Japan). This scope had a zoom lens placed just distal to the CCD. The CCD was located at the tip of the endoscope, and the optical power of magnification was 115 times. To maintain the optimal distance of the magnifying focus, a transparent plastic cap was attached at the scope tip.

Patients

From November 2007 to May 2009, at the King Chulalongkorn Memorial Hospital Endoscopy Unit, we recruited all patients with GIM previously diagnosed by routine endoscopic biopsy. Generally, the initial endoscopy was performed for dyspepsia, and a random biopsy was performed at that time. Patients with abnormal coagulopathy, patients who refused to give informed consent, and patients who had previous subtotal gastrectomy were excluded from the study. There were 38 eligible patients enrolled who had a prior history of GIM. All patients underwent, 1 year apart, two upper endoscopies with NBI targeted biopsy. The last procedure was performed in May 2009. The study protocol was approved by the Ethical Committee of the Faculty of Medicine, Chulalongkorn University.

Endoscopic criteria for GIM diagnosis

All of the endoscopic readings were performed at 115 x magnification. Based on the previous studies results^[11,12], we selected three criteria as positive readings for GIM: (1) Normal gastric mucosa was defined as a uniform pattern of round pit gastric mucosa (Figure 1A); (2) Light blue crest (LBC) was defined as a fine, blue-white line on the crests of the epithelial surface, which looked like light reflection from the mirror (Figure 1B)^[11]; (3) Villous pattern (VP) was defined as a raised area of villi above the gastric mucosal surface (Figure 1C)^[12]; and (4) Large long crest (LLC) was defined as a combination of linear dark and light areas that differed from the normal gastric epithelium (Figure 1D)^[12].

Procedures and biopsy protocol

All endoscopies were performed by one gastroenterology fellow (BI) under supervision of one senior attending endoscopist (RR). Both endoscopists had experience in using NBI for other lesions, including colonic adenoma and minimal erosive reflux esophagitis, in more than 200 cases. After obtaining consent, 5 mg intravenous midazolam was injected to sedate each patient. In addition, 10 mg hyoscine was also given intravenously to decrease bowel movement for easier endoscopic visualization. Simethicone solution was used to reduce mucus and gas bubbles in the stomach. We elected to do biopsies from the an-

GIM: Gastric intestinal metaplasia

trum and incisura (area with the possible highest probability of GIM). In detail, a screening non-magnifying white light endoscopy was performed first. Then NBI was performed to target GIM. Six NBI snapshot images were obtained from four quadrants of the antrum and two areas of the gastric incisura. If there was any positive finding by one of the three criteria mentioned above (LBC or VP or LLC), that area was counted as positive for GIM and a targeted biopsy was taken from the positive lesion(s). If there was no positive finding from that area, one random biopsy was taken from that quadrant as a GIM negative specimen. Therefore, six magnifying images and their

targeted biopsies were derived from each patient. Pilot cohorts ($n = 10$) were used for training in biopsy techniques and endoscopic readings. *Helicobacter pylori* infection was examined by a rapid urease test. Eradication of *H. pylori* was carried out if the urease test or histology was positive for infection. A standard triple therapy in this study consisted of amoxicillin, clarithromycin, and omeprazole given orally for 14 d. One year after the first endoscopy, eligible patients underwent the second surveillance gastrointestinal (GI) endoscopy, using a similar protocol to the first surveillance.

Histological assessment and monitoring of GIM

All gastric specimens were immersed in formalin and processed by embedding in a paraffin block. A 4 μm section of the specimen was later stained with hematoxylin-eosin, Alcian blue and Giemsa stain. A clinically blinded pathologist (NK) reviewed all the specimens. The updated Sydney classification^[15] was referred to as the gold standard for gastric histological classification. Regarding GIM monitoring on each patient, a comparison was made between the first and second gastric biopsy results. Patients were classified as having persistence, regression, or progression of GIM based on the existence or absence of GIM on the first and second histologies.

Diagnostic accuracy and statistical analysis

The diagnostic accuracies of all three criteria (LBC or VP or LLC) were judged after the index endoscopy by

Table 2 Validity scores with confidence intervals of the first endoscopic targeting biopsy for gastric intestinal metaplasia, mean (range)

| Criteria | Sensitivity (%) | Specificity (%) | PPV (%) | NPV (%) | LR + (%) |
|--------------|---------------------|---------------------|---------------------|---------------------|--------------------|
| LBC | 70.59 (59.57-79.72) | 83.22 (75.75-88.75) | 71.43 (60.37-80.49) | 82.64 (75.24-88.25) | 4.21 (2.85-6.21) |

| LLC | 17.65 (10.53-27.75) | 95.10 (89.79-97.84) | 68.18 (45.12-85.26) | 66.02 (59.06-72.36) | 3.60 (1.53-8.48) |
| All criteria | 78.82 (68.34-86.64) | 82.51 (75.08-88.16) | 72.83 (62.38-81.33) | 86.76 (79.63-98.73) | 4.51 (3.11-6.55) |

PPV: Positive predictive value; NPV: Negative predictive value; LR +: Likelihood ratio of positive test; LBC: Light blue crest; VP: Villous pattern; LLC: Large long crest.

comparing the endoscopic diagnosis with histology results from that site. A descriptive comparison between endoscopic and pathological readings was performed. The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and likelihood ratio of positive test (LR+) for the diagnosis of GIM were calculated. The calculations were performed with SPSS statistical software (SPSS version 15, Inc., Chicago, IL, USA).

RESULTS

During the initial surveillance endoscopy, there were 38 patients (20 male, 18 female) with a previous diagnosis of GIM (Table 1). The mean age \pm SD was 59.9 ± 11.5 years (range, 27-80 years). The median time from diagnosis of GIM to the first surveillance endoscopy was 2.2 years. The median interval between the two surveillance endoscopies was 1 year. Twenty-six patients returned for a second surveillance study. The reasons for those 12 patients not attending the second study were: being diagnosed as having another type of cancer and requiring further treatment ($n = 4$), withdrawal from the second study ($n = 4$), loss to follow-up ($n = 2$), and diagnosis with early gastric cancer from the first surveillance endoscopy ($n = 2$).

From the first surveillance endoscopy, most of the background endoscopic findings indicated atrophic gastritis. Thirty one of 38 patients (81.6%) were found to have GIM. The overall number of positive specimens was 85/228 (37.3%). Each GIM positive patient had two specimens positive for GIM on average. All GIM cases were complete GIM (type I). Of these, 12 patients had a positive rapid urease test (31.6%) and all received standard triple therapy for eradication. Under standard white light endoscopy, five patients were suspected to have GIM because of a whitish color change with plaques or patches. With NBI, the sensitivity, specificity, PPV, NPV, and LR+ of the three endoscopic criteria were 78.8%, 82.5%, 72.8%, 86.8%, and 4.5, respectively, while LBC possessed the highest LR+ compared with VP and LLC (Table 2).

The first surveillance study was able to detect early gastric cancer in two patients. The first patient was diagnosed with GIM a year before recruitment. NBI was able to demonstrate a focal area of depressed mucosa with loss of the normal vascular pattern. At that time, the technique of endoscopic submucosal dissection (ESD) was

not available in Thailand, hence the patient was sent for a subtotal gastrectomy. The gastric pathology confirmed a minute area of signet ring carcinoma involving only the submucosal area. The patient has been doing well without evidence of recurrence after a 2-year follow-up. The second patient had been treated as having a Helicobacter-associated antral ulcer, and found to have diffuse GIM. Six months later, at the first surveillance endoscopy, *H. pylori* eradication and healing of the previous ulcer were confirmed but a new elevated lesion with abnormal subepithelial vascular network in the lesser curvature was discovered. Pathology confirmed it as an intestinal type gastric adenocarcinoma. This patient underwent a successful ESD. The resected specimen showed malignant cells confined to the submucosal level without any vascular invasion.

During the second surveillance endoscopy, two patients still had persistent *H. pylori* infection confirmed by a rapid urease test. Six other patients became positive for *H. pylori* infection in the second rapid urease test. All these patients, including those with a persistent positive rapid urease result, received standard triple therapy for eradication. Clarithromycin was replaced with metronidazole for the second round of triple therapy in the two patients with persistent infection. During the second surveillance endoscopy, 17/26 patients were persistently positive for GIM, 5/26 had disappearance of GIM, and 4/26 were persistently negative for GIM. No new GIM was detected in those who were previously negative for GIM. No gastric cancer was found in this second study. The sensitivity, specificity, PPV, NPV, and LR+ from the second endoscopy were 91.3%, 89.1%, 77.8%, 96.1%, and 8.4, respectively (Table 3).

DISCUSSION

Sequential NBI has been well recognized as an excellent tool to detect abnormal mucosal GI lesions in certain Asian countries such as Japan, Korea, and Hong Kong, and in some US/Europe research centers^[16-18]. However, most GI endoscopists worldwide have no access to this system and instead, they are more familiar with the non-sequential system. Many endoscopists are impressed with the difference in the contrast and the brightness of the non-sequential image compared with those images published in the literature using sequential NBI^[13,19].

Table 3 Validity scores with confidence intervals of the second endoscopic targeting biopsy for gastric intestinal metaplasia, mean (range)

| Criteria | Sensitivity (%) | Specificity (%) | PPV (%) | NPV (%) | LR + (%) |
|----------|---------------------|---------------------|---------------------|---------------------|---------------------|
| LBC | 82.61 (68.05-91.68) | 92.73 (85.74-96.58) | 82.61 (68.05-91.68) | 92.73 (85.74-96.58) | 11.36 (5.75-22.42) |
| VP | 21.74 (11.45-36.76) | 98.15 (92.81-99.67) | 83.33 (50.88-97.06) | 74.65 (66.53-81.40) | 11.74 (2.67-51.48) |
| LLC | 43.48 (29.25-58.79) | 99.07 (94.20-99.95) | 95.24 (74.13-99.75) | 80.45 (72.49-86.61) | 46.95 (6.49-339.58) |
| ALL | 91.30 (78.31-97.17) | 89.09 (81.36-93.98) | 77.78 (64.05-87.52) | 96.07 (89.69-98.73) | 8.37 (4.87-14.38) |

PPV: Positive predictive value; NPV: Negative predictive value; LR +: Likelihood ratio of positive test; LBC: Light blue crest; VP: Villous pattern; LLC: Large long crest.

Studies of the feasibility of NBI to detect a minute abnormality in the GI tract mucosa have been widely published^[10-12,16-18]. Certain patterns of abnormal gastric mucosa have been described^[16-18]. LBC is an important endoscopic marker for GIM described by distinctive sharp blue and white on the gastric epithelial crest. This lesion can be best assessed by at least 80 × magnification with NBI. When sequential NBI was applied in 107 consecutive GIM patients, Uedo *et al*^[11] reported that LBC criteria had a sensitivity of 89% [95% confidence interval (CI): 83-96], a specificity of 93% (95% CI: 88-97), a PPV of 91% (95% CI: 85-96), a NPV of 92% (95% CI: 87-97), and an accuracy of 91% (95%CI: 88-95).

VP and LLC represent the thickness of the abnormal GIM epithelium on top of the regular gastric surface. In one non-magnifying sequential NBI study, Bansal *et al*^[12] reported that the sensitivity, specificity, and PPV of the VP and LLC criteria (the original series naming villous and ridge patterns) to diagnose GIM were 80%, 100%, and 100%, respectively.

We found that LBC was the most sensitive recognized endoscopic pattern (71.2% and 82.6% during the first and second endoscopic surveillances, respectively). It seems that our LBC sensitivity was lower than the results reported by Uedo *et al*^[11]. We speculate that different types of NBI may have had a bearing on the difference in the results. In addition, from our observation that the background gastric mucosa in Thais with GIM contained some gastric inflammation, determining LBC from an unclear gastric mucosal background can be quite difficult. Despite magnifying the images, we found less impressive results using VP and LLC criteria when compared with the original series results (46.2% during the first endoscopy and 65.2% during the second endoscopy). When we combined all three criteria together (LBC, VP and LLC), the overall sensitivities went up to 78.8% and 91.3% during the first and second surveillances respectively. In addition, our VP and LLC criteria provided comparable results on the specificity (82.7%-99.1%), PPV (71.4%-88.2%), NPV (69.7%-96.1%), and LR+ (69.2%-89.7%) with those of LBC.

When compared with the first surveillance results, the second surveillance in our study provided higher levels of all validity scores (sensitivity, specificity, PPV, NPV, and LR+). However, these did not reach statistical difference.

During the present study, we were able to detect two

early gastric cancers. Both were detected during the first surveillance and underwent successful resection. After resection both patients have been doing well.

Although a gastric cancer screening and surveillance program is only available in certain countries such as Japan and Korea, many countries have seen an increase in the prevalence of this cancer^[20]. In Thailand, gastric cancer screening has not yet become a national health policy due to an insufficient number of the endoscopists, and a lower prevalence of gastric cancer in Thailand^[21].

H. pylori infection, smoking, chronic atrophic gastritis, heavy alcohol use, and several dietary factors have been recognized as risk factors for gastric cancer^[22]. The potential factors for gastric cancer in our population are chronic/atrophic gastritis and *H. pylori* infection. The majority of our patients had chronic or atrophic gastritis as their background. *H. pylori* infection rates were found in one third. No other significant risk factors could be determined in our cohorts. None of our patients were smokers and none had a family history of gastric cancer. They were in middle age and the youngest patient was only 32 years old. Despite few risk factors being identified, we were able to detect two early gastric cancers from these cohorts.

To put this into a more practical surveillance protocol, we may have to look for patients with atrophic gastritis by standard white light endoscopy first and later do a targeted GIM biopsy by NBI. However, cost effectiveness may be an issue for a country with low gastric cancer prevalence, such as Thailand.

GIM can either progress or regress depending on its nature and environmental stimuli^[23]. *H. pylori* eradication may help the regression of GIM. All patients infected with *H. pylori* (12/38; 31.6%) received an eradication regimen after the first surveillance. During the second surveillance, we found disappearance of GIM in only 5/26 patients (19.2%). Interestingly, those were patients with positive for *H. pylori* infection from the first study and GIM disappeared after *H. pylori* eradication (data not shown).

Furthermore, we identified two patients who had persistent infection with *H. pylori* during the follow-up endoscopy. These two received different triple therapy. In addition, six more patients had newly discovered *H. pylori* infections during the second endoscopy. All were patients persistently positive for GIM. The explanation for the finding of new infection was uncertain, but we speculate that these were false negative cases in the first urease tests.

It had been our routine to discontinue proton pump inhibitor, H2 blocker, and antibiotics at least 2 wk prior to the test for *H. pylori*. Thus prior medication use was not a cause for our false negative. Gastric mucosa has dynamic regeneration. This regenerated mucosa may be a factor in the re-growth of the occult *H. pylori* infection.

The limitations of the present study are mainly the small number of patients and the short 1-year duration of follow-up. Some patients dropped out from the second surveillance endoscopy for a variety of reasons. Despite these limitations, we were able to identify two early gastric cancers (5.3%) from this high risk cohort, and this was the first time in Thailand that we were able to select a group that may gain benefit from this intensive endoscopic surveillance.

In conclusion, non-sequential NBI is an interesting technique that can facilitate GIM detection by targeted biopsy. It helps the detection of early gastric cancer in patients with atrophic gastritis and GIM. However, the precise protocol regarding the frequency and duration of follow-up, and how to identify this target group still requires further study.

COMMENTS

Background

Gastric intestinal metaplasia (GIM) is considered as a precancerous lesion. The benefit of annual endoscopic surveillance in patients with GIM has been shown to improve survival by enhancing the detection of gastric cancer at the early stage. However, conventional white light endoscopy has a limitation in its sensitivity. In addition, this technique is quite cumbersome because it is time consuming and may miss small lesions.

Research frontiers

Previously, chromoendoscopy has been proven to provide a good validity score for GIM targeted biopsy. Without a need of dye spray and only switching on a button, magnifying NBI has become a good alternative for the detection of GI precancerous lesions including colonic polyps, Barrett esophagus, and GIM. However, these pioneer results were based on the sequential NBI system and there may be slight differences in color spectrum between sequential and non-sequential NBI.

Innovations and breakthroughs

The present study supports the majority of practices that use the non-sequential system. It showed a higher accuracy for targeted biopsy in GIM suspicious lesions over previously reports with conventional white light endoscopy.

Applications

Instead of using a dye spray, the non-sequential NBI system can be more practical in routine practice. With comparable accuracy to the sequential system, it provides high diagnostic yields for GIM detection.

Terminology

Light blue crest (LBC) is defined as a fine, blue-white line on the crests of the epithelial surface, which looks like light reflection from a mirror. Villous pattern (VP) is defined as a raised area of villi above the gastric mucosal surface. Large long crest (LLC) is defined as a combination of linear dark and light areas that are different from normal gastric epithelium.

Peer review

The present study described the usefulness of non-sequential NBI, that is much more available worldwide, for targeted biopsy of GIM and surveillance for early gastric cancer. This system showed high sensitivity, specificity, positive predictive value, negative predictive value, and likelihood ratio of positive test for GIM prediction. Among the three criteria proposed by the authors, LBC seems to provide the best diagnostic value. Although the number of patients was limited, these patients with GIM provided a good set for this observation.

Abstract

AIM: To search for the optimal surgery for gastrinoma and duodenopancreatic neuroendocrine tumors in patients with multiple endocrine neoplasia type 1.

METHODS: Sixteen patients with genetically confirmed multiple endocrine neoplasia type 1 (MEN 1) and Zollinger-Ellison syndrome (ZES) underwent resection of both gastrinomas and duodenopancreatic neuroendocrine tumors (NETs) between 1991 and 2009. For localization of gastrinoma, selective arterial secretagogue injection test (SASI test) with secretin

or calcium solution was performed as well as somatostatin receptor scintigraphy (SRS) and other imaging methods such as computed tomography (CT) or magnetic resonance imaging (MRI). The modus of surgery for gastrinoma has been changed over time, searching for the optimal surgery: pancreaticoduodenectomy (PD) was first performed guided by localization with the SASI test, then local resection of duodenal gastrinomas with dissection of regional lymph nodes (LR), and recently pancreas-preserving total duodenectomy (PPTD) has been performed for multiple duodenal gastrinomas.

RESULTS: Among various types of preoperative localizing methods for gastrinoma, the SASI test was the most useful method. Imaging methods such as SRS or CT made it essentially impossible to differentiate functioning gastrinoma among various kinds of NETs. However, recent imaging methods including SRS or CT were useful for detecting both distant metastases and ectopic NETs; therefore they are indispensable for staging of NETs. Biochemical cure of gastrinoma was achieved in 14 of 16 patients (87.5%); that is, 100% in 3 patients who underwent PD, 100% in 6 patients who underwent LR (although in 2 patients (33.3%) second LR was performed for recurrence of duodenal gastrinoma), and 71.4% in 7 patients who underwent PPTD. Pancreatic NETs more than 1 cm in diameter were resected either by distal pancreatectomy or enucleations, and no hepatic metastases have developed postoperatively. Pathological study of the resected specimens revealed co-existence of pancreatic gastrinoma with duodenal gastrinoma in 2 of 16 patients (13%), and G cell hyperplasia and/or microgastrinoma in the duodenal Brunner's gland was revealed in all of 7 duodenal specimens after PPTD.

CONCLUSION: Aggressive resection surgery based on accurate localization with the SASI test was useful for biochemical cure of gastrinoma in patients with MEN 1.

INTRODUCTION

Controversy has surrounded the treatment strategy for gastrinoma and neuroendocrine tumors (NETs) in patients with multiple endocrine neoplasia type 1 (MEN 1) and Zollinger-Ellison syndrome (ZES)^[1-14]. It has been confirmed that ZES in patients with MEN 1 is caused mostly by duodenal gastrinomas^[15,16]. Some surgeons have not recommended surgery for duodenopancreatic gastrinoma, because of both low biochemical cure rate of gastrinoma and early recurrence of gastrinoma after surgery^[8,9]. In contrast, surgeons who have performed aggressive duodenopancreatic resection have reported a higher biochemical cure rate of gastrinoma after surgery, although these studies included relatively small numbers of patients^[4-7,11-14].

We have performed curative resection surgery for gastrinoma in 41 patients with ZES guided by localization using the selective arterial secretagogue injection test (SASI test)^[17,18]. Guided by localization with the SASI test, pancreaticoduodenectomy (PD) was performed for 10 patients, of whom 3 patients were classified as MEN 1, and all of them have been cured of gastrinoma postoperatively. Pathological examination of the duodenopancreatic specimens resected from the MEN 1 patients revealed single or multiple gastrinomas < 10 mm only in the duodenum, but not in the pancreas head. Thus, we have changed the modus of resection surgery for gastrinomas in patients with MEN 1 from PD to transduodenal excisions of the duodenal gastrinomas or partial duodenectomy (LR) with dissection of the regional lymph nodes, while seeking for less invasive and optimal surgical resection for gastrinomas in MEN 1 patients. Recently, we have performed pancreas-preserving total duodenectomy (PPTD) for MEN 1 patients with multiple gastrinomas and/or numerous microgastrinomas in the duodenum^[19,20]. Here, we report the results of our surgical strategy for both gastrinoma and pancreatic NETs in MEN 1 patients, and discuss the optimal surgery for

patients with MEN 1 and gastrinomas from a viewpoint of the staging of both gastrinoma and pancreatic NET in these patients.

MATERIALS AND METHODS

Patients

Sixteen patients with genetically confirmed MEN 1 and gastrinoma underwent resection surgery for gastrinomas and pancreatic NETs by a team comprising a chief surgeon (senior author) and co-surgeons (co-authors) at the Departments of Surgery of Graduate School of Medicine, Kyoto University, Osaka Saiseikai Noe Hospital and Kansai Electric Production Company Hospital between March 1991 and March 2010.

All patients were examined for MEN 1 gene mutations by a co-author (MK) at the Medical Gene Research Center, Kyoto University. A diagnosis of ZES was established by confirming the co-existence of gastric hyperacidity and hypergastrinemia. Levels of gastrin were > 80 pg/mL in patients who had undergone distal or total gastrectomy and > 200 pg/mL in patients who had not undergone distal gastrectomy^[21]. Gastric hyperacidity was confirmed using 24 h pH monitoring, and was diagnosed when the percentage of the time that the gastric pH was 0-4 was > 70%^[21]. Either the secretin test or the calcium test was performed for all patients^[22-24]. The secretin test was performed by bolus intravenous injection of secretin (3 U/kg body weight). Blood samples were collected from a cubital vein before and 2, 4, and 6 min after secretin injection. An increase in serum immunoreactive gastrin concentration (IRG) both of > 20% of the basal serum IRG and > 80 pg/mL, 4 min after secretin injection was considered positive. The calcium test was performed by injecting 1.17 mEq calcium solution (1 mL of 0.39 mEq calcium gluconate hydrate) diluted with 2 mL physiological saline over 30 s into a cubital vein^[22-24]. The intraoperative secretin test was performed using the same method as the preoperative secretin test, and results were obtained within 60 min using rapid radioimmunoassay of serum gastrin levels^[25].

Localization of gastrinoma

For localization of gastrinoma, the SASI test with secretin (Secrepan[®] 30 units) or calcium solution (0.39 mEq calcium gluconate diluted with 2 mL physiological saline) was performed for all patients as described previously^[17,18,26]. The principle of the SASI test is to identify the feeding artery of gastrinoma by stimulating gastrinoma to release gastrin using a secretagogue^[17]. We used secretin until 2004, since then we have used calcium gluconate hydrate solution, because production of secretin in Japan ended in 2004^[10]. CT, MRI or US have been used primarily for detection of distant metastases, such as hepatic metastases or large lymph nodes^[11,10,11].

PPTD

PPTD was performed using a new technique described

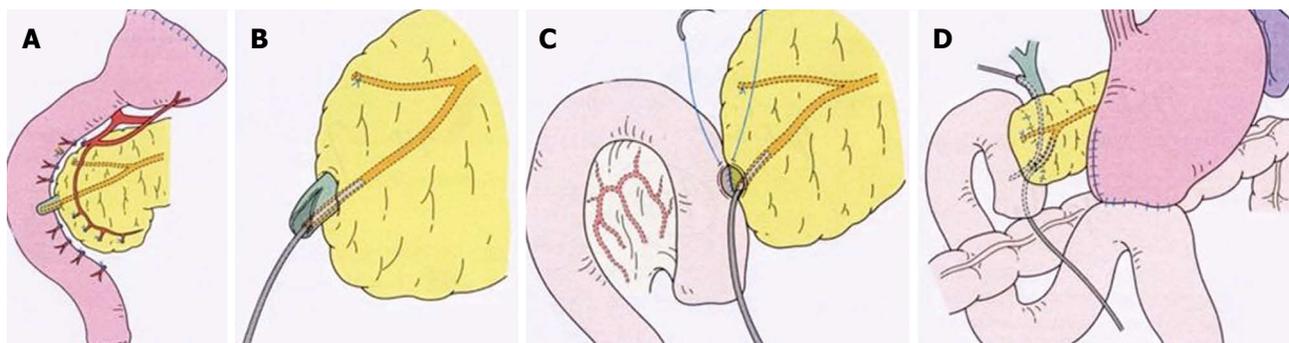

Figure 1 Pancreas-preserving total duodenectomy technique. A: The duodenum is separated from the head of the pancreas by cutting the branches of the pancreaticoduodenal arcade vessels. The choledochal trunk is saved and only the membrane of the major papilla is shaved sharply. The accessory pancreatic duct is ligated and cut; B: Papillotomy is performed on the major papilla at 0, and then a catheter is inserted into the main pancreatic duct for stenting; C: Bilio-jejunal reconstruction. The edge of the common bile duct is sewn to a small opening on the jejunum with 4-0 absorbable knotted sutures; D: The final reconstruction schema of the alimentary tract.

elsewhere^[20]; briefly, when resecting the entire duodenum, only a mucosectomy is performed on the duodenal major papilla portion, retaining the structure of the major papilla, and after an 8 mm long sphincterotomy, the opened papilla is anastomosed to the incisional opening of the jejunum^[20]. Details of the procedure are shown in Figure 1.

Pathological examination of the resected specimens

Resected duodenopancreatic tissues including any suspected NETs or lymph nodes were fixed in a 10% formalin solution and embedded in paraffin. Paraffin-embedded sections were stained with Masson-Fontana, Grimelius, and Hellerstrom-Hellman silver stains. Immunohistochemical staining was performed with Simple Stain MAX-PI (Multi) (mouse and rabbit/horseradish peroxidase) reagent (Nichirei, Tokyo, Japan) using polyclonal rabbit anti-human gastrin serum (Dako, Glostrup, Denmark).

Criteria of biochemical cure of gastrinoma

Cure of gastrinoma was defined as a normal fasting serum IRG < 150 pg/mL in patients without a history of gastrectomy and < 80 pg/mL in patients with a history of gastrectomy, and/or a negative secretin test or a negative calcium test during the 6 mo follow-up surveillance period. Survival curve analysis was performed using the Kaplan-Meier method.

RESULTS

PD

Between 1991 and 1997, PD was performed for 3 patients with ZES based on localization guided only by the SASI test, because imaging methods (CT, MRI, US) did not visualize any tumor in the abdomen (Table 1). In 3 patients, the SASI test localized the gastrinoma in the upper part of the duodenum and/or the head of the pancreas, thus PD was performed for all patients. Preoperative localization by the SASI test was correct, and gastrinomas were proved in the duodenum; that is, 7 duodenal gastrinomas in 1 patient (No. 2) and only 1 duodenal gastrinoma in 2 patients

(Nos. 1 and 3). Metastatic lymph nodes associated with the duodenal gastrinoma were identified in 2 patients. Two patients (Nos. 1 and 2) had multiple nonfunctioning NETs in the head of the pancreas (Table 1). The preoperative serum IRG of these patients ranged between 310 and 800 pg/mL, and the postoperative serum IRG decreased in all patients to < 33 pg/mL. The postoperative secretin test was negative in all patients. One patient died of other causes 4 year after undergoing the PD. Two patients are alive and well, and biochemical cure of gastrinoma has continued for 18 year 5 mo and 12 year, postoperatively.

LR

Since 1996, 5 patients have successively undergone local resection of duodenal gastrinoma through duodenectomy after a 7 year intermission. 1 patient (No. 9) underwent DX in 2009 based on localization by the SASI test, duodenoscopy revealed duodenal submucosal NETs in 3 patients, and CT visualized a few metastatic lymph nodes more than 2 cm with a pancreatic NET more than 1 cm in 2 patients (Table 2). Localization by the SASI test was correct in all of them. In case No. 9, gastrinoma was located not only in the duodenum, but also in the head of the pancreas. Size of duodenal gastrinoma was between 1-15 mm in diameter. Any pancreatic NETs > 1 cm were treated by enucleation and/or distal pancreatectomy. In 3 patients, metastatic lymph nodes were associated with duodenal gastrinoma.

Most of these patients were biochemically cured of gastrinoma after the first LR, but ZES recurred in 2 patients (Nos. 5 and 6). In patient No. 5, the serum IRG increased from 140 to 170 pg/mL 8 year postoperatively, and in patient No. 6, the serum IRG increased from 68 to 400 pg/mL 6 year postoperatively. Based on localization by the SASI test, a second LR was performed for these patients, and their serum IRG levels decreased to within normal ranges postoperatively. They have been biochemically cured of gastrinoma since the second LR for 5 year, 8 mo and 2 year, 7 mo, respectively, postoperatively.

Patient No. 9 had undergone a distal pancreatectomy

for multiple insulinoma 31 year before visiting our clinic. She also had a history of a total parathyroidectomy with a forearm subcutaneous parathyroid transplantation and gamma knife therapy for a pituitary NET. Her serum IRG was 49 500 pg/mL. Multiple submucosal gastric NETs and multiple duodenal submucosal NETs were identified by gastroduodenoscopic examination. A few large metastatic lymph nodes around the head of the pancreas were visualized using CT; therefore, advanced stage of gastrinoma was suspected. The SASI test localized the gastrinoma in the duodenum and/or the head of the pancreas. We performed LR and an enucleation NET in the head of the pancreas with dissection of the peripancreatic lymph nodes. A partial resection of the middle part of the stomach for multiple gastric tumors was also performed. Her serum IRG decreased to < 150 pg/mL and plasma chromogranin A concentration was normalized. Pathological examination revealed 3 duodenal gastrinomas and 1 pancreatic gastrinoma with 3 metastatic lymph nodes from duodenopancreatic gastrinoma. The gastric NET was a type II NET.

PPTD

PPTD was first performed for case No. 10, in whom a substantial numbers of NETs were palpated intraoperatively and a few large metastatic lymph nodes were detected, without any pancreatic head tumors. Pathological study revealed numerous submucosal microgastrinomas throughout the duodenum. Her serum IRG did not decrease to within normal range and she developed hepatic metastases 3 year after the PPTD. In order to save the head of the pancreas, PPTD was performed for the following 6 patients in whom the SASI test diagnosed gastrinoma in the pancreatic head and/or the duodenum and considerable numbers of duodenal NETs were suspected during surgery (Table 3). In one patient (case 16) the SASI test localized gastrinoma not only in the head of the pancreas and/or the duodenum, but also in the tail of the pancreas, so PPTD and a distal pancreatectomy were performed curatively, and the patient has since been free of gastrinoma. Any serious postoperative morbidity was experienced in this series of patients.

Hyperplasia of G cells or microgastrinomas in the duodenal Brunner's gland

In 7 PPTD patients, duodenal gastrinomas were numerous in only 2 patients, and there were 4 or more in 2 additional patients. In 3 other patients, only 1 tumor was diagnosed as gastrinoma, and the other submucosal tumors were mostly diagnosed as hyperplasia of the duodenal Brunner's gland. Not expecting these results, we carefully re-examined the duodenal mucosal membrane with anti-gastrin antibody and identified clusters of gastrin-producing cells in or adjacent to the Brunner's gland, some of which were diagnosed as microgastrinoma. The clusters of gastrin-producing cells were found in all 7 duodenal specimens after PPTD (Figure 2).

Five patients post-PPTD have been cured of gastrinoma for lengths of time ranging from 2 year to 6 year 8 mo. However, in 2 patients in whom their preoperative serum IRG levels were as high as 18 200 pg/mL or

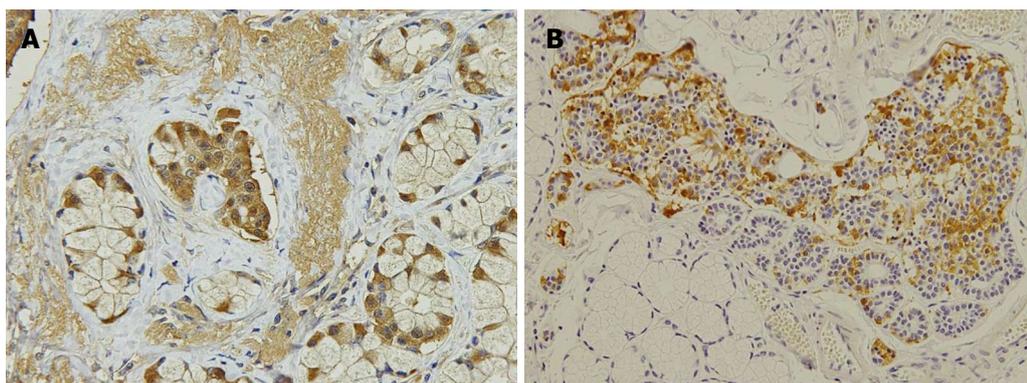

Figure 2 Hyperplasia (A) and a cluster of gastrin-producing cells (B) in the duodenal Brunner's glands (in patient No. 12, who underwent pancreas-preserving total duodenectomy for numerous duodenal microgastrinomas) were detected by immunohistochemical gastrin staining.

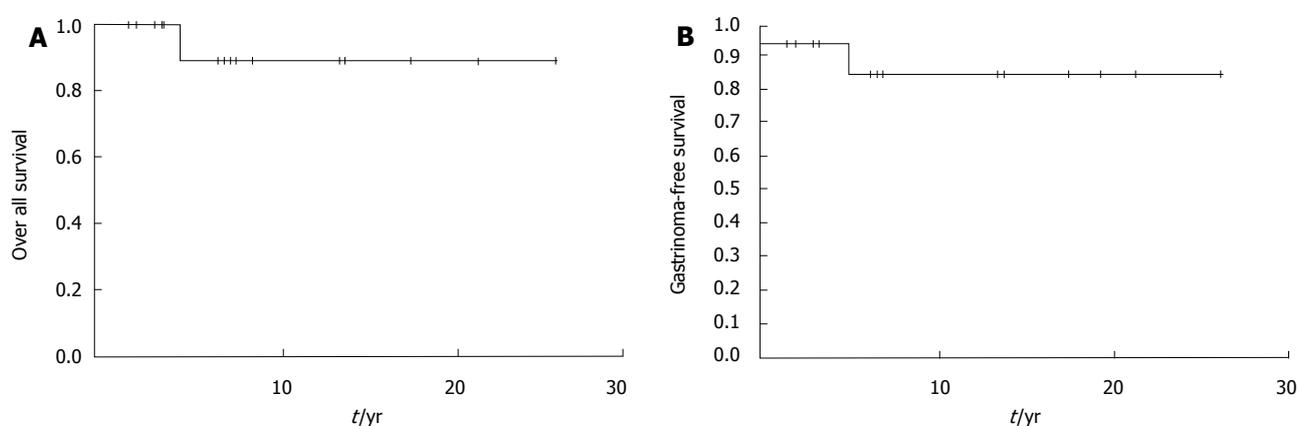

Figure 3 Survival curve of 16 patients with multiple endocrine neoplasia type 1 and neuroendocrine tumors. A: Overall survival after initial resection surgery. The survival rate at 10 years was 90.9%; B: Gastrinoma-free survival after initial resection surgery. The survival rate at 10 years was 82.0%.

13 900 pg/mL after parathyroidectomy, and advanced stages of gastrinoma were suspected, PPTD was non-curative (Table 3). In one of them, hepatic metastases have become apparent on CT film within 3 year postoperatively, and in the other patient, distant lymph nodes metastases have developed.

Results of surgery and survival curves

Of the 16 patients in this series, 7 patients had single duodenal gastrinoma and 9 patients had multiple gastrinomas. More specifically, 2, 4, 5, 6, and 9 duodenal gastrinomas were detected in 1 patient each; 7 duodenal gastrinomas in 2 patients; and numerous duodenal gastrinomas in 2 patients. In 2 patients (13%), pancreatic gastrinoma co-existed with duodenal gastrinoma which were localized by the SASI test.

To date, 14 patients have been cured of gastrinoma and 2 patients have been noncurative, postoperatively. The overall patient survival curve is shown in Figure 3A, with a survival rate of 90.9% at 10 years. The gastrinoma-free survival curve is shown in Figure 3B, with a survival rate of 82.0% at 10 years.

DISCUSSION

Controversy has surrounded the treatment strategy for

gastrinoma and pancreatic NET in patients with MEN 1 and ZES^[1-14]. It is difficult to determine whether aggressive surgical resection of both gastrinoma and pancreatic NETs improves survival rates and the long term biochemical cure of gastrinoma in MEN 1 patients, because of the rarity of the disease^[1-4,10-14]. Many recently published articles support aggressive surgery, such as PD or multiple LR of a few duodenal gastrinomas and distal pancreatectomy for pancreatic NETs, for both biochemical cure of gastrinoma and prolongation of survival^[1,4,10-14]. On the other hand, Gibril *et al*^[27] reported the results of an important prospective study on the natural history of gastrinoma in patients with MEN 1, in which 57 patients with MEN 1 and ZES were followed for 8 year without performing surgical resection for duodenopancreatic NETs until the tumors grew to > 2.5 cm. In this study, 13 patients (23%) developed hepatic metastases and 3 patients died of duodenopancreatic NETs. They suggested that biochemical cure of gastrinoma might be impossible in patients with MEN 1 and that prolongation of survival of MEN 1 patients with an aggressive type of NETs would not be realized until the development of a tool to differentiate an aggressive type of NET from another slow growing type of NET. Their results themselves, we think, support the idea that early resection should be necessary for decreasing the rate of hepatic metastases from duodenopancreatic NETs

in MEN 1 patients.

The present study shows that aggressive surgical resection for gastrinoma in MEN 1 patients using PD or aggressive LR, or PPTD guided by localization with the SASI test, was useful for long term biochemical cure of duodenopancreatic gastrinoma, and that aggressive resection of pancreatic NETs was also useful for prevention of hepatic metastases. So, we would like to recommend early aggressive surgical resection of duodenopancreatic NETs for MEN 1 patients.

Goudet *et al.*^[28] performed a cohort study of 758 patients with MEN 1 and found that gastrinoma was a statistically significant high-risk factor for death of patients with MEN 1 secondary to the nonfunctioning pancreatic NETs, and suggested earlier resection surgery for both gastrinoma and nonfunctioning pancreatic NETs in patients with MEN 1. Gauger and Thompson reported a 94% 15 year survival rate of patients with functioning NETs (gastrinoma or insulinoma) in MEN 1 patients after local resections of duodenal gastrinomas and a distal pancreatectomy with enucleations of NETs in the head of the pancreas without any operative morbidity^[2]. These results suggest that early resection of gastrinoma in MEN 1 patients is useful for normalization of serum gastrin levels and prevention of distant metastases.

Identification of gastrinoma among multiple NETs in the duodenopancreatic region of patients with MEN 1 is essentially impossible by imaging techniques alone^[17,18]. The SASI test localizes gastrinomas or metastatic lymph nodes by judging whether or not gastrin is secreted from NETs in the area of interest by stimulation with a secretagogue, so it can differentiate functioning gastrinoma among multiple NETs in MEN 1 patients.

On the other hand, SRS and other imaging methods [CT or MRI or ultrasonography (US)] are useful for identification of hepatic metastases, although it is difficult to tell the absence of gastrinoma in the area of interest. We have used secretin for stimulating gastrinoma to release gastrin during the SASI test for a long time, but now we use calcium gluconate hydrate solution (Calciol[®]), because secretin has not been produced in Japan since 2004. We compared the results with both secretagogues and found the results were identical^[21].

In 1991, imaging methods were not sensitive for visualizing < 1 cm gastrinoma; thus we performed resection surgery of both gastrinoma and microgastrinoma based on localization with the SASI test. When the SASI test localized gastrinomas in the feeding area of the gastroduodenal artery, we performed PD. In the first 3 patients with MEN 1, the SASI test localized < 1 cm gastrinomas in the head of the pancreas and/or the duodenum, so we performed PD for them and all of them were cured of gastrinoma; 2 patients have been alive and healthy for more than 12 year, although a patient died of other causes 4 year postoperatively (Table 1). In the resected specimens of the first 3 patients, < 1 cm gastrinomas were located only in the duodenum and not in the pancreas. In those days, endocrine surgeons working in the USA or EU gradually found that the gastrinomas in patients with MEN 1

were localized mostly in the duodenum and rarely in the pancreas^[15,16]. Thompson *et al* have started to perform LR for duodenal gastrinoma and distal pancreatectomy with enucleation of NET in the head of the pancreas in MEN 1 patients^[1]. According to our results and theirs, we also started to perform local excisions of duodenal gastrinomas and enucleation or a distal pancreatectomy for pancreatic NETs, which are less invasive compared to PD. Since then, 6 patients have undergone LR for duodenal gastrinomas, which has been successful in all patients, although in 2 patients duodenal gastrinoma recurred and second LR was performed 8 year 8 mo and 6 year after the first LR.

We performed PPTD for 7 patients in whom duodenal gastrinomas were thought to number more than 5 during surgery. The duodenal gastrinomas were numerous in only 2 of 7 patients and the duodenal tumors in the other 5 patients were mostly diagnosed as hyperplasia of the duodenal Brunner's glands postoperatively (Table 3). Not expecting these results, we immunohistochemically stained the duodenal wall with anti-gastrin antibody and found a cluster of gastrin-producing cells or microgastrinomas in or adjacent to the Brunner's gland. The clusters of gastrin-producing cells in the Brunner's gland were found in all of the duodenal specimens after PPTD.

Klöppel *et al.*^[29] have reported that in patients with MEN 1, mutations in the *menin* gene can cause hyperplasia of gastrin-producing cells in the duodenal Brunner's glands, which are the precursor lesion of gastrinoma. Our results are consistent with their report. Thus, in the duodenum of MEN 1 patients with substantial numbers of duodenal gastrinomas and/or microgastrinomas, de novo gastrinoma might develop during the patient's lifetime.

Of the 16 patients in the present study, 7 patients (43.8%) had 1 duodenal gastrinoma and 9 patients (56.2%) had multiple duodenal gastrinomas. Gastrinoma did not recur in patients belonging to the former group, but recurred in 2 patients (22.2%) belonging to the latter group who had 3 and 5 duodenal gastrinomas, respectively. PPTD may be useful for preventing both residual microgastrinoma and recurrence due to development of de novo duodenal gastrinoma in MEN 1 patients with substantial numbers of gastrinomas and microgastrinomas.

