RESULTS: The median follow-up period was 47 mo (range: 6-85 mo). The characteristics of 35 (25.7%) patients with HER2 over-expression of liver metastatic GC are presented. HER2 over-expression was detected in 23 out of 49 (46.9%) patients with intestinal GC, and 9 out of 35 (25.7%) patients with diffuse GC. 29 out of 59 (49.2%) patients aged < 60 years were HER2-positive, while 8 out of 25 (32%) patients aged ≥ 60 were HER2-positive; a significant difference ($P < 0.05$). Univariate analysis (log-rank test) showed that HER2 over-expression, sex, Lauren classification, differentiation and disease-free interval were correlated with poor survival ($P < 0.05$). Survival analysis with a survival curve showed that HER2 over-expression was significantly relevant, with a reduced survival time in GC patients with liver metastases ($P < 0.01$). 2-year survival was not associated with the patient's age. A disease-free survival longer than 12 mo has a significant association with extended overall survival (OS) in GC patients with liver metastases. The median survival time after the diagnosis of liver metastases was 18 mo [95% confidence interval (CI): 9.07-26.94] among HER2 positive GC patients with liver metastases. In comparison, for 49 (69.4%) out of 84 HER2 negative patients with liver metastatic GC, the median survival time was 47 mo (95% CI: 19.37-74.63). In patients with HER2 positive liver metastatic GC, the median OS was significantly shorter than in HER2 negative patients (median, 20.32 mo; 95% CI: 16.51-24.13 *vs* median, 50.14 mo; 95% CI: 37.83-62.45; $P < 0.01$).

CONCLUSION: HER2 over-expressing GC patients with liver metastases have a poor prognosis. Overall survival was significantly lower in HER2 positive patients. HER2-overexpression is correlated with a lower survival rate.

Key words: Human epidermal growth factor receptor 2;

INTRODUCTION

Although the incidence of gastric cancer (GC) has slightly declined in the past several decades, it remains the second leading cause of cancer death worldwide, especially in Asia[1]. GC with human epidermal growth factor receptor 2 (HER2) over-expression accounts for 9%-38% of GC, and HER2 is mainly expressed on the cell membrane. Yan et al[2] studied HER2/neu protein expression and gene amplification in gastric carcinoma and their relationship. They recommended that all samples with immunohistochemistry (IHC) as HER2 expression should be analyzed with fluorescence *in situ* hybridization and found that the detection of *HER2* gene amplification can assess the malignant biological behaviors and prognosis of gastric cancer. Zhang et al[3] found HER2 over-expression in 18.6% of GC and HER2 located mostly on the membrane, which was consistent with what was previously reported. Yu et al[4] examined the expressions of Grb2 and HER2 in normal gastric mucosa, primary gastric cancer, and lymph node metastatic foci in 1143 GC patients by using tissue microarray assay, which suggested the importance of Grb2 and HER2 in GC development and progression. Matsubara et al[5] investigated 86 patients who received first-line chemotherapy for advanced GC. Their results showed that patients with high HER2 expression had a longer survival time than those with low HER2 expression. However, there is controversy with regard to the hypothesis that HER2 expression serves as a factor in predicting the prognosis of GC patients[6-10]. In a prospective study of 63 patients with resectable CG (in which follow-up was performed for 40.7 mo), membranous epidermal growth factor receptor (EGFR) was detected by random and double blind assays, and cytosolic HER2 by immuno-enzymatic assay. Results showed that high expression of EGFR and HER2 in cancers were associated with a poor outcome in patients with resectable GC[11].

Detection of micrometastatic foci may allow for a more accurate assessment of the prognosis, along with aiding in the selection of candidates for intensive chemotherapy among GC patients. Bone marrow micrometastasis has been shown to influence the prognosis of GC patients[12,13]. Matsunami et al[14] used ion mobility spectrometry to improve detection sensitivity in their study, and their results showed that only 30% of patients showed the development of bone marrow micrometastasis. The positive rate was lower than that in Western patients[15], but similar to those of the Japanese[15]. In the present study, we investigated the prognosis of GC patients with HER2 over-expression in the liver metastatic foci in Chinese patients.

MATERIALS AND METHODS

Patient selection and clinicopathologic parameters

A total of 84 GC patients recruited from the General Hospital of the People's Liberation Army (PLA) between 2003 and 2010 were randomly enrolled in this study. All patients underwent radical dissection and chemotherapy, and/or radiotherapy. The study group consisted of 66 men and 18 women, with an average age of 54 years (range: 19-74 years). GC tissue and adjacent normal tissue were collected for pathologic examination. The detailed pathologic results were obtained from the Department of Pathology of the General Hospital of the PLA.

The histologic type of GC was defined according to Lauren's classification. This classification divides GC into intestinal (in which well-formed tubules were found) and diffuse (in which diffuse tumor infiltration and signet ring cells were noted, but well-formed tubules were absent) types. In our study, 53 patients were pathologically diagnosed with intestinal GC and 31 with diffuse GC.

Patients were followed-up for 6-85 mo. Informed consent was obtained before the study, and the protocol was approved by the Clinical Research Ethics Committee of the General Hospital of the PLA.

Immunohistochemistry

Formalin-fixed and paraffin-embedded sections (5 μm) were deparaffinized in xylene, rehydrated through an ethanol series, and treated for 10 min in a microwave oven at 98 ℃ for antigen retrieval. Sections were then blocked in 3% hydrogen peroxidase, followed by incubation with a protein-blocking agent. Sections were treated with fetal bovine serum (10%), with or without the HER2 antibody (1:100), for 30 min at 37 ℃ then counterstained with hematoxylin and mounted. Omission of the primary antibody was used as a negative control for tissue sections. Anti-HER2 monoclonal antibody (Dako Herceptin Test kit; Dako, Glostrup, Denmark), and Dako EnVisionTM Kit (Dakocytomation, Dako) were used for IHC. The sections were examined microscopically and interpreted in a blinded fashion by two pathologists. HER2 protein expression on the cell membrane was scored according to the following criteria: 0: No staining or < 10% of tumor cells; 1+: Faint/barely perceptible partial staining in > 10% of tumor cells; 2+: Weak to moderate staining of the entire membrane or cytoplasm in > 10% of tumor cells; 3+: Strong staining in > 10% of tumor cells. Tumors with scores of 0 and 1+ were evaluated as negative while those with scores 2+ and 3+ were positive.

Table 1 Human epidermal growth factor receptor 2 expression in the liver metastatic foci in gastric cancer patients

Parameter	Patient (*n*)	HER2 + patients (*n*)	Ratio (%)	*P* value
Age (yr)				
< 60	59	29	49.2	< 0.05
⩾ 60	25	8	32	
Gender				
Male	66	28	42.4	> 0.05
Female	18	7	38.9	
Tumor type				
Intestinal	49	23	46.9	< 0.05
Diffuse	35	9	25.7	

The proportion of patients with human epidermal growth factor receptor 2 (HER2) over-expression was higher in patients with gastric cancer (GC) of the intestinal-type than in those with GC of the diffuse-type.

Table 2 Clinicopathologic parameters and survival

Parameter	Patient (*n*)	2-yr survival (%)	*P* value
Age (yr)			> 0.05
< 60	56	66.1	
⩾ 60	28	60.7	
Gender			< 0.05
Male	66	78.6	
Female	18	21.4	
HER2 over-expression			< 0.05
Absent	49	58.3	
Present	35	41.7	
Lauren classification			< 0.05
Intestinal	49	58.3	
Diffuse	35	41.7	
Differentiation			< 0.05
High/middle	4	80	
Low/null	50	63.3	
Disease-free interval (*n* = 84)			< 0.05
⩾ 12 mo	63	75	
< 12 mo	19	22.6	

Disease-free survival longer than 12 mo has significant association with extended overall survival in gastric cancer patients with liver metastasis. HER2: Human epidermal growth factor receptor 2.

Statistical analysis

A total of 35 GC patients with HER2-positive liver metastases were included in this study. Liver metastatic GC was pathologically diagnosed by pathologists at the National Comprehensive Cancer Network. Patients with clinical symptoms suggesting liver metastasis were diagnosed by abdominal magnetic resonance imaging (MRI) or computed tomography (CT) clinical information was collected from medical records, including the date of initial diagnosis of GC, the development of liver metastases, the date of chemotherapy, and death or the last follow-up, as well as disease sites at the start of chemotherapy and the details of treatment. We also evaluated the clinical response of other metastatic diseases according to the Response Evaluation Criteria in Solid Tumors at the time of diagnosis of liver metastasis. The baseline characteristics and prognostic factors for GC were reviewed, including age, sex, differentiation and GC type, and disease-free interval.

Figure 1 Kaplan-Meier survival curve in patients positive and negative for human epidermal growth factor receptor 2 in the liver metastatic gastric cancer. HER2: Human epidermal growth factor receptor 2.

Overall survival (OS) served as a main outcome.

SPSS version 17.0 software package (SPSS, Chicago, IL, United States) was used for statistical analysis. Frequency comparisons of HER2 expression status and clinicopathologic variables were performed with the *F* test (two-sided). Log-rank test was used for survival analysis. Survival curves were computed according to the Kaplan-Meier method. A value of *P* < 0.05 was considered statistically significant.

RESULTS

HER2 expression in the liver metastatic in gastric cancer patients

The median follow-up period was 47 mo (range: 6-85 mo). The characteristics of 35 (25.7%) patients with HER2 over-expression in liver metastatic GC are presented in Table 1. The results showed no significant differences between the sexes, although significant associations were observed between intestinal and diffuse (*P* < 0.05) types of GC. Over-expression of HER2 was observed as being higher for patients younger than 60 (*P* < 0.05).

HER2 over-expression was detected in 23 out of 49 (46.9%) patients with intestinal GC and 9 out of 35 (25.7%) patients with diffuse GC. The proportion of patients with HER2 over-expression was higher in patients with GC of the intestinal-type than in those with GC of the diffuse-type (*P* < 0.05). In addition, 29 out of 59 (49.2%) patients aged < 60 years were HER2-positive, while 8 out of 25 (32%) patients aged ⩾ 60 were HER2-positive, which was a significant difference (*P* < 0.05). However, there was no significant difference with regards to gender for HER2 over-expression (Table 1).

HER2 over-expression and overall survival

Univariate analysis (log-rank test) showed that HER2 over-expression, sex, Lauren classification, differentiation and disease-free interval were correlated with poor sur-

vival ($P < 0.05$), while age was not correlated with 2-year survival ($P > 0.05$) (Table 2). Survival analysis with a survival curve (Figure 1) showed that HER2 over-expression was significantly relevant with decreased survival time in GC patients with liver metastases ($P < 0.01$).

2-year survival was not associated with a patient's age. A disease-free survival (DFS) longer than 12 mo had significant association with an extended OS in GC patients with liver metastasis (Table 2).

The median survival time after diagnosis of liver metastases was 18 mo [95% confidence interval (CI): 9.07-26.94] among those HER2 positive with liver metastases in GC. In comparison, for 49 (69.4%) out of 84 HER2 negative patients with liver metastatic GC, the median survival time was 47 mo (95% CI: 19.37-74.63).

In patients with HER2 positive liver metastatic GC, the median OS was significantly shorter than in HER2 negative patients (median, 20.32 mo; 95% CI: 16.51-24.13 mo *vs* median, 50.14 mo; 95% CI: 37.83-62.45 mo; $P < 0.01$).

DISCUSSION

The HER2, an important member of the HER family, is encoded by a gene located on chromosome 17q21. During tumorigenesis, HER2 has been identified to act as an oncogene to modulate the proliferation, invasion and apoptosis of tumor cells. In cancer formation, HER2 acts as an oncogene to regulate the proliferation, invasion, and apoptosis of cancer cells. HER2 over-expression was reported in 9%-38% of GC, and was mainly found on the cell membrane[16]. The concordance between protein and mRNA over-expression of HER2 was recently elucidated in tumorigenesis, especially in cancers scored 3+ by IHC[17].

In approximately 25.7% of invasive GC, the HER2 tyrosine kinase receptor is over-expressed. HER2 consists of four different receptors and is associated with cell proliferation, differentiation, and survival. The HER2 over-expressing GC is more aggressive and has a poor prognosis. With respect to the importance of HER2 heterodimer in tumorigenesis, the signaling pathways and downstream effectors of the HER family have become key molecules in exploring strategies for anti-cancer therapy. For example, herceptin, a humanized monoclonal antibody targeting HER2/neu, has been used as a first-line anti-cancer drug in the treatment of breast cancer over-expressing HER2/neu[18,19]. Evidence from preclinical trials also indicated that herceptin could benefit GC patients[20,21].

To date, a high incidence of liver metastases has been observed in patients with HER2 over-expressing GC, which may be attributed to the biological characteristics of GC and the treatments for GC. A retrospective analysis has identified HER2 as a risk factor for the development of liver metastases and relapse. The 5-year incidence of liver metastases is significantly higher in patients with HER2 over-expressing GC. In particular, improvements in the treatment of systemic diseases have enabled

patients with HER2 over-expressing metastatic GC to survive for a relatively long period of time. MRI and CT have been routinely used for the diagnosis of liver metastases in these patients and found that the incidence of liver metastases is increasing. However, the association between liver metastases and HER2 expression remains largely unclear.

The results of the present study demonstrated that 25.7% of GC patients with liver metastases had HER2 over-expression, and that HER2 was mostly expressed in the membrane, which is consistent with what has been previously reported. The present study aimed to investigate the predictive factors in GC patients with HER2 over-expressing liver metastases.

GC of the two histologic types (intestinal and diffuse) differs in their epidemiology, pathogenesis, clinical outcome, and even genetic profiling[22]. The study showed tumors of two Puerto Rican (PR) patients with overexpressed Her2/neu and the resulting partial clinical responses motivated us to compare Her2/neu expression in PR ($n = 101$) and Caucasian non-Hispanic ($n = 95$) patients. The immunohistochemistry of tumors showed overexpression of *P*-Stat3, Cyclin D1, and Her2/neu, compared to non-neoplastic mucosa. Her2/neu and EGF-R protein levels were statistically significantly different, with higher levels of both proteins in the PR group. Importantly, Her2/neu expression was strong and diffuse in tumors with signet-ring morphology, while other histo-pathological subtypes showed higher intra-tumoral Her2/neu heterogeneity than typically observed in breast cancer. Targeted therapies in gastric cancer directed at EGF-R and Hers-2/neu pathways warrant further investigation. These therapies may be especially effective in PR patients and in patients with signet-ring cell morphologies with a dismal prognosis[23]. The study showed that overexpression of HIF-1a had no association with clinicopathological status, patient prognosis, or chemosensitivity; the expression of HIF-1a mRNA is up-regulated by a signal transduction pathway from a tyrosine kinase receptor, such as HER2[24]. Our results showed HER2 positivity differed significantly by histologic subtype (intestinal: 46.9%; diffuse: 25.7%). The mechanisms of HER2 over-expression in intestinal-type GC are complex and still largely unclear. Depending on the depth of invasion (T), the involvement of lymph nodes (N), and the presence of distant metastasis (M), the TNM stage is the most important prognostic factor for GC in clinic practice[25]. The role of HER2 over-expression as a prognostic factor in GC is still controversial[26,27]. Recently, increasing evidence has showed a direct correlation between HER2 over-expression and poor survival[28]. In a series of 260 GC patients, Okegawa *et al*[29] found that HER2 over-expression was an independent factor and correlated with serosal invasion and lymph node metastases. Our results demonstrated that HER2 over-expression was closely associated with a lower survival rate in GC patients with liver metastases ($P < 0.01$). HER2 may become a novel molecule in tumorigenesis of GC and a potential candi-

date for molecule-targeted therapy, especially in diffuse-type GC.

In our study, liver metastases in GC patients with HER2-overexpression had a shorter DFS (75% *vs* 22.6%, $P < 0.05$), which was consistent with what had previously been reported[30]. Tumor type was significantly associated with liver metastases (intestinal 46.9% *vs* diffuse 25.7%, $P < 0.05$), but age was not associated with GC. The association between liver and other location metastases suggests that high tumor load contributes to the development of hematogenous metastases, and supports the results in the present study that GC in half of patients was refractory to systemic chemotherapy.

Patients with liver metastases had a shorter survival time than those without, and the median survival time of 18 mo was comparable with previously reported results. In our study, HER2 negative GC patients with liver metastases remained stable, in contrast to other location metastases at the time of diagnosis of liver metastases.

Furthermore, HER2 positive patients with liver metastases exhibited progressive bone and other metastases and 75% of them had a general condition that allowed further systemic therapy, from which most of them benefited. Therefore, although liver metastases seem to appear at the late stage in patients with GC, other metastatic foci are still more or less chemosensitive, and thus treating liver metastases has an important influence on prognosis.

In our study, HER2 over-expressing GC patients seemed to develop symptomatic liver metastases at about 2.5 years after the diagnosis of recurrent or metastatic GC, which poses the question as to whether liver metastases should be monitored. If surveillance is carried out, who would be the candidates and what timing for surveillance should be further investigated? To date, there has been no evidence to suggest that the surveillance of liver metastases in GC patients is beneficial for patient survival or cost-effectiveness.

In conclusion, our findings reveal that the liver metastases in GC patients with HER2-overexpression had a poor prognosis. The low survival was correlated with sex, HER2 over-expression, Lauren classification, differentiation, and disease-free interval. In our future studies, the optimal regimens for chemotherapy will be studied in GC patients with liver metastases who acquire prolonged OS.

ACKNOWLEDGMENTS

COMMENTS

Background

Gastric cancer (GC) is the second leading cause of cancer death worldwide, especially in Asia. There are many risk factors used for predicting the prognosis of GC patients. A high incidence of liver metastases has been reported among patients with human epidermal growth factor receptor 2 (HER2) over-expressed GC. However, there is some controversy regarding the hypothesis that HER2 expression serves as a factor for predicting the prognosis of GC patients.

Research frontiers

HER2, an important member of the HER family, is encoded by a gene located on chromosome 17q21. In cancer formation, HER2 acts as an oncogene to regulate the proliferation, invasion, and apoptosis of cancer cells. The current research hotspot is to study the risk factors for liver metastasis and the prognosis in patients with HER2 over-expressing GC.

Innovations and breakthroughs

Although HER2 is over-expressed about 38% of gastric cancer patients, few studies are available on HER2 status in the liver metastases of gastric carcinoma patients and there is also little data on the evaluated prognosis for Chinese patients. A total of 84 GC patients recruited from the General Hospital of the People's Liberation Army in China between 2003 and 2010 were randomly enrolled in this study. All patients underwent radical dissection and chemotherapy, and/or radiotherapy. HER2 over-expression was detected with immunohistochemistry in gastric cancer with liver metastasis patients. Liver metastasis was diagnosed by magnetic resonance imaging or computed tomography. The authors also evaluated the clinical response of other metastatic diseases according to the Response Evaluation Criteria in Solid Tumors at the time of diagnosis of liver metastasis. The baseline characteristics and prognostic factors for GC were reviewed, including age, sex, differentiation and GC type, and disease-free interval. Overall survival (OS) served as a main outcome. From the results, the authors drew the conclusion that HER2 over-expressing GC patients with liver metastases have a poor prognosis, and the overall survival was significantly lower in HER2 positive patients.

Applications

Immunohistochemistry may be used to screen the HER2 status in gastric carcinoma patients with liver metastasis patients, and to study the risk factors for liver metastasis in gastric cancer. Since the sample size of our study was not large enough, that limited this study's ability to provide robust evidence. Therefore, larger-scale, multicentric studies are needed to test the results. Even so, the authors believe the current study provides preliminary and powerful data of evaluating the prognosis in patients with HER2 over-expressing GC, and contributes to determining whether target therapy is necessary for gastric carcinoma with liver metastasis.

Terminology

HER2 is the human epidermal growth factor receptor 2, an important member of the HER family, that is encoded by a gene located on chromosome 17q21. During tumorigenesis, HER2 has been identified to act as an oncogene to modulate the proliferation, invasion and apoptosis of tumor cells.

Peer review

The authors provide a retrospective study which reviewed 84 patients with HER2 expressing liver metastases in gastric cancer between 2003 and 2010. The study shows that HER2-overexpression has no correlation with liver metastases in gastric cancer. However, OS was obviously lower for HER2 negative patients. HER2-overexpression had correlation to a lower survival rate. Overall, this is an interesting and good study.

Abstract

AIM: To investigate the diagnostic value of glypican-3 (GPC3) and its relationship with hepatocellular carcinoma (HCC) recurrence after liver transplantation.

METHODS: HCC tissue samples (n = 31) obtained from patients who had undergone liver transplantation were analyzed. GPC3 mRNA and protein expression were analyzed by TaqMan real-time reverse transcription-polymerase chain reaction and immunohistochemistry. Correlation between the GPC3 expression and clinicopathological features was analyzed. The potential prognostic value of GPC3 was investigated by comparing recurrence-free survival between HCC patients with and without GPC3 expression.

RESULTS: Using a cutoff value of 3.5×10^{-2}, 20 of 31 cancerous tissues had expression values of > 3.5×10^{-2}, whereas 3 of 31 adjacent non-neoplastic parenchyma and 0 of 20 control liver tissues had expression values of > 3.5×10^{-2} ($P < 0.001$). GPC3 protein was immunoexpressed in 68% of cancerous tissues, but not in adjacent non-neoplastic parenchyma and control liver tissues. Vascular invasion was significantly related to GPC3 expression ($P < 0.05$). Recurrence-free survival was significantly longer for patients without GPC3 mRNA overexpression (> 3.5×10^{-2}) and those without vascular invasion ($P < 0.05$ for both).

CONCLUSION: GPC3 expression may serve as a valuable diagnostic marker for HCC. GPC3 mRNA overexpression may be an adverse indicator for HCC patients after liver transplantation.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common tumors in the world. More than 600 000 deaths globally per year have been reported, with 82% of cases (and deaths) occurring in "developing" countries (with 55% in China)[1,2]. HCC is up to four-times more common in men than in women, and 60%-90% of these tumors develop in

a cirrhotic liver[3]. About 200 000 patients die from HCC every year in China.

Liver transplantation offers the potential to resect the entire tumor-bearing liver and eliminate the cirrhosis. Liver transplantation therefore holds great theoretical appeal in treating this disease. Furthermore, the liver is entirely removed at liver transplantation, so recurrence must derive from extrahepatic dissemination that occurred before or during transplantation, reflecting highly aggressive tumor biology. Given the current shortage of organs and the risk of aggressive recurrence, selection of candidates for liver transplantation is crucial and controversial[4-6]. Therefore, predicting outcomes for patients is a challenge for clinicians and researchers.

Glypican-3 (GPC3) is a heparan sulfate proteoglycan and locates on the cell surface by a mechanism involving the glycosylphosphatidylinositol anchor[7]. GPC3 has been discovered to be a potential serologic and immunohistochemical diagnostic marker for HCC in general[8-10] and to promote the growth of HCC cells through stimulation of the canonical Wnt signaling pathway[11]. Zhu et al[12] and Sung et al[13] reported that GPC3 mRNA was significantly elevated in most HCC compared with normal liver as well as in livers with focal nodular hyperplasia and liver cirrhosis. This result was later confirmed by Libbrecht et al[14] using reverse transcription-polymerase chain reaction (RT-PCR), who mainly studied small HCC. Despite this clinical interest in GPC3, until now, the relationship between GPC3 expression and post-transplant HCC recurrence has not been clarified.

In our previous study, GPC3 mRNA-expressing cells in peripheral blood had no clinical value in the diagnosis of HCC[15]. The present study is an extension of the study mentioned above. We designed the study to assess the diagnostic value of GPC3 mRNA and protein expression in HCC tissues and to investigate their relationship with HCC recurrence after orthotopic liver transplantation (OLT).

MATERIALS AND METHODS

Patients

HCC tissue samples (*n* = 31) were obtained from patients who underwent OLT at the Department of Transplantation Surgery, Tianjin First Central Hospital (Tianjin, China) during 2008. Histological types were assigned according to the classification set by the World Health Organization. The clinicopathological features of OLT patients with HCC are summarized in Table 1. All recipients had undergone successful OLT (livers were from cadaveric donors who had agreed to donate their organs in the event of death). Liver-tissue specimens were obtained intraoperatively from cancerous tissues and adjacent non-neoplastic parenchyma. The controls were normal liver tissues from 20 patients (15 men, 5 women; mean age, 48 years; age range 30-65 years) with hepatic hemangioma. There were no statistically significant differences in age and sex between the study groups ($P > 0.05$). Liver-tissue

Tumor diameter (< 5 cm/≥ 5 cm)	16/15
Tumor number (< 3/≥ 3)	26/5
Vascular invasion (present/absent)	16/15
Serum AFP (≤ 20 μg/L/> 20 μg/L)	11/20
Histological differentiation (good/moderate and poor)	6/25

HBV: Hepatitis B virus; HCV: Hepatitis C virus; TNM: Tumor, node and metastasis; AFP: α fetoprotein.

specimens were fixed in 10 % formalin and embedded in paraffin for routine histological examination. The remaining tissue was immediately snap-frozen in liquid nitrogen and stored at -80 ℃ until examination.

All patients received standard post-liver transplantation care in the Intensive Care Unit. They received the same immunosuppressive therapy: tacrolimus, daclizumab, mycophenolate mofetil, and methylprednisolone. The diagnosis of HCC recurrences (follow-up of 24 mo) was based on elevation of serum levels of alpha-fetoprotein (AFP) and ultrasonography, hepatic arteriography, or computed tomography. Fine-needle aspiration cytology was used for confirmation of recurrence if necessary.

The present study was approved by our institutional ethics committee. Informed consent was obtained from each patient. The procedure met all applicable guidelines of our institute as well as governmental regulations concerning the ethical use of donated organs.

Real time reverse transcription-polymerase chain reaction assay

Total RNA was extracted from frozen liver tissues using Trizol reagents according to manufacturer instructions (Invitrogen, Carlsbad, CA, United States). Reverse transcription to complementary DNA (cDNA) was undertaken using random primer and Superscript RNase H-reverse transcriptase (Invitrogen).

A total of 1 μL of cDNA was mixed with the TaqMan probe[15], RNase-free water, and TaqMan Universal PCR Master Mix. Real-time PCR amplification and data analyses were carried out using an ABI PRISM 7300 Sequence Detector System (Applied Biosystems, Foster City, CA, United States) according to the manufacturer's protocol. β-actin was used as an internal control. Each sample was assayed in duplicate in a MicroAmp optical 96-well plate. The thermo-cycling condition was 2 min at 50 ℃ and 15 min incubation at 95 ℃, followed by 40 two-temperature cycles of 20 s at 95 ℃ and 1 min at 60 ℃. Data were analyzed with Sequence Detection Software. Mean and standard-deviation values were calculated from the data obtained. The level of expression was

Figure 1 Receiver operating characteristic curve of glypican-3 mRNA levels for the detection of hepatocellular carcinoma. The area under the receiver operating characteristic curve is 0.878 (95% confidence interval: 0.802-0.953) ($P < 0.001$).

calculated using the formula: Relative expression = (copy number of target molecule/copy number of β-actin)[16].

Immunohistochemical analyses

Sections of formalin-fixed, paraffin-embedded tissue cell blocks (4 μm) were tested for the presence of monoclonal antibody directed against GPC3 (Santa Cruz Biotechnology, Santa Cruz, CA, United States). The method used for the immunohistochemical analysis has been described previously[17].

For the immunohistochemical analysis of GPC3, we evaluated the area of GPC3-positive staining in one slide for each patient. At first, to analyze GPC3 expression, the results of immunohistochemical staining were classified according to the area of GPC3-positive stained cells as follows: -, Negative (< 10%); ±, Weakly positive (10%-30%); and +, Positive (> 30%). Finally, we classified two groups between GPC3-negative (< 10%) and GPC3-positive (> 10%). The expression of GPC3 was judged to be positive if the percentage of immunoreactive cells was assessed semi-quantitatively as being ≥ 10% in focal lesions.

Statistical analysis

Data are mean ± SD. For comparisons of continuous variables, one-way analysis of variance with the Bonferroni *post-hoc* test was used to compare differences among the three groups. We generated receiver operating characteristic curves for GPC3 mRNA levels to determine the cutoff points that yielded the sensitivity and specificity for predicting the diagnosis of HCC. Correlations between GPC3 results and various clinicopathological parameters in the tissue samples were evaluated using the chi-square test. The distribution of time to recurrence was estimated according to the Kaplan-Meier method, and differences assessed using log-rank statistics. $P < 0.05$ was considered significant. Statistical analyses were done using SPSS ver12 (SPSS, Chicago, IL, United States).

Table 2 Correlation between glypican-3 expression and clinicopathological features in 31 orthotopic liver transplantation patients with hepatocellular carcinoma

RESULTS

Glypican-3 mRNA expression in hepatocellular carcinoma tissues

GPC3 mRNA expression in adjacent non-neoplastic parenchyma ($n = 31$, $2.00 \pm 1.91 \times 10^{-2}$) and in control liver tissues ($n = 20$, $1.41 \pm 1.57 \times 10^{-2}$) was much lower than in cancerous tissues ($n = 31$, $5.64 \pm 3.06 \times 10^{-2}$) ($P < 0.001$). There were no significant differences between adjacent non-neoplastic parenchyma and normal liver tissues with respect to GPC3 mRNA expression ($P = 0.270$). A cutoff value for GPC3 mRNA expression of 3.5×10^{-2} was diagnostic of HCC with a sensitivity of 68%, specificity of 94%, positive predictive value (PPV) of 87%, and negative predictive value (NPV) of 83% [area under the curve, 0.878; 95% confidence interval (CI): 0.802-0.953, $P < 0.001$] (Figure 1). Twenty of 31 (64%) cancerous tissues had expression values of $> 3.5 \times 10^{-2}$, whereas 3 of 31 (10%) adjacent non-neoplastic parenchyma and 0 of 20 control liver tissues had expression values of $> 3.5 \times 10^{-2}$ ($P < 0.001$).

The expression of GPC3 mRNA was evaluated in relation to clinicopathological features. GPC3 mRNA overexpression ($> 3.5 \times 10^{-2}$) was closely associated with vascular invasion ($P = 0.006$). No significant correlation was found between GPC3 mRNA overexpression and tumor, node, metastasis (TNM) stages, Milan criteria, tumor diameter, tumor number, serum AFP levels, and histological differentiation (Table 2).

Figure 2 Hepatocellular carcinoma immunohistochemical staining (× 400). Glypican-3 expression in hepatocellular carcinoma by immunohistochemical analyses. A: Negative expression in HCC tissue; B: Weakly positive expression in HCC tissue; C: Positive expression in HCC tissue; D: Negative expression in adjacent non-neoplastic parenchyma. HCC: Hepatocellular carcinoma.

Figure 3 Kaplan-Meier survival curve for recurrence-free interval in 31 patients who underwent liver transplantation.

GPC3 protein expression in hepatocellular carcinoma tissues

GPC3 protein was immunoexpressed in 21 of 31 (68%) cancerous tissues, but not in any adjacent non-neoplastic parenchyma and control liver tissues ($P < 0.001$). In GPC3-positive cases, protein expression was localized in the cytoplasm and membrane of cells (Figure 2). The sensitivity, specificity, PPV, and NPV of GPC3 protein expression was 0.68, 1.0, 1.0, and 0.84. Vascular invasion was significantly related to GPC3 protein expression ($P = 0.015$) (Table 2).

Association between glypican-3 expression and hepatocellular carcinoma recurrence

Up-to-date analyses after a follow-up of 24 mo revealed that 10 (32%) patients developed HCC recurrence. The median duration of HCC recurrence was 8.1 (range, 3-18 mo) after OLT (Figure 3). Assessment of Kaplan-Meier curves showed that patients without GPC3 mRNA overexpression had significantly longer recurrence-free survival than those with GPC3 mRNA overexpression ($P = 0.034$, log-rank test) (Figure 4A). Recurrence-free survival was significantly longer in patients without evidence of vascular invasion compared with those with vascular invasion ($P = 0.016$, log-rank test). Patients who met the Milan criteria had longer recurrence-free survival than those who did not, though the difference was not statistically significant ($P = 0.077$, log-rank test). There was no significant difference in recurrence-free survival between patients with positive and negative GPC3 protein expression ($P = 0.231$, log-rank test) (Figure 4B).

DISCUSSION

OLT is an excellent therapeutic choice for patients with cirrhosis complicated by HCC because it provides simultaneous treatment for both diseases. However, due to the limited availability of organs, prior selection of candidates most likely to benefit from OLT is very important. Thus, screening for potential early prognostic markers and therapeutic targets is very urgent for better selection

Figure 4 Kaplan-Meier survival curves for recurrence-free survival after liver transplantation for hepatocellular carcinoma. A: with or without glypican-3 mRNA overexpression (> 3.5 × 10^{-2}) (P = 0.034, compared by log-rank test); B: with or without glypican-3 protein expression (P = 0.231, compared by log-rank test).

of HCC patients for liver transplantation.

More recent studies have demonstrated upregulation of GPC3 in HCC at the protein level. GPC3 expression has been noted in 57% to 90% of HCC cases using immunohistochemistry[17-20]. In the present study, immunohistochemical analyses revealed that HCC expressed GPC3 protein in 68% of HCC tissues tested. RT-PCR analyses showed that, with a cutoff value of 3.5 × 10^{-2}, 20 of 31 HCC tumors showed much stronger expression of GPC3 mRNA than adjacent non-neoplastic parenchyma. It was proposed that GPC3 expression could be a useful tissue marker to distinguish between benign and malignant hepatocellular lesions. Nevertheless, in some studies, HCC and non-malignant liver originated from different patients, so these studies could not exclude the possibility that HCC and adjacent non-neoplastic parenchyma have similar GPC3 expression[12,21]. We can presume that retained carcinoma cells in the adjacent non-neoplastic parenchyma of surgical specimens with large tumors and tumor invasion may be the cause of GPC3 protein expression or GPC3 mRNA overexpression. This suggests that detection of GPC3 expression in adjacent non-neoplastic parenchyma could indicate whether or not the tumor is completely resected. It may also serve as a reference value in deciding if further treatment after resection is required.

Although GPC3 mRNA and protein show expression in HCC tissues, in our previous study, we examined GPC3 mRNA-expressing cells in peripheral blood in liver-transplant recipients during the transplant period, and found no clinical diagnostic value for HCC. Studies showed that GPC3 was a potential serologic diagnostic marker for HCC. However, the diagnostic value of GPC3 protein in sera remains questionable. Yasuda *et al*[22] found that GPC3 is not a serologic marker for detection of HCC. We speculate that GPC3 serves as a potential tissue-specific diagnostic marker for HCC. Some liver-transplant candidates undergo locoregional tumor treatments, so obtaining tissue samples for preoperative molecular marker analyses would not be problematic.

In the clinicopathological analysis, TNM stages, Milan criteria, tumor diameter, tumor number, or serum AFP levels were not clearly associated with increase in GPC3 expression. GPC3 may therefore play an important part in the malignant transformation of cells in HCC. Up until now, AFP has been regarded as the most useful marker of HCC, although its sensitivity is limited[23]. Our data show that GPC3 mRNA and protein expression in HCC without serum AFP elevation ($\leqslant$ 20 μg/L) were 54% and 54%, respectively, and in HCC of diameter < 5 cm were 56% and 69%, respectively. These findings suggest that GPC3 is a sensitive marker in small HCC and negative-serum AFP patients not only in resection[24,25] but also in OLT. Vascular invasion has been consistently reported to be a significant factor for a poor prognosis after liver transplantation for HCC[15,26,27]. Interestingly, in the present study, vascular invasion was significantly related to GPC3 expression. Zhu *et al*[12] using *in-situ* hybridization signals, showed that pushing HCC expressed significantly more GPC3 mRNA than the invading HCC. Their observations suggested that GPC3 may promote the growth of local cancer cells, and may also inhibit tissue invasion and metastasis. Their finding is different to ours. In addition, expression of GPC3 was lower in well-differentiated HCC than in moderately and poorly differentiated HCC, though the difference was not statistically significant, a finding consistent with previous reports[17,19]. The present study suggests that GPC3 expression may facilitate the growth of cancer cells, the degree of malignancy, and contribution to HCC progression.

Recurrence of HCC after transplantation remains a formidable problem despite refined selection criteria and exhaustive preoperative staging. In the present study, recurrence-free survival was longer in patients who had tumors with no evidence of vascular invasion. Microscopic vascular invasion in the explant is known to be a risk factor for HCC recurrence after transplantation. In addition, recurrence-free survival was longer in patients who met the Milan criteria, though the difference was not statistically significant. This could be because (1) the sample size in the present study was relatively small to allow apprecia-

tion of significant differences in the frequency of HCC recurrence in the groups; and (2) the patients in the Milan group had worse pathological stages. In our previous study, GPC3 mRNA-expressing cells in peripheral blood carried no predictive value for HCC recurrence after liver transplantation[15]. Hence, we used liver tissue instead of peripheral blood to determine if GPC3 expression in tumor tissues was associated with HCC recurrence after liver transplantation. In the present study, HCC patients with GPC3 mRNA overexpression had a significantly shorter recurrence-free survival than those with lower GPC3 mRNA expression after liver transplantation. This finding indicated that GPC3 mRNA overexpression could be an independent factor of a poor prognosis in HCC. Thus, we hypothesized that GPC3 may have a role in promoting carcinogenesis and in the development of HCC.

In general, GPC3 has been reported to interfere with different pathways and growth factors, and has a tissue- and stage-specific role in the development and tumor growth[28]. Ishiguro *et al*[29] showed that anti-GPC3 antibody can be used as a potential antitumor agent for human liver cancer, and can provide a novel treatment option for liver-cancer patients with GPC3-positive tumors. Evaluation of GPC3 as a diagnostic and immunotherapeutic target may be worthwhile for the prevention and treatment of HCC. Further studies must be completed to clarify these issues.

In conclusion, GPC3 is a valuable diagnostic marker sensitive and specific for HCC in liver-transplant patients. The most valuable finding in the present study was that GPC3 mRNA overexpression may act as a prognostic factor for recurrence-free survival in HCC after liver transplantation. The number of samples used in the present study was small. Confirmation of the findings of our study using more samples is warranted.

COMMENTS

Background
Given the current shortage of organs and the risk of aggressive recurrence, selection of candidates for liver transplantation is crucial and controversial. Establishment of direct and accurate methods to detect hepatocellular carcinoma (HCC) and predict HCC recurrence after liver transplantation is needed.

Research frontiers
Glypican-3 (GPC3) has been discovered to be a potential serologic and immunohistochemical diagnostic marker for HCC. Despite clinical interest in GPC3, until now, the relationship between GPC3 expression and post-transplant HCC recurrence has not been clarified.

Innovations and breakthroughs
In the previous study, the level of GPC3 mRNA in peripheral blood had no clinical value in assessing tumor recurrence after liver transplantation. Therefore, the present study further examined the diagnostic value of GPC3 expression as retrospectively analyzed by real-time reverse transcription- polymerase chain reaction and immunohistochemistry in explant tumor samples. The principal finding was that GPC3 mRNA overexpression may act as an adverse indicator for HCC patients after liver transplantation because it was associated with significantly shorter recurrence-free survival.

Applications
The results of the present study suggest that GPC3 is a valuable diagnostic marker sensitive and specific for HCC in liver-transplant patients. Also, GPC3 mRNA overexpression may act as a prognostic factor for recurrence-free survival in HCC after liver transplantation.

Terminology
GPC3 is a heparan sulfate proteoglycan which is bound to the cell surface by a mechanism involving the glycosylphosphatidylinositol anchor. GPC3 is highly expressed in fetal but not in normal adult liver.

Peer review
Authors focused on the role of GPC3 mRNA and protein expression in the diagnosis of recurring HCC after liver transplantation. For this purpose, patient samples were analyzed according to clinicopathological features, mRNA expression levels, protein expression, and recurrence-free survival. They concluded that GPC3 expression could serve as a diagnostic marker for HCC and as an adverse indicator for HCC patients after liver transplantation.

Abstract

AIM: To evaluate survival and recurrence after salvage liver transplantation (SLT) for the treatment of hepatocellular carcinoma (HCC) compared with primary liver transplantation (PLT) using a meta-analysis.

METHODS: Literature on SLT versus PLT for the treatment of HCC published between 1966 and July 2011 was retrieved. A meta-analysis was conducted to estimate pooled survival and disease-free rates. A fixed or random-effect model was established to collect the data.

RESULTS: The differences in overall survival and disease-free survival rates at 1-year, 3-year and 5-year survival rates were not statistically significant between SLT group and PLT group ($P > 0.05$). After stratifying the various studies by donor source and Milan criteria, we found that: (1) Living donor liver transplantation recipients had significantly higher 1-year survival rate, lower 3-year and 5-year survival rates compared with deceased-donor liver transplantation (DDLT) recipients. And in DDLT recipients they had better 1-year and 5-year disease-free survival rate in SLT group; and (2) No difference was seen in 1-year, 3-year and 5-year survival rates between two groups who beyond Milan criteria at the time of liver transplantation.

CONCLUSION: SLT can be effectively performed for patients with recurrence or deterioration of liver function after hepatectomy for HCC. It does not increase the perioperative mortality and has a similar long-term survival rates compared to PLT.

INTRODUCTION

In a normal liver, liver resection for hepatocellular carcinoma (HCC) is the primary treatment of choice. But in cirrhotic livers, the presence of HCC and the limited liver capacity are the two intertwined issues rendering the HCC unresectable. Primary liver transplantation (PLT) is the most effective treatment for such HCC patients, especially for those who meet Milan criteria (solitary liver nodule not exceeding 5 cm in maximum diameter, or 2 or 3 tumors not exceeding 3 cm in diameter)[1]. It has been manifested to provide a considerable disease-free

survival and to be the first choice for these patients. Due to shortage of available donors, long waiting times may harm the benefit that might be acquired from PLT. Salvage liver transplantation (SLT) has been proposed and performed for those who undergo primary liver resection for HCC or HCC recurrence or deterioration of liver function[2]. SLT proposes liver resection as a bridge to prevent tumor progression in the waiting list. Although SLT might be an alternate choice for HCC patients as the preferred treatment, long-term results are difficult to ascertain. Moreover, few data are available on the overall and disease-free survival of patients. A few researches concern on the comparison between the result of SLT and PLT. In order to reduce research bias and difference, we did a meta-analysis to compare survival and recurrences for SLT strategy versus PLT in the treatment of HCC patients, in order to provide a reference for clinical practice.

MATERIALS AND METHODS

Literature search strategy
Search was applied to the following electronic databases: PubMed (1966 to July 2011), Embase (January 1996 to July 2011), CNKI (January 1996 to July 2011) and Cochrane database. The following key words were used: "liver resection" or "hepatectomy"; "liver transplantation" or "transplantation" or "salvage liver transplantation" or "salvage transplantation"; "hepatocellular carcinoma" or "HCC". The search was limited to the English language and humans. The relevant reference lists of reviews were also searched at the same time. Abstracts or unpublished studies were not considered. If more than 1 study was published by the same author using the same case series, only the most detailed study was included. And if necessary, authors were contacted to obtain more data on their study.

Definitions
SLT was defined as a liver transplantation performed for recurrent HCC or deterioration of liver function after primary liver resection.

Inclusion, exclusion criteria and quality of the studies
Inclusion criteria were as follows: (1) having definition of SLT; (2) follow-up 12 mo at least; (3) case-control or cohort design; and (4) sufficient data were obtained to calculate odds ratio (OR) with confidence interval (CI). Reasons for exclusion were: (1) no-control; (2) duplicate; and (3) no useable data reported. We also excluded articles published before 1996 because there was no definition for "SLT".

The scoring system was adapted from Stahl, the Cochrane Collaboration and others[3-5]. This system suits not only randomized control trial (RCT) but controlled trial or other studies well. Questions were placed on a 3 point scale: unclear/inadequate (0), adequate (1), good (2). Articles were considered for inclusion if their summary score exceeded 30.

Table 1 Details of studies included in the meta-analysis

Author	Year	Country	Study design	SLT (cases)	PLT (cases)	Score

SLT: Salvage liver transplantation; PLT: Primary liver transplantation.

Data extraction
All data were extracted independently by 2 reviewers according to the selection criteria. We resolved disagreement through discussion. The following data were extracted: the last name of the first author, study design, publication year, definition of SLT, the type of population described [adults or children (< 18 years)], country of transplant center, number of SLT cases and control (PLT) studies, overall survival, overall recurrence and assessment of risk factors.

Statistical analysis
Meta-analysis was performed using fixed-effect or random-effect methods, depending on the absence or presence of significant heterogeneity. Statistical heterogeneity between trials was evaluated by the Cochran χ^2 test and was considered significant when $P < 0.10$. In the absence of statistically significant heterogeneity, the Mantel-Haenszel method in the fixed-effect model was used for the meta-analysis. Otherwise, the DerSimonian and Laird method in the random-effect model was selected.

The OR with 95% CI was used to assess treatment efficacy. The combined result was an average OR and 95% CI weighted according to the standard error of the OR of the trial. $P < 0.05$ was considered statistically significant. We used funnel plots to assess the publication bias, and tested for funnel plot asymmetry using Egger's test and Begg's test. All analyses were performed with Review Manager version 5.0.23 (RevMan, Cochrane Collaboration, Oxford, England).

RESULTS

Studies included in the meta-analysis
There were 410 papers relevant to the search words. Via steps of screening the title, abstract reviewing and article reviewing, 11 studies which included 141 SLT cases and 872 PLT cases were identified to match our inclusion criteria[6-16]. Studies had been carried out in France, Italy, USA, China, Spain, Korea and Chinese Taiwan. Details of studies and the methodological quality of the studies assessed according to a score system described above are described in Table 1.