In 7 patients who underwent PPTD, no postoperative complications, such as pancreatic leakage, acute pancreatitis, abscess or surgical site infections, have been experienced. Thus, PPTD is less invasive surgery compared to PD. On the other hand, dissection of the regional lymph nodes may be incomplete by PPTD compared to PD. As duodenal gastrinoma metastasizes to the regional lymph nodes independent of size, any regional lymph nodes around both the pancreas head and the common hepatic artery have to be dissected. Lymph nodes along the superior mesenteric artery have to be resected when they are palpated hard^[20].

When considering the optimal surgery for patients with MEN 1 and gastrinoma, we must first seriously consider the risk of hepatic metastases from pancreatic NETs^[1,7-9,14,28,30]. Hepatic metastases from pancreatic

NETs are more serious than those from duodenal gastrinoma, and the rate of hepatic metastases from pancreatic NETs is at least several times more frequent than those from duodenal NETs^[6,7,16,28,30]. Thus, we recommend distal pancreatectomy for pancreatic NETs with enucleations of NETs in the pancreatic head more than 1 cm, as recommended by Thompson^[1].

As for optimal surgical resection for sporadic duodenal NET, recently several articles have dealt with the subject relating to the staging of duodenal nonfunctioning NETs. Evans's group have performed a retrospective analysis of patients with duodenal NETs operated at their institute and they proposed a standard strategy for duodenal NETs using a staging based on the depth of tumor invasion and the grading of the development of the distant metastases^[31]. Sarr's group also published a similar study^[32]. Both groups recommended endoscopic excisions for duodenal NET smaller than 1 cm, and open transduodenal resection with dissection of the regional lymph nodes for duodenal NET between 1 cm and 2 cm, because rate of lymph node metastases cannot be ignored in duodenal NET between 1 and 2 cm in diameter. Both groups recommended PD for duodenal NET more than 2 cm with lymph node metastases^[31,32]. However, both groups intentionally excluded duodenal gastrinoma from their retrospective analytical studies, because the natural history of duodenal gastrinoma seemed quite different from other duodenal NETs, which suggested a more aggressive progression of duodenal gastrinoma^[31,32].

In our study, 7 of 16 patients had only 1 duodenal gastrinoma, but 3 of the 7 patients had metastatic lymph nodes, and 1 of them (No. 14) had distant metastases resulting in noncurative resection of gastrinoma (Table 3). So, instead of endoscopic excision, local resection with dissection of lymph nodes may be recommended for a few < 1 cm duodenal gastrinomas in MEN 1 patients^[1,2]. For substantial numbers of < 1 cm duodenal gastrinomas with multiple pancreatic NETs in MEN 1 patients, we would like to recommend PPTD with distal pancreatectomy and enucleation of > 1 cm NETs in the head of the pancreas, because cure of duodenal gastrinoma is not likely to be achieved for a long time due to both possible residual microgastrinoma and development of de novo gastrinomas in the duodenum^[20,29]. PD might be indicated for MEN 1 patients with a substantial number of both duodenal gastrinomas and metastatic regional lymph nodes with a few > 1 cm pancreatic NETs. Of course, curative resection has to be indicated before development of hepatic micrometastases.

In this series, only one patient has died of other diseases and the other patients have been alive and well to date. Overall survival curve of the patients is shown in Figure 3A. Evaluating together with the gastrinoma-free survival curve of these patients (Figure 3B), we would like to conclude that resection surgery was useful for cure of gastrinoma and prolongation of survival of the patients with MEN 1 and gastrinoma.

Given that pancreatic gastrinoma co-existed with duo-

denal gastrinoma in 12.5% of our patients, caution is advised, because many surgeons and pathologists have believed that pancreatic gastrinoma is rare in MEN 1 patients^[33]. To date, total pancreatectomy has rarely been performed for MEN 1 patients, but we think that total pancreatectomy may be indicated for a few MEN 1 patients according to decisions based on the clinicopathological genetic analysis of pancreatic NET in such patients^[34].

In conclusion, aggressive resection surgery based on accurate localization was useful for biochemical cure of gastrinoma in patients with MEN 1 and gastrinoma. Given that pancreatic gastrinoma co-existed with duodenal gastrinomas in 2 of 16 patients (13%), we would like to recommend the SASI test for preoperative localization of gastrinoma in MEN 1 patients.

ACKNOWLEDGMENTS

The authors thank Dr. Tomika Harada for his statistical analyses in this study and Drs. Masahiko Tsuboi, Kentaro Isoda, Takahiro Nishio, Wataru Hirata, Mikiko Ueda, Yukito Adachi, Kiyoshi Hirai, Yoshiyuki Miura, Hidekazu Esaki, Yohei Hosoda and Yoshiro Taki for their assistance during surgery. These individuals are with the Departments of Surgery of Saiseikai Noe Hospital and Kansai Electric Power Company Hospital.

COMMENTS

Background

Treatment strategy for gastrinoma and pancreatic neuroendocrine tumors (NETs) in patients with multiple endocrine neoplasia type 1 (MEN 1) has been controversial. Most doctors have thought that gastrinomas in MEN 1 cannot be cured because curative resection is rare and recurrence rate is high, and pancreatectomy for pancreatic NETs in MEN 1 does not make sense, since NETs and micro-NETs exist diffusely in the pancreas. On the other hand, recent reports by a few aggressive surgeons show that a high cure rate of gastrinomas and long term prolongation of survival have been achieved by aggressive surgery. For achieving curative resection of gastrinomas in MEN 1, correct localization of gastrinomas is essential for guiding curative surgery, and in order to prolong the life of patients with MEN 1 and duodenopancreatic NETs, surgical resection of these NETs before development of hepatic metastases is essential, because hepatic metastases is the most significant prognostic factor.

Research frontiers

The authors should select an optimal modus of surgery for curing gastrinoma and pancreatic NETs in MEN 1 patients, otherwise surgery may end non-curatively or may become too invasive to ensure quality of life for patients. For the best balance between curability of surgery and postoperative good quality of life, the best modus of surgery should be applied for patients with MEN 1 and gastrinoma by estimating the stage of duodenopancreatic NETs.

Innovations and breakthroughs

The present study shows that cure of gastrinomas in MEN 1 patients can be obtained when you resect gastrinomas guided by localization with the SASI test, and prevention of hepatic metastases can be obtained by resection of > 1 cm pancreatic NETs by pancreatectomy of enucleations. As for the modus of surgery, we are the first to propose pancreas-preserving total duodenectomy (PPTD) for multiple or numerous duodenal gastrinomas in MEN 1 as the optimal extent of aggressive surgery. The authors have also proved that pancreatic gastrinoma co-exists with duodenal gastrinoma in 13% of patients with MEN 1, although recently most surgeons and some pathologists have reported that gastrinomas exist only in the duodenum in MEN 1 patients.

Applications

By understanding the fact that curative surgical resection is possible by correct localization, and by further development of clinicopathological genetic analysis

of the disease, the optimal surgical strategy corresponding to the stage of the disease will be established for gastrinomas and duodenopancreatic NETs in MEN 1 patients in the near future.

Terminology

PPTD is the modus of surgery by which total duodenum is resected without resecting pancreas tissue. Traditionally, for resecting malignant tumors in the duodenum, pancreatoduodenectomy has been used by which one third of the pancreas is resected with the duodenum.

Peer review

The study evaluates the standard surgery for patients with gastrinoma in MEN 1 guided by accurate preoperative localization.

Hemi-hepatectomy in pediatric patients using two-surgeon technique and a liver hanging maneuver. *World J Gastroenterol* 2011; 17(10): 1354-1357 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i10/1354.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i10.1354>

Abstract

AIM: To evaluate the efficacy of the two-surgeon technique with the liver hanging maneuver (LHM) for hepatectomies in pediatric patients with hepatoblastoma.

METHODS: Three pediatric patients with hepatoblastoma were enrolled in this study. Two underwent right hemi-hepatectomies and one underwent a left hemi-hepatectomy using the two-surgeon technique by means of saline-linked electric cauterization (SLC) and the Cavitron Ultrasonic Surgical Aspirator (CUSA; Valleylab, Boulder, CO) and the LHM.

RESULTS: The mean operative time during the parenchymal transections was 50 min and the mean blood loss was 235 g. There was no bile leakage from the cut surface after surgery. No macroscopic or microscopic-positive margins were observed in the hepatic transections.

CONCLUSION: The two-surgeon technique using SLC and CUSA with the LHM is applicable to even pediatric patients with hepatoblastoma.

INTRODUCTION

The safety and efficacy of saline-linked electric cauterization (SLC) in hepatectomies has been described^[1,2]. A two-surgeon technique utilizing SLC and the Cavitron Ultrasonic Surgical Aspirator (CUSA) is used in the hepatic resections performed in our department, especially in living donor liver transplantations (LDLT), to reduce intraoperative hemorrhage and to prevent bile leakage from the cut surface^[3].

The liver hanging maneuver (LHM) was reported to be a safe approach for hepatectomies during parenchymal transections in many investigations including ours^[4].

We herein describe the hepatectomy procedure using this two-surgeon technique with the LHM in pediatric patients with hepatoblastoma.

MATERIALS AND METHODS

From January 2007 to December 2009, 3 hepatectomies for hepatoblastoma were performed in pediatric patients. Two underwent right hemi-hepatectomies, while one underwent a left hemi-hepatectomy.

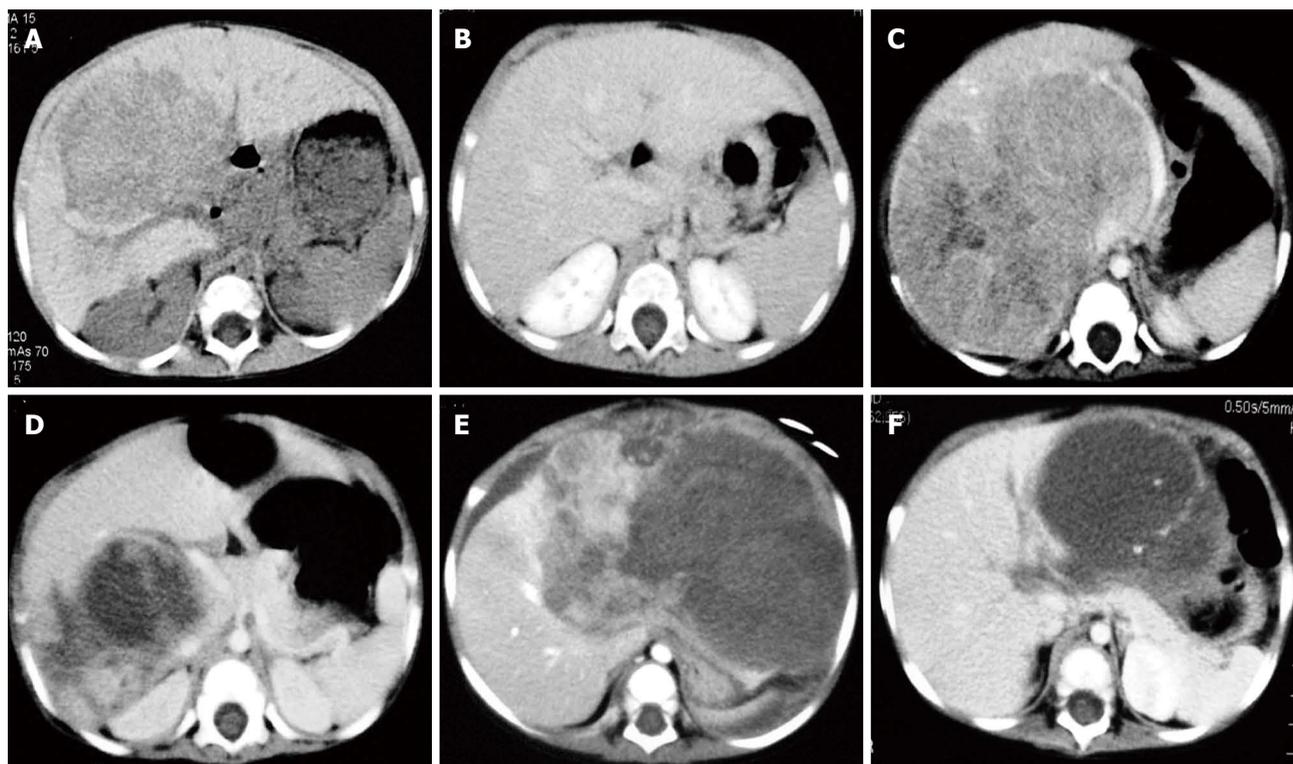

Figure 1 Each tumor location on contrast-enhanced computed tomography. A: Prechemotherapeutic computed tomography (CT) of case 1; B: Preoperative CT of case 1; C: Prechemotherapeutic CT of case 2; D: Preoperative CT of case 2; E: Prechemotherapeutic CT of case 3; F: Preoperative CT of case 3.

Following laparotomy, the upper surface of the liver was exposed up to the anterior surface of the suprahepatic inferior vena cava (IVC). The space between the right and middle hepatic veins was dissected and the tape was pulled upward and to the left to allow the exposure of the anterior surface of the infrahepatic portion of the IVC^[5]. In LHM, the mobilization of liver was not needed in adult patients^[5]. However, for right hemi-hepatectomies, we mobilized the right liver lobe prior to the dissection procedure since blind dissection between the liver and the IVC is challenging with a very narrow space, especially in pediatric cases. For the left hemi-hepatectomies, the middle hepatic vein was carefully encircled. Subsequently, tape was entered between the middle hepatic vein and the left hepatic vein and then placed along Arantius' ligament^[4].

The 3-0 polypropylene stay sutures were placed at the antero-caudal edge of the liver along the plane of intended transection. The chief surgeon dissected the hepatic parenchyma from the patient's right side using the CUSA System, while the assistant surgeon used the SLC device (Dissecting Sealer DS 3.5; TissueLink Medical, Inc, Dover, NH) from the patient's left side. The occlusion of the hepatic arterial and portal inflow was not used in any case. The liver parenchyma was dissected with CUSA, and the intraparenchymal vascular anatomy was defined so that a decision on the hemostatic technique could be made based on the vessel size. The SLC device was used to coagulate and divide the dissected vessels that were 3 mm or smaller in diameter. Vessels larger than 3 mm in diameter were ligated with 3-0 or 4-0 silk ties and were sharply di-

vided. The few larger vessels were ultrasonically dissected and controlled with 4-0 absorbable monofilament transfixing sutures, and were then sharply divided. The traction on the stay sutures was used to separate and to expose the deepening transection plane^[3].

During the parenchymal dissection, the upward traction on the tape (hanging maneuver) allowed the surgeon to follow a direct plane and facilitated the exposure and hemostasis of the deeper parenchymal plane in front of the IVC^[5].

A closed suction drain was inserted at the conclusion of each procedure.

RESULTS

Patient data were shown in Table 1. All patients were 1 year old and male. The mean height was 74 cm, and mean weight was 8.53 kg. Each tumor location was shown in Figure 1.

The results were shown in Table 1. The mean operative time was 292 min (range: 178-368 min). The mean operative time during the parenchymal transections was 50 min (range: 30-84 min). The number of vessel ligations during the parenchymal transections was 23 in the first patient, but only 9 in the 2 subsequent patients. The mean blood loss was 235 g (excluding irrigation saline). In case 2, the blood loss was increased in separation/adhesion between tumor and right adrenal gland. There was no bile leakage from the cut surface after surgery. There were no intraoperative or postoperative complica-

Table 1 Patient data and results

| Case | Age (mo) | Gender | Height (cm) | Weight (kg) | Tumor location | Hepatectomy | Operative time (min) | Blood loss (g) | Parenchymal transection | | Complication | Outcome | Follow up (mo) |
|------|----------|--------|-------------|-------------|----------------|-------------|----------------------|----------------|-------------------------|--------------------|--------------|---------|----------------|
| | | | | | | | | | Operative time (min) | Number of ligation | | | |
| 1 | 18 | M | 75 | 9.2 | Right lobe | Right | 368 | 125 | 84 | 23 | None | CR | 43 |
| 2 | 12 | M | 70 | 8.4 | Right lobe | Right | 178 | 420 | 38 | 9 | None | CR | 34 |
| 3 | 17 | M | 77 | 8 | Left lobe | Left | 330 | 160 | 30 | 9 | None | CR | 29 |

tions and no macroscopic or microscopic-positive margins were seen in any of the patients.

All 3 patients could restart projected postoperative chemotherapy treatments from postoperative day 7, and all had complete remissions and no recurrences during the writing of this manuscript.

DISCUSSION

Reducing blood loss is one of the goals in liver surgery, and several technical inventions have been introduced to achieve it including the Pringle maneuver^[6] and selective vascular occlusion^[7], among other techniques. CUSA has contributed to safe hepatectomies by making it easy to identify the vessels during parenchymal transections^[8]. However, because CUSA has no function in the sealing of tissues, meticulous ligation is required to avoid bleeding or bile leakage from the cut surface of the liver. SLC is another novel device that contributes to the ligation reduction during liver parenchymal transections with its effect on tissue sealing^[1]. To guard against these possible disadvantages, Aloia *et al.*^[2] introduced a two-surgeon technique in hepatectomies for neoplasms in adults with promising results. Palavecino *et al.*^[9] demonstrated the mean intra-operative blood loss was significantly decreased after introduction of the two-surgeon technique compared with other techniques (stapling alone, ultrasonic dissection alone, saline-linked cautery alone, and clamp-crush technique). There were no differences in mean operative time between our data (292 min) and those data reported by Tannuri *et al.*^[10] (290.4 min) using the CUSA or LigaSure electrocautery by the chief surgeon and bipolar electrocautery by the assistant surgeon. There were no differences in mean intraoperative blood loss between our data (235 g) and those reported by Liu *et al.*^[11] (221 cm³) using total hepatic occlusion.

We previously demonstrated that SLC could be safely adapted to living liver donor surgery without injuring either the graft or the remnant liver^[3]. In pediatric patients, SLC is more effective because the vessels are smaller than those in adult patients. On the other hand, the LHM is more difficult because the space between the right and middle hepatic veins is narrower. In our department, a safer and more comfortable technique is performed to encircle the liver using a surgical probe with smaller tape^[4]. In these pediatric patients, the reason why the number of vessel ligations and the operative time in parenchymal transection decreased with the latter two patients without increased blood loss was because we could make progress

developing the technique.

The two-surgeon technique using SLC and CUSA with the LHM is therefore considered to be a feasible and safe surgical modality for hepatectomies in pediatric patients.

COMMENTS

Background

A two-surgeon technique utilizing saline-linked electric cautery (SLC) and the Cavitron Ultrasonic Surgical Aspirator (CUSA), and a liver hanging maneuver (LHM) is reported to be a safe approach for hepatectomies.

Research frontiers

CUSA is an easy way to identify the vessels and SLC contributes to the ligation reduction with its effect on tissue sealing during liver parenchymal transections.

Innovations and breakthroughs

Recent reports have highlighted the safety and efficacy of a two-surgeon technique and a liver hanging maneuver for hepatectomies in adults. This study reports the feasibility and safety of the two-surgeon technique and the LHM for hepatectomies in pediatric patients.

Applications

This study shows that the two-surgeon technique and the LHM could become common therapeutic modalities in the hepatectomies of pediatric patients in the future.

Terminology

The SLC device is used to coagulate and divide the dissected vessels that are 3 mm or smaller in diameter. In the two surgeon technique, the chief surgeon dissects the hepatic parenchyma using the CUSA system, while the assistant surgeon uses the SLC device. In the liver hanging maneuver, the upward traction on the tape allowed the surgeon to follow a direct plane and facilitated the exposure and hemostasis of the deeper parenchymal plane in front of the IVC.

Peer review

The authors described their technique and outcomes of performing hepatectomy using two-surgeon technique and liver hanging maneuver (LHM) in children. Data regarding such technique in children is quite limited in literature.

Abstract

AIM: To study the clinical characteristics, diagnosis and surgical treatment of congenital bronchoesophageal fistulae in adults.

METHODS: Eleven adult cases of congenital bronchoesophageal fistula diagnosed and treated in our hospital between May 1990 and August 2010 were reviewed. Its clinical presentations, diagnostic methods, anatomic type, treatment, and follow-up were recorded.

RESULTS: Of the chief clinical presentations, non-specific cough and sputum were found in 10 (90.9%), recurrent bouts of cough after drinking liquid food in 6 (54.6%), hemoptysis in 6 (54.6%), low fever in 4 (36.4%), and chest pain in 3 (27.3%) of the 11 cases, respectively. The duration of symptoms before diagnosis ranged 5-36.5 years. The diagnosis of congenital bronchoesophageal fistulae was established in 9 patients by barium esophagography, in 1 patient by esophagoscopy and in 1 patient by bronchoscopy, respectively. The congenital bronchoesophageal fistulae communicated with a segmental bronchus, a main bronchus, and an intermediate bronchus in 8, 2 and 1 patients, respectively.

The treatment of congenital bronchoesophageal fistulae involved excision of the fistula in 10 patients or division and suturing in 1 patient. The associated lung lesion was removed in all patients. No long-term sequelae were found during the postoperative follow-up except in 1 patient with bronchial fistula who accepted reoperation before recovery.

CONCLUSION: Congenital bronchoesophageal fistula is rare in adults. Its most useful diagnostic method is esophagography. It must be treated surgically as soon as the diagnosis is established.

INTRODUCTION

Congenital bronchoesophageal fistula is usually associated with esophageal atresia and readily diagnosed in infancy. However, it may persist until adulthood if not associated with esophageal atresia. Its pathogenesis is not absolutely clear. A persistent attachment between tracheobronchial tree and esophagus, produced by abnormal growth of the trachea during its severance from the esophagus, has been accused for it. The chief symptoms are bouts of cough after drinking and recurrent respiratory infections. Eleven cases of congenital bronchoesophageal fistula in adults were diagnosed and oper-

ated in our hospital between May 1990 and August 2010. Its etiology, pathophysiology, clinical presentations, diagnosis, complications, and treatment were discussed for its early diagnosis.

MATERIALS AND METHODS

Eleven adult cases (7 males and 4 females) of congenital bronchoesophageal fistula admitted to our hospital between 1990 and 2010 were reviewed. Their average age was 36 years (range 20-66 years) at diagnosis. Its clinical presentations, diagnostic methods, anatomic type, treatment, and follow-up were recorded.

RESULTS

Clinical presentations

The chief symptoms included nonspecific cough in 10 patients, recurrent bouts of cough after taking liquid food in 6 patients, hemoptysis in 6 patients, and bouts of chest pain in 3 patients, respectively. The duration of symptoms before diagnosis was 5-36.5 years and exceeded 15 years in 9 patients (Table 1).

Of the 11 patients, 3 had a history of heavy smoking, 1 had a history of tuberculosis, and 7 had no history of malignant disease, heavy smoking, tuberculosis, chest trauma, or occupational exposure to toxic agents.

Diagnosis

The diagnosis of congenital bronchoesophageal fistula was established by barium esophagography in 9 patients (Figure 1), by esophagoscopy in 1 patient, and by instillation of methylene blue into the esophagus during bronchoscopy in 1 patient (Table 1). Esophagoscopy showed esophageal orifice of the fistula in 7 out of 10 patients and bronchoscopy showed bronchial orifice of the fistula in 4 out of 9 patients, respectively. Preoperative chest computed tomography (CT) showed the extent of associated lung lesions (Figure 2).

Anatomic types

The exact levels of connection between esophagus and tracheobronchial tree are listed in Table 2. The fistula was communicated with the bronchial tree on the right side in 7 patients and on the left side in 4 patients, with a segmental bronchus in 8 patients and a main or intermediate bronchus in 3 patients. The fistula communicated with the lower third of the esophagus in 9 patients and with the middle third in 2 patients.

Treatment

Thoracotomy was performed from the right side in 7 patients and from the left side in 4 patients. The fistula was completely removed in 10 patients and the tract was simply divided with the end sutured in 1 patient. A pleural flap was inserted between esophagus and bronchial tree in all patients (Table 1). The associated lung lesion was removed due to sequestration, multiple epithelialized

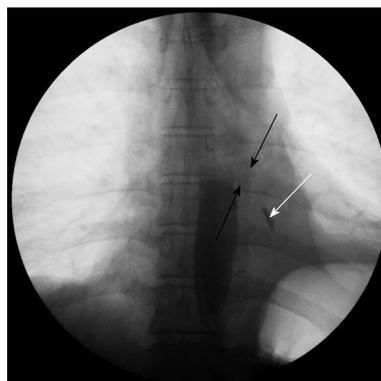

Figure 1 Barium esophagography showing the esophageal orifice of fistula (black arrows) and some barium in the left lower lobe (white arrow) demonstrating the downward direction of the fistula from esophagus to the left lower lobe bronchus.

Figure 2 Preoperative chest computed tomography scan demonstrating abnormal communication between the lower third of esophagus and the left segmental bronchus (arrow) and a mass measuring 3.0 cm in diameter with irregular borders encircling the basal segmental bronchi of the left lower lobe caused by bronchoesophageal fistula.

pulmonary cysts, and bronchiectasis, respectively, in 1, 6, and 4 patients (3 underwent lobectomy and 1 pneumonectomy). Extensive conglutination was found in the thorax of all patients. Large-volume bleeding (200-1000 mL) occurred during the operation, with a blood loss of over 400mL in 8 patients (Table 3).

Outcome

The postoperative course was uneventful in all patients but one who developed a bronchial fistula which was settled with conservative management and reoperation before recovery (Table 3). One patient died of chronic respiratory failure 10 years after operation.

DISCUSSION

Congenital bronchoesophageal fistula or tracheoesophageal fistula was first reported by Negus in 1929^[1]. Congenital bronchoesophageal or tracheoesophageal fistula is rare in adults^[2-5]. Its diagnosis is difficult due to the nonspecific nature of its symptoms. Benign bronchoesophageal fistula can remain undiagnosed for years.

Table 1 Clinical features, diagnosis, and treatment of congenital bronchoesophageal fistula

| Symptoms | Patients (n) | Diagnosis | Patients (n) | Treatment | Patients (n) |
|------------------------|--------------|----------------|--------------|--------------------------|--------------|
| Cough (nonspecific) | 10 | Esophagography | 9 | Right thoracotomy | 7 |
| Cough (after drinking) | 6 | Esophagoscopy | 1 | Left thoracotomy | 4 |
| Hemoptysis | 6 | Bronchoscopy | 1 | Resection of fistula | 10 |
| Chest pain | 3 | | | Division and suture | 1 |
| Low fever | 4 | | | Pleural flap insertion | 11 |
| | | | | Associated lobectomy | 10 |
| | | | | Associated pneumonectomy | 1 |

Table 2 Anatomic types of congenital bronchoesophageal fistulae

| Anatomic types | Patients (n) |
|---------------------------|--------------|
| Lower third of esophagus | 9 |
| Main bronchus | 1 |
| Intermediate bronchus | 1 |
| Segmental bronchus | 7 |
| Middle third of esophagus | 2 |
| Main bronchus | 1 |
| Segmental bronchus | 1 |

Table 3 Blood loss during operation, hospital stay time, and outcome of patients with congenital bronchoesophageal fistula

| Blood loss (mL) | Patients (n) | Hospital stay time | Patients (n) | Postoperative complication | Patients (n) |
|-----------------|--------------|--------------------|--------------|----------------------------|--------------|
| 200-400 | 3 | ≤ 2 wk | 8 | Bronchial fistula | 1 |
| 400-800 | 6 | 2 wk-1 mo | 2 | Esophageal fistula | 0 |
| 800-1000 | 2 | >1 mo | 1 | Respiratory failure | 1 |
| | | | | Circulation failure | 0 |

It was reported that bouts of cough when swallowing liquids (Ohno’s sign) are pathognomonic for this condition and present in 65% of all cases^[3,4]. The duration of symptoms varies from 6 mo to 50 years before diagnosis^[2,4,6,7]. The duration of symptoms in our 11 patients before diagnosis was 5-36.5 years and over 15 years in 9 patients. Of the 11 patients, 6 were misdiagnosed as multiple pulmonary cysts, 4 as bronchiectasis, and 1 as empyema, with a misdiagnosis rate of 100%. Smith^[8] has given an embryologic explanation for the development of these fistulae. He stated that they are the result of persistent attachment between tracheobronchial tree and esophagus due to rapid elongation of the trachea and its separation from the esophagus.

From the pathological point of view, three points should be considered for congenital bronchoesophageal fistulae, including the long standing respiratory signs and symptoms even from infancy, the presence of bronchial or oesophageal epithelium lining the interior of the fistulous tract, and the absence of relevant inflammatory lesions in periphery of the fistula. Our 11 patients fulfilled these criteria and were therefore considered to have a congenital bronchoesophageal fistula. The fact that this type of lesions causes symptoms later in life can be explained by the occasional presence of membranes that can become permeable with time.

Conventional barium esophagography is the most sensitive means for the diagnosis of bronchoesophageal fistula^[4-7,9,10]. However, it is hard to detect tiny fistulae in a single scan. Therefore, a repetitive multi-positional esophagography is helpful for improving the detection rate of bronchoesophageal fistula. In this study, congenital bronchoesophageal fistulae were found in 6 cases during the first scan, and tiny fistulae were found in 3 cases during the multi-positional esophagography, indicating that both bronchoscopy and esophagoscopy should be performed

Table 4 Braimbridge and Keith’s classification of bronchoesophageal fistula

| | |
|----------|--|
| Type I | Congenital bronchoesophageal fistula associated with congenital oesophageal diverticulum |
| Type II | Simple bronchoesophageal fistula |
| Type III | Bronchoesophageal fistula with an intralobar cyst |
| Type IV | Bronchoesophageal fistula communicating with a pulmonary sequestration |

in these cases because they cannot always demonstrate the fistulous orifice. However, they help us to choose the modus operandi^[2,4-7]. CT scanning can rule out the presence of neoplasm and adenopathy, and define the extent of coexisting pulmonary disease, which may need resection^[5,7,11].

Braimbridge *et al.*^[12] have classified congenital bronchoesophageal fistula into 4 types (Table 4). Type II is the most prevalent and comprises almost 90% of all cases in some series^[2]. In our series, types I - IV were found in 2, 7, 2, and 1 cases, respectively, with an associated lung sequestration.

Despite the benign nature of this disease, it may lead to fatal complications if untreated^[5,7,13]. In order to avoid distal pulmonary lesions, early diagnosis and treatment are important. A high index of suspicion should be borne in mind for patients with repeated pulmonary infections or with coughing spells associated with ingestion.

Thoracotomy is the traditional treatment procedure for most cases of fistula^[2,4,6,7]. The two main treatment procedures are division and suturing of the ends of fistula and complete resection. The insertion of a muscular or pleural flap can prevent any refistulization^[4,7,9,13]. Pulmonary resection is often needed in patients with coex-

istent pulmonary diseases such as bronchiectasis and recurrent pneumonitis. In our series, fistula and associated lung lesions were completely removed in 10 patients, and the ends of fistula were sutured in 1 patient. The prognosis of the patients was excellent after the procedure. The postoperative course was uneventful in all patients but one who was complicated by bronchial fistula due to intraoperative contamination of the pleural space by oesophageal materials. However, the patient recovered after treatment. The less effective treatment modality is occlusion of the esophageal opening with biologic glue or a Celestin tube^[14], or with sodium hydroxid and acetic acid solution *via* a bronchoscope or an esophagoscope^[15]. We believe these techniques should be considered only when the condition of patients does not allow a thoracotomy.

Currently, most studies concerning congenital bronchoesophageal fistula in adults are case reports, and few clinical data are available based on large samples. In this study, 11 cases of congenital bronchoesophageal fistula admitted to our hospital in recent 20 years were analyzed.

In conclusion, a high index of suspicion should be borne in mind for patients with repeated pulmonary infections, especially with symptoms of recurrent bouts of cough after taking liquid food. Conventional barium esophagography is presently the most sensitive means for the diagnosis of congenital bronchoesophageal fistula. However, multi-positional esophagography should be performed for tiny or horizontal fistulae. Due to the long duration before diagnosis and repeated pulmonary infections, patients often suffer from severe conglutination in the thorax. A large volume bleeding may occur during operation and adequate blood preparation is necessary. Surgical management is the vital point for the prognosis of patients with congenital bronchoesophageal fistula. Fistula and associated lung lesions shall be completely removed to avoid recrudescence.

COMMENTS

Background

Congenital bronchoesophageal or tracheoesophageal fistula is rare in adults. Its diagnosis is difficult due to the nonspecific nature of its symptoms.

Research frontiers

The clinical characteristics, diagnosis and surgical treatment of congenital bronchoesophageal fistulae in adults were investigated.

Innovations and breakthroughs

Currently, most studies concerning congenital bronchoesophageal fistula in adults are case reports, and few clinical data are available based on large samples. In this study, 11 cases of congenital bronchoesophageal fistula admitted to hospital in recent 20 years were analyzed.

Peer review

This is an interesting case series report on a difficult and often misunderstood clinical condition.

Abstract

AIM: To evaluate the association between of the interleukin-10 (IL-10) promoter polymorphisms and survival of advanced gastric cancer (GC) patients.

METHODS: The IL-10 (-1082, rs1800896; -819, rs1800871; and -592, rs1800896) genotypes in 234 patients with advanced gastric cancer and in 243 healthy controls were determined by polymerase chain reaction-restriction fragment length polymorphism assay. Odds ratios (OR) and 95% confidence intervals (CI) were calculated by unconditional logistic regression for the associations between IL-10 genotypes and the risk of GC. The Kaplan-Meier method with log-rank testing was used to evaluate the association between genotype and survival of the patients.

RESULTS: The IL-10 -1082 G allele and GCC (-1082, -819 and -592) haplotype were associated with increased gastric cancer risks (OR 1.2, 95% CI 0.6-3.2, $P = 0.007$, for -1082 G allele, OR = 2.3, 95% CI, 1.2-4.1, $P = 0.005$, for GCC haplotype, respectively). However, none of the three IL-10 gene polymorphisms (-1082, -819 and -592) was correlated with gastric cancer survival ($P > 0.05$), and none of the genotypes of the three IL-10 sites was found as independent prognostic risk factors in the multivariate test.

CONCLUSION: IL-10 gene promoter polymorphisms may not be associated with the prognosis of advanced gastric cancer.

INTRODUCTION

Deregulated components of the immune system, such as cytokines, may be linked to the incidence and clinical course of malignant diseases with development of acute or chronic inflammatory reactions at tumor sites. Deregulated expression of defined subsets of cytokines

was found to be associated with the transformation of lymphatic cells either as autocrine growth factors for the transformed cells or as factors in rebuilding the tumor microenvironment, likely affecting tumor progression and dissemination^[1].

The mechanisms underlying differences in immune response between individuals are complex, but include inherited genetic variation. Some reports suggest that functional polymorphisms in the genes regulating the immune and inflammatory response may contribute to the susceptibility to and clinical outcome of gastric cancer^[2-4]. Interleukin-10 (IL-10) is a pleiotropic cytokine produced by macrophages, T-helper 2 cells and B lymphocytes and can suppress and stimulate the immune response^[5-7]. IL-10 has been shown to inhibit various immune functions, such as antigen presentation, cytokine production, macrophage activation, and antigen-specific T-cell proliferation^[8,9]. By interfering with antigen-presenting cells, IL-10 reduces antigen-specific T-cell proliferation. It has been postulated that IL-10 plays a key role in the oncogenetic and metastatic ability of neoplasms^[10,11]. Increased levels of serum IL-10 were found in patients with solid and hematopoietic tumors^[12]. However, a large body of evidence in different animal tumor models showed that IL-10 can favor immune-mediated cancer rejection^[13,14].

The gene encoding IL-10 is located on chromosome 1 (1q31-1q32). Several SNPs have been identified in the IL-10 gene promoter region. These include IL-10-1082 A/G, -819T/C and -592A/C, which influence the transcription of IL-10 messenger RNA and the expression of IL-10 *in vitro*^[15,16]. Although several studies have shown the possible involvement of IL-10 in the pathogenesis of gastric cancer^[17-21], its association with prognosis of gastric cancer was not extensively studied. The only study by Deans *et al*^[22] found that GG for IL-10-1082 was associated with reduced survival of gastric cancer patients, but it was not an independent prognosis factor for gastric cancer. The aim of this study was, therefore, to explore the relationship between polymorphisms of IL-10 -1082, -819 and -592 and the prognosis of patients with advanced gastric cancer in the northern area of China.

MATERIALS AND METHODS

Study population

A total of 234 patients (162 men and 72 women) with histologically or cytologically confirmed advanced gastric cancer registered from July 2005 to July 2008 at the Department of Oncology, Shandong Cancer Hospital and Institute were included in this study. The patients should have a histological diagnosis of gastric carcinoma with an unresectable primary tumor and/or metastases that were measurable or assessable by means of clinical examination, X-ray, computed tomography (CT) or ultrasound. The median age of the patients was 61.2 years (range, 27-79 years). There were 147 cases of antrum gastric cancer, 35 gastric cardia cancer, and 52 cases of other types, including 150 cases at stage III B and 84 cases at stage IV. Pathologically, 10 patients had

well-differentiated adenocarcinoma, 45 had moderately differentiated adenocarcinoma, 161 poorly differentiated adenocarcinoma, and 18 signet ring cell carcinoma. Two hundred and six patients were treated with conventional and 5-fluorouracil (5-FU)-based chemotherapy. Among them, 96 cases were treated with capecitabine/fluorouracil + cisplatin/oxaliplatin regimen and 89 cases were treated with docetaxel + oxaliplatin + fluorouracil regimen. The median chemotherapy courses consisted of 5 (1-11) cycles. Follow-up time was calculated from the initiation of diagnosis to July 2009, with a median of 13.3 mo (range, 3.5-34.4 mo). Thirty-three patients were lost to follow-up and 188 patients died, including 3 patients who died from causes other than gastrointestinal carcinoma during the follow-up.

We also selected 243 control individuals (aged 26-79 years) who visited the Shandong Cancer Hospital and Institute between July 2005 and July 2008 for general physical exams. The control individuals were screened to ensure that none had ever been diagnosed with cancer or other serious diseases. The selected controls were age matched to the cases (± 5 years). All the subjects were unrelated ethnic Han Chinese, and written informed consent was obtained from each participant. The study was approved by the Review Board of Shandong Cancer Hospital and Institute. A 2-mL peripheral blood sample was collected from each study participant.

Genotyping

Genomic DNA was extracted from peripheral blood using a Genomic DNA Extraction Kit (Fastagen, Shanghai, China) according to the manufacturer's protocol. IL-10 promoter polymorphisms were identified by PCR amplification and restriction analysis (PCR-RFLP), (Table 1). Each PCR reaction was performed in a GeneAmp PCR System 9600 thermocycler (Applied Biosystems, Foster, CA) at a final volume of 25 μ L (containing 5 pmol for each primer, 50 ng genomic DNA, 1.5 mmol/L MgCl₂, 5 μ mol/L dNTPs and 1 U of Taq DNA polymerase in PCR buffer containing 10 mmol/L Tris). PCR cycles used were as follows: 95°C for 5 min, 35 cycles of denaturing at 95°C for 40 s, annealing at the indicated temperature for 1 min, extension at 72°C for 40 s, and a single final extension at 72°C for 10 min. The amplified products were digested with corresponding restriction endonucleases (New England Biolabs, MA, USA), and separated by electrophoresis on a 10% polyacrylamide gel stained with silver nitrate for visualization.

Statistical analysis

Statistical analysis was performed using SPSS 13.0 software (SPSS, Florida, USA). Demographic data between the study groups were compared using the Chi-square test and Student's *t* test. Each polymorphism was tested for deviation from the Hardy-Weinberg equilibrium by comparing the observed and expected genotype frequencies using the χ^2 test. Genotype frequencies of IL-10 were compared between groups using the χ^2 test, and odds ratios (OR) and 95% confidence intervals (CIs) were calculated using unconditional logistic regression

with adjustment for age and sex. The haplotypes of IL-10 (-1082, -819 and -592) were analyzed using the SHEsis software (Bio-X Inc., Shanghai, China), which uses a full-precise-iteration (FPI) algorithm to reconstruct haplotypes. The Kaplan-Meier method with a log-rank test was used to evaluate the association between genotype and survival. Multivariate analysis was performed using Cox proportional hazards regression. Statistical significance was interpreted as *P* < 0.05.

RESULTS

IL-10 polymorphism and gastric cancer risks

The genotype and allele frequencies of the IL-10 SNP in 234 gastric cancer patients and 243 healthy controls are shown in Table 2. All genotype frequencies in both patient and control groups were in the Hardy-Weinberg equilibrium (*P* < 0.05). There were significant differences in the genotype and allele frequencies of the IL-10 promoter -1082 A/G polymorphism between gastric cancer and

control groups. The -1082 AG genotypes were associated with a significantly increased risk of gastric cancer as compared with the -1082 AA genotypes (OR 1.9, 95% CI 1.1-3.4, *P* = 0.019). The -1082 G allele was associated with a significantly increased risk of gastric cancer as compared with the -1082 A allele (OR 1.2, 95% CI 0.6-3.2, *P* = 0.007). However, genotype and allele frequencies of the IL-10 -819 T/C and -592 A/C polymorphisms in gastric cancer patients were not significantly different compared with those in healthy controls (*P* > 0.05). The estimated haplotype frequencies of IL-10 polymorphisms in gastric cancer patients and controls are also shown in Table 2. Complete linkage disequilibrium was observed between locus -819T/C and locus -592A/C. Four possible haplotypes were demonstrated in our population. The most frequent haplotype in both patients (60.3%) and controls (64.6%) was the ATA (-1082A, -819T and -592A) haplotype. By haplotype analyses, we found that the GCC (-1082G, -819C and -592C) haplotype was associated with a significantly increased risk of gastric cancer as compared with the ATA haplotype (OR = 2.3, 95% CI 1.2-4.1, *P* = 0.005).

IL-10 polymorphism and survival of advanced gastric cancer

Of the 234 patients, 33 were lost to follow-up. We compared the IL-10 genotype with survival time in 201 patients with advanced gastric cancer. The median follow-up time was 13.3 mo (range, 3.0-30.3 mo), and the median survival time was 11.2 mo. The median survival time was 11.4 mo for patients with the IL-10 -1082AA genotype, 10.8 mo for patients with the GA genotype, and 11.0 mo for patients with the GG genotype. The IL-10 -1082 genotypes were not associated with the prognosis of gastric cancer (*P* = 0.709, log-rank test). Similarly, the median survival time was 11.5 mo for patients with the IL-10 -819TT/-592AA genotype, 10.8 mo for patients with the -819TC/-592AC genotype, and 10.2 mo for patients with the -819CC/-592CC genotype (*P* = 0.090, log-rank test). When stratified by the clinical stage, the association between the IL-10 gene polymorphisms (-1082, -819 and -592) and the gastric cancer survival was not statistically significant either in stage IIIB or stage IV (Figure 1). Multivariate Cox regression was used to analyze the effect of different risk factors (IL-10-1082A/G, -819T/C and -592A/C genotype, chemotherapy regimen, age, gender, disease stage, and histology) on survival time. However, none of the genotypes of the three IL-10 sites

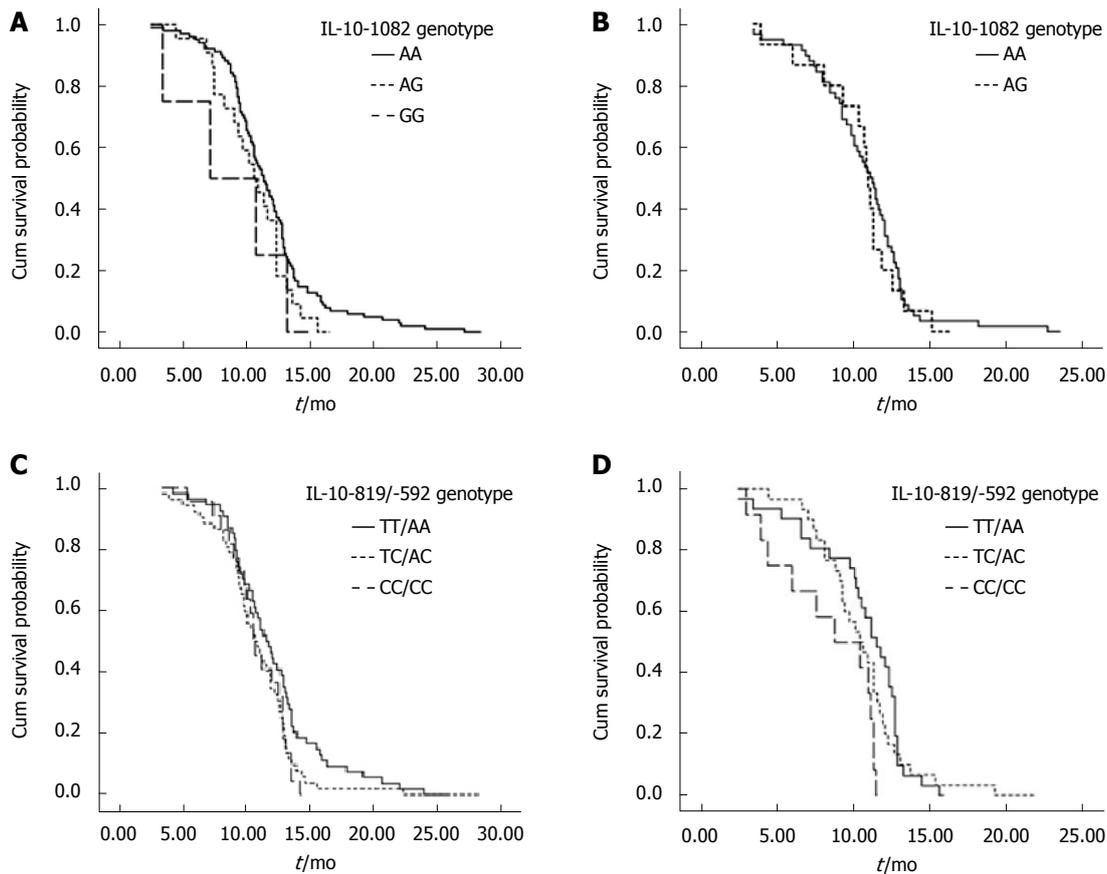

Figure 1 Kaplan-Meier survival plot for advanced gastric cancer patients by interleukin-10 genotype. A: Interleukin (IL)-10 -1082 genotype in stage III B; B: IL-10 -1082 genotype in stage IV; C: IL-10 -819/-592 genotype in stage III B; D: IL-10 -819/-592 genotype in stage IV.

Table 3 Cox regression analysis of variables affecting prognosis in advanced gastric cancer patients

| Variable | P | Hazard ratio | 95% CI for hazard ratio | |
|-------------------------|-------|--------------|-------------------------|-------|
| | | | Lower | Upper |
| IL-10-1082 genotype | 0.815 | 1.2 | 0.8 | 1.7 |
| IL-10-819/-592 genotype | 0.671 | 1.1 | 0.5 | 1.9 |

| Stage | 0.234 | 1.2 | 0.9 | 1.5 |
| Histology | 0.519 | 1.2 | 0.7 | 2.1 |

was recognized as an independent prognostic indicator (Table 3).

DISCUSSION

Cytokines play a crucial role in the regulation of key pathways of immunity, the balance between cell-mediated (Th1) and humoral (Th2) responsiveness. IL-10, which is produced mainly by macrophages and T lymphocytes, is an important anti-inflammatory and immunosuppressive cytokine, it inhibits the Th1-type pathway activation, prevents antigen-presenting cells (APC) from obtaining access to tumor antigens, and down-regulates surface expression of costimulatory molecules CD80 or CD86 on

tumor cells^[5-7]. Due to its immunosuppressive and anti-inflammatory properties, it has been hypothesized that IL-10 may contribute to the escape of tumor cells from immune surveillance and favor tumor growth. On the other hand, several studies showed that IL-10 may regulate angiogenesis in various cancers and is believed to play a protective and preventive role against tumors^[13,14].

Although the genetic control of IL-10 expression is not clearly understood yet, polymorphisms in promoter regions have been reported to determine inter-individual differences in IL-10 production. Previous studies indicated that three common-1082 A/G, -819 T/C and -592 A/C polymorphisms of the IL-10 promoter may influence production and expression of IL-10. IL-10 promoter-1082G allele or GCC haplotype (defined by three SNPs at positions of -1082, -819 and -592) is associated with increased IL-10 production and ATA haplotype is generally assumed to be a lower IL-10 responder^[15,16].

In this study we evaluated the association between the polymorphisms of the IL-10 promoter and advanced gastric cancer in a Chinese population. Our data showed significant differences in allele, genotype and haplotype frequencies between gastric cancer patients and healthy controls. In concordance with our study, Lee *et al.*^[20], Sugimoto *et al.*^[21] and several studies from China^[18,19] reported that the IL-10 gene promoter polymorphisms were associated with the risk of gastric cancer in Korean, Japanese and Chinese populations. However, these

results are not consistent with studies previously conducted in American and Spain, in which the IL-10 promoter genotype was not associated with gastric cancer risk^[23,24]. Although it is difficult to determine the reasons behind the contradictory results in these studies, the different genetic background of study populations may be one of the main factors.

Although the IL-10 promoter polymorphisms are associated with increased risk of advanced gastric, few studies have investigated the relationship between IL-10 promoter polymorphisms and gastric cancer prognosis. In this study, we investigated whether there are any associations between the three IL-10 promoter SNPs and survival time of advanced gastric cancer patients. Our results showed that the three IL-10 gene polymorphisms (-1082, -819 and -592) did not correlate with the advanced gastric cancer survival. Multivariate testing also found no genotype of the three IL-10 sites as independent prognostic risk factors. Several studies have observed that serum IL-10 is of independent prognostic utility in patients with advanced gastrointestinal carcinoma, and the reasonable interpretation is that the higher serum IL-10 level is secreted by the tumor itself rather than the inflammatory infiltration^[25,26]. However, only one study focused on the polymorphisms of cytokine genes and gastric cancer prognosis and found GG in IL-10-1082 to be associated with reduced survival of gastric cancer patients, but not an independent prognosis factor for gastric cancer^[22]. The reason why our study did not show the association between IL-10 genotype and gastric cancer prognosis may be the relatively small series of patients examined (the number of gastric cancer patients with GG genotype at position -1082 in our study population is small, only six cases). It remains to be confirmed whether the relationship is reproducible in larger Chinese samples.

In conclusion, our results suggested that IL-10 promoter polymorphisms were associated with an increased risk of gastric cancer, but these polymorphisms did not influence the prognosis of the Chinese patients with advanced gastric cancer. As this is the first report of the association between IL-10 promoter polymorphism and prognosis of the Chinese patients with gastric cancer, the results of the present study should be viewed cautiously. Since the dual biological effects of IL-10 and the functional significance of IL-10 promoter polymorphisms in determining IL-10 expression still need to be elucidated, further investigations are required to explore the relationship of the polymorphisms of IL-10 promoter and clinical outcome of gastric cancer.

COMMENTS

Background

The immune dysfunction may be linked to the incidence and clinical course of malignant cancers. Interleukin-10 (IL-10) is a pleiotropic immunoregulatory cytokine which is involved in inflammatory reaction and immune regulation and is considered to exert effects in malignant transformation. IL-10 promoter polymorphisms have been reported to determine inter-individual differences in IL-10 production and are associated with the risk and pathogenesis of several cancers.

Research frontiers

Several studies have shown the possible involvement of IL-10 polymorphisms in the pathogenesis of gastric cancer, although its association with prognosis of gastric cancer was not well explored. The aim of this study was to explore the association between polymorphisms of IL-10 promoter and the prognosis of patients with advanced gastric cancer.

Innovations and breakthroughs

This study indicated that IL-10 promoter polymorphisms were associated with an increased risk of gastric cancer, but these polymorphisms did not influence the prognosis of the patients with advanced gastric cancer.

Applications

This is the first report of the association between IL-10 promoter polymorphism and prognosis of the Chinese patients with gastric cancer. The results of this study will help understand the genetic background of the immune-related gene and gastric cancer incidence and prognosis.

Terminology

IL-10 is an important anti-inflammatory and immunosuppressive cytokine, which inhibits the Th1-type pathway activation, prevents antigen-presenting cells from obtaining access to tumor antigens, and down-regulates surface expression of costimulatory molecules CD80 or CD86 on tumor cells.

Abstract

AIM: To investigate the endoscopic hemostasis for gastrointestinal bleeding due to Dieulafoy's lesion.

METHODS: One hundred and seven patients with gastrointestinal bleeding due to Dieulafoy's lesion were treated with three endoscopic hemostasis methods: aethoxysklerol injection (46 cases), endoscopic hemoclip hemostasis (31 cases), and a combination of hemoclip hemostasis with aethoxysklerol injection (30 cases).

RESULTS: The rates of successful hemostasis using the three methods were 71.7% (33/46), 77.4% (24/31) and 96.7% (29/30), respectively, with significant differences between the methods ($P < 0.05$). Among those who had unsuccessful treatment with aethoxysklerol injection, 13 were treated with hemoclip hemostasis and 4 underwent surgical operation; 9 cases were successful in the injection therapy. Among the cases with unsuccessful treatment with hemoclip hemostasis,

7 were treated with injection of aethoxysklerol and 3 cases underwent surgical operation; 4 cases were successful in the treatment with hemoclip hemostasis. Only 1 case had unsuccessful treatment with a combined therapy of hemoclip hemostasis and aethoxysklerol injection, and surgery was then performed. No serious complications of perforation occurred in the patients whose bleeding was treated with the endoscopic hemostasis, and no re-bleeding was found during a 1-year follow-up.

CONCLUSION: The combined therapy of hemoclip hemostasis with aethoxysklerol injection is the most effective method for gastrointestinal bleeding due to Dieulafoy's lesion.

INTRODUCTION

Dieulafoy's lesion was first reported by Gallad in 1884, and a systemic description was made by Dieulafoy in 1903. It is also called Dieulafoy's vascular malformation^[1]. Patients with gastrointestinal bleeding due to Dieulafoy's lesion in our hospital were treated with the endoscopic

hemostasis, and a satisfactory therapeutic efficacy was achieved.

MATERIALS AND METHODS

Patients

One hundred and seven patients with gastrointestinal bleeding due to Dieulafoy's lesion were enrolled in this study. There were 70 males and 37 females, with a mean age of 54 years. Clinical presentations were repeated hematemesis, a dark or bloody stool, the amount of blood loss of 800-2000 mL, shock occurring in some patients, and hemoglobin 46-80 g/L. No obvious epigastric discomfort and abdominal pain were noted, and there was no history of peptic ulcer or heredity disease.

Diagnostic standards

(1) The bottom of the ulcer had exposed vessels (most were dilated small arteries); (2) The ulcer was superficial and small, and the diameter was less than 0.5 cm; (3) Spurting blood from the ulcer was observed in the active phase, and if bleeding stopped, a black blood scab was observed with endoscopic examination and was easily misdiagnosed; (4) Dieulafoy's lesion occurred mostly in elderly people, possibly because of a small vascular malformation or arteriosclerosis; and (5) Dieulafoy's lesion was mostly located at the gastric body, or at the juncture of the gastric fundus and the gastric body^[2-4].

Endoscopic findings

Emergent endoscopic examination was performed for all the patients. Blood clotting was observed and they were flushed with saline. Fresh blood clotting covered the mucosa in 42 cases (39.3%), blood spurting from a small artery occurred in 32 cases (29.9%), ruptured vessels occurred in 33 cases (30.8%), and no obvious hyperemia was observed in the surrounding mucosa. Lesions were found in the following areas: the upper part of the gastric corpus (36 cases, 33.6%), surrounding the cardia (28 cases, 26.2%), the gastric fundus (18 cases, 16.8%), the middle of the gastric body (5 cases, 4.7%), the lower part of the gastric body (4 cases, 3.7%), the gastric antrum (3 cases, 2.8%), the duodenum (2 cases, 1.9%), the descending part of the duodenum (2 cases, 1.9%), the rectum and colon (6 cases, 5.6%), and the esophagus (3 cases, 2.8%).

Endoscopic therapy

Patients were randomly divided into 3 groups according to the three types of endoscopic therapy used.

Group one: patients received aethoxysklerol injection ($n = 46$ cases). A concentration of 1% aethoxysklerol was injected around the blood vessels beneath the mucosa and 0.5 mL was used for each injected site. Three to 6 sites were injected and the amount of aethoxysklerol used was 3-5 mL. Aethoxysklerol was injected into the ruptured site of the blood vessel (Figure 1).

Group two: patients were treated with endoscopic hemoclip hemostasis ($n = 31$ cases). We used an Olym-

pus HX-5LR-1 and Olympus clip HX-600-135 for bleeding arteries. Hemoclip hemostasis was performed until the vessel stopped bleeding (Figure 2).

Group three: patients received a combined therapy of hemoclip hemostasis and aethoxysklerol injection ($n = 30$ cases). For bleeding arteries, hemoclip hemostasis was used until the bleeding stopped. A concentration of 1% aethoxysklerol was injected around the blood vessel beneath the mucosa, and 0.5 mL was used for each injected site. Three to 6 sites were injected and the amount of aethoxysklerol used was 3-5 mL (Figure 3).

Criteria for determining successful endoscopic hemostasis

The criteria for determining successful endoscopic hemostasis were as follows. (1) Endoscopic demonstration: blood spurting or capillary hemorrhage stopped, and the endoscopic field of view became clear; (2) Clinical manifestations: there was no hematemesis or dark stool after treatment, blood pressure rose to a normal range and was stable, and pulse rate decreased and strengthened.

Criteria for determining unsuccessful endoscopic hemostasis

Criteria for determining unsuccessful endoscopic hemostasis were as follows: (1) hematemesis and/or dark stool occurred 48 h after endoscopic treatment; (2) hemoglobin was decreased by more than 20 g/L; (3) there was evidence of hypovolemic shock; and (4) there was manifestation of bleeding and blood transfusion was necessary. Re-bleeding was confirmed at the original site as demonstrated by endoscopic examination.

Statistical analysis

Rates of successful hemostasis and perforation among the groups were compared using the χ^2 test (SPSS 10.0). $P < 0.05$ was considered as a significant difference.

RESULTS

One hundred and seven patients received endoscopic hemostasis in this study. Eight cases had unsuccessful treatment with endoscopic hemostasis and underwent a surgical operation. No serious complications such as perforation occurred in the 99 cases whose bleeding was treated with endoscopic hemostasis, and no re-bleeding was found during a 1-year follow-up.

Success of hemostasis

The success rate of hemostasis by aethoxysklerol injection was 71.7% (33/46). Re-bleeding occurred in 13 cases in a short period after treatment (less than 48 h). For the re-bleeding cases, the hemoclip hemostasis was used; 9 cases were successfully treated and 4 cases whose bleeding was not controlled received a surgical operation.

The success rate of hemostasis by endoscopic hemoclip hemostasis was 77.4% (24/31). Re-bleeding occurred in 7 cases in a short period after treatment (less than 48 h)

and was treated with aethoxysklerol injection. Four cases were successfully treated and 3 unsuccessful cases were treated surgically.

The successful rate of hemostasis by the combined therapy of hemoclip hemostasis with aethoxysklerol injection was 96.7% (29/30). Re-bleeding occurred in 1 case in a short period after treatment (less than 48 h), and he was treated by surgical operation.

DISCUSSION

Dieulafoy's lesion is a type of rare congenital vascular malformation, and it is also called "Dieulafoy's ulcer" or "constant diameter artery bleeding". The lesion can occur in any part of the gastrointestinal tract, such as the esophagus, colon, and small intestine. However, it often

occurs in the lesser curvature of the stomach 6 cm from the cardioesophageal junction^[5-8]. While Dieulafoy's lesion has no specific symptoms and is not easily diagnosed, the emergent endoscopic examination is an effective means for its diagnosis. The endoscopic presentations of Dieulafoy's lesion are as follows: (1) a superficial notch in the gastric mucosa, blood vessels in the mucosa, and coagulum on its surface; (2) a focal defect of lesser curvature of stomach mucosa complicated with active bleeding; (3) small arteries can protrude on the mucosa and active bleeding can occasionally be detected; and (4) occasionally, blood permeation can be detected from the mucosa, and is often detected when bleeding^[9-12].

The bleeding of Dieulafoy's lesion can be unexpected, with no obvious cause. Patients often do not have other bleeding diseases such as peptic ulcers and cirrhosis, since

the ruptured vessel is an artery with a constant diameter. If the bleeding is serious, patients often complain of hematemesis or hematemesis accompanied by a dark stool^[13-16]. The pathogenesis of Dieulafoy's lesion is considered as a congenital vascular malformation. Normally, the diameter of the gastrointestinal artery gradually decreases to 0.12-0.2 mm, branching to the mucosa. However, the diameter of the artery in a Dieulafoy's lesion does not decrease; it is abnormally dilated and its diameter is 0.4-4 mm. This constant arterial diameter leads to the pathology of Dieulafoy's lesion. The abnormally dilated artery travels under the mucosa. The mucosa in Dieulafoy's lesion is compressed and becomes ischemic, atrophied and thin. A small ulcer can form with the decay of digestive juice and friction from chyme, and if the small artery is exposed, it can rupture and bleed. The artery is often the branch of the left gastric artery; therefore, the bleeding lesion is often located at the lesser curvature of the stomach 6 cm from the cardioesophageal junction^[17-19]. When a small artery bleeds, blood pressure decreases, and vasoconstriction and thrombosis occur in the bleeding artery. Bleeding can temporarily stop and the artery is invisible when bleeding stops. It might not be detected by endoscopic examination, even with a surgical operation. If blood pressure rises to normal or the blood clot is shed, serious bleeding can reoccur.

Generally, it is considered that medical treatment plays a minor role in the treatment of Dieulafoy's lesion; endoscopic therapy and surgery are often performed. The use of pituitrin and somatostatin causes bowel vessels to contract and blood flow to decrease, and these drugs are used for endoscopic therapy and surgical operations. The Dieulafoy's lesion before the 1980's was mainly treated with surgical operations. Since Boron first successfully treated 3 cases of Dieulafoy's lesion in 1987 with the endoscopic therapy^[20], an increasing number of doctors have treated this lesion with endoscopic therapy. The death rate decreased from 60%-70% to 20%. Endoscopic treatment has the advantages of being simple in operation, which is easily replicated, is microtraumatic, safe and useful, and it can be performed during the examination. Methods used include injection beneath the mucosa, electric coagulation, laser, heat probe, microwaves, ligation and hemoclips. The efficacy was reported to be more than 80%^[21-28].

Three types of endoscopic therapy were used in this study for the treatment of bleeding due to Dieulafoy's lesion. Aethoxysklerol injection therapy can result in sclerosis and emphysema to prevent re-bleeding. Local tissue edema occurred and the surrounding pressure of the bleeding site increased when aethoxysklerol was injected. The artery was compressed and thrombosis occurred in the vessel. When aethoxysklerol was injected around the vessel, edema and inflammation rapidly occurred, with fibroblast proliferation. Forty-six cases received this type of therapy and the rate of successful hemostasis was 71.7% (33/46). We also treated patients with endoscopic hemoclip hemostasis. The mechanism of hemoclip hemostasis is similar to that of surgical vascular suturing. In our study, 31 cases received this type of therapy, and the rate of suc-

cessful hemostasis was 77.4% (24/31). The third method we used in this study was a combined therapy of hemoclip hemostasis with injection of aethoxysklerol. Thirty cases received this therapy, and the rate of successful hemostasis was 96.7% (29/30). We found that this combined therapy was the most effective method for stopping bleeding from a Dieulafoy's lesion, and it could effectively reduce the re-bleeding rate as well.

Hemoclip hemostasis is widely used for non-variceal active bleeding, and it is indicated for Dieulafoy's lesion^[29,30]. Our study used the following procedure. A clip was assembled on the delivery device. When a bleeding lesion was detected, the delivery device was inserted into the endoscopic working channel to push it to the anterior extremity of the endoscope. The clip was stretched out of the endoscope, and then the clip was stretched open to the largest width (1.2 cm). The direction of the clip could be adjusted with the rotating device on the delivery system. The stretched clip was collimated to the lesion, the gliding lug on the device was pushed back, and the clip was locked. The clip was then released and the delivery device was pulled out. One clip was used for ordinary lesions, and for larger lesions, 2-3 clips were needed. We believe that the key points for successful clipping are as follows: (1) the lesion needs to be directly observed; (2) the lesion and its surrounding tissue should be fully exposed, and the angle of the clip and bleeding site should be in a range of 45-90°; and (3) the depth of the clip should be considered. The optimal depth is where the exposed vessel and deep tissue are able to be clipped. The clip should not be superficial, and if it is superficial, the clip can come off in a short period, and then re-bleeding is inevitable. The clip often releases automatically in 1-3 wk. It is mixed with food debris and the stool, and it is then eliminated from the body. This method is considered as microtraumatic. If it is not successful at the first time, it can be replicated. Even if it fails, it can mark the bleeding site, thereby making the surgical operation easier, and avoiding blind resection. This method is effective for the treatment of Dieulafoy's lesion, and it is increasingly recognized by doctors. We found that if aethoxysklerol was injected after clipping, the re-bleeding rate in Dieulafoy's lesion was effectively decreased.

COMMENTS

Background

Generally, it is considered that medical treatment plays a minor role in the treatment of bleeding from Dieulafoy's lesion. Endoscopic therapy and surgical operations are the preferred treatments for this lesion. In recent years, an increasing number of doctors have treated bleeding from a Dieulafoy's lesion with endoscopic therapy, and the death rate has decreased. The purpose of this study was to explore a new endoscopic method for the treatment of bleeding due to Dieulafoy's lesion.

Research frontiers

Patients with gastrointestinal bleeding due to Dieulafoy's lesion were treated with the endoscopic hemostasis. Three methods were used: aethoxysklerol injection, endoscopic hemoclip hemostasis, and a combination of hemoclip hemostasis with aethoxysklerol injection.

Innovations and breakthroughs

The authors concluded that a combined therapy of hemoclip hemostasis with aethoxysklerol injection is the most effective method for gastrointestinal bleeding due to Dieulafoy's lesion.

Applications

A combined therapy of hemoclip hemostasis with injection of aethoxysklerol, can be applied successfully in the treatment of bleeding due to a Dieulafoy's lesion.

Terminology

Dieulafoy's lesion: Dieulafoy's lesion is a type of rare congenital vascular malformation, and it is also called "Dieulafoy's ulcer" or "constant diameter artery bleeding". It was first reported in 1898 by a French surgeon named Dieulafoy.

Endoscopic hemostasis: A kind of endoscopic method to control bleeding.

Peer review

Since the nature of bleeding from Dieulafoy's lesion poses several technical difficulties in its identification and its nonsurgical treatment, several endoscopic modalities have been used, but the treatment of choice is still unclear. Therefore, comparison of the efficacy and safety among two single hemostatic methods and a combined method applied to more than 100 patients provided useful results. In addition, the technical details given in the text may be helpful for endoscopists for the diagnosis and treatment of bleeding from a Dieulafoy's lesion.

Isopropyl- β -D-Thiogalactopyranoside (IPTG) induction at 37°C for four hours. The levels of serum autoantibodies against MMP-7 were significantly higher in patients with ESCC than in the matched-control samples (OD450 = 1.69 \pm 0.08 vs OD450 = 1.55 \pm 0.10, P < 0.001). The area under the receiver operating characteristic (ROC) curve was 0.87. The sensitivity and specificity for detection of ESCC were 78.0% and 81.0%, respectively, when the OD450 value was greater than 1.65. Although the levels of autoantibodies against MMP-7 were also significantly higher in patients with gastric cancer compared to control samples (OD450 = 1.62 \pm 0.06 vs OD450 = 1.55 \pm 0.10, P < 0.001), the diagnostic accuracy was less significant than in ESCC patients. The area of ROC curve was 0.75, whereas the sensitivity and specificity were 60.5% and 71.7%, respectively, when the cut-off value of OD450 was set at 1.60.

CONCLUSION: Serum autoantibody levels of MMP-7 may be a good diagnostic biomarker for esophageal squamous cell carcinoma.

Abstract

AIM: To evaluate the diagnostic values of serum autoantibodies against matrix metalloproteinase-7 (MMP-7) in patients with esophageal squamous cell carcinoma (ESCC).

METHODS: The MMP-7 cDNA was cloned from ESCC tissues, and MMP-7 was expressed and purified from a prokaryotic system. MMP-7 autoantibodies were then measured in sera from 50 patients with primary ESCC and 58 risk-matched controls, using a reverse capture enzyme-linked immunosorbent assay (ELISA) in which autoantibodies to MMP-7 bound to the purified MMP-7 proteins. In addition, MMP-7 autoantibody levels in sera from 38 gastric cancer patients and from control serum samples were also tested.

RESULTS: The optimum conditions for recombinant MMP-7 protein expression were determined as 0.04 mmol/L

Key words: Matrix metalloproteinase-7; Serum autoantibody; Esophageal squamous cell carcinoma; Gastric cancer; Biomarker

Autoantibodies against MMP-7 as a novel diagnostic biomarker in esophageal squamous cell carcinoma. *World J Gastroenterol* 2011; 17(10): 1373-1378 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i10/1373.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i10.1373>

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC), the major

histological form of esophageal cancer in East Asian countries, is one of the leading causes of cancer death worldwide^[1,2]. The high mortality of this disease is largely due to the lack of a screening strategy to detect early stage disease. ESCC survival is highly stage dependent. Patients with localized disease are 12 times more likely to survive five years than those with distant disease^[3]. Unfortunately, most cases are diagnosed with ESCC when they have already reached an advanced stage^[4]. Thus there is a growing need to identify useful biological markers for early, non-invasive diagnosis of ESCC^[5].

The traditional serological tumor markers for ESCC, which are mainly secreted tumor antigens, i.e. CEA, SCCA, CYFRA21-1, and DKK-1, have been found to be useful but not sufficiently sensitive for early detection of the disease^[6,7]. Autoantibodies against tumor-associated antigens were recently reported in sera from patients with ESCC and other cancers as a promising approach for early cancer detection^[8-10]. Changes in the level of gene expression and aberrant expression of tissue-restricted gene products are factors that lead to humoral immune response in cancer patients, usually at the early stage of cancer development^[11,12]. Therefore identifying novel autoantibody biomarkers may lead to early diagnosis or prediction of disease progression in patients with ESCC.

The matrix metalloproteinases (MMPs) are a family of zinc-dependent proteolytic enzymes capable of degrading the extracellular matrix (ECM). MMPs play a key role in the physiological degradation of the ECM in angiogenesis, tissue repair, and tissue morphogenesis^[13]. They also regulate cell growth and inflammation by cleaving non-matrix proteins like growth factors, cytokines and chemokines, and their respective receptors^[14]. MMP-7, as the smallest molecule of the MMPs, has been found overexpressed in a variety of epithelial and mesenchymal tumors, such as esophagus, colon, liver, renal, and pancreas. Its expression is correlated with unfavorable prognosis^[15]. Increased circulating levels of MMP-7 proteins were correlated with the presence of metastatic disease and poor patient survival in colorectal and renal cell cancer^[15-17]. However, as one of the early immune responses to cancer development, levels of autoantibodies against the MMP-7 protein have not been studied. This humoral immune response to MMP-7 might be a good early indicator of ESCC.

In this study, we evaluate the diagnostic values of serum autoantibodies against MMP-7 in ESCC and gastric cancer patients using purified MMP-7 proteins. We further discuss the possibility of the utility of these autoantibodies to MMP-7 as tumor markers in clinical diagnosis.

MATERIALS AND METHODS

Clinical samples

A total of 108 individuals' serum samples (50 ESCC patients and 58 risk-matched controls) were collected from Baoding Tumor Hospital, Hebei, China. About 10 g of ESCC tumor samples were also collected in parallel. In ad-

Table 1 Characteristics of normal and patient serum *n* (%)

dition, 38 serum samples were collected from patients with gastric cancer from the same hospital. Detailed information on the serum samples is listed in Table 1. All the clinical samples were collected after informed consents were obtained.

Cloning the MMP-7 cDNA from ESCC tissues

About 10 g of each ESCC tissue sample was snap-frozen in liquid nitrogen. RNA extraction was performed according to procedures described in the TRIzol Reagent manual (Invitrogen, USA). Primers were designed according to the sequence of the MMP-7 mRNA (GenBank, NM_002423.3). The sequence of the forward primer was 5'-GGAATTC^uCCATATGTC^uACTATTTCCAAATAGCCC-3' and the sequence of reverse primer was 5'-CCC^uAAGCITTTATCCATATAGTTTCTGAATGCC-3'. *Nde* I and *Hind* III (underlined) restriction sites were introduced into the sequences of forward and reverse primers, respectively.

RT-PCR reactions were carried out under the following conditions. After heating at 94°C for 4 min, the reactions were exposed to 30 cycles of 94°C for 30 s, 63°C for 40 s, and 72°C for 1 min; with a final extension at 72°C for 10 min. The final products were then subjected to electrophoresis on 1% agarose. The amplified inserts were purified using a DNA purification kit (QIAGEN, USA), digested with *Nde* I and *Hind* III, and then ligated to a prokaryotic expression vector pET28b(+) (Novagen, USA) that was also digested with the same restriction enzymes. The constructed plasmid was transformed into competent *E. coli* DH5α cells and grown in Luria-Bertani (LB) broth supplemented with kanamycin (30 μg/mL). The recombinant plasmid was confirmed by double endonuclease digestion and DNA sequencing.

MMP-7 protein expression and purification

The recombinant plasmid pET-28b/MMP-7 was transformed into expression strain *E. coli* Rosetta (DE3) cells by heat-shock. One colony was picked and grown in

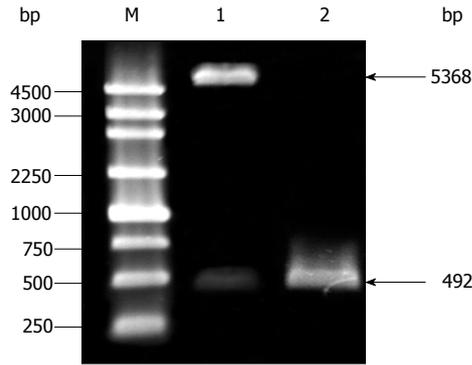

Figure 1 Double endonuclease digestion of the recombinant vector pET-28b/matrix metalloproteinase-7. M: DNA maker; Lane 1: Double digestion with NdeI and HindIII; Lane 2: Positive bacterial clone.

20 mL LB medium containing 30 µg/mL kanamycin at 37°C until an optical density (OD) at 600 nm of 0.6 was reached. Isopropyl-β-D-Thiogalactopyranoside (IPTG) was then added to induce protein expression at 28°C and 37°C. To determine the optimal condition for MMP-7 expression, DE3 cells were induced at different concentrations (0.4, 0.8, and 1.0 mmol/L) of IPTG for different lengths of time (1, 2, 4, 6 and 7 h). At the end of each condition, cells were harvested by centrifugation, resuspended in 1 mL PBS, and sonicated on ice until the suspension became transparent (5 min). The lysate was centrifuged for 30 min at 12000 *g*, and then both the supernatant and the pellets were tested for the MMP-7 protein expression by 15% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

To purify this His-tagged MMP-7 recombinant protein, a QIAexpressionist (QIAGEN, USA) kit was used. Briefly, 3 mL of cell culture at the most optimal expression conditions was pelleted and resuspended in 600 µL lysis buffer (8 mol/L Urea, 10 mmol/L NaH₂PO₄, 10 mmol/L Tris.Cl, pH8.0) at room temperature for 4 h. Cell debris was cleared by centrifugation, and the supernatants were transferred to a fresh tube and incubated with 60 µL of a 50% slurry of Ni-NTA resin (10 µL resin has a capacity for 50-100 µg His-tagged protein) for 60 min at 4°C with agitation. The resin was then pelleted by centrifugation and washed twice with 300 µL wash buffer (8 mol/L Urea, 100 mmol/L NaH₂PO₄, 10 mmol/L Tris.Cl, pH6.3). The protein was then eluted three times with 30 µL elution buffer (8 mol/L Urea, 100 mmol/L NaH₂PO₄, 10 mmol/L Tris.Cl, pH4.5). The purification process was tested by 15% SDS-PAGE followed by Coomassie Brilliant Blue staining.

Measurement of serum autoantibodies against MMP-7

Ninety-six-well Costar ELISA plates (Jet Biofil, Beijing, China) were coated with 2 µg/mL of the purified MMP-7 protein and incubated overnight at 4°C. The plates were washed four times with PBST (PBS buffer containing 0.05% Tween 20), and then blocked with PBS containing 1% BSA at 37°C for 1 h, followed by four washes in PBST. Serum samples (ESCC or gastric cancer patients

or control) were diluted 1/150 in 1% BSA and incubated in the MMP-7-coated ELISA plates at 37°C for 1 h. After washing four times with PBST, 100 µL of goat anti-human IgG-HRP (1:1000 dilutions) was added to each well for 1 h at 37°C. After washing four times with PBST, the color was developed with 3,4,5-trimethoxy benzaldehyde (TMB) for exactly 15 min, and then stopped with 0.5 mol/L H₂SO₄. The absorbance of each well was read at 450 nm by a plate microplate reader (Beijing's New Air Electrical Technology, Beijing, China). Each serum sample was tested in triplicate.

Statistical analysis

To analyze the difference of autoantibodies reaction to MMP-7 proteins between cancer and matched control sera, the absorbance of each serum sample in the ELISA plate was averaged from triplicate experiments. Student's *t*-test was performed between cancer and matched-control samples. Nonparametric receiver-operating curves (ROCs), in which the value for sensitivity was plotted against false-positive rate (1-specificity), were generated. In addition, an area under the ROC curve (AUC) with 95% confidence intervals (CI) was calculated for each marker. In all tests, a *P*-value of ≤ 0.05 was considered to be statistically significant. All statistical analysis was done with the SPSS software package version 16.0 (SPSS, Chicago, IL, USA).

RESULTS

MMP-7 expression and purification

The cDNA of MMP-7 was cloned from ESCC tissues and inserted into a prokaryotic expression plasmid, pET-28b. After double endonuclease digestion and PCR confirmation, a single band of 492 bp was obtained (Figure 1) at the expected location. The insert DNA was further purified and sequenced. The sequence was found to be a perfect match to the sequence of MMP-7 deposited in NCBI GenBank.

This pET-28b/MMP-7 plasmid was transformed into DE3 cells for MMP-7 expression. Optimal IPTG concentration and time course determinations were performed for the kinetics of protein expression in the bacterial culture. The results showed that DE3 cells had the highest MMP-7 protein expression level after 4 h of 0.4 mmol/L IPTG induction at 37°C (Figure 2A and B). The pET-28b/MMP-7 recombinant proteins were mainly observed in the precipitate of the DE3 lysate, which indicated that the expressed protein was mainly in sequestered to inclusion bodies. The expressed proteins were further purified to approximately 95% purity by Ni-NTA resin (Figure 3).

Comparison of MMP-7 autoantibodies between cancer and control samples

To test serum autoantibodies against MMP-7 proteins, the purified MMP-7 proteins were coated onto 96-well ELISA plates. Serum samples from 50 patients with ESCC or 38 with gastric cancer were tested, along with 58 control serum samples, using indirect ELISA. The mean OD450

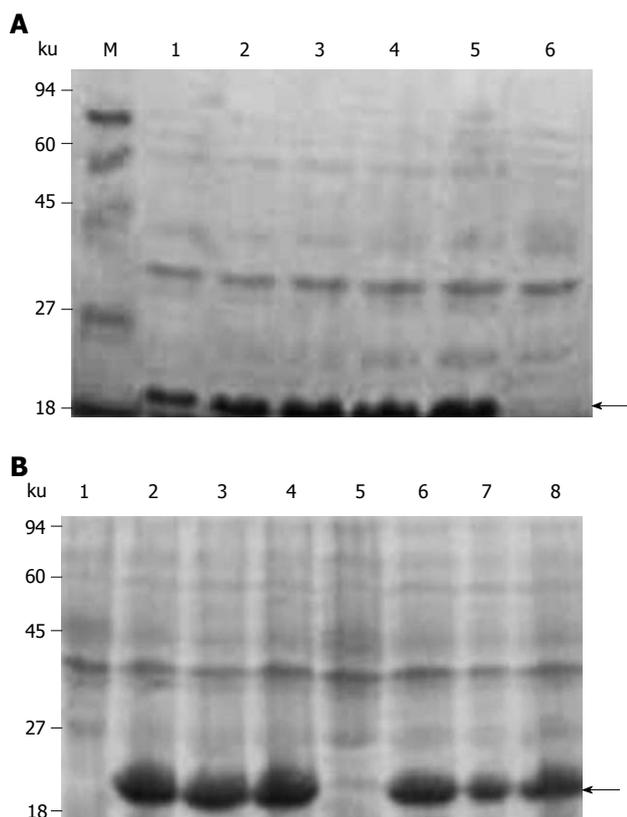

Figure 2 pET-28b/matrix metalloproteinase-7 protein expression by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. Panel A: Time course analysis of pET-28b/matrix metalloproteinase-7 (MMP-7) protein expression by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). M: Protein marker; 1-5: Samples for different time points (1, 2, 4, 6, and 7 h) at 37°C after 0.4 mmol/L IPTG induced; 6: Uninduced bacterial lysate. Panel B: SDS-PAGE showing pET-28b/MMP-7 protein expression induced by different amounts of IPTG. 1, 5: Uninduced bacterial lysate; 2-4: Samples induced at different concentrations of IPTG (0.4, 0.8, 1 mmol/L) at 37°C for 4 h; 6-8: Samples induced at different concentrations of IPTG (0.4, 0.8, 1 mmol/L) at 28°C for 4 h.

(\pm SD) of serum autoantibodies against MMP-7 in 50 ESCC patients was 1.69 ± 0.08 , and was 1.55 ± 0.10 in 58 control individuals. The mean OD450 (\pm SD) of serum autoantibodies against MMP-7 in 38 gastric cancer patients was 1.62 ± 0.06 . The serum levels of autoantibodies against MMP-7 were significantly higher in ESCC than in healthy donors ($P < 0.001$, Figure 4A). The difference between healthy individuals and gastric cancer patients was also significant ($P < 0.001$, Figure 4B).

ROC curves were plotted to identify a cut-off value that would distinguish case from control samples. According to the ROC curve, the optimal cutoff value for ESCC was 1.65, providing a sensitivity of 78.0% and a specificity of 81.0%. The AUC for MMP-7 was 0.87 (95% CI: 0.80-0.93, Figure 4C) in ESCC patients. For gastric cancer, according to the ROC curve, the optimal cutoff value was 1.60, providing a sensitivity of 60.5% and a specificity of 71.7%. The AUC for MMP-7 was 0.75 (95% CI: 0.64-0.84, Figure 4D).

DISCUSSION

Immune response with antibody production can be elic-

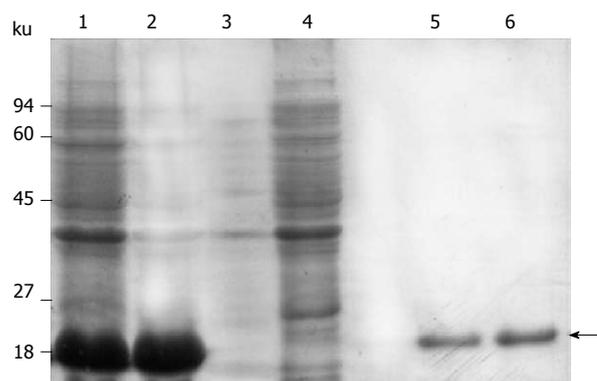

Figure 3 Soluble analysis and purification. 1: Samples induced with IPTG (0.4 mmol/L) for 4 h at 37°C; 2: Precipitate from the lysate of pET-28b/matrix metalloproteinase-7 (MMP-7) induced by IPTG; 3: The lysate supernatant of pET-28b/MMP-7 induced by IPTG; 4: Uninduced bacterial lysate; 5-6: Purified recombinant protein.

ited due to the overexpression of cellular proteins, such as Her2^[18], by the expression of mutated forms of cellular protein, such as mutated p53^[19], or by the aberrant expression of tissue-restricted gene products, such as cancer-testis antigens^[20] by cancer cells. These autoantibodies are raised against these specific antigens from the cancer cells; therefore, the detection of these antibodies in patients' sera can be exploited for cancer diagnosis in these patients. Furthermore, the immune system is especially well adapted for the early detection of cancer, because it can respond to low levels of an antigen by mounting a very specific and sensitive antibody response. Autoantibodies against cancer-specific antigens have been identified in cancers of the colon^[21], breast^[22], lung^[23], ovary^[24], prostate^[25], and head and neck^[26]. Thus, the use of the immune response as a biosensor for early detection of cancer through serum-based assays holds great potential as an ideal screening and diagnostic tool^[27,28].