Figure 1　Fixed-effect model of odds ratio for 1-year survival rates (A), 3-year survival rates (B) and 5-year survival rates (C) after salvage liver transplantation and primary liver transplantation (Experimental: Salvage liver transplantation; Control: Primary liver transplantation). SLT: Salvage liver transplantation; PLT: Primary liver transplantation.

Meta-analysis

1-year survival after SLT and PLT: A total of 1013 patients were included in 11 articles. According to χ^2 test of heterogeneity ($P = 0.78$), a fixed-effect model was used. No difference between SLT group (82.3%) and PLT group (85.7%) were seen in the 1-year survival rate (OR: 0.74, 95% CI: 0.46-1.21, $P = 0.23$, Figure 1A).

3-year survival after SLT and PLT: A total of 967 patients were included in 10 articles. According to χ^2 test of heterogeneity ($P = 0.40$), a fixed-effect model was used. No difference between SLT group (72.2%) and PLT

Figure 3 Fixed-effect model of odds ratio for 1-year (A) and 5-year (B) disease-free survival rates for deceased-donor liver transplantation recipients after salvage liver transplantation and primary liver transplantation (Experimental: Salvage liver transplantation; Control: Primary liver transplantation). DDLT: Deceased-donor liver transplantation; SLT: Salvage liver transplantation; PLT: Primary liver transplantation.

to χ^2 test of heterogeneity ($P = 0.08$), a random-effect model was used. No difference between SLT group (65.7%) and PLT group (65.0%) were seen in the 5-year disease-free survival rate (OR: 0.75, 95% CI: 0.29-1.96, $P = 0.56$, Figure 2C).

When stratifying for the donor source, compared with deceased-donor liver transplantation (DDLT) recipients, we found that living-donor liver transplantation (LDLT) recipients had significantly higher 1-year survival rate (OR: 1.02, 95% CI: 0.26-4.10, $P = 0.97$), lower 3-year survival rate (OR: 0.54, 95% CI: 0.20-1.47, $P = 0.23$) and lower 5-year survival rate (OR: 0.54, 95% CI: 0.21-1.35, $P = 0.19$). DDLT recipients had significantly lower 1-year survival rate (OR: 0.66, 95% CI: 0.38-1.15, $P = 0.14$), higher 3-year survival rate (OR: 0.99, 95% CI: 0.62-1.59, $P = 0.97$) and higher 5-year survival rate (OR: 0.77, 95% CI: 0.47-1.26, $P = 0.30$). No useable data about disease-free survival rates can be extracted from LDLT researches. And in DDLT recipients they had better 1-year disease-free survival rate (OR: 0.53, 95% CI: 0.29-0.95, $P = 0.03$, Figure 3A) and better 5-year disease-free survival rate (OR: 0.42, 95% CI: 0.23-0.74, $P = 0.003$, Figure 3B) in SLT group. No difference between SLT group and PLT group were seen in the 3-year disease-free survival rate (OR: 0.95, 95% CI: 0.26-3.52, $P = 0.94$).

When stratifying for Milan criteria, we found that no difference was seen in 1-year survival rates (OR: 0.26, 95% CI: 0.01-4.94, $P = 0.37$), 3-year survival rates (OR: 0.41, 95% CI: 0.01-24.54, $P = 0.67$) and 5-year survival rates (OR: 0.55, 95% CI: 0.07-4.48, $P = 0.57$) between SLT group and PLT group who beyond Milan criteria at the time of liver transplantation (LT). No usable data for patients who met Milan criteria at the time of LT.

Publication bias

Publication bias may exist when no significant findings remain unpublished, thus artificially inflating the apparent magnitude of an effect. Funnel plots of our study results are shown in Figure 4. The funnel plots on survival and disease-free survival following SLT or PLT for the treatment of HCC showed basic symmetry, which suggested no publication bias.

DISCUSSION

As one of the radical treatments for HCC, LT is nowadays limited by organ shortage. Due to the prolonged waiting times before transplantation, tumor progression and deterioration of liver function may counteract its benefit[2]. The outcome of liver resection is mainly influenced by a high rate of recurrence that limits long-term survival rates. But previous research noted that most of patients with recurrence after primary liver resection were still eligible for LT[2]. Hence, hepatectomy and LT should be considered as complementary, not competitive, treatments for HCC in cirrhotic patients with well-preserved

Figure 4 Funnel plot. A: 11 articles in the meta-analysis of 1-year survival after treatment; B: 10 articles in the meta-analysis of 3-years survival after treatment; C: 8 articles in the meta-analysis of 5-years survival after treatment; D: 8 articles in the meta-analysis of 1-year disease-free survival after treatment; E: 8 articles in the meta-analysis of 3-year disease-free survival after treatment; F: 6 articles in the meta-analysis of 5-year disease-free survival after treatment. SE: Standard error; OR: Odds ratio.

liver function. Resection of the liver tumor is an optional bridge treatment[17-19]. SLT was proposed in order to reduce the impact of a long waiting times, donor shortage and tumor recurrence after resection in HCC patients.

The increased technical difficulty during SLT and the risk for impaired posttransplant survival worried most of surgeons. Heavy adhesions and portal hypertension are often encountered after prior liver resection. Inattentive dissection of perihepatic adhesions could result in uncontrollable bleeding at the dissection surface. Also due to heavy adhesions, the relationship between hepatic vein and inferior vena cava are hard to identify. Hwang *et al*[11] found that SLT did not increase the operative risks or postoperative complications. The two major techni-

cal concerns-bleeding and reconstruction of the hepatic vein outflow can be solved successfully by steady and meticulous sharp dissection and sufficient dissection of the recipient inferior vena cava. Kim *et al*[12] showed that end-to-end anastomosis for bile ducts and hepatic artery was feasible, too. Our study showed that SLT had no bad effect on overall survival and disease-free survival in comparison with PLT.

Considering different surgical methods may have an effect on survival rates, the whole patients were stratified to LDLT recipients and DDLT recipients. In each subgroup, no difference between SLT group and PLT group were seen in 1-year survival rates, 3-year survival rates and 5-year survival rates. But LDLT recipients may have

a significant higher 1-year survival rates than DDLT recipients, while a significant lower 3-year survival rates and 5-year survival rates. This may be a result of improvement of surgical technique and perioperative management. However, because of a relatively higher incidence (up to 30%) of biliary complication after LDLT[20-23], LDLT recipients may have a lower long-term survival rates than DDLT recipients. Different results in DDLT recipients' disease-free survival rates seem hard to explain. We consider a better tumor stage at the time of transplantation (meet Milan criteria) may contribute to better 1-year disease-free survival rates and 5-year disease-free survival rates. A lager sample and more randomized controlled studies may resolve this conflict and draw a right conclusion.

The tumors' stage at the time of resection and LT is another risk factor for postoperative overall survival and disease-free survival. Some studies were theoretical and assessed the salvage transplantability according to the pattern of recurrence after resection for HCC within Milan criteria and found that 76% to 87% of recurrences were considered eligible for SLT on imaging grounds[2,12,24,25]. For HCC patients not meeting Milan criteria, SLT could be applied for those cases with less aggressiveness, namely tumor size less than 6 cm and pathological well differentiation. For those cases meeting Milan criteria, PLT seems to be the first option. SLT could be performed for those patients with recurrence within Milan criteria after primary resection and without delay before recurrence with advanced disease manifestations. But there is no consensus about the survival rates for patients with recurrence beyond Milan criteria. Our result reveals that SLT group has similar survival rates compared with PLT group beyond Milan criteria at the time of LT. Unfortunately, data extracted from our including studies are not enough to do further meta-analysis on patients' survival rates meeting Milan criteria at the time of LT and the corresponding disease-free survival rates.

Moreover, in countries with a higher incidence of HCC, a higher proportion of HCC patients on the waiting list and/or a longer median time-to-transplant, SLT could offer a gain in life-expectancy to the remaining waiting-list patients[26].

This review has some limitations. Although funnel plots may be suggestive of publication bias with lack of negative small RCTs, a firm conclusion about bias is difficult to make as the asymmetry of the funnel plots is minimal. And funnel plots can show asymmetry for other reasons. Therefore, our pooled OR might be an overestimate of the true effect. Due to data constraints, this meta-analysis could not analyze the quality of life score and was unable to carry out stratified analyses of other possible confounding factors. The method need to be more effective. Larger samples and randomized controlled studies with longer follow-up are required. Our conclusions also need more detailed data to confirm the results. The search language was limited. The integrity of the data was affected to a certain extent.

In conclusion, this new strategy SLT can be effectively performed for patients with recurrence or deterioration of liver function after hepatectomy for HCC. It does not increase the perioperative mortality and has a similar long-term survival rates compared to PLT. When surgical technique is no longer a problem for SLT, more patients will benefit from it.

COMMENTS

Background
Due to shortage of available donors, salvage liver transplantation (SLT) has been proposed and performed for the patients who undergo primary liver resection for hepatocellular carcinoma (HCC) or HCC recurrence or deterioration of liver function. This meta-analysis was designed to evaluated survival and recurrence after SLT for the treatment of HCC compared with primary liver transplantation (PLT).

Research frontiers
The study evaluated survival and recurrence after SLT for the treatment of HCC compared with PLT using a meta-analysis of all relevant controlled studies.

Innovations and breakthroughs
This is the first systematic review and meta-analysis on the survival and recurrence after SLT for the treatment of HCC compared with PLT. The author made a comprehensive search of studies. Several important conclusions might be used for future selection in SLT or PLT for HCC patients' treatments.

Applications
This meta-analysis shows that SLT has a similar survival rates in comparison with PLT. SLT offers an alternative treatment method for HCC patients in facing a shortage of available donors.

Terminology
SLT was defined as a liver transplantation performed for recurrent HCC or deterioration of liver function after primary liver resection.

Peer review
The article should be published as it is a nice overview on the topic after some revisions are performed.

Abstract

AIM: To investigate the expression of Popeye domain containing 3 (Popdc3) and its correlation with clinicopathological features and prognosis of gastric cancer.

METHODS: The method of immunohistochemistry was used to investigate the expression of Popdc3 in 306 cases of human gastric cancer and 84 noncancerous gastric tissues. Simultaneously, the relationship between Popdc3 expression and the survival of the patients was retrospectively analyzed.

RESULTS: Popdc3 was detected in 72 (85.71%) of 84 human nontumor mucosa. High expression of Popdc3 protein was detected in 78 (25.49%) of 306 human gastric cancer cases, and low expression was detected in 228 (74.51%). Low expression of Popdc3 correlated with depth of invasion ($P < 0.0001$), regional lymph nodes ($P < 0.0001$) and distant metastasis ($P = 0.02$), and tumor, nodes, metastasis (TNM) stages ($P < 0.0001$). On multivariate analysis, only the patient's gender, regional lymph node metastasis, distant metastasis, TNM stages, and the expression of Popdc3 were independent prognostic factors in patients with gastric cancer. The Kaplan-Meier plot showed that low Popdc3 expression had a much more significant effect on the survival of those patients with early-stage tumors ($\chi^2 = 104.741$, $P < 0.0001$), with a > 51.9% reduction in the three-year survival compared with high Popdc3 expression. In late stages, the difference was also significant ($\chi^2 = 5.930$, $P = 0.015$), with a 32.6% reduction in the three-year survival.

CONCLUSION: Reduced expression of Popdc3 may play a significant role in the carcinogenesis and progression of gastric cancer. Popdc3 may be an independent prognostic factor.

INTRODUCTION

Gastric cancer is the second leading cause of cancer-related deaths worldwide because advanced or metastatic gastric cancer constitutes the majority of patients in clinical practice[1]. The incidence of gastric cancer has been falling globally in terms of both incidence and mortality rates since World War Ⅱ. In the United States in 2009, 21 130 new diagnoses of gastric cancer were estimated and 10 620 deaths expected[2]. Although there has been a noticeable decrease in gastric cancer mortality rate, there is a higher prevalence of gastric cancer in China than in the Western countries[3-7]. The prognosis of advanced gastric cancer is apparently poor, and the 5-year survival rate is less than 30% in the patients after surgery[8,9]. Therefore, it is of great clinical value to further understand the molecular mechanisms involved in gastric cancer and to find valuable diagnostic markers as well as novel therapeutic strategies.

The Popeye domain containing (Popdc) gene family consists of Bves/Popdc1, Popdc2 and Popdc3[10]. They were discovered in 1999 by two independent laboratories using screens to identify novel genes that were highly expressed in the developing heart[11,12]. Several studies have illuminated that within one species, Bves was 24% and 28% identical to Popdc2 and Popdc3, respectively, while Popdc2 and Popdc3 were approximately 50% identical[13-15]. In 2004, the expression pattern of Popdc2 in the heart of chick was reported, but no study had been conducted to test the function of this protein[14]. Until now, Bves is still the most studied member of the Popdc family[10]. After that, Kim *et al*[16] found that frequent silencing of Popdc3 was associated with promoter hypermethylation in gastric cancer. Although questions about Popdc3 remain unanswered, general trends are beginning to emerge. Previous studies have led us to the hypothesis that Popdc3 may play a role in cell adhesion, cell motility, DNA methylation and tumorigenesis. Nevertheless, further work is required to elucidate its molecular mechanisms in the biology of cancer.

As far as we know, no report is available on the actual expression level of Popdc3 and the correlation between clinicopathologic features and prognosis of gastric cancer patients. Therefore, in this study, we investigated the Popdc3 protein expression profile in 306 primary gastric cancer patients, and found that Popdc3 was lowly expressed in 228 (74.51%) of 306 human gastric cancer cases, suggesting that the low expression level of Popdc3 may be a reliable indicator for the poor prognosis of gastric cancer patients.

MATERIALS AND METHODS

Patients and tissue samples

A total of 306 patients with primary gastric cancer, who underwent routine surgery at the Department of Surgery, the Second Affiliated Hospital of Kunming Medical University from February 1996 to March 2007, were enrolled in this study. The study was approved by the hospital's ethics committee. Patient diagnosis was established pathologically, and no patient had received any treatment before admission. All patients had follow-up records for over 5 years. The follow-up deadline was April 2011. The survival time was counted from the date of surgery to the end of the follow-up or date of death, which was mostly caused by recurrence or metastasis. According to the tumor, nodes, metastasis (TNM)-7th edition 2009 (UICC/AJCC) and Japanese Classification 2010 in Gastric Cancer[17,18], there were 8 papillary adenocarcinomas, 209 tubular adenocarcinomas, 52 mucinous adenocarcinomas, 37 signet ring cell carcinomas, and 17 highly differentiated adenocarcinomas; 100 were classified as well or moderately differentiated adenocarcinomas, 177 as poorly differentiated adenocarcinomas, and 12 as undifferentiated adenocarcinomas or others. Seventy-three cases were categorized as stage Ⅰ, 109 were stage Ⅱ, 92 were stage Ⅲ, and 32 were stage Ⅳ. Eighty-four cases of noncancerous human gastric tissues were obtained from gastrectomies of adjacent gastric cancer margins greater than 5 cm and served as controls.

Immunohistochemistry

Immunohistochemical analysis was undertaken to study altered protein expression in 84 cases of noncancerous human gastric tissues and 306 cases of human gastric cancer tissues[19,20]. According to the protocol for immunohistochemistry on paraffin-embedded tissue sections, slides were baked at 60 ℃ for 2 h followed by deparaffinization with xylene and rehydrated. The sections were submerged into ethylene diamine tetraacetic acid antigenic retrieval buffer and microwaved for antigenic retrieval, after which they were treated with 3% hydrogen peroxide in methanol to block endogenous peroxidase activity, followed by incubation with 1% bovine serum albumin to block nonspecific binding. Sections were incubated with rabbit anti-Popdc3 polyclonal antibody (ProteinTech Group, Chicago IL) overnight at 4 ℃. Normal goat serum was used as a negative control. After rinsing twice for 5 min with Tris buffered saline tween-20, tissue sections were treated with secondary antibody in Tris buffered saline solution for 1 h at room temperature, developed with chromogen at room temperature, and observed under microscope. After that, all tissue sections were counterstained with hematoxylin, dehydrated and mounted. The cytoplasm with strong Popdc3 expression was stained as buffy, whereas weak expression was associated with cell membranes.

Assessment of Popdc3 staining in the tissue sections

The degree of immunostaining was reviewed and scored independently by at least two observers based on the proportion of positively stained tumor cells and intensity of staining[21,22]. Tumor cell proportion was scored as follows: 0 (≤ 5% positive tumor cells), 1 (6%-25% positive tumor cells), 2 (26%-50% positive tumor cells), and 3 (>

Figure 1 Immunohistochemical staining for Popeye domain containing 3 in gastric cancer lesions and noncancerous tissues. A: Popeye domain containing 3 (Popdc3) was highly expressed in noncancerous tissues, × 400; B: Popdc3 was highly expressed in intestinal metaplasia cells, × 400; C, D: Popdc3 was lowly expressed in tubular adenocarcinoma, × 200 and × 400, respectively.

51% positive tumor cells). Staining intensity was graded according to the following criteria: 0 (no staining), 1 (weak staining, light yellow), 2 (moderate staining, yellow brown), and 3 (strong staining, brown). Staining index was calculated as the staining intensity score and the proportion of positive tumor cells. Using this method of assessment, we evaluated Popdc3 expression in benign gastric epithelia and malignant lesions by determining the staining index with scores of 0, 1, 2, 3, 4, 6, or 9. The cutoff value for high and low expression levels was chosen based on the heterogeneity measured using the log-rank test with respect to overall survival. An optimal cutoff value was identified as follows: a staining index score of ≥ 4 was used to define tumors with high Popdc3 expression, and a staining index score of ≤ 3 was used to indicate low expression.

Statistical analysis

All statistical analyses were performed using the SPSS 17.0 software. Correlation of Popdc3 expression with immunohistochemistry and clinicopathologic parameters was evaluated by χ^2 test or Fisher's exact probability test. Overall survival rate was calculated by the Kaplan-Meier method and the difference in survival curves was analyzed by the log-rank test. The follow-up time was calculated from the date of surgery to the date of death, or the last known follow-up. Independent prognostic factors were analyzed by the Cox proportional hazards regression model. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of Popdc3 in gastric cancer and noncancerous mucosa

In our current study, immunohistochemical analysis was done to examine the Popdc3 expression in 306 gastric cancer lesions and 84 noncancerous tissues. Popdc3 was detected in 72 (85.71%) cases of 84 human nontumor mucosa. High expression of Popdc3 protein was detected in 78 (25.49%) cases of 306 human gastric cancer, and low expression was detected in 228 (74.51%). Popdc3 staining was detected mainly in the majority of normal cells, especially in chief cells and smooth muscle. Besides, we also found Popdc3 expression in intestinal metaplasia. However, Popdc3 was mainly localized in the cytoplasm of tumor cells and its weak staining in cell membranes. The differences of Popdc3 expression between gastric cancer and noncancerous mucosa were also statistically significant ($\chi^2 = 1.010E2$, $P < 0.0001$, Figure 1).

Reduced Popdc3 expression and clinicopathologic features

Reduced expression of Popdc3 correlated with depth of invasion, regional lymph node and distant metastasis, and TNM stages ($P < 0.05$). Popdc3 expression did not correlate with age, gender, location of tumor, size of tumor, histologic type and histologic differentiation ($P > 0.05$, Table 1). The factors for possible prognostic effects in gastric cancer were analyzed by Cox regression analysis.

Table 1 Patient characteristics and Popeye domain containing 3 expression in gastric cancer *n* (%)

| Clinical parameters | *n* | Popdc3 | | χ^2 | *P* value |
		Low	High		
Age (yr)					
< 50	105	72 (68.6)	33 (31.4)

TNM: Tumor, nodes, metastasis; Popdc3: Popeye domain containing 3.

The multivariate analysis suggested that the patient's gender ($P = 0.016$), regional lymph node metastasis ($P < 0.0001$), distant metastasis ($P < 0.0001$), TNM stages ($P = 0.002$), and the expression of Popdc3 ($P < 0.0001$) were independent prognostic factors in patients with gastric carcinoma. However, patient's age, tumor location, size of tumor, histologic type, histologic differentiation and depth of invasion had no prognostic value (Table 2).

Correlation between Popdc3 expression and patient prognosis

In stages I and II, the 3-year survival rate of patients with a low expression of Popdc3 was significantly lower than in patients with high Popdc3 expression. The survival estimates showed a dramatic difference in median survival between the high and low Popdc3 expression: the former averaged 55 mo [95% confidence interval (CI): 53.515-56.485], whereas the latter 23 mo (95% CI:

Table 2 Multivariate analysis for disease-related deaths (Cox regression model)

Variables	*P* value	Hazard ratio	95% CI
Popdc3	< 0.0001	0.193	0.133-0.282
Gender	0.016	1.388	1.063-1.814
Regional lymph nodes	< 0.0001	1.344	1.156-1.564
Distant metastasis	< 0.0001	11.591	6.131-21.915
TNM stages	0.002	1.486	1.159-1.905

CI: Confidence interval; TNM: Tumor, nodes, metastasis; Popdc3: Popeye domain containing 3.

Figure 2 Kaplan-Meier curves with univariate analyses (log-rank) for patients with low Popeye domain containing 3 expression *vs* high Popeye domain containing 3 expression tumors in all gastric cancer. The cumulative and 3-year survival rates were 88.46% and 84.6%, respectively in the high Popeye domain containing 3 (Popdc3) protein expression group, but was only 76.75% and 16.7% in the low expression group ($\chi^2 = 145.095$, $P < 0.0001$).

21.201-24.799). For patients with low Popdc3 protein expression, 1- and 3-year survival rates were 76.75% and 16.7%, respectively, which were significantly lower than in patients with high Popdc3 expression (88.46%, 84.6%, respectively, $\chi^2 = 145.095$, $P < 0.0001$). Based on this result, we suggested that diminished expression of Popdc3 is a prognostic indicator of poor survival for patients with gastric cancer. In addition, we further compared the survival between the patients in early TNM stage (stages I and II) or late stages (stages III and IV) with different Popdc3 expression. The results showed that low Popdc3 expression had a much more significant effect on the survival of the patients with early stage tumors ($\chi^2 = 104.741$, $P < 0.0001$), with a > 51.9% reduction in the 3-year survival compared with that of patients with high Popdc3 expression. In late stages, the difference was also significant ($\chi^2 = 5.930$, $P = 0.015$), with a 32.6% reduction in the 3-year survival. Therefore, these data suggested that Popdc3 expression was as an independent prognostic variable for gastric cancer in early stage and late stage (Figure 2 and Table 3).

DISCUSSION

The cause of cancer remains elusive and may be multifac-

Table 3 Survival estimates and 95% confidence intervals for disease-related deaths

Groups	Median survival (mo)	1-yr survival rate (%)	3-yr survival rate (%)	χ^2	*P* value
Low Popdc3 expression	23 (21.20-24.79)	175 (76.75)	38 (16.7)		
High Popdc3 expression	55 (53.51-56.48)	69 (88.46)	66 (84.6)	145.095	< 0.0001
Stage Ⅰ-Ⅱ with low Popdc3 expression	29 (21.00-38.00)	97 (87.39)	44 (39.64)

Popdc3: Popeye domain containing 3.

torial[23,24]. Work by many researchers has illuminated that epigenetic alterations, like mutations and chromosomal abnormalities, can be causally involved in carcinogenesis[25,26]. Previous publications discovered that aberrant DNA methylation was more frequently present in cancers than mutations[27,28].

As a prototypical member of the Popdc family, Bves is mostly studied over the past several decades. Many reports have shown that Bves is highly conserved and has been identified in a wide variety of vertebrates and invertebrates[29,30]. Both mRNA and protein of Bves are highly expressed in striated and smooth muscles and in various forms of epithelial cell types in the embryo and adult[31,32]. It seems that Bves plays a critical role in cell-cell adhesion and in maintaining epithelial integrity, suggesting that loss of Bves function could result in abnormal cell behavior and disease[33-35]. In 2008, Feng *et al*[36] used MethyLight assays to analyze DNA methylation status of 27 genes on 49 paired cancerous and noncancerous tissue samples from non-small cell lung cancer (NSCLC) patients and found that Bves were methylated significantly more frequently in tumor tissues than in noncancerous tissues. Methylation of Bves was present in 80% of NSCLC tissues but only in 14% of noncancerous tissues. It is, so far, the first report of a modification of Bves in cancer.

In 2010, Kim *et al*[16] conducted the first detailed research on the Popdc family and discovered that frequent silencing of Bves and Popdc3 was associated with promoter hypermethylation in gastric cancer. Expression of Bves and Popdc3 was downregulated in 73% of the gastric cancer cell lines and in 69% (Bves) and 87% (Popdc3) of the gastric cancer tissues. Bves and Popdc3 were hypermethylated in 69% (Bves) and 64% (Popdc3) of the gastric cancer tissues. They also found that combined treatment with a DNA methylation inhibitor and a histone deacetylase inhibitor strongly induced Bves and Popdc3 expression. These observations suggested that frequent methylation and inactivation of Bves and Popdc3 in early-stage gastric cancer might predispose cells to other critical changes that cause cancer metastasis.

These results are similar to our study. However, the clinical impact of Popdc3 expression or the prognostic value for gastric cancer was not completely clarified because the number of gastric cancer patients was too small. Actually, it is the first study to explore the correlation between Popdc3 expression and clinical and prognostic factors in gastric cancer. Our study demonstrated

that Popdc3 was frequently downregulated in gastric cancer tissues in comparison with those in normal gastric tissues. We examined the relationship between Popdc3 expression and clinicopathological factors in gastric cancer. As a result, reduced level of Popdc3 protein expression in gastric cancer lesions was found mainly associated with depth of invasion, regional lymph node and distant metastasis, and TNM stages. Bves is required for maintenance of E-cadherin in the membrane and plays an important role in cell adhesion and in maintaining epithelial integrity[32]. In development of tumor tissues or diseases, downregulation or mislocalization of E-cadherin is associated with epithelial-mesenchymal transition (EMT)[37]. EMT is considered to be essential for proper development and underlies embryonic processes such as chick gastrulation and coronary vasculature formation[38]. When spontaneously or aberrantly induced in the adult, however, EMT as a hallmark of cancer, may result in loss of epithelial organization and cell tumor tissues invasion of previously normal tissues[39]. Therefore, interfering with E-cadherin function, loss of Bves could result in abnormal cell behavior and disease by promoting EMT programs[40]. Bves was 28% identical to Popdc3 among Popeye family members[12], indicating that Popdc3 may play a role in tumor suppression and interact with Bves.

In this study, multivariate analysis revealed that patient's gender, regional lymph node and distant metastasis, TNM stages, and the expression of Popdc3 were independent prognostic factors for the disease. Although abnormal expression of Popdc3 in gastric cancer might play an important role in the process of tumorigenesis, its biochemical mechanism and potential impact on patient's survival is unknown. So we further analyzed and assessed the impact of expression of Popdc3 on patient's survival. The result indicated that low levels of Popdc3 protein were closely correlated with the prognosis of gastric cancer. A survival curve plotted by the Kaplan-Meier method showed that in patients with low Popdc3 protein expression, the 1- and 3-year survival rates were 76.75% and 16.7%, respectively, which were significantly lower than in patients with high Popdc3 expression (88.46% and 84.6%, respectively). Besides, we further compared the survival between the patients with Popdc3 expression in early TNM stage (stages Ⅰ and Ⅱ) or late stage (stages Ⅲ and Ⅳ). We found that low Popdc3 expression had a much more significant effect on the survival of those patients with early stage tumors, with a > 51.9% reduc-

tion in the 3-year survival as compared with high Popdc3 expression. In late stages, the difference was also significant, with a 32.6% reduction in 3-year survival. These results suggested Popdc3 expression is an independent prognostic variable for gastric cancer in early stage and late stage. In this regard, routine detection of methylation of Popdc3 in blood might be useful in monitoring and detecting tumor recurrence in early-stage gastric cancer after curative surgical resection.

In conclusion, our study suggests that degradation of Popdc3 is a common feature in gastric cancer that might play an important role in the progression and metastases of gastric cancer. In addition, the potentially important consequence of our work is that Popdc3 may be an attractive therapeutic candidate for gastric cancer. Thus, we believe that more researches on Popdc3 will further provide a basis for the development of potential biomarkers for the diagnosis and prognosis of gastric cancer.

COMMENTS

Background
Although many molecular and biological studies have shown risk factors for gastric cancer, the exact molecular mechanism of gastric cancer has not been clarified completely. There is an urgent need to find special markers closely related to tumor outcome and therapy.

Research frontiers
The Popeye domain containing (Popdc) gene family consists of Bves/Popdc1, Popdc2 and Popdc3. As a prototypical member of the Popdc family, Bves is mostly studied over the past decades. However, the clinical impact of Popdc3 expression on cancers is still unknown. This study was carried out to investigate the alterations in the expression of Popdc3 in surgical specimens of gastric cancer, to explore the possible correlation between Popdc3 expression and clinicopathologic variables, to correlate expression of Popdc3 with lymph node metastasis and distant metastasis.

Innovations and breakthroughs
This is the first study attempting to elucidate the role of Popdc3 in gastric cancer and its prognostic significance. The findings suggest that Popdc3 is downregulated in gastric cancer tissues in comparison with those in normal gastric tissues. This study further demonstrates that degradation of Popdc3 is associated with gastric cancer progression and survival of the patients.

Applications
The results will open an avenue for further research to evaluate the role of Popdc3 in gastric cancer. Popdc3 expression may represent a potential prognostic marker and therapeutic target for gastric cancer.

Terminology
Popdc3, as a member of the Popdc family, was firstly detected in developing and adult striated muscle in vertebrates. Chromosomal mapping indicates that Popdc3 gene is clustered on mouse chromosome 10. Frequent methylation and inactivation of Popdc3 are observed in early-stage gastric cancer might predispose cells to other critical changes that cause cancer metastasis.

Peer review
This is a very well written article about the clinical significance of Popdc3 protein expression observed by IHC in gastric cancer. The message of this article was very clear but the author only did IHC to see the expression of Popdc3. This weakened the strength of this article.

Abstract

The case of a 52-year-old woman with a past history of thymoma resection who presented with chronic diarrhea and generalized edema is the focal point of this article. A diagnosis of *Giardia lamblia* infection was established, which was complicated by protein-losing enteropathy and severely low serum protein level in a patient with no urinary protein loss and normal liver function. After anti-helmintic treatment, there was recovery from hypoalbuminemia, though immunoglobulins persisted at low serum levels leading to the hypothesis of an immune system disorder. Good's syndrome is a rare cause of immunodeficiency characterized by the association of hypogammaglobulinemia and thymoma. This primary immune disorder may be complicated by severe infectious diarrhea secondary to disabled humoral and cellular immune response. This is the first description in the literature of an adult patient with an immunodeficiency syndrome who presented with protein-losing enteropathy secondary to giardiasis.

INTRODUCTION

Protein-losing enteropathy (PLE) is a rare syndrome of gastrointestinal protein loss that may complicate a variety of diseases. The diagnosis of PLE should be considered in patients with hypoproteinemia, especially hypoalbuminemia, after other causes have been excluded, such as malnutrition, proteinuria, and impaired protein synthesis. The diagnosis is most commonly based on the determination of fecal α-1 antitrypsin clearance, though scintigraphy (technetium-99m-labeled human serum albumin scan-^{99m}Tc-HSA) aids in localizing the site and quantifying enteric protein loss[1].

The pathogenic mechanism can be divided into erosive gastrointestinal disorders, nonerosive gastrointestinal disorders, and disorders involving increased central venous pressure or mesenteric lymphatic obstruction[1]. Al-

though not extensively studied, certain enteric infections (*Salmonella*, *Shigella*, *Rotavirus*, and *Giardia lamblia*) can also damage the intestinal mucosa leading to excessive protein loss, particularly in an immunocompromised host[2,3].

Giardia lamblia is a protozoan that frequently infects the gut and plays an important role in the public health of developing countries, such as Brazil[4]. Transmission occurs through oral-fecal contact or intake of contaminated water and food by the infecting forms (cysts or oocysts). Although normally presenting with mild symptoms, such as cramps and chronic diarrhea, more severe complications can take place and malabsorptive syndrome may develop[5]. In this case report, severe giardiasis is illustrated in an adult patient with a past history of thymoma who developed PLE, a rare complication that particularly affects infants.

CASE REPORT

A 52-year-old black woman was referred to our hospital because of chronic diarrhea and generalized edema. She had gained 10 kg over the last year because of peripheral edema, and complained about asthenia and fatigue. She had no abdominal pain, fever or stool bleeding. Two years before the event, while under investigation for chronic cough and chest pain, the diagnosis of a type AB thymoma was made according to World Health Organization classification and she underwent a sternal thymectomy. Anatomopathological analysis showed no signs of capsular, vascular or lymphatic invasion.

The patient presented mild steatorrhea on a semi-quantitative stool analysis, negative proctoparasitologic examination and severe hypoproteinemia on serum protein electrophoresis (Figure 1A). A hepatic cause of hypoproteinemia was ruled out by clinical and laboratory parameters and urinary sedimentary analysis was normal with no proteinuria. There was altered coagulation testing related to vitamin K deficiency, normocytic normochromic anemia, and normal leucocyte and platelet count.

She was submitted to ^{99m}Tc-HSA which demonstrated mild protein loss from the small bowel though no specific site was able to be localized. She had a normal colonoscopy and an upper digestive endoscopy that showed moderate duodenitis. On duodenal biopsy, there were structures identified as *Giardia lamblia*, moderate non-specific active chronic duodenitis, and preserved villi:crypt ratio. Giardiasis was not attributed at first to be the cause of the enteric protein loss. In subsequent investigations, anterograde enteroscopy was undergone, demonstrating only non-specific duodenal and jejunal lesions. No remarkable findings were verified on histological samples.

Nevertheless, after anti-helmintic treatment with oral metronidazole, she ended up recovering from diarrhea and edema. No signs of enteric protein loss were verified by scintigraphy and serum albumin level normalized, though hypogammaglobulinemia persisted (Figure 1B).

On evaluation of intermittent asthma and rhinitis since childhood and recurrent pneumonia, antibody de-

ficiency was diagnosed, including immunoglobulins IgA, IgE, IgG and IgM. Cytometry analysis of peripheral blood lymphocytes revealed a marked decrease in CD19+ B-cells. Bone marrow biopsy demonstrated a chromosome 9 inversion with chromosome 16 deletion [*46,X X,inv(9),del(16)(q22)*] with unknown significance and no additional important findings. Based on previous history of thymoma and current hypogammaglobulinemia, the diagnosis of Good's syndrome (GS) was made even though no evidence of cell-mediated immune defects was verified.

DISCUSSION

Giardia lamblia is a flagellated intestinal protozoan with oral-fecal transmission. Infection takes place in the proximal small gut, especially duodenum, where motile trophozoites live adhered to enterocytes[5].

Examination of concentrated, iodine-stained wet stool preparations and modified-trichrome-stained permanent smears has been the conventional approach to the diagnosis. Despite three negative stool samples, the diagnosis of giardiasis could be made by duodenal biopsy in this case report. In fact, cysts and trophozoites are present only intermittently in feces, offering a low sensitivity of approximately 50%, even with examination of multiple specimens. Identification of trophozoites within small intestinal biopsy specimens requires careful examination of multiple microscope fields to ensure accuracy[6], although on direct sampling of duodenal contents (e.g., duodenal aspiration or the "string test"), sensitivity can be improved to approximately 80%. Therefore molecular tests based on enzyme linked immunosorbent assay or direct immunofluorescent antibody microscopy should be the first diagnostic test to be performed because of high accuracy, with sensitivities greater than 90% and specificities approaching 100%.

Worldwide, *Giardia* affects infants more commonly than adults and has different pathogenicity in experimental human infections. Infected patients, especially those immunocompromised, may present malabsorptive diarrhea of yet unknown mechanism. Trophozoites adhere (perhaps by suction) to the epithelium of the upper small intestine, using a disk structure located on their ventral surface. There is no evidence that trophozoites invade the mucosa. On biopsy, pathologic changes range from an entirely normal-appearing duodenal mucosa (except for adherent trophozoites) to severe villous atrophy with a mononuclear cell infiltrate that resembles celiac sprue[7].

The severity of diarrhea appears to correlate with the severity of the pathologic change[6]. In fact, the host immune response plays a critical role in limiting the severity of giardiasis; this is mediated by humoral immune response, both systemic (IgM and IgG) and mucosal (IgA). Certain populations, including children younger than 2 years of age and patients with hypogammaglobulinemia, are more likely to develop serious disease. When infected with *Giardia*, individuals with common variable immuno-

deficiency develop severe, protracted diarrhea and malabsorption with sprue-like pathologic changes that resolve with treatment[3] such as immunoglobulin replacement[6]. The importance of a cellular immune response is yet to be determined. On immune reconstitution, severe inflammatory changes and villous atrophy develop in the intestine, suggesting that the immune response to infection may contribute to pathology, although severe infections that are resistant to treatment or an increased frequency of giardiasis have been noted only rarely in patients with acquired immune deficiency syndrome[7].

PLE is a rare complication associated with Giardia infection, as formerly described in infants[1-3]. As illustrated in this article, this infection may cause severe enteric mucosal damage that leads to an inflammatory process and exudative protein loss. Sometimes, especially when there is associated lymph leakage, secondary immunodeficiency may develop as decreases in serum lymphocytes and hypogammaglobulinemia occur[1].

As previously mentioned, although PLE is better diagnosed by the determination of fecal α-1 antitrypsin clearance because of high accuracy of the method, scintigraphy was the option chosen for the diagnosis in this case and it could localize protein loss from the small gut at non-specific sites. ^{99m}Tc-HSA scan possesses high sensitivity and specificity; it may demonstrate the site and semi-quantify protein loss, despite some false positives resulting from active gastrointestinal bleeding and *in vivo* breakdown of ^{99m}Tc-HSA, yielding free pertechnetate from radiolabeling[8]. The former is easily excluded by fecal occult blood examination and the latter by the absence of stomach or thyroid visualization.

At first, the hypothesis of hypogammaglobulinemia secondary to gut protein loss was put forward for this patient since severe universal hypoproteinemia was verified in pre-treatment serum protein electrophoresis. Nevertheless, after metronidazole was instituted, every serum protein fraction increased but gammaglobulin remained very low. This led to the belief that she possessed an

immune disorder, which could explain the advanced enteropathy caused by *Giardia* infection and the persistent hypogammaglobulinemia in spite of medical treatment.

Patients with thymoma may suffer from specific types of paraneoplastic syndrome or remote effects of cancer which have underlying autoimmunity origins. They include myasthenia gravis, pure red cell aplasia, and hypogammaglobulinemia (Good's syndrome), with approximate occurrence of 30%, from 1.6% to 5%, and from 3% to 6%, respectively. Autoimmunity to B lymphocyte lineage causes severe deficiency in B lymphocytes and hypogammaglobulinemia, resulting in acquired immunodeficiency vulnerable especially to bacterial infection. Although most paraneoplastic syndromes have been documented to recover after tumor resection, some previous case reports seem to indicate that hypogammaglobulinemia without improvement can last even after tumor resection for as long as 9 years[9].

GS is a rare association of thymoma and immunodeficiency first described more than 50 years ago by Dr. Good. The diagnosis of thymoma usually precedes the diagnosis of hypogammaglobulinemia and other clinical manifestations, such as infection or diarrhea, in almost half of the cases. Recurrent sinopulmonary infection is commonly the first clinical manifestation followed by chronic diarrhea, the mechanism of which is not identified in the majority of cases, although bacteria, such as *Salmonella spp.*, and other pathogens, like cytomegalovirus and *Giardia lamblia* might the etiological factor[9,10].

GS, in contrast to other primary immunodeficiency disorders such as common variable immunodeficiency disease, usually affects adults in the fourth or fifth decade of life, equally male and female, and almost always associated with hypogammaglobulinemia. Although there are no formal diagnostic criteria for this disorder, GS is characterized by low to absent B cells in the peripheral blood, hypogammaglobulinemia, and variable defects in cell-mediated immunity; with a CD4 lymphopenia, an inverted CD4/CD8+ T-cell ratio and reduced T-cell mitogen pro-

liferative responses[4]. In clinical practice, as illustrated in this report, serum flow lymphocytometry shows absence of B lymphocytes, discrete low CD4 T lymphocyte count and inverted CD4/CD8 ratio[9-11].

It has long been known that giardiasis is a frequent infection of the gastrointestinal tract, especially in infants and in developing countries, typically manifesting as chronic diarrhea, abdominal cramps and fatigue. The diagnosis may be challenging as conventional methods of stool examination can lack sensitivity. In cases of strong clinical suspicion, serum serology is of great value when available, though upper digestive endoscopy is a reliable tool to demonstrate degree of duodenal damage and direct diagnosis can be made through histological sample. As far as we know, this is the first time in the literature that Giardia infection complicated with PLE has been reported in an adult patient. In fact, whenever severe giardiasis occurs in adulthood, immunodeficiency should always be kept in mind because of humoral IgA-mediated immunological pathogenicity, and clinical investigation should be directed towards this suspicion, even though rare in cause.

Abstract

Enteropathy-associated T-cell lymphoma (EATL) is a rare peripheral T-cell lymphoma classified into 2 types, with or without celiac disease, based on histology. Type 2 EATL is less commonly associated with celiac disease, in which cells are characterized by being monomorphic and small- to medium-sized. Cells are characterized by CD8 and CD56 expression and c-MYC oncogene locus gain. We present an atypical case of type 2 EATL in the jejunum, with human T-lymphotropic virus-1 that was CD4- CD8+ CD56- CD30- CD25- TIA-1+ and granzyme B+ on immunohistological staining. It also displayed translocation of chromosome 8p24 (c-MYC), as de-termined by fluorescent *in situ* hybridization. Mucosal spreading and intraepithelial invasion by lymphoma with villous atrophy were detected adjacent to the mucosal layer. The lymphoma may be derived from in-traepithelial CD8+ T cells, similar to celiac disease.

INTRODUCTION

Gastrointestinal lymphomas account for 4%-20% of all non-Hodgkin's lymphomas. Enteropathy-associated T-cell lymphoma (EATL) is a primary extranodal T-cell lympho-ma arising in the gastrointestinal tract, a rare subtype of peripheral T-cell lymphoma, and accounts for less than 1% of all non-Hodgkin's lymphomas[1-3]. There are two dif-ferent sub-classifications: type 1 EATL (with) and type 2 EATL (without) celiac disease[1,4]. The disease is seen with greater frequency in areas with a high prevalence of celiac disease, but it is rare in Japan[5]. Type 2 EATL accounts for 10%-20% of cases, and is less commonly associated

with celiac disease[1,4]. The tumor cells are monomorphic and small- to medium-sized, with infiltration of the intestinal crypt epithelium without inflammation[1,4]. Type 2 EATL often occurs without a history of celiac disease and shows strong expression of CD56 (> 90%) and CD8 (80%) based on immunohistochemical staining[1]. EATL generally has a poor prognosis because it is often diagnosed late, has spread, and is therefore refractory to treatment. We report a case with human T-lymphotropic virus-1 (HTLV-1) in which a type 2 EATL was CD8+, CD56-, T cell restricted intracellular antigen-1 (TIA-1)+ on immunohistological staining, and possessed a unique chromosomal change as determined by fluorescent *in situ* hybridization (FISH).

CASE REPORT

A 66-year-old woman with a past medical history of hypertension presented to the emergency department with a sudden onset of severe abdominal pain. Her weight was 43.5 kg and body mass was 19.7 kg/m^2. A physical examination revealed a high fever (39 ℃) with chills; diffuse, severe, constant abdominal pain; and muscular guarding. She had experienced abdominal distension for a month, but did not have diarrhea, weight loss, a history of malnutrition, or a food intolerance. We could not detect any palpable peripheral lymph nodes. The laboratory data on admission showed mild leukocytosis (white blood cell count of 10 400/mm^3) and hypoproteinemia (total protein 5.4 g/dL). Persistent hypoproteinemia was recognized at 4 mo prior, based on previous medical records. No atypical lymphocytes were detected in the peripheral blood. A computed tomography showed free air and wall thickening in the pseudo-aneurysmally dilated small bowel within the pelvic area, with a defect of the intestinal wall (Figure 1). Laparotomy was performed and showed a pseudo-aneurysmally dilated and perforated jejunum 80 cm from the ligament of Treitz, with massive purulent ascites fluid. We performed a segmental resection of the lesion and a side-to-side anastomosis. The resected jejunum was generally thickened and there was diffuse transmural infiltration by monomorphic and medium-sized atypical lymphoid cells, with villous atrophy of the intestinal glands (Figure 2A). Intramucosal spreading of lymphoma was found in an adjacent mucosal layer, and many atypical intraepithelial lymphocytes were detected (Figure 2B and C). Immunohistochemical staining was positive for CD3, CD7, CD8, TIA-1 granzyme B, c-MYC and Ki-67, and negative for CD4, CD5, CD20, CD25, CD30, CD56, and CCR4 (Figure 2D and E). FISH analysis revealed translocation of chromosome 8q24 (c-MYC) (Figure 2F). Polymerase chain reaction analysis of *TCRγ* gene rearrangements were performed using the BIOMED-2 procedure[5]. Rearrangement bands were detected in 4 VγIf, Vγ9, Vγ10, Vγ11, and Jγ1.1/2.1, and Jγ1.3/2.3 consensus primers.

Based on these findings, we made a diagnosis of type 2 EATL. On postoperative day 10, the patient was

Figure 1 Computed tomography scan of the dilated and perforated small bowel.

discharged without any complications. After the diagnosis, we performed additional laboratory tests. Serum soluble interleukin-2 receptor was elevated (822 U/mL), and serum HTLV-1 antibodies were positive. 67 Gallium scintigraphy and fluorodeoxyglucose positron-emission tomography did not show any site of involvement. Bone marrow biopsy did not reveal malignant cells. Based on these results, we diagnosed clinical stage 2E. The patient received high-dose chemotherapy with autologous hematopoietic cells 6 mo after surgery.