MMP-7 is closely related to tumor invasion and metastasis: many studies have shown MMP-7 to be overexpressed in colorectal cancer^[29], esophagus^[30], stomach^[31], pancreatic cancer^[32], breast cancer^[33], prostate cancer^[34], and renal cell carcinoma^[35]. In addition, recent studies have shown that MMP-7 could be detected in the serum of cancer patients, including patients with ovarian^[36] and colorectal cancer^[17]. However, there has been no report regarding the diagnostic values of the serum autoantibodies against MMP-7 for any kind of cancers. In this study, we chose ESCC and gastric cancer as two typical gastrointestinal cancers to evaluate the diagnostic values of autoantibodies against MMP-7. Our results clearly suggested that serum autoantibodies against MMP-7 have the potential to be a tumor marker for ESCC and gastric cancer. MMP-7 is overexpressed in many cancers; therefore, elevated levels of autoantibodies against MMP-7 may also be present in other cancers as a nonspecific cancer biomarker. The samples in this study were mostly late stage serum samples; therefore, it is necessary to further validate these results using a large cohort of well-characterized patient samples, especially with early stage patient samples. It might be also

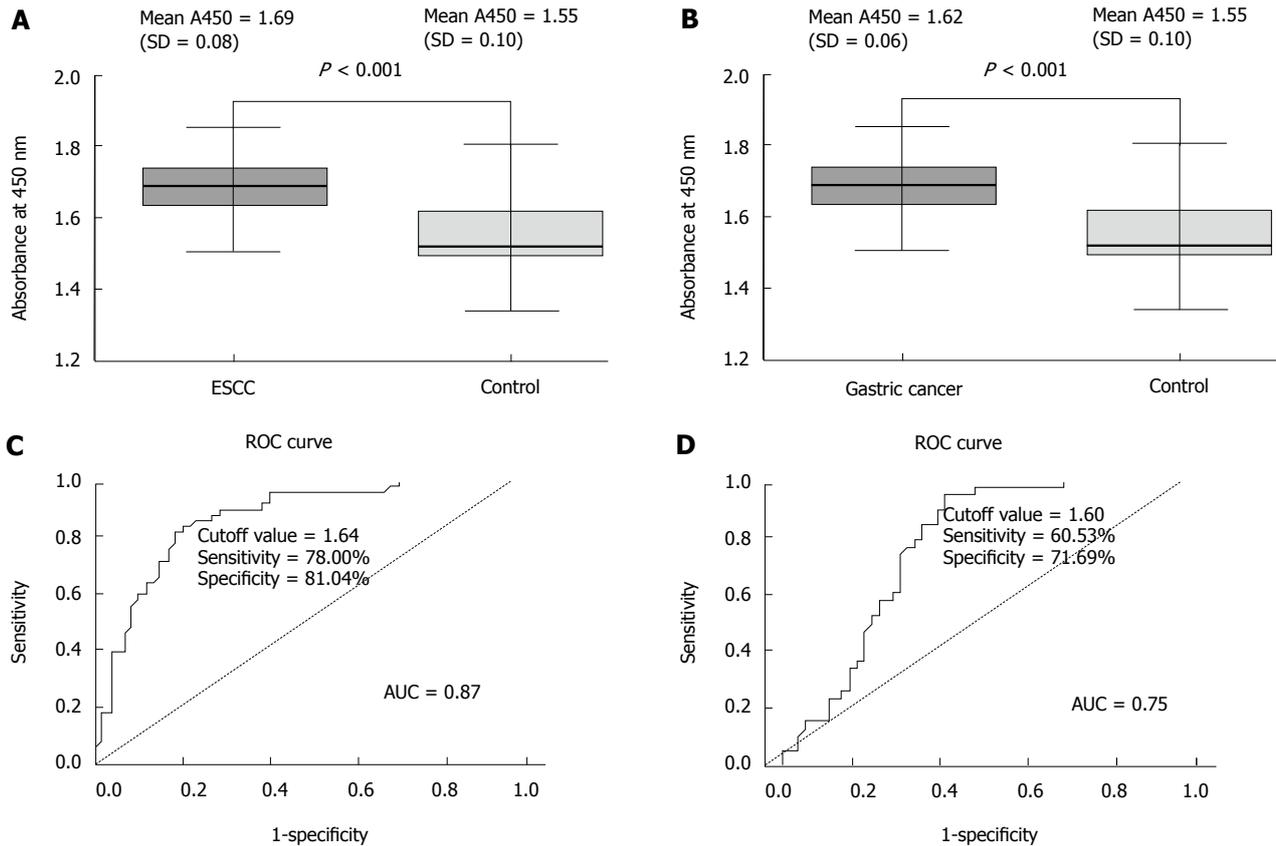

Figure 4 Comparison of the specificity and sensitivity of matrix metalloproteinase-7 autoantibodies. A: matrix metalloproteinase-7 (MMP-7) autoantibodies were detected by enzyme-linked immunosorbent assay (ELISA) in sera from patients with esophageal squamous cell carcinoma (ESCC) and control samples (Control); B: MMP-7 autoantibodies were detected by ELISA in sera from patients with gastric cancer (Gastric cancer patients) and controls (Control); C: ROC curve for ESCC serum antibodies against MMP-7; D: ROC curve for gastric cancer serum antibodies against MMP-7.

a good approach to further analyze the MMP-7 autoantibody diagnostic values in combination with the current tumor markers in ESCC and gastric cancer.

In conclusion, the results in this study are encouraging, even though further investigations are needed to evaluate its usefulness in population screening for ESCC. Moreover, the assay is easy to set up, because the recombinant proteins expressed and purified from *E. coli* are cost-effective and easy-to-standardize as serological reagents^[37].

COMMENTS

Background

Early diagnosis of esophageal squamous cell carcinoma (ESCC) has resulted in a significant reduction in morbidity and mortality, and new diagnostic markers could improve the results of screening. Matrix metalloproteinase-7 (MMP-7) is closely related to tumor invasion and metastasis. Increased MMP-7 levels have been found in ESCC. The present study aims to determine whether serum autoantibodies against MMP-7 in patients with ESCC could be used as biomarkers for diagnosis of the disease.

Research frontiers

New serum-based markers that could improve the accuracy of early detection of cancer are being sought. Recent findings suggested that MMP-7 is aberrantly expressed in ESCC. However, a prospective consecutive study of the evaluation of serum autoantibodies against MMP-7 as a diagnostic marker for ESCC has not been established.

Innovations and breakthroughs

Autoantibodies as biomarkers for early cancer detection have been recently

studied in other cancers. This is the first report to show that autoantibodies against MMP-7 could be a potential biomarker for ESCC diagnosis.

Applications

Serum autoantibodies against MMP-7 could become an important biomarker for ESCC early detection in clinics if this observation is further validated with a large cohort of patient samples.

Terminology

The Humoral Immune Response: is the aspect of immunity that is mediated by secreted antibodies (as opposed to cell-mediated immunity, which involves T lymphocytes) produced in the cells of the B lymphocyte lineage (B cell). B Cells (with co-stimulation) transform into plasma cells that secrete antibodies. Humoral immunity is so named because it involves substances found in the humors, or body fluids. Autoantibody: antibody that reacts with antigens found on the cells and tissues of an individual's own body. Autoantibodies can cause autoimmune diseases.

Peer review

The research described is very interesting. The manuscript is well written.

Abstract

Photodynamic therapy (PDT) is an established endoscopic technique for ablating Barrett's esophagus with high-grade dysplasia or early-stage intraepithelial neoplasia. The most common clinically significant adverse effect of PDT is esophageal stricture formation. The strictures are usually superficial and might be dilated effectively with standard endoscopic accessories, such as endoscope balloon or Savary dilators. However, multiple dilations might be required to achieve stricture resolution in some cases. We report the case of stricture that recurred after dilation with a bougie, which was completely relieved by a self-expandable metal stent.

INTRODUCTION

Photodynamic therapy (PDT) has been approved as an endoscopic treatment for Barrett's esophagus with high-grade dysplasia, and appears to be effective in the treatment of early esophageal cancer^[1-3]. The most common clinically significant adverse effect of PDT is esophageal stricture formation^[2]. In some published series, > 30% of the patients treated with PDT developed esophageal strictures^[3,4]. In the context of benign esophageal disease, stents have been used to seal esophageal perforations as a result of postoperative complications, endoscopic dilation procedures for achalasia^[5], and those associated with dilation of post-radiation strictures^[6]. Self-expandable metal stents (SEMSs) have been used for this indication.

We describe our experience with the successful resolution of an intractable post-PDT stricture using an SEMS in early esophageal cancer.

CASE REPORT

A 67-year-old man visited our hospital with dysphagia that involved solid and liquid food. Two months earlier, he had undergone PDT for early esophageal cancer. Initial endoscopy showed a flat, reddish lesion in the mid-esophagus. This lesion did not stain with Lugol's solution (Figure 1). Endoscopic biopsy revealed squamous cell carcinoma. Chest computed tomography (CT) showed no definite distant metastasis or lymph node enlargement. The patient refused surgical treatment, therefore, PDT was performed. The patient was given porfimer sodium (Photofrin II; Axcan Pharma, Quebec, Canada) intravenously at a dose of 2 mg/kg, 48 h before endoscopic photoradiation. Light was delivered from a laser (Ceralas PDT 633; CeramOptec, Bonn, Germany) that produced 630-nm light, with an

adjusted power output of 400 mW/cm, through a fiber that delivered a total energy of 180 J/cm fiber energy to the lesion. Two days after PDT, endoscopy showed circumferential coagulation necrosis with an ulcer involving the PDT-treated lesion (Figure 2). Two months after PDT, the patient complained of severe dysphagia. At that time, endoscopy showed luminal narrowing with fibrous scarring of the PDT-treated lesion (Figure 3). The patient underwent dilation three times with a Savary dilator (Cook Medical, Bloomington, IN, USA). However, the post-PDT stricture recurred within 1 mo. Consequently, a SEMS (Choo stent, 18 mm × 100 mm; MI Tech, Seoul, Ko-

rea) was placed through the stricture site (Figure 4). Two months after stenting, we removed the stent with grasping forceps, with no complications. After removing the stent, endoscopy showed a wide opening of the previous stricture and a biopsy revealed chronic inflammation with no tumor (Figure 5).

DISCUSSION

A stricture is the most common clinically significant ad-

verse effect of PDT^[2]. Patients who develop strictures after porfimer PDT typically present with symptomatic dysphagia 3 wk after treatment. The mechanism of stricture formation after PDT with porfimer sodium is unknown. It has been hypothesized that the deep, circumferential tissue injury and resultant inflammatory reaction produced by porfimer sodium PDT induces a fibrotic response that produces structuring^[4]. Other significant predictors of stricture formation are endoscopic mucosal resection before PDT, prior history of esophageal stricture, and multiple treatments of the same esophageal segment^[3,7,8].

Can the incidence of post-PDT strictures be reduced or even prevented? One study has shown that the use of oral prednisone beginning at the time of PDT light delivery did not prevent development of porfimer PDT strictures^[9]. One of the most important ways to prevent esophageal stricture may be to prevent circumferential mucosal injury of the esophagus during PDT.

The strictures are usually superficial and might be dilated effectively with standard endoscopic accessories, such as endoscope balloon or Savary dilators^[10]. However, multiple dilations might be required to achieve stricture resolution in some cases. The clinical course of post-PDT strictures appears to differ from that of other benign esophageal strictures. In a series of patients with peptic esophageal strictures, the median number of dilations needed for complete relief of dysphagia was only one^[11]. Compared with this, Prasad et al have reported that the median number of dilations for post-PDT strictures was four (range: 1-42). Another study has reported the need for multiple dilations in 11 of 34 patients^[8].

To predict which type of stricture is most likely to recur and benefit from stent placement, it is important to differentiate between esophageal strictures that are simple and those that are more complex^[12]. Simple esophageal strictures are focal, straight, and most have a diameter that allows passage of a normal-diameter endoscope. These strictures can successfully be treated with bougie or balloon dilation. Complex esophageal strictures are long, tortuous, or have a narrow diameter that does not allow the passage of any size of endoscope. The most common causes include caustic ingestion, anastomotic stricture, and severe peptic injury^[13]. Some post-PDT strictures are complex. These strictures are more difficult to treat, requiring at least three sessions, and are associated with high recurrence rates. If these strictures cannot be dilated to an adequate diameter, recur within a short time interval, or require ongoing dilation, they are considered to be refractory. Various stent designs, both SEMSs and self-expandable plastic stent (SEPSs), have been used to dilate these types of strictures.

As the long-term clinical success rate of both SEMSs and SEPSs in refractory benign strictures is well below 50%^[13], it is important to analyze which factors have played a part in these disappointing results. Factors related to long-term success were type of stricture, with post-radiation strictures being more successfully treated than peptic, anastomotic or achalasia strictures^[14], and length

of stricture, with shorter strictures being at lower risk of re-stricturing^[15]. However, there has been no report of long-term outcome of SEMSs for post-PDT esophageal stricture.

In the present case of stricture that recurred after dilation with a bougie, a SEMS completely relieved the post-PDT stricture. The stricture has not recurred during follow-up for > 1 year. The optimal timing of stent removal has been the subject of debate. Generally, when managing benign disease, the stent should be removed within 2 mo so that late stent-related problems are avoided^[15,16]. Tissue hyperproliferation at the ends of the stents represents a major limitation to long-term stent placement. Hyperplastic tissue ingrowth or overgrowth is the cause of stent-induced stricture or failure to remove a stent. Strictures that are longer or tighter require longer duration of stent placement^[16,17]. However, further study is needed with a larger number of patients and long-term follow-up to demonstrate a role for SEMSs in the treatment of post-PDT esophageal stricture.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Baishideng Publishing Group Co., Limited

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the

revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of *Gastroenterology*

World J Gastroenterol 2011 March 21; 17(11): 1383-1518

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (3), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

ABOUT COVER Kang EJ, Jeong SW, Jang JY, Cho JY, Lee SH, Kim HG, Kim SG, Kim YS, Cheon YK, Cho YD, Kim HS, Kim BS. Longterm result of endoscopic Histoacryl® (N-butyl-2-cyanoacrylate) injection for treatment of gastric varices: focus on primary prophylaxis. *World J Gastroenterol* 2011; 17(11): 1494-1500
<http://www.wjgnet.com/1007-9327/full/v17/i11/1494.htm>

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Helicobacter pylori (*H. pylori*) has co-evolved with humans to be transmitted from person to person and to colonize the stomach persistently. A well-choreographed equilibrium between the bacterial effectors and host responses permits microbial persistence and health of the host, but confers a risk for serious diseases including gastric cancer. During its long coexistence with humans, *H. pylori* has developed complex strategies to limit the degree and extent of gastric mucosal damage and inflammation, as well as immune effector activity. The present editorial thus aims to introduce and comment on major advances in the rapidly developing area of *H. pylori*/human gastric mucosa interaction (and its pathological sequelae), which is the result of millennia of co-evolution of, and thus of reciprocal knowledge between, the pathogen and its human host.

Key words: *Helicobacter pylori*; Gastric mucosa; Pathogen/host interaction; Gastric diseases; Bacterial virulence factors; CagA; VacA

Peer reviewer: Dr. Nawfal Hussein, PhD, Centre for Biomolecular Sciences, University of Nottingham, University Park, Nottingham, NG7 2RD, United Kingdom

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a Gram-negative microaerophilic, spiral bacterium that specifically colonizes the gastric mucosa, and it is the most common bacterial infection worldwide. Typically acquired during childhood, the infection can persist in the gastric ecosystem throughout the life span of the host, if untreated^[1]. Colonization of the stomach by *H. pylori* causes chronic gastritis that, during the decades that follow initial infection, can remain silent, due to the dynamic equilibrium between the bacterium and its human host, or evolve into more severe diseases, such as atrophic gastritis, peptic ulcer, lymphoma of the mucosa-associated lymphoid tissue or gastric adenocarcinoma^[2]. Gastric cancer, despite its declining incidence rate, remains the fourth most common cancer, the second leading cause of cancer-related death, and the 14th most common cause of death overall worldwide, which kills > 700 000 people each year^[3,4]. Early stages of the disease are often clinically silent, with patients having advanced stage disease at the time of diagnosis, and reported 5-year survival rates are approximately 20%^[5]. *H. pylori* infection is the strongest known risk factor for gastrointestinal malignancies that arise within the stomach, and epidemio-

logical studies have determined that the attributable risk for gastric cancer conferred by *H. pylori* is approximately 75%^[6]. While *H. pylori* infection increases the risk of developing both types of gastric cancer (i.e. diffuse and intestinal), chronic inflammation is not a prerequisite for development of diffuse-type cancer, thus suggesting that different mechanisms underlie the ability of *H. pylori* to induce gastric malignancies. Also, it is likely that *H. pylori* influences early stages in gastric carcinogenesis, as suggested by the demonstration that eradication of the infection significantly decreases the incidence of gastric cancer only in patients without premalignant lesions at the time of diagnosis^[7].

Development of gastric adenocarcinoma occurs in < 1% of *H. pylori*-infected subjects^[8]. Also, incidences of gastric carcinoma in *H. pylori*-infected individuals may vary dramatically among different geographical areas^[9]. This might be accounted for by *H. pylori* strain diversity within different geographical areas and/or within different individuals^[10], and further suggests that factors other than the bacterium may be involved in the carcinogenic process.

Evidence increasingly indicates that *H. pylori*-related gastric carcinogenesis is likely to be the result of a well-choreographed interaction between the pathogen and host, which is in turn, dependent on strain-specific bacterial factors, host genotypic traits and permissive environmental factors.

The present editorial thus aims to introduce and comment on major advances in the rapidly developing area of *H. pylori*/human gastric mucosa interaction (and its pathological sequelae), which is the result of millennia of co-evolution of, and thus of reciprocal knowledge between, the pathogen and its human host.

HOST FACTORS

The basic process that mediates *H. pylori*-induced damage is gastritis with its associated humoral and cell-mediated immune mechanisms. The outcome of *H. pylori* infection depends on the severity and the anatomical distribution of the gastritis induced by the bacterium. Individuals with corpus-predominant gastritis (so-called “gastric cancer phenotype”), which accounts for almost 1% of infected subjects, are more likely to develop hypochlorhydria, gastric atrophy, and eventually, gastric cancer; those with antrum-predominant gastritis (so-called “duodenal ulcer phenotype”), which accounts for up to 15% of infected subjects, have excessive acid secretion and are more likely to develop duodenal ulcer. Finally, subjects with mild, mixed antrum and corpus gastritis (so-called “benign gastritis phenotype”), which accounts for up to 85% of infected subjects, have almost normal acid secretion and, generally, no serious disease. These clinical outcomes seem to be mutually exclusive, and are largely influenced by a genetically regulated inflammatory response of the host gastric mucosa to the infection^[5,6].

A combination of polymorphisms in the host interleukin-1 (*IL1*) gene cluster (i.e. in the *IL1B* gene, which

encodes IL-1 β , a pro-inflammatory cytokine and a powerful inhibitor of gastric secretion, and in *IL1RN*, which encodes IL-1ra, the naturally occurring receptor antagonist of IL-1), and in the genes that encode tumor necrosis factor (TNF)- α , and IL-10, which result in elevated levels of IL-1 β and TNF- α and in low levels of IL-10 (which inhibits production of pro-inflammatory cytokines), confer a 27-fold increased risk of developing gastric cancer^[11]. Also, it has recently been demonstrated that polymorphisms in the promoter of *IL-8* gene, which enhance the transcriptional activity in response to IL-1 β or TNF- α , are associated with increased risk of gastric cancer in patients with *H. pylori* infection^[12,13]. This chemokine belongs to the CXC family and is a potent chemoattractant for neutrophils and lymphocytes, and has effects on cell proliferation, migration and tumor angiogenesis.

H. pylori infection is first handled by receptors of the innate immune response, and it is therefore conceivable that functionally relevant polymorphisms in genes of this arm of the immune system could affect the magnitude and subsequent direction of the host's response against the infection. In particular, toll-like receptor (TLR)4 is a member of a family of pattern recognition receptors that activate pro-inflammatory signaling pathways in response to microbes or pathogen-associated molecular patterns^[14]. TLR4 transduces signals that promote transcription of genes that are involved in immune activation, including nuclear factor (NF)- κ B and mitogen-activated protein (MAP) kinase pathways^[15]. A functional polymorphism at position +896 in exon 4 of the *TLR4* gene has been demonstrated^[16], which renders carriers hyporesponsive to lipopolysaccharide challenge by disrupting transport of TLR4 to the cell membrane, or impairing ligand binding or protein interactions^[16]. The defective signaling through TLR4 leads to an exaggerated inflammatory response with severe tissue destruction that causes gastric atrophy and severe hypochlorhydria. Two independent case-control studies have demonstrated that *TLR4*+896G carriers have an almost eightfold increase in OR for hypochlorhydria and gastric atrophy, and a 2.5-fold increase for gastric cancer^[17].

It is likely that subjects with an overall pro-inflammatory genetic makeup based on a combination of markers from the adaptive and innate immune systems, respond to *H. pylori* infection by creating an environment within the stomach that is chronically inflamed and with markedly reduced acidity. These environmental conditions favor the growth of other bacteria within the gastric milieu, which leads to sustained inflammation and decreased levels of vitamin C in gastric juice. This facilitates the formation of mutagenic N-nitroso compounds and reactive oxygen species (ROS)^[6,11], which ultimately leads to increased oxidative/genotoxic stress. Moreover, the profound inhibition of acid secretion that is associated with these pro-inflammatory genotypes favors a shift from an antrum-predominant to corpus-predominant gastritis with the onset of gastric atrophy and intestinal metaplasia (i.e. precancerous lesions).

H. PYLORI-INDUCED CELL SIGNALING IN GASTRIC CARCINOGENESIS

The host response to *H. pylori* infection may contribute to gastric carcinogenesis by promotion of a chronic inflammatory response that contributes to mucosal cell damage, or by interference with the mechanisms of proliferation and/or survival that regulate epithelial cell homeostasis^[2,6,10].

H. pylori proteins and induced responses play a major role in the increased disease risk associated with the infection, but they are not absolute determinants of gastric carcinogenesis. The chronic inflammation that develops in response to this organism greatly contributes to transformation. In this respect, bone-marrow-derived cells (BMDCs) have been demonstrated to home to and engraft the inflamed gastric mucosa of mice infected with *Helicobacter felis*. This phenomenon takes place within foci in which tissue injury induces excessive apoptosis and overwhelms the population of endogenous tissue stem cells^[18]. Subsequently, BMDCs in the inflamed gastric environment degenerate into adenocarcinoma, thus suggesting that gastric adenocarcinoma originates from BMDCs.

It is generally accepted that *H. pylori* infection results in a Th1-dominant response and that gastric inflammation largely depends on Th1 cell response with increased production of IL-1 β , TNF- α and IL-8, but not IL-4 and IL-10^[2,6,10,19,20]. A novel subset of effector T cells, identified by secretion of IL-17, has been defined as Th17 cells, which are distinct from Th1 and Th2 cells in their differentiation and function^[21]. TNF- α and IL-6 from activated macrophages/dendritic cells (DCs) are required for Th17 cell differentiation, whereas IL-12 and interferon- γ promote Th1 cell development, and IL-4 primes Th2 cell differentiation. Recently, it has been suggested that *H. pylori* infection mainly leads to a specific Th17/Th1 immune response that plays a major role in *H. pylori* infection, which promotes mucosal inflammation and contributes to bacterial colonization^[22]. In fact, *H. pylori* burden and inflammation are both reduced when IL-17 activity is blocked *in vivo* or IL-17^{-/-} mice are used^[22]. The dynamics of Th cell immune responses to *H. pylori* suggest that Th17 cell responses are induced earlier than Th1 cell responses, thus implying that Th17 and Th1 cells promote inflammation at different stages. It is likely that the Th17/IL-17 pathway modulates Th1 cell responses, and Th17 and Th1 cells may act synergistically to induce gastritis during *H. pylori* infection, by triggering the recruitment of inflammatory cells, including Th1 cells, into the gastric mucosa through the induction of chemokines. Also, the activated Th17/Th1 pathway may destroy gastric tissue by inducing matrix metalloproteinase (MMP) production, which favors subsequent pathogen dissemination and persistent infection. This might have implications also for the carcinogenic process associated with *H. pylori* infection. In fact, Th17 cells have been reported to contribute to gastric cancer pathogenesis^[23].

A concomitant helminthic infection that triggers a

Th2 cell response may blunt the Th17/Th1 cell responses associated with *H. pylori* infection, thus limiting the pathological consequences of *H. pylori* gastric colonization; in particular, gastric atrophy. This might partially explain why in African countries, where the prevalence of *H. pylori* infection acquired during childhood is close to 80%, the prevalence of gastric cancer is very low and accounts for < 2% of all malignant tumors^[24].

Variation in the ability of *H. pylori* strains to trigger the production of chemokines from gastric epithelium depends on the presence of a functional type IV secretion system (TFSS), which is encoded by the *cag* pathogenicity island (PAI). Although the *cag* PAI facilitates the translocation of CagA, the effect of this bacterial protein on cytokine synthesis is controversial; the majority of reports show no effect of CagA on cytokine synthesis, thus suggesting that other effectors are involved in the epithelial cytokine and chemokine response to *H. pylori* infection^[10,25,26]. Indeed, it has been shown that induction of pro-inflammatory responses in epithelial cells infected by *H. pylori* is mediated by the host protein CARD4 (also known as Nod1), an intracellular pathogen-recognition molecule, and that the effect is dependent on the delivery of peptidoglycan to host cells by the TFSS^[27]. Consistent with involvement of CARD4 in host defense, *Card4*-deficient mice are more susceptible to infection by *H. pylori* strains that contain the *cag* PAI than are wild-type mice^[27]. However, two studies have demonstrated that CagA directly induces IL-8 release from gastric mucosal cells^[28,29].

Although *H. pylori* elicits innate and acquired immune responses, the host is unable to eliminate the organism from the gastric mucosa, and chronic infection is the usual outcome^[2,6,30]. *H. pylori* antigenic variation (i.e. modification of bacterial antigenic determinants due to mutation or intragenomic homologous recombination) and mimicry of host antigens (i.e. bacterial expression of antigens similar to those expressed by the host)^[31], as well as induction of apoptosis by *H. pylori* in DC precursor monocytes^[20] and the intracellular persistence of the bacteria in gastric epithelial progenitor cells^[32], might be crucial for evasion of the immune response. Also, it has recently been demonstrated that *H. pylori* evades TLR5 innate immunity^[33]. In fact *H. pylori*, although being a flagellated organism, does not release flagellin, and recombinant *H. pylori* flagellin is much less active than *Salmonella typhimurium* flagellin in activating TLR5-mediated IL-8 secretion^[33].

Although it fails to eliminate the organism, the inflammatory response induced by *H. pylori* increases cellular damage. Activation of the TNF receptor by TNF- α results in the induction of apoptosis and mucosal cell damage. Increased apoptosis through direct or cytochrome-c-mediated activation of caspases is also contributed to by CD95/FAS and VacA. Recently, we have shown that *H. pylori* infection upregulated IL-21 levels in gastric epithelial cells *in vitro*, as well as in the gastric mucosa of *H. pylori*-infected humans^[34]. IL-21 overexpression is associated with increased production of MMP-2 and

MMP-9, through an NF- κ B-dependent mechanism. Increased MMP-2 and MMP-9 levels might contribute to chronic gastric damage and inflammation by degrading extracellular matrix proteins and by favoring the recruitment of circulating cells into inflamed tissue^[35,36].

Other ways in which pro-apoptotic pathways are induced during *H. pylori* infection include superoxide production by infiltrating neutrophils, elevated nitric oxide production by inducible nitric oxide synthase (iNOS), which is over-expressed in infected gastric mucosa^[2,6,37], and generation of ROS by bacterial secretion of γ -glutamyltranspeptidase (γ -GT) in the presence of glutathione (GSH) and transferrin, as a source of iron^[38]. In fact, it has been shown that γ -GT is important for *H. pylori*-mediated apoptosis of AGS (a cell line derived from a human gastric adenocarcinoma) gastric epithelial cells^[39]. It is also interesting to note that inflammatory stimuli that activate cytokine receptors and p38 (a stress-activated MAPK) can induce apoptosis. Conversely, activation of cytokine receptors and p38 might also inhibit apoptosis through NF- κ B and c-Jun activation^[6].

Inhibition or induction of apoptosis could both be relevant to *H. pylori*-related carcinogenesis. Induction of apoptosis might favor the development of atrophic gastritis and gastric gland recruitment of bone-marrow-derived precursor cells that might ultimately develop into intraepithelial cancer^[18]. Inhibition of apoptosis, on the other hand, represents the loss of a physiological safeguard against perpetuating the acquisition of DNA damage that can lead to the malignant transformation of cells^[2,6,10].

Proliferative response

Several signal transduction pathways are activated during the proliferative response of gastric epithelial cells to *H. pylori*-induced cell damage^[2,6]. The compensatory hyperproliferative response of gastric epithelial cells during *H. pylori* infection might be sustained by hypergastrinemia, increased expression of epidermal growth factor (EGF)-related peptides, and activation of the EGF receptor (EGFR) signal transduction pathway in gastric epithelial cells^[2,6,40-42]. In addition, translocation of CagA into gastric epithelial cells induces a growth-factor-like-response through activation of the Ras-MAPK pathway^[26]. Finally, it has been shown that *H. pylori* upregulates the expression of cyclooxygenase (COX)-2, the inducible isoform of the enzyme that is responsible for prostaglandin production, in human gastric epithelial cells *in vitro* and in human gastric mucosa *in vivo*^[37,43].

EGFR-related pathway is upregulated in a number of malignancies and is an important target for treatment of several neoplasms of the gastrointestinal tract. *H. pylori* has been shown to upregulate amphiregulin and HB-EGF, members of the EGFR ligands family, and to activate EGFR in MKN 28 cells^[40]. Subsequently, it has been demonstrated that EGFR transactivation by *H. pylori* is mediated through metalloproteinase-dependent cleavage of HB-EGF. The required metalloproteinases are likely to be members of a disintegrin and metalloproteinase (ADAM)

family. In particular ADAM17 is the ideal candidate enzyme for the regulation pathway^[42].

H. pylori-induced upregulation of COX-2 and EGF-related peptide expression in human gastric epithelial cells depends on the bacterial production of γ -GT^[38]. Activation of phosphatidylinositol-3'-kinase (PI3K)-dependent and/or p38-dependent pathways is responsible for *H. pylori* γ -GT-induced upregulation of COX-2 and EGF-related peptide expression in gastric mucosal cells^[38]. However, another study has demonstrated that upregulation of HB-EGF by *H. pylori* in human gastric epithelial cells is dependent on MAP kinase kinase activation, thus suggesting that EGF-related peptide expression might be regulated by different signal transduction pathways^[42]. In keeping with this, it has been demonstrated that COX-2 expression in gastric epithelial cells is also regulated by extracellular signal-regulated kinase (ERK)/MAPK activation^[43,44].

The upregulation of growth factor and COX-2 expression might increase the mitogenic activity of *H. pylori*-infected gastric mucosa, and protect cells from *H. pylori*-induced cell damage, which might therefore be regarded as early events in the development of *H. pylori*-associated gastric carcinogenesis^[2,6]. Upregulation of COX-2 and iNOS expression might also contribute to the high levels of oxidative DNA damage seen during *H. pylori* infection, and this could increase the mutation rate in infected hyperproliferative gastric mucosa^[2,37]. More recently, blockade of EGFR activation by HB-EGF neutralizing antibody or by abrogating ADAM17 expression, has been shown to protect gastric epithelial cells from *H. pylori*-induced apoptosis. The anti-apoptotic effect of EGFR activation seems to depend on PI3K-dependent activation of the anti-apoptotic factor Akt, increased expression of the anti-apoptotic factor Bcl-2, and decreased expression of the pro-apoptotic factor Bax^[45]. Because EGFR activation is linked to increased proliferation, reduced apoptosis, disruption of cell polarity and enhancement of cell migration, transactivation of EGFR by *H. pylori* might represent an attractive target for studying early events that may precede transformation. Also, the EGFR-related pathway might be regarded as a molecular target for treatment of gastric cancer^[46]. However, surveys of human gastric cancer specimens for evidence of overexpression or mutations of EGFR have found both events to be rare^[47].

The activation of a pathway mediated by EGFR, MAPK and COX-2 is also responsible for the induction of vascular endothelial growth factor (VEGF) expression in *H. pylori*-infected gastric epithelial cells^[44]. This effect is specifically related to the VacA toxin of *H. pylori*^[44], and is associated with a significant increase in blood vessel formation, suggesting that neoangiogenesis might contribute to tumor growth in *H. pylori*-related gastric carcinogenesis^[48]. *H. pylori* infection also promotes gastric epithelial cell invasion by inducing the production of MMP-7 through MAPK activation^[49], and MMP-9 and VEGF expression through an NF- κ B- and COX-2-mediated pathway^[50].

Another host effector that is aberrantly activated during *H. pylori*-induced gastric carcinogenesis is β -catenin, a ubiquitously expressed molecule that regulates the expression of several genes, including *c-myc*, the cyclin D genes, *MMP7* and *PTGS2* (which encodes COX-2)^[51]. Membrane-bound β -catenin is a component of adherens junctions that link cadherin receptors to the actin cytoskeleton. Cytoplasmic β -catenin is a downstream component of the Wnt signal transduction pathway. In the absence of Wnt ligand, the inhibitory complex composed of axin, adenomatous polyposis coli (APC) and glycogen synthase kinase 3 β (GSK3 β) induces the degradation of β -catenin, and maintains low steady-state levels of free β -catenin in the cytoplasm or nucleus. After binding of Wnt to its receptor Frizzled, Dishevelled is activated, thus preventing GSK3 β from phosphorylating β -catenin. This allows β -catenin to translocate to the nucleus and activate the transcription of target genes that are involved in carcinogenesis. Increased β -catenin expression or *APC* mutations are present in up to 50% of gastric adenocarcinomas^[52]. Moreover, an oncogenic *H. pylori* strain can induce nuclear translocation of β -catenin and activation of the LEF/TCF transcription factor that regulates the expression of β -catenin-responsive genes^[51]. β -catenin activation is dependent on the translocation of CagA into host epithelial cells, which reinforces the evidence that *cagA*⁺ *H. pylori* strains induce stronger activation of the signal transduction pathways that regulate the proliferation, invasion and survival of gastric epithelial cells^[51]. Recently, activation of PI3K and Akt has been shown to induce phosphorylation and inactivation of GSK3 β , which permits β -catenin to accumulate in the cytosol and nucleus^[53]. Sustained induction of PI3K/Akt signaling in response to *H. pylori* infection with subsequent β -catenin activation has been demonstrated to be due to the interaction of CagA with Met, the hepatocyte growth factor receptor, *via* CRPIA (for conserved repeat responsible for phosphorylation-independent activity), a conserved motif in the C-terminal region of CagA^[53]. Also, EGFR transactivation by *H. pylori* leads to activation of PI3K/Akt signaling, which ultimately leads to β -catenin activation^[45,54].

H. pylori has co-evolved with humans to be transmitted from person to person and to colonize the stomach persistently. A well-choreographed equilibrium between the bacterial effectors and host responses permits microbial persistence and health of the host, but confers a risk for serious diseases including gastric cancer. During its long coexistence with humans, *H. pylori* has evolved complex strategies to limit the degree and extent of gastric mucosal damage and inflammation, as well as of immune effector activity. Severe disease, associated with bacterial colonization, might reflect loss of this control^[51]. In this respect, we have recently demonstrated that Hp(2-20), a cationic α -helical peptide that has been isolated from the N-terminal region of the *H. pylori* ribosomal protein, L1, by interacting with formyl peptide receptors (FPRs), stimulates migration and proliferation of gastric epithelial cells *in vitro* and accelerates gastric mucosal healing *in vivo*^[55].

This raises the intriguing possibility that *H. pylori*, through the production of Hp(2-20) and its interaction with FPRs is also able to modulate the capacity of gastric mucosa to maintain or recover its integrity.

H. PYLORI INVASIVENESS AND INTERACTIONS WITH NON-EPITHELIAL CELLS: *IN VIVO* VERITAS

H. pylori is commonly considered an essentially extracellular, non-invasive bacterium. In an infection, 80%-90% of the bacteria freely swim into the mucus layer of the stomach, while the residual 10%-20% are in intimate contact with surface epithelial cells^[54,56]. As a consequence, a prominent immune-inflammatory response is invariably mounted in the underlying lamina propria. An intact epithelium should form a structural barrier that prevents direct contact between the bacterium on the luminal side and reactive inflammatory cells on the stromal side. Therefore, to explain how a strong mucosal and systemic reaction may be elicited, *H. pylori*-induced functional changes in the epithelium have been considered, such as a bacterial activation of the accessory immune competence inherent in the gastric epithelium, which in turn may modulate underlying stroma cells. Among pertinent epithelial changes so far documented are *de novo* or increased expression of pro-inflammatory cytokines, proteases (like cathepsins E, B, L, S and D) known to be involved in antigen processing, or HLA-DR and co-stimulatory molecules like B7-1 and B7-2 that are involved in antigen presentation^[57]. However, a few early light and electron microscopy studies have suggested the presence of *H. pylori* cells inside the gastric mucosa, either in epithelial cells and intraepithelial intercellular spaces, or in the underlying lamina propria^[57-59]. Nevertheless, the scientific community has exhibited a widespread reluctance to accept this published evidence. By contrast, a lot of *in vitro* studies have been carried out to investigate epithelial cell invasion by *H. pylori*, as well as roles and molecular mechanisms of direct interactions between *H. pylori* or *H. pylori* products/virulence factors and immune cells such as T or B lymphocytes, DCs, macrophages, monocytes, and mast cells^[57,59,60]. However, despite this interest, the importance of these *in vitro* studies has been questioned because of a lack of convincing evidence that *H. pylori* actually invades the gastric mucosa and interacts with non-epithelial cells, thus it is highly questionable whether any of these observations have clinical relevance^[60]. In this respect, Lu et al^[60] have strongly stressed the fact that *in vitro* studies are in theory designed to allow deeply detailed molecular study of *in vivo* events, whereas it is easy but meaningless to generate *in vitro* data irrespective of whether the experiment has an *in vivo* correlation. Similarly, other leading investigators^[61,62] have underlined the problem that *in vitro*-derived findings and considerations may make sense in terms of cell biology, but it remains to be established how and to what extent they apply to the *in vivo* situation,

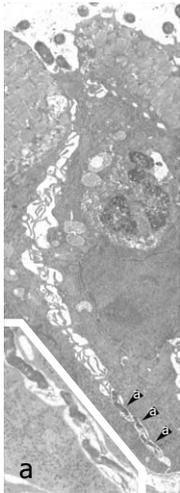

Figure 1 *Helicobacter pylori* penetration in human gastric epithelium *in vivo*. Three *Helicobacter pylori* (*H. pylori*) organisms (enlarged in a; 16 800 ×) lying in the deep intercellular intraepithelial space, just above the basal membrane. Note also luminal bacteria (top) overlying an apparently preserved tight junction, dilation of the underlying intercellular space, filled with lateral membrane plications, and an intraepithelial granulocyte (middle right, 6300 ×). which is now needed to be investigated in detail and in quantitative terms. Thus, only *in vivo* veritas!

Indeed, recently there has been a re-emerging interest for *in vivo* investigations of *H. pylori*/human gastric mucosa interaction. By microscopy and molecular investigations, Semino-Mora *et al*^[63] have demonstrated the presence of intracellular and interstitial *H. pylori* in preneoplastic as well as in neoplastic lesions of human gastric mucosa, with persistent intracellular expression of *H. pylori* virulence genes. These findings may substantially expand current concepts on the role of the bacterium in gastric carcinogenesis.

In a transmission electron microscopy study, Necchi *et al*^[57] have unequivocally detected *H. pylori* in intraepithelial, intercellular and stromal sites of the majority of human gastric biopsies, and have shown bacteria on their luminal side (Figures 1 and 2). In keeping with *in vitro* demonstration that *H. pylori* can functionally disrupt tight junctions, possibly through intraepithelial delivery of CagA^[64], CagA has been found to accumulate over and around tight junctions of colonized gastric epithelium, as well as ultrastructural alterations of the tight junctions that cover intercellular spaces that have been penetrated by *H. pylori* cells^[57]. These *in vivo* findings support the hypothesis that functional and structural alterations of the tight junctions may open the way to bacterial penetration into deep intercellular spaces, up to the underlying lamina propria. Consistent transepithelial penetration of *H. pylori* into infected gastric mucosa may help understand how the colonized mucosa invariably mounts a prominent local immune-inflammatory response, as well as a systemic immune reaction and, under special genetic conditions, even extra-gastric autoimmune pathology. In fact, direct contact (including intracellular penetration in some cases) between *H. pylori* or its remnants and immune-inflammatory stroma cells has been observed^[57].

The morphological and cytochemical detection of *H. pylori* (often well preserved, VacA- and CagA-storing, and apparently vital) inside intact epithelial cells of human gastric mucosa (Figure 2) has confirmed the intracellular pathogenic potential of the bacterium. This

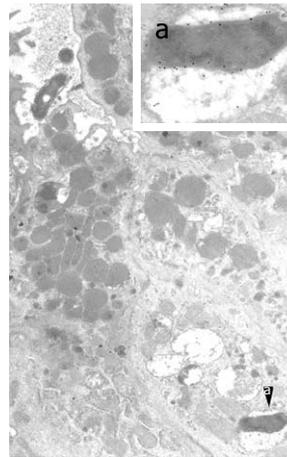

Figure 2 Intracellular *Helicobacter pylori* in human gastric epithelium *in vivo*. A well-preserved *Helicobacter pylori* (*H. pylori*) organism in a cytoplasmic vacuole, enlarged in a (55200 ×; 15 nm gold particles) to show immunoreactivity with anti-VacA antibody. Note two *H. pylori* in a luminal cleft (top left, 13500 ×). Reprinted from Necchi *et al*^[57], with permission from Elsevier.

observation confirms and extends previous *in vitro* observations that *H. pylori* exhibits an invasion frequency similar to that of *Yersinia* and greater than that of *Shigella*^[65]; both *bona fide* invasive pathogens. This is also in keeping with the expression of Nod1, a known intraepithelial pathogen-recognition molecule, by *H. pylori*-colonized epithelial cells^[27], as well as with the predominantly Th1 type of immune response that is elicited. In addition, confirmation of the intracellular occurrence of *H. pylori* is crucial when choosing appropriate antibiotics for bacterial eradication, as well as when monitoring their *in vivo* effectiveness after completion of treatment.

Of high interest is the presence of *H. pylori* in intestinal metaplasia (IM). Indeed, this finding substantially extends the possible interaction between *H. pylori* and IM in gastric carcinogenesis, from an early preneoplastic step that corresponds to epithelial progenitors^[32] and IM genesis, to the whole process of its progression to neoplasia. Indeed, it supports a persistent *in vivo* activity of several *H. pylori*-activated molecular mechanisms of gastric carcinogenesis such as CagA-mediated intracellular disruption of growth regulation^[26,66], inflammation-elicited NF-κB transcription factor activation^[67], and silencing of DNA mismatch repair genes^[68]. The demonstration by Necchi *et al*^[57] of *H. pylori* occurrence in dysplastic as well as in neoplastic growths, in agreement with that of Semino-Mora *et al*^[63], further substantiates and extends the *H. pylori* contribution to gastric carcinogenesis, and may explain some beneficial effects of bacterial eradication on IM-related cancer risk, as well as on cancer recurrence^[57].