DISCUSSION

EATL is a rare subtype of peripheral T-cell lymphoma, with an incidence of 0.25% of all lymphomas in Japan[3,6]. Since gluten allergy is uncommon in Japan, it is extremely rare for celiac disease to be a basal disorder, and type 2 EATL is more common than type 1 EATL[5]. EATL most commonly arises in the proximal jejunum, and typically presents with abdominal pain. It is often associated with intestinal obstruction, perforation, or bleeding, and is diagnosed by histology tests. Type 2 EATL consists of monomorphic and small- to medium-sized tumor cells that frequently express CD8 and CD56[3]. The prognosis of EATL is usually poor based on results of conventional combination chemotherapy, although high-dose chemotherapy with autologous hematopoietic cell transplantation may have longer survival rates[2,7].

The pathological findings of this case showed monomorphic, small- to medium-sized tumor cells with villous atrophy of the mucosa. Combined with the mucosal spreading and increased intraepithelial lymphocytes (IELs), we made a diagnosis of type 2 EATL. Type 2 EATL is usually positive for CD8 and CD56 (> 90%), but this patient was CD56 negative[3]. Several studies have suggested that the Epstein-Barr virus plays an etiological role in EATL pathogenesis, but this is still a subject of debate. In this case, Epstein-Barr encoded RNAs and latent membrane proteins were not expressed, suggesting that Epstein-Barr virus was not involved in tumor proliferation. Test results showed HTLV-1 infection based on serological antibodies, but the tumor cells were different from adult T cell lymphoma/leukemia immunopheno-

Figure 2 Pathological findings of the specimen. type features with respect to CD4, CD8, CD25, CCR4 and cytotoxic proteins[8]. FISH analysis, however, showed gene translocation at 8q24, which is the c-MYC oncogene locus. It has been suggested that c-MYC protein plays a role in lymphoid proliferation and the apoptotic pathway in malignant lymphomas[9]. In type 2 EATL pathogenesis, about 70% of cases show a gain of 8q24, suggesting c-MYC is an important transcription factor in EATL[4]. We present here the first EATL case with translocation of chromosome 8q24 (c-MYC region).

Some studies suggested chronic inflammation might contribute to the development of neoplastic lymphocyte growth in EATL[4,10]. Celiac disease is characterized by villous atrophy, crypt hyperplasia, and an increased invasion of CD8+ IEL. Celiac disease may progress to type 1 EATL[10], especially in patients with refractory celiac disease, in which IELs have aberrant phenotypes and genetic alterations due to persistent inflammation[4,10]. This is supported by the fact that refractory celiac disease and type 1 EATL rarely show aberrant CD8 expression[4,10]. This case showed protein-losing enteropathy and lymphoma cells with IEL-like features in the mucosa, and villous atrophy. We considered the possibility of persistent enteropathy, which is consistent with hypoproteinemia 4 mo before the surgery. Celiac-like enteropathy, rare in Japan, is consistent with the clinical symptoms, and in this case, persistent enteropathy might cause CD8+ IELs to transform to neoplastic cells *via* c-MYC. The immunophenotype of this

case was different from typical type 2 EATL cases, regarding CD3+ CD4- CD8+ CD30- CD56-.

In summary, we report the unique case of a 66-year-old HTLV-1 woman diagnosed with type 2 EATL, which was CD3+ CD4- CD8+ CD30- CD56- on immunostaining, and displayed translocation of the c-MYC region.

Abstract

Spontaneous hematomas are rare and most occur secondary to hematologic disorders or during anticoagulant therapy. Most spontaneous hematomas occur above the sigmoid colon, and rarely in the rectum. Herein we present the case of a patient with a spontaneous perforating hematoma of the rectum who presented with severe abdominal pain after a bloody stool. The hemoglobin level decreased by 33 g/L within 20 h. An abdominal sonogram showed a hydrops in the lower abdomen with a maximum depth of 7.0 cm. A hematoma, 8 cm × 6 cm × 5 cm in size, was noted intra-operatively in the rectosigmoid junction, with a 1.5-cm perforation in the hematoma and active hemorrhage. Thus, a partial rectectomy and sigmoidostomy were performed. Three months later, a second operative procedure to re-establish intestinal continuity was performed. The patient is in good condition 12 mo after the last surgery. In addition to this case, the causes of spontaneous perforating hematomas and the treatment are discussed.

INTRODUCTION

Intramural hematomas may occur in every portion of the alimentary tract from the esophagus to the sigmoid colon, but rarely occur in the rectum. Intramural hematomas most often result from blunt trauma[1]. Non-traumatic spontaneous hematomas usually reflect an underlying blood dyscrasia, anticoagulant therapy, and hematologic diseases[2]. Spontaneous rectal hematomas have rarely been reported. Herein we present this unusual case of a spontaneous perforating hematoma.

CASE REPORT

A 52-year-old male was admitted to our hospital with a 20-h history of severe abdominal pain after passing a small amount of bloody stool. The patient had no history of trauma before admission and clearly related the acute onset of pain with straining to have a bowel movement. The patient had 5-year history of oral warfarin sodium use after mitral valve replacement and coronary stent implantation. The physical examination revealed diffuse abdominal tenderness, rebound tenderness, widespread perianal ecchymosis, and muscular tension without na-

Figure 1 Pre-operative photograph of the perineum (knee-chest position) revealing widespread perianal ecchymosis (marked with black arrows).

Figure 2 Intra-operative photograph of a large intramural hematoma arising beneath the rectosigmoid junction.

Figure 3 Extensive oozing of blood in the muscular layer of the resected rectal and fibrinoid necrosis within the vascular wall (hematoxylin and eosion stain, × 20).

usea and vomiting (Figure 1). There was a persistent drop in hemoglobin from 94 g/L to 61 g/L over a 20-h interval. The prothrombin time was prolonged (44.40 s; approximately four times the normal prothrombin time). An abdominal sonogram showed a large hydrops in the lower abdomen with a maximum depth of 7.0 cm. After admission, active resistance to shock treatment was given, and the abdominal symptoms did not remit, thus emergent surgery was performed. A palpable hematoma, 8 cm × 6 cm × 5 cm in size, was noted in the rectosigmoid junction intra-operatively (Figure 2). Furthermore, there was a perforation in the hematoma, 1.5 cm in diameter, and active hemorrhage. After confirming that the perforating hematoma of the rectum was the cause of the generalized peritonitis and the extensive oozing of blood could not be stopped, a partial rectectomy and sigmoidostomy were performed. A histopathologic examination of the removed specimen revealed extensive oozing of blood in the muscular layer of the rectum and fibrinoid necrosis within the vascular wall (Figure 3). The patient recovered without complications and was discharged on the 8th post-operative day. Three months later, the patient returned for re-establishment of intestinal continuity. The patient was in good health and completely asymptomatic during the 12-mo follow-up period after the second surgical procedure.

DISCUSSION

Intramural hematomas of the alimentary tract are unusual. Intramural hematomas mainly occur above the sigmoid colon, and rarely in the rectum. The duodenum is the most common site for intramural hematomas[1]. In a review of the medical literature, most rectal intramural hematomas occur following blunt trauma. Spontaneous perforating hematomas of the rectum have rarely been reported[3].

Of all intramural hematomas, 15%-36% are spontaneous in patients with underlying hematologic diseases or on anticoagulant therapy[2]. As shown in the current case, the patient had a long history of oral warfarin sodium use, and the prothrombin time was prolonged to 44.40 s, which is approximately four times the normal prothrombin time. Anticoagulation-induced intramural hematomas can occur in patients with therapeutic prothrombin times, but the majority of intramural hematomas occur in patients with abnormally prolonged prothrombin times[2]. Thus, anticoagulant therapy was thought to be closely related with the hematoma in this patient. In addition, increased abdominal pressure during straining may play an important role in hematoma formation. Specifically, when a patient strains to have a bowel movement, the abdominal pressure increases and the rectum contracts. The contracted rectum increases the intramural pressure which leads to decreased vascular compliance, and even rupture, thus causing a rectal intramural hematoma. When the pressure of the intramural hematoma is greater than the capacity of the hematoma wall, the hematoma breaks and clinical symptoms appear.

Most patients with intramural hematomas present with signs of intestinal obstruction[3]. Conservative therapy is usually sufficient because the hematomas will undergo spontaneous resorption[4], but treatment decisions depend on the symptoms and clinical findings[4,5]. Relief of the tamponade effect during conservative therapy could lead to further bleeding[1]. In patients in whom the cause of obstruction is not known, or in patients with complete obstruction or who have failed medical management, surgical intervention is required[6]. Draining the

hematoma might increase the risk of serious infection, as reported previously[7]. According to the decreasing hemoglobin concentration and failed conservative therapy, we performed a partial rectectomy and sigmoidostomy. The patient recovered without complications.

Therefore, testing prothrombin times regularly and avoiding severe abdominal pressure in a patient who has a long-term oral anticoagulant drug history might help prevent complications associated with intramural hematomas, such as perforation.

Abstract

To present problems that might severely impact the conclusions drawn by the authors of an article on antioxidant treatment in chronic pancreatitis (*World J Gastroenterol* 2010; 16: 4066-4071). We analyzed and discussed this paper by Shah *et al*, and found that promising as it is, this study has some methodological shortcomings, such as: cross-sectional nature of the study, lack of initial evaluations of quality of life and regular follow-ups to determine the dynamics and real directions of changes in quality of life. We therefore concluded that the results of the study by Shah *et al* are biased and, although very promising, should not be considered as scientifically relevant.

Stefaniak T, Vingerhoets A, Sledzinski Z. Does antioxidant therapy influence every aspect of quality of life? *World J Gastroenterol* 2012; 18(19): 2441-2442 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i19/2441.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i19.2441

TO THE EDITOR

We have read with great interest an article by Shah *et al*[1] (*World J Gastroenterol* 2010; 16: 4066-4071). Exciting news about the clinical use of antioxidant therapy seem to open an entirely new chapter in treatment of chronic pancreatitis. We have already published information on possibilities concerning the role of oxygen free radicals in experimental acute pancreatitis as well as the potential role of antioxidants in treatment the disease[2]. As a team of scientists and clinicians intensively involved in the treatment of pancreatic chronic pain, we have found the study presented by Shah *et al*[1] very promising.

Unfortunately, despite very good rationale and biochemical background, the manuscript cannot be considered as free of significant bias, that most probably severely impacts the final conclusions. The pain and quality of life (QoL) scores were obtained only after a 6-mo period of follow-up, there was no initial score at the beginning of the therapy. Moreover, the authors presented only measurement of pain and QoL, which does not seem to be sufficient in context of complexity of interactions (such as social and emotional) that chronic pancreatitis patients may experience[3,4]. In that circumstances, we would recommend that follow-up measurements should be made every month, as presented in other studies on pain in chronic pancreatitis and/or pancreatic cancer[3,4]. Lack of initial information, randomization and pain and QoL dynamics assessment leaves a suspicion that the patients treated with antioxidants suffered from less pain, had better QoL and consumed less opioids from the very beginning of this doubtlessly non-prospective, uncontrol-

led trial. Significant differences in almost every variable of QLQ-C30 seem to confirm our point of view. It is difficult to explain in any psychological paradigm or biochemical formulae, what possible influence could antioxidant therapy exert on cognitive or emotional functioning or, most interestingly on body image, alcohol-related guilt or even financial problems.

To sum up, we believe that antioxidants may offer a very interesting and promising supplementation to the treatment of chronic pancreatitis, but unfortunately, methodological problems presented in the article of Shah *et al*[1] completely disqualify the conclusions of the authors. We would be most happy to see a randomized prospective trial with dynamic evaluations that would confirm the results presented in this article.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520. pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-beled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi. nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean $\pm$ SD or mean $\pm$ SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 µg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/1007-9327office/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World J Gastroenterol 2012; 18(20): 2502-2510

http://www.wjgnet.com/1007-9327/full/v18/i20/2502.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol, WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Hepatitis B is caused by the host immune response and T cells play a major role in the immunopathogenesis. More importantly, T cells not only destroy hepatocytes infected by hepatitis B virus (HBV), but also control HBV replication or eradicate HBV in a noncytolytic manner. Therefore, analysis of T cell immune response during acute and chronic HBV infection is important to develop a strategy for successful viral control, which could lead to immunotherapy for terminating persistent HBV infection. There have been many attempts at immunotherapy for chronic HBV infection, and some have shown promising results. High viral load has been shown to suppress antiviral immune responses and immunoinhibitory signals have been recently elucidated, therefore, viral suppression by nucleos(t)ide analogs, stimulation of antiviral immune response, and suppression of the immunoinhibitory signals must be combined to achieve desirable antiviral effects.

INTRODUCTION

Hepatitis B virus (HBV) is not cytopathic, and hepatitis B is caused by the host immune response, mainly T-cell-mediated, against virus-related peptides expressed on hepatocytes in conjunction with human leukocyte antigens (HLAs). In acute self-limiting hepatitis, a broad T-cell immune response occurs that is strong enough to eradicate the virus or suppress viral replication[1]. However, there are many mechanisms that hamper the antiviral immune response, leading to persistent infection. To develop an optimal strategy to stimulate antiviral immune response with therapeutic potential, extensive analyses of immune mechanisms for successful viral eradication and immunosuppressive mechanisms induced by viral infection during persistent infection are required. In this review, I focus on T cell immune response during HBV infection, and summarize attempted immunotherapeutic approaches against persistent HBV infection.

T CELL RESPONSE IN ACUTE HBV INFECTION

Immunological analysis has been extensively performed in transgenic and chimpanzee models of acute HBV infection. In one model, transgenic mice, in which infectious HBV virions replicate in the liver with expression of all HBV-related antigens, were injected with hepatitis B surface antigen (HBsAg)-specific cytotoxic T lymphocytes (CTLs) that had been induced in nontransgenic mice. The injected CTLs produced interferon (IFN)-γ and tumor necrosis factor (TNF)-α, which purged viral

RNA and DNA without destroying infected hepatocytes[2-4]. Importantly, this noncytolytic clearance of intracellular HBV is more efficient at controlling HBV replication than the killing of infected hepatocytes. In this sense, hepatitis is not only a harmful event but also represents an effective mechanism by which CTLs suppress HBV. Noncytolytic viral eradication can account for recovery from acute HBV infection in that most HBV is cleared from hepatocytes with only a fraction of the hepatocytes being destroyed. This was confirmed in a chimpanzee infection model; HBV DNA level was markedly decreased in the liver and blood of acutely infected chimpanzees before peak serum alanine aminotransferase (ALT) concentrations were reached[5], suggesting that this noncytopathic T cell effector mechanism results in early viral inhibition or eradication, whereas a cytopathic T cell effector mechanism is required to eliminate the remaining virus by destroying infected hepatocytes.

In humans, the HBV-specific T cell response during incubation phase of acute hepatitis B has been analyzed extensively using HLA class I tetramer and cytokine staining[6]. The data showed that maximal reduction in HBV DNA in the serum occurred before the peak of ALT elevation; again indicating that suppression of HBV replication occurs without hepatocyte injury. Moreover, infiltration of HBV-specific CD8+ T cells into the liver has been observed several weeks before the peak of liver injury, suggesting that HBV-specific T cell infiltration occurs at an early stage of infection, resulting in suppression of HBV replication. Thereafter, recruitment of mostly nonspecific cells induced by cytokines or chemokines produced by HBV-specific T cells contributes to significant liver damage. Interestingly, in the HBV transgenic mouse model of acute hepatitis, administration of antibodies against the chemokines, IFN-inducible protein (IP-10) and monokine induced by interferon-(Mig), reduced the recruitment of mostly antigen-nonspecific mononuclear cells into the liver that had been induced by cytokines and chemokines produced by injected CTLs, leading to a reduction in the severity of hepatitis without affecting the antiviral activity of the CTLs[7]. These observations have important therapeutic implications, because suppression of antigen-nonspecific mononuclear cell recruitment may suppress hepatitis, while retaining the antiviral function of the CTLs.

The overall data from studies in chimpanzees and humans are essentially the same, and indicate that a sufficient T cell response to HBV at an early phase of infection is important for eradication of virus infection, and that an insufficient T cell response may lead to persistent viral infection.

The contributions of CD4+ and CD8+ T cells to the control of viral infection have been analyzed in a chimpanzee model of acute hepatitis B by depleting either T cell population with monoclonal antibodies. The data show that CD8+ T cells are the main effector cells responsible for virus elimination[8].

Antigen specificity of T cell response in acute HBV infection

The antigen specificity of the T cell response to HBV in acute hepatitis has been analyzed, and it is clear that acute viral hepatitis involves a vigorous CTL response to multiple epitopes in the viral nucleocapsid, envelope, and polymerase proteins, whereas these are not seen in patients with chronic hepatitis[1]. Although multispecificity of the CTL response is characteristic in acute hepatitis, there is known to be a hierarchy of epitope-specific CD8+ T cell responses determined by cytokine production after peptide stimulation. In acute hepatitis B, CD8+ T cell response to HBc18-27 (HLA-A2 restricted epitope) is dominant followed by the response to polymerase epitope (455-463), whereas envelope epitopes are always subdominant[9]. The hierarchy is clearly distinct from that observed in chronic hepatitis, in which the CD8+ T cell response to envelope epitope (183-191) is always dominant. Interestingly, chronic hepatitis patients with lower HBV DNA levels in the serum show greater responses to HBc18-27 than those with high HBV DNA. These findings imply that the T cell response to hepatitis B core antigen (HBcAg) is important for viral control, which is important for designing peptide vaccines for the treatment of chronic HBV infection.

Long-lasting T cell immune response after resolution of acute hepatitis B

In humans, most HBV is cleared after resolution of acute hepatitis. However, it has been shown that trace amounts of HBV DNA can be detected for several years after resolution of acute hepatitis, and the long-lasting memory T cell response is maintained by persistent replication of HBV[10], indicating that low levels of HBV replication could continue in most patients even in the convalescent phase of acute hepatitis in balance with immunological pressure.

T CELL RESPONSE IN CHRONIC HBV INFECTION

In peripheral blood, HBV-specific helper T lymphocytes and CTLs are barely detectable in patients with chronic hepatitis B (CHB)[11], possibly due to exhaustion by high viral load or tolerance to HBV.

In contrast, several studies have characterized intrahepatic CD4+ and CD8+ T lymphocytes in CHB. Intrahepatic CD4+ T lymphocytes in patients with CHB have been found to contain T helper (Th)0 cells, which produce not only IFN-γ, but also interleukin (IL)-4 and IL-5, thus differing from cells in the livers of patients with chronic hepatitis C, which are mostly Th1 cells[12]. CD4+ T lymphocytes that produce IL-17 infiltrate into the livers of patients with CHB and are involved in liver inflammation[13].

Livers of patients with low HBV replication contain intralobular CD8+ T lymphocytes[14], and the percent-

ages of virus-specific T lymphocytes in the liver have been clarified by immunohistochemical staining with peptide-MHC tetramer. The proportion of CD8[+] T lymphocytes in the livers of patients with chronic HBV specific for HBc18-27, a major HBV epitope, has been found to range from 0.18% to 1.28%[15]. Maini *et al*[16] have reported that the number of HBc18-27-specific CD8[+] T cells, detected using tetramers, was the same in livers with low HBV DNA/ALT as in those with high HBV DNA/ALT. Hence, HBV-specific T cells recognize HBV antigens and carry out immune surveillance in the liver. Thus, they have an important role in controlling HBV replication in the liver without causing hepatic necroinflammation in low DNA/ALT anti-HBe[+] HBV carriers. It remains unknown why HBV-specific T cells fail to control effectively HBV replication in the liver with chronic hepatitis. However, recent advances in immunology have given some insight into the mechanism as described below.

IMMUNOSUPPRESSIVE MECHANISM RESPOSIBLE FOR PERSISTENT HBV INFECTION

Regulatory T cells

Regulatory T (Treg) cells expressing the forkhead family transcription factor, FoxP3, are specialized cells that exert negative control on a variety of physiological and pathological immune responses, resulting in maintenance of immunological self-tolerance[17]. They show diverse phenotypes, occurring in both CD4[+] and CD8[+] T cell subsets, and express CD25 (IL-2 receptor chain) and/or cytotoxic T-lymphocyte antigen 4 (CTLA-4) in addition to Foxp3.

In HBV infection, hepatitis B e antigen (HBeAg)-positive patients with high HBV DNA levels in the serum show elevated numbers of CD4[+]CD25[+] Treg cells in the blood compared to patients with acute and chronic hepatitis C virus (HCV) infection[18]. Significant accumulation of CD4[+]CD25[+]FoxP3[+] Treg cells in the liver is found in patients with chronic HBV infection. Moreover, patients with high viral load have a higher proportion of Treg cells in the liver[19], suggesting that intrahepatic Treg cells suppress antiviral immune responses in the liver in chronic HBV infection.

Th cells that produce IL-17 (Th17 cells) have recently been identified as the third subset of effector T cells[20], which produce IL-17A, IL-17F, IL-22 and IL-21[21]. Recently, IL-6 has been shown to induce the generation of Th17 cells from naïve T cells together with transforming growth factor (TGF)-β and inhibits TGF-induced Treg cell differentiation[22]. Importantly, there is a reciprocal relationship between Th17 and Treg cells; not only in development, but also in their effector function, indicating that the Treg/Th17 balance may determine the quality and magnitude of immune responses in the liver[20]. Unexpectedly, the increases in circulating and intrahepatic Th17 cells are positively correlated with HBV DNA in the serum, serum ALT levels, and histological activity index of the livers with CHB, suggesting that activation of Th17 cells does not exert antiviral function in CHB[23].

Programmed death-1

Programmed death-1 (PD-1) is a surface receptor critical for the regulation of T cell function[24,25]. Binding to PD-1 by its ligands PD-L1 and PD-L2 results in the antigen-specific inhibition of T cell proliferation, cytokine production, and cytolytic function, leading to exhaustion of T cells. In the liver, PD-1 is expressed on lymphocytes; PD-L1 is expressed on lymphocytes, hepatocytes and sinusoidal endothelial cells; and PD-L2 is expressed on Kupffer cells and dendritic cells (DCs)[26]. HBeAg-positive patients with high HBV DNA levels in the serum show increased PD-1 and CTLA-4 expression on HBV-specific CD8[+] T cells[27]. Moreover, PD-1 expression on CD4[+] T cells is correlated positively with serum HBV DNA load in CHB patients[28]. Intrahepatic HBV-specific CD8[+] T cells express higher levels of PD-1, and upregulation of intrahepatic PD-1/PD-L1 is associated with liver inflammation and ALT elevation[29]. Although the mechanism underlying the upregulation of PD-1 on CD8[+] T cells in the inflamed liver is unknown, signals from PD-1 inhibit HBV-specific T cells, resulting in insufficient antiviral responses, leading to failure of viral control and persistent liver inflammation. Importantly, PD-1/PD-L1 blockade increased CD8[+] T cell proliferation and enhanced IFN-γ and IL-2 production by intrahepatic lymphocytes[29]. These findings suggest that inhibition of PD-1/PD-L1 may have therapeutic potential for the control of hepatitis B.

IL-10

IL-10 is an important cytokine with anti-inflammatory properties, and is produced by activated monocytes/macrophages and T cell subsets, including Treg and Th1 cells[30]. Immunosuppression by IL-10 is associated with functional exhaustion of memory T cells in chronic lymphocytic choriomeningitis virus (LCMV) infection, and blockade of IL-10 receptors could terminate chronic LCMV infection[31]. In chronic HBV infection, HBcAg stimulates the production of IL-10, which negatively regulates HBcAg-specific Th17 cell responses in CHB patients[32].

T cell immunoglobulin- and mucin-domain-containing molecule-3

It has been reported that not all exhausted T cells show upregulation of PD-1 and downregulation of CD127 (IL-7 receptor), and blockade of the PD-1/PD-L1 signaling pathway does not always restore proliferation and cytokine production[33]. Recently, another inhibitory molecule, T cell immunoglobulin- and mucin-domain-containing molecule-3 (Tim-3), has been reported. A high frequency of Tim3-expressing CD4[+] and CD8[+] T cells are found in chronic HBV infection, and the frequency of Tim-3[+] T cells is positively correlated with the severity of liver inflammation, and negatively correlated with plasma IFN-γ levels[34].

Table 1 Immunotherapeutic approaches for animal models of hepatitis B virus infection

Animal model	Immunotherapy	Results	Ref.
Peptide vaccination			
HBV transgenic mice	A synthesized fusion peptide, consisting HBcAg18-27 and HIV Tat49-57	Decrease in serum HBV DNA levels and the expression levels of HBsAg and HBcAg in the liver	[40]
Protein vaccination			
HBV transgenic mice	HBsAg vaccine	Most of the mice showed reduction of HBV DNA levels and disappearance of HBeAg and HBsAg	[41]
Woodchuck hepatitis virus infection	Combination of vaccine of HBV large surface protein and clevudine	Restoration of T-cell response to Pre-S and S region	[42]
DNA immunization			
Acute DHBV infection	DNA vaccine expressing DHBc and Pre-S/S and entecavir Boosted with fowl poxvirus vectors expressing DHBc and Pre-S/S	Clearance of DHBV infection at a rate of 100%	[43]
Chronic DHBV infection	DNA vaccine encoding the HBV large envelope and/or core protein with or without lamivudine	Reduction of viremia and liver DHBV cccDNA in 33% of ducks Seroconversion to anti-pre S in 67% of ducks showing cccDNA clearance	[44]
DC immunization			
HBV transgenic mice	Activated bone marrow-derived DCs	Break CTL tolerance to HBsAg	[45]
HBV transgenic mice	Anti-CD40 agonistic monoclonal Ab	Induction of noncytopathic inhibition of HBV replication mediated by antiviral cytokines (IL-12 and TNF-α) produced by activated intrahepatic APCs	[46]
HBV transgenic mice	HBV-specific peptide-pulsed DCs	Reductions in the serum HBsAg and HBV DNA	[47]
Cytokines and adjuvants			
HBV transgenic mice	Recombinant IL-12	Marked inhibition of HBV replication in the liver	[48]
HBV transgenic mice	α-galactosylceramide that can activate NK T cells	Complete inhibition of HBV replication	[49]
HBV transgenic mice	Recombinant IL-18	Inhibition of HBV replication noncytopathically, mediated by activation of resident intrahepatic NK cells and NK T cells	[50]
Gene therapy			
HBsAg transgenic mice	Lentivectors expressing HBsAg and IgFc fusion Ag	Induction of seroconversion to anti-HBs	[51]

HBV: Hepatitis B virus; DHBV: Duck HBV; DC: Dendritic cell; HBsAg: Hepatitis B surface antigen; HBcAg: Hepatitis B core antigen; HIV: Human immunodeficiency virus; APC: Antigen-presenting cell; IL: Interleukin; NK: Natural killer; CTL: Cytotoxic T lymphocyte; TNF: Tumor necrosis factor; cccDNA: Covalently closed circular DNA; Ab: Antibody; Ag: Antigen.

Dysfunction of DCs

DCs are specialized antigen-presenting cells that orchestrate immune responses. They stimulate innate and acquired immune responses, but also act as tolerogenic cells for immune responses in a variety of situations. In viral hepatitis, dysfunction of DCs from peripheral blood has been reported. In patients with CHB, maturation of DCs from peripheral blood of patients after incubation with cytokines is lower than that of normal subjects with lower expression of HLA-DR and co-stimulatory molecules in the former population[35], leading to low allostimulatory function of DCs from CHB patients. The mechanism of impairment of DC function in patients with CHB is unclear, but both HBV particles and purified HBsAg may have immunomodulatory capacity and may directly contribute to the dysfunction of myeloid DCs[36]. Interestingly, impaired function of monocyte-derived DCs from patients with CHB could be reversed by inhibiting viral replication with nucleos(t)ide analogs such as lamivudine[37]. Type 2 precursor plasmacytoid dendritic cells (pDCs), which are the most important cells in antiviral innate immunity, are also reported to have quantitative and qualitative impairment in patients with chronic HBV infection[38]. Recently, HBV itself was shown to inhibit the functions of pDCs[39]. These data indicate that DCs in patients with CHB have impaired function leading to insufficient T cell response to HBV, which could be the mechanism responsible for persistent viral infection.

IMMUNOTHERAPY FOR VIRAL HEPATITIS

In chronic HBV infection, strong long-term viral suppression can now be achieved with various nucleoside or nucleotide analogs. However, there are some problems that must be solved in the near future. One of the problems with treatment with nucleos(t)ide analogs is a low rate of HBe seroconversion even after long-term administration in HBeAg$^+$ patients. Moreover, reactivation rate of HBV replication is high in both HBeAg$^+$ and HBeAg$^-$ patients after cessation of treatment, although drug-free viral controls would be better than long-term administration of the drugs in terms of control of medical costs and avoidance of adverse effects of these agents. It could be possible to achieve long-term viral eradication even after cessation of nucleos(t)ide analogs, if viral suppression with nucleos(t)ide analogs could be combined with efficient immunotherapies.

Previous animal studies and human trials in HBV infection are listed in Tables 1 and 2, respectively.

IMMUNOTHERAPEUTIC APPROACHES FOR HBV INFECTION

Immunotherapeutic strategies for CHB include suppres-

Table 2 Immunotherapeutic trials for chronic hepatitis B virus infection in humans

Immunotherapy	Results	Ref.
Peptide vaccination		
A vaccine with HBc18-27 peptide comprised of a T-helper cell epitope and two palmitic acid residues	Low levels of CTL activity were induced but no significant changes in liver biochemistry or viral serology were observed	[52]
Protein vaccination		
PreS2/S (GenHevac B) or S (Recombivax)	HBe/anti-HBe seroconversion in 13% and HBV DNA negativity in 16% of the treated patients	[53]
Intradermal HBsAg vaccine and laimvudine in combination with IL-2	Induction of significant HBV DNA loss in the serum in two of five the treated patients	[54]
Oral administration of HBV envelope proteins (HBsAg + preS1 + preS2)	Induction of histological improvement in 30%, HBeAg negativity in 26.3% and HBsAg-specific T cell proliferation in 78% of the treated patients	[55]
IFN-α-2b monotherapy (9 mo) or IFN-α-2b plus pre-S2/S vaccine	Greater reduction in HBV DNA in patients with combination HBV therapy than those who received IFN-α-2b monotherapy	[56]
The combination with lamivudune and HBsAg vaccine in HBeAg$^+$ cases	No improvement of HBe seroconversion rate in comparison with lamivudine therapy alone	[57]
Combination of lamivudine and HBsAg vaccine	Induction of sustained negativity of HBV DNA in 1/4 of patients	[58]
Combination of lamivudine and HBsAg vaccine	HBV DNA became undetectable in 64% of the patients, and was decreased in the remaining patients	[59]
DNA immunization		
DNA vaccine encoding HBV envelope protein	Induction of an increase in HBV-specific IFN-γ-secreting T cells in nonresponders to conventional therapies, and HBV DNA levels were transiently decreased in 50% of vaccinated patients	[60]
DNA vaccine encoding PreS and S in patients with lamivudine breakthrough	Development of IFN-γ-producing T cells specific for preS or S antigen; Two of 10 patients showed seroconversion to anti-HBe	[61]
DC immunization		
Peripheral blood-derived DCs, activated with GM-CSF and IL-4 pulsed with HBsAg	Both patients with normal and elevated ALT responded equally to DC vaccine and 53% of the patients showed induction of HBeAg negativity	[62]
Activated DCs from PBL with GM-CSF and IL-4, pulsed with two peptides, HBc18-27 and PreS2 44-53	Undetectable HBV DNA was achieved in 46.3% and 3.1% of HBeAg$^-$ and HBeAg+ patients, respectively. ALT normalization was observed in 69% and 30.5% of HBeAg- and HBeAg+ patients, respectively	[63]
Cytokines		
GM-CSF	Safe and tolerable up to 1.0 μg/kg body weight, and induced HBV DNA negativity in 4/8 patients	[64]
Combination therapy with GM-CSF and HBsAg vaccine in HBV carrier children	Significant reduction of serum HBV DNA	[65]
High dose of IL-12 (0.5 μg/kg)	HBV DNA clearance was observed in 25% of the patients	[66]
Combination of IL-12 and lamivudine	Stimulation of T cell response to HBV with IFN-γ production. However, IL-12 was unable to suppress re-elevation of HBV DNA after cessation of lamivudine	[67]
Combination of IL-12 and IL-18	Stimulation of IFN-γ production by CD4+ T cells isolated from peripheral blood in response to HBcAg, and the effect was greater than those observed with either cytokine alone	[68]
α-galactosylceramide	Poorly tolerated and showed no clear suppressive effect on serum HBV DNA or ALT levels	[69]
Tα1		
Combination of Tα1 and IFN-α	No statistically significant differences as compared with IFN-α monotherapy with respect to HBeAg seroconversion, changes in histology, normalization of ALT or loss of HBV DNA	[70]
Tα1 alone	At 12 mo after cessation of therapy, 36.4% of patients treated with 1.6 mg of Tα1 achieved ALT normalization, 15% achieved HBV DNA clearance by transcription-mediated amplification, and 22.8% achieved clearance of HBeAg	[71]
Comparative effect of Tα1 and IFN-α	Tα1 treatment was more effective in achieving ALT normalization and HBV DNA negativity at the end of the follow-up period than IFN-α	[72]
Combination of Tα1 and lamivudine	No any additional antiviral effect compared with lamivudine monotherapy as determined by HBe seroconversion and the emergence of viral breakthrough	[73]
Combination therapy with lamivudine and Tα1	Induction of significantly higher rates of ALT normalization, virological response, and HBeAg seroconversion than lamivudine monotherapy	[74]

HBV: Hepatitis B virus; Tα1: Thymosin α1; IFN: Interferon; ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen; GM-CSF: Granulocyte-macrophage colony-stimulating factor; IL: Interleukin; CTL: Cytotoxic T lymphocyte; DC: Dendritic cell; HBsAg: Hepatitis B surface antigen; HBcAg: Hepatitis B core antigen; PBL: Peripheral blood lymphocytes.

sion of viral replication, stimulation of T cell immune response to hepatitis virus, activation of nonspecific cells, and administration of cytokines with antiviral activity (Tables 1 and 2).

Suppression of viral replication
High viral load has been shown to suppress CD4$^+$ and CD8$^+$ T cells in addition to induction of Treg cells, which could be reversed by antiviral therapy in CHB[75].

Therefore, immunotherapy followed by restoration of virus-specific T cell response with antiviral therapy could be more efficient in CHB.

Stimulation of immune response to HBV

Peptide immunization: A peptide vaccine containing highly immunogenic HBc18-27 has been developed and administered to CHB patients[52], but the results were disappointing because there was no induction of a significant antiviral T cell response.

Protein immunization: In a model of HBV in transgenic mice, vaccine on the base of surface antigen in complete Freund's adjuvant once monthly for 1 year induced reduction in HBV DNA, and the disappearance of HBeAg and HBsAg in most mice treated[41]. Moreover, it is important to note that some mice developed anti-HBs in the sera. However, several human trials with HBsAg vaccine showed limited efficacy if used as monotherapy.

Recently, hepatitis B vaccine containing not only S protein but also preS has been used with increased immunogenicity[53,55], or has been combined with lamivudine or IFN-α[56], leading to potential improvement of clinical efficacy. However, analysis of the T cell epitope hierarchy has indicated that the most important epitope for viral control is HBc18-27, and not the HBsAg epitope in HLA-A2 patients[9], suggesting the necessity to reconsider antigen selection for vaccination that could lead to better viral control.

DNA immunization: Injection of plasmid DNA has been shown to elicit strongly both cellular and humoral immune responses, and is now known to be safe and well-tolerated both in mice and humans. In a model of duck HBV infection, DNA vaccine encoding HBV large envelope and/or core protein was shown to induce reduction in not only viremia but also covalently closed circular DNA (cccDNA) in the liver in one thirds of ducks receiving DNA monotherapy or combination treatment with lamivudine[44]. This finding is encouraging because clearance of cccDNA from the liver is the goal of treatment for HBV infection, but is difficult to achieve using IFN-α or nucleos(t)ide analogs. Clinical trials have also been performed in HBV infection with some encouraging results, which remain to be confirmed by future randomized large-scale trials.

DC immunization: DCs are specialized antigen-presenting cells that can induce strong immune responses in T and B cells. We have previously shown that activated bone-marrow-derived DCs can break CTL tolerance to HBsAg in HBV transgenic mice[45]. Thereafter, several immunotherapies with activated DCs have been applied in both animals and humans. In a recent study performed in HBV transgenic mice, peptide-pulsed DCs were shown to reduce significantly the concentrations of serum HBsAg and HBV DNA[47], indicating therapeutic potential in chronic HBV infection. Recently, DCs treated with peptide inhibitors of IL-10 have been shown to induce strong anti-HCV T cell responses in HCV transgenic mice[76], suggesting a strategy to augment the immunogenic function of DCs. Moreover, when intrahepatic antigen-presenting cells, including DCs, are activated by injection of an anti-CD40 agonistic antibody, HBV replication is inhibited by a noncytopathic mechanism, possibly through production of antiviral cytokines such as TNF-α and IL-12[46]. Although no CTL response against HBV antigens was reported in this study, the *in vivo* activation of DCs could be an alternative way for inducing antiviral immune responses, including possible activation of CTLs against HBV. In humans, injection of activated DCs loaded with HBV peptide or protein has achieved a reduction in HBV DNA level in some patients[62,63]. HBeAg negativity was achieved in more than half of the treated patients in one study[62]. Although preparation of activated and mature DCs incurs financial costs and requires experienced researchers, immunotherapy with DCs is a promising method.

Natural killer T cells: A single injection of α-galactosylceramide abolished HBV replication by activating natural killer (NK) T cells in the liver in HBV transgenic mice[49]. However, α-galactosylceramide was poorly tolerated in humans and showed no clear antiviral effect[69], possibly due to smaller numbers of NKT cells in the human liver than in the mouse liver.

Cytokines and thymosin-1: Cytokines such as IL-12[48] and IL-18[50] have been shown to inhibit HBV replication noncytopathically in HBV transgenic mice. In humans, granulocyte–macrophage colony-stimulating factor[64,65] and IL-12[66,67] have been used for treatment with some antiviral effects. They have been used as monotherapy or in combination with hepatitis B vaccine or lamivudine.

Thymosin (T)α1, a synthetic 28-amino acid peptide, is able to enhance the Th1 immune response and also exerts a direct antiviral mechanism of action. It has been used for the treatment of chronic HBV infection in humans[70-73], and has shown some antiviral efficacy. Although antiviral effect by the addition of Tα1 to lamivudine or IFN-α therapy was controversial, a meta-analysis has demonstrated that combination therapy with lamivudine and Tα1 shows significantly higher rates of ALT normalization, virological response, and HBeAg seroconversion as compared with lamivudine monotherapy[74]. It is of note that HBeAg seroconversion rate was 45% in the combination group, which was significantly higher than that with lamivudine monotherapy (15%).

Blockade of immunoinhibitory signals

Recently, there have been several basic attempts to improve the efficacy of immunotherapy. Among these reports, augmentation or restoration of T cell response by blocking the inhibitory signals has been extensively analyzed *in vitro*. It has been demonstrated that exhausted T

cells express not only PD-1, but also CTLA-4[77], CD244[78] or Tim-3[33], and blocking of these molecules in combination could be better than blocking any single molecule to achieve full activation of the exhausted T cells.

CONCLUSION

There have been several attempts to apply immunotherapy for the control of chronic HBV infection, and some of the data are promising. Viral suppression, stimulation of antiviral immune response with cytokines or immunization with peptide, protein, DNA or DCs, and suppression of the immunoinhibitory signals must be combined to achieve desirable antiviral effects, although further studies are required to explore the best protocols and their most efficient combinations.

Abstract

Hyperplastic polyps have traditionally been considered not to have malignant potential. New pathological classification of serrated polyps and recent discoveries about the serrated pathway of carcinogenesis have revolutionized the concepts and revitalized the research in this area. Until recently, it has been thought that most colorectal cancers arise from conventional adenomas *via* the traditional tumor suppressor pathway initiated by a mutation of the *APC* gene, but it has been found that this pathway accounts for only approximately 70%-80% of colorectal cancer (CRC) cases. The majority of the remaining colorectal cancer cases follow an alternative pathway leading to CpG island methylator phenotype carcinoma with BRAF mutation and with or without microsatellite instability. The mechanism of carcinomas arising from this alternative pathway seems to begin with an activating mutation of the *BRAF* oncogene. Serrated polyposis syndrome is a relatively rare condition characterized by multiple and/or large serrated polyps of the colon. Clinical characteristics, etiology and relationship of serrated polyposis syndrome to CRC have not been clarified yet. Patients with this syndrome show a high risk of CRC and both sporadic and hereditary cases have been described. Clinical criteria have been used for diagnosis and frequent colonoscopy surveillance should be performed in order to prevent colorectal cancer. In this review, we try to gather new insights into the molecular pathogenesis of serrated polyps in order to understand their possible clinical implications and to make an approach to the management of this syndrome.

INTRODUCTION

Colorectal cancer (CRC) is a common and lethal disease. It is a major health issue in western countries where it represents the second most common fatal malignancy after lung cancer[1]. Until recently, it has been thought that most CRCs arise from conventional adenomas *via* the traditional tumor suppressor pathway initiated with a mutation of the *APC* gene, but it has been found that this pathway accounts for only approximately 70%-80% of CRC cases[2-4]. The majority of the remaining CRC cases follow an alternative pathway leading to CpG island methylator phenotype (CIMP+) carcinoma with *BRAF* mutation and with or without microsatellite instability. This pathway is called the serrated pathway of colorectal carcinogenesis[3]. The mechanism of carcinomas arising from this alternative pathway seems to begin with an activating mutation of the *BRAF* oncogene. This *BRAF* mutation provokes the development of serrated lesions that are mainly microvesicular hyperplastic polyps or sessile serrated polyps[5]. These lesions are prone to methylation of CpG islands in the promoter regions of genes resulting in their epigenetic silencing. The best characterized gene silenced by this mechanism is *MLH1*. This gene is one of the mismatch repair genes and its epigenetic silencing results in sporadic tumors with microsatellite instability (MSI). However, other genes such as *P16*, *MGMT*, or *IGFBP7* may also be epigenetically inactivated. The serrated polyposis syndrome (SPS) is a relatively rare condition characterized by multiple and/or large serrated polyps of the colon. Diagnosis of this disease is made by the fulfillment of any of the World Health Organization's (WHO) clinical criteria[6] (Table 1). SPS exhibits an increased risk of CRC[7], which occurs on average in subjects aged between 50 to 60 years. There is a high incidence of synchronous cancers[8] and CRC shows a trend to be located in the proximal colon[9]. These patients and their relatives should receive strict surveillance strategies because of the high risk of CRC. This review focuses on the SPS, its genetics and management.

SERRATED POLYPOSIS SYNDROME

Serrated polyposis syndrome is the paradigm of the serrated pathway of carcinogenesis and an excellent and interesting human model for the study of the features that drive progression from hyperplastic polyps (HP) to serrated carcinoma (Figure 1). These patients show clinical, pathological and molecular features that are very useful for expanding the knowledge of this particular and alternative carcinogenetic pathway.

Diagnostic criteria

Diagnostic criteria of SPS were first defined by Burt and Jass in 2000 for the WHO. These criteria have been recently redefined and this entity is now called Serrated Polyposis[6]. A patient is diagnosed with SPS if at least one of the following criteria is met: (1) At least five serrated polyps proximal to the sigmoid colon, two of

Table 1 The World Health Organization's clinical criteria for the identification of serrated polyposis

Criterion A	At least five serrated polyps proximal to the sigmoid colon, two of which are greater than 10 mm in diameter
Criterion B	Any number of serrated polyps occurring proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis
Criterion C	More than 20 serrated polyps of any size distributed throughout the colon

A diagnosis of serrated polyposis syndrome can be made if a patient fulfils any of these criteria.

Table 2 Summary findings from publications including patients that fulfil World Health Organization criteria of serrated polyposis syndrome

Author	Patients (*n*)	Age at diagnosis (median, yr)	CRC (%)	CRC family history (%)
Lage *et al*[12]	14	54	43	36
Ferrández *et al*[10]	15	52	7	0
Rubio *et al*[13]	10	61	70	10
Chow *et al*[9]	38	44	26	50
Boparai *et al*[7]	77	56	35	NR

CRC: Colorectal cancer; NR: Not reported.

which are greater than 10 mm in diameter; (2) Any number of serrated polyps occurring proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis; and (3) More than 20 serrated polyps of any size distributed throughout the colon (Table 1). This arbitrary definition has been considered over the years somewhat restrictive. Moreover, SPS probably comprises a heterogeneous group of patients that includes several phenotypes of serrated polyposis. However, until the molecular basis of this syndrome is better understood, this clinical definition is applicable.

Clinical characteristics

Characteristics of patients with SPS have been defined mainly based on the publication of series of cases[7,9-13] (Table 2). There is no sex predominance and the mean age at diagnosis is around 55 years. SPS has largely been considered a genetic disease, but the pattern of inheritance remains unknown: both autosomal recessive and autosomal dominant patterns have been suggested. Published case series report that between 10%-50% of patients meeting SPS criteria have a family history of CRC[9,11-13]. In this way, Boparai *et al*[14] have recently described an increased risk of CRC [relative risk (RR) = 5.4] and SPS (RR = 39) in first-degree relatives of probands diagnosed with SPS compared to the general population.

It is important to point out that conventional adenomas may coexist with serrated polyps in patients with SPS[7,9-13]. Some authors have suggested the existence of various phenotypes within the SPS definition. Kalady *et al*[11] described three phenotypic patterns in a series of 115 patients with multiple serrated polyps: (1) The patients presented a right-sided phenotype with large sessile serrated adenomas (SSAs)

Figure 1 Model of serrated pathway of colorectal carcinogenesis. MVHP: Microvesicular hyperplastic polyp; SSA: Sessile serrated adenoma; MGMT: Methylguanine methyltransferase; MSI: Microsatellite instability; MSS: Microsatellite stable; CRC: Colorectal cancer; CIMP: CpG island methylator phenotype; GCSP: Goblet cell serrated polyp; TSA: Traditional sessile adenomas.

and with a CRC onset in younger individuals (48%); (2) Left-sided phenotype with a greater amount of small polyps (16%); and (3) Mixed phenotype with shared features of the previous phenotypes (37%). These different patterns should be revised in future studies.

Environmental factors could be partially responsible for the phenotypic differences and model the unknown pattern of inheritance. Smoking, being overweight and some drugs have been postulated as potential risk factors of HPs. Samowitz et al[15] described a statistically significant dose-response association between CIMP+ CRC and smoking. Moreover, Walker et al[16] found a strong association between cigarette smoking and SPS (odds ratio = 8.3; 95% CI: 3.0-22.9) in a case-control study comparing SPS patients with a population-based registry. Wallace et al[17], using the data of multicenter chemoprevention trials, came upon the association of some environmental factors with an increased risk of colonic serrated polyps (not necessary SPS criteria). On the one hand, in the left colon, obesity, smoking, increased dietary fat and red meat intake were linked with serrated polyps. On the other hand, in the right colon, the risk factors were folate intake and family history of polyps, whereas aspirin treatment was shown as a protective factor. These results should be confirmed by targeted studies.

Somatic molecular characteristics of polyps in patients with serrated polyposis syndrome

Molecular heterogeneity among polyps from patients with SPS has been described[18]. In fact, although a mixed phenotype has been identified[11], SPS patients can be molecularly classified into two defined groups[19]. The first group is characterized by the presence of relatively few large right-sided polyps which show BRAF mutation while the other group presents with many small left-sided polyps associated with KRAS mutation[11,19]. Mutations in KRAS and BRAF are more common in HPs from SPS patients as well as in younger cases. The frequency of BRAF mutations in SPS patients is higher than KRAS mutations[19].

The combined incidence of BRAF and KRAS mutations in serrated polyps ranges from 64% to 75%[19,20]. The presence of epithelial dysplasia is associated with higher rates (90%) of mutation in either BRAF or KRAS, indicating the importance of the activation of the RAS-RAF-MAP kinase pathway in the pathogenesis of the serrated lesions[20]. Furthermore, nearly 90% of all CIMP+ CRCs have either BRAF or KRAS mutations[21]. Serrated polyps from patients with SPS have different frequencies of BRAF mutation and it is higher in those lesions that show typical features of SSA[21-23]. However, there are differences between studies due to the methodology used for the detection of BRAF mutation[22] or because of the lack of consensus about the diagnostic terms for serrated lesions[24,25].

Carvajal-Carmona et al[19] proposed molecular criteria that could complement the clinical WHO criteria for SPS. They recommended that SPS should be diagnosed

Figure 2 Segment of colectomy in a case of serrated polyposis. Polyps are frequently small (arrows) and flat, making their endoscopic detection difficult.

if *BRAF* or *KRAS* mutations are present at a significantly higher frequency in a patient's polyps than in sporadic HPs. In addition, SPS could be excluded if both *BRAF* and *KRAS* mutations are present in less than 10% of HPs from one patient, or if less than 5% of HPs are MSI.

Genetic predisposition in patients with serrated polyposis syndrome

SPS is a very heterogeneous condition[26] and it has been suggested that each phenotype may result from different underlying genetic causes[11]. Familial cases of SPS have been reported[19,26]. Although the genetic basis of SPS remains unknown, both recessive and dominant transmission patterns have been proposed[9,23,26]. Young *et al*[27] provided evidence for a syndrome of familial CRC distinct from hereditary nonpolyposis colorectal cancer by describing 11 families, of which 6 met the Amsterdam I criteria, with multiple members across several generations with CRC with variable MSI phenotype, *BRAF* mutation in 70% and hypermethylation of MINT31 in 80%. Moreover CRCs showed early age at diagnosis and were more likely to show a serrated architecture. Frazier *et al*[28] observed that patients whose CRC show methylation in *p16*, *MINT1*, *MINT31* and *MLH1* are 14 times more likely to have a family history of cancer than patients with methylation at none of the four loci. Taking into account these studies and the fact that extensive DNA methylation in normal colorectal mucosa has been described in patients with SPS[19,29,30], it has been postulated that the hypermethylation of gene promoters is due to genetic predisposition[23].

On the other hand, patients meeting criteria for hereditary nonpolyposis colorectal cancer may also fulfil criteria of SPS[31]. Occasional HPs have also been described in MYH-associated polyposis (MAP) patients and some of them met the criteria for SPS. Moreover HPs and SSAs can also be considered a phenotypic expression of MAP[32] and pathogenic biallelic *MYH* mutations were detected in 1 patient with SPS[9]. For that reason *MYH* mutations should be studied in SPS patients, especially when adenomas occur simultaneously with HPs in the same patient[9]. *PTEN* mutations have also been identified in patients with a combination of hyperplastic and adenomatous polyps[33].

A recent study from Roberts *et al*[34] has showed linkage to 2q32.2-q33.3 in approximately half of the SPS families studied. Sequencing of coding regions and exon-intron boundaries of five potential candidate genes in this region did not reveal any variants segregating with disease.

Together these data support the existence of more than one genetic cause of SPS. Identification of the underlying genetic defect of SPS will help to improve management of these patients and may identify therapeutic targets for the treatment of CRC associated with this disease.

Risk of cancer in serrated polyposis syndrome

Serrated polyposis syndrome has been associated with an increased incidence of CRC. In the published series[7,9,10,12,13], about 25%-70% of patients with SPS had CRC at time of diagnosis or during follow-up. In the largest series with patients meeting WHO criteria for SPS[7], 35% of patients had CRC (28.5% at initial endoscopy and 6.5% during the mean follow-up of 5.6 years). In this study, increased number of polyps and the presence of serrated adenomas were associated with CRC. The results of the larger published series are summarized in Table 2. In addition, first degree relatives of SPS patients have an increased risk for both CRC and SPS compared to the general population[14].

Recommendations for treatment and surveillance

The management of patients with SPS should be based on regular screening colonoscopies in order to remove potential premalignant lesions. It is important to point out that it could be difficult to detect these serrated polyps and colonoscopy should be done under high quality conditions (Figure 2). Serrated polyps are less likely than adenomas to bleed, so fecal occult blood test could be less suitable for an early diagnosis. Surveillance recommendations can be done as follows[4]: (1) Colonoscopy with pancolonic chromoendoscopy every 1-2 years with removal of all polyps. It is recommended that this resection be performed at a tertiary centre, if possible; (2) If colonoscopy does not allow the total control of colonic polyps because of their size or number or the patient does not wish to have such frequent colonoscopies or cancer is detected, colectomy with ileorectal anastomosis should be indicated; and (3) First-degree relatives should be offered 1-2 years screening colonoscopy from 10 years younger than the index case and if it is possible by pancolonic chromoendoscopy.

Pedunculated polyps can be removed by conventional electrocautery snare polypectomy. The technique of choice for removal of flat and large HPs is endoscopic mucosal resection. Besides, it may be advisable to apply argon plasma coagulation in the lesion borders in order to reduce the risk of recurrence[35].

SERRATED PATHWAY OF CARCINOGENESIS

In 1999, Iino *et al*[36] suggested that a proportion of

hyperplastic polyps may serve as precursors of some CRC cases. Now, there is increasing evidence showing that, in some conditions, hyperplastic polyps can be the initial premalignant lesion in the serrated pathway of carcinogenesis. Some studies have reported the existence of *BRAF* mutations in sporadic MSI CRCs which show CIMP[21,23,27,37-41] suggesting the existence of this alternative pathway. *BRAF* mutations and DNA methylation would be early events in this pathway with serrated polyps as precursor lesions[4,21,27,41]. The lack of adenoma-specific mutations such as *APC, KRAS* and *TP53* in sporadic MSI CRCs, and the fact that *BRAF* mutation and methylation of CpG islands are exceptional in classic adenomas[42] supports the existence of this pathway[43]. Tumors following this pathway show some specific characteristics, being more frequent in females and located in the right colon[4]. Moreover, some preliminary studies suggest that these tumors could be unresponsive to 5-fluorouracil chemotherapy[44].

Molecular characteristics of serrated polyps

As mentioned above, *BRAF* mutations and DNA methylation would be early events in this pathway. In fact, epigenetic changes in normal mucosa in patients with SPS have been described[29]. The first role of *BRAF* in the serrated pathway is probably to allow the apoptosis evasion[21,45]. Then, under normal conditions, these cells are eliminated by regular senescence. However, the silencing of key cell cycle regulatory genes such as *p16*, *IGFBP7* or *p53* through promoter methylation allows the cell to escape from senescence[4], facilitating its proliferation (Figure 1). When cells acquire other mutations, activated *BRAF* itself could also drive proliferation[21] and facilitate the maintenance of an invasive phenotype[45]. *BRAF* mutation has even been observed in serrated hyperplastic aberrant crypt foci, suggesting that these lesions are probably the earliest histological evident lesions in the serrated pathway[4,46].

There are several lines of evidence suggesting the existence of two parallel serrated pathways depending on the oncogene involved: *BRAF* or *KRAS* (Figure 1). The serrated pathway that involves *BRAF* mutations usually leads to CIMP tumors[4,29,43,47] and tumors are located in the proximal colon[38,47,48]. These tumors will be MSI or microsatellite stable (MSS) depending on the involvement of *MLH1*. As has been already stated, SSA seems to be the precursor lesion in the *BRAF* serrated pathway. In contrast, serrated tumors with *KRAS* mutations are more frequently MSI-low or MSS and are frequently associated with *MGMT* silencing[47,49]. These tumors are predominantly located in the left colorectum[4,29,47,48]. Differently, traditional sessile adenomas (TSA) would be the intermediate lesion in the *KRAS* serrated pathway.

CpG island methylator phenotype in colorectal cancer

CpG islands are 0.5- to 2-kb regions rich in cytosine guanine dinucleotides and are present in the 5' region of approximately 50% of human genes[21,29]. CIMP is characterized by methylation of CpG islands within the promoter regions of multiple genes resulting in the silencing of gene expression[18,21,29,45]. It might be assumed that methylation of CpG islands in most cancers arises stochastically[18,23,50]. This phenomenon can alter the expression of genes which are known to be important in neoplastic development, such as *p16*, *MGMT*, and the mismatch repair gene *MLH1*. However, the role of some genes affected by hypermethylation is not associated with colorectal carcinogenesis suggesting that not all de novo events are subject to growth selection. Taking into account that particular sequence motifs are significantly overrepresented among promoters vulnerable to CIMP, it is not surprising that some CpG islands are more likely to undergo hypermethylation than others[23]. The balance between DNA methyltransferases and the transcriptional machinery will determine the extent of methylation. Moreover, an active transcription may provide protection from de novo methylation[50]. The CIMP pathway is heterogeneous with respect to MSI status[27] and appears to be responsible for approximately 30% of all sporadic CRC[27,39].

There are different studies showing that a high proportion of polyps in SPS are CIMP+[18,29]. Chan *et al*[29] also observed that 75% of serrated polyps from patients with SPS showed CIMP frequently and had methylation of the *p16* gene. Moreover, extensive DNA methylation in normal colorectal mucosa has been described in patients with SPS[19,29,30], suggesting a field defect in epigenetic regulation and, consequently, a possible underlying genetic predisposition to extensive and early onset of DNA methylation. Furthermore, this phenomenon would be associated with a predisposition to CRC that would arise through the serrated pathway[51].

Endoscopic characteristics of serrated polyps

Serrated and hyperplastic polyps present endoscopic features that could help to differentiate them from adenomatous polyps. HPs appear pale, glistening, and very similar to the surrounding mucosa and usually covered by mucus. The vascular network is weak, in contrast to that of hypervascular adenomas. In addition, serrated polyps, mainly SSAs, are typically sessile or flat, making their detection even more difficult[48] (Figures 2 and 3, panels A and B). Since the malignant potential of these lesions, particularly in the context of SPS, has been shown, early endoscopic detection becomes more important. In this regard, the new advanced endoscopic techniques such as chromoendoscopy and narrow-band imaging (NBI) (Figure 3, panels C and D) become significant.

Chromoendoscopy in the SPS should be carried out by spraying contrast over the entire surface of the colon and using a magnification endoscope. The most widely used contrast is indigo carmine, which accumulates in pits and innominate grooves of the colonic mucosa, outlining the limits of flat lesions and drawing the described Kudo patterns[52]. Hyperplastic and serrated polyps typically show Kudo type I (normal) or type II ("stellate" or

Figure 3 Endoscopic appearance of serrated polyps. A and B: Sessile serrated adenoma (SSA) (arrows) as flat polyp on conventional optical colonoscopy; C: Narrow-band imaging appearance of polyp (arrow) seen in panel A; D: Chromoendoscopy image of SSA revealing Kudo II pattern (Images courtesy of Dr. Adolfo Parra, Hospital Central de Asturias, Oviedo, Spain).

Figure 4 Confocal endomicroscopy of (A) tubular adenoma, low-grade dysplasia and (B) serrated polyp. Both types of polyps show different shape as well as differences in the cellular structures (Images courtesy of Dr. Maria Pellisé, Hospital Clinic, Barcelona, Spain).

"papillary") (Figure 3, panel D). Published randomized trials have shown that pancolonic chromoendoscopy almost doubles the rate of detection of sporadic serrated polyps compared to conventional endoscopy[53-56]. In these studies, HPs were found in 20% of patients using chromoendoscopy *vs* 10% of patients with conventional endoscopy, and this difference was statistically significant. New endoscopic technologies, such as NBI and confocal laser endomicroscopy (CLE) should also be taken into consideration (Figure 4).

It is accepted that the vascular pattern evaluation by chromoendoscopy or NBI could be an appropriate method to differentiate adenomas from HPs[57,58], but it has not been specifically studied in the SPS. In this way, Boparai *et al*[59] ran a prospective series including 7 patients with SPS who underwent a colonoscopy with trimodal imaging (high resolution, AFI and NBI): they obtained an unsatisfactory diagnostic accuracy for differentiate between HPs and SSAs but distinguishing adeno-

mas from HPs was possible with NBI (accuracy 94%). Highest accuracy (76%) was achieved by the combination of a size of 3 mm or larger and a proximal location. Comparing CLE with virtual chromoendoscopy, it was shown that CLE demonstrated higher sensitivity (91% *vs* 77%; *P* = 0.010) with similar specificity in histological classification of colorectal polyps. However, further studies are needed to implement the CLE in clinical practice. The limited field of view and the horizontal sections of CLE hinder the detection of architectural distortion of sessile polyps (Figure 4).

Pathological characteristics of serrated polyps

Confirmation of the serrated character of polyps can only be made by pathological study. Serrated polyps are defined as epithelial lesions that show serrated appearance on histological section due to infolding of crypt epithelium. There are different types of serrated polyps (Table 3). HPs, considered for a long time as a benign and non-

Table 3 Characteristics of serrated polyps

Polyp name	Alternative terminology	Morphology and significance	Predominant location	Molecular features
Hyperplastic polyp, goblet type	Type 1 hyperplastic polyp	Subtype of hyperplastic polyp with conspicuous goblet cells and showing the least morphologic deviation from normal; Described as goblet-cell rich type	Distal colon: Sigmoid and rectum	Frequent *KRAS* mutation (54%)
Hyperplastic polyp, microvesicular type	Type 2 hyperplastic polyp	Variant of hyperplastic polyp in which columnar cells have mucin-filled vesicles within the apical cytoplasm and goblet cells are relatively inconspicuous	Right colon and distal colon	Frequent *BRAF* mutation (76%) and CIMP (68%)
Sesile serrated adenoma	Sessile serrated polyp; Serrated polyp with atypical proliferation	Advanced type of serrated polyp with abnormalities of architecture and proliferation but lacking the classic features of epithelial dysplasia (intraepithelial neoplasia)	Right colon	Frequent *BRAF* mutation (75%-82%) and CIMP (92%)
Sessile serrated adenoma with cytological dysplasia	Mixed polyp	Rare serrated polyp that includes two separate components: Nondysplastic (usually SSA) and either traditional adenoma or serrated adenoma	Right and left colon	Frequent *BRAF* mutation, (89%)
Serrated adenoma	Mixed hyperplastic adenomatous polyp; Atypical hyperplastic polyp; TSA	Relatively rare neoplastic polyp having a serrated architecture reminiscent of hyperplastic polyp but with unequivocal traditional adenomatous dysplasia; Comprises < 5% of serrated polyps	Left colon	Marked molecular heterogeneity; May have either *KRAS* or *BRAF* mutation

SSA: Sessile serrated adenoma; TSA: Traditional serrated adenoma; CIMP: CpG island methylator phenotype.

Figure 5 Pathological types of serrated polyps. A: Microvesicular serrated polyp; B: Sessile serrated adenomas; C: Traditional serrated adenoma; D: Mixed polyp.

premalignant colorectal lesion, SSA, mixed polyps (MP), and TSA are included in this group[4,48,60,61] (Figure 5).

HPs are the most common colorectal polyps. Sporadic HPs are usually small (2-5 mm)[10], multiple and mainly distributed in the rectum and sigmoid colon[10,47]. HPs have been divided into two main histological subtypes: microvesicular serrated polyps (MVSPs) (Figure 5, panel A), in which columnar cells have mucin-filled vesicles within atypical cytoplasm, and goblet cell serrated polyps (GCSPs) with conspicuous goblet cells that are predominantly found in the distal colon[4,23,47]. MVSPs seem to be the precursor lesion of SSA, especially when located in the right colon. In fact, both have the same molecular genetic abnormalities such as mutations in *BRAF* and CIMP. MVSPs show large and regular stellate pit openings. However, the large GCSPs are likely to have *KRAS* mutation, which is infrequently found in SSA. There is some evidence that large GCSPs are potential precursors of dysplastic serrated polyps which show *KRAS* mutations[47,61,62]. A third type of HP has been added, mucin poor type, but its frequency and importance is lower than the two main HP types[6].

SSA is an atypical HP variant described by Torlakovic and Snover in 1996[63]. SSAs are larger than (usually greater than 1 cm) HPs and more frequently located in the right colon[10]. Histologically, SSAs are distinguished from

typical HPs by the presence of inverted T- or L-shaped crypt bases that reflect disordered proliferation (Figure 5, panel B). Other features include dilated crypts and serration extending into the lower third of the crypt. Focal nuclear stratification, mild nuclear atypia, or dystrophic goblet cells may be seen in the crypt bases[47,60,61]. Moreover, SSAs show increased mucin production, absence of enteroendocrine cells, and absence of a thickened basement membrane under the surface[43]. Other less common features include small foci of pseudostratification and eosinophilic change (identical to that seen in TSAs) of the surface epithelium. Small prominent nucleoli, open chromatin, and irregular nuclear contours also might be present, along with mitoses in the upper third of the crypts or on the surface itself[61]. SSAs are thought to represent approximately 2% of all colonoscopically removed polyps, over 8% of all polyps that were previously diagnosed as HPs and around 18% of all serrated polyps[60].

MP, also called SSA with cytological dysplasia include two separate hyperplastic and adenomatous components (Figure 5, panel C)[21,23]. One component is usually SSA (nondysplastic) whereas the second dysplastic component is either adenoma or TSA.

TSAs, usually present on distal location, are dysplastic serrated polyps which lack SSA patterns and more closely resemble conventional adenoma with tubulovillous architecture (Figure 5, panel D)[4,24,47,60]. Ectopic crypt formation, defined by the presence of crypts with bases not seated adjacent to the muscularis mucosae, is a feature that makes it possible to distinguish between TSAs and SSAs[4]. Columnar cells from the epithelium show eosinophilic cytoplasm, centrally placed elongated nuclei that are hyperchromatic and display pseudostratification[46].

There is no strong morphological evidence suggesting that SSAs are the precursor of TSAs, otherwise there are some histological and epidemiologic differences for keeping these lesions apart in different categories[4,61]. SSAs have been associated with proximal CRCs, high level of CIMP, *BRAF* mutations and MSI-high[47,48]. TSAs have been associated with distal location and MSS, CIMP-low CRCs with KRAS mutations[48]. SSAs, TSAs and MPs are described as "advanced serrated polyps" and represent approximately 5%-15% of all serrated polyps found in colonoscopy patients[23].

FUTURE DIRECTIONS

Advances in the knowledge about the serrated pathway of carcinogenesis are making it possible to differentiate a new type of CRC with different natural history, prognosis and response to chemotherapy treatment. For this reason it is important to be able to easily identify this kind of colorectal tumor and its precursors. Identification of molecular markers in both polyps and cancers that follow this pathway will provide the opportunity of a better understanding of how these tumours grow and how we could explain differences in clinical presentation, evolution and symptoms in different types of CRC. These molecular markers will also allow improvement

in the identification of patients with serrated polyposis, moving forward the currently used clinical criteria, and will give us better rationale for appropriate management and surveillance intervals for patients and their relatives.

Abstract

Globus is a persistent or intermittent non-painful sensation of a lump or foreign body in the throat. It is a commonly encountered clinical condition that is usually long-lasting, difficult to treat, and has a tendency to recur. Furthermore, due to the uncertain etiology of globus, it remains difficult to establish standard investigation and treatment strategies for affected patients. As a first step for managing globus, careful history taking and nasolaryngoscopy are essential. Given the benign nature of the condition and the recent notion that gastroesophageal reflux disease is a major cause of globus, empirical therapy with a high dose of proton pump inhibitors is reasonable for patients with typical globus. If patients are nonresponsive to this therapy, definitive assessments such as endoscopy, multichannel intraluminal impedance/pH monitoring, and manometry should be considered. Speech and language therapy, anti-depressants, and cognitive-behavioral therapy can be helpful in patients whose symptoms persist despite negative investigations.

INTRODUCTION

Globus, a persistent or intermittent non-painful sensation of a lump or foreign body in the throat, is a well-defined clinical symptom that is usually long-lasting, difficult to treat, and has a tendency to recur. This symptom frequently improves with eating and is generally unaccompanied by dysphagia or odynophagia[1]. It is a common condition that accounts for approximately 4% of new referrals to ear, nose and throat (ENT) clinics, and it is reported by up to 46% of apparently healthy individuals, with a peak incidence in middle age[2,3]. This condition is equally prevalent in men and women, though the latter are more likely to seek health care for

this symptom[4].

Hippocrates first noted globus pharyngeus approximately 2500 years ago[5]. In 1707, Purcell[6] was the first to accurately describe the condition; he believed that globus resulted from pressure on the thyroid cartilage due to contraction of the strap muscles of the neck. In the past, globus was described as "globus hystericus" because of its frequent association with menopause or psychogenic factors. However, Malcomson[7] coined the more accurate term "globus pharyngeus" in 1968 after discovering that most patients experiencing globus did not have a hysterical personality. The etiology of globus is still unknown but appears to be multifactorial (Table 1). Although data are limited, recent studies have focused on gastroesophageal reflux disease (GERD), abnormalities of the upper esophageal sphincter (UES), psychological and psychiatric disorders, and stress as major factors contributing to the globus sensation. The variety of potential etiologies has made it difficult to establish standard investigation and treatment strategies for affected patients.

The aim of this review is to present the current literature on globus and to discuss its natural history and potential causes, current trends in its diagnosis, and methods for its treatment.

NATURAL HISTORY

Since few long-term follow-up studies have been conducted on patients with globus, the natural history of this condition has not been fully elucidated. In one study that followed 74 globus patients for an average of 7 years and 7 mo, 45% of the patients had persistent symptoms during the follow-up period[8]. An in-depth analysis of the features at clinical presentation failed to reveal any reliable prognostic indicators. In another long-term follow-up study, 60% of the patients had improved or resolved symptoms over a 5-year period, and the male patients with a history of globus less than 3 mo and who did not complain of any associated throat symptoms were reported to have the greatest chance of becoming asymptomatic or symptomatically improved[9].

POTENTIAL CAUSES OF GLOBUS

Gastroesophageal reflux disease

Although there is still considerable debate about the causative role of GERD in patients with globus, gastroesophageal reflux (GER) has been suggested to be a major etiology of this symptom, potentially accounting for 23%-68% of globus patients[10-18].

Malcomson[7] was the first to link GERD to the globus sensation through the use of barium swallow to uncover the presence of reflux in over 60% of patients with globus. Moreover, Koufman[16] found that 58% of patients with globus had abnormal pH results, and Cherry *et al*[19] demonstrated that 10 out of 12 subjects complained of globus when acid was infused into the

Psychological factors and stress

distal esophagus. In a study that performed 24-h double-probe pH monitoring on 25 patients with globus and hoarseness, 72% of the patients exhibited pathologic reflux[20], and the globus symptom score was significantly higher in patients with GERD than in those without[21]. Additionally, globus sensation improved after 8 wk of proton pump inhibitor (PPI) therapy[22]. Several population-based surveys have supported such a potential link between GERD and the globus symptom by demonstrating an increased risk of globus among patients with GERD symptoms[23-25]. In a study by Dore *et al*[26], 38.7% of patients with GERD had the globus symptom, and the globus sensation was more prevalent in the non-erosive reflux disease group. Discordant data have also been reported[4,27-31]. However, it is clear that many patients with globus have concomitant GERD and that there is a true association between GERD and globus.

Two basic mechanisms have been proposed to explain the association between GERD and the globus sensation[14,32,33]: (1) Direct irritation and inflammation of the laryngopharynx by retrograde flow of gastric contents, also known as laryngopharyngeal reflux (LPR)[15,16,34]; (2) Vagovagal reflex hypertonicity of the UES triggered by acidification or distention of the distal esophagus[18].

Abnormal upper esophageal sphincter function

Abnormal UES function has also been suggested to be a cause of globus sensation[20,35-38]. Elevated UES pressure has been found to be much more frequent in patients with globus sensation than in controls (28% *vs* 3%), suggesting that hypertensive UES is a background factor for globus[30]. Additionally, injection of botulinum toxin into the cricopharyngeal muscle in a patient with both globus and extremely high UES pressure led to a resolution of the globus symptom and a decrease in UES pressure[35]. In a study of high-resolution manometry in patients with globus sensation, normal controls, and GERD patients without globus, hyperdynamic respiratory UES pressure changes were most prevalent in patients reporting globus[38]. However, other studies have reported contrary results[39-41].

Esophageal motor disorders

The prevalence of esophageal motor disorders has been

reported to be 6%-90% in patients with globus, suggesting that esophageal motor disorders are a possible cause of, or a contributing factor in the development of globus[27,28,31,42]. Esophageal manometry has revealed abnormalities in as many as 67% of globus patients, with nonspecific esophageal motility disorder being the most frequent finding[31]. Moser et al[43] noted that esophageal motor disorders might, before giving rise to dysphagia, be sensed more vaguely and induce the globus sensation. However, to infer an etiological significance of this disorder in globus, it must be shown that the sensation resolves after treatment for the motor disorder.

Pharyngeal inflammatory causes
Many conditions that cause irritation and inflammation of the pharynx, such as pharyngitis, tonsillitis, and chronic sinusitis with postnasal drip, can be the cause of globus sensation by producing increased local sensitivity[28,44].

Upper aerodigestive tract malignancy
The presence of pharyngolaryngeal or upper esophageal malignancy must be excluded in patients with globus sensation, particularly in cases with "high risk" symptoms, such as weight loss, dysphagia, throat pain, and lateralization of pathology[5,45].

Hypertrophy of the tongue base
Globus can be induced by severe hypertrophy of the tongue base, probably due to the follicles touching the posterior wall of the pharynx. Mamede et al[46] demonstrated that hypertrophied follicles were frequent in patients with signs and symptoms of GER and that the symptoms of hypertrophy of the tongue base could be confused with those of GER.

Retroverted epiglottis
Through contact with the tongue base or the posterior pharyngeal wall, retroverted epiglottis may cause globus sensation. Symptom relief has been observed after partial epiglottectomy[47,48].

Thyroid diseases
Impalpable, ultrasound-detectable abnormalities in the thyroid are known to be more common in patients with globus sensation than in controls[32]. Burns et al[49] noted that as many as one-third of patients with a thyroid mass complained of globus-like symptoms. Post-thyroidectomy patients may also complain of globus pattern symptoms, but these frequently diminish with time. Although the exact mechanism of the association between globus and thyroid diseases is poorly understood, some reports have concluded that a thyroidectomy could improve the globus symptom[49-51].

Cervical heterotopic gastric mucosa
Globus sensation has also been linked to the presence of cervical heterotopic gastric mucosa (CHGM)[52-54],

and acid secretion from CHGM appears to cause symptoms similar to those of GERD, including globus sensation. Patients with CHGM who complained of globus sensation and/or sore throat experienced a significant decrease in their symptoms after argon plasma ablation of CHGM[55,56]. Recently, it has been suggested that the globus symptom may be related to Helicobacter pylori infection of the CHGM[57].

Rare tumors
Smooth muscle tumors of the pharynx and post cricoid lymphangioma, as well as oropharyngeal metastasis of Merkel cell carcinoma, have been reported in patients complaining of globus[58-60]. These cases illustrate that patients with persistent globus should be further investigated to exclude rare lesions[32].

Psychological factors and stress
Psychogenic problems have often been thought to cause or trigger the globus sensation. Personality studies have found higher levels of alexithymia, neuroticism, and psychological distress (including anxiety, low mood, and somatic concerns) and lower levels of extraversion in patients presenting with globus[61,62]. In addition, several studies have reported increased numbers of stressful life events preceding symptom onset, suggesting that life stress might be a cofactor in symptom genesis and in exacerbation. Indeed, up to 96% of patients with globus report symptom exacerbation during periods of high emotional intensity[63,64]. However, some reports have found no differences in the psychological states of patients with globus compared to normal controls[4,10,65]. In actuality, psychiatric diagnoses are prevalent in subjects seeking health care for globus, but an explanation distinct from ascertainment bias has not been established, causing the etiological significance of these psychological characteristics to remain uncertain[1,65]. Two recent studies reported that psychological status might be different between LPR-positive and LPR-negative patients with globus[15,66]. Globus patients with LPR exhibited weaker psychological symptoms than non-LPR globus patients[15], and globus patients who did not respond to PPI had significantly higher anxiety scores[66].

Others
There have been numerous isolated case reports that have suggested an association of globus with cervical osteophytes[67], temporomandibular joint disorders[68], hyperviscosity of the nasopharyngeal mucosa[69], Eagle's syndrome[70], excessive laryngeal and pharyngeal tension[61], and salivary hypofunction[33].

DIAGNOSIS
There has been no consensus regarding how best to diagnose and manage globus. A study of United Kingdom-based ENT specialists found that 14% performed no

tests on globus patients but rather simply prescribed antacid medication if clinically indicated[71]. The remaining 86% investigated globus symptoms in a variety of ways, including rigid endoscopy (61%), barium swallow (56%), or a combination of these methods (17.5%).

Since globus is essentially a benign disorder, investigation is primarily aimed at identifying those few cases with upper aerodigestive malignancy. Thus, the first step of an investigation of globus symptoms should be to take a detailed patient history, paying particular attention to the presence of "high risk" symptoms, associated reflux symptoms, and psychological problems. Additionally, physicians should perform a physical examination of the neck followed by nasolaryngoscopic examination of the laryngopharynx, although the routine use of nasolaryngoscopy in patients with typical globus symptoms remains controversial[1]. Patients with typical globus symptoms usually require no further investigation beyond an outpatient nasolaryngoscopy[5]. However, patients with "alarm signs", such as dysphagia, odynophagia, throat pain, weight loss, hoarseness, and lateralization of pathology, should undergo more extensive evaluation[1].

Reflux symptom index and reflux finding score

The symptoms and physical findings of LPR are nonspecific and can be confused with other laryngeal conditions caused by smoking, allergies, infections, vocal abuse, postnasal discharge, or neurogenic mechanisms as well as non-pathological variations[72]. Belafsky *et al*[73,74] proposed a useful self-administered tool, the reflux symptom index (RSI), for assessing the degree of LPR symptoms and developed the reflux finding score (RFS) based on 8 endolaryngeal signs for documenting the physical findings and severity of LPR. However, Park *et al*[15] demonstrated that RFS and RSI have low specificity in globus patients, suggesting that these may not be valid diagnostic tools for LPR in patients with globus.

Barium swallow

Barium swallow studies have been reported to identify benign lesions in up to one-third of patients with globus, and the most common findings include hiatal hernia and/or reflux (8%-18%), cervical osteophytes (0.4%-23%), and cricopharyngeal spasm (2.2%)[27,29,75,76]. However, given the prevalence of these findings in the general population, it is difficult to link these disorders to globus[45]. Two studies demonstrated that barium swallow did not identify any malignancy in typical globus patients[5,29]. Additionally, no pharyngeal or esophageal malignancy was found in a study that reviewed 1145 barium swallows in patients presenting with globus, prompting the authors to conclude that barium swallow should not be systematically requested for the exclusion of malignancies in patients with globus[77]. Thus, this test seems to have limited diagnostic value in the investigation of patients with globus.

Videofluoroscopy

Of 23 globus patients who received videofluoroscopy, 8 patients showed abnormal results; 5 had laryngeal aspiration, 2 had barium stasis in the vallecula and pyriform sinuses, and 4 had poor pharyngeal elevation[78]. Although it is unlikely that this indicates a causal relationship, videofluoroscopy may help to identify pharyngeal dysfunction in a substantial proportion of globus patients.

24-h dual-probe ambulatory pH monitoring

Whereas dual-probe ambulatory pH monitoring has been widely used in the clinical assessment of supraesophageal GERD, this technology is not yet standardized, and its usefulness in the definition of a clinically relevant association with GERD is under debate. This technique has been used to show abnormal esophageal acid exposure in some globus patients[4,11]. However, reflux symptoms such as acid regurgitation and/or heartburn were also noted in these study populations. In a study of globus patients without reflux-like symptoms, all 24 focal individuals had normal dual-probe pH results[78]. Therefore, ambulatory pH monitoring seems to be less helpful for the evaluation of globus without reflux-like symptoms.

24-h multichannel intraluminal impedance monitoring

The results from several trials indicate that the best way to detect GER in patients with extraesophageal manifestations of GERD is to conduct multichannel intraluminal impedance (MII)/pH monitoring. In patients experiencing persistent globus during PPI therapy, MII/pH monitoring increased the diagnostic yield of standard pH testing in the identification of positive symptom indices through the detection of nonacid reflux; furthermore, proximal reflux was a significant predictor of the globus symptom[79]. In studies investigating the utility of MII/pH monitoring in patients displaying atypical symptoms while "off PPI", MII/pH monitoring increased the diagnostic yield for objective detection of atypical manifestations of GERD[80-82]. Thus, this technique appears to be a more promising method of obtaining reliable data for the detection of LPR than 24-h dual probe monitoring, as it can monitor acid as well as nonacid reflux events and can distinguish between liquid and gaseous events. Therefore, MII/pH monitoring appears to be useful for ruling out GERD and for redirecting management of patients with suspected extraesophageal manifestations of GERD.

Flexible esophagogastroscopy

Endoscopy has been shown to be superior to barium swallow as a principal means of diagnosing upper aerodigestive tract malignancy[83]. Excellent views of the pyriform fossa and the postcricoid area can be achieved by insufflating air *via* flexible esophagogastroscopy[75]. Moreover, this procedure enables full esophageal evalu-

Figure 1 Algorithm for management of globus. GERD: Gastroesophageal reflux disease; PPI: Proton pump inhibitor; MII: Multichannel intraluminal impedance.

ation and diagnosis of reflux esophagitis and/or upper esophageal malignancy as a cause of globus. However, in general, endoscopy is known to have low sensitivity and to be of limited value for the diagnosis of extra-esophageal GERD. A study of 58 patients with pH-documented LPR found that only 19% had esophagitis or Barrett's metaplasia[84]. In another study of patients with suspected LPR symptoms, esophagitis was generally prevalent[85] but occurred least in patients with globus and throat symptoms. Due to the association between globus and CGHM, it is necessary to carefully evaluate the cervical esophagus[54].

Manometry

If abnormal UES function and esophageal motor disorder are suspected to be the potential cause of globus, manometry is a useful tool for assessing UES and lower esophageal sphincter pressure, esophageal body contraction amplitude, and peristaltic sequence. However, the etiological significance of such a disorder is difficult to define.

TREATMENT

A suggested algorithm for the management of globus patients based on available evidence is shown in Figure 1. Since there is a paucity of controlled studies on the treatment of globus, evidence-based treatment concepts are currently not available, and a review of the litera-

ture reveals that there is no single effective treatment. Given the benign nature of the condition, the likelihood of long-term symptom persistence, and the absence of highly effective pharmacotherapy, the mainstays of treatment are explanation and reassurance[1]. Other established treatment options include anti-reflux therapy, speech and language therapy, anti-depressants, and cognitive-behavioral therapy[86].

Anti-reflux treatment

Since GER has been suggested to be a major cause of globus[10-18], it seems practical that anti-reflux treatment should be the first attempted method for managing patients with globus. As diagnostic tests for GERD are somewhat invasive and costly and because a negative study result does not definitively rule out GER, it seems reasonable to use empirical PPI therapy as a combined method of diagnosis and treatment[87-92]. Although there are no controlled trials looking at the role of PPIs specifically for the treatment of globus, there is a variety of literature addressing the role of PPIs in LPR management[34,91,93-95]. Current evidence shows that the clinical response to PPIs in LPRD is variable[96,97] and that LPR symptoms improve more slowly than esophageal symptoms following acid-suppression therapy[98]. It is now widely accepted that extraesophageal GERD requires more aggressive and more prolonged therapy than typical GERD[32]. Empirical twice-daily therapy with PPIs for at least 3 mo is recommended; this can be extended

for a maximum period of 6 mo[87-92,99-102]. A PPI should be taken 30-60 min before meals so that it has reached its highest concentration by the time food intake stimulates the proton pumps. After 3-6 mo, responders can be weaned, whereas non-responders should undergo a definitive assessment, such as endoscopy, pH monitoring, or MII/pH monitoring. If available, MII/pH monitoring is preferable to simple pH monitoring because it facilitates the detection of nonacid reflux. Nocturnal acid breakthrough (NAB) may cause incomplete treatment response[103,104]. The addition of h.s. histamine-2 receptor antagonists to twice-daily PPI therapy has been suggested to control NAB[103], but it is currently unclear whether this method offers any additional benefit to the long-term control of LPRD[105,106]. Prokinetics are utilized when it is necessary to speed up esophageal and gastric emptying; they can be useful when the clinical response to PPIs is unsatisfactory[16]. Diet and behavioral modification can also decrease the amount of reflux. Recommended dietary modifications include a reduction in the intake of chocolate, fats, citrus fruits, carbonated beverages, spicy tomato-based products, red wines, caffeine, and late-night meals. Additionally, patients should make more general behavioral modifications, including exercising regularly, avoiding smoking and alcohol, elevating the head of the bed (10-15 cm), avoiding tight clothes around the waist, and losing weight. Sleeping on one's left-hand side also helps to decrease reflux. Steward *et al*[107] demonstrated that lifestyle modification was an independently significant variable in determining the response to pharmacological therapy. An alternative therapeutic strategy is anti-reflux surgery, with some authors having reported good improvement rates of LPR symptoms after laparoscopic nissen fundoplication[108-114]. To achieve a better patient outcome, a surgical approach must be taken into consideration in a carefully selected patient population, especially for patients who respond to treatment but are unable to tolerate PPIs due to side effects, those with confirmed pathological GER who do not respond to maximal medical treatment, and those in whom nonacid reflux has been demonstrated by a MII study[115]. However, if symptoms do not improve in the 4 mo following aggressive acid suppression, laparoscopic fundoplication may be unlikely to yield additional benefits[116]. Previous clinical responses to pharmacological acid suppression and abnormal pharyngeal pH results are preoperative predictors of relief from atypical symptoms[117].

Speech and language therapy/relaxation techniques

Speech therapy/relaxation techniques, including neck and shoulder exercises, general relaxation techniques, voice exercises, and voice hygiene to relieve vocal tract discomfort and tension, have successfully been used to treat patients with persistent globus symptoms[61]. In one uncontrolled study using these techniques on 25 globus patients, 92% experienced improvement following treatment. Khalil *et al*[118] randomly allocated 36 globus pa-

tients to either a speech therapy group or a reassurance group. Those in the speech therapy group used a number of exercises to relieve pharyngolaryngeal tension, including yawning, adopting a "giggle posture" (which helps retract the false vocal cords), and a "wet swallow" (as opposed to a "dry" or "check swallow," which patients often perform habitually and which tends to aggravate the globus symptom). Patients also attempted to eliminate throat clearing and promote adequate hydration by avoiding smoking, excess tea, and coffee. At the end of 3 mo, patients in the speech therapy group demonstrated significantly better globus symptom scores compared with those recorded prior to the intervention. Individuals in the speech therapy group also experienced significant improvements in globus symptoms when compared with controls. However, further research is needed to distinguish whether speech therapy has a specific effect or whether patients simply benefit from general attention and reassurance[119].

Cognitive-behavioral therapy/antidepressants

Globus is the fourth most common symptom of somatization disorder after vomiting, aphonia, and pain in the extremities[120]. Cognitive-behavioral therapy has emerged as the best treatment for a variety of somatoform disorders and medically unexplained symptoms[121]. Although there has not yet been a substantial trial of cognitive-behavioral therapy in globus patients, it is likely to be a promising treatment for repeat attenders whose symptoms remain refractory[76].

A small series of anti-depressants have been found to be beneficial for some globus patients with concomitant psychiatric disorders, such as panic, somatization, major depression, and agoraphobia[122,123].

Other treatment strategies

Thyroidectomy in patients with thyroid disorder[49-51] or partial epiglottectomy in selected cases whose retroverted epiglottis made contact with the tongue base[47,48], were both reported to significantly relieve the globus symptom. In addition, ablation of CHGM by argon plasma coagulation has shown some promise in improving chronic globus symptoms[55,56]. Although additional research of these techniques is needed, these approaches would provide some benefit to patients with unexplained chronic globus who are refractory to any medical treatments.

CONCLUSION

Although globus is a common clinical condition, its etiology remains uncertain, and there is no standard protocol for its diagnosis and management. The results of recent studies have strongly suggested that GERD is a major cause of globus, though this remains under considerable debate. Numerous other disorders, such as abnormal UES function, esophageal motility disorders, structural head and neck diseases, and psychological factors, have

been suggested as potential causes of globus. However, it has been rather difficult to establish a causal relationship between globus and these disorders because most of the reported studies were uncontrolled, had a small sample size, or were case reports. Currently, careful history taking and nasolaryngoscopy are essential as a first step in managing globus. Given the benign nature of the condition, patients with typical globus do not appear to need further investigation; rather, a 3-mo treatment with high-dose PPIs seems to be a reliable treatment option. If patients are nonresponsive to PPI therapy, they should undergo a definitive assessment, such as endoscopy, pH monitoring, or MII/pH monitoring; MII/pH monitoring in particular may increase the diagnostic yield of GER in globus patients. In cases with negative clinical investigations and consistent globus symptom, other treatment strategies, including speech therapy, antidepressants, and cognitive-behavioral therapy, should be considered. In the future, well-designed, randomized controlled studies are needed to definitively determine the effect of PPI treatment on globus. In addition, it is necessary to ascertain the etiology of globus *via* large-scale studies.

Abstract

AIM: To determine the anti-*Helicobacter* property of *Lactobacillus plantarum* B7 (*L. plantarum*) B7 supernatants *in vitro* and the protective effects of *L. plantarum* B7 on serum tumor necrosis factor-alpha (TNF-α), gastric malondialdehyde (MDA) level, apoptosis, and histopathology in *Helicobacter pylori* (*H. pylori*)-induced gastric inflammation in rats.

METHODS: *In vitro*, the inhibition of *H. pylori* growth was examined using *L. plantarum* B7 supernatants at pH 4 and pH 7 and at the concentration of 1×, 5× and 10× on plates inoculated with *H. pylori*. The inhibitory effect of *H. pylori* was interpreted by the size of the inhibition zone. *In vitro*, male Sprague-Dawley rats were randomly divided into four groups including group 1 (control group), group 2 (*H. pylori* infected group), group 3 (*H. pylori* infected with *L. plantarum* B7 10^6 CFUs/mL treated group) and group 4 (*H. pylori* infected with *L. plantarum* B7 10^{10} CFUs/mL treated group). One week after *H. pylori* inoculation, *L. plantarum* B7 10^6 CFUs/mL or 10^{10} CFUs/mL were fed once daily to group 3 and group 4, respectively, for one week. Blood and gastric samples were collected at the end of the study.

RESULTS: *In vitro*, at intact pH 4, mean inhibitory zone diameters of 8.5 mm and 13 mm were noted at concentrations of 5× and 10× of *L. plantarum* B7 supernatant disks, respectively. At adjusted pH 7, *L. plantarum* B7 supernatants at concentrations of 5 × and 10× yielded mean inhibitory zone diameters of 6.5 mm and 11 mm, respectively. In the *in vitro* study, in group 2, stomach histopathology revealed mild to moderate *H. pylori* colonization and inflammation. The level of gastric MDA and epithelial cell apoptosis were significantly increased compared with group 1. The serum TNF-α level was significant decreased in group 3 compared with group 2 (*P* < 0.05). In addition, *L. plantarum* B7 treatments resulted in a significant improvement in stomach pathology, and decreased gastric MDA level and apoptotic epithelial cells.