Another *in vivo* study^[69] has recently shown that, in human superficial-foveolar gastric epithelium and its metaplastic or dysplastic foci, *H. pylori* products/virulence factors (sometimes coupled with bacterial bodies or remnants) accumulate in a discrete cytoplasmic structure that is characterized by 13-nm-thick cylindrical particles of regular punctate-linear substructure. This structure resembles the proteasome complex in size and structure, while being different from VacA-induced vacuoles, phagosomes, aggresomes or related bodies. Inside this novel cell compartment, named PaCS (for particle-rich cytoplasmic structure), co-localization of VacA, CagA,

urease and outer membrane proteins (OMPs) with NOD1 receptor, ubiquitin-activating enzyme E1, polyubiquitinated proteins, proteasome components and potentially oncogenic proteins like SHP2 and ERKs has been demonstrated^[69]. These findings suggest that PaCS is a novel, proteasome-enriched structure arising in ribosome-rich cytoplasm at sites of *H. pylori* product accumulation. As a site of selective concentration of bacterial virulence factors, the ubiquitin-proteasome system and interactive proteins, PaCS is likely to modulate immune-inflammatory and proliferative responses of the gastric epithelium of potential pathological relevance; also taking the mounting evidence for a role of the ubiquitin-proteasome system in cancer origin or progression^[70].

A hotly debated question waiting for a definitive answer is whether human gastric DCs are able to send cell processes that cross the epithelium, reach the lumen and directly contact and engulf *H. pylori*, as shown to occur for DC-mediated pathogen-sensing at the intestinal level. The dendritic, epithelial, granulocytic or macrophagic nature of the cell that first interacts with the bacterium seems to be important, given the different type and cellular distribution of microbial product receptors shown by different immunocompetent cells, and the different chemokines and interleukins that they release when activated^[27,62,71]. In fact, DCs have been found to respond differently when interacting directly with bacteria rather than secondarily to epithelium-bacteria contact, with IL-12 secretion and Th1 response preferentially activated only in the former case^[72].

By ultrastructural immunocytochemistry on endoscopic biopsy samples, clear-cut *in vivo* evidence has been provided^[73] of direct DC contact with *H. pylori* in the human gastric mucosa (Figure 3), which greatly extends the relevance of previous *in vitro* studies carried out on purified DCs. DCs have been shown to be present inside superficial-foveolar epithelium of *H. pylori*-infected (but not *H. pylori*-free) human gastric mucosa, and to send cytoplasmic extensions to the lumen, to which bacteria preferentially adhere (Figure 3). In addition, intraepithelial DCs are found to accumulate bacterial products like VacA, urease and OMPs in their cytoplasm. The importance of intraepithelial, lumen-contacting DCs lies in the well-known crucial role of these cells as sensors of pathogens, and as the first line of antibacterial immune defense of both innate and adaptive type^[74]. In fact, DCs have been shown to act as main processing and presenting cells of internalized antigens, and major regulators of cells involved in the mucosal inflammatory response. Depending on their mode of activation, they may secrete pro-inflammatory or anti-inflammatory cytokines and chemokines that dictate the composition of the cellular infiltrate, in addition to activating NK and T cells with either Th1 or Th2 effector and T regulatory cell responses^[73]. Thus, the direct interaction of DCs with *H. pylori* during active gastritis may be of key relevance. Also worth noting is the finding of a close adherence of DCs to surrounding epithelial cells along all or most of

their confronting membranes, with involvement of lateral folds and formation of focal interdigitating complexes. It has been speculated that this pattern, possibly related to the capacity of immature DCs to produce tight and adherens junction proteins, may be finalized to preserve the barrier function of the epithelium^[73].

Granulocytes have also been seen to contact and heavily phagocytose luminal *H. pylori*, while macrophages remain confined to basal epithelium, although taking up bacteria and bacterial products^[73]. The inhibitory role of VacA on phagolysosome formation and acidification with resulting persistence of engulfed *H. pylori* has been outlined^[73]; this may well allow macrophages and DCs to retain and translocate vital *H. pylori* to gastric lymph nodes, from which they have been cultivated^[76]. The substantial restriction of intraepithelial DCs to active, granulocyte-rich gastritis seems of interest, especially considering the dominant role of granulocytes in early, first-contact *H. pylori* gastritis. Although no direct morphological interactions have been observed between DCs and granulocytes, both have shown coexistence in the same mucosa and direct interaction with *H. pylori*, resulting in phagocytosis and intracellular accumulation of bacterial virulence factors^[73]. DC intracellular accumulation of *H. pylori* virulence factors like VacA, urease or OMPs, as documented in this paper, may also be of relevance for DC function and integrity; either as a source of antigenic material promoting the immune response or of cytotoxic damage. Indeed, signs of cellular damage have been observed in several intraepithelial DCs, including focal mitochondrial swelling, cytoplasmic edema and vacuolation and formation of autophagic vacuoles. These findings raise the issue of a possible impairment of DC function by accumulated bacterial toxins, which may reduce the effectiveness of the immune response and favor persistence of bacterial infection. Thus, this complex *in vivo* interaction of DCs, granulocytes and macrophages with *H. pylori* and *H. pylori*-infected epithelium is likely to have an important role in the origin, type specification, and outcome of the innate and adaptive immune responses.

VacA TOXIN AND ITS FUNCTIONAL INTERACTION WITH CagA: THE ART OF PRESSING THE BRAKE AND GAS PEDALS AT ONCE

VacA, the “vacuolating cytotoxin”, and CagA, the product of the cytotoxin-associated gene *A*, are virulence factors playing a pivotal role in *H. pylori*-induced pathogenesis. While VacA is defined as an A-B toxin (even though no enzymatic activity has been so far identified for any of its domain), CagA is usually defined as an effector protein: a bacterial protein delivered into host cells by a specialized bacterial machine so as to modulate a variety of cellular functions. Indeed, CagA is supposed to be directly injected into host cells by a TFSS. Many excellent reviews have been recently published on these two *H. pylori* virulence

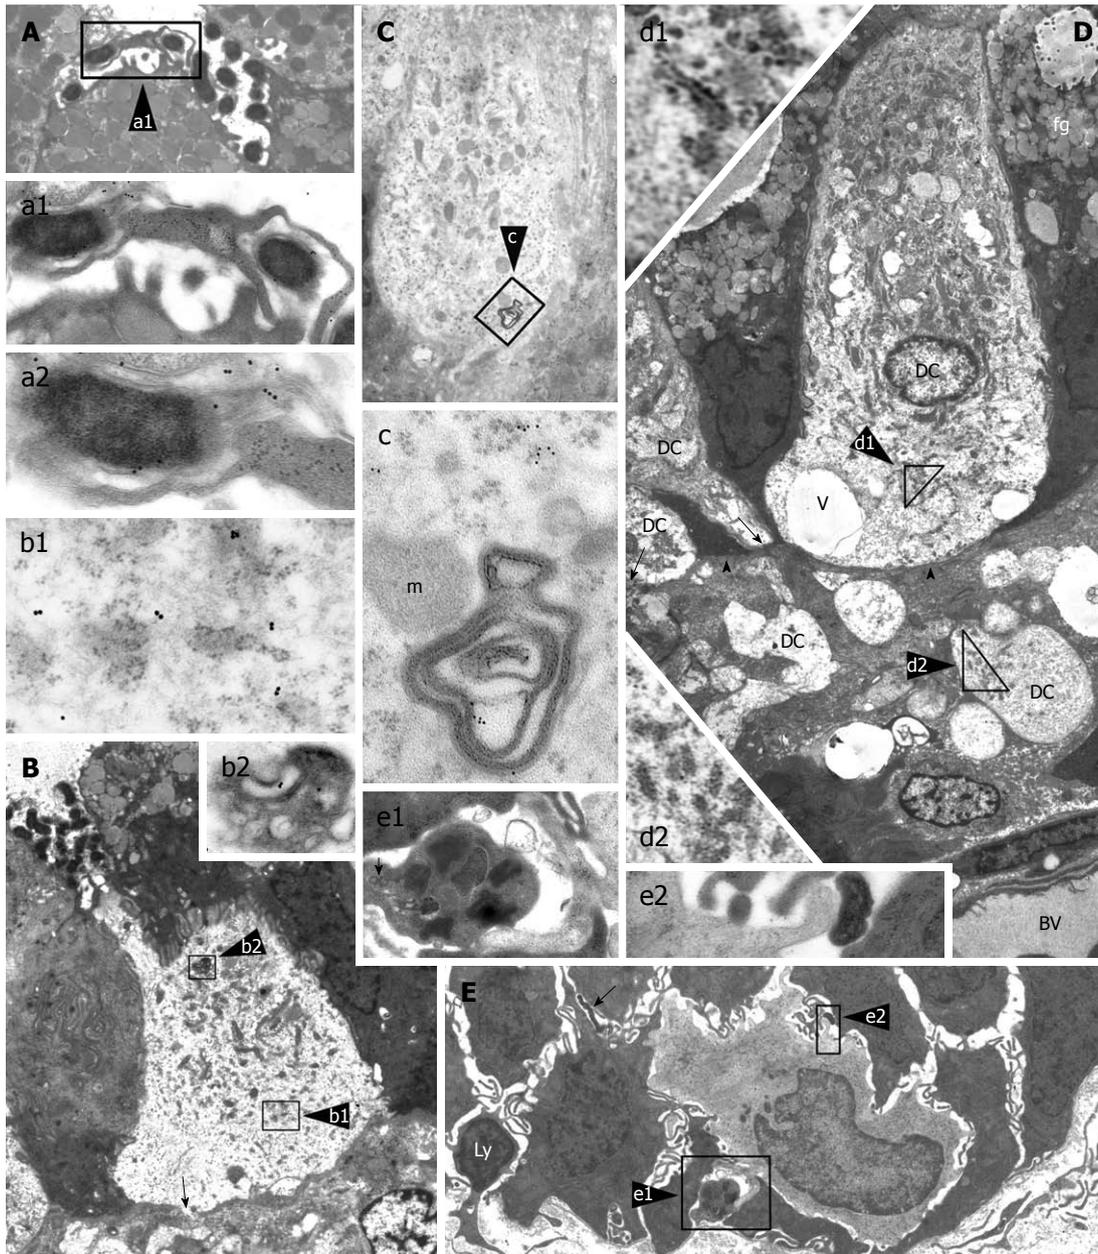

Figure 3 Intraepithelial dendritic cells in *Helicobacter pylori*-positive human gastric biopsies with active inflammation. A (5000 ×): Luminal ending of a dendritic cell (DC) process abutting on a collection of *Helicobacter pylori* (*H. pylori*); enlarged in a1 (16 000 ×) to show envelopment of a bacterium by caliceal veils (right); note in a2 (28 000 ×; detail of a1), close adherence of a clubbed process (bottom left) to another bacterium showing VacA immunoreactivity of outer membrane and flagella (upper right); B (3000 ×): Intraepithelial DC with a narrow luminal process directly contacting bacteria; note close membrane adhesion to surrounding epithelial cells, focal interruption of the basal lamina (arrow), and outer membrane protein (OMP) immunoreactivity of cytoplasmic vacuoles (b1, 32 000 ×) and a multivesicular late endosome/lysosome body (b2, 22 000 ×); C (8000 ×): DC with clear cytoplasm, close adherence to surrounding epithelial cells, numerous mitochondria, sparse ribosomes and small rough endoplasmic reticulum (RER) cisternae; cytoplasmic vesicles and membranous remnants of an intracellular bacterium, enlarged in c (42 000 ×), show VacA immunoreactivity; D (2000 ×): Nucleated DC with abundant supranuclear mitochondria, no secretory granules, small tubular RER cisternae (enlarged in d1, 18 000 ×), several cytoplasmic vesicles, scattered vacuoles (v), and close adhesion to epithelial cells. On the left, two DC processes (arrows) are contacting the basal membrane (arrowheads). Several cross or longitudinal sections of partly swollen cell processes are observed in the lamina propria; the largest of which (enlarged in d2, 12 000 ×) shows ultrastructural homology with DC cytoplasm, including scattered, small RER cisternae and vesicles; the precise cells of origin of such lamina propria processes could not be assessed. BV: Blood vessel; fg: Foveolar granules; E (2000 ×): Base of foveolar epithelium showing an immature monocytoïd cell (DC precursor?) with kidney-shaped nucleus, scattered ribosomes, a few juxtannuclear lysosomes, and no vesicles or granules; note a caliceal process embracing a mast cell (enlarged in e1, 15 000 ×; scroll bodies, arrow), a clubbed process adhering to *H. pylori* (enlarged in e2, 55 000 ×), a lymphoid cell (Ly) crossing the epithelium basal membrane and another intercellular bacterium (arrow). factors^[77-80], thus, we do not intend to discuss the well-known characteristics of these proteins in detail. Here, we focus on the most recent experimental data that shed new light on their structure/activity relationships, on their

internalization and trafficking in the host cells, and finally, on the apparent paradox of why *H. pylori* simultaneously produces two different virulence factors counteracting the effect of each other on host cells.

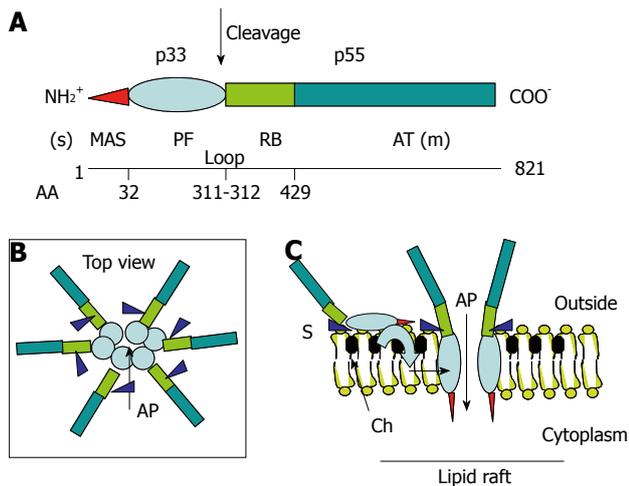

Figure 4 Structure-function relationships in the VacA toxin. A: VacA is an 88-kDa protein that can be cleaved into two subunits designated p33 (red and light blue) and p55 (light green and dark green). The cleavage between the subunit occurs in a flexible loop between residues 311 and 312. The two subunits are probably attached by non-covalent bonds between the p33 carboxy terminus and the N-p55 terminus. The amino-terminal part of p33 consists of 32 hydrophobic amino-acid stretch that is involved in the recognition of mitochondria (red) (MAS) (where the “s” toxin subtype site is located) followed by the p33 “core” subunit that forms, upon entry into the lipid membrane and oligomerization, an anionic channel (PF) (light blue). The toxin nicking site is located in the flexible loop domain. The amino-terminal part of p55 contains the cell receptor domain (about 110 amino acids) (RB; light green) followed by the type Va auto-transporter domain (AT; dark green) that is involved in the secretion of the toxin by the bacterium (where the “m” toxin subtype site is located); B and C: VacA binds as a monomer to its cell surface receptor sphingomyelin (S) with low affinity, then the p33 core progressively is embedded (light blue curve arrow) in the lipid membrane bilayers, at the level of lipid rafts [containing saturated lipid such as sphingomyelin and cholesterol (Ch)] and forms an anionic channel (AP) by oligomerization of p33. This multiplies by 6 the number of toxin cell receptors associated with the oligomerized VacA, thus increasing greatly the toxin affinity for the target cells.

VacA toxin

VacA has three well-confirmed cell activities, namely: cell vacuolation, apoptosis, and CD4⁺ T-lymphocyte activation and proliferation^[77,81]. This toxin was discovered as a secreted protein of *H. pylori* (at that time known as *Campylobacter pylori*) that induces a massive cytoplasmic vacuolation *in vitro*^[82]. About 55% of isolates of *H. pylori* are able to induce that cytopathic effect^[82]. VacA was shown later to form anionic channels into artificial lipid membranes, as well as cell membranes^[77]. VacA channel drives first an hyperacidification of late endocytic compartments by inducing, *via* the transport of anions into the lumen of these organelles, overactivity of the V-ATPase. Accumulation, by protonation, of weak bases such as ammonia (produced by *H. pylori* urease activity) into these compartments creates an osmotic imbalance that results in their swelling^[77,81].

Deep-etch electron microscopy of VacA preparations has revealed that the toxin forms regular oligomers with either six- or sevenfold radial symmetry^[77]. Oligomerization of the toxin molecules creates a cavity in the center of the oligomer and mimics the structure of a pore-forming toxin (Figure 4) such as the α hemolysin

of *Staphylococcus aureus*^[83]. In its mature state, VacA is a 88-kDa protein that can be cleaved into two subunits (Figure 4). According to their molecular mass, the N-terminal subunit is denominated “p33”, whereas “p55” is the C-terminal one (Figure 4). The N terminus of the mature p33 toxin subunit consists of a stretch of 32 uncharged hydrophobic amino acids (found in the VacA s1 subtype^[77,80]). The presence of additional residues to p33 (found in the s2 subtype), ablation deletions within the hydrophobic residues, or specific point mutations of amino acids in this stretch inhibit the vacuolating activity of VacA. From these results, it has been concluded that VacA channel formation involves the N-terminal 32 amino acids of p33^[77,80,84,85]. Other observations have led to the hypothesis that, in addition to the p33 N-terminal part and p33 itself^[85], a toxin domain localized in about the first 110 residues of the p55 is also required for the proper oligomerization of the toxin, for channel formation. This is supported by the fact that the minimal intracellular active domain of VacA contains the full p33 domain and about 110 residues of the N-terminal part of p55^[86,87]. In these experiments, the p33 toxin subunit, produced alone within cells, does not induce vacuolation^[86,87].

In addition to its vacuolating activity, VacA exhibits apoptotic activity^[88-90]. Importantly, these studies have revealed that the p33 VacA subunit is targeted to mitochondria and only is required for apoptosis^[88], and that a toxin mutant without vacuolating activity is non-apoptotic^[89]. Collectively, these data indicate that VacA induces, through the p33 subunit alone, apoptosis by acting on mitochondria, and most likely involves the toxin channel activity. Recently, it has been demonstrated that p33 oligomerizes without the need of p55 and forms an anionic channel with characteristics identical to that of the whole VacA molecule^[91]. Furthermore, ablation of the 32 N-terminal residues of p33 does not alter the pore-forming activity of the VacA subunit, but impairs the mitochondrial targeting activity of p33^[91]. Altogether, these new data indicate that the portion of p33 without its first 32 N-terminal residues (that we call the “core p33”) oligomerizes and contains all the channel activity of VacA. Domańska *et al*^[91] have clarified the following, formerly puzzling, observations: (1) that a mutant toxin with a major deletion in the p33 N-terminal hydrophobic amino acids (VacA delta 6-27), albeit inhibiting the vacuolation process, nonetheless induces anionic channels in artificial bilayers, even though exhibiting a longer delay of formation than the wild-type toxin^[85]; and (2) that a single deletion (δ 49-57) in the p33 core domain inhibits the oligomerization of the toxin and the vacuolation^[92]. Indeed, in the light of the study of Domańska *et al*^[91], these observations are well explained by the role of the p33 core without the N-terminal hydrophobic amino-acid stretch in forming the toxin channel by oligomerization.

As depicted in Figure 4, the structure-activity of VacA would thus be the following: starting from the N terminus, the 32-amino-acid stretch consists of a mem-

brane/mitochondrial targeting motif (which however does not participate in the toxin channel formation)^[91]. Then, the p33 channel core forms the channel activity, either in endosomal membranes or in the inner mitochondrial membrane (IMM)^[91]. At the end of the p33 subunit, there is the loop domain (58 residues) in which the toxin-nicking site is located (between residues 311 and 312). We speculate that a peptide motif just after the nicking site (i.e. residing in the 110 residues of the N-terminal part of p55 subunit) is implicated in the recognition of the toxin cell receptor. This is at odds with the current view that the toxin receptor domain is located in the so-called mid-region (m1/m2; i.e. residues 470-662) of p55^[77,80]. How to reconcile the recent data of Domańska *et al*^[91] with previous results indicating that the intracellular minimum portion of the VacA molecule active in the cytosol requires, in addition to p33, the 110 N-terminal residues of p55 for VacA oligomerization^[84,86,87]? Taking in account that the p33 toxin subunit oligomerizes alone and supports all the pore-forming ability of VacA^[91], why does expression of this toxin subunit alone into cells not lead to cell vacuolation^[86,87]? We speculate that the different intracellularly expressed (by cDNA transfection) toxin domains might induce their vacuolating activities not after intracellular synthesis, but rather only after leaking out of the producing cells, followed by endocytosis *via* the VacA cognate receptor. This would point to the 110 residues present at the N-terminal part of p55 as containing the VacA cell receptor motif (Figure 4). This position would indeed be ideally suited to recognize a cell surface molecule close to the lipid bilayers (Figure 4). The 3D structure of the p55 VacA subunit has been recently resolved^[93] and shows that a large part of this toxin subunit has the classical fold of autotransporter structures of the bacterial Va secretion system (by which the toxin is transported), which is mostly implicated in the bacterial secretion of VacA. This is supported by previous experiments showing that several deletions in the p55 subunit abolish the production of VacA by the bacterium^[85]. Gangwer *et al*^[93] have proposed that a conserved pocket, located in the m1/m2 regions of p55, is the receptor domain of VacA, which becomes fully accessible to the cell receptor when the toxin is assembled in either a single- or double-layered oligomeric structure. However, it is well known that it is necessary to disrupt the oligomeric structure of VacA (by acidic or alkaline treatments) to render it able to bind to its cell receptor. Furthermore, the mutant toxin δ 49-57, which does not form oligomeric structures, does not require to be acid-activated to bind the VacA cell receptor^[92]. This demonstrates that the toxin receptor domain is probably not fully accessible in the VacA oligomeric form. More recently, González-Rivera *et al*^[94] have shown that a mixture of purified p33 and p55 does not form oligomeric structures in aqueous solvent, but only monomeric structures, whereas, upon addition of a detergent that mimicks a lipid membrane environment, there is formation of oligomeric structures. This result suggests that the hydrophobic environment induces the oligomer-

ization, most likely by the p33-dependent formation of the channel. Importantly, it has also been shown that the p33 subunit markedly increases the cell binding of p55^[94]. Thus, VacA as a monomer first binds one cell receptor with low affinity, while upon oligomerization, bound to six receptors, it exhibit a very high affinity (Figure 4).

An important breakthrough, seminal for the identification of the VacA receptor, has been the finding that the toxin requires the integrity of lipid rafts and glycosylphosphatidylinositol-anchored proteins (GPI-APs) for its full vacuolating activity, which suggests that VacA follows the GPI-AP pathway of endocytosis by a lipid raft-dependent, clathrin-independent pathway^[95]; later described in detail by Sabharanjak *et al*^[96]. The first vacuolar organelles collecting the incoming GPI-APs involve new intracellular compartments that have been named GPI-AP-enriched early endosomal compartments (GEECs), which differ from classical early endosomes^[96]. This endocytic pathway, which also requires the small Rho GTPase Cdc42^[96], is currently named the GEEC endocytic pathway^[97,98], and has been confirmed to be exploited by VacA for its internalization^[99-102] (Figure 5). It was later shown that the GEEC pathway requires the presence, in the cell plasma membrane, of the unsaturated lipid sphingomyelin, and that the length of the sphingomyelin acyl chain determines its endocytic intracellular trafficking^[103]. This prompted an investigation that has demonstrated the role of sphingomyelin as the VacA cell receptor^[103]. Accordingly, it has been demonstrated that the length of the sphingomyelin acyl chain also determines the VacA intracellular trafficking^[102]. Normal cells contain in their lipid membrane a high proportion of long acyl chain sphingomyelin (C18), and VacA bound to this lipid follows the GEEC pathway^[102]. In contrast, when cells are artificially enriched in short-acyl-chain sphingomyelin (C2), the toxin does not follow the GEEC pathway but is recycled back to the plasma membrane in a Cdc42-independent fashion^[102].

Upon VacA treatment, transformed human CD4⁺ T lymphocytes (Jurkat cells) block their constitutive production of IL-2^[104]. It is well established that, in T lymphocytes, the nuclear factor NFAT, upon processing by the calcium-activated calcineurin protease, activates the transcription of the *IL-2* gene. Massive entry of calcium, through the voltage-dependent Ca²⁺ release-activated Ca²⁺ (CRAC) channels, is required to activate calcineurin. However, a VacA mutant without vacuolating activity has no effect on NFAT inhibition in Jurkat cells^[105]. Possibly, inhibition of NFAT by VacA is due to the electric depolarization of the lymphocytic plasma membrane, induced by the toxin anionic channel, which inhibits CRAC channels. Human primary T lymphocytes are, however, not sensitive to the deactivation of NFAT induced by VacA^[106]. Treatment of primary human T lymphocytes by phorbol myristate acetate, which induces their migratory activity, together with the expression of the CD18 β -integrin at their surface, restores the VacA-induced inhibition of NFAT^[107]. Furthermore, the direct

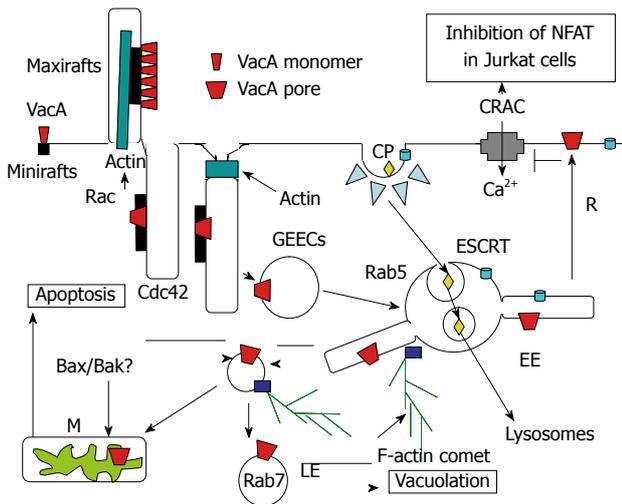

Figure 5 Endocytosis and intracellular trafficking of VacA. Monomeric VacA may bind sphingomyelin on small rafts. Then, by formation of membrane extensions by actin polymerization *via* Rac activation, VacA is clustered in macrorrafts where the p33 subunit oligomerizes and forms a channel that enters the membrane lipid bilayers. By a Cdc42-dependent process, VacA bound to sphingomyelin associated to lipid rafts is transferred into cell membrane invaginations (tubules?), which are then pinched out from the membrane, with the help of F-actin filament, which leading to the formation of the glycosylphosphatidylinositol-anchored protein-enriched early endosomal compartment (GEEC) compartment that contains VacA. The toxin is then transferred to Rab5-positive early endosomes (EEs). In EEs, VacA is selectively addressed to EE tubular extensions that are formed by an F-actin process. These tubular extensions are pinched out from the EEs and form highly motile vacuoles that are propelled by F-actin comets. These motile vesicles then fuse with mitochondria (M) or late endosomes (LEs), where VacA induces apoptosis or vacuolation. The proapoptotic channels Bax and Bak may be brought to mitochondria by binding on VacA-containing motile vacuoles. Some VacA molecules may be recycled (R) back to the plasma membrane where the channel activity of the toxin, by altering the electric transmembrane potential, inhibits the voltage-dependent Ca^{2+} release-activated Ca^{2+} (CRAC) channel. This blocks entry of calcium that activates the calcineurin protease, which is required for processing of the nuclear factor (NFAT), and therefore inhibits the transcription of the interleukin 2 (*IL-2*) gene in Jurkat T-lymphocytes. Ligands entering the coated-pit pathway (CP) are directed, by the endosomal sorting complex required for transport (ESCRT) complex, towards internal vesicles of EEs and form the multivesicular body (MVB). MVBs are directed to lysosomes, by being propelled along microtubules, where the contents of EE internal vesicles are transferred and degraded.

expression of CD18 into primary human T lymphocytes renders them able to respond to VacA^[107]. It has therefore been concluded that CD18 is the receptor for VacA in immune cells^[107]. This result is puzzling because, for all the different toxins studied so far, the cell binding activity always depends on a unique molecule (or a family of closely related molecules). However, a few observations do not support the role of CD18 as the sole VacA receptor in immune cells. Indeed, it has been demonstrated that, although human primary lymphocytes do not deactivate the nuclear factor NFAT, they respond perfectly to VacA by blocking their induced proliferation (i.e. blockage of their cell cycle) due to a mitochondria-induced depletion of ATP^[106,108,109]. This fact clearly indicates that VacA binds and penetrates into primary lymphocytes without needing CD18 (probably using the sphingomy-

elin receptor). The fact that VacA, entering *via* sphingomyelin in primary T cells, does not inactivate NFAT can be explained by the possibility that the toxin channel is probably not recycled (or only weakly recycled) to the plasma membrane, and therefore, is unable to block calcium cell entry through CRAC channel inhibition. We speculate that CD18 may not be a real receptor for VacA, but rather activates a signaling pathway (perhaps *via* the direct activation of CD18 by VacA, because association of VacA with CD18 has been reported^[107]) that modifies the intracellular trafficking of the toxin. For instance, stimulation of the migratory activity of T lymphocytes by CD18 signaling might activate Cdc42 boosting of the entry of VacA^[99], and increasing its recycling to the cell surface. It has recently been reported that the GEEC pathway is pivotal during cell migration^[98]. Another possibility would be that CD18-driven signaling drastically changes the lipid membrane content of long-acyl-chain sphingomyelin molecules toward short ones forcing the toxin to recycle back to the plasma membrane as recently described^[102].

How is VacA transferred from early endosomes to mitochondria and/or late endosomes to induce apoptosis and vacuolation? It is well known that ligands or membrane receptors taken up and routed for degradation into lysosomes are endocytosed by the clathrin-dependent pathway and targeted to the luminal vesicles of endosome-forming multivesicular bodies (MVBs) by the endosomal sorting complex required for transport (ESCRT) complex^[110] (Figure 5). Propelled along microtubules, MVBs then move to lysosomes where the content of MVB internal vesicles is selectively delivered for degradation. Several lines of evidences indicate that MVBs and lysosomes are not the cell compartments that undergo vacuolation by VacA activity: (1) no internal vesicles are observed by electron microscopy in VacA-induced vacuoles and the enlarged compartment does not have the structure of lysosomes^[95,111]; (2) the vacuolated compartment contains markers of both late endosomes and lysosomes^[112]; and (3) disruption of microtubules does not block VacA-induced vacuolation^[113]. Thus, the organelles that are vacuolated by VacA are likely post-lysosomal compartments that are required to recycle the membrane of MVBs from lysosomes. VacA is probably transferred directly to that compartment by an F-actin-dependent mechanism of endosome motility^[101]. Indeed, upon entry of VacA into early endosomes *via* the GEEC pathway, VacA-containing early endosomes exhibit F-actin comet tails associated with their cytosolic membrane surface, and are rapidly moving in the cytosol^[101]. Inhibition of these F-actin structures blocks the VacA transfer into the late endosomal compartment and vacuole genesis^[101], but also VacA-induced apoptosis and the localization of toxin molecules in mitochondria^[114]. These findings suggest that VacA is addressed to late endosomes and mitochondria by the same mechanism that relies on F-actin-driven vesicular motility. F-actin structures have recently been shown to take place at the level of the early endosomal

surface to induce budding of tubular structures followed by their cleavage to yield vesicles that retain F-actin tails^[115]. It is thus tempting to speculate that VacA might be first transferred from GEECs to the early endosomal limiting membrane, then into these tubular extensions, and finally into the membrane of the ensuing F-actin motile vesicles (Figure 5). These vesicles are then brought to late endosomes and/or mitochondria *via* stochastic fusion events by F-actin-driven vesicular motility (Figure 5). In this model, the transfer of VacA (or only of its p33 subunit) from the donor membrane to the recipient membrane (late endosomes or mitochondria) would be achieved by the membrane/mitochondrial N-terminal 32 residues of p33^[91] that may stick out of the membrane (Figure 4). This would explain why point mutations, or deletion or modification of the length of this amino-acid stretch might modulate the vacuolating process without altering the pore-forming capacity of the toxin^[91]. Importantly, according to this model, the toxin would never be released free in the cytosol^[90], which differs from the enzymatic subunits of canonical A-B toxin. By remaining associated with lipid membranes, out of reach of degradative processes, the VacA channel would keep its full activity for a long time, as observed several years ago^[111].

Inside mitochondria, the p33 subunit (or the full VacA molecule) induces, probably by the rupture of IMM integrity^[91], the release of cytochrome *c* (cyt *c*) and induction of apoptosis^[88]. However, pro-apoptotic channels must be activated or transferred into the outer membrane of mitochondria to ensure the release into the cytosol of cyt *c*, which, by activation of the Apaf1 molecule, induces the stimulation of the caspase cascade that results in cell death. Accordingly, the pro-apoptotic channels Bax and Bak have been shown to be activated during VacA-induced apoptosis^[116,117], and VacA is unable to induce apoptosis in Bax- and Bak-deficient mouse embryonic fibroblasts^[117]. It has been recently proposed that Bax and Bak might be directly recruited from the cytosol by endosomes containing functional VacA channels in their membranes, which allows their juxtaposition with mitochondria^[117]. This would be an ingenious way to combine the transfer of VacA channels to the IMM (and thereby the release of cyt *c* in the mitochondrial intermembrane space) and the leakage of cyt *c* in the cytosol.

Thus VacA is probably not really a multifunctional toxin, as previously defined^[77]. The diversity of VacA activities observed may be simply explained by the channel formed by the p33 subunit that is addressed to different cell membranes by the intracellular trafficking of the toxin, which may be different in different cell types or during cell differentiation (Figure 5).

Functional relationship between VacA and CagA

The gene encoding VacA is present in all the *H. pylori* strains, although only 55% express an active vacuolating toxin. This is due to either additions or deletions of peptide sequences in the toxin that probably impair the VacA intracellular trafficking or its binding to the cell surface,

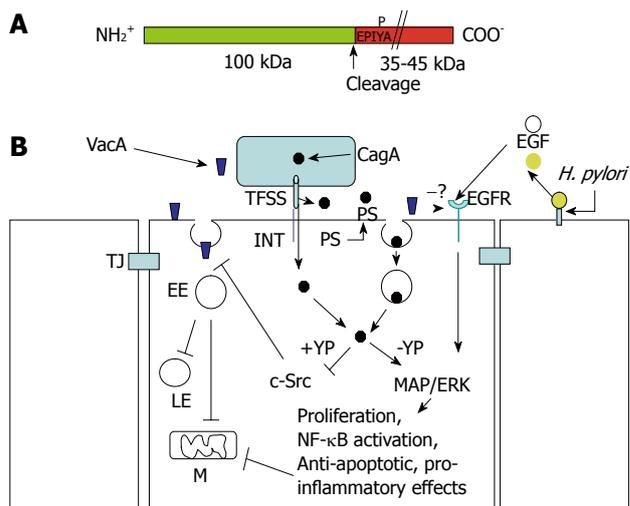

Figure 6 Structure of CagA and signaling cross-talk between VacA and CagA. A: CagA encompasses two fragments: the N-terminal 100-kDa fragment may contain the cell binding domain [to phosphatidylserine (PS)?]. Cleavage of CagA may take place just at the beginning of the first EPIYA motif, which can be tyrosine-phosphorylated by the c-Src tyrosine kinase. The C-terminal portion of CagA, which contains all the signaling activity of the molecule, may have a different molecular mass (up to 45 kDa) due to the repetition of the EPIYA-containing domain; B: CagA produced within the bacterium is transferred in the external medium by the type IV secretion system (TFSS) machinery. Two possibilities for CagA transfer into the target epithelial cell: (a) by binding to an integrin (INT), the TFSS punches the cell membrane and injects CagA; or (b) the TFSS induces the flipping of PS on the outer cell surface. By its 100-kDa N-terminal fragment, CagA binds PS and, upon endocytosis, which is transferred into the gastric cells. In the cytosol, the CagA signaling domain can be tyrosine-phosphorylated (+YP) and inhibits the c-Src kinase activity that is required to allow the transfer of VacA from glycosylphosphatidylinositol-anchored protein-enriched early endosomal compartments (GEECs) to early endosomes (EEs). This blocks vacuolation in late endosomes (LEs) and mitochondria (M)-dependent apoptosis induced by VacA. In an unphosphorylated (-YP) state, CagA activates mitogen-activated protein (MAP)/extracellular signal-regulated kinase (ERK) and nuclear factor (NF)-κB anti-apoptotic and pro-inflammatory pathways, which also counteract VacA-induced apoptosis. VacA interferes with epidermal growth factor (EGF) receptor (EGFR) activation and endocytosis, thus impairing the signaling pathway that is triggered by this receptor. Free EGFR ligands (EGF) are liberated from the cell-surface-bound molecules *via* cleavage triggered by *Helicobacter pylori* (*H. pylori*). TJ: Tight junction.

as we have described above. It is now well-established that the most severe gastric pathology (i.e. peptic ulcer and gastric cancer) is restricted to *H. pylori* type 1 strains, which contain in their chromosome a PAI named *cag* PAI, and which secrete an active vacuolating VacA toxin^[10]. The *cag* PAI encodes for the CagA protein and for the TFSS machinery that is implicated in the transport of CagA out of the bacterium, and its transfer to the host cell cytosol^[78,79]. CagA is a 135-145-kDa protein that contains its full intracellular signaling activity in its 35-45-kDa C-terminal part^[78,79,118] (Figure 6). Nevertheless, it is still unclear how and where the *cag* TFSS recognizes and target gastric epithelial cells so as to transfer CagA into their cytosol. Recently, two mechanisms have been proposed. One points to the recognition and binding of the TFSS to an integrin^[119,120], then, through a mechanical sliding due to bound integrins, the TFSS might punch the cell surface and deliver CagA into the cytosol^[120]. One caveat

for this mechanism is that *H. pylori* might deliver CagA at the apical pole of colonized epithelial gastric cells, whereas integrins are localized on the basolateral pole. On the other hand, it has been proposed that the TFSS does not punch the cell surface but induces the flipping out of the lipid phosphatidylserine (PS) from the inner (where it normally resides) to the outer leaflet of the target cell membrane^[121]. In this model, CagA, which is secreted constitutively by the TFSS, binds to PS through a lipid-binding peptide motif that is present in its 100-kDa N-terminal part^[121]. Following this binding step, a novel type of endocytosis (not yet better characterized nor defined) is induced that carries CagA, associated with PS, into epithelial gastric cells^[121]. If this is true, CagA should no longer be defined as an effector protein, but rather as a new type of A-B toxin that is released only in close proximity to the target cells.

Inside the cell, CagA may be tyrosine phosphorylated by the p60 c-Src kinase^[118]. Phosphorylation occurs on the 35-45-kDa C-terminal part of CagA on specific five-amino-acid motifs called EPIYA, which can be repeated several-fold and increase the size of this fragment^[26,78]. CagA can be split into two fragments by proteases^[122,123]. This generates a 100-kDa N-terminal fragment and a C-terminal 35-45-kDa one that contain all the cell signaling activity of CagA^[114]. Proteolytic cleavage of CagA does not require its tyrosine phosphorylation, and the nicking site is localized just at the onset of the first EPIYA motif (Boquet and Ricci, unpublished data). The 100-kDa N-terminal part of CagA might be involved in the cell recognition and transfer of the 35-45-kDa C-terminal part to the cytosol, as suggested by recent data^[121]. Therefore, CagA would indeed behave as a typical A-B toxin.

Two main intracellular activities of CagA are now well established. In its tyrosine phosphorylated state, CagA may act, either directly or upon association and activation of the tyrosine phosphatase SHP2^[78], to inhibit the c-Src kinase and therefore to affect many regulating proteins that depend on this enzyme, among which are those involved in the actin cytoskeleton assembly/regulation^[124]. In its non-tyrosine-phosphorylated form (or independent of the phosphorylation state), CagA activates the MAP/ERK and NF- κ B pathways^[53,125], which induce cell proliferation, inhibition of apoptosis, a typical cellular elongation called "hummingbird phenotype"^[66], and inflammatory response^[28] (Figure 6).

An increasing body of evidence suggests that CagA and VacA have several opposing cellular effects. It has been shown that, while CagA activates the NFAT nuclear factor, VacA inhibits it^[126]. Then, it has been demonstrated that CagA decreases VacA-induced vacuolation, while in turn, VacA reduces CagA-induced hummingbird phenotype formation^[127]. It has also been shown that VacA can downregulate CagA effects on epithelial cells by interfering with activation and endocytosis of EGFR, thus impairing the signaling pathway triggered by this receptor, and which plays a pivotal role in cell proliferation and hummingbird phenotype formation^[128]. Taken together,

these findings raise the hypothesis that VacA and CagA may downregulate the cell effects of the other, allowing *H. pylori* interaction with epithelial cells, while avoiding excessive cell damage.

We have recently shown that CagA interferes with VacA action by two complementary mechanisms^[114]. In its tyrosine-phosphorylated state, CagA inhibits the c-Src kinase and, in doing so, blocks VacA in the GEECs and thus its delivery to early and late endosomes (inhibition of the vacuolation) or mitochondria (inhibition of apoptosis). In its unphosphorylated state, CagA stimulates the NF- κ B pathway and, in doing so, induces anti-apoptotic activity (mediated possibly by the anti-apoptotic factor Bcl2) that also blocks VacA-induced apoptosis. We hypothesize that, once bacteria have colonized the gastric niche, the apoptotic action of VacA might be detrimental for the survival of *H. pylori* that are adherent to the mucosa, and thus the CagA counteracting action gives a rationale for the association of these two virulence factors in the most pathogenic *H. pylori* strains^[114]. This would be a new, highly ingenious mechanism by which a bacterium locally protects its ecological niche against the action of one of its own virulence factors. However, while exerting a beneficial role for survival and growth of the bacterium by counteracting VacA toxin, CagA injection in the gastric epithelial cells triggers pro-inflammatory and anti-apoptotic responses that are detrimental for the human host in the long-term, because they favor the development of ulcer and cancer.

Because it simultaneously delivers to its host two independent virulence factors that antagonize each other, *H. pylori* appears to act like a driver that presses the brake and gas pedals at once. This apparently paradoxical behavior is now emerging as an intriguing strategy to achieve the best fit between the bacterium and the hostile gastric environment that represents its ecological niche.

CONCLUSION

With regard to the pathogen, illness is often inadvertent; the result of exquisite tricks learned long ago and played on human cells to achieve the paramount goal of the microorganism: conservation of the species^[56,129]. Taken together, all the new findings described above strongly reinforce the notion that *H. pylori* is a skilled bacterium that has been smart enough to: (1) learn about the physiology of its host; (2) keep this information in its genetic library; (3) share the gene book with other organisms; (4) be "open minded" about acquiring new knowledge and discarding obsolete information; and, of key importance; and (5) know how to communicate with its human host, realizing that killing the host would oblige it to find a new one very quickly to ensure its reproductive success^[56,129,130]. *H. pylori* makes a long and hard, but also successful, journey in the human stomach, given that *H. pylori* is widespread and has probably been part of the human biota since time immemorial^[51,56,130]. Although *H. pylori* seeking survival may be sometimes achieved at the expense of the well-being

of the stomach and the host, human physiology and immunology have co-evolved in the presence of persistent gastric *H. pylori* colonization, and so are disrupted by its absence^[130]. As emphasized by Atherton *et al.*^[130], this imbalance of a long-lasting pathogen/host equilibrium, caused by progressive disappearance of *H. pylori* from some populations, may however result in an increased incidence of other diseases such as reflux esophagitis and esophageal carcinoma, as well as obesity, type 2 diabetes, and allergic disorders.

Abstract

Nodular regenerative hyperplasia (NRH) is a rare liver condition characterized by a widespread benign transformation of the hepatic parenchyma into small regenerative nodules. NRH may lead to the development of non-cirrhotic portal hypertension. There are no published systematic population studies on NRH and our current knowledge is limited to case reports and case series. NRH may develop *via* autoimmune, hematological, infectious, neoplastic, or drug-related causes. The disease is usually asymptomatic, slowly or non-progressive unless complications of portal hypertension develop. Accurate diagnosis is made by histopathology, which demonstrates diffuse micronodular transformation without fibrous septa. Lack of perinuclear collagen tissue distinguishes NRH from typical regenerative nodules in the cirrhotic liver. While the initial treatment is to address the underlying disease, ultimately the therapy is directed to the management of portal hypertension. The prognosis of NRH depends on both the severity of the underlying illness and the prevention of secondary complications of portal hypertension. In this review we detail the epidemiology, pathogenesis, diagnosis, management, and prognosis of NRH.

INTRODUCTION

Nodular regenerative hyperplasia (NRH) belongs to the category of liver diseases responsible for non-cirrhotic intrahepatic portal hypertension (NCIPH)^[1], which include sinusoidal obstruction syndrome, perisinusoidal fibrosis, hepatoportal sclerosis and incomplete septal cirrhosis (Figure 1). In these conditions, the etiology is ascribed to an intrahepatic hypercoagulable state, possibly secondary to sinusoidal endothelial injury. In many Asian countries, the most frequent cause of NCIPH is schistosomiasis.

NRH was first defined by Steiner^[2] in 1959 as a condition characterized by diffuse benign transformation of the hepatic parenchyma into small regenerative nodules distributed evenly throughout the liver with minimal or no fibrosis in the perisinusoidal or periportal areas. This feature distinguishes NRH from other causes of NCIPH^[1]. The presence of fibrous septa between the nodules definitively excludes NRH. However, in rare cases, one patient may exhibit histopathologic features of both NRH and other NCIPH disorders. These observations suggest that similar etiological factors may induce various adaptive liver reactions.

Over the last two decades, multiple labels have been applied to describe what we now define as NRH. Terms such as “miliary hepatocellular adenomatosis”, “non-cirrhotic nodulation”, “hepatocellular adenomatosis”, or “adenomatous hyperplasia” have been previously used. Although our current knowledge is limited to single case reports and case series, the number of patients being given the diagnosis of NRH has dramatically increased in recent years. Up to the year 2000 approximately 200 patients had been reported, whereas in the last decade more than 260 new cases of NRH were reported worldwide.

EPIDEMIOLOGY

As stated previously, our understanding of the epidemiology of NRH is based upon case reports rather than systematic population studies. In the United States National Library of Medicine/National Library of Medicine (PubMed) database (<http://www.ncbi.nlm.nih.gov>) 375 case reports have been published since 1975, however, not all cases meet the strict histopathologic criteria for NRH. For example, earlier publications used the term “nodular regenerative hyperplasia” as a misnomer for large regenerative nodules (LRN), associated with post-sinusoidal obstructive conditions such as congestive cardiomyopathy or Budd-Chiari syndrome.

NRH comprises 27% of all cases of non-cirrhotic portal hypertension in Europe and about 14% in Japan^[3-5]. Autopsy studies indicate an overall incidence ranging between 0.72% and 2.6%^[6-8]. Timely clinical diagnosis of NRH is challenging, because the majority of patients do not present with symptoms of portal hypertension. In cases where the etiology of portal hypertension was unclear the histology disclosed NRH in less than 1%^[9,10]. While NRH is rare in comparison to other causes of portal hypertension, its presence is being increasingly recognized.

In the case reports we reviewed, the majority of patients were between 25 and 60 years old at diagnosis, with rare cases in children and even fetuses^[1]. According to autopsy studies, the risk of development of NRH and its potential complications increases with age. In 2500 autopsies the incidence of NRH after 80 years of age was 6%, seven times greater than in people under 60 years of age^[6]. One case series reported the prevalence of NRH in six siblings distributed in three unrelated families indicating the possibility of a family distribution of this disease^[11]. Sex and ethnicity seem to play no role in development of NRH.

ETIOLOGY

Portal vasculopathy

NRH appears to be a result of an adaptive hyperplastic reaction of hepatocytes. Normally, the mitotic activity of hepatocytes is very low; hyperplasia is considered to be a physiological response to injury. Increased oxygen and nutrient demand, chronic inflammation, hormone-mediated dysfunction or compensation for damage or disease

elsewhere play an important role in this process.

The pathogenesis of NRH seems to be related to abnormalities of portal hepatic blood flow akin to the “atrophy-hypertrophy complex”. Hemodynamic disturbances at the level of the hepatic microvasculature occur either secondary to a mechanical obstruction or functional blood flow alterations. One hypothesis is that local portal venous hypoperfusion leads to apoptosis and hepatocyte atrophy, coexisting with maintained or increased blood supply to adjacent acini cells. Local hyperperfusion leads, in turn, to elevated levels of cell growth activators which act as autocrine or paracrine peptides. This hypothesis has been supported by both histopathologic examinations of liver biopsies as well as animal experiments, which showed microvascular changes involving either portal vein radicles or less frequently, arterial or hepatic vein branches. Wanless coined a “portal obliterative venopathy” phenomenon of recurrent embolization of the portal venules by platelet aggregates or thrombi originating in the portal venous system or in the spleen. The ensuing vascular inflammation and fibrosis results in reduced luminal patency of portal vein radicles and local reduction in blood supply to the liver, confirmed in 64 autopsies^[6]. Nakanuma *et al.*^[5] also provided evidence of obliterated portal venules in 107 liver biopsies of patients with NRH. There are few case reports of NRH without vasculopathy^[12], e.g. diffuse carcinoid tumor, where multifocal liver ischemia is due to a functional and not an organic cause^[13].

NRH is commonly found in patients with Abernathy's Syndrome a condition that includes the rare anomaly of congenital absence of the portal vein. The intestinal and splenic veins drain directly into the inferior vena cava, bypassing the liver entirely. It is an extreme model of vascular pathology, where the entire liver relies upon high-pressure arterial perfusion. Rare cases of NRH were also reported in patients with thrombosis of portal vein trunk^[14,15].

Immunosuppressant and chemotherapeutic drugs

Immunosuppressive medications may induce NRH by damaging endothelial cells of small hepatic veins. There are several reports of NRH developing in response to prolonged treatment with thiopurines, including azathioprine (AZA), 6-mercaptopurine and 6-thioguanine (6-TG). NRH was found in a single case among 30 patients treated with thiopurines for Crohn's disease. Accumulation of toxic metabolites may be a factor, as NRH was found more frequently in post-transplant patients with impaired metabolism of AZA due to the thiopurine-methyltransferase mutation^[16]. In another study NRH was found on liver biopsy in three patients treated with AZA for inflammatory bowel disease for more than 1 year, who presented with elevated liver enzymes^[17]. Gane *et al.*^[18] demonstrated histological regression of NRH with normalization of liver enzymes in four patients after withdrawal of AZA, after being used for an average of 64 mo. While the etiology of this remains to be elucidated, it has been stated that 6-TG, used in treatment

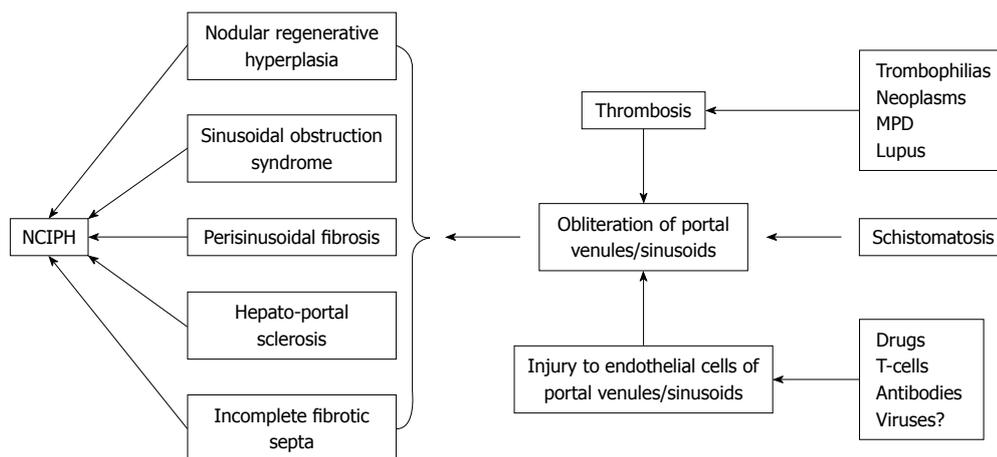

Figure 1 Development of nodular regenerative hyperplasia and other liver adaptive reactions causing non-cirrhotic intrahepatic portal hypertension. NCIPH: Non-cirrhotic intrahepatic portal hypertension; MPD: Myeloproliferative diseases.

of AZA-resistant forms of inflammatory bowel disease, may have a higher potential to induce NRH than other thiopurines^[19].

Other authors reported NRH in 8% of a human immunodeficiency virus (HIV)-positive cohort receiving highly active antiretroviral therapy (HAART)^[20]. Didanosine, a HAART drug responsible for liver injury and pulmonary hypertension, appears to induce NRH^[21].

An analysis of 334 liver biopsies from patients with metastatic colorectal cancer demonstrated that vascular pathology (as compared to chemotherapy-associated steatohepatitis) is a predominant histopathologic finding in chemotherapy-induced liver injury^[22]. There are numerous reports on NRH developing in patients with disseminated cancer after use of cytostatic drugs. Older reports associate NRH with use of busulphan, thioguanine or cyclophosphamide and, in more recent reports, with oxaliplatin-based therapies. Among 274 patients treated with oxaliplatin, sinusoidal obstruction syndrome and NRH were found in the histopathological study in 54% and 24.5% of patients, respectively. Peliosis and perisinusoidal or perivenular fibrosis were other vasculopathy-related liver diseases^[23]. Overall, about 70 cases of oxaliplatin-related NRH were reported in the literature (Table 1).

Underlying disease

NRH may develop as a result of underlying disease of autoimmune, inflammatory, neoplastic, or idiopathic origin (Table 1)^[143]. In patients with systemic lupus erythematosus (SLE), rheumatoid arthritis, and a host of other autoimmune diseases (including sarcoidosis or other granulomatous liver diseases)^[90], antibody reaction to the endothelial cells of small hepatic vessels combined with local hypercoagulation^[144] may predispose to NRH. Ziol *et al.*^[145] found intrasinusoidal infiltrate composed of cytotoxic CD8+ T-lymphocytes in 32% of 44 patients with NRH. These T-cells were located near atrophic liver cell plates and were adjacent to endothelial cells exhibiting evidence of apoptosis. Moreover, in patients with SLE, anticardiolipin antibodies could be incriminated for por-

tal vasculopathy leading to NRH^[78,79,86], although this is not a universal finding in SLE^[68].

NRH has also been associated with hematologic disorders, especially myeloproliferative diseases and congenital thrombophilias, where the hypercoaguable state may induce a progressive splenic and portal vein thrombosis and subsequent portal hypertension^[2].

DIAGNOSIS

One should consider a diagnosis of NRH in all patients with clinical symptoms of portal hypertension (splenomegaly, esophageal varices, ascites) but with normal transaminases and no manifestations of cirrhosis (gynecomastia, palmar erythema, spider nevi). There are mildly increased liver enzymes, usually alkaline phosphatase, in 11%-25% of patients^[4,127,146]. It is estimated that NRH is complicated by clinically overt portal hypertension in at least 50% of cases, with an augmented hepatic venous pressure gradient confirming sinusoidal obstruction^[147,148]. Close surveillance of patients with predisposing conditions is important for early diagnosis, especially in situations where drug toxicity may play a role. In patients on AZA for autoimmune hepatitis, the occurrence of splenomegaly should alert the clinician to the development of portal hypertension secondary to NRH.

In all cases of NCIPH, more common treatable causes (viruses, alcohol, metabolic and autoimmune disorders) should be eliminated first, followed by an assessment of the usual exposures (acetaminophen, vitamin A, copper sulfate, vinyl chloride, arsenic salt). Portal and hepatic venous thrombosis may be excluded on radiographic imaging.

Imaging

Imaging methods have poor sensitivity and specificity for NRH. A diffusely heterogeneous hepatic parenchyma may be the only imaging abnormality. On ultrasound, regenerative nodules are usually not visible due to a small size or isoechogenicity. The presence of well-delineated hypoechoic or isoechoic tiny lesions with a sonolusent rim are indistinguishable from metastases^[149]. Hyperchoic nodules have been reported in very rare cases of NRH^[150]. On computed tomography (CT), regenerative nodules remain isodense or hypodense in both arterial and portal venous phases, distinguishing NRH from focal nodular hyperplasia and adenomas^[3].

The significance of magnetic resonance imaging in the diagnosis of NRH is still controversial, although because of its inherent propensity to resolve soft tissue details it may be superior to CT in visualization of regenerative nodules. NRH lesions appear hyperintense on T1-weighted images and iso- or hypointense on T2-weighted images^[67,151], with a sensitivity and specificity of 70%-80% when using gadolinium contrast^[152]; others found more disappointing results^[153].

Histopathology

Grossly, NRH presents as diffuse fine nodularity of the liver with 1-3 mm diameter nodules. Granularity of the hepatic surface may resemble micronodular cirrhosis^[77,144]. Rarely, nodules are larger^[7,144], and may coalesce into a large tumor^[154,155]. NRH nodules appear paler than the surrounding normal hepatic tissue. Mild hepatomegaly may be present.

The diagnosis of NRH is secured by histopathology demonstrating regenerative nodules without parietal thick-

ening of portal venules, and no or minimal perisinusoidal and portal fibrosis on reticulin staining. Hepatocytes commonly show feathery degeneration of cytoplasm suggesting impairments of bile production or transport. Two morphologically distinct populations of hepatocytes coexist within the nodules: hypertrophied hepatocytes centrally surrounded by atrophic hepatocytes peripherally. Hypertrophic cells may compress terminal hepatic venules, which frequently appear shrunken and may be undetectable. Heterogeneity may be explained by uneven perfusion. Dilated sinusoids and thrombosed portal vein radicles are occasionally present^[24,156,157].

If a dominant large regenerative nodule is sampled, adenoma-like features with discrete cytoplasmic and/or nuclear atypia can be seen. Therefore, sampling a single nodule may yield an incorrect diagnosis and multiple liver sampling becomes necessary. Dysplastic large hepatocytes were seen in 42% of NRH samples, without high-degree dysplasia^[9]. NRH should also be distinguished from LRN occurring in livers with disturbed hepatic venous outflow (e.g. Budd-Chiari syndrome, veno occlusive disease, or congestive pericarditis) but well developed compensatory arterialization and preserved hepatic venous collaterals.

It should be kept in mind that in small biopsy samples histologic features of NRH may be lacking or incomplete^[158]. The diagnosis can be made after careful examination by the experienced hematopathologist with a high index of suspicion. In justified cases a laparoscopy with open wedge biopsy should be done.

Overlap syndromes, involving both NRH and portal or pericentral fibrosis due to hepatitis C viral infection, alcoholic, or non-alcoholic liver disease, can occur and in such cases the diagnosis of NRH may be easily overlooked^[24,77,156]. Fibroscan or fibrotest panels may rule out cirrhosis, but have limited clinical value^[153].

TREATMENT

Treatment of NRH therapy is directed towards elimination of the causative factor, once established. Concomitant diseases should be treated appropriately and with attention to minimizing drug toxicity. Long-term anticoagulation treatment is usually indicated in the thrombophilias. Anticoagulation therapy was found to be beneficial in early stages of NRH induced by HAART in HIV-infected patients^[57].

In patients with NRH, the mainstay of management is directed primarily to prevention and treatment of complications related to portal hypertension, i.e. variceal bleeding, the main source of mortality. Treatment of portal hypertension is standard: low sodium diet, diuretics, and endoscopic banding of esophageal varices. Splenectomy is not indicated. A portosystemic surgical shunt or transjugular intrahepatic portosystemic shunt may offer a significant therapeutic benefit, especially in the case of severe recurrent esophageal variceal hemorrhage^[56]. Liver transplantation is rarely necessary and is reserved for patients with hepatic failure^[159-162].

NATURAL HISTORY AND PROGNOSIS

Generally, the prognosis of NRH is better than that of chronic liver disease and is related to the complications of portal hypertension and the severity of the associated diseases, if present. In most cases the disease is slowly progressive, although the rate of nodular growth may be accelerated for unknown reasons^[163]. The long-term prognosis is uncertain and considers the level of underlying myeloproliferative, thrombophilic, or autoimmune processes. There are several case reports demonstrating the presence of both NRH and hepatocellular carcinoma without underlying cirrhosis, although a neoplastic process has yet to be proven^[163-167].

CONCLUSION

NRH is a rare condition of NCIPH liver diseases. Our understanding of the epidemiology of NRH is based upon case reports rather than systematic population studies. Timely diagnosis is challenging, because the majority of patients do not present with overt signs of portal hypertension. The pathogenesis of NRH is not well established, but an adaptive hyperplastic reaction of hepatocytes appears to be related to abnormalities of hepatic venous perfusion. Immunosuppressive medications may induce NRH by damaging endothelial cells of small hepatic veins. NRH may also develop as a result of underlying autoimmune, inflammatory, neoplastic, or idiopathic disease.

The knowledge on tumorigenesis in NRH is virtually non-existent as compared with hepatocellular carcinoma, adenoma and even cirrhotic regeneration. Genetic studies indicate that *RASSF1A*, a gene acting in the proapoptotic pathway, is increasingly methylated in hepatocellular hyperplastic hepatocytes^[168]. Moreover, in ceramide synthase 2 null mice that are unable to synthesize very long acyl chain ceramides, an extensive hepatocellular anisocytosis with widespread formation of regenerative nodules composed of hyperplastic hepatocytes was found^[169]. This finding emphasizes the role of ceramide synthase 2 activity and altered hepatic sphingolipid profile for liver proliferative homeostasis.

Common causes of extrahepatic and intrahepatic portal hypertension should be excluded before making a diagnosis of NRH. Imaging may be helpful during the initial clinical encounter with liver biopsy as the gold standard for diagnosis. An accurate diagnosis can only be made on histopathology, which shows diffuse micronodular transformation without fibrous septa. Management is directed primarily for prevention and treatment of complications related to portal hypertension. Outcome and prognosis is related to the severity of both portal hypertensive complications and the underlying associated diseases. Further studies may be helpful to elucidate a molecular mechanism for the vasculopathy that appears to play a central role in the adaptive hyperplastic reaction universally seen in NRH.

Abstract

Non-cirrhotic portal hypertension (PHT) accounts for about 20% of all PHT cases, portal vein thrombosis (PVT) resulting in cavernous transformation being the most common cause. All known complications of PHT may be encountered in patients with chronic PVT. However, the effect of this entity on the biliary tree and pancreatic duct has not yet been fully established. Additionally, a dispute remains regarding the nomenclature of common bile duct abnormalities which occur as a result of chronic PVT. Although many clinical reports have focused on biliary abnormalities, only a few have evaluated both the biliary and pancreatic ductal systems. In this review the relevant literature evaluating the effect of PVT on both ductal systems is discussed, and findings are considered with reference to results of a prominent center in Turkey, from which the term "portal ductopathy" has been put forth to replace "portal biliopathy".

INTRODUCTION

Although liver cirrhosis is a major cause of portal hypertension (PHT), in 20% of cases PHT is classified as non-cirrhotic, occurring as a result of portal vein thrombosis (PVT), congenital hepatic fibrosis, idiopathic PHT and other rare disorders. The portal vein, which is 12 mm in diameter, carries blood from intra-abdominal organs to the liver at a rate of approximately 1200 mL/min. Thrombotic occlusion of the portal vein, whatever the cause, is rapidly followed by compensatory mechanisms such as attempts at re-canalization and the development of new collaterals around the occluded portal vein, bile ducts and gall bladder, aimed at reestablishing portal blood flow to the liver. The portal vein is eventually replaced by a "cavernoma" after what is now known as portal vein cavernous transformation (PVCT). Splenomegaly, esophageal and gastric varices, portal gastropathy, and rarely ascites, are well recognized and extensively studied complications of PHT due to PVCT. However, the effects of PVCT on the biliary tree and pancreatic duct are as yet to be unequivocally identified. Furthermore, a dispute remains regarding the nomenclature of common bile duct (CBD) abnormalities which occur as a result of PVCT. Till today, many of the published case series have described biliary abnormalities resulting from PVT, but only a few have focused on both duct systems, the biliary and pancreatic^[1,2].

In a prospective study published in 1992, abnormalities of the biliary tree in patients with PVCT which resulted in an appearance mimicking cholangiocellular carcinoma on endoscopic retrograde cholangiopancreatography (ERCP) were described^[3]. Meanwhile the descriptive terms “pseudosclerosing cholangitis”^[4] and “portal biliopathy” have also been introduced into the literature^[5]. Till today, the issue of proper nomenclature of this phenomenon has not been sufficiently discussed, and there is a dire need for clarification.

DEFINITION AND NOMENCLATURE

Since the introduction of the term “pseudocholangiocellular carcinoma sign” to describe radiologic abnormalities mimicking cholangiocarcinoma caused by the compression of bile ducts by the thrombosed portal vein and its collaterals^[3], several different terms have been coined, including “portal biliopathy”^[6], “cholangiopathy associated with portal hypertension”^[7], and “portal cavernoma-associated cholangiopathy”^[8]. Finally, Dhiman *et al*^[9] proposed the term “portal hypertensive biliopathy” to refer to abnormalities of the biliary tree, cystic duct and gall bladder in patients with PHT.

It would seem that “pseudo sclerosing cholangitis” and “portal biliopathy” do not appropriately represent or define abnormalities of the biliary system which occur as a result of PHT. Biliary strictures in patient with PVCT are smooth rather than irregular, making the term “pseudosclerosing cholangitis” an erroneous description^[4]. “Portal biliopathy” is also a misnomer as it implies abnormal content of bile, which has never been reported before in any of the studies describing abnormalities of the biliary tree. Although in cases of PVCT jaundice is a common clinical finding, bile composition is considered to be normal. Additionally, the term “biliopathy,” suggests that the pathology is limited to the biliary tree, whereas PVCT has been shown to also affect the pancreatic ducts in most patients. Moreover, ERCP findings of cholangiocarcinomas rarely resemble those associated with PVCT, which also renders the term “pseudo-cholangiocarcinoma sign” inadequate.

The pancreatic ducts of patients with PVCT have been thoroughly evaluated at Hacettepe University for the past two decades (since 1992), where 78 patients with PVCT have undergone ERCP procedures. Seventy of the 78 (90%) patients had involvement of the biliary tree, 54 of whom (70%) had both biliary and pancreatic duct involvement. Considering that PVCT results in “morphological” abnormalities in both ductal systems, it would be expected the nomenclature should reflect the ductal changes observed in these patients instead of misleading physicians to associate this entity with changes in biliary content. The term “portal ductopathy” may provide a more satisfactory means of depicting abnormalities seen in the biliary and pancreatic duct systems in patients with PVT.

PATHOGENESIS OF PORTAL DUCTOPATHY

PVT was first described by Balfour *et al*^[10] in 1964. The re-canalization of the thrombosed portal vein at the hepatic hilum leads to this clinical and radiological condition. Ohnishi *et al*^[11] demonstrated that after complete obstruction, the “venous rescue” begins immediately and is completed in about 5 wk. The newly formed small collaterals are mostly observed around the intrahepatic and extrahepatic biliary tract, cystic duct and around the gall bladder. There are two venous plexuses of the bile ducts and gall bladder; the so-called epicholedochal venous plexus of Saint^[12], and the paracholedochal veins of Petren^[13]. Saint’s plexus, which forms a fine reticular web located on the outer surface of the CBD and hepatic ducts, becomes dilated and causes fine irregularities in the biliary tract^[12-14]. Petren’s plexus, on the other hand, runs parallel to the CBD and is connected to the gastric, pancreaticoduodenal and portal veins and to the liver directly. When the portal vein is occluded by a thrombus or tumor, both plexuses become dilated and cause extrinsic compression of the CBD. External compression and protrusion of these newly formed vessels on the biliary tree have been shown to be responsible for portal ductopathy in the biliary tree. However, the reasons behind changes to the pancreatic duct are yet to be elucidated. Extension of newly formed vessels towards the pancreas may be implicated, although this remains largely speculative.

In spite of the well established role of newly developed vessels around the bile system in the development of biliary abnormalities (more appropriately called portal ductopathy), most studies have overlooked other important factors. Ischemia, fibrosis, direct compression of the thrombosed vessels and excessive connective tissue formation around the biliary system have a major impact on the formation of biliary abnormalities. These factors contribute to the formation of a “frozen portal hilum” so that even if the PHT is relieved by any effective means, the cholestasis usually does not improve^[15-17]. The entire process mimics the reaction of wound healing in which neovascularization, collagen formation and tissue turnover occur and re-cycle for a long period of time. Duration of PVT does not seem to have an effect on the extent of the radiological appearance of the ductal abnormalities. Biliary strictures leading to complete biliary obstruction may be caused by ischemia or by encasement within a solid tumor-like cavernoma^[18]. The mechanism of ischemia causing bile duct changes in patients with PVCT remains unexplained. Venous damage due to portal thrombosis results in ischemic necrosis of bile ducts by compressing the vascular supply at the level of capillaries and the arterioles^[9], resulting in biliary strictures and cholangiectasis^[19]. Segmental strictures and dilatations seen on ERCP may involve both intra- and extra-hepatic bile ducts, morphologically very similar to those seen in ischemic cholangiopathy after liver transplantation^[20].

In a prospective study^[21], the biliary tree, either intra- or extra-hepatic, was found to be affected in almost all patients with known PVCT. Additionally, pancreatic duct abnormalities were apparent in a large proportion of this patient group. Use of the term “portal double ductopathy” was suggested to describe involvement of both systems. Involvement of any of the ductal systems individually would be referred to as either “portal biliary ductopathy” or “portal pancreatic ductopathy”.

CLINICAL IMPLICATIONS OF PARTIAL BILIARY DUCTOPATHY

It is well known that PHT, whatever its etiology, results in many complications such as ascites, portal gastropathy, esophageal and gastric varices, hypersplenism and severe coagulopathy, which pose a great challenge for clinicians in daily medical practice. Although PVT has been associated with many biliary abnormalities, the majority of cases are asymptomatic and only a small percentage of this patient population develop signs and symptoms of biliary obstruction, presenting with jaundice, pruritus, fever and abdominal pain.

Cholestasis, one of the main clinical features of portal biliary ductopathy, may be explained by the mass effect of enlarged collaterals or chronic thrombus compressing on the intra- and/or extra-hepatic biliary lumen. Ensuing ischemia and fibrosis may also be implicated. In some cases compression may be so severe as to result in secondary biliary cirrhosis due to longstanding severe cholestasis. Fortunately this complication is rare; one which at Hacettepe University has been encountered in only 2 cases, both of whom eventually underwent liver transplantation. Both patients are still under follow-up and are healthy, productive members of society. Mild jaundice seen in these cases because of incomplete obstruction of CBD is not uncommon, usually leading to unnecessary investigative tests towards the cause of the direct hyperbilirubinemia. Cholestatic enzymes are generally elevated in parallel with bilirubin levels.

PVCT has been reported to result in an increase in the frequency of biliary stone disease and related complications. Regardless of age, sex and underlying etiology, an association between PVCT and an increased incidence of biliary tree diseases has consistently been reported in the literature^[4,6,7,15,22]. In such cases, direct bilirubin levels are quite elevated. Stone formation is facilitated by the chronic but incomplete obstruction caused by the above-mentioned factors. It is necessary to stress that incomplete obstruction at multiple levels of the intra- and extra-hepatic biliary system may exist simultaneously. The occurrence of fever and abdominal pain during follow-up of a patient with biliary stones associated with PVCT should raise a suspicion of cholangitis.

According to Dhiman *et al*^[9], choledocal varices were observed in 7.5% of cases with PVCT. It is important to note that these varices may bleed severely, thus complicating the clinical picture. Additionally, endoscopic pro-

cedures such as stenting and stone extraction may also result in bleeding from these otherwise silent varices^[23-25]. Endoscopic ultrasonography (EUS) with Doppler is a particularly useful technique in diagnosing bile duct varices and differentiating them from bile duct stones. Great care should be taken when undertaking interventional procedures such as stone extraction and sphincterotomy, as even gentle balloon dilatation may lead to bleeding from these small varices. Of note, such patients may already have thrombocytopenia and some degree of coagulopathy because of splenomegaly and tissue congestion caused by PHT. Liver function tests are typically normal in patients with PVT in the absence of an underlying disorder such as polycythemia vera or Behçet's disease. However, according to unpublished data at Hacettepe University, most patients have prolonged prothrombin times compared to healthy controls, without having any other signs of compromised liver function, an entity which as yet remains unexplained.

CLINICAL IMPLICATIONS OF PARTIAL PANCREATIC DUCTOPATHY

Chronic congestion due to PHT affects almost all intra-abdominal organs, including the pancreas. The effects of PVCT on pancreatic parenchyma and duct have not been fully established. In the only study to investigate pancreatic exocrine function in this patient group, Egesel *et al*^[21] demonstrated that the pancreatic ducts of PVCT patients tended to be smaller than normal controls. Additionally, in 15 of the 18 patients with chronic PVT who had pancreatic atrophy, they found that urinary excretion of para-aminobenzoic acid was significantly less than in control subjects. Moreover, the authors have attributed some uncertain symptoms in these patients, such as abdominal discomfort, abdominal pain and anorexia, to latent pancreatic insufficiency shown by bentiromide test. As the pancreas has a tremendous capacity to manipulate the body needs, the manifestation of symptoms occurs after a latent period, requiring significant pancreatic parenchymal pathology. More sensitive tests are needed to clarify the extent of exocrine and endocrine dysfunction of the pancreas associated with this disorder.

Three other studies have demonstrated significant changes in the pancreatic ducts of patients with PVCT^[1,2,21]. In a report published in 2008^[1], 31 of 36 (86.1%) patients with PVT had luminal narrowing throughout the pancreatic duct, local atrophy at the head of pancreas with moderate dilatation behind the narrowed segment and other unclassified pancreatic duct abnormalities. Since 2008, 22 more patients with PVCT due to portal thrombosis have been evaluated at Hacettepe University, 16 of whom (72%) had pancreatic duct abnormalities demonstrated by ERCP. In total, 78 patients with PVCT have been seen since 1992, all of whom underwent ERCP as part of a work-up for unexplained elevations in ALP, GGT and direct bilirubin levels. Approximately 70% of patients had pancreatic abnormalities. Although the clinical sig-

nificance of these ductal abnormalities has not been well delineated, as stated above, partial pancreatic insufficiency and some other patient complaints such as abdominal pain and dyspepsia may be explained by chronic congestion due to PHT. It is possible that PVT contributes to more severe pancreatic congestion when compared to cirrhotic causes of PHT, as extension of the thrombus to the splenic vein may hinder pancreatic venous drainage. As a result, pancreatic duct and parenchyma may be more significantly affected. Further studies are needed to investigate this phenomenon.

DIAGNOSIS OF PORTAL DUCTOPATHY

Biochemical tests

Characteristically, the majority of patients with PVCT have a predominant cholestatic pattern of elevated liver enzymes. This biochemical finding reflects the biliary duct changes secondary to PVCT. Despite the presence of PHT manifesting as massive splenomegaly and large esophageal varices, serum albumin levels are usually within normal limits, unless massive bleeding occurs. Mild ALP and GGT elevations occur at any one time during the follow-up period of such patients. Clinicians must bear in mind that portal ductopathy may be responsible for such mild elevations, in order to avoid further unnecessary testing towards a cause of the cholestatic picture. In the presence of biliary strictures or stones, more marked elevations in cholestatic enzymes and bilirubin levels may be observed.

Liver biopsy

Although not part of the diagnostic work-up for portal ductopathy, a liver biopsy is essential in establishing whether PVT is due to cirrhotic or non-cirrhotic causes. It is necessary to perform this procedure to rule out the presence of liver cirrhosis, particularly in patients with atrophic livers with heterogeneous parenchyma on sonographic examination. Usually liver biopsies show normal or nearly normal histology, sometimes with signs of portal vein dilatation in the portal tract, or segmental narrowing of bile ducts with dilated small intrahepatic bile ducts. In congenital hepatic fibrosis, where histopathological examination is vital for making a diagnosis, portal vein abnormalities mimicking PVCT are relatively more common^[26,27].

Ultrasonography

Ultrasonography has traditionally been the most widely utilized modality for demonstrating biliary duct abnormalities in patients with chronic PVT. However, this technique has many shortcomings. For example, the presence of a high level of echoes in the porta hepatis may obscure the biliary system. Similarly, CBD may be hidden behind multiple collaterals demonstrating themselves as anechoic tubular and fibrotic structures. Color Doppler examination may help confirm the presence of multiple tortuous structures in the porta hepatis of patients with

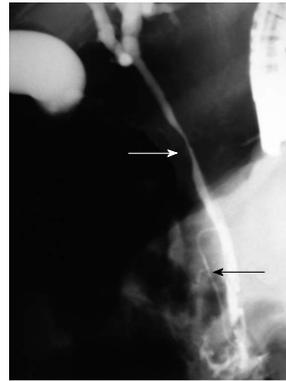

Figure 1 Endoscopic retrograde cholangiopancreatography showing typical portal ductopathy with external compression of the common bile duct (white arrow) leading to almost complete obstruction and dilatation of the intrahepatic bile ducts. The pancreatic duct is atrophic (black arrow).

PVCT. The nature of these tubular structures may not be correctly identified as blood vessels initially on grayscale. Real time and Doppler sonographic findings compatible with PVCT may prompt further evaluation by splenoportography, either with digital subtraction angiography or by computed tomography to confirm the diagnosis.

ERCP

This modality has established itself as one the most important procedures in diagnosing and defining the extent of involvement of the intrahepatic and/or extrahepatic biliary tree. As PVT may occur in either or both intra- and extra-hepatic portions of the portal vein, any part of the biliary system, including the gall bladder, may be affected by this thrombotic event. The development of cavernous changes, located at the portal hilum, may still affect the left and right intrahepatic biliary channels, usually manifesting as dilations. Changes described so far include undulation on the CBD along with narrowing and irregularity of various lengths and degree, sometimes leading to nearly complete obstruction (Figure 1), as well as segmental upstream and asymmetrical dilatation.

In contrast to obstruction of the CBD where both intrahepatic and extrahepatic bile ducts are proportionately dilated above the level of the obstruction, the most consistent radiologic finding that has been encountered at Hacettepe University is that the CBD tended to be narrower than the intrahepatic biliary ducts. In other words, the left or right hepatic ducts were usually dilated either alone or in combination with a dilated common hepatic duct.

Irregularities on the gallbladder wall may be seen, most probably because of intraluminal varices in a few cases. These varices may also be present in the CBD, manifesting themselves as filling defects, although rarely leading to bleeding, or so-called hemobilia.

There are mainly three types of pancreatic duct abnormalities: (1) Diffuse pancreatic duct abnormality in which the whole duct is narrowed with kinking, distortion of the normal anatomic pathway, thumb-printing type

of compression and with local luminal irregularities. The whole pancreatic duct is atrophic (Figure 1); (2) Proximal pancreatic duct abnormality in which the narrow part of the duct is limited to the level of head of pancreas, in contrast to the normal pancreatic duct in which the widest caliber is at the head of pancreas. Interestingly, the distal segment of these ducts appeared relatively dilated compared to the head region; and (3) unclassified abnormalities in which multiple small ducts connect to each other (different from pancreas divisum). Indentation, displacement and angulations occur.

Splenoportography with digital subtraction angiography

Although splenoportography is invasive with several reported complications, we have been utilizing this procedure in our hospital for a long time for the diagnosis of PVCT without the occurrence of any adverse effects. This technique is best for providing a clear image of the PVCT as well as other collaterals; however it does not evaluate the biliary system. Nowadays the use of CT portography as a less invasive imaging modality may be preferred.

Computed tomography with contrast

This procedure which helps to diagnose portal vein obstruction is particularly useful in identifying the presence of cavernous transformation, as well as for evaluating the dimension of bile duct abnormalities. Recently, CT portography has been introduced as an alternative to conventional angiographic splenoportography.

Magnetic resonance cholangiography with magnetic resonance portography

Not only is this technique non-invasive, but it is also more informative in that it allows for clear visualization of portal vein collaterals when confirming the presence of a cavernoma. However, in some cases ERCP is superior with regards to evaluation of the bile duct system. With the advent of high-resolution magnetic resonance (MR), MR cholangiography (MRCP) may eventually replace ERCP as the modality of choice for examining abnormalities of the intra-hepatic bile ducts, as it offers the advantage of being less invasive with fewer associated complications. If available, MRCP with MR portographic evaluation should follow real time or Doppler ultrasonography when investigating the bile duct system and portal vein.

EUS with Doppler

After conventional ultrasonography and Doppler ultrasound, the advent of EUS has been particularly useful in identifying CBD varices and/or bile duct stones, both of which may be the primary cause of biliary obstruction in patients with PVCT^[28]. Recognizing stones and differentiating them from varices is important as any intervention in the form of balloon dilatation or stone extraction may result in severe bleeding. In patients where an obstructive clinical picture is predominant, EUS with Doppler should

be performed to properly identify the cause of the obstruction, whether it is due to bile duct varices, stones, strictures or a tumor. In this perspective, EUS is a quite useful, even inevitable procedure.

TREATMENT

Most patients with portal ductopathy who are asymptomatic do not require any treatment. When symptoms due to stone formation, obstructive jaundice and cholangitis occur, treatment should be adjusted individually according to patient characteristics. Naturally, the occurrence of PVT warrants investigation into the cause, whether there is an underlying myeloproliferative disorder, deficiency of anticoagulant proteins, or an autoimmune disease. In the presence of an underlying thrombophilic condition, anticoagulant treatment may be indicated. On a different note, a proportion of patients may first present with variceal bleeding from the upper GI tract. Although the management of variceal bleeding is beyond the scope of this paper, it is important to stress that bleeding from gastric and esophageal varices may prove very challenging.

As mentioned before, PVCT results in a pathological condition involving ductular organs; CBD and pancreatic duct. Since bile composition is not an issue, all efforts should instead focus on the management of strictures, stones or sludge in the biliary tree. In cases such as these, endoscopic papillotomy and, if indicated, stone extraction and balloon dilatation, are the treatment modalities of choice. In some cases, concomitant presence of severe biliary stricture and biliary stones may be observed^[14]. This poses a challenge for the endoscopist, since after performing a sphincterotomy followed by stricture dilatation, great care should be taken while extracting any stone, since underlying thrombocytopenia due to hypersplenism and the presence of small or large varices in the peri-ampullary area and inside the CBD result in the risk of severe bleeding, further complicating an already complex and delicate clinical condition. In fact, some cases may even require the use of a mechanical lithotripter to crush large stones into small pieces.

Liver transplantation should be reserved for patients who develop secondary biliary cirrhosis or severe liver failure. At Hacettepe University, only 2 female patients developed secondary biliary cirrhosis due to biliary strictures and stone formation, both of whom underwent successful liver transplantation. To date, both patients are under follow-up with no significant restrictions in their daily activities.

CONCLUSION

Several disorders result in thrombosis of the portal vein which eventually undergoes cavernous transformation. The intra- and extra-hepatic bile ducts are affected by these changes in almost all cases, with relatively less frequent involvement of the pancreatic duct. Although sev-

eral terms such as “portal biliopathy” and “pseudocholangiocarcinoma sign” have been postulated to describe these changes, to allay any doubts regarding abnormalities in bile composition, use of the term “portal ductopathy” may be more appropriate. Involvement of both duct systems may be further described as “portal double ductopathy”. Clinical implications of portal ductopathy consist of cholestasis, stone formation, and consequently cholangitis.

Abstract

Crohn's disease (CD) is a chronic inflammatory bowel disease. Research has identified genetic predisposition and environmental factors as key elements in the development of the disease. However, the precise mechanism that initiates immune activation remains undefined. One pathway for luminal antigenic molecules to enter the sterile lamina propria and activate an immune response is *via* transcytosis. Transcytosis, although tightly regulated by the cell, has the potential for transepithelial transport of bacteria and highly antigenic luminal molecules whose uncontrolled translocation into the lamina propria can be the source of immune activation. Viewed as a whole, the evidence suggests that unregulated intestinal epithelial transcytosis is involved in the inappropriate presentation of immunogenic luminal macromolecules to the intestinal lamina propria. Thus fulfilling the role of an early pre-morbid mechanism that can result in antigenic overload of the lamina propria and initiate an immune response culminating in chronic inflammation characteristic of this disease. It is the aim of this paper to present evidence implicating enterocyte transcytosis in the early etio-pathogenesis of CD.

INTRODUCTION

Crohn's disease (CD) is a chronic, lifelong, and unrelenting inflammatory bowel disease that mainly strikes young people in the prime of their productive life^[1]. There are over 600 000 individuals with CD in North America, with up to 40 000 new cases being diagnosed each year, and double that amount at risk, based on a monozygotic concordance rate of 50%^[1-3]. The effects on the patient and their family are devastating, with lifelong medication and repeated abdominal surgeries to relieve obstructed bowel, intestinal bleeding, or abdominal pain. Studies have shown that the age adjusted mortality risk from CD is over 50% greater than in the general population^[2,4].

Current treatment for CD consists of inhibiting the immune response with powerful immunosuppressive agents. These medications have serious side effects and can eventually lose their therapeutic effect^[5]. More importantly, immunosuppressive agents do not alter the natural history of this disease, suggesting that the immune response in these individuals is a secondary reaction to an, as yet

undiscovered, primary cause, which results in chronic immune activation within the intestinal wall^[5,6].