CONCLUSION: *L. plantarum* B7 supernatant inhibits *H. pylori* growth. This inhibition was dose-dependent and greater at pH 4. Moreover, *L. plantarum* B7 attenuated *H. pylori*-induced gastric inflammation.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a gram-negative, spiral shaped bacterium that has the unique ability of being able to colonize the human gastric mucosa and infects more than half of the world's population. *H. pylori* causes chronic gastritis, plays an etiologic role in peptic ulcer disease and is considered a risk factor in the development of gastric cancer and gastric lymphoma[1]. In 1994, *H. pylori* was classified as a type I carcinogen by the World Health Organization[2].

H. pylori infection is characterized by enhanced production of proinflammatory mediators such as tumor necrosis factor-alpha (TNF-α), interleukin (IL)-1β, IL-2, IL-6 and IL-8 and the infiltration of lamina propria with inflammatory cells. *H. pylori* lipopolysaccharides (LPS) and released surface proteins stimulate lamina propria mononuclear cells and macrophages to produce proinflammatory cytokines such as TNF-α, IL-1β, and the generation of reactive oxygen species (ROS)[3]. TNF-α and IL-1β are potent inducers of IL-8 expression in many cell types. Furthermore, *H. pylori* is capable of interacting with epithelial cell surfaces to produce IL-8. The release of these inflammatory mediators results in the expression of CD11b/CD18 on leukocytes and intercellular adhesion molecule-1 on endothelial cells, the migration of leukocytes to a site of inflammation, and finally the generation of ROS[4].

ROS can react with the double bonds of polyunsaturated fatty acids (PUFAs), present in the membranes of phospholipids, resulting in lipid peroxidation. One of the major secondary oxidation products of peroxidized PUFAs is malondialdehyde (MDA)[5]. *H. pylori* also induces gastric epithelial cell apoptosis both *in vitro*[6] and *in vivo*[7]. Studies have shown that the *H. pylori* colonized stomach contains more apoptotic epithelial cells than normal epithelial cells. Moreover, the increased numbers of apoptotic epithelial cells decrease to normal after eradication of *H. pylori*[7].

H. pylori eradication is suboptimal because current treatment regimens result in adverse side effects, poor compliance, and an increasing prevalence of antibiotic resistance[8]. Therefore, alternative treatments are of interest.

Lactobacilli are probiotics which, when administered in adequate amounts, may confer a benefit to the host[9]. The most commonly used organisms in probiotic products are *Lactobacillus sp.* and *Bifidobacterium sp.*[10]. *L. plantarum* is commonly found in the human gastrointestinal tract (GI-tract). It is important in the production of a variety of fermented foods such as sauerkraut, Korean kimchi, cheese, sausages and stockfish, and is also used as a probiotic. Moreover, there is increasing evidence that *L. plantarum* has anti-*Helicobacter* activity and shows modulatory effects on the immune system[11,12]. Importantly, *L. plantarum* is acid and bile tolerant, survives passage through the GI-tract, and is safe in humans and animals.

The aim of this study was to examine the *in vitro* anti-*Helicobacter* activity of *L. plantarum* B7 supernatants using the disk diffusion method and the effects of *L. plantarum* B7 on gastric histopathology, serum TNF-α, gastric MDA level, and cell apoptosis in *H. pylori* infection *in vivo*.

MATERIALS AND METHODS

In vitro study

The disk diffusion method was used to assess the anti-*H. pylori* activity of *L. plantarum* B7 supernatants at intact and neutralized pH and various concentrations of 1×, 5× and 10× against *H. pylori*.

Bacterial strains and culture conditions: *H. pylori* ATCC 43504 was grown on Columbia agar (Oxoid, Basingstoke, United Kingdom) containing 7% sheep blood and 7% horse serum. Plates were incubated at 37 ℃ under microaerophilic conditions (10% CO_2, 5% O_2 and 85% N_2) produced by a gas generating system, Anaero-Pack (MGC, Japan), for 72 h in an anaerobic jar (Oxoid, Basingstoke, United Kingdom).

L. plantarum B7, isolated from Thai dyspeptic patients, was stored in de Man-Rogosa-Sharpe (MRS) broth (Oxoid, Basingstoke, United Kingdom) with 20% glycerol at -80 ℃. This strain was recovered from frozen stock and cultivated twice on MRS agar anaerobically (10% CO_2, 10% H_2 and 80% N_2) at 37 ℃ in an anaerobic jar for 48 h. A single colony of *L. plantarum* B7 was then inoculated into 10 mL of MRS broth and grown at 37 ℃ under anaerobic conditions for 24 h in a 15 mL conical centrifuge tube (Corning, New York, United States). The OD600 of the culture was determined using a spectrophotometer (Bio-Rad Smart SpecTM Plus), adjusted to OD600 with 0.1 in 10 mL of MRS broth and incubated for 48 h. After incubation, the culture supernatant was collected by centrifugation at $1000 \times g$ for 10 min at 4 ℃ and then filtered using a 0.22 μm pore size filter unit (Minisart, Germany). The supernatant of *Lactobacillus* without the cell pellet was called the *Lactobacillus* condition media (LCM). The concentration and pH of LCM were adjusted to 1×, 5× and 10× by speed-vacuum drying (speed-vacuum, Savant Instruments, United States) and resuspending in an appropriate volume of intact pH 4 and adjusted pH 7 MRS broth. Sterile 6 mm-membrane disks (Whatman, Maidstone, United Kingdom) were then dipped into the resuspended LCM for at least 1 h at room temperature.

Disk diffusion method: The various concentrations of *L. plantarum* B7 supernatants were evaluated at two pH values, intact pH 4, and adjusted pH 7 with NaOH.

H. pylori was spread on Columbia blood agar plates, and *L. plantarum* B7 (LCM) disks were placed directly on the surface of the agar. The plates were incubated under microaerophilic conditions at 37 ℃ for 72 h, after which the diameters of the inhibition zones were measured in millimeters. In this study, the MRS broth was used as a negative control. The experiments were carried out in duplicate and mean values of the growth inhibition zones were measured.

In vivo study

Bacteria preparation: *H. pylori* was subcultured twice on Columbia blood agar. Plates were incubated at 37 ℃ under microaerophilic conditions for 72 h. *L. plantarum* B7 was originally obtained from Thai dyspeptic patients who visited King Chulalongkorn Memorial Hospital. This strain was cultivated twice on MRS agar anaerobically at 37 ℃ for 48 h.

Animal preparation: Thirty-two male Sprague-Dawley rats (Salaya Research Animal Center, Mahidol University, Bangkok, Thailand), weighing about 150-250 g at the beginning of the experiment, were used. The experimental protocol was approved by the Ethical Committee of Medicine Faculty, Chulalongkorn University, Thailand. The animals were housed in Macrolon cages (5 animals per cage), given food and tap water *ad libitum* at room temperature (18 ℃-22 ℃), humidity 55%, and a 12/12 h-light/dark cycle.

Experimental protocol: The rats were randomly divided into four experimental groups (eight rats each group) as follows. Group 1: Rats were fed phosphate buffered saline (PBS) 1 mL/rat by gavage twice a day at an interval of four hours for three consecutive days. Then, they were housed with free access to water and standard food for 1 wk. After that, the animals were treated with PBS 1 mL/rat by gavage once daily for 1 wk. Group 2: Rats were inoculated with *H. pylori* using the method of Thong-Ngam *et al*[13]. Briefly, the rats were pre-treated with streptomycin suspended in tap water (5 mg/mL) for three days before *H. pylori* inoculation. The *H. pylori* suspension (5×10^{10} CFUs/mL) in PBS was administered (1 mL/rat) by gavage twice daily at an interval of four hours for three consecutive days. One week after the inoculation, the animals were treated with PBS (1 mL/rat) by gavage once daily for one week. Group 3: One week after *H. pylori* inoculation, the rats were treated by gavage with *L. plantarum* B7 10^6 CFUs/mL suspended in PBS once daily for 1 wk. Group 4: One week after *H. pylori* inoculation, the rats were treated by gavage with *L. plantarum* B7 10^{10} CFUs/mL suspended in PBS once daily for 1 wk.

At the end of the experiment, animals were sacrificed by an overdose of intraperitoneal thiopental sodium. Blood samples were then collected for TNF-α determination using enzyme-linked immunosorbent assay (ELISA). The stomach was removed. One-half of the stomach was frozen in liquid nitrogen, and stored at -80 ℃ for MDA analysis. The remainder of the stomach was fixed in 4% paraformaldehyde in phosphate buffer solution to determine histopathology and epithelial cell apoptosis.

Determination of serum cytokine levels: Blood samples were taken by cardiac puncture, allowed to clot for two hours at room temperature before centrifuging for 20 min at approximately $1000 \times g$. Then, the serum was removed and stored at -80 ℃ for determination of TNF-α level using an ELISA kit (R and D Systems, United States).

Assessment of *H. pylori* infection and examination of histopathology: The presence of *H. pylori* infection in the rats was determined by the urease test and histopathological examination by a blinded pathologist. After completing the experiment, the rats were sacrificed. The stomach was removed and 2 mm² of gastric mucosa from the antrum was immediately dissected and placed in the urease tube to examine urease activity.

The remaining tissue from the gastric antrum biopsy was fixed in 4% paraformaldehyde in phosphate buffer solution at pH 7.4 and room temperature. The tissue was processed and stained with hematoxylin-eosin. The slides were observed by light microscopy and the presence of *H. pylori* was detected by Warthin-Starry staining in unclear cases. The level of bacterial colonization was evaluated using a grading system as follows. Score 0: No bacteria detected; Score 1: Mild colonization in some gastric crypts; Score 2: Mild colonization in most gastric crypts; Score 3: Moderate colonization in all gastric crypts. The results are presented as the bacterial colonization scores for each group. In addition to *H. pylori* colonization, the gastric inflammation level was estimated and scored following the updated Sydney System[14]. The infiltration of polymorphonuclear leukocytes in the gastric mucosa, defining the inflammatory scores, was recorded. Scores from 0 to 3 represented normal, mild, moderate and marked histopathological changes, respectively.

Determination of gastric malondialdehyde: Gastric MDA level was measured using the thiobarbituric acid (TBA) reactive substances assay kit (Cayman, United States). The principle is that the reaction of one molecule of MDA and two molecules of TBA form a red MDA-TBA complex under high temperature (90 ℃ -100 ℃) and acidic conditions, which can be quantitated using a spectrophotometer at 532 nm. The assay procedures were performed as described. The content of MDA was expressed in terms of nmol/mg protein.

Determination of gastric epithelial cell apoptosis: Apoptosis was measured by the identification of apoptotic nuclei in sections of stomach using fragment end labeling of DNA (Apoptosis detection kit, Chemicon, United States). In brief, the DNA fragments were al-

Concentration of *L. plantarum* B7 supernatant	Diameters of inhibition zone (mm)

L. plantarum: *Lactobacillus plantarum*; MRS: Man-Rogosa-Sharpe.

Figure 1 A bar graph shows the mean ± SD of inhibitory zone diameters (mm) of all *Lactobacillus plantarum* B7 supernatant concentrations at intact pH 4 and adjusted pH 7 (*n* = 2). *L. plantarum*: *Lactobacillus plantarum*; MRS: Man-Rogosa-Sharpe.

lowed to bind an antidigoxigenin antibody that was conjugated to a peroxidase. Diaminobenzidine was applied to develop a dark brown color and the slides were counterstained with hematoxylin. The positive stained cells showed dark brown nuclei under light microscopy. To verify the incidence of apoptosis, the dark brown-stained cells were counted. One thousand gastric epithelial cells were counted for each rat. The data were shown as a percentage (%) of apoptotic cells calculated as: the percentage of apoptotic cells (%) = (numbers of positive stained cells × 100)/1000.

Statistical analysis

All data are presented as mean ± SD. The means were compared by one-way analysis of variance followed by least significant different post hoc test. All statistical tests were performed using SPSS for Windows version 13.0 (SPSS Inc, Chicago, IL, United States). Differences were considered statistically significant at *P* < 0.05.

RESULTS

In vitro study

Disk diffusion method: At intact pH 4, mean inhibitory zone diameters of 8.5 ± 0.7 mm and 13 ± 0 mm were noted at the concentrations of 5× and 10× of *L. plantarum* B7 supernatant disks, respectively. At adjusted pH 7, mean inhibitory zone diameters of 6.5 ± 0.7 mm and 11 ± 1.4 mm were noted at the concentrations of 5× and 10× of *L. plantarum* B7 supernatant disks, respec-

Figure 2 A bar graph shows the mean ± SD of serum tumor necrosis factor-alpha level (pg/mL) in all groups. CON: Control group; HP: *Helicobacter pylori* (*H. pylori*) infected group; HP + L (L): *Lactobacillus plantarum* (*L. plantarum*) B7 10^6 CFUs/mL treated group; HP + L (H): *L. plantarum* B7 10^{10} CFUs/mL treated group. Each group is represented by the mean of 8 rats. [a]*P* < 0.05 *vs H. pylori* infected group. TNF-α: Tumor necrosis factor-alpha.

tively (Table 1). Both intact pH 4 and adjusted pH 7 of *L. plantarum* B7 supernatants showed dose-dependent anti-*H. pylori* activity. The supernatant of pH 4 *L. plantarum* B7 at the concentration of 10× showed the clearest inhibition (Figure 1).

In vivo study

Changes in TNF-α level: The serum TNF-α level was not significantly different between the control group and *H. pylori* infected group. However, in the *L. plantarum* B7 10^6 CFUs/mL treated group, a significant decrease in serum TNF-α level was noted compared with the *H. pylori* infected group (*P* = 0.019). The average concentrations of serum TNF-α were 17.22 ± 0.63 pg/mL, 18.05 ± 1.94 pg/mL, and 16.52 ± 0.84 pg/mL in the control, *H. pylori* infected, and in the *L. plantarum* B7 10^6 CFUs/mL treated group, respectively. The average serum TNF-α levels in all groups are shown in Figure 2.

Histopathological examination: *H. pylori* infection in rats was determined by the urease test and histopathology. Histopathology in the control group was normal, while in the *H. pylori* infected group there was moderate *H. pylori* colonization and inflammation. The *L. plantarum* B7 10^6 CFUs/mL treated and *L. plantarum* B7 10^{10} CFUs/mL treated groups showed reduced *H. pylori* colonization and improved stomach inflammation (Figures 3 and 4). The histology scores for *H. pylori* colonization and gastric inflammation are summarized in Table 2.

Determination of gastric malondialdehyde: The level of gastric MDA increased significantly in the *H. pylori* infected compared with the control group (3.46 ± 1.25 nmol/mg *vs* 1.05 ± 0.41 nmol/mg protein, *P* = 0.000, respectively). After one week of 10^6 CFUs/mL or 10^{10} CFUs/mL of *L. plantarum* B7 suspension, there was a significant decrease in elevated gastric MDA level in both *L. plantarum* B7 treated groups compared with the *H. pylori* infected group (1.28 ± 0.69, 1.37 ± 0.66 nmol/mg *vs* 3.46 ± 1.25 nmol/mg protein, *P* = 0.000, respectively) (Figure 5).

Determination of gastric epithelial cell apoptosis: The percentage of apoptotic cells was significantly in-

Figure 3 Hematoxylin-eosin stained gastric sections (×40). Table 2 Summary of the scores for bacterial colonization levels and gastric inflammation in all groups

Group	Number	Level of *H. pylori* colonization[1]				Gastric inflammation[2]			
		0	1	2	3	0	1	2	3
Control group	8	8	-	-	-	8	-	-	-
H. pylori infected group	8	1	5	2	-	-	3	5	-
L. plantarum B7 10[6] CFUs/mL treated group	8	4	4	-	-	-	8	-	-
L. plantarum B7 10[10] CFUs/mL treated group	8	3	5	-	-	-	8	-	-

[1]The stomach samples were evaluated for *Helicobacter pylori* (*H. pylori*) colonization by the pathologist using the following scoring system. Score 0: No bacteria detected; Score 1: Mild colonization in some gastric crypts; Score 2: Mild colonization in most gastric crypts; Score 3: Moderate colonization in all gastric crypts. [2]The gastric inflammation level was estimated and scored by the pathologist following the updated Sydney System[16]. The infiltration of polymorphonuclear leucocytes in the gastric mucosa defining the inflammatory scores was recorded. Scores from 0 to 3 represented normal, mild, moderate and marked histopathology changes, respectively. *L. plantarum*: *Lactobacillus plantarum*.

creased in the *H. pylori* infected group when compared with the control group (7.44 ± 2.65 *vs* 0.58 ± 0.13, $P = 0.0001$, respectively). After treatment with 10[6] CFUs/mL or 10[10] CFUs/mL of *L. plantarum* B7 suspension, the percentage of apoptotic cells was significantly decreased at 10[6] CFUs/mL ($P = 0.027$) and 10[10] CFUs/mL ($P = 0.038$) compared with the *H. pylori* infected group. The average percentages of apoptotic cells in all the groups are shown in Figure 6. Figure 7 shows gastric sections processed for apoptosis by the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) reaction.

DISCUSSION

The *in vitro* study with intact pH 4 and adjusted pH 7 of *L. plantarum* B7 supernatants showed concentration-dependent anti-*H. pylori* activity, however, the culture supernatants of intact pH 4 *L. plantarum* B7 supernatant showed higher inhibition. This implied that low pH values are important for anti-*H. pylori* activity. In a study by Boyanova *et al*[15], the anti-*Helicobacter* activity of *L. delbrueckii subsp. bulgaricus* cultures was strain-dependent and better at their native pH.

It is known that *Lactobacillus* secretes metabolic products such as lactic acid which exerts activity against *H. pylori*[16]. Lactic acid inhibits the urease activity and viability of *H. pylori*. Several studies have reported that bacteriocin, peroxide, proteinase, exopolysaccharide and cell wall components, called *Lactobacillus*-inhibitory factors, have antibacterial effects[17,18]. In addition, Coconnier *et al*[19] showed that a heat-stable antimicrobial substance secreted by *L. acidophilus* LB was active against *H. pylori* infection.

In summary, our *in vitro* study found that *L. plantarum* B7 supernatant inhibited *H. pylori* growth in a dose-dependent manner and was better at intact pH 4 indicating that the amount of antimicrobial substance released by

Figure 5 A bar graph shows the mean ± SD of gastric malondialdehyde levels (nmol/mg protein) in all groups. L. plantarum B7 correlated with the intensity of the inhibitory effect against *H. pylori*. Furthermore, the anti-*H. pylori* activity of this substance was supported by low pH values.

The present *in vivo* study showed that the gastric histopathology in the *H. pylori* infected group revealed mild to moderate *H. pylori* colonization and inflammation as well as increased gastric MDA and gastric epithelial cell apoptosis.

H. pylori induces a host inflammatory response including production of cytokines, resulting in mucosal damage. The produced cytokines lead to infiltration of inflammatory cells, namely polymorphonuclear neutrophils (PMNs), lymphocytes and macrophages, at the site of infection. These inflammatory cells then release large amounts of ROS, causing tissue injury. Wilson *et al*[20] showed that the gastric mucosal levels of proinflammatory cytokines, such as TNF-α, IL-1β, IL-6 and IL-8, were significantly higher in *H. pylori* positive patients than in *H. pylori* negative patients. Crabtree *et al*[21] showed that increased gastric mucosal production of TNF-α and IL-6 was associated with *H. pylori* gastritis. Moreover, they implied that inflammatory cytokines generated locally within the gastric mucosa can be relevant to the gastric physiology of *H. pylori* infection.

As mentioned above, infection with *H. pylori* in the

Figure 7 Representative gastric sections processed for the apoptosis assay by terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling reaction (×20). A: Control group; B: *Helicobacter pylori* infected group; C and D: *Lactobacillus plantarum* (*L. plantarum*) B7 10⁶ CFUs/mL treated and *L. plantarum* B7 10¹⁰ CFUs/mL treated groups showed a decrease in gastric epithelium apoptosis. The arrows indicate terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling-positive gastric epithelial cell apoptosis.

gastric mucosa is known to activate the production of many proinflammatory cytokines including TNF-α, IL-1β, IL-6 and IL-8. The production of these proinflammatory cytokines is not limited to the local site of infection, as these cytokines are produced in numbers and contribute to the systemic circulation. In 2006, Prabjone *et al*[22] investigated the effects of chronic *H. pylori* infection on serum TNF-α level in rats. They found a significant increase in serum TNF-α in the *H. pylori* infected groups compared with the control groups. In the present study, no significant increase in serum TNF-α level was observed in the *H. pylori* infected group.

Several studies have shown that *H. pylori* strains with the *cagA*⁺/*vacAs1* genotype are more virulent than strains with other genotypes[23]. Similarly, Azuma *et al*[24] reported that *H. pylori cagA*⁺ strains were involved in more intense tissue responses than *cagA*⁻ strains. Moreover, epidemiological studies have shown that colonization with *cagA*⁺ *H. pylori* is associated with an increased risk for the development of both peptic ulcer disease and gastric cancer. In an *in vitro* study, Zhang *et al*[25] demonstrated that *H. pylori cagA*⁺ strains induced an increased oxidative burst in PMNs with higher ROS production. Recently, studies have shown that ROS production in gastric mucosa is enhanced by infection with *cagA*⁺ *H. pylori* species with an extensive accumulation of neutrophils in both patients with chronic gastritis and gastric ulcer[4,5]. In this study, rats infected with *H. pylori cagA*⁺, *vacA*⁺ strains were found to have significantly increased gastric MDA levels,

suggesting that oxidative stress may be associated with the *cagA*⁺ status of *H. pylori*.

Furthermore, we demonstrated that *H. pylori cagA*⁺, *vacA*⁺ strains can induce epithelial cell apoptosis in rats. The *cagA* gene or expression of VacA might be involved in gastroduodenal diseases by affecting apoptosis. The *cagA* gene is a marker of the presence of the pathogenicity island that encodes disease-associated virulence factors and is associated with the expression of VacA[26]. In 2006, Cabral *et al*[27] showed that the expression of pro-apoptotic proteins such as Bax and Bak was higher than anti-apoptotic proteins including Bcl-2 and Bcl-XL in most gastric biopsies from patients with *H. pylori* gastritis and was significantly higher in patients infected by *cagA*⁺ strains than in those infected by *cagA*⁻. Moreover, they found that Bak expression was higher at the lesser curvature (antrum and incisura) than in the other regions and was correlated with atrophy. These results suggest that in addition to *cagA, vacA* plays a crucial role in the induction of apoptosis. In the present study, our data also showed that infection with *H. pylori cagA*⁺, *vacA*⁺ strains leads to elevated gastric MDA levels, as previously mentioned. MDA, a major product of lipid peroxidation, can react with DNA to form MDA-DNA adducts, resulting in DNA damage.

Several previous investigations have shown the anti-inflammatory properties of *Lactobacillus*. A study by Johnson-Henry *et al*[28] found that the probiotic combination containing *L. rhamnosus* R0011 and *L. acidophilus*

R0052 decreased the effects of *H. pylori* infection in a C57BL/6 mouse model of infection by reducing *H. pylori* colonization and alleviating *H. pylori*-induced gastric mucosa inflammation. In 2003, Peña *et al*[29] showed that *L. rhamnosus* GG was able to antagonize *H. pylori* LPS-induced TNF-α production in murine macrophages *in vitro* by a contact-independent mechanism. Ko *et al*[12] reported that *L. plantarum* was capable of inhibiting epithelial barrier dysfunction and reducing IL-8 secretion induced by TNF-α. In addition to anti-inflammatory activity, several studies have shown that *Lactobacillus* also has effective antioxidative and anti-apoptotic properties. Truusalu *et al*[30] found that *L. fermentum* ME-3 suppressed excessive oxidative stress-associated inflammation induced by *S. typhimurium* infection in a mouse model. Using the same experimental typhoid fever model, they also showed that treatment with *L. fermentum* ME-3 alone or in combination with an antimicrobial quinolone (ofloxacin) leads to a significant decrease in lipid peroxidation and the glutathione redox ratio (GSSG/GSH). In 2010, Zhang *et al*[31] reported that oral *L. plantarum* treatment in rats with obstructive jaundice increased GSH levels in the liver and stimulated GSH biosynthesis, resulting in attenuated oxidative damage. Using the TUNEL assay, they also showed that treatment with *L. plantarum* significantly decreased hepatic apoptosis. In addition, Lam *et al*[32] showed that pre-treatment of rats with *L. rhamnosus* GG markedly reduced ethanol-induced mucosal lesion area and gastric cell apoptosis.

Interestingly, all of these studies were concordant with our results. In the current study, we found that *L. plantarum* B7 treatment resulted in improved stomach pathology, and decreased serum TNF-α level, gastric MDA level, and apoptotic epithelial cells. However, the mechanisms of action are unclear and require further investigation.

In conclusion, the present study showed that *H. pylori* infection induced gastric injury by increasing levels of *H. pylori* colonization and inflammation, gastric MDA and epithelial cell apoptosis. *L. plantarum* B7 may have anti-*H. pylori* activity *in vitro* and anti-inflammatory effects on *H. pylori* infection by improving stomach histopathology, and reducing serum TNF-α levels, gastric MDA and epithelial cell apoptosis.

COMMENTS

Background
Helicobacter pylori (*H. pylori*) infection induces the production of proinflammatory mediators such as tumor necrosis factor-alpha (TNF-α), interleukin (IL)-1β, IL-2, IL-6 and IL-8, and infiltration of the lamina propria with inflammatory cells as well as the generation of reactive oxygen species (ROS). However, these *H. pylori*-induced inflammatory responses do not appear to confer protective immunity, and may lead to the excess production of ROS, oxidative bursts caused by phagocytic cells, and gastric tissue damage. *Lactobacillus plantarum* (*L. plantarum*) B7 has anti-*H. pylori* activity *in vitro* and anti-inflammatory properties resulting in the alleviation of gastric injury in *H. pylori*-induced gastritis in rats.

Research frontiers
L. plantarum is a non-pathogenic gram-positive bacterium that exerts anti-*H. pylori* activity and immunomodulatory effects. *H. pylori* infection can cause gastric mucosal damage by increasing *H. pylori* colonization and inflammation levels, gastric malondialdehyde (MDA) and epithelial cell apoptosis. The hallmark of this study was the interesting results which showed an inhibitory effect of *L. plantarum* B7 supernatant on *H. pylori* growth *in vitro*, and an improvement in stomach pathology, reduction in serum TNF-α level, gastric MDA and epithelial cell apoptosis following treatment with *L. plantarum* B7.

Innovations and breakthroughs
A previous study showed that *L. plantarum* B7 has anti-inflammatory properties *in vitro*. However, it is not clear whether *L. plantarum* B7 has *in vivo* effects on *H. pylori*-induced gastric inflammation. Therefore, in this study, the authors examined the anti-inflammatory effect of *L. plantarum* B7 in rats and found that *L. plantarum* B7 ameliorated *H. pylori*-induced gastritis by improving stomach pathology, and decreasing TNF-α production, gastric MDA level and epithelial cell apoptosis. Moreover, supernatants of *L. plantarum* B7 showed anti-*H. pylori* activity *in vitro*.

Applications
L. plantarum B7 may be beneficial in clinical application, and can be used as an adjunct to antibiotics to decrease *H. pylori*-induced gastric inflammation and reduce side effects of triple therapy.

Peer review
This is an experimental study on the effect of *H. pylori* infection in gastric inflammation. This study shows the efficacy of *L. plantarum* B7 in treatment of *H. pylori*-induced gastritis reflects in attenuated levels of *H. pylori* colonization, gastric inflammation, cytokine production, gastric MDA, and apoptotic cells. Also, the results from *in vitro* study demonstrates the inhibitory effect of *L. plantarum* B7 supernatants on *H. pylori* growth.

Abstract

AIM: To investigate the key factors in developing the trinitrobenzene sulfonic acid (TNBS)-induced post-inflammatory irritable bowel syndrome (PI-IBS) model in rats.

METHODS: TNBS was administered to rats at the following conditions: (1) with different doses (20, 10, 5 mg/0.8 mL per rat); (2) with same dose in different concentrations (20 mg/rat, 25, 50 mg/mL); (3) in different ethanol percentage (25%, 50%); and (4) at depth either 4 cm or 8 cm from anus. At 5 d and 4 wk after TNBS administration, inflammation severity and inflammation resolution were evaluated. At 4 and 8 wk after TNBS application, visceral hyperalgesia and enterochromaffin (EC) cell hyperplasia were assayed by abdominal withdrawal reflex test, silver staining and capillary electrophoresis.

RESULTS: Our results showed that: (1) TNBS induced dose-dependent acute inflammation and inflammation resolution. At 5 d post TNBS, the pathological score and myeloperoxidase (MPO) activity in all TNBS treated rats were significantly elevated compared to that of the control (9.48 ± 1.86, 8.18 ± 0.67, 5.78 ± 0.77 *vs* 0, and 3.55 ± 1.11, 1.80 ± 0.82, 0.97 ± 0.08 unit/mg *vs* 0.14 ± 0.01 unit/mg, $P < 0.05$). At 4 wk post TNBS, the pathological score in high and median dose TNBS-treated rats were still significantly higher than that of the control (1.52 ± 0.38 and 0.80 ± 0.35 *vs* 0, $P < 0.05$); (2) Intracolonic TNBS administration position affected the persistence of visceral hyperalgesia. At 4 wk post TNBS, abdominal withdrawal reflex (AWR) threshold pressure in all TNBS-treated groups were decreased compared to that of the control (21.52 ± 1.73 and 27.10 ± 1.94 mmHg *vs* 34.44 ± 1.89 mmHg, $P < 0.05$). At 8 wk post TNBS, AWR threshold pressure in 8 cm administration group was still significantly decreased (23.33 ± 1.33 mmHg *vs* 36.79 ± 2.29 mmHg, $P < 0.05$); (3) Ethanol percentage affected the TNBS-induced inflammation severity and visceral hyperalgesia. In TNBS-25% ethanol-treated group, the pathological score and MPO activity were significantly lowered compared to that of the TNBS-50% ethanol-treated group, while AWR threshold pressure were significantly elevated (36.33 ± 0.61 mmHg *vs* 23.33 ± 1.33 mmHg, $P < 0.05$); and (4) TNBS (5 mg/0.8 mL per rat, in 50% ethanol, 8 cm from anus)-treated rats recovered completely from the inflammation with acquired visceral hyperalgesia and EC cell hyperplasia at 4 wk after TNBS administration.

CONCLUSION: TNBS dosage, concentration, intraco-

Ionic administration position, and ethanol percentage play important roles in developing visceral hyperalgesia and EC cell hyperplasia of TNBS-induced PI-IBS rats.

INTRODUCTION

Post-infectious irritable bowel syndrome (PI-IBS) is a subgroup of IBS in which the IBS patients developed their symptoms after recovery from an acute gastrointestinal infection[1,2]. The features of PI-IBS, such as urgency, loose stool, and abdominal pain, are very similar to those of the diarrhea-predominant IBS[3,4]. Prospective studies indicate that 3%-36% of enteric infections may lead to the generation of new IBS symptoms; the precise incidence mainly depends on the infecting organism and the host responses[1]. Though the term "PI-IBS" was first coined by Chaudhary and Truelove in 1962[5], little attention has been paid to it until recently[1]. The causes and/or underlying mechanisms of PI-IBS are still not fully understood, although it is believed that altered gut flora, changed intestinal permeability, activated gut immunity, and functional or structural changes in enteric nervous system are important factors[1,6].

Validated animal models, which aim to mimic one or more features of human disease, play important roles in the studies of mechanisms and potential therapeutic agents for diseases. Based on the current understanding of the clinical features and underlying mechanisms of PI-IBS, the ideal model for PI-IBS should bear the character with one or more features of IBS, such as visceral hypersensitivity, motility dysfunction, alterations in permeability or secretion, and enterochromaffin (EC) cell hyperplasia, and complete recovery from initial infection/inflammation[7]. The chemical agent-induced post-inflammatory IBS animal models have been widely used in mechanistic studies of PI-IBS because the chemical agent-induced inflammatory response and host immune activation can, to some extent, mimic the characteristics of PI-IBS[8,9], and these alterations are consistent with the findings from clinical studies[10,11]. Our previous systematic review showed that the trinitrobenzene sulfonic

acid (TNBS)-induced model is the most commonly used PI-IBS model[7], and the major features of IBS (i.e., visceral hypersensitivity, motility dysfunction, and alteration in permeability or secretion), can be developed in this model. However, there are large variations in the protocol of model development, such as TNBS dosage and concentration, position of intracolonic TNBS administration, ethanol percentage, and the optimal time after intracolonic TNBS administration for model application, *etc*.[7]. These variations make comparison between studies to be very difficult, if not impossible.

As a chemical hapten, TNBS is capable of binding to tissue proteins and stimulating T helper 1 cell mediated immunity; thus, it has been widely used to induce acute colitis by intracolonic administration[12]. It has been reported that TNBS-induced acute inflammation and damage becomes maximal from 3 d to 1 wk after instillation[9]. Previous studies have shown that TNBS had dose-dependent effects on mucosal inflammation[13,14], suggesting dosage is an important factor in TNBS-induced inflammation severity and colonic recovery from such inflammation. However, in previous studies on the TNBS-induced PI-IBS model, the dosage of TNBS varied from 20 mg per rat to 30 mg per rat[7]. Further, there is no consensus on how long it will take for TNBS-induced inflammation recovery after TNBS administration. Some studies, using TNBS (30 mg/rat), took 4 or 6 wk for inflammation recovery after intracolonic TNBS administration[15,16], while another study took at least 8 wk[17]. In addition, TNBS is generally administered into the colon lumen at either 4 cm or 8 cm from the anus[7]. Given the anatomical and physiological differences between these two sites (descending colon *vs* transverse colon), it is possible - but not known - whether the position of TNBS administration influences the results. Furthermore, ethanol is routinely used as a breaker to the mucosal barrier in TNBS-induced PI-IBS studies, and previous studies have shown that 30%-50% ethanol alone induced acute inflammation and hyperemia[18,19]. The commonly used ethanol percentage in developing TNBS-induced PI-IBS model are 25% and 50%[14,20]; and whether the ethanol percentage influences the development of TNBS-induced PI-IBS rat model is still not clear.

Concerning the above variations in developing protocol of the TNBS-induced PI-IBS rat model, the present study aimed to investigate the effects of some impact factors (i.e., TNBS dosage and concentration, position of TNBS administration, and ethanol percentage) on TNBS-induced acute inflammation, inflammation resolution, and later acquired features of IBS (i.e., visceral hyperalgesia and EC cell hyperplasia).

MATERIALS AND METHODS

Materials

TNBS (2,4,6-trinitrobenzenesulfonic acid solution), hexadecyltrimethylammonium bromide, o-dianisidine dihydrochloride, sodium hyposulfite, and silver nitrate were

all purchased from Sigma-Aldrich (St. Louis, MO, United States). Chloral hydrate was purchased from Kou Hing Hong Scientific Supplies (Hong Kong, China).

Animals
Male Sprague-Dawley rats (aged 6 wk with body weight around 220 g) were obtained from the Laboratory Animal Services Centre, The Chinese University of Hong Kong. Rats were housed 5 per cage and maintained at 25 ℃ under 12 h-12 h alternating light-dark cycle with free access to food and water. Rats were maintained in laboratory conditions for 1 wk to adapt to the environment before each experiment. All animal studies were carried out in accordance with the guidelines of the Committee on Use of Human and Animal Subjects in Teaching and Research, Hong Kong Baptist University.

Experimental design
The rats were randomly divided into 7 groups. TNBS (20 mg/0.4 mL per rat) was given to rats in group 1 (*n* = 10). The rats in group 2 (*n* = 10), group 3 (*n* = 10), and group 4 (*n* = 14) were intracolonically administered with TNBS at a dose of 20, 10 and 5 mg per rat in 0.8 mL ethanol, respectively. In the above 4 groups, TNBS in 50% ethanol saline solution was administered at a depth of 8 cm from the anus. Rats in group 5 (*n* = 14) were given TNBS (5 mg/0.8 mL per rat in 50% ethanol) at a depth of 4 cm from the anus, while rats in group 6 (*n* = 14) were given TNBS (5 mg/0.8 mL per rat in 25% ethanol) at 8 cm from the anus. Group 7 (*n* = 14) was set as a control; rats in this group were given saline 0.8 mL at a depth of 8 cm from the anus (Table 1).

Five days after TNBS or saline administration, 4 rats in each group were selected randomly, and the colon tissues from these rats were harvested for inflammation evaluation. The remaining rats were allowed to recover until the pain threshold pressure was measured. At 4 wk after TNBS administration, five rats in each group were selected randomly for pain threshold pressure evaluation; then the colon tissues were collected for inflammation recovery examination. At 8 wk after TNBS administration, the rest of the rats in each group went through pain threshold pressure evaluation to test the stability of visceral hyperalgesia. In order to further investigate

if the TNBS-induced PI-IBS model had EC cell hyperplasia in the colon tissue, a part of proximal and distal colon tissues were also collected for EC cell number counting and serotonin [5-hydroxytryptamine (5-HT)] content determination.

Induction of colitis
Colitis was induced according to previous reports, with little modification[16]. Briefly, rats were fasted for 24 h before experiments, and then deeply anesthetized with chloral hydrate (350 mg/kg, i.p.). A fine plastic catheter (external diameter = 0.96 mm) was gently inserted into the descending colon at a depth of 4 cm or 8 cm from anus. The rats were kept in a head-down vertical position, and then TNBS was instilled slowly into the colon lumen within 1 min. After TNBS instillation, the catheter was left in place for 1 min and then slowly removed. The TNBS-treated rats were left on a warm mound of bedding in head-down position to prevent drug leakage until they regained consciousness. The control rats were similarly administered with 0.8 mL saline instead of TNBS.

Tissue preparation
Rats were deeply anesthetized with chloral hydrate (350 mg/kg, i.p.); then an approximately 6 cm long piece of colon tissue with drug administration position in the middle was removed. After the photos were taken, 3 cm of the distal part (proximal to the anus) was fixed in 4% paraformaldehyde for histological evaluation., the remaining 3 cm (distal to the anus) was placed in liquid nitrogen and stored in a freezer at -80 ℃ for myeloperoxidase activity assay. In addition, approximate 3 cm of proximal colon (1-2 cm from cecum) and 3 cm of distal colon (1-2 cm from anus) tissue were also harvested from the PI-IBS model rats; the proximal part (about 1 cm) was fixed in 4% paraformaldehyde for EC cell number counting; the rest was placed in liquid nitrogen, and stored at -80 ℃ for 5-HT content determination.

Histological evaluation
The colon sections (5 μm thick) collected at 5 d and 4 wk after TNBS administration were all stained with hematoxylin and eosin (H and E). Masson trichrome staining[21] was performed on sections collected at 4 wk after TNBS administration for fibrosis evaluation. All sections were examined under a Nikon light microscope (Nikon Inc., Japan). The severity of the acute inflammation and the degree of inflammation resolution was graded using the macroscopic and histological scoring criteria (Tables 2 and 3), which were modified based on previous reports[22,23] according to the pathologist's suggestion. Five random fields were selected in each slide; images were captured with 100 × magnifications and analyzed using Image J NIH software. For fibroplasia evaluation, the area stained blue by Masson trichrome staining was measured and adjusted to reflect the total area of the colon tissue[21].

Myeloperoxidase activity assay
Myeloperoxidase (MPO) is an enzyme released by neu-

Table 2 Criteria for macroscopic scoring of colonic ulceration and inflammation

Score	Appearance
0	Normal appearance
1	Ulceration with inflammation at 1 or 2 sites
2	More sites of ulceration and inflammation
3	Major sites of damage extending > 1.5 cm along length of colon
4	Major sites of damage extending > 3 cm along length of colon

trophils in tissue under inflammatory conditions, and the level of MPO activity correlates directly with severity of inflammation[17]. In this study, MPO activity was measured by the modified method described by Krawisz *et al*[24] and Diop *et al*[18]. Briefly, the colon tissues were cut into small pieces and homogenized in 0.5% hexadecyltrimethylammonium bromide 1 mL per 100 mg of colon tissue. The homogenates were centrifuged at 19 000 *g* at 4 ℃ for 15 min. Aliquots of 80 mL supernatant were mixed with 120 μL potassium phosphate buffer (50 mmol, pH 6.0) with 0.0005% o-dianisidine dihydrochloride and 0.1% hydrogen peroxide. MPO activity was calculated from the rate of absorbance change during 1 min at 460 nm; one unit of MPO activity is equal to 1.13×10^{-2} changes in absorbance at 25 ℃. The results were normalized to the wet weight of colon tissue and expressed as MPO units/mg tissue.

Abdominal withdrawal reflex

Abdominal withdrawal reflex (AWR) test was performed as previously described to detect the pain threshold pressure[25]. Briefly, rats were lightly anesthetized with ether in order to place a 6 cm long flexible latex balloon into the descending colon and rectum through the anus. The end of the balloon was secured at least 1 cm proximal to the anal verge. Rats were then allowed to recover for at least 30 min. The tube of the balloon was connected *via* a Y-connector to a sphygmomanometer and colorectal distension was applied in increments of 5 mmHg until a visible contraction of the abdominal wall was observed by an investigator blinded to the treatment. The pain threshold pressure was defined as the intensity of colorectal distension that elicited an observable AWR, i.e., a sudden and persistent abdominal muscle contraction with abdomen lift off the platform (Score 3). The pain threshold pressure of all groups was recorded and repeated five times with intervals of at least 5 min for recovery.

Enterochromaffin cell counting

Tissue sections (5 μm thick) were deparaffinized in xylene, and rehydrated with graded ethanol for silver staining according to a method previously described, with little modification[26]. Sections were incubated with 5% ammoniacal silver solution for 4 h at room temperature, then 2 h in 56 ℃ and subsequently 12 h at room temperature in a dark humidified chamber. After rinsing

with water, 5% sodium hyposulfite was added and sections were incubated for 5 min at room temperature. The brown to black silver precipitate in the cytoplasm of EC cells was considered as a positive reaction. Five random fields at 200× magnifications for each section were captured and saved in the same size and resolution by a researcher blinded to treatment. After calibration, the mucosal fields were circled, and the areas of mucosa were calculated using Image J NIH software. EC cell density was calculated and expressed as the number of EC cells per mm^2 of mucosal area.

Serotonin content assessment

5-HT content in the colonic tissue was assayed following the previously reported procedure[27]. Briefly, the colon segment was homogenized in 15% iced trichloroacetic acid; the supernatant of each sample was filtered using 0.22 μm filters and extracted with diethyl ether, then the prepared samples were added to derivatization solution and analyzed by capillary electrophoresis with laser-induced fluorescence detection.

Statistical analysis

Data are presented as mean ± SE. Differences between two groups were analyzed by Student *t* test. When multiple groups were compared, data were analyzed using one-way analysis of variance followed by the Student-Newman-Keuls test. Differences were considered significant when $P < 0.05$.

RESULTS

Effect of trinitrobenzene sulfonic acid concentration on body weight and mortality rate

Based on the findings from our previous systematic review, TNBS (20 mg/rat, in 50% ethanol) was selected and given to rats at 8 cm from anus in 0.4 or 0.8 mL volume. As shown in Table 4, compared to the control group, the body weight of TNBS-treated rats all decreased markedly with loose and bloody stools at 5 d post-TNBS ($P < 0.01$). Moreover, the body weight in high-concentration TNBS (50 mg/mL)-treated rats was significantly lowered when compared to that treated with low-concentration TNBS (25 mg/mL) ($P < 0.05$), and 3 rats in the high-concentration TNBS (50 mg/mL)-treated group were found dead. At 4 wk after TNBS administration, the average body weight of high-concentration TNBS-treated rats was still significantly decreased compared to that of rats treated with low-concentration TNBS and saline ($P < 0.05$); no significant difference was found in the body weight between low-concentration TNBS-treated rats and the saline-treated ones.

Effect of trinitrobenzene sulfonic acid dosage on the severity of acute inflammation and inflammation resolution

Five days after TNBS administration, the results from MPO activity assay and histopathological evaluation showed that, TNBS, when administered at the doses of

Table 3 Criteria of histological scoring in colon tissue

Variables	Severity and scoring			
	0	1	2	3
Ulceration	No ulcer	Ulcerations not exceeding lamina muscularis mucosae	Ulcerations not exceeding submucosa	Ulcerations exceeding submucosa
Edema	Normal thickness	Submucosal expansion < 30%	Submucosal expansion 30%-100%	Submucosal expansion > 100%
Inflammatory cells	No infiltration	Few scattered cells	Distributed but not dense	Dense
Fibroplasia	Normal collagen	Increase < 30%	Increase 30%-50%	Increase > 50%

20, 10, and 5 mg/0.8 mL per rat in 50% ethanol, dose-dependently induced acute inflammation and damage in the colon tissue of rats (Figure 1). The results indicate that the higher the dose TNBS used, the more severe the inflammation and damage induced. As shown in macroscopic appearance and H and E sections (Figure 1A and B), high dose TNBS (20 mg/rat) induced multiple larger and deeper ulcerations, and dense inflammatory cell infiltration when compared to that treated with low dose TNBS.

As shown in Figure 2, four weeks after TNBS (5-20 mg/rat) administration, there was no significant difference in MPO activity between TNBS-treated rats and the control groups, suggesting no acute inflammation was left at this period. However, results from pathological evaluation showed that the histological scores in high dose (20 mg/rat) and median dose (10 mg/rat) TNBS-treated groups were still significantly higher compared to that of the control ($P < 0.05$), but no significant difference was found between low dose TNBS-treated rats and the control, suggesting low dose TNBS-treated rats had completely recovered from the initial inflammation at 4 wk post TNBS. As shown in Figure 2A and B, the colons from high and medium dose TNBS treated rats lost their normal appearance, and more collagen was found in the submucosa and smooth muscle in Masson staining sections, suggesting the occurrence of fibroplasia.

Effect of trinitrobenzene sulfonic acid administration position, and ethanol percentage on the severity of acute inflammation and inflammation resolution

Knowing that low dose TNBS (5 mg/0.8 mL per rat in 50% ethanol)-treated rats can completely recover from initial inflammation at 4 wk after TNBS administration, further studies were based on this dosage selection. As shown in Figure 3, compared to the control, MPO activ-

ity assay and histopathological evaluation all demonstrated that low dose TNBS (5 mg/0.8 mL per rat, in 50% ethanol), when given to rats at 8 cm or 4 cm from anus, induced marked acute inflammation and ulcers at 5 d post TNBS administration ($P < 0.01$), no difference was found between these two groups. However, the same dose TNBS (5 mg/0.8 mL per rat, 8 cm depth) in 25% ethanol induced significant mild non-ulcer inflammation compared to that treated with TNBS in 50% ethanol ($P < 0.01$). Four weeks after TNBS administration, there were no significant differences in MPO activity and histopathological score among all TNBS-treated groups and the control, suggesting that the rats treated with low dose TNBS (5 mg/0.8 mL per rat) had all completely recovered at 4 wk after TNBS administration.

Effect of trinitrobenzene sulfonic acid administration position, and ethanol percentage on the visceral hyperalgesia

To investigate whether the low dose TNBS (5 mg/0.8 mL per rat)-treated rats acquired long-lasting visceral hyperalgesia after inflammation resolution, AWR test was applied to all these TNBS-treated rats at 4 and 8 wk after TNBS administration. As shown in Figure 4, at 4 wk after TNBS administration, the pain threshold pressure in all TNBS-treated rats was decreased significantly compared to the control ($P < 0.05$), but no significant difference was found among these TNBS-treated rats. At 8 wk after TNBS administration, the pain threshold pressure in rats treated with TNBS at the depth of 8 cm was still significantly decreased compared to that of the controls ($P < 0.05$), but no significant difference was found in rats treated with TNBS at 4 cm from anus or in 25% ethanol.

Enterochromaffin cell hyperplasia in trinitrobenzene sulfonic acid-induced post-infectious irritable bowel syndrome rat model

To investigate whether the rats treated with low dose TNBS (5 mg/0.8 mL per rat, in 50% ethanol) at 8 cm from anus also acquired other features of PI-IBS, the EC cell number and 5-HT content in the proximal and distal colon tissues were further tested at 4 and 8 wk after TNBS administration. As shown in Figure 5, compared to the control, 5-HT content in the proximal colon, but not the distal colon, were significantly increased, with 32% ($P < 0.01$) and 23% ($P < 0.05$) increased at 4 and 8 wk after TNBS administration, respectively. A

Figure 1 Acute colonic inflammation and damage induced by different doses of trinitrobenzene sulfonic acid at 5 d after trinitrobenzene sulfonic acid administration. Panel A depicts the appearance of colon tissue in saline (A1), high dose trinitrobenzene sulfonic acid (TNBS) (20 mg/rat, A2), medium dose TNBS (10 mg/rat, A3), and low dose TNBS (5 mg/rat, A4)-treated groups; Panel B depicts the representative histological changes of colon tissue in saline (B1), high dose TNBS (B2), median dose TNBS (B3), and low dose TNBS (B4)-treated groups (hematoxylin and eosin staining, 100×); Statistical analysis of myeloperoxidase (MPO) activity is shown in panel (C), and pathological score in panel (D). Data are shown as mean ± SE, *n* = 4 per group. [a]*P* < 0.05, [b]*P* < 0.01 *vs* saline-treated group; [c]*P* < 0.05 *vs* high dose TNBS-treated group (one-way analysis of variance, Student-Newman-Keuls).

similar trend can also be found in the EC cell number; i.e., there were 68% and 60% increases at 4 and 8 wk after TNBS administration, respectively (*P* < 0.01), suggesting this TNBS-induced PI-IBS model also presents EC cell hyperplasia in the colon tissue.

DISCUSSION

TNBS is an agent commonly used in inducing post-inflammatory IBS model currently. Concerning the variations in developing a protocol of the TNBS-induced PI-IBS rat model and the three necessary features of PI-IBS animal model (i.e., initial inflammation/infection, inflammation/infection resolution, and acquired symptoms of IBS), the present study investigated the effects of TNBS dosage and concentration, intracolonic TNBS administration position, and ethanol percentage on the development of the TNBS-induced PI-IBS rat model. Our results showed that: (1) TNBS induced dose- and concentration-dependent acute inflammation and inflammation resolution at the dose range of 5-20 mg/rat; (2) Intracolonic TNBS administration position affected the persistence of later acquired visceral hyperalgesia, but not the initial inflammation severity; (3) Ethanol percentage affected the TNBS-induced inflammation severity and later acquired visceral hyperalgesia, and low ethanol percentage reduced the degree of TNBS-induced acute inflammation and shortened the persistence of acquired visceral hyperalgesia; and (4) The protocol with TNBS at 5 mg/0.8 mL per rat, dissolved in 50% ethanol, intracolonically administered 8 cm from anus may be a proper protocol in which rats can recover completely from the

Figure 2 Effect of trinitrobenzene sulfonic acid dosage on severity of acute inflammation and inflammation resolution. The colon tissue was collected at 4 wk after trinitrobenzene sulfonic acid (TNBS) administration. mg per rat, the higher the dose of TNBS, the more severe the acute inflammation and mucosa damage. This finding is consistent with previous reports that the severity and duration in TNBS-induced inflammation is dose-dependent[13,14,17]. It is notable that the same dose of TNBS (20 mg/rat) when given to rats in different vehicle volumes induced different degrees of damage; a higher TNBS concentration (50 mg/mL) induced

Figure 5 Persistent increases of enterochromaffin cell number and serotonin content in the colon tissue of trinitrobenzene sulfonic acid-induced post-infectious irritable bowel syndrome rat model. The colon tissue was collected at 4 wk and 8 wk after trinitrobenzene sulfonic acid (TNBS) administration. Panel A depicts the representative enterochromaffin (EC) cell staining in colon mucosa, the samples were from rats treated with saline (A1), or TNBS (A2) at 4 wk post TNBS (Scale bar, 100 μm). Statistical analysis of serotonin content is shown in panel (B), and EC cell number in panel (C). Data are shown as mean ± SE, *n* = 5 per group. more severe damage, even causing animal death in the acute phase. Our pathological results also showed that high-concentration TNBS-treated rats presented localized more severe inflammation and deeper ulcerations around the position of TNBS administration, which may be responsible for the occurrence of colitis complications, i.e., intestinal obstruction, intra-abdominal infection, and animal death. Concerning the fact that inflammation severity and duration have close correlation with TNBS dosage, the effects of TNBS dosage on inflammation resolution was assessed at 4 wk after TNBS administration. According to the pathologist's suggestion, fibroplasia evaluation index was added into the pathological evaluation criteria for the first time, so as to exactly evaluate inflammation resolution. Our results showed that the animals receiving low dose TNBS (5 mg/rat) recovered completely at 4 wk after TNBS administration, but those receiving high (20 mg/rat) and medium (10 mg/rat) dose were not recovered. This result seems to somewhat conflict with the finding from a previous study in which the rats receiving TNBS (5-20 mg/rat, in 25% ethanol) all recovered after 4 wk[14]. We speculate that this discrepancy may come from the protocol differences between these two studies, such as ethanol percentage, animal strain, or evaluation criteria. Consistent with our findings, the previous study showed that colonic inflammation induced by TNBS (30 mg/rat, in 50% ethanol) lasted for at least 8 wk[17], suggesting the

inflammation resolution is also dose-dependent. Based on previous findings and our results, TNBS dosage plays a critical role in TNBS-induced inflammation severity and resolution, and low dose TNBS (5 mg/rat)-induced inflammation can recover completely at 4 wk after TNBS administration.

Currently, 25% and 50% ethanol are both used as the carrier of TNBS in establishing TNBS-induced PI-IBS model and TNBS is commonly given to rats at the depth of either 4 cm or 8 cm from the anus. Based on low dose TNBS (5 mg/0.8 mL per rat) selection, we further investigated the effects of ethanol percentage and intracolonic administration position on the severity and resolution of TNBS-induced inflammation. Our results showed that rats treated with low dose TNBS at a depth of 4 cm or 8 cm presented similar inflammation severity and resolution, while the rats treated with TNBS in 25% ethanol developed milder non-ulcer inflammation compared to those treated with TNBS in 50% ethanol. As the carrier of TNBS, ethanol is known as a breaker to the mucosal barrier, and 30%-50% ethanol alone has been proved to induce acute inflammation and hyperemia[18,28]. Moreover, previous study have shown that 30% ethanol alone induced small areas of hyperemia, while TNBS combined with 30% ethanol induced larger area of necrosis and hyperemia in the colon[18]. These findings indicate that ethanol alone can induce concentration-dependent inflammation, and can be considered

Table 5 Detailed protocols in developing trinitrobenzene sulfonic acid induced post-inflammatory irritable bowel syndrome model in Sprague-Dawley rats

Procedures	Cautions
1. 7-wk-old male Sprague-Dawley rats, fast 24 h before TNBS administration	
2. Mix 1 volume of 12.5 mg/mL TNBS-saline solution with 1 volume of absolute ethanol	Fresh preparation
3. Weight and anesthetized rats with chloral hydrate (350 mg/kg, i.p.)	Anesthetization may last for 3-4 h
4. Insert a catheter into the colon at 8 cm from anus	Proceed carefully to avoid damage the colon wall
5. Keep the rat with head-down vertical position, instill 0.8 mL TNBS solution slowly into the colon lumen within 1 min	Handle slowly to avoid TNBS leakage
6. Keep the rat in head-down vertical position for 1 min before gently removing the catheter	
7. Put the rats in a mound of bedding in head-down position until consciousness recovery	Ensure TNBS solution remains completely in the colon; Keep the rats warm
8. On day 3, 7, 14, 21 and 28, observe and weight the rats	On day 3, body weight decreased by 10%-20% with unformed bloody stool; On day 7, body weight regained and reached the original level, the stool become formed but still soft; From day 7 to day 28, body weight increased smoothly, and finally reached the control level

TNBS: Trinitrobenzene sulfonic acid.

as an invasive helper in enhancing the effects of TNBS. Therefore, it seems reasonable that milder inflammation was induced in rats treated with equal dose of TNBS (5 mg/rat) but in lower ethanol percentage (25%). These results can also explain why high dose or high concentration TNBS have also been used by some researchers in establishing a PI-IBS model: low concentration ethanol may ameliorate the effects of TNBS[13,14].

Visceral hyperalgesia, the major feature of IBS, was further tested in low dose TNBS (5 mg/0.8 mL per rat) treated rats. From 4 wk to 8 wk post TNBS intracolonic administration at a depth of 8 cm, significant and persistent decrease in visceral pain threshold pressure was found, while the intracolonic TNBS administration at a depth of 4 cm or in 25% ethanol presented short-term acquired visceral hyperalgesia. Nowadays, the duration and severity of inflammation are considered as important risk factors in the development of PI-IBS[29], and severe inflammation which results in deep impairment of the underlining nerve fibers has been proposed to play an important role in the pathogenesis of IBS[30]. Based on the above evidence, we believe the unstable visceral hyperalgesia (i.e., lasting for less than 4 wk) in rats treated with TNBS in 25% ethanol may have close correlation with the mild non-ulcer inflammation observed at the acute phase of inflammation. These results also provide us with the information that mild inflammation, even without ulceration, can induce later short-term visceral hyperalgesia. However, it seems interesting that the same dose of TNBS when given at the different positions of colon (transverse *vs* descending) induced different features of acquired visceral hyperalgesia (persistent *vs* short-term), even though the TNBS-induced acute inflammation and damage was similar at first. Considering the unclear and complex pathogenesis of visceral hypersensitivity in PI-IBS, it is not easy to provide a clear explanation for the current findings. However,

during the acute phase of TNBS-induced inflammation, obvious colon dilation and a large amount of retained feces were found in the inflamed transverse colon, but not in the inflamed distal colon. We speculate that the persistent colonic inflammation and dilation may play important roles in enteric nerve system plasticity, and thus influence the feature of acquired visceral hypersensitivity. Currently, peripheral and central neuroplastic changes are considered to be associated with post-inflammatory persistent visceral hypersensitivity[1,31]. It is also well known that transient colorectal distension in the neonatal period can result in chronic visceral hypersensitivity and motility dysfunction in adulthood[25,32], and the underlying mechanism is thought to be associated with alterations in peripheral and central nerve systems[33]. Moreover, considering the different structure and functions of the transverse and descending colons, the regional differences in gut flora[34], mast cells[35] and EC cells[36] may also contribute to the different feature of acquired visceral hypersensitivity observed in our study. Further studies are needed to clarify these issues.

EC cell hyperplasia has been found in the colonic specimens of IBS and PI-IBS patients[37-39], and EC cell hyperplasia has been reported to play important role in the development of visceral hypersensitivity in IBS patients[40,41]. To identify whether visceral hyperalgesia is also accompanied with EC cell hyperplasia in the TNBS-induced PI-IBS rat model, EC cell number and 5-HT content were further investigated in the proximal and distal colon of PI-IBS rats. As shown in our study, the EC cell number and 5-HT content in the proximal colon, but not the distal colon, were significantly and persistently increased in this TNBS model, suggesting the occurrence of EC cell hyperplasia. However, this result differed from the finding from IBS patients, as EC cell hyperplasia in rectal mucosa was commonly reported[3]. This may be explained by the different distribution of

EC cells in the gut mucosa between human beings and rats: the vast majority of EC cells in humans mainly resides in the small intestine and rectum[42] while the major source of EC cells in rats largely locates in the cecum with a decline trend from the proximal to the distal colon[36]. Consistent with our findings, previous studies also showed that 5-HT content in the rat proximal colon tissue was significantly higher (about 5 fold) than that in the distal colon[43,44]. Therefore, it seems that EC cell hyperplasia in the proximal colon can be regarded as one of the features of the TNBS-induced PI-IBS rat model.

This present study, for the first time, showed that TNBS dosage and concentration, position of intracolonic TNBS administration, and ethanol percentage play important roles in developing the TNBS-induced PI-IBS model in Sprague-Dawley rats, suggesting more attention should be paid to these factors when developing a PI-IBS model with TNBS. Concerning the gene differences among animal strains, the protocol set up here may need some modulation when other rat strains except Sprague-Dawley rats, are used. Though this TNBS model presented persistent visceral hyperalgesia and EC cell hyperplasia for as long as 4 wk, more studies are still needed to observe the long-lasting visceral hyperalgesia and identify other features of PI-IBS in this model.

In the present study, we found out that the protocol with TNBS at 5 mg/0.8 mL per rat, dissolved in 50% ethanol, intracolonically administered at 8 cm from the anus resulted in persistent visceral hyperalgesia and colonic EC cell hyperplasia after complete recovery from the initial inflammation in rats. With this protocol, low-dose TNBS-induced mild mucosa damage and colonic inflammation is reproducible without any animal loss; visceral hyperalgesia and EC cell hyperplasia which last for at least 4 wk occur as early as 4 wk after TNBS administration. The details of this protocol are presented in Table 5. Ensuring the results from different laboratories would be comparable, we believe that widespread adoption of a recommended protocol will save a great quantity of time and resources.

ACKNOWLEDGMENTS

COMMENTS

Background
Post-infectious irritable bowel syndrome (PI-IBS) is a subgroup of IBS in which the patients developed their symptoms after recovery from an acute gastrointestinal infection. Previous systematic review showed that the trinitrobenzene sulfonic acid (TNBS)-induced model is the most commonly used PI-IBS model, but there are large variations in the protocol of model development. These variations make comparison between studies to be very difficult, if not impossible.

Research frontiers
This study aimed to investigate the effects of TNBS dosage, concentration, intracolonic administration position, and ethanol percentage on TNBS-induced acute inflammation, inflammation resolution, and later acquired features of IBS

(i.e., visceral hyperalgesia and enterochromaffin cell hyperplasia).

Innovations and breakthroughs
Recent studies have highlighted the important status of PI-IBS in functional diseases, as the clear onset and well defined pathophysiological changes of PI-IBS will help people understand not only the PI-IBS but also other subtypes of IBS. Moreover, the validated animal models, which aim to mimic one or more features of human disease, play important roles in the studies of mechanisms and potential therapeutic agents for diseases. This is the first study aimed to investigate the effects of key factors on developing TNBS-induced PI-IBS model in rats. The results and recommended protocol presented in this study will save a great deal of time and resources and ensure the results from different laboratories be comparable.

Applications
This study provides direct information about the effects of key factors on TNBS-induced acute inflammation, inflammation resolution, and later acquired features of IBS. More attention should be paid to these key factors when developing PI-IBS rat model with TNBS.

Peer review
This is a good descriptive study in which authors investigate the effects of TNBS dosage and concentration, intracolonic administration position, and ethanol percentage on the developing TNBS-induced PI-IBS rat model. The topic is interesting and useful for the study of pathophysiology of PI-IBS and the development of therapeutic agents.

Abstract

AIM: To estimate the cost-benefit of endoscopic screening strategies of esophageal cancer (EC) in high-risk areas of China.

METHODS: Markov model-based analyses were conducted to compare the net present values (NPVs) and the benefit-cost ratios (BCRs) of 12 EC endoscopic screening strategies. Strategies varied according to the targeted screening age, screening frequencies, and follow-up intervals. Model parameters were collected from population-based studies in China, published literatures, and surveillance data.

RESULTS: Compared with non-screening outcomes, all strategies with hypothetical 100 000 subjects saved life years. Among five dominant strategies determined by the incremental cost-effectiveness analysis, screening once at age 50 years incurred the lowest NPV (international dollar-I$55 million) and BCR (2.52). Screening six times between 40-70 years at a 5-year interval [i.e., six times(40)f-strategy] yielded the highest NPV (I$99 million) and BCR (3.06). Compared with six times(40)f-strategy, screening thrice between 40-70 years at a 10-year interval resulted in relatively lower NPV, but the same BCR.

CONCLUSION: EC endoscopic screening is cost-beneficial in high-risk areas of China. Policy-makers should consider the cost-benefit, population acceptance, and local economic status when choosing suitable screening strategies.

INTRODUCTION

Esophageal cancer (EC) is the eighth most common cancer and the sixth most common cause of cancer death worldwide[1]. Although the mortality of EC has

sharply reduced over the last three decades, EC remains the fourth leading cause of cancer death in China with a mortality of 15.21/100 000[2]. According to the "Third National Retrospective Sampling Survey of Death Causes Report in 2004-2005 of China", EC continues to be the major public health burden in some high-risk areas, where the mortality of EC was three times higher than the average of the country. EC is a fatal disease, with a 5-year survival rate of less than 20% even in developed countries[3,4].

To explore suitable control measures in high-risk areas of China, a great number of EC screening studies using endoscopic examinations (i.e., endoscopy with mucosal iodine staining and index biopsy as a screening technology, combined with pathological examination for confirming and staging the disease) have been conducted for several decades[5-10]. Through early detection and subsequent treatment, the 5-year survival rate of EC increased to 86%[10]. Furthermore, obvious reductions in incidence and mortality rates of EC were observed under endoscopic screening[11].

A national screening program for EC in high-risk areas has become available in 73 sites of 27 provinces of China based on evidence from previous studies. Nevertheless, due to lacking comprehensive health economic evaluations on such programs, two key public health questions remain to be answered: is the endoscopic screening cost-beneficial in the long run? Should we use the same screening strategy in both developed and developing high-risk areas of China?

The objective of this paper is to explore appropriate screening strategies for EC in high-risk areas of China from the health economic perspective by comparing the long-term cost-benefits of 12 endoscopic screening alternatives. It will provide valuable data for policy makers to make decisions on the current screening program.

MATERIALS AND METHODS

Decision analysis model

A Markov model was constructed to evaluate the cost-benefit of different screening strategies for EC. In each strategy simulation, a hypothetical cohort with 100 000 participants entered the model at age 40 years and were followed up until the age of 70 years. Costs and benefits were all discounted at an annual rate of 3%[12]. TreeAge Pro 2009 Suite by TreeAge Software Inc. was used for all analysis.

The natural history of EC was categorized as the following health status: normal, mild dysplasia (mD), moderate dysplasia (MD), severe dysplasia/carcinoma *in situ* (SD/CIS), intramucosal carcinoma (IC), submucosal carcinoma ($T_1N_0M_0$) (SC), invasive carcinoma (INC), and death. Figure 1 depicts the detailed transition processes of EC in the Markov model. Each rectangle represents a health state. During a Markov cycle (1 year), one could transit from his/her current health state to another (indicated by arrows between different states) or remain in the same state (indicated by half-circle arrows on the rectangles). Prior to the development of IC, the condi-

Figure 1 Bubble diagram representing the health states of esophageal cancer and transitions in natural-history Markov model.

tion could spontaneously regress. Once IC developed, no regression could occur. We used the model to evaluate all screening alternatives and non-screening outcomes.

Screening strategies

In the context of lacking guidelines for EC screening worldwide, we explored 12 screening strategies using endoscopic examinations. These strategies were performed at varying starting age for screening (40, 45 or 50 years), screening frequency (once, twice, thrice, or six times in the lifetime), and intervals of follow-up for mD and MD cases (e.g., 5 or 3 years). The strategies were listed as "t(y)nf/t(y)f", where t denotes the screening frequency, y represents the starting age of screening, nf means we do not follow up the mD and MD cases diagnosed by screening, and f means the mD and MD cases are followed up every 5 years and 3 years, respectively. For twice and thrice screening strategies in the lifetime, the screening intervals were 10 years; for six times screening strategy, the screening intervals were 5 years.

Screening, diagnosis, and treatment procedures for the strategies were all based on the current practice manuals. The participants were screened using endoscopy with iodine staining. If endoscopy revealed a suspected lesion (mD or worse), index biopsy combined with pathological examination were performed consecutively. The detailed procedures of endoscopy were the same with those in the literature[13]. For SD/CIS and IC cases detected by screening, Endoscopic Mucosal Resection and/or Argon Plasma Coagulation served as the standard treatment. For detected patients with SC or worse, therapies included esophagectomy, radiotherapy, and other routine treatments. Subjects who were not screened would be diagnosed and treated if they presented with symptomatic EC. All patients were followed up once by endoscopy in the first year after treatment.

Model parameters

The data used in the model were compiled from a variety of sources: (1) the results of our prospective cohort study based on the EC chemoprevention trial of selenomethionine and celecoxib in "early detection of EC" (EDEC) program; (2) the results of our population-based

Table 1 Non-age-specific parameters

mD: Mild dysplasia; MD: Moderate dysplasia; SD/CIS: Severe dysplasia/carcinoma *in situ*; IC: Intramucosal carcinoma; SC: Submucosal carcinoma (T₁N₀M₀); INC: Invasive carcinoma; I$: International dollar. [1]For compliance, sensitivity and specificity of endoscopy, screening and treatment costs, and discount rate, the numerals before and in the parenthesis denote the base case and ranges used in sensitivity analysis; [2]Data were calculated in terms of the project called "Early Detection and Early Treatment of Esophageal Cancer in Demonstration Centers in China"; [3]Data were collected from the death registry report of Linzhou County during 2004-2006; [4]Post-SD/CIS, post-IC, post-SC and post-INC represent the "health" condition after treatment of SD/CIS, IC, SC and INC; [5]Costs and life years were discounted during the Markov cycles.

screening project "Early Detection and Early Treatment of EC in Demonstration Centers in China" (EDETEC); (3) surveillance data; (4) published literatures; and (5) unpublished data.

In the chemoprevention trial of EDEC program, 2213 asymptomatic adults from Linzhou County, Henan Province of China, underwent an endoscopic screening in 1999[14]. Among them, 2189 participants who had histological diagnoses at the baseline evaluations were surveilled until 2007. The primary end-point was the occurrence of EC, confirmed by village doctors through checking the histological diagnoses in medical records. The project EDETEC covering 11 high-risk areas of EC was launched by the Chinese central government in 2005. The purpose was to increase the early detection and treatment rate as well as the 5-year survival rate of EC, and to improve the screening, early detection and treatment program and so forth[15].

Probabilities

At the initial model cycle, a hypothetical cohort of 100 000 participants was distributed among various health states based on the proportion of each pathologic stage of EC in the 40-44 years age group. The proportions were calculated in terms of the screening results of Linzhou County in the project EDETEC between 2005 and 2008. Among the 8267 asymptomatic participants aged 40-69 years, 8.2% cases were identified as mD in the 40-44 years age group. Full details are presented in Tables 1 and 2.

In each cycle of a Markov process, the transitions among health states occurred with annual transition prob-

abilities. They were estimated in terms of: (1) published literatures[9,16-21]; and (2) the results of both EDEC and EDETEC projects in Linzhou County (Tables 1 and 2).

It is believed that persons with SD/CIS or lesser abnormality may not die from EC and that patients with IC or SC may die from all causes including EC. In patients with INC, we assumed that they may mainly die from EC. Therefore, in our model, the corresponding death probabilities for three different populations above were converted from non-esophageal-cancer mortality, all-cause mortality, and case fatality rate of EC, respectively. All age-specific mortality rates were obtained from the death registry reports of Linzhou County between 2004 and 2006. And they were converted to probabilities by the formula: Probability = 1 - Exp (-rt), where "r" represents the rate and 't' denotes the time (Tables 1 and 2).

Screening compliance

The compliance of EC screening in different settings varied from 33.4% to 77.1%[22]. In the EDETEC program, the screening compliance of EC in Linzhou County during 2005-2008 was 67% (8267/12 294), which was used as a baseline in this analysis (Table 1).

Screening and treatment cost

In our model, both screening and treatment costs included direct and indirect costs, which were calculated from a societal perspective. Direct costs referred to those associated with drugs, disposable supplies, equipment and facilities, staff, *etc*. In this study, we used costs rather than charges. And they were collected using Micro-costing methods in

the EDETEC program[23]. Indirect cost was also estimated from our EDETEC program, including those related to transportation, accommodation, and the productivity losses of both patients and their caregivers[24,25]. Considering differences in purchasing power, costs were presented in 2008 international dollars (I$).

Screening cost per capita using endoscopic examination was I$69.81. In screening group, the treatment costs for patients with SD/CIS or worse ranged from I$2964 to I$6136. In control group, the treatment cost for INC cases was I$10 414, much higher than that in screening group (Table 1).

Other variables and assumptions
According to a previous study in Linzhou County, the sensitivity and specificity of endoscopic examination were 96% and 90%, respectively[6] (Table 1). For individuals diagnosed as having precancerous lesions or EC (i.e., SD/CIS or worse), we assumed that they would complete the entire treatment procedures.

Health economic evaluation
The basic outcomes of the model were total costs (including screening costs and treatment costs) and expected life years. Then the net present values (NPVs) and the benefit-cost ratios (BCRs) were calculated under each of the strategies (for a hypothetical cohort of 100 000 subjects followed up from 40 years to 70 years of age).

For each screening cohort, the benefit consisted of the treatment cost averted and productivity gains from screening programs[25], and counted by the formula: benefit = GDP per capita of Linzhou in 2008 (I$6542) × (life years of screening cohort - life years of "non-screening" group) + treatment cost of "non-screening" group. The NPV was the benefit minus the total cost of the screening group; the BCR equaled to the benefit divided by the

total cost. The strategies with a NPV > 0 and a BCR > 1 were considered cost-beneficial.

In addition, the screening alternatives were compared using an incremental cost-effectiveness analysis. The strategies that were more expensive and gained fewer life years (dominated), or less costly and less cost-effective (extended dominated) than an alternative were excluded.

Sensitivity analysis
Given the uncertainty about some parameters, univariate sensitivity analyses were used to assess the robustness of the model results by varying the values of screening compliance, discount rate, screening cost, treatment cost, sensitivity and specificity of endoscopy within reasonable ranges (Table 1).

Model validation
Based on the established natural-history model, the validity of the Markov model was assessed by comparing the model-predicted age-specific incidence and the age-specific proportion of each stage of EC with the observed data in real-world conditions.

RESULTS
Baseline results
Compared with non-screening outcomes, the screening strategies could save life years of 2539-15 384 for a hypothetical population of 100 000, with NPVs of I$24 million-I$99 million and BCRs of 1.61-3.06. Strategies with higher screening frequencies were more cost-beneficial than those with lower screening frequencies (Table 3).

When compared with each other, it indicated that the once(50)f-, twice(40)f-, twice(45)f-, thrice(40)f-, and six times(40)f-strategies were cost-effective, dominating or extended dominating others. In other words, other

Table 3 Estimated epidemiological and economic effects for each strategy with 100 000 people under baseline assumptions

Screening strategies t(y)nf/ t(y)f[1]	Life years	Life years saved (LYS)	Costs (I$)	ICER (I$/LYS)	Benefit (I$)	NPV (I$)	BCR

I$: International dollar. ICER means incremental cost-effectiveness ratio, which is defined as the additional cost of a specific strategy divided by its additional life years, as compared with the next-less-expensive strategy. D means dominated, e.g., the screening strategy is more expensive and less effective than another strategy. ED means extended dominated, e.g., if a screening strategy has a higher ICER than the next more costly, more effective strategy, it is extendedly dominated by that more cost-effective strategy. NPV: Net present value; BCR: Benefit-cost ratio. [1]t(y)nf/t(y)f: t denotes the frequencies of screening, y represents the starting age of screening, nf means we do not follow up the mild dysplasia and moderate dysplasia cases diagnosed by screening, and f means the mild dysplasia and moderate dysplasia cases diagnosed by screening are followed up every five and three years, respectively. For twice and thrice screening strategies in the lifetime, the screening intervals were 10 years; for the six times screening strategy in the lifetime, the screening intervals were five years. "-": Life years saved, benefits, NPVs and BCRs of screening strategies were all calculated by comparing with non-screening group, accordingly, those are null for non-screening group; "/": As the cheapest strategy, the ICER is null for the once(50)f-strategy.

strategies cost more and saved fewer lives, and were excluded. Among the cost-effective screening alternatives, the once(50)f-strategy saved the lowest life years of 6841, and resulted in the fewest NPV of I$55 million and BCR of 2.52. The highest life years saved were observed in the six times(40)f-strategy, with the maximum NPV of I$99 million and BCR of 3.06. Compared with six times(40)f-strategy, the thrice(40)f-strategy saved fewer life years and yielded lower NPV, but had the same BCR.

Sensitivity analysis

When the sensitivity and specificity of endoscopy, screening and treatment costs, discount rate, and screening compliance were changed once at a time (Table 1), once(50)f-, twice(40)f-, twice(45)f-, thrice(40)f-, and six times(40)f-strategies kept dominant. Uncertainty in those parameters had little effect on the choice of cost-effective strategies.

NPVs and BCRs changed obviously with screening cost, compliance, and discount rate under all cost-effective strategies. Both NPVs and BCRs were relatively less affected by the treatment cost, sensitivity and specificity of endoscopic examination. No matter how these parameters varied within the ranges, the results showed that screening was cost-beneficial with positive NPVs and BCRs > 1. In general, our results were robust (Figure 2).

Model validation

Comparison of incidence: The cancer registry report in Linzhou County during 2004-2006 showed that the age-specific incidence rates of EC were 47.44 per 100 000, 247.77 per 100 000, and 398.00 per 100 000 for the age groups of 40-49, 50-59, and 60-69 years, respectively. The corresponding model-predicted rates were

46.19/100 000, 248.14/100 000, and 424.78/100 000, respectively. The modeled estimates were about 94%-103% of the observed rates.

Comparison of proportions: First and most important, in any age group, the proportion of each histological grade of EC predicted by model was quite close to the screening results of the EDETEC program in Linzhou County during 2005-2008. And the estimated proportions were within the 99% confidence intervals of the observed data. Secondly, in each age group, the proportions decreased with the severity of the disease. And the proportions of mD ranked first. Last but not the least, for each pathologic grade of EC, the proportions increased with age, and reached the top in the 65-69 year-old group. Such tendency fit the characteristics of natural history of EC, and was also in agreement with the previous reports in other high-risk areas of China[26,27]. In summary, the validity of the model was satisfactory (Figure 3).

DISCUSSION

It was the first comprehensive cost-benefit assessment for the EC screening using endoscopic examination in China. Compared with no screening, all 12 screening strategies covering a hypothetical population of 100 000 resulted in substantial NPVs and high BCRs. However, when compared with each other, only five strategies were cost-effective based on the incremental cost-effectiveness analysis. Among all cost-effective strategies, screening once at age 50 yielded the lowest NPV (I$55 million) and BCR (2.52). Screening six times for those between 40-70 years of age at a 5-year interval yielded the highest NPV (I$99 million) and BCR (3.06). Compared with the six times(40)f-

Figure 2 One-way sensitivity analyses for each cost-effective screening strategy. Strategies are expressed as t(y)f: t denotes the frequencies of screening; y denotes the starting age of screening; f means the mild dysplasia and moderate dysplasia diagnosed by screening were followed up every five and three years. For twice and thrice screening strategies in the lifetime, the screening intervals were 10 years; for the six times screening strategy in the lifetime, the screening intervals were 5 years. A: Treatment costs for invasive carcinoma of "non-screening" group; B: Treatment costs for invasive carcinoma of screening group; C: Treatment costs for submucosal carcinoma ($T_1N_0M_0$); D: Treatment costs for severe dysplasia/carcinoma *in situ*/intramucosal carcinoma; E: Screening costs; F: Specificity; G: Sensitivity; H: Screening compliance; I: Discount rate. Solid vertical lines represent the base cases of net present value (NPV)s/benefit-cost ratio (BCR)s. For B, C, D, E and I, the left of each bar, the lowest bound of NPVs/BCRs range, was counted on the basis of the maximum values of related parameters; and the right of each bar, the highest bound of NPVs/BCRs range, was counted according to the minimum values of related parameters. For other parameters, the left/right of each bar was calculated based on their minimum/maximum values.

Figure 3 Comparison of modeled age-specific proportion of each pathologic stage of esophageal cancer with screening results. EC: Esophageal cancer; mD: Mild dysplasia; MD: Moderate dysplasia; SD/CIS: Severe dysplasia/carcinoma *in situ*; IC: Intramucosal carcinoma; SC: Submucosal carcinoma ($T_1N_0M_0$); INC: Invasive carcinoma.

strategy, screening thrice between 40-70 years of age at a 10-year interval saved fewer life years and produced lower NPV, but had the same BCR. Under these strategies, the mD and MD cases diagnosed by screening were followed up every 5 years and 3 years, respectively; all patients with SD/CIS or worse found by screening were treated, and followed up once by endoscopy in the first year after treatment. The validation assessment and the sensitivity analysis showed that our results were reliable.

Previously, two similar investigations presented BCRs of 4 and 4-12 for EC screening in China, which were higher than those in our analysis[25,28]. Explanations of the discrepancy from our estimates were: (1) Liu *et al*[28] and Wei *et al*[25] investigated 40-69 year old asymptomatic persons using cross sectional analyses, while we conducted a hypothetic birth cohort analysis, and followed up the cohort from 40 years to 70 years of age. Previous studies did not consider that some "normal/mild/moderate" cases defined by screening would progress and suffer from EC in the following life years[9,19-20,29]. A prospective study found that 23.7% mD and 50% MD cases developed EC during the 13-year follow-up[19]. The treatment costs may be very high for these EC patients. Neglecting them would overestimate BCRs; (2) Compared with non-screening, most of the EC patients in the screening group were diagnosed at earlier stages (87% *vs* 8%)[24]. As a result, the treatment cost per capita for EC patients in the screening group was lower than that in "non-screening" group. According to the formula of BCR, we found that BCR was positively associated with the difference of treatment cost per person between screening and control groups. Unlike Wei *et al*[25], we estimated the costs from the perspective of resource expenditure other than hospital charges. The difference of treatment costs between the groups in our study was much smaller than that in prior studies. That could account for the difference of BCRs to some extent;

and (3) The costs and benefits were not discounted in previous studies[25,28]. Our sensitivity analysis showed that the discount rates were inversely associated with BCRs. And the BCRs of almost all strategies increased to nearly 4 when the discount rate declined to zero.

As the most widely used summary measures in health economic evaluations, the NPV and BCR are used to determine the return on any investment. Our study demonstrated that an investment of I$ 36 117 125 would result in a return of I$ 54 991 003 under once(50)f-strategy. These economic benefits resulted from a reduction in the incidence and mortality of EC, and the productivity gains of the prolonged life years through early detection and subsequent treatment. Our results revealed that the return increased with the screening frequency, and the six times 40)f-strategy resulted in the highest NPV. Although thrice(40)f-strategy yielded lower benefits, it was much less costly than the six times(40)f-strategy. It means that the thrice(40)f-strategy was a suitable alternative for the six times(40)f-strategy if there was an emphasis on capital constraints.

In addition to cost-benefit outcomes, some other factors should be considered when choosing reasonable screening strategy in different settings. First of all, endoscopy is an invasive examination. Concerns related to the high frequency of screening (e.g., six times in the lifetime) can lead to the great deduction of the compliance if it is not appropriately addressed, especially in the areas with low compliance at the time of initial screening, such as some villages of Ci County (33.7%)[22]. Moreover, the total costs of the screening strategy, life years saved, local economic level, and health resource status should also be weighed and balanced by policy makers. In summary, we recommended that once(50)f-strategy which was the cheapest would be suitable in underdeveloped settings with inadequate health resources, and that thrice(40)f-

strategy which could save more life years would be preferable in developed settings with adequate health resources.

One issue needed to be emphasized in our analysis was that most data used in our model were calculated from specific epidemiological data of Linzhou, the highest incidence area of EC worldwide. A great number of endoscopic screenings in this area have been performed since the 1980s, and systematic cancer incidence and death registration have been established. Therefore, the related data from Linzhou County were available and reliable. Our sensitivity analyses displayed that variation in some important parameters within wide ranges did not have a significant effect on our results. This further confirmed that our evaluation results mainly based on data from Linzhou were objective and applicable for other similar high-risk areas in China.

It is known that the cost-benefit of screening for EC (or any other cancer) is highly dependent on the incidence (and subsequent mortality) of that particular cancer. Based on our model prediction and area-specific incidence of EC in Cancer Registry Annual Report of China in 2004, we preliminarily and roughly estimated the cost-benefit of screening program in moderate-(around the national average level of EC incidence, 15.22/100 000), and low-risk areas (less than half of the national average level for EC incidence, 7.61/100 000). In moderate-risk areas, the BCRs ranged from 1.09-1.59, and screening once at age 50 incurred the highest BCR. In low-risk areas, only the strategy of screening once at age 50 remained cost-beneficial (with a highest BCR of 1.09). The results revealed that in moderate- or low-risk areas, screening program was not so cost-beneficial as that in high-risk areas. The screening once at age 50 was relatively preferable. Therefore, our results should be prudential to be used in moderate- or low-risk areas. However, more researches are needed in the future.

Our analysis had several limitations. First, the screening and treatment costs did not include program costs, which might account for a large part of the total costs[12]. The underestimation of costs may result in overrating the benefits of screening strategies, whereas the one-way sensitivity analysis of costs found that even when the costs were increased by over 20%, the screening was still considered as cost-beneficial. Second, in this study, the transition probabilities of all health states should change with age. However, those of normal, mD and MD states were fixed due to the unavailability of the data, which could affect the models' results to some extent. Hence, further studies on the natural history of EC appear warranted. Finally, although we performed one-way sensitivity analyses to evaluate the impact of each uncertainty on the results, we could not quantify the total impact of combinations of the parameter values. We did not conduct a multivariate probabilistic sensitivity analysis, since data on the probability distributions of variables were unavailable. This may more or less influence the outcomes of the sensitivity analysis.

In conclusion, EC endoscopic screening is cost-beneficial in high-risk areas of China. The strategy with once screening at age 50 years in the lifetime is the cheapest but saves fewer life years. If decision makers wish to save more life years and get more benefit, the strategy of thrice screening from 40 years of age at an interval of 10 years would be preferable. In different high-risk areas of EC, policy makers should consider the cost-benefit of screening, acceptability in the population, local health resources and economic level when choosing appropriate screening strategies.

ACKNOWLEDGMENTS

COMMENTS

Background

Esophageal cancer (EC) remains the fourth-leading cause of cancer death in China, and continues to be the major public health burden in some high-risk areas. Previous studies found that EC screening program using endoscopic examination (*i.e.*, endoscopy with mucosal iodine staining and index biopsy as a screening technology, combined with pathological examination for confirming and staging the disease) could increase the 5-year survival rate, decrease the incidence and mortality of EC. A national screening program for EC in high-risk areas has become available in 73 sites of 27 provinces of China. Nevertheless, the health economic effects in the long run on such programs remain unknown. And whether screening strategy is suitable in regions with different health resources and economic level is not clear.

Research frontiers

To assess the cost-benefit of screening program in the long run, large-population-based perspective studies are difficult and expensive to conduct, and results would be obtained in decades. Instead, in the area of health economic evaluation for secondary prevention of cancer, the research hotspot is to use Markov model to explore suitable strategies which are cost-effective and cost-beneficial.

Innovations and breakthroughs

Previous researches with regard to cost-benefit analyses of EC screening program in China were cross-sectional studies without follow-up, and only evaluated the health economic effects of one screening strategy which is used currently. The authors conducted a hypothetic birth cohort analysis and followed up the cohort from 40 years to 70 years of age on the basis of Markov model, and compared 12 hypothetic screening strategies (different at starting age of screening, screening intervals, *etc*.) so as to explore preferable screening strategies in different areas.

Applications

The study results suggest that EC endoscopic screening is cost-beneficial in high-risk areas of China. The strategy, screening once at age 50 years in the lifetime, is the cheapest but saves fewer life years. If decision makers wish to save more life years and get more benefit, the strategy, screening thrice from 40 years of age at an interval of 10 years, would be preferable. The results will provide policy makers important information on updating such screening program in high-risk areas.

Terminology

Markov model: Markov model is considered as a powerful tool for simulating the development process of chronic diseases. In Markov models, health states passed through by patients are defined separately; and then through modeling on the basis of a system of transitional probability among states within a cycle (usually 1 year), the development of diseases and the medical resources used in population could be estimated; Cost-benefit analysis: Cost-benefit analysis is a systematic process for calculating and comparing benefits and costs of a project to see whether the benefits outweigh the costs for two purposes: (1) to determine if it is a sound investment; and (2) to see how it compares with alternate projects.

Peer review

The authors present the results of a decision analysis of endoscopic screening for esophageal squamous cell cancer for a high-risk region in China. They conclude that endoscopic screening, compared to no screening, is cost-effective, with several different screening schedules that could be used. Overall, this is a nicely done study and is well-written.

Abstract

AIM: To demonstrate the feasibility of optical coherence tomography (OCT) imaging in differentiating cervical inlet patch (CIP) from normal esophagus, Barrett's esophagus (BE), normal stomach and duodenum.

METHODS: This study was conducted at the Veterans Affairs Boston Healthcare System (VABHS). Patients undergoing standard esophagogastroduodenoscopy at VABHS, including one patient with CIP, one representative patient with BE and three representative normal subjects were included. White light video endoscopy was performed and endoscopic 3D-OCT images were obtained in each patient using a prototype OCT system. The OCT imaging probe passes through the working channel of the endoscope to enable simultaneous video endoscopy and 3D-OCT examination of the human gastrointestinal (GI) tract. Standard hematoxylin and eosin (H and E) histology was performed on biopsy or endoscopic mucosal resection specimens in order to compare and validate the 3D-OCT data.

RESULTS: CIP was observed from a 68-year old male with gastroesophageal reflux disease. The CIP region appeared as a pink circular lesion in the upper esophagus under white light endoscopy. OCT imaging over the CIP region showed columnar epithelium structure, which clearly contrasted the squamous epithelium structure from adjacent normal esophagus. 3D-OCT images obtained from other representative patients demonstrated distinctive patterns of the normal esophagus, BE, normal stomach, and normal duodenum bulb. Microstructures, such as squamous epithelium, lamina propria, muscularis mucosa, muscularis propria, esophageal glands, Barrett's glands, gastric mucosa, gastric glands, and intestinal mucosal villi were clearly observed with OCT and matched with H and E histology. These results demonstrated the feasibility of using OCT to evaluate GI tissue morphology *in situ* and in real-time.

CONCLUSION: We demonstrate *in situ* evaluation of CIP microstructures using 3D-OCT, which may be a useful tool for future diagnosis and follow-up of patients with CIP.

INTRODUCTION

Cervical inlet patch (CIP) is characterized by the presence of heterotopic columnar gastric mucosa in the upper esophagus, most commonly located just below the upper esophageal sphincter (UES). Other sites for heterotopic gastric mucosa have been reported in the duodenum, jejunum, cystic duct, ampulla of vater, gallbladder, rectum and the anus[1-7], but their etiology and pathological significance remain unclear. The incidence of CIP has been reported from as low as 1%, to as much as 10% of endoscopic cases in different adult studies[8,9]. A large autopsy series of 1000 children demonstrated a prevalence of 4.5%[10]. During esophagogastroduodenoscopy (EGD), the region just below the UES is often quickly traversed after overcoming the initial resistance. CIP is usually best seen at the end of an EGD exam while withdrawing back through the esophagus and specifically looking for the condition. One study found almost a 6-8 fold increase in the incidence, from 0.3% to 2.3%, depending upon the endoscopist's awareness of this entity and thoroughness of examination[11]. Although generally asymptomatic, CIP can present with dysphagia[12], stricture[13], ulcers[14], bleeding[15] or fistula[16]. It is unclear whether CIP is congenital or acquired. One postulate is that CIP originates from incomplete embryonic replacement of the stratified epithelium, which normally starts at the 4th month of gestation. The greater incidence of CIP seen in pediatric populations and in the upper esophageal pouch of children with tracheoesophageal fistula supports this hypothesis[10,17,18]. Also, immunohistochemical studies suggest an embryologic origin for CIP on account of differences in endocrine markers such as serotonin, glucagon, pancreatic polypeptide, somatostatin and neurotensin in histologic specimens of CIP and Barrett's esophagus (BE)[19].