The etiology of CD is currently unknown. It is generally attributed to a faulty immune system; however, despite decades of research, no antecedent immune abnormality has been identified in these individuals. A closer review of pertinent studies reveals that the immediate causal mechanism of CD may have its origin in a process of unregulated transcytosis of intestinal luminal contents by intestinal epithelial cells.

The data presented in this paper suggests that a primary inherited cell membrane defect may be responsible for the initiation and perpetuation of a pathological transcytotic state, allowing bacteria and other intestinal contents to persistently penetrate into the bowel wall and initiate a chronic life-long inflammatory response characteristic of this disease.

The aim of this paper, therefore, is to present evidence that unregulated intestinal transcytosis may have a significant role in the initiation of CD, and to provide data implicating an antecedent cell membrane abnormality as a primary inheritable factor capable of initiating this pathologically altered transcytotic state.

WHAT IS TRANSCYTOSIS?

Transcytosis is the transport of macromolecules (cargo) from one side of a cell to the other within a vesicular cell membrane-bound carrier. Conceptually, transcytosis can be divided into three distinct processes; absorption of molecules (endocytosis), conveyance of cargo through the cell (transcellular transport), and extrusion of cargo at the other side of the cell (exocytosis). During endocytosis, extracellular macromolecules converge upon the cell as a portion of the plasma membrane is invaginated at the point of contact and pinched off forming a cytoplasmic membrane-bounded vesicle called an endosome, which contains the engulfed cargo. Material packaged within the endosome may undergo processing by the cell, after which the cytoplasmic vesicle can move to the opposite side and fuse with the plasma membrane, releasing its contents to the extracellular space during the process of exocytosis (Figure 1).

Cytoplasmic material can also be extruded from the cell, forming plasma membrane bound extracellular vesicles called exosomes, in a similar, but reverse process, to endocytosis^[7,8].

Endocytosis is required for a vast amount of cellular functions that are paramount to the survival and wellbeing of the cell. Internalizing thousands of molecules, and up to five times its surface area per minute, the cell membrane is a seething cauldron of continuous endocytotic invaginations involved in the non-stop absorption of nutrients and water, in addition to cell surface receptors, antigens, cell signaling molecules, protein homeostasis, and maintenance of plasma membrane lipids^[9-14].

While inside the cell, the cargo is enclosed in a vesicle formed by the invagination of membrane lipids, called an

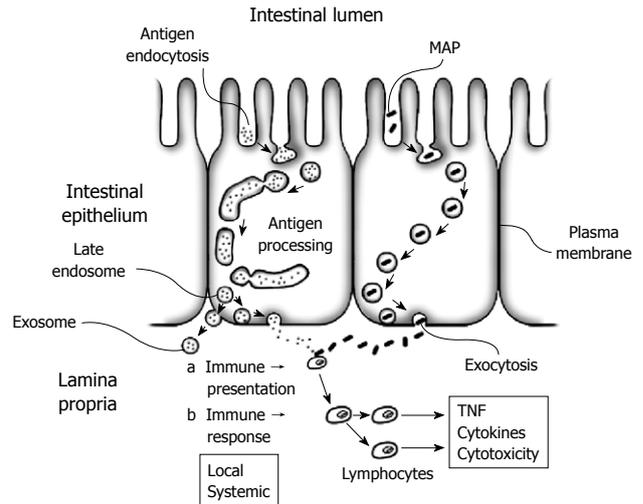

Figure 1 Antigenic exposure (a) of luminal antigens to the immune system can occur through either transcellular (through cells) or paracellular (between cells) pathways. Transcellular transport is mediated via transcytosis of processed antigen within discrete intracellular vesicles, termed endosomes, which are transported from apical to basal membrane prior to undergoing exocytosis, where immune recognition may occur within the lamina propria. Bacteria and macromolecules are transported in this fashion as they are too large to penetrate the tight intercellular space (paracellular pathway) maintained by tight junctional proteins. An immune response (b) can ensue subsequent to antigenic penetration into the lamina propria. Continuous unregulated transcytosis of luminal antigens and *Mycobacterium avium paratuberculosis* (MAP) into the lamina propria can initiate a chronic immune reaction. Inhibition of immune response (b) with immunosuppressive agents may temporarily restore epithelial integrity, but will not prevent transcytosis of luminal antigen, which continues upon discontinuation of immunosuppressive therapy. Mitigation of luminal antigenic exposure via restrictive diets or parenteral therapy cannot prevent subsequent transcytosis and relapse once normal dietary activity is resumed. A three pronged approach for acute therapy consisting of: (1) reduction of antigenic exposure via temporary dietary restriction; (2) temporary immunosuppression to inhibit immune mediated tissue damage and speed epithelial healing; and (3) Inhibition of transcytosis via endocytosis blocking agents to prevent future immune activation, may offer a therapeutic paradigm on which to base clinical decision making. Anti-MAP antibiotics may additionally be utilized to speed systemic removal of this bacterium and hasten downregulation of the immune response. Limited evidence suggests that inhibition of transcytosis may reduce intestinal antigenic exposure sufficiently to allow long term dietary activity with minimal restrictions. Maintenance therapy with endocytosis inhibiting agents may provide a safe and effective means of inducing long-term remission and interrupting the natural history of Crohn's disease. TNF: Tumor necrosis factor.

endosome. The endosome can be destined for transport to areas within the cell or undergo transcellular transport to the opposite side, where fusion with the cell membrane results in exocytosis and deposition of the cargo (in the intestinal epithelium) into the lamina propria^[15-17].

A multitasking membrane machine, the intestinal epithelium simultaneously integrates the transcytosis and processing of hundreds of distinct nutrient molecules into the lamina propria, while providing a single cell thickness physical barrier to luminal antigens that maintains sub-epithelial sterility, and does so while serving as a non-stop conveyor belt for the continual migration of new enterocytes to the surface epithelium.

Despite its highly dynamic physical state, the intestinal epithelium is very efficient at preventing translocation of luminal antigens into the lamina propria. This efficiency

however notwithstanding, the translocation of intact proteins through the intestinal epithelium has been demonstrated and cell mechanisms exist for the endocytosis of entire bacteria. At least ten mechanistically distinct endocytotic mechanisms have been described, from phagocytosis and macropinocytosis, employed for the absorption of cargo over 500 nm, to clathrin coated pits and caveoli mediated endocytosis for smaller particulate macromolecules^[9,15,18].

Endocytosis is highly dependent on the composition and organization of the cell membrane and experimentally induced changes in membrane properties can alter the cell's ability to appropriately engage extracellular particulate matter leading to alterations in one or more mechanisms of endocytosis^[9,15,19].

This implies that pathological endocytosis of luminal antigenic material (endo cytopathy) may result in transcytotic antigenic overload of the lamina propria, with subsequent immune activation and the establishment of a chronic inflammatory state. An endo cytopathic state would, in theory, present as an increased permeability of the intestinal epithelium prior to the start of inflammation, such as that observed in CD. It is therefore reasonable to speculate that an inherited endo cytopathy may be involved as an early etiopathogenetic mechanism in CD, with the participation of one or more endocytotic mechanisms contributing to the disease process.

The following section examines studies of early lesions of Crohn's epithelium for evidence of endocytopathy.

IS ABERRANT TRANSCYTOSIS INVOLVED IN CD?

Transcytosis is a normal endosomal generating process that is regulated by the cell. Pathologically triggered, unregulated, transcytosis can differ from its normal physiological counterpart by an increased endosomal generation rate; manifesting as an excess amount of cellular endosomes when compared to normal cells. Thus, a defining characteristic of unregulated transcytosis can be an increased cellular endosomal load.

This aspect of cellular function was evaluated by several studies, which documented multiple endosomes in 19 out of 19 cases of CD. No endosomes were observed in six control cases. Nor were they observed in radiation ileitis, celiac disease, experimental *Yersinia enterocolitica*, or in all of 155 cases of diagnosed ulcerative colitis^[20]. Normal colonocytes had no visible endosomes.

The cellular location of endosomes in apical, basal, and lateral portions of the cell suggests a process of active transcytosis. Although diminished exocytosis could account for increased endosomes, the presence of concurrent inflammation suggests ongoing deposition of antigenic material into the lamina propria, along with active exocytosis. The absence of endosomes in both negative and active control groups suggests that the endosomal structures observed in all CD study patients are the result

of a pathological transcytotic state, triggered by inappropriate endocytosis.

A more detailed analysis of the role of transcytosis in the pathogenesis of CD was undertaken in a study that examined the effects of autologous infusion of intestinal contents into the excluded ileum of three individuals who had undergone a resection of the terminal ileum with the creation of a temporary loop ileostomy. In this surgical procedure, the two openings from a bisected loop of ileum are brought through the abdominal wall to the surface^[21]. After 3-6 mo of diversion, the patients were infused, *via* a catheter, with 60cc of ileal effluent (collected from the proximal limb) into the distal limb four times daily for 7 d.

Distal ileal biopsies obtained prior to infusion were histologically normal without evidence of inflammation. Biopsies obtained 1 d after the last infusion (day eight) revealed a moderate increase of mononuclear cells, eosinophils, and polymorphonuclear cells in the lamina propria. Neutrophils were also noted in the small vessels and epithelium without cryptitis or crypt abscesses.

Epithelial electron micrographs revealed dilation of rough endoplasmic reticulum (ER) and Golgi apparatus (GA), in addition to basally located transport vesicles (endosomes). Mitochondria appeared damaged and dilated.

These ultrastructural changes are characteristic of biosynthesis [i.e. major histocompatibility complexes (MHC) peptides] and antigen processing during transcytosis prior to presentation of antigen-MHC complexes on the cell surface^[17,22]. Basal transport vesicles suggest late endosomes prior to exocytosis and exposure of antigen within the lamina propria (Figure 1).

Dilated mitochondria suggests sudden elevated metabolic activity, which is consistent with high ATP demand resulting from protein synthesis and the processing of a large influx of antigen by TAP (transporter associated peptide) during intracellular conjugation of processed antigen to MHC molecules. This process is estimated to consume 50 000 molecules of ATP per second/cell in prokaryotes during normal antigen processing, and is likely to consume more in eukaryotic (human) cells that may be undergoing excessive antigenic processing^[17,23-25]. The appearance of damaged mitochondria suggests that excess reactive oxygen species (i.e. superoxide, hydrogen peroxide, and hydroxyl radicals), generated during an acute excessive demand for ATP, had overwhelmed mitochondrial reductive (antioxidant) capacity, with resultant activation of the mitochondrial permeability transition pore leading to the observed structural mitochondrial and epithelial cell damage. The presence of minute collections of lymphocytes within the lamina propria (aphthous lesions), which are not associated with superficial erosions or lymphoid follicles in CD, is compatible with local antigenic presentation to the lamina propria^[26].

The above studies suggest that excessive transcytosis of luminal antigens is an early concomitant in the pathogenesis of CD intestinal inflammation. However, are luminal antigens actually transcytosed in CD and is this

transcytosis pathological and able to account for the initiation of inflammation in CD?

An elegant study designed to evaluate enterocyte transcytosis of luminal antigens in CD was performed on mucosal biopsies taken from ileal mucosa after *in-vivo* incubation with luminally applied ovalbumin (OVA) in patients undergoing ileoscopy^[27]. The authors found OVA associated with MHC within cytoplasmic late endosomes (the stage prior to exocytosis) and with exosomes in the intercellular space (Figure 1). OVA was also found in the lamina propria. Importantly, OVA cytoplasmic trafficking and antigen processing showed no qualitative differences between CD patients (active disease or histologic remission) and controls.

This study indicated that a luminal antigen can be transcytosed by intestinal epithelial cells and the intracellular antigenic processing in both CD and normal controls is qualitatively similar, regardless of disease state. The absence of a significant demonstrable difference between normal and CD enterocyte antigenic processing suggests that a disorder may exist during the initiation of transcytosis at the level of the cell membrane. This is suggested by studies documenting multiple endosomes in CD enterocytes which were not present in normal controls implying a quantitative difference in antigenic transcytosis rather than a qualitative one^[20].

This interpretation is supported by studies in individuals undergoing small intestinal allograft transplantation as a result of short bowel syndrome subsequent to surgery required to treat CD^[28]. In a series of four CD patients receiving small intestinal allografts, early characteristic CD lesions were documented in two patients, *via* allograft biopsy, at 3 and 5 wk after transplantation. None of the four transplant recipients developed clinical or endoscopic recurrence during the follow-up period of 20-40 mo. No similar histological findings were observed in any of 57 non-CD patients receiving small intestinal allografts at this institution.

The appearance of lamina propria lymphoplasmacytosis and inter-epithelial neutrophil infiltration suggests antigenic presentation by the allograft to the recipient's immune system. This would not appear to be the result of aberrant immune processing by allograft tissue, since allograft donors are carefully screened prior to transplantation, and studies have documented similar enterocyte antigenic processing in both CD and normal controls (above). Likewise, there is no indication of abnormally increased intestinal permeability in allograft donors and no antecedent immune abnormality has been identified in CD to account for this immune reaction in the allografts.

An allograft immune reaction so soon after transplantation suggests a normal constitutive process of antigen presentation to the recipient's immune system and studies have shown the presence of a constitutive apical internalization pathway in enterocytes^[16,27]. This suggests that the allograft immune reaction in CD recipients is due to a heightened immune response to normal intestinal antigenic presentation as a result of normal constitutive en-

docytosis in CD individuals hypersensitized as a result of previous excessive exposure to intestinal luminal antigens.

Therefore, if normal antigenic transcytosis from a normal transplanted gut can cause characteristic histological CD lesions in allograft recipients, then it is reasonable to speculate that excessive luminal antigenic exposure *via* unregulated transcytosis may play a significant role in early pathogenic events leading to the development of CD.

Why individuals with CD may have unregulated transcytosis is examined in the next section.

WHAT CAUSES UNREGULATED TRANSCYTOSIS?

The cell membrane is the gateway that mediates all interaction with the external environment. This is largely accomplished *via* membrane coated vesicles that constantly bud off from the cell membrane and enter the cytoplasm, while others arrive from the cytoplasm and fuse with the cell membrane (transcytosis). The composition, integrity, and 3-dimensional arrangement of plasma membrane components are crucial to control of the vesicular fission/fusion process, which in turn contributes to maintaining the composition of the plasma membrane as vesicles are recycled back into the cell membrane^[10,15,29].

Luminal antigenic sampling by enterocytes depends upon a controlled transcytotic antigenic presentation to the immune system; therefore, any alteration in the composition, properties, or structure of enterocyte cell membranes can have a significant impact on the immunological functionality of the entire gastrointestinal tract. Too little antigenic presentation and the gut cannot fulfill its role of immune surveillance; too much presentation can lead to a heightened immune response and chronic inflammation^[9].

Studies have shown that alterations in cell membrane properties can have a profound effect on endocytosis and transcytosis. Treatment of cells with the cell membrane intercalating agent phorbol ester can initiate spontaneous endocytosis^[15,30]. Enhanced endocytosis of non-targeted membrane enzymes has been observed during fat absorption, suggesting that this physiological process, which increases cell membrane fatty acid content, disturbs local membrane organization^[16,31]. A change in cell membrane fatty acid composition can modify membrane properties and its interaction with cytosolic proteins involved in endocytosis^[18].

Analysis of synthetic liposome transcytosis across cell membranes revealed that cell membrane fluidity is the most important factor influencing transcytosis, followed by surface charge^[19]. Other significant cell surface properties affecting transcytosis, such as lipid composition and surface density, have been described by other researchers in the field^[19]. These studies indicate that biochemical and biophysical properties of cell membranes are major factors controlling cellular uptake and transcytosis. Combined

with data suggesting unregulated intestinal transcytosis in CD, it is reasonable to consider the possibility of enterocyte cell membrane abnormalities as a contributing factor to unregulated transcytosis in the early pathogenesis of CD.

The next section will explore this aspect.

ARE CELL MEMBRANE ABNORMALITIES PRESENT IN CD?

Significant decreases in cell membrane fluidity, in addition to disturbances in cell membrane lipid composition, were observed in a study conducted on erythrocytes of individuals with active and inactive CD^[32]. A separate study examining the mucosal fatty acid profile in uninvolved (never inflamed) colonic mucosa in individuals with CD demonstrated altered lipid composition compared to healthy controls^[33].

Studies regarding cell membrane properties and lipid composition in CD are rare. Abnormal lipid profiles in uninvolved (never inflamed) colonic mucosa raises the possibility of an antecedent metabolic defect. Erythrocyte cell membrane fluidity abnormalities in CD are consistent with the possibility that membrane abnormalities may be present in other tissues, including the intestinal epithelium, resulting in deleterious effects on enterocyte transcytosis.

Further basic scientific data are necessary to identify potential cell membrane abnormalities and their role in enterocyte transcytosis. However, if unregulated transcytosis is involved in the pathogenesis of CD, then endocytosis blocking agents should have a beneficial therapeutic effect on the clinical parameters and progression of disease.

In the next section we evaluate the therapeutic effect of endocytosis blocking agents upon CD.

DO ENDOCYTOSIS BLOCKING AGENTS REDUCE INFLAMMATION IN CD?

Therapeutic measures available for the treatment of CD can be divided into three general categories; dietary measures, antibiotics, and immunosuppressive agents. No mechanism of action employed by these therapeutic interventions, either singly or in combination, has been proven to modify the natural history of CD. This suggests that an unrecognized pathogenetic mechanism is involved in the development of this disease. Clinical reports of complete remission in refractory CD after administration of non-conventional agents have been documented. One of these agents, thalidomide, a known endocytosis blocker, has been shown to be effective for induction and long term maintenance of remission in both intestinal and extraintestinal CD^[34-44].

Studies have demonstrated a reduction in inflammation and inflammatory parameters in CD using the cholesterol lowering agent atorvastatin^[45,46]. These agents inhibit

the biosynthesis of cholesterol, a critical membrane lipid constituent required for the formation of endosomal vesicles^[29].

The polyene antibiotic Nystatin, which inhibits endocytosis by cholesterol sequestration within cell membranes, has been used in combination therapy to reduce inflammatory activity in CD^[29,47].

Azithromycin, a macrolide antibiotic, was observed to markedly inhibit endocytosis and has also been used in therapeutic regimens to reduce inflammation in CD^[48-50].

Macrolide antibiotics, including azithromycin, are considered among the most effective therapeutic agents for the treatment of CD^[51,52]. The rationale for the use of endocytosis blocking agents in CD is to prevent enterocyte transcytosis of luminal antigens into the lamina propria. A reduction in intestinal transcytotic antigenic load is also consistent with the mucosal healing and decrease in inflammatory cytokines, mucosal permeability, and clinical disease activity observed with the use of specific dietary exclusion measures in the treatment of active CD^[53-56].

To date, no study has evaluated the effect of endocytosis blocking agents in the treatment of CD. The limited amount of data in which therapeutic agents with adjunct endocytotic blocking activity show a beneficial effect in the treatment of CD is consistent with the involvement of transcytosis in the pathogenesis of this disease. Further research is required to determine if specific endocytosis blocking agents are beneficial in the treatment of CD.

Certain questions, however, remain unanswered. For instance, what is the role of *Mycobacterium avium* paratuberculosis (MAP), a bacterium that has been uniquely associated with CD, and what is the genetic nature of the putative membrane abnormality proposed for CD?

A transcytosis mechanism for CD suggests answers to these questions, which are explored in following section.

THE ROLE OF MAP IN CD?

CD is the result of a complex interaction between the body's immune system and environmental (luminal) factors, played out at the gastrointestinal epithelial interface. The data presented in this paper suggests that unregulated transcytosis of luminal antigens plays a significant role in the early pathogenesis of this disease.

The adult mammalian intestinal epithelium is normally very selective regarding the absorption of luminal molecules, with macromolecules being degraded prior to entering the bloodstream. The neonatal intestinal epithelium, however, has a greater capacity for non-selective absorption, and undergoes a gradual change in permeability that restricts the uptake of macromolecules. This process of decline in intestinal permeability to immunologically recognizable molecules is called intestinal closure and, for most species, is complete by the end of the perinatal period 1 to 4 wk after birth^[16,57,58].

The process of intestinal closure is age dependent, and is accompanied by developmental changes and re-

modeling in membrane phospholipids, which become a potential regulator of intestinal transport^[57]. Thus, alterations in the composition of cell membrane lipids can alter membrane properties, such as hydrophobicity, molecular structure, and fluidity. These alterations can lead to dysfunction of cell membrane dependent processes, such as intestinal epithelial transcytosis resulting in enhanced uptake of immunologically active molecules or luminal organisms.

One organism that stands out regarding its association with CD is *Mycobacterium avium* paratuberculosis (MAP). Since its initial isolation from CD patients in 1984, detection studies have shown that up to 95% of CD patients harbor this bacterium^[59-61]. The association with CD is unique to MAP, and has not been described for other species of mycobacteria.

MAP is ubiquitously present in the environment, the water supply, and the human food chain^[60,62,63]. It infects many wild and domesticated animals, including up to 68% of milk producing dairy herds in any geographical area. Infected animals can develop chronic diarrhea and wasting called Johne's disease^[52,64]. Although MAP can be acquired from drinking water, contaminated vegetables, and aerosol droplets, the principal reservoir of MAP for transmission to humans is the intestinal tract of infected cattle, which serves as a distribution point for dissemination of MAP into dairy products such as milk, cheese, and other dairy by-products^[60,63,65].

Studies suggest that, once in the GI tract, the interaction of MAP with CD patients is specific and not the result of a random generic process^[66-69]. In other words, once contact is made, unique characteristics inherent in both Crohn's intestinal epithelium and the MAP cell wall favor continued adherence and transcytosis into the lamina propria, leading to an immune reaction.

Exposure of normal human, 12 wk old, fetal intestinal epithelia to MAP revealed almost no internalization of MAP by enterocytes, with uptake limited to goblet cells^[70]. This is consistent with resistance of normal human intestinal epithelium to MAP transcytosis, with a transitory gestational permeability effect on goblet cells, since oral Crohn's lesions can appear on stratified squamous gingival mucosa, which is devoid of both dendritic and goblet cells. Goblet cells have not been observed to serve as unique foci of inflammation in early Crohn's lesions^[21,71-76]. This suggests that specific inherited cell membrane abnormalities in Crohn's intestinal epithelium interact with unique MAP cell wall constituents that are not present in other mycobacterial species, conferring upon MAP the role of a transcytosis triggering agent when in contact with Crohn's intestinal epithelium. Once processed within intestinal epithelial cells, luminal derived antigens are deposited within the lamina propria, which evokes an immune response characteristic of CD. This implies a predisposing disease genotype whose phenotypic expression is associated with cell membrane composition; a consideration that is further developed below.

WHAT ARE THESE DISTINCTIVE CELL WALL COMPONENTS AND WHAT CELL WALL PROPERTIES MIGHT ENHANCE MAP TRANSCYTOSIS BY CROHN'S INTESTINAL EPITHELIUM?

MAP is unique in having a cell wall that differs significantly from that of other bacteria^[77,78]. The cell wall is composed of a thick layer of extremely hydrophobic lipid molecules. Long chain α branched lipids (mycolic acids) and species-specific glycopeptidolipids contribute to the extreme hydrophobicity of this organism^[77,78].

MAP is also highly negatively charged, and studies have demonstrated a greater attachment of MAP to like-charged particles compared to similarly charged bacteria because of the extreme hydrophobic nature of the MAP cell wall^[77]. Additional studies have demonstrated that MAP is highly predisposed to surface adherence, being the primary colonizers on a variety of external surfaces, the degree of which varies with the characteristics of the surface material being colonized^[79].

Thus, the combination of uniquely strong hydrophobicity and high electronegative charge present on the MAP outer surface can aid in its adherence to a genetically altered Crohn's intestinal epithelium, facilitating its transcytosis and ultimate dispersal from a negatively charged basal surface epithelium into the lamina propria, where an immune reaction can ensue^[80]. Studies have shown that cell surface hydrophobicity may play an important role in the rate of internalization of bacteria^[81].

Consequently, MAP can be considered an environmental response modifier that interacts with the biological expression (phenotype) of certain susceptibility genes, whose genotype contributes to the composition of cell membranes^[82-84]. To be consistent with this interpretation, alterations in cell membrane function should elicit a Crohn's inflammatory phenotype. This has been observed with epidemiological studies linking the ingestion of aspirin, a nonsteroidal anti-inflammatory drug (NSAID) with increased risk of developing CD^[85]. Aspirin, which is strongly lipophilic, binds to, and accumulates within, cell membranes altering their microviscosity, molecular structure, physical state, and biological function^[86,87]. Aspirin, and other NSAIDs, have also been demonstrated to induce disorders of cell membrane lipid assembly, as well as rearrangements in membrane protein patterns^[88,89].

NSAID-induced enteropathy is reported to have close similarities to CD and is not infrequently reported by the pathologist as consistent with CD^[90,91]. NSAID-induced alterations in model cell membranes provoke membrane fusion, suggesting the possibility that pre-existing cell membrane anomalies may also contribute to the high occurrence of intestinal fistulas in CD^[92]. NSAIDs increase the risk of developing *de-novo* CD, induce an enteropathy that can be histologically indistinguishable from CD, and alter cell membrane properties known to be involved in

transcytosis (fluidity, viscosity, composition). It is reasonable, therefore, to speculate that the genetic predisposition in CD is an inherited membrane abnormality that gives rise to unregulated enterocyte transcytosis, which ultimately leads to chronic intestinal inflammation.

IF A CELL MEMBRANE ABNORMALITY DOES EXIST IN CD; IS THERE ANY EVIDENCE THAT MIGHT PROVIDE SOME IDENTIFYING CHARACTERISTICS FOR A CANDIDATE GENE?

It has been known for some time that smoking increases the risk of developing CD, and will worsen existing disease^[93,94]. A clue to a potential underlying mechanism is the clinical observation of significant disease worsening above a threshold of 10-15 cigarettes per day^[93,95]. A phenotypic threshold effect is characteristic of mitochondrial involvement in disease pathogenesis^[96,97].

Smoking has been documented to cause considerable mitochondrial dysfunction, with up to 80% inhibition of electron transport chain activity and significant decreases in ATP production and availability^[98-105]. Conversely, smoking cessation is associated with both normalization of mitochondrial function and clinical improvement in CD activity, suggesting a cause and effect relationship between mitochondrial bioenergetics and CD severity^[93,95,106]. This unveils the possibility that an energy (ATP)-requiring enzyme participating in a cell membrane lipid biosynthetic pathway may be involved in CD pathogenesis.

A candidate enzyme fulfilling these criteria is long chain acyl Co-A fatty acid synthetase isoform 6 (ACSL6, E.C.6.2.1.3). The gene for this enzyme is located on 5q31, which has been designated as IBD susceptibility locus 5 (IBD5)^[107-109].

These isoenzymes, located on the peroxisomal surface membrane, have a crucial role in plasma membrane phospholipid turnover, *de novo* lipid biosynthesis, fatty acid catabolism, and remodeling of biological membranes. They also use ATP to convert fatty acids into an activated form that can be incorporated into cell membranes^[110-116].

Studies have shown a decrease in peroxisomal frequency in Crohn's mucosal biopsies^[117]. This suggests a mechanism in which a genetically dysfunctional or depleted ACSL6 enzyme may be further compromised by smoking-induced depletion of ATP, leading to cell membrane abnormalities that can enhance transcytosis of luminal antigens, resulting in development or worsening of the disease.

Smoking, however, does not affect all individuals with CD^[93]. This suggests the involvement of other, non-ATP-requiring enzymes involved in cell membrane biogenesis, such as LPCAT2 (Lysophosphatidylcholine acyltransferase2, E.C. 2.3.1.67)^[118]. The gene for this enzyme is located on 16q12, which has been designated IBD susceptibility locus 1 (IBD1); a locus that also contains the NOD2/CARD15 gene, which has been linked to CD.

LPCAT2 is involved in the biosynthesis of membrane lipids, suggesting the possibility of membrane abnormalities as a result of a compromised LPCAT2 enzyme, that may disrupt cell membrane properties regulating transcytosis leading to enhanced antigen deposition in the intestinal lamina propria and a chronic immune reaction^[119].

Finally, studies demonstrating that up to 50% of healthy individuals harbor MAP in their blood suggest a spectrum of intestinal mucosal affinity for MAP, in addition to variations in MAP exposure and interindividual immune response, as determining factors contributing to disease development and severity (Figure 1)^[120,121].

CONCLUSION

Evidence presented in this paper provides a reasonable basis for the premise that unregulated transcytosis may be fundamentally involved in the development and early pathogenesis of CD. Unregulated transcytosis is compatible with the repeated clinical observation that mucosal healing does not alter the fundamental disorder present within the intestinal epithelium, leading to disease relapse upon discontinuation of treatment^[5,122]. Present at birth, a genetic predisposition towards unregulated transcytosis (transcellular defect) can increase local concentrations of inflammatory cytokines that are known to trigger tight junctional barrier (paracellular) defects, which have been reported in CD patients and healthy first-degree relatives^[123]. The presence of MAP in a significant percentage of mucosal biopsies and blood of children with CD is consistent with an inherited congenital mucosal anomaly favoring mucosal adherence and transcytosis of MAP^[124].

Within this pathogenetic chronology, the immune-mediated paracellular permeability defect present in CD arises as a consequence of a primary inherited pathological transcellular transport of luminal antigens, resulting in a vicious cycle of paracellular antigenic overload, which is exacerbated by continuous unregulated transcytosis of immunogenic luminal macromolecules. Increased intestinal permeability to polyethylene glycol (a transcellular permeability probe) has been demonstrated in CD^[125-128].

Supporting this interpretation is a report of prodromal symptoms, including fever, occurring from 7-10 years prior to a diagnosis of CD in almost 28% of 29 patients enrolled in a questionnaire based study. In contrast, none of the 15 ulcerative colitis patients enrolled in the study reported fever occurring prior to diagnosis^[129].

This is compatible with a continuous stream of transcytosed immunogenic macromolecules resulting in systemic subclinical immune activation. Unregulated transcytosis is also consistent with other studies that implicated an inherent cell membrane permeability defect independent of inflammation^[130,131].

Since the term "natural history" was introduced for CD in 1965, there has been no hard evidence for change in disease outcome^[4,6]. The urgent need for a natural-history modifying therapy remains a priority. Although immune-mediated tissue damage is clearly evident, in a

complex condition such as CD it may not be what you see when you look, but how you look at what you see that provides the answer.

ACKNOWLEDGMENTS

I wish to thank Dr. William W Taylor for his continuous constructive feedback and support. I am deeply indebted to Kimberly D Shepherd whose courageous existence made this work possible.

Abstract

AIM: To evaluate whether FDG-positron emission tomography (PET)/computed tomography (CT) may be an accurate technique in the assessment of the T stage in patients with colorectal cancer.

METHODS: Thirty four consecutive patients (20 men and 14 women; mean age: 63 years) with a histologically proven diagnosis of colorectal adenocarcinoma and scheduled for surgery in our hospital were enrolled in this study. All patients underwent FDG-PET/CT preoperatively. The primary tumor site and extent were evaluated on PET/CT images. Colorectal wall invasion was analysed according to a modified T classification that considers only three stages (\leq T2, T3, T4). Assessment

of accuracy was carried out using 95% confidence intervals for T.

RESULTS: Thirty five/37 (94.6%) adenocarcinomas were identified and correctly located on PET/CT images. PET/CT correctly staged the T of 33/35 lesions identified showing an accuracy of 94.3% (95% CI: 87%-100%). All T1, T3 and T4 lesions were correctly staged, while two T2 neoplasms were overstated as T3.

CONCLUSION: Our data suggest that FDG-PET/CT may be an accurate modality for identifying primary tumor and defining its local extent in patients with colorectal cancer.

INTRODUCTION

In patients with colorectal cancer, accurate preoperative staging is essential for the planning of optimal therapy considering the many therapeutic options available.

Correct evaluation of the local extent (T) of the tumor and of the regional lymph nodes (N) is crucial since it influences the local surgical approach as well as the therapeutic management of the distant metastases (M). Various treatments of the primary tumor are available including radical or limited resection, palliative derivative surgery, local excision, laparoscopic surgical approach, preoperative neoadjuvant chemotherapy and/or radiotherapy: for example the laparoscopic surgical approach is used preferentially for T1 and T2 staged tumors; preoperative neoadjuvant therapy for advanced rectal cancer (T3, T4); limited resection or palliative derivative surgery for diffusely invasive cancers^[1-7]. Moreover, only if the whole primary tumor mass can be completely removed, the surgical option for liver, lung or non-regional lymph nodes metastases is considered^[8-10].

In daily practice, tumor size and infiltration of adjacent structures in colorectal cancer are assessed initially by contrast-enhanced computed tomography (ceCT)^[11-14]. Magnetic resonance imaging (MRI) and endorectal ultrasound (US) represent an accurate diagnostic option for rectal cancer^[15-19].

Non-enhanced FDG-positron emission tomography (PET)/CT^[20-21] and more recently contrast-enhanced FDG-PET/CT (PET/ceCT)^[22-24], are gaining a progressively more important role in the evaluation of the N and the M stages in the staging and follow-up of colorectal cancer, however, the performance of this modality in the evaluation of the T parameter has not been extensively investigated. A single study has recently proposed the evaluation of TNM staging by PET/CT colonography in patients with colorectal cancer and reported good assessment of the T parameter^[6-8]; the PET/CT colonography protocol requested previous bowel preparation with a solution containing polyethylene glycol-electrolytes, the iv injection of N-butyl scopolamine, administration of a rectal water enema, a water-based negative oral contrast agent assumption and the iv injection of iodinated contrast medium. This protocol may not be tolerated well by some patients, can be time consuming, is not recommended in patients with impaired renal function and requires additional costs.

The aim of this study was to evaluate whether FDG-PET/CT, without iv contrast medium or colonography technique, may be considered a proper diagnostic tool in the assessment of local primary tumor extent (T) in patients with colorectal cancer.

MATERIALS AND METHODS

Patients

The study protocol was approved by our institutional review board and informed consent was obtained from all patients.

The study population consisted of 34 consecutive patients (20 men and 14 women; age range, 29-81 years; mean age: 63 years) with a histologically proven diagnosis (the histological specimen was obtained during conventional colonoscopy) of colorectal adenocarcinoma and

scheduled for surgery in our hospital. Exclusion criteria were refusal to participate in the study.

Before surgery all patients underwent FDG-PET/CT in our Institution. Surgery was scheduled within 10 d of the examination, with the exception of three patients with rectal cancer who underwent neoadjuvant radio-chemotherapy after PET/CT and before surgery.

PET/CT technique

Dual modality imaging was performed with a PET/CT system (Discovery-LS, GE-Medical-Systems, Milwaukee, USA) consisting of a PET scanner and a four-row MDCT system.

All patients had been instructed to fast for a minimum of 6 h prior to the examination. Blood glucose levels were found to be in the normal range prior to 18FDG injection by blood sampling. PET/CT was carried out 60 min after administration of 370 MBq of 18FDG.

MDCT scans were acquired from the base of the skull to the upper thighs using the following parameters: 4 mm × 5 mm collimation (140 kV, 80 mAs), 0.5 s rotation time, a pitch of 6. 18FDG-PET data were acquired with the patient in the same position on the table at four bed positions (5 min for each bed position) covering the same field of view as CT.

Data obtained from the CT acquisition were used for attenuation correction of 18FDG-PET emission data. 18FDG-PET images were reconstructed with a 4.5 mm thickness.

18FDG-PET, CT and fused 18FDG-PET/CT images were reviewed on the dedicated workstation (Xeleris, GE Medical System).

Imaging interpretation

PET/CT examinations were interpreted before surgery by two pairs of observers, each pair composed of a radiologist and a nuclear medicine physician (each with > 5 years of experience). The images were interpreted jointly within each pair and independently by the two pairs of observers. In cases of disagreement, a consensus panel consisting of the original four observers plus a third blinded party (with 10 years experience) made the final decision.

PET/CT images were evaluated to determine the primary tumor site and extent and the lymph nodes status.

For determination of the primary tumor site and extent, and the lymph nodes status, each pair of observers could use the CT, the PET and the fused PET/CT images individually and simultaneously in no established order. This approach was dictated by the aim of our study which was to evaluate PET/CT exclusively as a single complex technique for local colorectal cancer staging.

For the localization of each lesion, the large intestine was divided into nine anatomic segments: rectum, rectosigmoid colon junction, sigmoid colon, descending colon, splenic flexure, transverse colon, hepatic flexure, ascending colon and caecum.

For the identification of each lesion, the tumor had to be depicted either morphologically or metabolically (a polypoid, annular, semiannular or flat lesion had to be

associated with focal abnormal FDG uptake, or focal abnormal FDG uptake had to be associated with a polypoid, annular, semiannular or flat lesion).

Abnormal FDG uptake was defined as focal increased activity higher than the background activity of soft tissues. The evaluation of each focal radiotracer uptake was qualitative and quantitative (the standard maximum uptake value (SUVmax) was calculated; the SUVmax was defined as abnormal when it appeared to be higher than the SUVmax of the background activity of soft tissues). Diffuse radiotracer uptake was assumed to represent normal or non-malignant bowel activity.

Colorectal wall invasion was analysed according to a modified T classification^[1,2] that considers only three stages (\leq T2, T3, T4). A parietal lesion concentrating the 18-FDG in the absence of extra-parietal radio-tracer uptake, was considered as a tumor confined to the bowel wall and defined as a \leq T2 lesion. A tumor either with a spiculated outer contour or with rounded or nodular advancing edges showing intra- and extra-parietal radiotracer uptake was defined as a T3 lesion. A tumor infiltrating into adjacent organs as suggested by their increased glucose metabolism was defined as a T4 lesion.

Lymph node metastasis was evaluated in regional lymph nodes. The diagnosis of an abnormal lymph node on PET/CT was based on the presence of focal increased FDG uptake at a location that corresponded to a lymph node regardless of its size on CT scan. N1 was defined as focal FDG uptake in not more than three lymph nodes, while N2 was defined as focal FDG uptake in more than three lymph nodes.

On co-registered PET images, the SUVmax was calculated on the primary tumor as well as on contiguous organs appearing to be involved as well as on the lymph nodes with focal increased glucose metabolism.

Standard of reference

The standard of reference was represented by surgical findings and histopathological analysis of the surgical specimens.

Localization of the tumor was defined during surgical exploration.

Tumour invasion (T) and lymph node status (N) were based on the TNM classification of the surgical specimen.

Three patients with rectal cancer underwent neoadjuvant radio-chemotherapy after PET/CT and before surgery: considering the potential downstaging of the tumor, the T and the N evaluation obtained with both MRI and endorectal US was used as the standard of reference.

Statistical analysis

Data are expressed as mean \pm one SD or as proportion as appropriate. A commercial statistical software package was used (MedCalc[®]). Differences between continuous data were assessed using analysis of variance with post-hoc multiple groups comparison (Student-Newman-Keuls test). Categorical data were evaluated by χ^2 analysis, Fisher exact test, and McNemar test, as appropriate. Logistic

Table 1 T stage: positron emission tomography/computed tomography vs histology

| | Histology | | | Total |

analysis was used to evaluate significant determinants. A P value < 0.05 was considered significant.

RESULTS

Standard of reference

A total of 37 adenocarcinomas were found in the surgical specimens. Two synchronous lesions were found in 3 out of 34 patients (8.8%). Three adenocarcinomas showed a mucinous component on histopathological examination.

The regional distribution of the 37 tumors was as follows: rectum ($n = 6$), rectosigmoid colon junction ($n = 4$), sigmoid colon ($n = 15$), descending colon ($n = 3$), transverse colon ($n = 1$), hepatic flexure ($n = 3$), ascending colon ($n = 2$) and caecum ($n = 3$).

Five out of 37 (13.5%) tumors were classified as stage T1, 5 out of 37 (13.5%) as stage T2, 21 out of 37 (56.8%) as stage T3 and 6 out of 37 (16.2%) as stage T4. All three adenocarcinomas with a mucinous component were classified as T4.

Twenty one out of 37 (57%) lesions were classified as N- and 16 out of 37 (43%) as N+ (13/16 as N1 and 3/16 as N2).

Tumour identification and location

Thirty five out of 37 (94.6%) adenocarcinomas were identified and correctly located on PET/CT images. In two patients no lesions were disclosed on PET/CT images: the two lesions which were missed were located in the transverse colon and the sigmoid colon, respectively, and were flat and confined to the colonic wall resulting in T1 stage on histopathological examination, and measured 15 mm and 16 mm, respectively.

Tumour T staging

PET/CT correctly staged (Table 1) the T of 33/35 lesions identified, showing an accuracy of 94.3% (95% CI: 87%-100%). All T1, T3 and T4 lesions were correctly staged, while two T2 neoplasms, located in the sigmoid colon and rectum, respectively, were overstated as T3 (Figures 1 and 2).

For the six lesions correctly classified as T4, PET/CT showed infiltration of the uterus ($n = 1$), of the ovary ($n = 2$), of the small bowel ($n = 1$) and of the peritoneum ($n = 2$) (Figures 3 and 4).

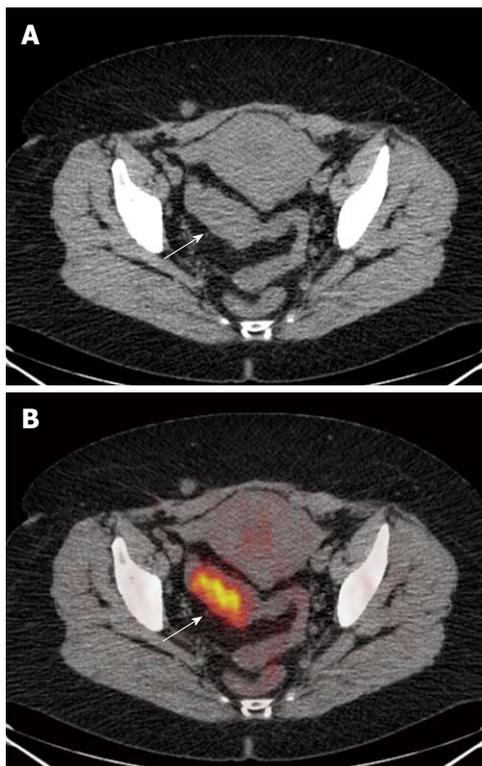

Figure 1 The computed tomography (A) and fused positron emission tomography/computed tomography (B) images. A: Neoplastic thickening of sigmoid colon walls, which show regular profiles with normal appearance of perilesional fat (arrow); B: Uptake of 18-FDG (arrow) (SUVmax 11) in the absence of extra-parietal radio-tracer uptake. The lesion was correctly classified as \leq T2.