A second postulate is that CIP, especially as noted in

adults, is an acquired metaplastic change occurring in the squamous mucosa of the esophagus and is associated with predisposing factors for gastroesophageal reflux disease (GERD), such as sliding hiatal hernia[20]. Its incidence is up to four-fold higher in patients having BE[21] and CIP was found in almost a third of patients having dysplastic BE or adenocarcinoma[22]. Thus, long-standing acid reflux is thought to lead to columnar metaplasia in the upper esophagus, similar to BE. Several reports suggest that CIP may progress to adenocarcinoma[23-26].

In this study, we evaluate whether optical coherence tomography (OCT) can assess epithelial differences in CIP compared to normal esophagus, BE, normal stomach and duodenum. OCT is an emerging medical imaging technology that enables micron-scale, cross-sectional, and three-dimensional (3D) imaging of biological tissues *in situ* and in real-time[27,28]. OCT is similar to ultrasound B-mode imaging, except that echoes of light, instead of sound, are used to achieve micron-scale image resolutions. *In vivo* endoscopic OCT imaging was first demonstrated in rabbit gastrointestinal (GI) and respiratory tracts in 1997[29], and was quickly adopted by multiple groups for investigations in the human GI tract[30-36]. A prospective study involving 121 patients demonstrated 97% sensitivity and 92% specificity for diagnosing BE[33]. Our group has developed a portable, catheter-based prototype OCT system, where the OCT probe can be passed through the accessory channel of a standard endoscope, and achieves imaging speeds of up to 100 000 axial scans per second with axial resolutions of 5 μm to 7 μm in tissues[37]. Real-time cross-sectional OCT image display and 3D capture capabilities were demonstrated in animals[37], and humans[36,38,39]. 3D-OCT volumetric imaging enables the synthesis of *en face* views (similar to magnification endoscopy images), the generation of virtual cross-sectional images with arbitrary orientation, the average of multiple frames to reduce speckle and improve contrast, and quantitative measurements of tissue morphology. To our knowledge, this is the first description of *in vivo* CIP microstructure using OCT.

MATERIALS AND METHODS

Imaging protocol

This study was conducted at the Veterans Affairs Boston Healthcare System (VABHS), in compliance with an approved protocol by the institutional review boards at VABHS, Harvard Medical School and Massachusetts Institute of Technology. Five male Caucasian patients undergoing regular EGD at VABHS from August 2009 to April 2011 were enrolled in this study. This includes one patient with CIP, one representative patient with BE and three representative normal subjects. The representative patient with BE and normal subjects were selected from a large cohort of subjects who were imaged using OCT for another study. White light video endoscopy was performed using the Evis Extra Ⅲ high definition system (Olympus America, Center Valley, PA), and endoscopic

Figure 1 Endoscopic view of cervical inlet patch.

3D-OCT images were obtained using the system described below.

Optical coherence tomography system

The 3D-OCT endomicroscopy system was developed in collaboration with LightLab Imaging - St Jude Medical, Inc. and is similar to the system previously described by our group[37]. A Fourier Domain Mode Locking swept laser with a center wavelength of 1310 nm and average output power of 42 mW at a sweep repetition rate of 59 kHz was used as the light source. The full-width-half-maximum bandwidth of the laser sweep was about 120 nm, which supports about 5 μm axial resolution in tissue. The system sensitivity was 103 dB with 13 mW of incident power. The imaging probe, with an outer diameter of 2.5 mm, was introduced through a standard working channel of a high-definition endoscope (Olympus GIF-Q180) to enable simultaneous video endoscopy and 3D-OCT imaging examination. The output beam from the probe was focused to a 15 μm spot and was emitted at an angle of about 80 ℃ from the probe axis by a prism. The internal optics in the probe was rotated rapidly for radial scanning at 60 (or 70) frames per second (fps). Each image frame had about 512 × 1000 pixels at 60 fps (or about 512 × 900 pixels at 70 fps). To acquire a spirally scanned, volumetric OCT data set of the GI tract, the probe was pulled back at 1.0 mm/s along the sheath, which corresponds to a frame-to-frame spacing of 14-17 μm. At this image acquisition speed, a 20 mm × 8 mm × 2 mm 3D-OCT data set was acquired in 20 s.

Individual 2D-OCT frames were displayed on screen for real-time preview. The volumetric data sets were acquired and streamed to a hard drive. During post-processing, each 2D radial frame was unwrapped to create a rectangular frame. A custom program was written to detect the surface of the plastic probe sheath in each frame, which is used to flatten the image. The flattened 3D-OCT data sets were then loaded into Amira (ResolveRT, Mercury Computer Systems) for 3D rendering and visualization in different orthogonal imaging planes.

Histology analysis

Standard hematoxylin and eosin (H and E) histology was performed by the pathology service at VABHS on biopsy or endoscopic mucosal resection (EMR) specimens in order to compare and validate the 3D-OCT data. Photomicrographs of the H and E slides were taken under a standard Olympus BX40 microscope using a 4× objective.

RESULTS

The endoscopic view of a CIP in a 68-year old patient referred for endoscopic treatment for long-segment BE is shown in Figure 1. During retraction of the endoscope, a pink circular lesion was observed under white light endoscopy in the upper esophagus (about 20 cm from the tooth). The histology of the biopsies taken from the lesion later confirmed the finding of CIP (Figure 2C). Endoscopic OCT imaging was performed over the CIP under direct simultaneous visualization with a white light endoscope. From cross-sectional OCT images shown in Figure 2A and B, regions with CIP and the adjacent squamous epithelium can be identified. In addition, the CIP region clearly shows shallower light penetration compared with the adjacent normal esophagus. This is similar to typical images from normal gastric mucosa of representative other subjects. Zoomed views shown in Figure 2D and E clearly demonstrate columnar and squamous epithelium in the CIP and the adjacent normal esophagus, respectively. The columnar features observed in the CIP are consistent with the corresponding H and E histology shown in Figure 2C.

For comparison, OCT images of a normal gastro-esophageal junction (GEJ) obtained from a representative patient with chronic heartburn symptom (Figure 3). The *en face* OCT projection image at 350 μm underneath the tissue surface clearly shows the GEJ. The OCT imaging probe scans a large field (20 mm × 8 mm) on the tissue, which is about 100× larger compared to the region sampled by a standard biopsy (1-2 mm²). Regions with gastric glandular mucosa (left) and esophageal squamous mucosa (right) exhibit clearly different patterns. Cross-sectional OCT images in Figure 3B-D show the GEJ and esophageal squamous epithelium along the probe pullback and rotation directions, respectively. The GEJ, squamous epithelium, lamina propria/muscularis mucosa, and esophageal glands underneath the squamous epithelium are clearly observed. Features observed in OCT images also match the representative histology of a normal GEJ shown in Figure 3E.

3D-OCT images from a representative patient with a long segment BE confirmed with histology (Figure 4). The *en face* projection OCT image at 200 μm underneath the tissue surface shows a similar angulated pattern compared with the *en face* image shown in the gastric mucosa (Figure 4A). Cross-sectional OCT images (Figure 4B and D) clearly show layered structures, where the original squamous mucosa in the esophagus is replaced by the columnar BE mucosa. Two hyper-scattering layers are observed underneath the BE mucosa, where the top layer corresponds to the newly formed muscularis mucosa layer which replaces the lamina propria, and the bottom

Figure 2 Endoscopic optical coherence tomography imaging of cervical inlet patch. A: Cross-sectional optical coherence tomography images of cervical inlet patch (CIP); B: Adjacent squamous epithelium, respectively; C: Corresponding hematoxylin and eosin histology obtained from a biopsy at the CIP site; D: 3× magnification of the CIP; E: Squamous epithelium (SE) region marked in (A). Scale bars: 1 mm.

Figure 3 Three-dimensional-optical coherence tomography images of a normal gastro-esophageal junction. A: *En face* projection optical coherence tomography (OCT) image at a depth of 350 μm; B: Regions with gastric mucosa and squamous mucosa show distinct features; Cross-sectional OCT image along the probe pullback direction showing the gastro-esophageal junction (GEJ) and normal squamous epithelium (SE) clearly; C, D: Cross-sectional images of the GEJ and SE, corresponding to the green and blue dashed lines marked in (A), respectively. Structures, such as SE, lamina propria (LP)/muscularis mucosa (MM), esophageal glands (arrows) (EG), and gastric mucosa, can be clearly identified; E: Representative histology at the GEJ. Scale bars: 1 mm.

layer corresponds to the muscularis propria. These OCT features are confirmed with corresponding histology of an EMR specimen obtained at the imaging area in the same patient.

Representative OCT images of normal stomach from a patient with chronic heart burn symptom (Figure 5).

Figure 4 Three-dimensional-optical coherence tomography images of a long segment Barrett's esophagus. A: *En face* projection optical coherence tomography (OCT) image at a depth of 200 μm; B: Cross-sectional OCT images of the long segment Barrett's esophagus (BE) along the probe pullback direction; C, D: Cross-sectional OCT images, corresponding to the green and blue dashed lines marked in (A). BE glands, the muscularis mucosa (MM), and the muscularis propria (MP) layers are clearly seen; D: Histology of an endoscopic mucosal resection specimen obtained from the same subject shows corresponding features observed in the OCT images. Scale bars: 1 mm.

The *en face* projection image (Figure 5A) at a depth of 250 μm under the tissue surface represents the typical angulated gastric glandular mucosa pattern. Cross-sectional OCT images (Figure 5B and C) clearly show the gastric glandular mucosa. Gastric pits and gastric glands can be observed from cross-sectional OCT images and the image features match the representative histology of gastric mucosa shown in Figure 5D. Light penetration in normal gastric tissues is also shallower compared with normal esophagus and BE.

Furthermore, 3D-OCT images of normal duodenum from a patient with chronic heart burn symptom are shown in Figure 6. Distinctive features of the intestinal mucosal villi are observed in the *en face* OCT projection image (Figure 6A), as well as in the cross-sectional OCT images (Figure 6B and C). The length of individual villi, measured to be around 300-600 μm, matches the corresponding histology shown in Figure 6E. These results demonstrate the feasibility of using OCT to evaluate GI tissue morphology *in situ* and in real-time.

DISCUSSION

CIP is an under-appreciated entity in general gastroenterologist's practice. In this study, we present imaging results from OCT, a relatively new imaging technology, to describe the gastric type of epithelial patterns in CIP, as clearly distinct from normal esophageal squamous epithelium, BE, or from normal duodenum. Under OCT, CIP exhibits similar columnar structures compared with normal gastric mucosa, and the imaging depth in both CIP and gastric tissues are low. In practice, obtaining biopsies from CIP in patients with troublesome supraesophageal or laryngeal symptoms may be difficult owing to poor view just below the UES. OCT may allow "optical biopsy" of the CIP epithelium without the need for obtaining tissue specimens, and may be used to assess changes suspicious for malignancy in the future. Given its small diameter (2.5 mm) and flexibility, the OCT probes may be introduced orally or nasally without an endoscope, and with better tolerance and potentially less motion artifacts. This may further negate the need for sedation, nursing, or use of the endoscopy unit which has implications beyond endoscopy costs.

There are a number of case reports of adenocarcinoma arising from heterotopic gastric mucosa in the upper esophagus[23-26,40]. To our knowledge, 31 cases have been reported in the literature where esophageal adenocarcinoma was found arising from an inlet patch[41-46] and two cases where laryngeal squamous cell carcinoma was found associated with or bordering inlet patches[47]. The pathogenetic link between BE and CIP raises concerns of dysplastic transformation in CIP. Using immunohistochemical markers to address potential cellular origins,

Figure 5 Three-dimensional-optical coherence tomography images of a normal stomach. A: *En face* projection optical coherence tomography (OCT) image at a depth of 250 μm; B: Cross-sectional OCT image along the probe pullback direction, corresponding to the red dashed line marked in (A); C: Cross-sectional images of the gastric mucosa, corresponding to the blue dashed line marked in (A). Gastric pits (GP) and gastric glands (arrows) (GG) can be identified; D: Representative histology of a gastric mucosa. Scale bars: 1 mm.

Figure 6 Three-dimensional-optical coherence tomography images of a normal duodenum. A: *En face* projection optical coherence tomography (OCT) image at a depth of 350 μm; B: Cross-sectional OCT images of the duodenum along the probe pullback direction; C: Cross-sectional OCT image, corresponding to the blue dashed line marked in (A); Mucosal villous structures (Vi) in the duodenum are clearly seen; D: Corresponding histology of the duodenum showing the villi. Scale bars:

Lauwers *et al*[48] demonstrated similar mechanisms of pathogenesis for CIP and BE on the basis of similarity between immunohistochemical staining patterns between the two entities. Furthermore, the similarity in the expression pattern for cytokeratins 7 and 20 and MUC6 mucin protein were not influenced by the presence or absence of GERD in these CIP patients[48-50]. Based on

these findings, Lauwers *et al*[48] suggested that CIP may arise as a metaplastic change occurring in the esophageal epithelium. In light of these findings and the pathogenetic similarity between CIP and BE based on the cytokeratin expression study by Lauwers, the suspicion that the CIP, at least in adults, arises from local stem cells within the esophagus at or near this "heterotopic" patch

is strong. However, unlike BE, a consensus guideline for surveillance of CIP has not been established on account of its relatively low incidence and lack of information on its natural history for dysplastic changes. In this study, we present an alternative approach to evaluate CIP based on OCT imaging. Recently, balloon based OCT probes have been developed in order to allow imaging over the entire esophageal lumen for screening purposes[35,51-53]. The balloon design also helps stabilize the imaging probe to minimize motion artifacts. The advantages of OCT, such as real-time imaging, large area of coverage, and depth resolved imaging, *etc*., suggest that it may be a useful tool for detection of various GI diseases, including CIP and Barrett's esophagus.

In addition, OCT enables visualization of the deeper esophageal glands underneath squamous mucosa, which may not be accessible with standard or jumbo biopsy forceps. As suggested by Lauwers *et al*[48] CIP may arise from submucosal esophageal mucous glands. If these glands are the origin of dysplasia or malignant transformation, 3D-OCT may be uniquely suited for identifying these early dysplastic changes and following them up. Recently, novel methods have been developed to perform OCT imaging with contrast agents, such as gold nanoparticles[54-57], and therefore enable molecular targeted imaging for early cancer detection. In the future, OCT may also be combined with biomarkers, e.g., the superficial expression of Lgr5 in BE. Localization with depth resolution of such markers may help with directed biopsies or targeted ablation.

Presently, there are no commercially available OCT systems for endoscopic applications. The OCT probe used in this study passes through the working channel of a standard white light endoscope, and the entire OCT system is portable and could fit in a standard endoscopy suite to provide complementary real-time information on tissue microstructures during endoscopy.

One limitation of the current study is the small sample size. Multiple normal subjects and patients with BE were imaged and representative results were shown from a large cohort, but only one subject with CIP was available. The objective of this pilot study is to demonstrate the feasibility of *in situ* imaging of CIP using 3D-OCT and identify characteristic imaging features of CIP compared to other organs in human upper GI tract. One set of representative OCT images from each organ was demonstrated. However, it is not possible to reach any statistical conclusion from this feasibility study.

In conclusion, we demonstrate *in situ* evaluation of CIP microstructure using endoscopic 3D-OCT. OCT imaging visualized columnar epithelial structures within the CIP region, which clearly contrasted with the squamous epithelium from adjacent normal esophagus, gastric mucosa in the stomach and villous structure in the duodenum. The microstructural features observed with OCT also matched those from H and E histological sections. These results demonstrated the feasibility of using OCT to evaluate GI tissue morphology *in situ* and

in real-time. Since OCT imaging can be performed with small diameter probes introduced orally or nasally, this emerging technology might be used to screen patients with troublesome upper esophageal symptoms for CIP, BE and other changes in the epithelium, even without endoscopy or the need for conscious sedation.

ACKNOWLEDGMENTS

COMMENTS

Background
Cervical inlet patch (CIP) is an under-appreciated entity encountered by gastroenterologists in general practice. Although rare, several reports suggest that CIP may progress to adenocarcinoma. Optical coherence tomography (OCT) is an emerging medical imaging technology that enables micron-scale, cross-sectional, and 3D imaging of biological tissues *in situ* and in real-time.

Research frontiers
This study evaluates whether OCT can optically assess epithelial differences in upper human gastrointestinal (GI) tract *in situ*.

Innovations and breakthroughs
OCT imaging over the CIP region showed columnar epithelium structure, which clearly contrasted the squamous epithelium structure from adjacent normal esophagus. OCT images obtained from other patients demonstrated distinctive patterns of the normal esophagus, Barrett's esophagus, normal stomach, and normal duodenum. Microstructures, such as squamous epithelium, lamina propria, muscularis mucosa, muscularis propria, esophageal glands, Barrett's glands, gastric mucosa, gastric glands, and intestinal mucosal villi were clearly observed with OCT and matched with hematoxylin and eosin histology. OCT may allow real-time "optical biopsy" of the CIP epithelium without the need for obtaining tissue specimens, and may be used to assess suspicious changes of malignancy in the future.

Applications
Given its small diameter and flexibility, the OCT probe may be introduced orally or nasally without an endoscope or need for moderate sedation, and with better tolerance and potentially less motion artifacts compared to endoscopy. In addition, the OCT imaging probe scans an approximately 100× larger field compared to biopsy, and therefore, might be useful in the future to screen for CIP.

Peer review
The paper is a very interesting piece of work exploring the utility of OCT primarily in characterizing cervical inlet patch but also in other esophageal disorders. It provides a reader with the future directions of and technological advances in upper GI endoscopy in an era when a number of non-white light endoscopic contrast techniques are competing for prime time use to more accurately delineate and diagnose pathology.

Abstract

AIM: To investigate the association between serum antibody levels and a subsequent celiac disease diagnosis in a large series of children and adults.

METHODS: Besides subjects with classical gastrointestinal presentation of celiac disease, the study cohort included a substantial number of individuals with extraintestinal symptoms and those found by screening in at-risk groups. Altogether 405 patients underwent clinical, serological and histological evaluations. After collection of data, the antibody values were further graded as low [endomysial (EmA) 1:5-200, transglutaminase 2 antibodies (TG2-ab) 5.0-30.0 U/L] and high (EmA 1: ≥ 500, TG2-ab ≥ 30.0 U/L), and the serological results were compared with the small intestinal mucosal histology and clinical presentation.

RESULTS: In total, 79% of the subjects with low and 94% of those with high serum EmA titers showed small-bowel mucosal villous atrophy. Furthermore, 96% of the 47 EmA positive subjects who had normal mucosal villi and remained on follow-up either subsequently developed mucosal atrophy while on a gluten-containing diet, or responded positively to a gluten-free diet.

CONCLUSION: Irrespective of the initial serum titers or clinical presentation, EmA positivity as such is a very strong predictor of a subsequent celiac disease diagnosis.

INTRODUCTION

Recent serological screening studies have revealed that up to 1%-2% of the Western population might be affected by celiac disease[1,2]. However, due to its heterogeneous clinical picture the disease remains markedly underdiagnosed. Sensitive serum endomysial (EmA) and transglutaminase 2 antibodies (TG2-ab) are widely used as a method to select subjects for further investigations, but the diagnosis is based on the presence of small-bowel mucosal villous atrophy and crypt hyperplasia[3,4]. Unfortunately, the histological definition of the disease involves several problems. First, invasive studies are needed to acquire the mucosal specimens. In addition, biopsy samples may be of poor quality or wrongly orientated, increasing the risk of false positive or negative results[5]. The mucosal damage may be patchy and missed even if several samples are taken[6,7]. Finally, the histological lesion develops gradually and interpretation of borderline cases can be challenging. Since particularly EmA and high values of TG2-ab seem to predict celiac disease with a high specificity, it has been advocated that in seropositive subjects endoscopic studies might not always be needed to establish the diagnosis[8-15]. However, most studies so far have been carried out in tertiary centers with high-risk patients, and the results might not be applicable in everyday clinical practice.

In our local health-care district active celiac disease case-finding has been carried out since the 1980s. As a result, a substantial part of the patients are detected because of atypical symptoms or by active risk-group screening, and currently about 0.7% of the population have a biopsy-proven diagnosis[16]. Hence, we now sought to establish whether the serum antibodies could predict subsequent celiac disease also in subjects with mild or atypical clinical presentation. Because of the high specificity, EmA has traditionally been considered the gold standard for celiac disease serology, and was thus chosen as the primary inclusion criterion[17,18]. In addition, the results were compared to the widely used serum TG2-ab.

MATERIALS AND METHODS

The study cohort comprised consecutive EmA positive children and adults investigated at the Departments of Pediatrics and Gastroenterology and Alimentary Tract Surgery, Tampere University Hospital. Primary care physicians were encouraged to refer individuals with celiac disease suspicion for further investigations applying a low index of suspicion. In addition, subjects who participated in population-based research studies were accepted. In the hospital demographic data, a family history of celiac disease and symptoms leading to the disease suspicion were recorded, and all subjects underwent extensive clinical, serological and histological evaluations. Thereafter, voluntary EmA positive children and adults continued in the trial. Participants who showed small-bowel mucosal villous atrophy and crypt hyperplasia (Marsh III) received a celiac disease diagnosis and were placed on a gluten-free diet. Subjects who had normal villi continued on a gluten-containing diet and were placed on regular serological and histological follow-up. In addition, the possibility to start an experimental trial with a gluten-free diet was offered to EmA positive individuals with normal villous structure (Marsh 0-II). Those who consented were re-evaluated after one year, and if a positive clinical, serological and histological response was observed, celiac disease diagnosis was established. Finally, serum TG2-ab were used for comparison in all from whom they were available.

Serum immunoglobulin A (IgA)-class EmA were measured by an indirect immunofluorescence method using human umbilical cord as antigen[19]. A dilution of 1:5 was considered positive, and positive sera were further diluted 1:50, 1:100, 1:200, 1:500, 1:1000, 1:2000 and 1:4000. The antibody titers were further graded as low (1:5-1:200) and high (1:500-1:4000). Serum IgA-class TG2-ab were measured by enzyme-linked immunosorbent assay (ELISA) (Celikey, Phadia GmbH, Freiburg, Germany) according to the manufacturers' instructions. Serum TG2-ab values $\geq$ 5.0 U were considered positive, and the values were further graded as low (5.0-29.9 U/L) and high ($\geq$ 30 U/L)[13]. Total IgA values were tested in all subjects negative to the IgA class serological tests. In case of IgA deficiency the corresponding antibodies were measured in immunoglobulin G (IgG) class.

Upon upper gastrointestinal endoscopy a minimum of three forceps specimens were taken from the distal duodenum, and small-bowel mucosal morphology was determined from several well-oriented biopsy sections as previously described[17]. The degree of mucosal damage was further graded according to the Marsh-Oberhuber classification, where Marsh 0 represents normal mucosa, Marsh I-II represents increased intraepithelial lymphocytosis without (I) or with (II) hyperplastic crypts and Marsh III partial (a), subtotal (b) or total (c) villous atrophy[20,21]. A patchy mucosal lesion was graded according to the most severe histological damage.

Genotyping of the participants for celiac disease-associated human leukocyte antigen (HLA)-DQB1*02 and DQB1*0302 alleles (DQ2 and DQ8) was performed using the DELFIA® Celiac Disease Hybridization Assay (PerkinElmer Life and Analytical Sciences, Wallac Oy, Turku, Finland) or the SSP™ DQB1 low resolution kit (Olerup SSP AB, Saltsjöbaden, Sweden) according to the

manufacturer's instructions.

χ^2 with cross-tabulation was used for statistical analysis. A *P* value less than 0.05 was considered statistically significant.

The study protocol was approved by the Ethics Committee of Tampere University Hospital. All subjects or their parents gave written informed consent.

RESULTS

In total, 405 EmA positive children and adults participated in the study. In 10 subjects the quality of the small-bowel biopsies was insufficient, in 14 EmA was determined as positive (1:5) without further dilution and in three subjects the clinical data were ambiguous. These cases were excluded from further statistical analyses. One patient had selective IgA deficiency and the corresponding antibodies were measured in the IgG class. Gastrointestinal symptoms remained the primary reason for celiac disease suspicion, but almost half of the patients were detected on the basis of extraintestinal symptoms or by screening of at-risk groups and the population (Table 1).

By definition, all participants were positive for EmA.

EmA: Endomysial.

Serum TG2-ab were measured in 316 EmA positive subjects and proved positive in 286 (91%) of them. Altogether 41% of the participants had high EmA and 54% high TG2-ab value defined at baseline. There was a significant association between serum TG2-ab level and clinical presentation, low antibody values being more common in the screen- than symptom-detected subjects (Table 2). A similar trend was observed with EmA, but the results were not statistically significant (*P* = 0.061).

Small-bowel mucosal villous atrophy and crypt hyperplasia (Marsh III) were found in altogether 85% of the EmA-positive subjects. There was a significant association between high antibody values and more severe small-bowel mucosal deterioration; in total 94% of those with high EmA titer evinced villous atrophy (Table 3). There was in this respect no significant difference between children and adults. The percentage of subjects evincing severe small-bowel mucosal damage increased progressively with higher EmA titers, but only the highest titer 1:4000 was 100% predictive of subsequent villous atrophy and crypt hyperplasia (Table 4).

In total, 40 patients had low and 17 high serum antibody values without simultaneous villous atrophy (Table 5). Irrespective of the baseline titers, 45 (79%) of these subjects (96% of those who remained on follow-up) either subsequently developed villous atrophy while on a gluten-containing diet, or experienced a positive clinical and serological response and disappearance of early mucosal changes on a gluten-free diet (Table 5). The pres-

ence of the celiac disease-associated HLA-DQ2 or DQ8 genotype was assessed in 299 EmA positive subjects and was found in all of them.

DISCUSSION

In our large series consisting of both children and adults, approximately half of the participants evinced high serum EmA levels, which was indicative of subsequent small-bowel mucosal villous damage in up to 94% of them. The results showed a high antibody titer to be an excellent predictor of villous atrophy and celiac disease also in high disease prevalence areas and in subjects with subtle or atypical symptoms. In the past few decades it has been observed that besides the classical gastrointestinal presentation, celiac disease patients may have a wide range of different extraintestinal symptoms. The patients may suffer for example from arthralgia or arthritis, osteoporosis, infertility and different neurological symptoms. In addition, screen-detected celiac patients may show only minor laboratory abnormalities or have no symptoms at all[3]. It was essential to investigate the performance of the celiac autoantibodies also in these atypical patients, as they are frequently seen in clinical practice, and may in fact represent the most common clinical presentation of celiac disease[16].

In patients with classical gastrointestinal celiac disease, Valdimarsson *et al*[8] observed a 100% positive predictive value of EmA for celiac disease in 19 adults, and suggested that histological confirmation might not be necessary in all such seropositive patients. Recently, similar results have been obtained with high values of TG2-ab. In a study by Barker *et al*[10], 48 out of 49 children having TG2-ab more than five times the upper limit of normal (ULN) had diagnostic small bowel mucosal damage. Likewise, Donaldson *et al*[11] observed a 100% positive predictive value for celiac disease by using the same cut-off level. In adults, Hill *et al*[13] suggested that TG2-ab levels more than ten times ULN would be exclusively indicative for celiac disease, and some other authors have presented comparable results[12].

Our findings thus largely accord with those in earlier studies carried out in specialized centers with high-risk patients having classical gastrointestinal presentation of celiac disease. Nevertheless, in the present study there was still a subpopulation of individuals in whom the current histological criteria were not fulfilled. Approximately 6% of the participants with high and up to 21% of those with low antibody values had normal small-bowel mucosal villous structure, and in total this was seen in 15% of the EmA-positive subjects. It could thus be argued that EmA are not sufficiently specific for a definite diagnosis of celiac disease as such. Interestingly, however, there is an increasing body of data showing that EmA positivity is a very strong predictor of forthcoming celiac disease also in subjects with initially normal villi[17,22-26]. In line with this conception, almost all of our EmA positive patients who had no structural villous damage either evinced a positive serological, clinical and histological response to a gluten-free diet, or subsequently developed villous atrophy while on a normal diet. The existence of a celiac-type disorder in these individuals was further supported by the presence of the relevant HLA type in all in whom it was measured. There is thus strong evidence that, irrespective of the initially normal villous morphology, these EmA positive subjects are truly suffering from celiac disease.

Our study is subject to some limitations. First, although a high percentage of the participants had mild or atypical clinical presentation, the number of those found by population-based serological screening was rather low. Consequently, the results cannot be generalized to this patient group, and further studies are needed[27]. Secondly, the mucosal biopsies were taken from the distal duodenum as previously recommended[28]. Judging from recent evidence, however, villous atrophy can occasionally be detected only in the bulb area of the small intestine, and in theory celiac disease might in such cases already have been confirmed at the time of the first biopsy[7]. Nevertheless, interpretation of bulb specimens may be biased on Brunner glands or peptic inflammation, and their role in the diagnostics remains controversial. In addition, a patchy small-bowel mucosal lesion is always possible in celiac disease, which further highlights the importance of serology in the diagnosis.

Although EmA shows excellent specificity for an untreated celiac disease, it has certain limitations. The immunofluorescence method is laborious, time-consuming and always somewhat subjective. Since TG2-abs can be easily measured using a practical ELISA method, it would be tempting to use it instead of EmA. Neverthe-

less, TG2-ab are measured by commercial tests which use different epitopes of TG2 as antigen, and thus the specificity figures for the method have been somewhat inconsistent. Consequently, the positive predictive value of TG2-ab has sometimes been rather low, particularly in low-risk populations[29]. TG2-ab can also be positive in some conditions such as in liver diseases[30]. For these reasons, we decided to use the more laborious and time-consuming but celiac disease-specific EmA as the primary inclusion criterion in our series. As a consequence, the results should not be applied to TG2-ab positive EmA negative subjects. Finally, since antibody-negative subjects were not included in our study, the overall sensitivity of the serological tests could not be obtained.

To conclude, EmA positivity as such is a very strong predictor of a subsequent celiac disease diagnosis also in patients with low serum antibody titers and subtle or atypical clinical presentation. Judging from the findings here, invasive endoscopic studies might not be obligatory in all such seropositive patients.

COMMENTS

Background
The diagnosis of celiac disease is based on the presence of small-bowel mucosal villous atrophy and crypt hyperplasia, but this histological definition involves several problems. Since particularly endomysial (EmA) and high values of transglutaminase 2 antibodies (TG2-ab) seem to predict celiac disease with high specificity, it has been advocated that in seropositive subjects with gastrointestinal symptoms endoscopic studies might not be obligatory to establish the diagnosis.

Research frontiers
New diagnostic criteria of celiac disease based to serological tests might make the burdensome and invasive endoscopic investigations unnecessary. The authors aimed to investigate the association between serum antibody levels and a subsequent celiac disease diagnosis in children and adults with a heterogeneous clinical presentation.

Innovations and breakthroughs
The results showed that high positive values of serological tests are excellent predictors of subsequent villous atrophy and celiac disease also in subjects with atypical or subtle clinical presentation. In addition, positivity of EmA is a very strong indicator of celiac disease diagnosis irrespective of the baseline titers.

Applications
These results indicate that gastrointestinal endoscopy might be omitted and celiac disease diagnosis established without further histological confirmation in children and adults with positive EmA.

Terminology
Celiac disease is a chronic autoimmune-based triggered by ingested gluten in genetically susceptible individuals. EmA and TG2-ab are serological test with high accuracy for an untreated celiac disease.

Peer review
This is a nice study that highlights the significance of positive EmA results in a large series of children and adults. The paper is well-written and adds pertinent information to the literature.

Abstract

AIM: To evaluate the efficacy and safety of adjunctive mosapride citrate for bowel preparation before colonoscopy.

METHODS: We conducted a randomized, double-blind, placebo-controlled study with mosapride in addition to polyethylene glycol (PEG)-electrolyte solution. Of 250 patients undergoing colonoscopy, 124 were randomized to receive 2 L PEG plus 15 mg of mosapride citrate (mosapride group), and 126 received 2 L PEG plus placebo (placebo group). Patients completed a questionnaire reporting the acceptability and tolerability of the bowel preparation process. The efficacy of bowel preparation was assessed by colonoscopists using a 5-point scale based on Aronchick's criteria. The primary end point was optimal bowel preparation rates (scores of excellent/good/fair *vs* poor/inadequate).

RESULTS: A total of 249 patients were included in the analysis. In the mosapride group, optimal bowel preparation rates were significantly higher in the left colon compared with the placebo group (78.2% *vs* 65.6%, *P* < 0.05), but not in the right colon (76.5% *vs* 66.4%, *P* = 0.08). After excluding patients with severe constipation, there was a significant difference in bowel preparation in both the left and right colon (82.4% *vs* 66.7%, 80.8% *vs* 67.5%, *P* < 0.05, *P* < 0.01). The incidence of adverse events was similar in both groups. Among the subgroup who had previous colonoscopy experience, a significantly higher number of patients in the mosapride group felt that the current preparation was easier compared with patients in the placebo group (34/72 patients *vs* 24/74 patients, *P* < 0.05).

CONCLUSION: Mosapride citrate may be an effective and safe adjunct to PEG-electrolyte solution that leads to improved quality of bowel preparation, especially in patients without severe constipation.

INTRODUCTION

Polyethylene glycol (PEG)-electrolyte solution is used worldwide for bowel cleansing. Approximately 2 L of this oral solution, along with a laxative, is usually required for adequate bowel preparation in Japan[1]. However, the need to drink such large volumes of liquid with an unpalatable taste has a negative impact on patient compliance[2]. A thorough bowel preparation is required for safe and effective colonoscopy, and inadequate preparation not only decreases the sensitivity, but also increases the difficulty of the procedure[3-5]. Therefore, more effective bowel preparation regimens for colonoscopy are required to improve the acceptability and tolerability of the procedure. Prokinetics such as domperidone, metoclopramide, and cisapride have been used in combination with PEG-electrolyte solution to improve the quality of bowel preparation[6-12]. However, the addition of prokinetic agents to PEG-electrolyte solution has not been proven to improve patient tolerance or colonic cleansing[10-12] and is sometimes associated with serious adverse effects. For example, domperidone and metoclopramide may cause extrapyramidal symptoms with long-term use[13]. Cisapride was withdrawn from the market because of severe cardiac side effects, including QT-interval prolongation and ventricular arrhythmias[14]. Thus, safer and more effective prokinetic agents are needed.

Mosapride citrate (mosapride) is a selective 5-hydroxy-tryptamine-4 (5-HT4) receptor agonist. Mosapride enhances gastric emptying and motility by facilitating acetylcholine release from the enteric cholinergic neurons, without blocking dopaminergic D2 receptors[15]. It is known to be effective in gastroesophageal reflex disease[16], functional gastrointestinal disorders, such as functional dyspepsia[17], chronic gastritis with delayed gastric emptying, and diabetic gastroparesis[18]. As 5-HT4 receptors are also located in the human colon and rectum[19,20], mosapride is also expected to have a prokinetic effect on the colo-rectum. A few clinical studies have reported that mosapride in combination with PEG may enhance bowel cleansing and improve patient acceptability and tolerability[21,22]. However, the efficacy and tolerability of a PEG-electrolyte solution with or without mosapride has not been studied in a double-blind, randomized trial.

Figure 1 Steps of preparation for colonoscopy.

We conducted this study to evaluate the efficacy, acceptability, and tolerability of mosapride as an adjuvant to PEG-electrolyte solution for colonoscopy preparation.

MATERIALS AND METHODS

This was a prospective, double-blind, randomized, controlled study that included patients who underwent colonoscopy at Aichi Cancer Center Hospital (ACCH), Nagoya, from January 2009 to October 2009. This study was reviewed and approved by the ethics committee of ACCH.

Study population

All consecutive outpatients aged 20-80 years who were scheduled for colonoscopy at ACCH were evaluated for study inclusion. Patients with the following clinical features were excluded: presence of significant cardiac, renal, hepatic, or metabolic comorbidities; presence of ascites or bowel obstruction; known allergy to PEG-electrolyte solution; history of gastric stapling or bypass procedure; or a history of prior colonic or rectal surgery. A gastroenterologist assessed patient eligibility, and written informed consent was obtained from each patient prior to inclusion.

Randomization and blinding

Patients were randomly allocated to receive one of two bowel preparation regimens using a computer-generated random-number list. Patients were randomized in block sizes of two, with serially numbered, sealed, opaque envelopes. Concealed allocation was accomplished through non-research personnel who were not involved in this study. Comparisons between subjects who received 2 L PEG plus mosapride (mosapride group) and 2 L PEG plus placebo (placebo group) were made in a double-blind fashion.

Bowel preparation methods

The colonoscopy preparation steps used in this study are shown in Figure 1. The day before colonoscopy, all patients were instructed to eat a pre-packaged, low-residue diet (Enimaclin CS; Horii Pharmaceutical Ind., Ltd., Osaka, Japan) that consisted of a lunch, snack, and dinner, and were asked to drink more than 2 L of clear

liquid. On the day of the colonoscopy, all participants reported to the endoscopy room at 9:00 am, and received in-hospital bowel preparation. In-hospital preparation is important to ensure the uniformity of procedures within the study, and to remove any confounding caused by poor patient adherence. More than 10 toilet facilities were made available in the endoscopy unit for patient comfort. Six mosapride tablets (15 mg) (Gasmotin; Dainippon Sumitomo Pharma Co., Ltd., Osaka, Japan) or six identical-looking placebo tablets were administered orally with water at 09:30. The timing of administration of the mosapride tablets was based on its pharmacokinetics[23]. After 30 min, both groups were instructed to drink 0.25 L of PEG-electrolyte solution (Niflec; Ajinomoto Pharmaceticals Co., Ltd., Tokyo, Japan) every 15 min.

Evaluation of bowel preparation

The efficacy of bowel preparation was assessed using Aronchick's criteria[24], as follows: (1) Excellent (small volume of clear liquid, or greater than 95% of colonic surface seen); (2) Good (large volume of clear liquid covering 5% to 25% of colonic surface, but greater than 90% of surface seen); (3) Fair (some semisolid stool that could be suctioned or washed away, but greater than 90% of surface seen); (4) Poor (some semisolid stool that could not be suctioned or washed away, and less than 90% of surface seen); and (5) Inadequate (repeat preparation and colonoscopy needed). Participating endoscopists were trained to use Aronchick's criteria to achieve a good level of agreement. Investigators performed calibration exercises involving more than 20 colonoscopies prior to study commencement, based on their interpretation of scale anchors, to ensure that their findings agreed. The final assessment of bowel preparation was divided into two categories: optimal and non-optimal. Bowel preparations rated as fair, good, or excellent, based on Aronchick's criteria, were considered optimal; poor or inadequate ratings were considered non-optimal. After colonoscopy, two observers, including the endoscopist performing the procedure, determined the score by mutual agreement. They scored the quality of the preparation in the right colon (proximal to the splenic flexure), and the left colon (distal to the splenic flexure) and rectum separately. If the decision was discordant, a third expert reviewer graded and scored the recorded images, and this evaluation was used in the final analysis.

During or immediately following the colonoscopy, the investigator completed a physician questionnaire regarding the assessment of bowel preparation, amount of irrigation fluid used, time to reach the cecum, and ease of insertion into the cecum and visualization of the colonic lumen regardless of peristalses.

Patient tolerance and other measurements

The nursing staff recorded the time required to drink the indicated volume of lavage solution. They also recorded the time and number of motions from start of ingestion to the appearance of clear excretions. The nursing staff checked excretions until 1 h after patients finished the PEG + mosapride solution. If there was a solid stool with muddy excretions or no excretion at that time, we gave the patient an additional preparation, such as additional PEG or enema. A warm water enema of 500 mL volume was given until the excretions were clear. Patients who received an additional preparation were defined by Aronchick's criteria as inadequate. The patient questionnaire, which was administered before bowel cleansing, consisted of 20 questions pertaining to patient characteristics, tolerability, and acceptability of study medication. It also included questions about the following: age; height; body weight; average number of bowel movements per week for the last year; number of previous colonoscopies; compliance with ingestion of PEG-electrolyte solution; willingness to repeat the same preparation regimen again, if required; ease/difficulty of taking the preparation compared with previous experiences; and presence of subjective symptoms while drinking PEG-electrolyte solution, such as nausea, vomiting, fullness, abdominal pain, and circulatory reactions such as palpitations or chest discomfort. We defined patients who suffered from constipation (defined as < 2 bowel movements per week) for > 1 year as having severe constipation. Patients completed the questionnaire before undergoing the colonoscopy and submitted the form to the nursing staff.

Endpoints

The primary endpoint was the difference in optimal rate of colon cleansing in the mosapride and placebo groups. Secondary endpoints included differences in patients' acceptability and tolerance of solutions, time to first defecation, frequency of defecation, complete time for colonic preparation, time needed to reach the cecum, amount of irrigation fluid used, and subjective difficulty in colonoscopy insertion to the cecum and in observing the lumen of the colo-rectum because of peristalses.

Statistical analysis

The study was designed to detect an inter-group difference of 11% in the percentage of patients with optimal bowel preparation, with an α error of 5% and a power of 80%. This difference was based on a previous study[21]. The number of patients needed to demonstrate an 11% difference was 125 per treatment group, assuming a dropout rate of 10%.

The primary efficacy analysis was based on an intent-to-treat analysis and included patients who were randomized and received any treatment. The preparation of patients in this group was considered optimal or non-optimal based on the colonoscopist's score regarding cleansing. Patients who did not undergo colonoscopy because of preparation-related adverse events, or preparation failure, or in whom the right colon could not be reached because of bowel obstruction or for technical reasons were excluded. The rates of optimal preparation were compared between the groups by the Chi-square test or Fisher's exact test for categorical variables.

For secondary endpoints, the Mann-Whitney *U* test was used for comparison between continuous variables. Categorical variables were analyzed using the corrected χ^2 or two-sided Fisher's exact tests, where appropriate. The criterion for statistical significance was $P < 0.05$.

All statistical analyses were performed using Statistical Analysis Software (SPSS, version 12.0J for the PC, SPSS Japan, Inc., Tokyo, Japan).

RESULTS

Patient characteristics

A total of 250 patients were randomized into two groups (Figure 2). Of those randomized to treatment, only one patient did not receive any treatment or undergo colonoscopy because he felt chilled and had a fever before treatment. Although 249 patients were analyzed, insertion of the colonoscope into the right colon failed in five (4%) patients in the mosapride group (advanced stenosing cancer in three and patient refusal in two), because of pain on colonoscopic advancement to the proximal colon. These five patients were excluded from the efficacy analysis of the right colon. Baseline characteristics of the patients are shown in Table 1. Differences in age, gender, body mass index, and the number of previous colonoscopies between the mosapride and placebo groups were not significant. However, significantly more patients suffering from severe constipation (defined as < 2 bowel

movements per week for > 1 year) were included in the mosapride group compared with the placebo group (*P* < 0.05). Therefore, we compared the efficacy, acceptability, and tolerability of the bowel preparation solution in subgroups of patients with or without severe constipation.

Bowel cleansing efficacy

As shown in Table 2, time to first defecation was significantly shorter in the mosapride group compared with the placebo group (*P* < 0.001). After excluding patients with severe constipation, the completion time for bowel preparation was significantly shorter in the mosapride group compared with the placebo group (*P* < 0.05). There were no differences in frequency of defecation, the elapsed time from last fluid intake to colonoscopy, time needed to reach the cecum, amount of irrigation fluid used, subjective difficulties in insertion to the cecum, and in observing the lumen of the colo-rectum between groups, or in the frequency of positive endoscopic findings.

The efficacy of bowel preparation is shown in Table 3.

Twenty-five (20.2%) patients required additional preparation in the mosapride group (mean 0.6 L additional PEG in 22 patients, 0.5 L enema in one patient, and both in two patients). Thirty-eight (30.4%) patients required additional preparation in the placebo group (mean 0.75 L PEG in 35 patients, 0.5 L enema in one patient, and both in two patients).

In the right colon, the number of bowel preparations rated as excellent was significantly higher in the mosapride group than in the placebo group (*P* < 0.05). However, the rate of optimal preparations did not differ significantly between groups (*P* = 0.08) (Table 3). After excluding patients with severe constipation, there were significant differences in the number of bowel preparations rated as excellent and the rate of optimal preparation in the mosapride group (*P* < 0.01 and *P* < 0.05 in the right colon and *P* < 0.05 and *P* < 0.01 in the left colon, respectively) (Table 4). In the left colon and rectum, the number of bowel preparations rated as excellent and the rate of optimal preparation were significantly higher

in the mosapride group than in the placebo group ($P < 0.05$ and $P < 0.05$, respectively). These significant differences were maintained even after excluding patients with severe constipation ($P < 0.05$ and $P < 0.05$, respectively).

Patient tolerability and safety
There were no significant differences in compliance, as defined by > 80% and 100% intake of the PEG solution between the two groups (Table 5). Frequencies of symptoms such as nausea, vomiting, distension, abdominal pain, and circulatory reactions were similar in both groups. The proportion of patients who were willing to repeat the same preparation regimen was also similar in the two groups. However, among the subgroup of patients who had undergone a colonoscopy more than twice in the past, a significantly higher number of patients in the mosapride group felt that the current preparation was easier compared with patients in the placebo group ($P < 0.05$). This significant difference was maintained even after excluding patients with severe constipation ($P < 0.05$).