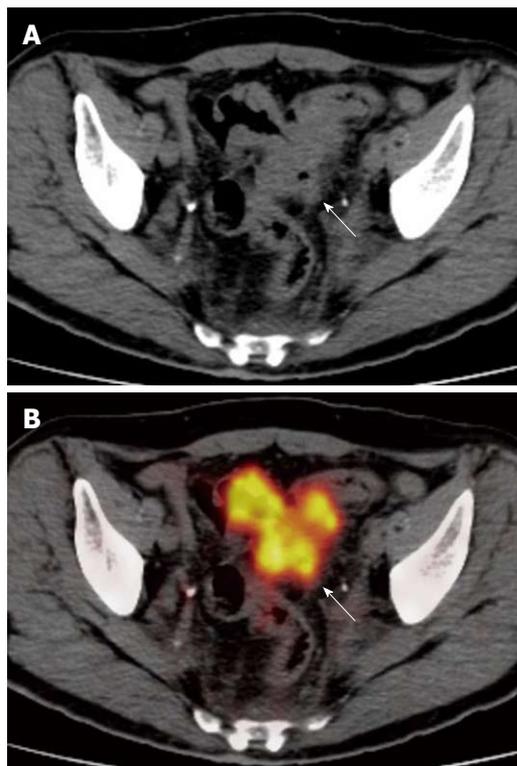

Figure 2 The computed tomography (A) and fused positron emission tomography/computed tomography (B) images show diffuse and irregular neoplastic thickening of sigmoid colon walls, which show rounded advancing margins with intense radiotracer uptake (arrows) (SUVmax 13). The lesion was correctly classified as T3.

Table 2 N stage: positron emission tomography/computed tomography *vs* histology

| Istologia | Histology | | Total |
|-----------|-----------|----|-------|
| | N+ | N- | |
| PET/CT | | | |
| N+ | 12 | 3 | 15 |
| N- | 4 | 15 | 19 |
| Total | 16 | 18 | 34 |

PET/CT: Positron emission tomography/computed tomography. χ^2 : 9.5, ($P < 0.005$). Accuracy: 79.4% (95% CI: 66%-93%).

The SUVmax of the identified lesions ranged from 1.8 to 27 with a mean of 14.3 ± 5.8 . Stratifying for T stages, the SUVmax of the T1 tumors ranged from 1.8 to 14 with a mean of 6.9 ± 6.4 , the T2 tumors ranged from 10 to 25 with a mean of 13.9 ± 6.3 , the T3 tumors ranged from 5.7 to 27 with a mean of 15.3 ± 5.5 , and the T4 tumors ranged from 9.4 to 21 with a mean of 14.7 ± 4.7 . No statistically significant difference between the SUVmax of each T group was found.

The SUVmax of the contiguous organs infiltrated ranged between 3.6 and 20 with a media of 11.5 ± 6.2 .

Tumour N staging

PET/CT correctly staged (Tables 2 and 3) the N of 27/34

Table 3 N stage: positron emission tomography/computed tomography *vs* histology with N1 and N2 stratification

| | Histology | | | Total |
|--------|-----------|----|----|-------|
| | N0 | N1 | N2 | |
| PET/CT | | | | |
| N0 | 15 | 4 | 0 | 19 |
| N1 | 3 | 9 | 0 | 12 |
| N2 | 0 | 0 | 3 | 3 |
| Total | 18 | 13 | 3 | 34 |

PET/CT: Positron emission tomography/computed tomography. χ^2 : 43.6, ($P < 0.001$). Accuracy: 79.4% (95% CI: 66%-93%).

patients, showing an accuracy of 79.4% (95% CI: 66%-93%). There were three false positive and 4 false negative results. 15/18 N0, 9/13 N1 and 3/3 N2 lesions were correctly classified.

The SUVmax of the lymph nodes with focal increased radio-tracer uptake ranged from 1.6 to 10.3 with a mean of 5.5 ± 3.1 . No statistically significant differences between the SUVmax of each N group were observed.

DISCUSSION

Our data shows that FDG-PET/CT is a useful diagnostic tool in identifying primary tumor extent in patients with colorectal cancer: the T stage of 33 out of 35 (94.3%)

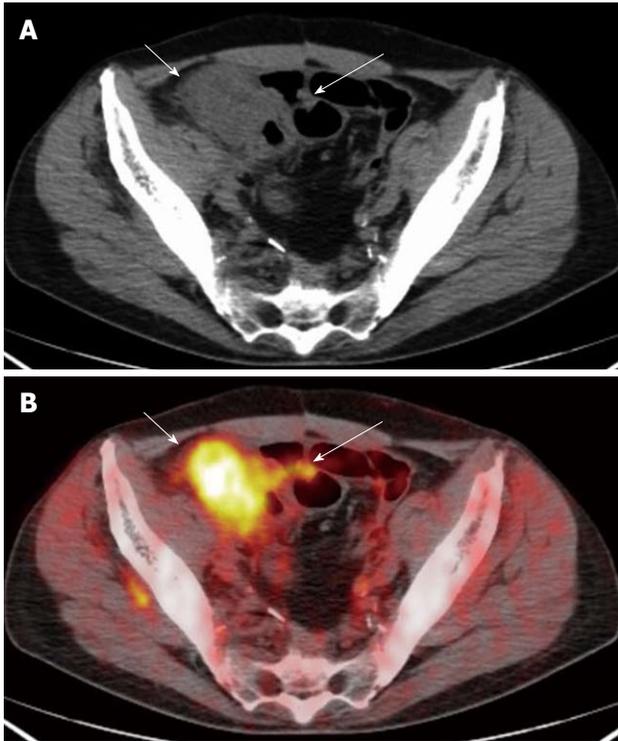

Figure 3 The computed tomography (A) and fused positron emission tomography/computed tomography (B) images show a neoplastic lesion of the caecum concentrating the radio-tracer (short arrows) (SUVmax 9.6). Focal radio-tracer uptake (SUVmax 3.6) of a contiguous ileal loop was disclosed on positron emission tomography/computed tomography (B) (long arrow) consistent with a short concentric wall thickening (A) (long arrow): the finding was suggestive of small bowel infiltration. The lesion was correctly classified as T4.

neoplastic colorectal lesions was correctly identified as well as the N stage of 27/34 (79.4%).

One of the major strengths of PET/CT as a cancer staging modality is its ability to identify systemic metastases. At any phase of cancer evaluation, the demonstration of systemic metastases has profound therapeutic and prognostic implications. Only in the absence of systemic metastases does nodal status become important, and only when unresectable nodal metastasis has been excluded does T stage become important. There are now accumulating data to suggest that PET/CT could be used as the first, rather than the last test to assess M and N stage in the evaluation of cancers^[25]. In this scenario, it would also be desirable for PET/CT to be accurate in the evaluation of the T stage. As a consequence, there is a great opportunity to use PET/CT as an all-in-one staging imaging modality in oncologic patients, and subsequently selecting and tailoring the performance of anatomically-based imaging modalities without or with iv contrast medium (US, MR, CT) to better define the abnormalities identified by PET/CT, when this information would be of relevance to management planning.

For these reasons, neither comparing the performance of PET/CT with other non-invasive imaging modalities nor investigating the added value of FDG information to CT data nor defining what was the contribution of

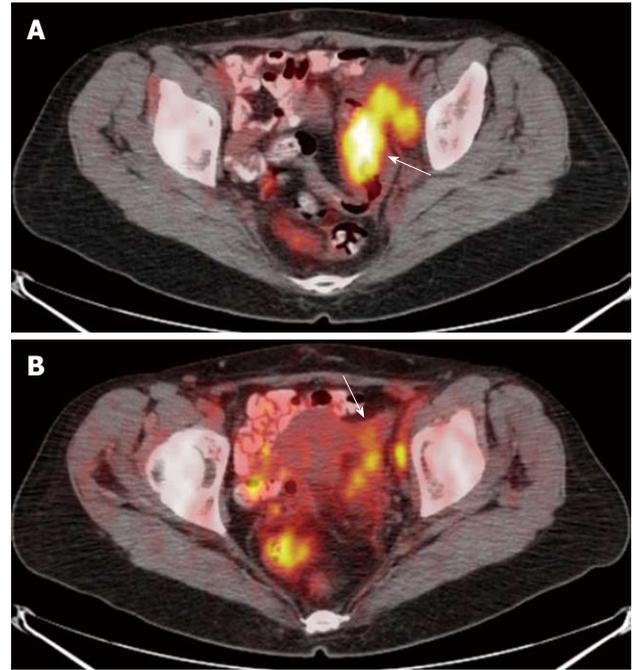

Figure 4 The fused positron emission tomography/computed tomography images show a neoplastic lesion of the sigmoid colon concentrating the radio-tracer (arrow) (SUVmax 14.6) (A) and focal radio-tracer uptake of the left ovary (arrow) (SUVmax 9) (B): the finding was suggestive of ovarian infiltration. The lesion was correctly classified as T4.

each component (PET, CT and fused PET/CT images) were our goals. On the contrary, the aim of our study was exclusively to evaluate PET/CT as a single complex technique in colorectal cancer T staging, comparing its performance directly with the gold standard of histological results.

In colorectal cancer, accurate assessment of the T stage and tumor size may aid in determining the correct way to access the lesion (local endoscopic excision, laparotomy, laparoscopy, or transanally), or the modality of surgery (radical or limited resection, palliative derivative surgery). Moreover, for rectal cancer, the T stage will be of major clinical relevance since its accurate preoperative assessment may help to select patients who will benefit from neoadjuvant therapy compared with resection alone.

In colorectal cancer, although various imaging modalities have been proposed for TNM staging, ceCT widely represents the first diagnostic step due to relatively low cost and widespread availability. For T staging, endorectal US and MRI are becoming mandatory in the management of rectal cancer^[15-19,26]. For N staging, malignant lymph node identification remains a problem and the use of the size criteria may lead to misdiagnosis: evaluation of the outline of the node and the features of signal intensity with MRI^[15-19,26] as well as the assessment of glucose metabolism with PET/CT^[22,23,27] have been shown to be more reliable. For M staging, particularly for liver metastases, the optimal imaging staging strategy has not yet been defined and the role of CT, MRI, PET/CT and US is still debated^[22,28-32].

As a result, if PET/CT is used as the all-in-one im-

aging modality in the staging of colo-rectal cancer, it is mandatory that it is demonstrated to be accurate in the evaluation of the T parameter, it adopts a minimal complex procedure, is well tolerated by patients, is less time consuming and is as inexpensive as possible.

Thus, the choice to perform PET/CT without the aid of iv contrast medium and colonography has been dictated by our interest in evaluating how accurate this modality, in its basal condition, is in T staging. The use of iv contrast medium allows better definition of the boundaries of structures and colonography permits easy identification of the primary tumor and a more accurate assessment of its local extent^[13,14]. However, the radio-tracer may play the role of “metabolic contrast agent” and is able to increase the contrast resolution of the structures, to characterize the perilesional tissues and to compensate for the absence of luminal distension on the unenhanced CT images, as demonstrated in our series in which 95% of adenocarcinomas were correctly identified and staged.

Moreover, a basal PET/CT protocol also offers the chance of colorectal cancer staging to those patients in whom the administration of iv contrast medium is contraindicated or not recommended, such as patients with impaired renal function or with an allergic history.

CT and PET/CT have limitations in distinguishing the wall layers of the colon, as a consequence, the differentiation of T1 and T2 tumors is not accurate^[13,14,22]. For this reason we decided to classify T1 and T2 tumors as a single group (\leq T2). Further technique developments concerning CT and PET resolution may improve their ability to differentiate the colonic wall layers and as a result T1 from T2 tumors. The distinction between T1 and T2 stage is not crucial for the therapeutic management of colorectal cancer because the mandatory information relates to whether the tumor is confined to the colonic wall or infiltrates the surrounding tissues.

In our series, a significant difference in SUVmax between each T group was not observed. As a result, it was not possible to identify a potential cut-off value of SUVmax for each T stage in our population.

It is well known that normal gastro-intestinal tract can accumulate FDG extensively, hindering pathological focal tracer uptake or simulating the presence of a tumor. The physiological FDG gastro-intestinal uptake was not the cause of misinterpretation in our series, as tumors were identified either morphologically or metabolically by the readers.

Neither bowel peristalsis nor respiratory motion resulted in mis-registered PET and CT datasets, hindering the interpretation of images in our population.

In our series, two lesions located in the transverse colon and in the sigmoid colon, respectively, were missed. In both cases, retrospective re-evaluation of the colonic segment involved allowed us to conclude that the flat morphology of the two lesions rather than their dimensions or the physiological bowel uptake hindered the identification of these lesions.

Although mucinous adenocarcinoma is a histopathological type of colorectal cancer known to have limited FDG PET sensitivity, the three mucinous adenocarcinomas were correctly identified and staged in our series.

Nodal status was correctly evaluated in 27/34 patients with an accuracy of 79.4%. The use of an un-enhanced PET/CT protocol did not invalidate the N stage as shown by our findings which are similar to those reported in other papers^[22,23]. Moreover, it has been demonstrated that contrast-enhanced PET/CT shows a trend towards more accurate N-staging of rectal cancer compared with non-contrast-enhanced PET/CT^[23]. Subcentimeter positive nodes are the major source of false negative results in nodal staging, being missed by both PET/CT with and PET/CT without contrast enhancement^[23]. As a result, the spatial resolution of PET/CT is not sufficient to detect small lymph node metastases and this limitation can not be obviated by the administration of iv contrast material.

In conclusion, our data suggest that FDG-PET/CT, without administration of iv contrast medium or colonography may be an accurate modality for identifying primary tumor and defining its local extent in patients with colorectal cancer. Further investigations using larger populations and PET/CT devices with improved spatial resolution need to be performed to confirm our observations.

COMMENTS

Background

In oncologic patients, the accurate evaluation of the T (tumor depth), the N (lymph node status) and M (distant metastases) of the primary neoplasm is a crucial point relative to therapeutic management. Although multiple imaging modalities, such as ultrasound (US), computed tomography (CT), magnetic resonance imaging and positron emission tomography (PET)/CT, are available for local tumor and distant staging, an all-in-one staging imaging modality would be a great opportunity to reduce the costs and the time of hospitalization.

Research frontiers

Un-enhanced FDG-PET/CT and more recently contrast-enhanced FDG-PET/CT (PET/ceCT) are gaining a progressively more important role in the evaluation of the N and the M stages in the staging and follow-up of colorectal cancer, however, the performance of this modality in the evaluation of the T parameter has not been extensively investigated.

Innovations and breakthroughs

Our findings suggest that FDG-PET/CT may be an accurate modality for defining local extent (T) of colorectal cancer.

Applications

If PET/CT accurately evaluated the T parameter, this would be a great opportunity to use PET/CT as an all-in-one staging imaging modality in colorectal cancer patients, and subsequently selecting and tailoring the performance of anatomically-based imaging modalities without or with iv contrast medium (US, magnetic resonance, CT) to better define the abnormalities identified by PET/CT, when this information would be of relevance to management planning.

Abstract

AIM: To detect the proteomic variabilities of pancreatic intraepithelial neoplasia (PanIN) and pancreatic carcinoma (PC) induced by 7,12-dimethylbenzanthracene (DMBA) in rat models and to identify potential biomarkers.

METHODS: Sixty adult male Sprague Dawley rats were randomized into three groups. The rats had DMBA implanted into their pancreas for one ($n = 20$) or two months ($n = 20$) or assigned to the normal group ($n = 20$). The rats were killed after one or two months, and were evaluated histopathologically. Three tissue samples from each group of rats with either normal pancreas, PanIN (PanIN-2) or PC were examined by 2D-DIGE. The different expression spot features were analyzed by matrix-assisted laser desorption/ionization-time of flight/time of flight (MALDI-TOF/TOF) tandem mass spectrometry. The expression of enolase 1, a differentially expressed protein, was identified by immu-

nohistochemistry.

RESULTS: There was significant difference in the proportions of neoplastic changes between the 1- and 2-month groups ($P = 0.0488$). There was an increase in the frequency of adenocarcinomas in the 2-month group compared with the 1-month group ($P = 0.0309$). No neoplastic changes were observed in any of the animals in the normal group. Enolase 1, pancreatic ELA3B, necdin, Hbp23, CHD3, hnRNP A2/B1, Rap80, and Gnb21 were up-regulated in the PanIN and PC tissues, and CEL, TPT1, NME2, PCK2, an unnamed protein product, and glycine C-acetyltransferase were down-regulated in the PanIN and PC tissues. The immunohistochemical results showed that enolase 1 expression was up-regulated in the pancreatic cancer tissues of rats and humans.

CONCLUSION: The pancreatic protein expression changes induced by DMBA suggest potential molecular targets for the early diagnosis and treatment of PC.

INTRODUCTION

Pancreatic carcinoma (PC) is one of the most lethal hu-

man cancers, and 80%-90% of PCs are pancreatic ductal adenocarcinomas. Pancreatic cancer is characterized by a late presentation, and for all stages of this cancer, the five-year survival rate is less than 5%. It is currently the fourth most common cause of cancer death for both men and women^[1]. This poor prognosis relates to the uniformly advanced disease stage at the time of diagnosis and its profound resistance to the existing therapies. An early detection of pancreatic cancer is required to improve its poor prognosis.

As the clinical diagnosis of pancreatic cancer is mostly at advanced stages, to study the mechanisms of PC and screen tumors for early diagnostic markers, it is important to establish animal models of precancerous pancreatic lesions and the early stages of PC with pathological characteristics resembling that of human PC. Pancreatic intraepithelial neoplasia (PanIN) has been identified as the precursor of pancreatic ductal adenocarcinoma^[2,3], and animal models of PanIN and pancreatic ductal adenocarcinoma can provide opportunities to investigate earlier pancreatic cancers that are rare in human samples. Animal models involve successful chemical carcinogens such as 7,12-dimethylbenzanthracene (DMBA). DMBA implantation into the pancreas is known to induce ductal PanIN and PC in mice and rats through pathways that consistently involve K-ras gene mutations and the activation of Notch signaling, as in human pancreatic cancer^[4-10]. At present, DMBA-induced pancreatic carcinogenesis models have been used in the identification of possible promoters or suppressors of PC^[8,11,12], stable isotope glucose-tracer studies^[13] and molecular analyses^[10].

Proteomic techniques are emerging as important tools for studying the mechanisms of disease and finding potential biomarkers and new therapeutic targets, which enable investigators to determine whether a particular protein level is increased or decreased when comparing two different conditions (e.g. a diseased state and a non-diseased state)^[14,15]. Although proteomic studies of PC in human samples have been reported, most of the samples were acquired from advanced PC but not precancerous pancreatic lesions or the early stages of PC. The protein expression changes from normal pancreas to PanIN and early stages of PC remain unclear. In the present research, we studied the proteomic variabilities of rat models of DMBA-induced PanIN and PC using proteomic techniques, two-dimensional fluorescence difference gel electrophoresis (2D-DIGE) and mass spectrometry, to reveal new potential biomarkers for PanIN and PC.

MATERIALS AND METHODS

Animal treatment

Sixty adult male Sprague Dawley (SD) rats (100-110 g) were randomized into three groups. The rats in the 1- ($n = 20$) and 2-mo groups ($n = 20$) had DMBA (10 mg/100 g) directly implanted into their pancreas, according to a previously established protocol^[9], and the surviving rats were killed after one month and two months, respective-

Table 1 Sample markers and gel distribution in 2D-DIGE analysis

ly. A normal group of 20 rats was killed after two months. The carcinogen implant site was separated from the rest of the pancreas, the pancreatic nodules were fixed in formalin and embedded in paraffin, and multiple 5-mm sections were prepared and stained with hematoxylin and eosin for routine histological examinations. The pancreas slides were reviewed by a single pathologist and evaluated histologically according to the PanIN classification system^[2,3].

2D-DIGE and image analysis

Three rat models with either normal pancreas (group A), PanIN (group B, PanIN-2), or PC (group C) were established, and three samples per group were collected. Approximately 300 mg of each tissue sample was divided into 3-mm³ pieces and then homogenized with a Dounce's homogenizer on ice in 1 mL lysis solution containing 7 mol/L urea, 2 mol/L thiourea, 4% CHAPS and a protease inhibitor mixture (Bio-Rad). The sample lysates were then placed into Eppendorf tubes and sonicated on ice for 10 s, and this procedure was repeated eight times. The sample lysates were centrifuged at 14000 rpm for 60 min, and the supernatants were collected. The total protein concentration in each sample was determined by the Bio-Rad method.

The protein concentration in each sample was dissolved to 5 µg/µL with lysis buffer, and equal amounts of protein from each individual sample were pooled to make the internal standard. The pH of all the samples and the internal standard was adjusted to 8.0-9.0. Five DIGE gels were included in the experimental design, as shown in Table 1. Two different samples in each gel contained 50 µg protein labeled with 1 µL green (Cy3) or red (Cy5) fluorescent dyes (Amersham Biosciences). The third sample contained 50 µg internal standard labeled with yellow (Cy2) fluorescent dye. The labeling reaction was performed on ice for 30 min in the dark and quenched with 1 µL of 10 mmol/L lysine for 10 min.

One-dimensional isoelectric focusing was carried out on an Amersham Biosciences Ettan IPGphor IEF system. The samples (100 µg) were loaded using 13-cm pH-3-10 IPG strips. Isoelectric focusing was performed at 30 V for 12 h, 500 V for 1 h, 1000 V for 1 h, 8000 V for 8 h and 500 V for 4 h. After IEF, the IPG strips were equilibrated with an equilibration buffer containing 50 mmol/L Tris-HCl, 6 mol/L urea, 30% glycerol, 2% SDS, and 1% DTT for 15 min at room temperature, followed by 2.5% iodoacetamide instead of 1% DTT in equilibration buffer for another 15 min. The equilibrated strip was transferred to the top of 1 mm of a 12.5% SDS-polyacrylamide gel and

fixed with 0.5% agarose. The second dimension of SDS-PAGE was performed at a constant current of 15 mA/gel for 30 min and 30 mA/gel until the bromphenol blue fronts reached 0.5 cm from the bottom of the gel.

The fluorescent dye-labeled proteins in each gel were scanned with a Typhoon 9400 fluorescence scanner (Amersham Biosciences) at different wavelengths specific for Cy2 (488/520 nm), Cy3 (532/580 nm) and Cy5 (633/670 nm). Image analysis of 2D-DIGE was performed with Decyder 5.0 software (GE Healthcare) according to the manufacturer's recommendations. Differential protein analysis of the three groups was carried out using one-way ANOVA. Differentially expressed protein spots ($P < 0.01$) were marked.

Protein identification

Two-dimensional electrophoresis of preparative gels containing 1 mg protein was performed like 2D-DIGE, and the gels were stained with Coomassie brilliant blue. The protein spots to be identified were manually excised from the preparative gels. The gel pieces were de-stained in 3% acetic acid and 100 mmol/L ammonium bicarbonate, and in-gel digestion was performed for 20 h at 37°C in 40 mmol/L ammonium bicarbonate containing 0.01 µg/µL trypsin. The tryptic peptides were extracted with 0.1% TFA (60% ACN from the supernatants), and the extracts were lyophilized and saved at -80°C.

The lyophilized peptide mixtures were re-dissolved in 0.1% TFA, the peptide solution was washed with 0.1% TFA, and the 60% ACN was mixed with HCCA (5 mg/mL). Matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) and MALDI-TOF/TOF mass spectrometry were obtained using a Bruker-Daltonics Autoflex TOF-TOF Lift mass spectrometer. Peptide mass fingerprints (PMFs) were acquired for each differentially expressed protein in positive-reflection mode (20 kV accelerating voltage, 23 kV reflecting voltage). The PMFs were searched in the database of the National Center for Biotechnology Information (NCBI) of *Rattus* using the software Mascot. Carbamidomethyl was specified as fixed modification, and the oxidation as variable modifications, and the peptide mass tolerance was ± 100 ppm. The statistically significant protein scores were found ($P < 0.05$), and, if more than one protein was identified, the single protein with the top score was matched to the protein spot.

Immunohistochemistry

Three pairs of rat normal pancreas and DMBA-induced PC tissues and 30 pairs of PC and adjacent non-carcinoma tissues from humans in a tissue microarray (Shanghai Outdo Biotech Co. Ltd, OD-CT-DgPan03-002, 19 male and 11 female) were used for immunohistochemical staining. All of the samples were formalin-fixed and embedded in paraffin. The sample sections were deparaffinized and successively rehydrated in xylene and alcohol and washed three times in phosphate buffered saline (PBS). The endogenous peroxidase activity was blocked with 3% hydrogen peroxide in PBS for 10 min, and the sections were then incubated with 0.05% trypsin for 30 min

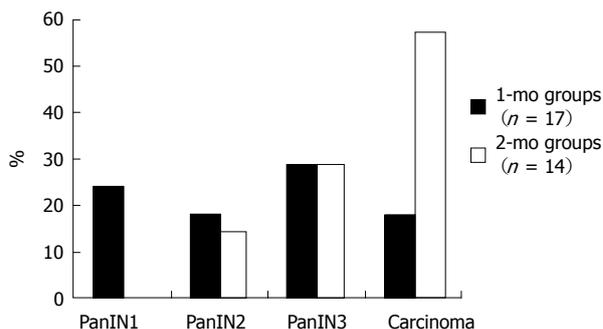

Figure 1 Pathological diagnoses in 1- and 2-mo groups after 7,12-dimethylbenzanthracene implantation. The difference between two groups was statistically significant ($P = 0.0488$), and there was an increase in the frequency of adenocarcinomas in the 2-mo group compared with the 1-mo group ($P = 0.0309$). PanIN: Pancreatic intraepithelial neoplasia.

at 37°C. After three washes with PBS, nonspecific binding was blocked with 10% BSA in PBS for 30 min at 37°C. The sections were then incubated overnight at 4°C with an enolase 1 antibody at a dilution of 1:400, and sections incubated with PBS instead of the enolase 1 antibody, served as control. DAB (1:50) was used to detect the enolase 1 with the deposition of a brown reaction product in the nuclei and cytoplasm of the positive cells. The proportion of positively stained cells in each section was averaged from three high-magnification images.

Statistical analysis

Differences between groups were analyzed by two-tailed Chi-square tests and two-tailed Fisher's exact tests. The significance level was defined as $P < 0.05$.

RESULTS

Rat models of DMBA-induced PanIN and PC

In the 1-mo group, 15% (3/20) of the rats died in the postoperative period, whereas 30% (6/20) died in the 2-mo group. No statistically significant difference in the death rate was observed between the groups ($P = 0.4489$). Pathologic evaluation revealed that 71% (12/17) of the rats had PanIN lesions and 18% (3/17) of the rats had adenocarcinomas in the 1-mo group. Of these, 24% (4/17) had PanIN1 lesions, 18% (3/17) had PanIN2 lesions and 29% (5/17) had PanIN3 lesions. In the 2-mo group, 14% (2/14) had PanIN2 lesions, 29% (4/14) had PanIN3 lesions, and 57% (8/14) had adenocarcinomas (Figure 1). The difference in the proportions of neoplastic changes was statistically significant between the two groups ($P = 0.0488$), and there was an increase in the frequency of adenocarcinomas in the 2-mo group compared with the 1-mo group ($P = 0.0309$). No neoplastic changes were observed in any of the animals in the normal group.

2D-DIGE analysis of differential proteomic expression of DMBA-induced PanIN and PC

After spot quantification and statistical analysis using the 2D-DIGE approach described above, 1445, 1469, 1380,

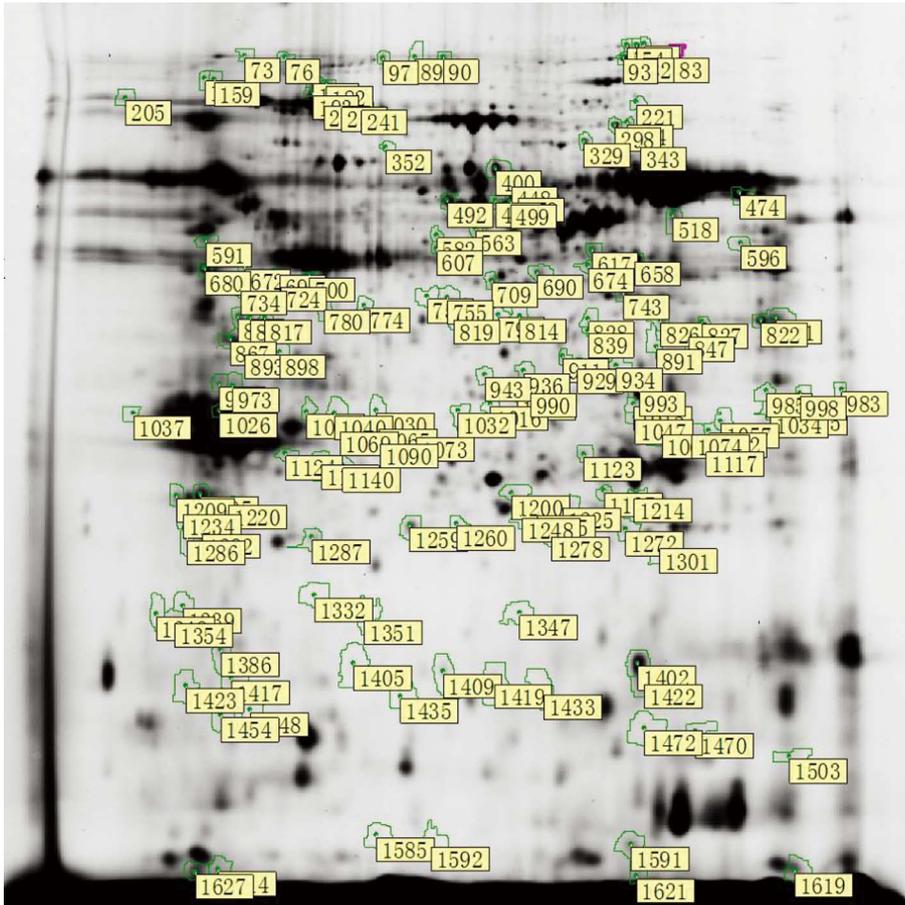

Figure 2 Map of 155 protein spots with significantly differential expression ($P < 0.01$) in normal pancreatic (group A), pancreatic intraepithelial neoplasia-2 (group B) and pancreatic carcinoma (group C) tissues. Thirty-one protein levels progressively increased, and 17 protein levels progressively decreased from normal pancreatic tissue to 7,12-dimethylbenzanthracene-induced pancreatic intraepithelial neoplasia and pancreatic carcinoma.

1512, and 1637 spots were identified in gel1, gel2, gel3, gel4 and gel5, respectively. After background subtraction and radiometric normalization, matched spots from all of the gels were used for statistical analysis. By using the criterion of $P < 0.01$, 155 spots were significantly differentially expressed by their relative abundances in groups A, B and C (Figure 2). Furthermore, 31 protein levels progressively increased from normal pancreas to pancreas with DMBA-induced PanIN and PC. Additional 17 protein levels progressively decreased, and 21 spots were selected for identification using a MALDI-TOF/TOF mass spectrometer. We found that the abundances of enolase 1, pancreatic elastase 3B (ELA3B), necdin, Hbp23, chromodomain helicase DNA-binding protein 3 (CHD3), heterogeneous nuclear ribonucleoprotein A2/B1 (hnRNP A2/B1), retinoid X receptor-interacting protein (Rap80), guanine nucleotide-binding protein (G protein), and beta polypeptide 2-like 1 (Gnb2l1) progressively increased with the severity of the disease. The abundances of carboxyl ester lipase (CEL), tumor protein translationally controlled 1 (TPT1), expressed in non-metastatic cells 2 (NME2), phosphoenolpyruvate carboxykinase 2 (PCK2), an unnamed protein product, and glycine C-acetyltransferase progressively decreased with DMBA-induced disease severity (Table 2).

Immunohistochemical analysis of enolase 1

Immunohistochemical staining showed that the expression level of enolase 1 was highest in the nucleus and cytoplasm; membranous immunoreactivity was also detected. The enolase 1 expression levels in DMBA-induced PC and normal rat pancreatic tissues were compared, and the staining results showed that the rat PC tissue had a higher enolase 1 expression level ($P = 7.5633E-014$). In the rat PC tissue, an average of 83% of cells expressed enolase 1, whereas only 31% of the cells in rat normal pancreatic tissues expressed enolase 1. The expression of enolase 1 was compared in pancreatic cancer and adjacent non-carcinoma tissues from 30 patients, and the average proportion of enolase 1-positive cells in the human pancreatic cancer tissue was 91%, and only 37% in adjacent non-carcinoma tissues. The expression of enolase 1 was also significantly increased in human PC tissues ($P = 3.3514E-015$) (Figure 3).

DISCUSSION

Animal models of PanIN and PC that resemble the human disease are very important for research. The characteristics of these models should include the following: (1)

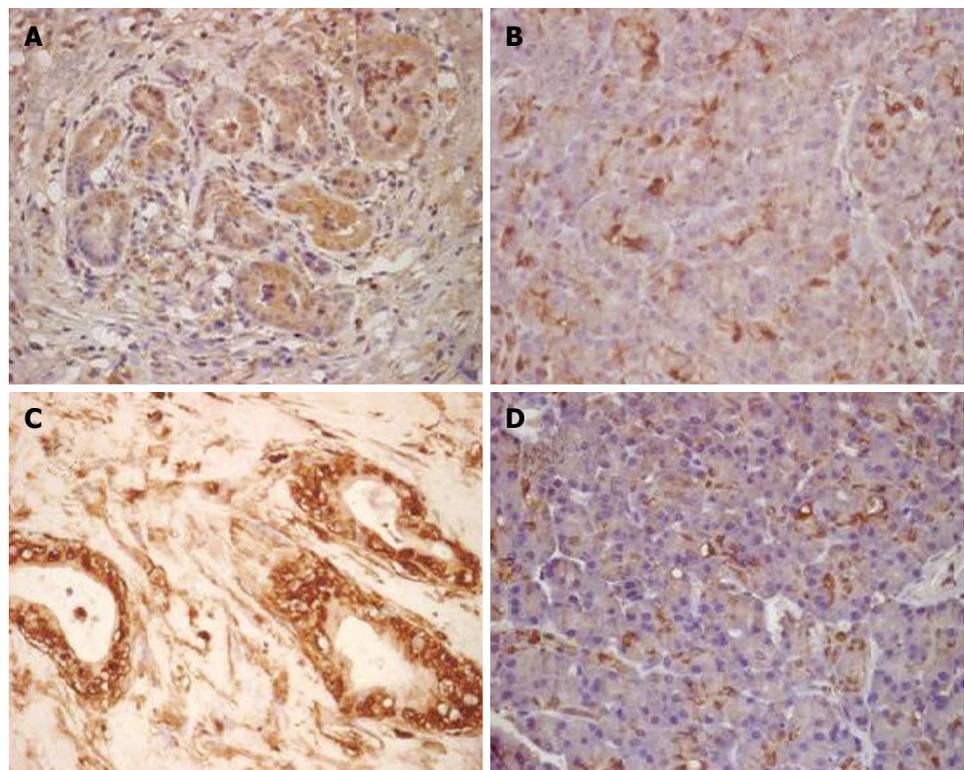

Figure 3 Enolase 1 expression was significantly increased in human and rat pancreatic carcinoma (immunohistochemistry, magnification × 400). A: Positive expression in rat pancreatic cancer; B: Weakly positive expression in the normal rat pancreas; C: Positive expression in human pancreatic cancer; D: Weakly positive expression in human adjacent non-carcinoma tissues.

A pancreatic ductal phenotype that arises from pancreatic ductal cells; (2) Extensive reactive proliferation of the

connective tissue; (3) Obstruction of the bile duct and stomach during disease progression; (4) Early neural, peritoneal, and liver metastases; and (5) High rates of K-ras, *P16* and *P53* gene mutations^[16]. The experimental models of PanIN and PC in the present study are chemical carcinogenesis models. DMBA-induced pancreatic carcinogenesis models resembled human PC in several previous studies. Rivera *et al*^[6] found that DMBA was one of the three different carcinogens reliably producing PC histology that is similar to human ductal adenocarcinoma. DMBA was either implanted directly into the pancreas or infused into the pancreatic ducts of SD rats, and the development of ductal hyperplastic, atypical, and dysplastic changes preceding and accompanying the invasive pancreatic ductal adenocarcinoma could be observed in this experimental model. Jimenez *et al*^[7] demonstrated that DMBA-induced rat tubular complexes and pancreatic adenocarcinomas strongly expressed ductal cell markers (keratin, cytokeratins 19 and 20) but not acinar cell markers (chymotrypsin), suggesting that these tumors arose from ductal cell transformation. K-ras mutations were significantly more frequent in DMBA-induced PC tissues than in normal tissues, with a prevalence of up to 91%^[8]. Pancreatic carcinogenesis induced by DMBA implantation in mice was re-evaluated according to the PanIN classification system after its establishment, and extensive pathological changes characteristic of PanIN could be observed one month after carcinogen implantation^[9]. We used the PanIN classification system in the histological analysis, and our pathologic evaluation showed that 71% (12/17) of the rats had PanIN lesions and 18% (3/17) had adenocarcinomas in the 1-mo group. In the 2-mo group, 43% (6/14) had PanIN lesions and 57% (8/14) had adenocarcinomas. The frequencies of PanIN and PC in our rat models were similar to a previous study in mice^[9]. Our models were satisfactory because the development of precursor lesions (PanIN) and an invasive adenocarcinoma were observed in all groups. There was an increase in the frequency of adenocarcinomas, and the PanIN classification increased with DMBA induction, reflecting the dynamic development of a normal pancreas into a cancerous pancreas.

There are several techniques available for protein separation, both gel- and non-gel-based. Gel-based techniques include traditional two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) and, more recently, 2D-DIGE. 2D-DIGE usually contains three samples labeled with three distinct fluorescent dyes: Cy2, Cy3 and Cy5. The Cy2 dye is typically used to label an internal standard; the strength of the internal standard helps map the spots/proteins between the gels, thus rendering different gels more comparable^[17-19]. In the current study, we used 2D-DIGE and MALDI-TOF/TOF tandem mass spectrometry to profile pancreatic proteins in rat models of DMBA-induced PanIN and PC and compared these profiles with those of normal rats. Our 2D-DIGE data showed that 155 spots were significantly differentially expressed based on their relative abundances in the three groups. Of these, 31 protein levels progressively increased from normal to PanIN and then to PC tissue, whereas 17 protein lev-

els progressively decreased. These results demonstrated synchronous dynamic changes in the pancreatic protein expression profile after DMBA induction. A number of novel proteins were identified that may be involved in important aspects of mRNA transcription, DNA damage repair, chromatin remodeling, oxidative stress, regulation of tumor growth and metastasis, glucose metabolism, and the synthesis and secretion of pancreatic enzymes.

Enolase 1, also known as α -enolase or non-neuronal enolase (NNE), is an isoenzyme of enolase, which is a glycolytic enzyme catalyzing the conversion of 2-phosphoglycerate into phosphoenolpyruvate. Recent researches have shown that enolase 1 plays an important role in several biological and pathophysiological processes. Enolase 1 is thought to play a potential role in tumorigenesis, cancer invasion and metastasis. Previous proteomic studies reported that enolase 1 was up-regulated in several cancers, such as hepatocellular carcinoma^[20-22], non-small lung cancer^[23,24], esophageal adenocarcinoma^[25], prostate cancer^[26], colon cancer^[27], oral epithelial and squamous cell carcinoma^[28]. In our study, we found a significant up-regulation of enolase 1 in rat models of DMBA-induced PanIN and PC with further verification by the immunohistochemical analysis of human and rat tissues. These results agree with other proteomic researches on human PC. Mikuriya *et al*^[29] found that the expression levels of glycolytic enzymes, including enolase 1, increased in the cancerous pancreatic tissues of 10 patients compared with the paired non-cancerous tissues, as determined by proteomic profiling using two-dimensional electrophoresis and liquid chromatography-mass spectrometry/mass spectrometry. Shen *et al*^[30] used a proteomic approach using two-dimensional gel electrophoresis and mass spectrometry to identify differentially expressed proteins in six PC cases, two normal adjacent tissues, seven cases of pancreatitis, and six normal pancreatic tissues. Alpha-enolase was also specifically overexpressed in tumors compared with normal and pancreatic tissues.

The hnRNP A2/B1 protein was shown to be up-regulated in our models. This protein plays an important role in the biogenesis and transport of mRNA. The over-expression of hnRNP A2/B1 indicates that normal transcriptional regulation is altered. A previous study also found high levels of hnRNP A2/B1 expression in a limited number of human pancreatic adenocarcinomas from smokers and two pancreatic tumor cell lines, HPAF-11 and SU 86.86^[31]. CEL is one kind of pancreatic exocrine enzyme, and we found that it was down-regulated after DMBA induction. Reuss *et al*^[32] verified strong CEL gene expression in the acinar cells of the normal pancreas, and adenocarcinomas showed no expression, which agrees with our results. The other differentially expressed proteins that we identified are rarely reported in PC, and their relationships with PC await further clarification.

In summary, our data have shown DMBA implantation into the pancreas is an effective method to establish rat models of PanIN and PC, and the protein changes observed in DMBA-induced PanIN and PC, such as enolase 1 up-regulation, demonstrate the feasibility of

identifying potential molecular targets for the early diagnosis and treatment of PC.

COMMENTS

Background

The early detection of pancreatic cancer (PC) is still difficult, but proteomic techniques are emerging as important tools to find potential biomarkers and new therapeutic targets for PC and precancerous pancreatic lesions.

Research frontiers

7,12-dimethylbenzanthracene (DMBA) implantation into the pancreas is known to induce PC and pancreatic ductal intraepithelial neoplasia (PanIN) in mice and rats that resemble human PC with K-ras gene mutations and the activation of Notch signaling.

Innovations and breakthroughs

Precancerous pancreas lesions and the early stages of PC among clinical diagnoses are rarely found. In the present research, the authors studied the proteomic variabilities of rat models of DMBA-induced PanIN and PC.

Applications

The protein changes in DMBA-induced PanIN and PC reported in this article, such as enolase 1 up-regulation, demonstrate the feasibility of identifying potential molecular targets for early PC diagnostics and therapeutics.

Terminology

Two-dimensional fluorescence difference gel electrophoresis is a gel-based technique that has recently been used for protein separation. It contains three samples labeled with three distinct fluorescent dyes: Cy2, Cy3 and Cy5.

Peer review

This is a good study to define the stages of pancreatic carcinoma in experimental models and its correlation with various markers.

Abstract

AIM: To establish a gastric cancer nude-mouse model with improved orthotopic implantation and investigate its biological characteristics at different time points.

METHODS: Human gastric cancer SGC-7901 cell suspensions were injected subcutaneously into a nude mouse to develop solid tumors, and the tumor tissue pieces were implanted under the serous coat. The nude mice were then euthanized in group every two weeks to observe the primary tumor growth and metastases.

RESULTS: Within 2-4 wk, there were no obvious chang-