DISCUSSION

This is the first prospective, randomized, double-blind, placebo-controlled study to evaluate the efficacy, accept-

ability, and tolerance of mosapride as an adjuvant to PEG-electrolyte solution for colonoscopy preparation. Mosapride is a benzisoxazole derivative prokinetic drug that is used for the treatment of gastrointestinal symptoms associated with chronic gastritis and functional dyspepsia[16,17,25-28]. It facilitates acetylcholine release from the enteric cholinergic neurons by its selective 5-HT4 receptor agonistic action[26]. It is also active through its main metabolite M1, which is a 5-HT3 agonist. The action of mosapride resembles that of a previously used 5-HT4 agonist, cisapride, which had been reported to be useful for bowel preparation[29,30]. Cisapride had additional effects of blocking K channels and D2 dopaminergic receptors and was withdrawn after its K channel blocking properties led to reports of QT interval prolongation and cardiac arrhythmias. In contrast to cisapride, mosapride does not block K channels or D2 dopaminergic receptors and is believed to have less cardiac toxicity[31].

5-HT4 receptors are present in the myenteric plexus and the muscle of stomach and colon, and mosapride has high affinity for these receptors[20,29,32]. In human studies, mosapride has been found effective for slow transit constipation, outlet obstruction-type constipation, constipation in Parkinson's disease, and constipation associated with irritable bowel syndrome[33-35]. Recently, in guinea

pigs, it was reported that mosapride enhanced the colon cleansing action of PEG *via* an increase in colonic transit, reducing not only fecal residue but also excessive fluid in the colonic lumen[36]. However, it is unclear whether mosapride would have additive beneficial effects on bowel cleansing before colonoscopy in humans.

We found that the rate of optimal preparation was significantly higher in the mosapride group compared with the placebo group in the left colon and rectum, but not in the right colon. The number of patients with bowel preparations rated as excellent was significantly higher for the mosapride group compared with the placebo group, especially for the right colon. Kim *et al*[37] have also described this differential efficacy of mosapride between the right and left colon in guinea pigs, and ascribed this finding to the differential distribution of colonic 5-HT4 receptors. Although the rates of optimal preparation were not significantly different in the right colon, the number of bowel preparations rated as excellent was significantly higher with the use of mosapride. Furthermore, after excluding patients with severe constipation, the rate of optimal preparation was significantly higher in the mosapride group compared with the placebo group. These findings support the efficacy of mosapride for bowel preparation.

In this study, many patients required additional bowel preparation. One possible reason may be that the nursing staff checked excretions 1 h after finishing the preparation, which may have been too short an interval for the PEG solution to adequately cleanse the colon. However, the rate of inadequate cleansing was significantly lower in the mosapride group compared with the placebo group. Furthermore, the time to first defecation was also significantly shorter in the mosapride group. The beneficial effect of mosapride on gastric emptying was expected to ameliorate nausea, vomiting, and fullness of the abdomen during bowel preparation. Mishima *et al*[22] showed that administration of mosapride prior to PEG solution significantly decreased the incidence of uncomfortable abdominal symptoms. However, there were no significant differences in the frequencies of these symptoms between the mosapride group and the placebo group in this study, and more patients were willing to repeat the same preparation regimen in the placebo group. This finding may be due to more abdominal distension and pain in the mosapride group due to its prokinetic effects. According to a postmarketing surveillance study, the most common adverse events associated with mosapride are abdominal pain and loose stools (both 0.35%)[38]. On the other hand, a larger proportion of patients in the mosapride group than in the placebo group felt that the preparation was easier to complete. These findings may support the efficacy of mosapride in terms of patient tolerance and acceptability. It is possible that 2 L of PEG solution is so large that these symptoms are unavoidable; in addition, it is also possible that the dose of mosapride was not sufficient to alleviate these symptoms.

Co-administration of laxatives such as sennoside and bisacodyl with lavage solution has been shown to improve colonic cleansing during colonoscopy. Addition of these adjunctive therapies has also allowed for lower volume PEG solutions to be administered with equivalent or increased efficacy. However, the adjunctive therapies have to be taken the day before the procedure. This may lead to sleep disturbances and inconvenience due to frequent defecation. If it is possible to begin the bowel preparation using mosapride on the same day as the colonoscopy, patient tolerability may improve.

Recently, it has been suggested that co-administration of mosapride and PEG-electrolyte solution is useful in preparing the colon for barium enema examination as it allows good evacuation of remaining feces[39]. As a result, mosapride is now approved in Japan for preparation for a barium enema examination, and a total dose of 40 mg mosapride is used. Major side effects have not been reported in Japan with this dose. In the present study, we administered 15 mg of mosapride for colonoscopy preparation, which is the recommended usual daily dosage of mosapride for adult patients with chronic gastritis. However because the effects of mosapride are reported to be dose-dependent[35,40], additional studies that address optimal dosage and timing of administration are required to clarify the best regimen for colonoscopy.

One of the limitations of this study was that there was a significant difference in the number of patients with severe constipation between the two groups. However, even with the inclusion of patients with severe constipation, there was a non-significant trend for improved preparation in the mosapride group, and this difference became significant after the exclusion of this subgroup. It is possible that for patients with severe constipation, the dose of 15 mg mosapride may be insufficient. The second limitation of this study was its single center location. Finally, we did not evaluate laboratory abnormalities, as co-administration of mosapride and PEG-electrolyte solution is already common in Japan for preparation for barium enema examination[39]. No serious laboratory abnormalities have been reported in Japan with a 40-mg dose of mosapride.

In conclusion, we demonstrated that co-administration of mosapride with PEG-electrolyte solution improves the quality of bowel preparation for colonoscopy in the left colon. Mosapride may be an effective and safe adjunct to PEG that leads to improved quality of bowel preparation, especially in patients without severe constipation.

COMMENTS

Background
Although prokinetics have been used in combination with polyethylene glycol (PEG)-electrolyte solution to improve patient acceptability and tolerance, as well as improve bowel cleansing, the efficacy and safety of these agents remain unproven. Prokinetics such as domperidone, metoclopramide, and cisapride have been used in combination with PEG-electrolyte solution to improve the quality of bowel preparation. However, the addition of prokinetic agents to PEG-electrolyte solution has not been proven to improve patient tolerance or colonic cleansing and can be sometimes associated with serious adverse effects. Thus, safer and more effective prokinetic agents are needed.

Research frontiers

Mosapride citrate (mosapride) is a selective 5-hydroxytryptamine-4 (5-HT4) receptor agonist. Mosapride enhances gastric emptying and motility by facilitating acetylcholine release from the enteric cholinergic neurons, without blocking dopaminergic D2 receptors. It is known to be effective in gastroesophageal reflex disease, functional gastrointestinal disorders, such as functional dyspepsia, chronic gastritis with delayed gastric emptying, and diabetic gastroparesis. As 5-HT4 receptors are also located in the human colon and rectum, mosapride is also expected to have a prokinetic effect on the colo-rectum. A few clinical studies have reported that mosapride in combination with PEG may enhance bowel cleansing and improve patient acceptability and tolerability.

Innovations and breakthroughs

This is the first prospective, randomized, double-blind, placebo-controlled study to evaluate the efficacy, acceptability, and tolerance of mosapride as an adjuvant in PEG-electrolyte solution for colonoscopy preparation. This study demonstrated that co-administration of mosapride with PEG-electrolyte solution improves the quality of bowel preparation for colonoscopy in the left colon.

Applications

The study results suggest that mosapride may be an effective and safe adjunct to PEG, leading to an improved quality of bowel preparation, especially in patients without severe constipation. Additional studies that address optimal dosage and timing of administration are required to clarify the best bowel preparation method for colonoscopy.

Terminology

PEG-electrolyte solution: PEG-electrolyte solution is used worldwide for bowel cleansing. Approximately 2 L of this oral solution with some laxatives is usually required for adequate bowel preparation in Japan. However, the need to drink such large volumes of liquid with an unpalatable taste has a negative impact on patient compliance.

Peer review

This is an interesting and well written study. The methodology and evaluation of data is correct. The conclusion sounds good and useful for the general practice.

Abstract

AIM: To determine the utility of endoscopic ultrasound-guided biliary drainage (EUS-BD) with a fully covered self-expandable metal stent for managing malignant biliary stricture.

METHODS: We collected data from 13 patients who presented with malignant biliary obstruction and underwent EUS-BD with a nitinol fully covered self-expandable metal stent when endoscopic retrograde cholangiopancreatography (ERCP) fails. EUS-guided choledochoduodenostomy (EUS-CD) and EUS-guided hepaticogastrostomy (EUS-HG) was performed in 9 patients and 4 patients, respectively.

RESULTS: The technical and functional success rate was 92.3% (12/13) and 91.7% (11/12), respectively. Using an intrahepatic approach (EUS-HG, $n = 4$), there was mild peritonitis ($n = 1$) and migration of the metal stent to the stomach ($n = 1$). With an extrahepatic approach (EUS-CD, $n = 10$), there was pneumoperitoneum ($n = 2$), migration ($n = 2$), and mild peritonitis ($n = 1$). All patients were managed conservatively with antibiotics. During follow-up (range, 1-12 mo), there was re-intervention (4/13 cases, 30.7%) necessitated by stent migration ($n = 2$) and stent occlusion ($n = 2$).

CONCLUSION: EUS-BD with a nitinol fully covered self-expandable metal stent may be a feasible and effective treatment option in patients with malignant biliary obstruction when ERCP fails.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP)

is a well-established technique for providing biliary decompression in patients with bile duct obstruction. The success rate for effective biliary decompression with ERCP ranges from 90% to 95%[1]. However, there are patients in whom ERCP fails because of unsuccessful biliary cannulation, or inaccessible papilla due to duodenal stenosis caused by tumor invasion. In these cases, percutaneous biliary drainage (PTBD) is required. However, PTBD can lead to significant complications, including biliary peritonitis, hemobilia, pneumothorax, hematoma, liver abscesses, and patient discomfort related to the catheter[2].

Therefore, endoscopic ultrasound-guided biliary drainage (EUS-BD) using plastic stents has been introduced as an alternative to PTBD in cases of biliary obstruction when ERCP fails[3-6]. However, plastic stent malfunction due to stent clogging after EUS-BD is not uncommon[3,7,8]. Fully covered self-expandable metal stent (FC-SEMS) with a large bore diameter may have advantages over plastic stents. Recently, EUS-BD with a FCSEMS was introduced in a few cases of malignant biliary obstruction after a failed ERCP[9]. The current study was conducted to determine the feasibility, outcomes, and risks of EUS-guided hepaticogastrostomy (EUS-HG) and EUS-guided choledochoduodenostomy (EUS-CD) with an FCSEMS as a biliary diversion technique in patients with malignant biliary obstruction for whom interventional ERCP was unsuccessful.

MATERIALS AND METHODS

Study population
We collected data on all patients who presented with obstructive jaundice and who underwent EUS-BD after a failed ERCP during a 20-mo period from February 2009 to September 2010. Failed ERCP was defined as the inability to relieve jaundice or failed biliary cannulation. A total of 2209 ERCPs at Wonkwang University Hospital (*n* = 780) and Jeonbuk National University Hospital (*n* = 1429) were performed during the study period, and 366 required biliary decompression. Of the 22 (6%) patients who underwent alternative methods for biliary decompression as a result of failed ERCP, 13 had EUS-BD. Study eligibility was determined as follows: (1) Initial biliary cannulation or bile duct decompression by ERCP failed because of accompanying duodenal obstruction, periampullary tumor infiltration, and difficult cannulation (*n* = 11); (2) A high-grade left-sided hilar stricture as a result of segmental tumor progression with an occluded biliary metal stent was unable to be crossed by a guidewire (*n* = 2); (3) The patient refused PTBD (*n* = 13).

ERCP was performed by 3 experienced endoscopists (Kim TH, Kim SH and Lee SO). Each endoscopist performs 400 to 450 ERCPs annually. EUS-BD was performed by 2 experienced endoscopists (Kim TH and Kim SH) who perform more than 250 EUS procedures for pancreaticobiliary diseases annually.

In this study, stent occlusion was classified as predominantly tumor ingrowth (seen on fluoroscopy as a narrowing within the stent), tumor overgrowth (seen

radiographically or endoscopically as a new narrowing at the proximal or distal margin of the stent), or sludge/debris (demonstrated as echoendoscopic findings or multiple radiographic filling defects that disappeared after extraction with a biliary balloon along with endoscopic visualization of the extracted sludge)[10]. The Institutional Review Boards at Wonkwang University Hospital and Jeonbuk National University Hospital, South Korea approved this study. All patients provided written informed consent for participation in this study.

Techniques
Antibiotics were permitted in all cases for 3 d to 5 d before and after the intervention. ERCP was initially attempted in each patient by using a therapeutic duodenoscope (TJF-240; Olympus Optical Co, Tokyo, Japan). When the ERCP was unsuccessful, an EUS was performed using a GF-UCT 240 linear-array echoendoscope (Olympus Corp., Tokyo, Japan) in a second session (on the same or next day). These patients underwent an EUS-HG or EUS-CD. Using the transgastric approach, the echoendoscope was placed in the cardia or the lesser curvature of the stomach to view the dilated segment 3 of the liver (Figure 1). Using the transduodenal approach, the echoendoscope was placed in the duodenal bulb to image the extrahepatic bile duct (Figure 2). Color Doppler ultrasonography was used to identify the regional vasculature, and a bile duct puncture was performed with a 19-gauge needle (EUSN-19-T; Cook Endoscopy, Winston-Salem, NC, United States). To confirm successful biliary access, contrast medium was injected under fluoroscopy to demonstrate biliary opacification. A 0.035-inch guidewire was introduced through the EUS needle and advanced in an antegrade or retrograde fashion. Afterwards, 6F and 7F tapered, biliary, bougie catheters (catheter tip, 4F; Cook Endoscopy) were inserted and removed, over the guidewire to dilate the tract. If there was resistance when advancing the 6F bougie catheter, a needle-knife (Microtome; Boston Scientific, Natick, MA, United States) with a 7F shaft diameter or tapered MTW catheter (WTW, Endoscopie, Wesel, Germany) was inserted over the guidewire to dilate the tract. To accomplish this, the tip of a needle-knife (Microtome) with a pure current was gently inserted over the guidewire into the biliary system. The needle was then withdrawn, and the needle-knife was pushed in to dilate the tract. A commercially available, fully silicon-covered metal stent with an 8F deployment system and an olive tip (BONASTENT, a nitinol stent with a 10-mm diameter and 6-cm length; Standard Sci Tech Inc., Seoul, South Korea) was placed under echoendoscopic and fluoroscopic view.

Definition of events
Technical success was defined as the deployment of the metal stent across the stomach or duodenum, along with the flow of contrast medium and/or bile through the stent. Functional success was defined as a reduction in bilirubin to less than 50% of the pretreatment value

Figure 1 Endoscopic ultrasound-guided hepaticogastrostomy. A: In the intrahepatic approach, the linear array echoendoscope was placed in the lesser curvature of the stomach for viewing the left intrahepatic system. A 0.035-inch guidewire was introduced through the endoscopic ultrasonography-needle and advanced in an antegrade manner; B and C: A fully covered metal stent was placed under echoendoscopic and fluoroscopic view.

Figure 2 Endoscopic ultrasound-guided choledochoduodenostomy. A: The extrahepatic approach was carried out using an echoendoscope in the duodenal bulb, permitting imaging of the choledochus. Bile duct puncture was carried out with a 19-gauge needle; B: A 0.035-inch guidewire was introduced through the endoscopic ultrasonography-needle and advanced in a retrograde fashion; C and D: A fully covered metal stent was placed under echoendoscopic and fluoroscopic view.

within 2 wk[11]. An early complication was defined as any stent-related complication within 30 d, including complications of bile leakage, pneumoperitoneum, bleeding, and stent migration. A late complication was defined as any stent-related complication, such as stent migration and stent occlusion, occurring 30 d after stent placement. Biliary reintervention was defined as any type of endoscopic, percutaneous, or surgical procedure that was required to improve biliary drainage after placement of the stent. Stent occlusion was defined as the recurrence of jaundice and cholestasis and/or evidence of a dilated biliary system on ultrasound (US) or computed tomography (CT) with a direct view of the upper endoscope, which in all cases would require biliary intervention. Procedure time was defined as the time between puncture of the biliary tract with a 19-gauge needle and placement

of an FCSEMS.

Follow-up

Follow-up continued from stent insertion until the death of the patient or to the end of the study. Biochemical parameters and simple abdominal films were assessed at 2 d, 1 wk and 1 mo after stent placement and every 2 mo thereafter. Patient follow-up was based on outpatient examination findings. Imaging (US or CT and simple abdominal films) was routinely checked every 3 mo.

Statistical analysis

Procedure time (intrahepatic and extrahepatic approaches) and liver function test before and after the EUS-BD using a metal stent were compared using a 2-sample Wilcoxon signed-rank test. Statistical analysis was carried out using

Table 1 Patients' clinical characteristics and results of endoscopic ultrasound-guided biliary drainage ($n = 13$)

No. of patient	Age/sex	Diagnosis	Reason for failed ERCP	Biliary drainage route	Device for puncture/dilatation	Diameter length of stent (mm/cm)	Technical success	Functional success	Complication	Reintervention	Duration (mo) of 1st stent placement	Status

F: Female; M: Male; CBD: Common bile duct; G: Gauge; NK: Needel knife; FN: Fine needle; PTBD: Percutaneous biliary drainage; ERCP: Endoscopic retrograde cholangiopancreatography.

SPSS 12.0 (SPSS, Chicago, IL, United States), and a 2-tailed P value of < 0.05 was considered statistically significant. Findings are expressed as the median and range.

RESULTS

Patient characteristics, procedural data, and follow-up results are presented in Table 1. A total of 13 patients (9 men and 4 women) with malignant biliary obstruction underwent EUS-BD with a fully covered metal stent after a failed ERCP. The etiology of biliary obstruction was pancreatic cancer in 5 patients, distal common bile duct cancer in 6 patients, Klatskin's tumor in 1 patient, and peripheral cholangiocarcinoma in 1 patient.

Reasons for failed ERCP were duodenal stenosis due to a previous duodenal ulcer ($n = 1$), tumor obstruction of the duodenum ($n = 1$), periampullary tumor infiltration ($n = 5$),

Table 2 Summary of published studies and current study on endoscopic ultrasound-guided biliary drainage with metal stent

Study	No. of EUS-BD-metal biliary stents	Technical success %	Clinical success %	Type of metal stent	Procedure-related complications (No. cases)

EUS-BD: Endoscopic ultrasound-guided biliary drainage.

failure to access the common bile duct (n = 2), high-grade stricture of the distal common bile duct with an occluded biliary plastic stent (n = 2), and high-grade left-sided hilar stricture from segmental tumor progression with an occluded biliary metal stent (n = 2). Patients with obstruction of the duodenum received a concomitant duodenal stent at time of the procedure.

Technical and functional success

Technical success was 92.3% (12/13); there was 1 failure of guidewire insertion after puncture through the transgastric approach, because the diameter of intrahepatic bile duct was so small and had sharp angulation. During EUS-BD, no wire passage for rendezvous was attempted in any of the patients. For biliary access, a cystostome only was used in 6 of the 12 patients (4 extrahepatic approach and 2 intrahepatic approach), a tapered MTW catheter and a cystostome together were used 3 of 12 patients, and just bougie dilatators were used in 3 patients, respectively. Median procedure time was 19.5 min (range, 14-35 min). Nine patients were treated using an extrahepatic approach (all transduodenal). Four patients were treated using an intrahepatic approach (all transgastric). The median diameter of the left intrahepatic bile duct as determined by EUS was 7.3 mm (range, 5.3-9.4 mm).

Functional success was 91.7% (11/12). After the placement of a EUS-BD, the median bilirubin level decreased significantly from 11.6 mg/dL to 1.7 mg/dL (P = 0.001). The median alkaline phosphatase level also decreased significantly from 1629.0 IU/L to 113.0 IU/L (P = 0.001). Migration of a metal stent to stomach occurred in 1 patient treated with the transgastric approach.

Early complications after endoscopic ultrasound-guided biliary drainage

With the intrahepatic approach (n = 4), there was stent migration to the stomach with mild peritonitis (n = 1). With the extrahepatic approach (n = 9), there was pneumoperitoneum with mild peritonitis (n = 1). All patients with peritonitis were managed conservatively with antibiotics. Bleeding and cholangitis were not observed in any of the enrolled patients after the procedure. In addition, there was no significant pain after the procedure. Two patients with duodenal obstruction also received duodenal metal stents.

Follow-up

One patient with distal common bile duct (CBD) cancer

underwent curative resection (Whipple's operation), and this procedure did not disturb the operative procedure. None of the patients, except the patients that underwent the operation, were lost during the follow-up period (median, 5 mo; range, 1-12 mo). With regard to re-intervention, there was re-intervention in 4 of the 13 cases (30.7%), which was necessitated by stent migration (n = 3) and stent occlusion (n = 1). Stent migration occurred 2 d later (EUS-HG) and 2 mo later (EUS-CD and EUS-HG), respectively. In the patients with stent migration, the stents passed spontaneously without lodgment in the bowel. A second FCSEMS was placed through the previous choledochoduodenostomy site in 1 patient. In 2 patients with stent migration, PTBD was inserted into the obstructed left hepatic duct due to his severe general weakness. In 1 patient with stent occlusion by tumor ingrowth into the metal stent (choledochoduodenostomy), an additional FCSEMS was placed through the previous choledochoduodenostomy site.

DISCUSSION

EUS-BD may be an alternative method in some patients when endoscopic biliary drainage is unsuccessful because of failed biliary cannulation or tumor infiltration, which limits the endoscopic approach to the major papilla. At present, there are 2 approaches for EUS-BD, the transgastric route and the transduodenal route. A plastic or metal stent can be placed by this method. However, most papers reported EUS-BD with a plastic stent[4,5,7,8,12-14]. We thought that FCMEMS with a large bore diameter may have advantages over the plastic stent. There are a few papers describing EUS-BD with a metal stent[6,9,15] (Table 2), however, there are no reports regarding preoperative drainage of biliary obstruction by EUS-BD. The current study demonstrated that transduodenal EUS-BD using a nitinol FCSEMS may be safe and feasible after a failed ERCP. The reasons for failed ERCP were duodenal stenosis by a duodenal ulcer, periampullary tumor invasion, and difficult biliary cannulation. In one patient with distal CBD cancer who had duodenal stenosis due to a previous duodenal ulcer, initially EUS-BD was performed to resolve cholangitis and bile drainage, and Whipple's operation was performed. But EUS-guided metal insertion in this patient did not disturb the operation procedure.

A significant number of self-expandable metal stent

(SEMS) and plastic stents placed to palliate malignant obstructions will be occluded. Repeat transpapillary stent placement may be unsuccessful for an occluded biliary metal or plastic stent after the placement of a hilar metal stent or combined duodenal and biliary metal stent placement. In such circumstances, PTBD may be uncomfortable for patients and has a 10%-30% complication rate, with complications such as cholangitis, bile leak, peritonitis, and stent occlusion[16]. EUS-HG with a FCSEMS may be recommended in such circumstances. In our 2 patients with a hilar metal stent, dilation of the left main duct caused by segmental tumor progression was shown to be aggravated. In another 2 patients with periampullary cancer drained by a pigtail plastic stent, this stent was occluded by tumor ingrowth and bile plug. Because these patients had jaundice and cholangitis, EUS-HG with a FCSEMS was performed. Some experts have recommended the intrahepatic approach because it seems to be safer[7,15]. In the intrahepatic approach, one-step placement of a partially covered wall stent may have been limited in earlier studies because there was 1 bile peritonitis and 1 cholangitis. However, we found the transduodenal or extrahepatic approach to be safer and more effective and it is probably less technically difficult compared with the intrahepatic approach. The advantage is that the duodenum is very close to the extrahepatic bile duct and the duodenal wall is thin without major vascular structures.

There were complications with EUS-BD, including stent migration, pneumoperito-neum, and cholangitis[17,18]. In this study, during follow-up (median, 3 mo), there was re-intervention (4/12, 33.3%) necessitated by stent migration ($n = 3$) and stent occlusion ($n = 1$). The 3 stent migrations occurred 2 d later (EUS-HG), 2 mo later (EUS-CD), and 2 mo later (EUS-CD). The stent migration rate (3/12, 25.0%) was higher than that reported (7%) in another paper[9]. Although a flare at both ends and minimal shortening of this newly designed nitinol stent may contribute to the prevention of stent migration[19], a slippery covered metal stent with low axial force may lead to migration. In addition, marked CBD dilatation may have affected FCSEMS floating resulting in the minimization of the anchoring effect of the proximal flared end of the FCSEMS.

Studies with uncovered SEMS reported stent occlusion rates ranging between 18% and 46%[20,21] with the main cause of obstruction being tumor ingrowth. Although partially or fully covered SEMS were designed to prevent this complication, these stents can not completely protect tumor ingrowth in the biliary metal stent[22]. Occasional authors have reported no tumor ingrowth with covered SEMSs. However, these series often include few patients and frequently have a relatively high prevalence of tumor overgrowth or sludge formation as a cause of stent failure[23-25]. Our study shows tumor overgrowth was observed in one case with distal CBD cancer.

During the EUS-BD procedure, the leakage of bile into the peritoneum with peritonitis can occur because the gap between the stent and the fistula is likely to occur. The shortening of metal stent can lead to failure of correct stent placement, and stent migration and dislocation after placement. Experience with partially coverd SEMS is lim-

ited and associated with a higher complication rates due to stent shortening[3,6]. To prevent bile leakage, we placed a FCSEMS that is made of nitinol. This stent, with both ends flared, was designed to prevent distal or proximal migration. The nitinol stent has less shortening compared with a partially covered Wall stent, and a fully covered metal stent may prevent bile leakage[19]. Therefore, due to the characteristics of this stent, it may prevent bile peritonitis. Because the diameter of the working channel of the linear array echoendoscope is only 3.7 mm, it is possible to quickly perform one-step placement of FCSEMS with an 8F-diameter delivery device. In this study, although bile leakage occurred during the procedure, all patients had only mild peritonitis and were treated with conservative management, such as antibiotics and nothing by mouth.

If the gap between the bile duct and the GI tract grows farther after EUS guided biliary drainage with stent, early migration of stent into the abdominal cavity may occur, particularly in the case of a transgastric approach. A fatal complication due to sepsis after development of large fistula related to stent migration into the abdominal cavity has recently been reported[26]. However, bile leakage *via* the relatively large fistula can make bile peritonitis and the bile duct collapse. Therefore, it may be difficult or impossible to carry out EUS-BD in these patients. In such a case, PTBD or emergency surgery must also be considered. To prevent severe complications, an endoscopist must have considerable knowledge about periduodenal and hepatobiliary anatomy in linear array EUS. Also, the procedure must be performed quickly and efficiently with appropriately sized stents. When selecting a stent, stent structure, axial force and shortening of stent should be considered.

In conclusion, EUS-guided transgastric or transduodenal biliary drainage with one-step placement of an FCSEMS may be a promising alternative method to PTBD. It may be a reasonable, feasible, and promising minimally invasive endoscopic approach in selected patients as indicated as above. However, several complications can occur, and special attention of the potential complications such as peritonitis and migration are needed. Therefore, additional experience and the development of new comfortable accessories for this procedure are needed. Also, a large case series and prospective trials are needed to further assess this technique.

COMMENTS

Background
For palliation of patients with malignant biliary obstruction, percutaneous biliary drainage (PTBD) is a classic method in some patients when endoscopic biliary drainage is unsuccessful because of failed biliary cannulation or tumor infiltration, which limits the endoscopic approach to the major papilla. Recently endoscopic ultrasonography-guided biliary drainage (EUS-BD) with plastic stent or uncovered self-expandable metal stent (SEMS) has been introduced as an alternative to PTBD in these cases of biliary obstruction.

Research frontiers
The authors thought that a nitinol fully covered SEMS (FCSEMS) with a large bore diameter may have advantages over the plastic stent and other types of metal stent.

Innovations and breakthroughs
Technical and functional success with FCSEMS for palliation of patients with malignant biliary obstruction was respectively 92.3% (12/13) and 91.7% (11/12). Although there was early mild complication such as one case of immediate

stent migration and 2 cases of bile peritonitis, all complications improved with conservative treatment.

Applications

EUS-guided transgastric or transduodenal biliary drainage with one-step placement of a nitinol FCSEMS may be a promising alternative method to PTBD. Additional experience and the development of new comfortable accessories for this procedure are needed. Also, a large case series and prospective trials are needed to further assess this technique.

Terminology

There are 2 approaches for EUS-BD, the transgastric route and the transduodenal route. EUS-guided hepaticogastrostomy was performed through the transgastric route, and EUS-guided choledochoduodenostomy through the transduodenal route.

Peer review

The authors reported high success rate with this challenging procedure. They clearly demonstrated that extrahepatic approach is easier and safer than intrahepatic approach, Although technical expertise is important, the authors demonstrated more than 90% technical success with low major complication rates. This paper motivates talented endoscopists to solve biliary obstruction *via* EUS guided technics.

Abstract

AIM: To investigate the clinical features and prognostic factors of advanced hepatocellular carcinoma (HCC) patients presenting with lung metastasis at initial diagnosis.

METHODS: Between 2001 and 2010, we recruited 76 consecutive HCC patients initially presenting with lung metastasis, without co-existing metastasis from other sites. These patients were divided into three groups: untreated group (n = 22), single treatment group (n = 19), and combined treatment group (n = 35).

RESULTS: Metastasis of bilateral lung lobes was common and noted in 35 patients (46.1%), and most of patients (59/76, 77.6%) presented with multiple lung metastatic nodules. Nineteen patients (25.0%) received single-method treatment, including hepatectomy in 4, transcatheter arterial chemoembolization in 6, radiotherapy in 5, and oral sorafenib in 4. Thirty-five patients (46.1%) received combined treatment modalities. The overall median survival of the all patients was 8.7 ± 0.6 mo; 4.1 ± 0.3, 6.3 ± 2.5 and 18.6 ± 3.9 mo, respectively in the untreated group, single treatment group and combined treatment group, respectively, with a significant difference (log-rank test, $P < 0.001$). Multivariate analysis revealed that Child-Pugh score, the absence or presence of portal vein tumor thrombus, and treatment modality were three independent prognostic factors affecting survival of patients with advanced HCC and concomitant lung metastasis.

CONCLUSION: Combined treatment modalities tend to result in a better survival as compared with the conservative treatment or single treatment modality for HCC patients initially presenting with lung metastasis.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world. The number of new cases is estimated to be 500 000-1 000 000 per year[1]. Overall, 80% of HCC are attributed to chronic hepatitis B and C infection. Surgical resection with complete extirpation of tumor gives the best chance of a cure for patients with HCC[2]. However, a majority of HCC patients are considered as advanced or even at end-stage at their first hospital visit, with extensive tumor status, for example, macroscopic vascular invasion, extrahepatic metastasis, *etc*. Of various metastatic sites, the most common site is lung, followed by lymph node, bone and brain[3].

As one type of advanced HCC, HCC presenting with lung metastasis is not unusual, and its prognosis is very poor[4]. Nowadays, there are various treatment modalities for both intrahepatic tumor and extrahepatic metastatic foci of HCC, including surgical resection, transcatheter arterial chemoembolization (TACE), radiotherapy, chemotherapeutics, and recent molecular targeted therapeutic drugs[2]. However, the prognosis and treatment outcomes of advanced HCC presenting with lung metastasis remain poorly evaluated. We investigated the prognosis, treatment outcomes, and independent prognostic factors affecting the survival of a series of HCC patients presenting with lung metastasis at initial diagnosis.

MATERIALS AND METHODS

Patients

From January 2001 to December 2010, 103 consecutive patients were diagnosed as having lung metastasis at the first time of HCC diagnosis in the 5th Department of Hepatobiliary Surgery, Eastern Hepatobiliary Surgery Hospital, Second Military Medical University, Shanghai, China. To evaluate the efficacy of anti-tumor treatment modality for patients with HCC and concomitant isolated lung metastasis, we excluded those patients who showed evidence of severe organ failure (renal, respiratory, or cardiologic problems), poor liver function (Child-Pugh class C) that could affect survival, or co-existing metastasis from other sites. Therefore, 76 of the 103 patients (59 males and 17 females) were recruited for the study. The last follow-up date was January 30, 2011. This study protocol was approved by the Institutional Review Board of the Eastern Hepatobiliary Hospital.

We used a prospectively maintained database and conducted a retrospective study among these patients. We focused on the prognosis and prognostic factors affecting the survival of HCC patients presenting with lung metastasis. To investigate whether local regional or systemic therapy could affect survival, we stratified these 76 patients into three groups: untreated group (*n* = 22), single treatment group (*n* = 19), and combined treatment group (*n* = 35). All of the patients in the untreated group refused any anti-tumor invasive treatment other than conservative treatment, including the support of liver function, after being informed of the expenses and the possible side effects of any anti-tumor invasive treatment. The single treatment method for these patients included hepatectomy, TACE, radiotherapy, chemotherapeutics, and oral sorafenib, while combined treatment modalities were defined as more than one of the above treatment methods or pulmonary metastasectomy.

Laboratory tests

Laboratory blood tests including hepatitis B virus (HBV) markers, anti-hepatitis C virus, serum α-fetoprotein (AFP), carcinoembryonic antigen, platelet, serum albumin, serum total bilirubin, alanine transaminase, aspartate aminotransferase, and prothrombin time were performed.

Diagnosis of HCC and lung metastasis

The diagnosis of HCC was based on concordance between two imaging examinations [ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI)] showing arterial hypervascularity in a focal lesion $\geqslant$ 2 cm or with the combined criteria of an imaging examination and a serum AFP level greater than 400 ng/mL, according to the criteria of the Conference of the European Association for Study of the Liver[5]. In the present study, the diagnosis of HCC was also confirmed by pathohistology in 20 patients.

Lung metastases were diagnosed in all the 76 patients using imaging techniques, including chest CT (*n* = 62), positron emission tomography-CT (*n* = 11), and chest MRI (*n* = 3). In addition, one patient was further confirmed by pathohistology after a biopsy, and four patients after pulmonary metastasectomy.

Statistical analysis

Continuous data were expressed as mean $\pm$ SD or median (range). Categorical variables were compared by the χ^2 test or Fisher exact test, and continuous variables were compared by the Student *t* test or one-way analysis of variance. The survival rate was calculated using the Kaplan-Meier method, and the log-rank test was used to compare survival rates among three groups. Cox's proportional hazards model was used for multivariate analysis. All statistical analysis in this study were done using software package SPSS11.0 (SPSS Inc., Chicago, IL). A *P* value < 0.05 was defined to be statistically significant.

RESULTS

Patient characteristics

The baseline characteristics of these 76 patients with advanced HCC initially presenting with lung metastasis are summarized in Table 1. The mean age of patients was 52.4 $\pm$ 10.7 years. The most common etiology of the liver disease was HBV infection, which occurred in 63 patients (82.9%). There was no statistical difference in the baseline characteristics among the untreated, single treatment and combined treatment groups, including age, etiology of the liver disease, the presence of cirrhosis or ascites, AFP level, Eastern Cooperative Oncology Group (ECOG) scale, Child-Pugh score, and liver function.

Characteristics of intrahepatic tumor and lung metastasis

For intrahepatic tumor status, there was no significant difference in tumor number, tumor location, and the probability of portal vein tumor thrombus or hepatic vein tumor thrombus among the three treatment groups, except for maximum tumor diameter (*P* = 0.007) (Table 2). As such, there is also no significant difference in number, location, and maximum diameter of lung metastatic nodules among these three groups (Table 2).

Treatment modalities

Among all the 76 patients, 22 patients did not receive any anti-tumor treatment but conservative treatment. We divided the remaining 54 patients into two groups according to their treatment schemes. Nineteen patients (25.0%) received single treatment modality (locoregional or systemic therapy), including hepatectomy in 4 patients, TACE in 6, radiotherapy for intrahepatic tumor and lung metastatic nodules in 5 (including γ knife radiosurgery in 3 and X-ray radiotherapy in 2), and oral sorafenib in 4. Thirty-five patients (46.1%) received combined treatment modalities (Table 3). The common treatment modality in the combined treatment group was radiotherapy (30/35, 85.7%), followed by hepatectomy (23/35, 65.7%), TACE (18/35, 51.4%), and oral sorafenib therapy (11/35, 31.4%).

In the combined treatment group, radiotherapy (γ knife radiosurgery in 24 and X-ray radiotherapy in 4) was mainly used for lung metastatic nodules (27/28) rather than intrahepatic tumor nodules (8/28). In addition, pulmonary metastasectomies were carried out in 4 patients who underwent hepatectomy during the same operation.

Overall survival

After a median follow-up of 8.7 ± 0.6 mo (range, 1.1-68.7 mo), 59 patients died and 17 patients remained alive. The causes of mortality were disease progression, including hepatic failure in 31 patients (52.5%); cachexia in 12 (20.3%); upper gastrointestinal bleeding in four (6.8%); pneumonia in one (1.7%); and pulmonary thromboembolism in one (1.7%). The cause of mortality of 10 patients was not confirmed. Among 17 surviving patients, only 4 patients were disease-free, including 3 patients who underwent hepatectomy and pulmonary metastasectomy, and one patient who received hepatectomy and subsequent γ-knife radiosurgery. Among 13 patients who were not disease-free but alive, 6 patients still took medicine of sorafenib, and achieved complete or partial response on radiographic examination (Figure 1A and B). The 6-mo, 1-year and 2-year cumulative survival rates of all these patients were 64.5%, 40.1% and 18.5%, respectively.

Table 2 Characteristics of intrahepatic tumor and lung metastasis of hepatocellular carcinoma patients presenting with lung metastasis (mean ± SD) *n* (%)

	Total (*n* = 76)	Untreated group (*n* = 22)	Single treated group (*n* = 19)	Combined treated group (*n* = 35)	*P* value

Transcatheter arterial chemoembolization + radiotherapy	6 (17.1)
Transcatheter arterial chemoembolization + radiotherapy + oral sorafenib	3 (8.6)
Transcatheter arterial chemoembolization + oral sorafenib	1 (2.9)
Radiotherapy + oral sorafenib	2 (5.7)

Figure 1 Overall survival. A: Computed tomography (CT) scan showing multiple metastatic nodules in both lung lobes before anti-tumor treatment in a 54-year-old male patient with lung metastasis due to hepatocellular carcinoma; B: CT scan showing the disappearance of previous lung metastatic nodules in 5 mo after γ-knife radiosurgery and oral sorafenib.

Comparison of survival among three treatment groups

The median survival time of combined treatment group was 18.6 ± 3.9 mo, which was longer than that of single treatment group (6.3 ± 2.5 mo) and untreatment group (4.1 ± 0.3 mo), and there was significant statistical differences among these groups (log-rank test, *P* < 0.001) (Figure 2). The 6-mo cumulative survival rate of combined treatment, single treatment and untreated group was 88.6%, 57.9% and 31.8%, respectively; and the 1-year survival rate of the three groups was 68.5%, 21.1% and 8.0%, respectively.

Univariate and multivariate analyses

In investigation of prognostic factors of survival of HCC presenting with lung metastasis at initial diagnosis, univariate analysis showed that ECOG score, Child-Pugh score, ascites, AFP level, maximum intrahepatic tumor diameter, the absence or presence of portal vein tumor thrombus, the absence or presence of hepatic vein tumor thrombus, lung metastatic tumor number, and treatment modality had prognostic significance (Table 4).

Patients at risk	Total	6 mo	12 mo	18 mo	24 mo	30 mo	36 mo	42 mo	48 mo	54 mo	60 mo
Combined treated	35	31	20	15	8	4	2	2	2	2	1
Single treated	19	11	3	0	0	0	0	0	0	0	0
Untreated	22	7	1	0	0	0	0	0	0	0	0

Figure 2 Comparison of survival among three treatment groups. Survival curves of untreated group (*n* = 22), single treatment group (*n* = 19), and combined treatment group (*n* = 35).

In the Cox proportional hazard model, Child-Pugh score, the absence or presence of portal vein tumor thrombus at the initial presentation, and treatment modality were three independent prognostic factors that affected the survival of HCC patients that presented with lung metastasis at initial diagnosis (Table 4).

DISCUSSION

To the best of our knowledge, this is the first study that investigates in detail the prognosis and prognostic factors of advanced HCC presenting with lung metastasis at initial diagnosis. In our study, the variables of tumor status and liver function status at initial diagnosis were almost comparable. However, the survival times from date of diagnosis until death or last visit among the three groups were significantly different, and patients underwent specific combined treatment modalities had longer survival than those treated with single method or those without anti-tumor treatment. However, it must be noted that there are many therapeutic modalities for tumor nodules, whether regional or systemic, which have their own indications and contraindications, and could not be applied altogether on a specific individual.

There are many case reports and clinical studies of patients with advanced HCC and lung metastasis who underwent radical hepatectomy and pulmonary metastasectomy[6-12]. In the present study, four patients also underwent combined surgical resection, three of whom were still alive at the end of follow-up. We think that the combined radical surgery should be positively considered if intrahepatic tumor and lung metastatic lesion were completely resectable, if the remaining volume of the liver was adequate, and the lung metastatic lesion was single[13]. In theory, removing all existing tumor lesions,

including primary and second lesions, is the only possible therapeutic approach till now.

Recently, with development in radiotherapy techniques, radiotherapy has been shown to play a potential role in a wide spectrum of HCC, therefore it is necessary to evaluate the effect of radiotherapy[14-16]. In our center, stereotactic radiotherapy, particularly γ knife radiosurgery, has become the major therapeutic mordality for lung and brain metastases of HCC. In the present study, there were 35 patients who underwent radiotherapy for intrahepatic HCC tumors and/or lung metastatic nodules, accounting for more than 50%, whether or not they are combined with other anti-tumor treatment modalities. Despite advances in radiotherapy delivery, liver toxicity following radiotherapy remains a dose-limiting factor, and investigations to better understand the pathophysiology of radiotherapy-induced liver toxicity are warranted. There is a particular interest in combining radiotherapy with anti-vascular endothelial growth factor targeting agents for their independent activity in HCC as well as their radiation sensitization properties[17].

Sorafenib is a multikinase inhibitor with effects against tumor proliferation and angiogenesis, and was recently approved for the treatment of advanced HCC[18,19]. Maintenance sorafenib would probably prevent or delay the intrahepatic and extrahepatic spread of HCC after radiotherapy, which provides the rationale for the combination of these treatment modalities[20]. In the present study, 15 patients received oral sorafenib. Although we did not find its significant efficacy in HCC presenting with lung metastasis due to few cases and less strict design, we believed that sorafenib could be used as one part of combined treatment modalities for HCC patients with lung metastasis. However, a large-scale randomized controlled trial is needed to confirm it. Combining surgical resection with sorafenib would be considered as the most optimal treatment modality for HCC patients with lung metastasis.. However, it remains to be confirmed by a randomized controlled clinical trial in the future.

Till now, we have not obtained enough evidences to confirm the role of locoregional hepatectomy in HCC patients with lung metastasis. In our opinion, hepatectomy can be performed when primary intrahepatic HCCs are completely resected, the number of lung metastases is less than 3, and the diameter of individual lung metastasis is less than 3 cm. In addition, any of treatment modalities, such as radiotherapy or TACE, should be used together for lung metastasis.

In the univariate and subsequent multivariate analyses, Child-Pugh score was an independent prognostic factor for HCC patients with lung metastasis. This indicates that although invasive treatment other than conservative treatment can prolong the survival in well-selected patients, one must be careful before applying invasive treatment to all patients.

This study has several limitations. First, it was designed retrospectively. Although the patients' status, including ECOG scale, Child-Pugh score, and liver function, was reviewed in the medical records and did not differ statistically among the three treatment groups, the clinical circumstances at the initial presentation might differ. Therefore, the decision for the treatment mordalities might be biased, and the subsequent patient stratification into various treatment groups might also be biased. Second, treatment modalities, i.e., radiotherapy, TACE, varied, and the number of patients treated was too small to confirm the effectiveness of each treatment modality. Third, the indications of specific treatment modality varied, and selective modalities were given to selective patients with advanced HCC and lung metastasis. It is very hard to build up a standard therapeutic regime for all patients, regardless of primary and secondary tumor site, size and number, liver functional reserve, and patients' general condition.

In conclusion, the present study showed that the prognosis of advanced HCC with concomitant lung metastasis at initial diagnosis is very poor, and combined comprehensive treatment modalities tended to significantly prolong the survival of the patients compared with conservative treatment or single treatment modality. Furthermore, further randomized trials might be required to investigate the optimal treatment modality in the near future.

COMMENTS

Background
The prognosis and treatment outcomes of advanced hepatocellular carcinoma (HCC) presenting with lung metastasis remain poorly evaluated.

Research frontiers
There are various treatment modalities for advanced HCC, including surgical resection, transcatheter arterial chemoembolization, radiotherapy, chemotherapeutics, and administration of molecular targeted therapeutic drugs. This study investigated the prognosis, treatment outcomes, and independent prognostic factors affecting the survival of a series of HCC patients presenting with lung metastasis at initial diagnosis.

Innovations and breakthroughs
In this study, the survival times from date of diagnosis until death or last visit between untreated group, single treatment group, and combined treatment group were significantly different, and patients underwent specific combined treatment modalities had longer survival than those treated with single method or those without anti-tumor treatment. Multivariate analysis revealed that Child-Pugh score, the absence or presence of portal vein tumor thrombus, and treatment modality were three independent prognostic factors affecting survival of patients with advanced HCC and concomitant lung metastasis.

Applications
As one type of advanced HCC, HCC presenting with lung metastasis is not unusual, and its prognosis is very poor. The findings in this study may contribute to its prognosis, and combined treatment modalities tend to result in a better survival for patients with advanced HCC initially presenting with lung metastasis.

Peer review
The authors firstly investigated that combined treatment modalities tended to yield better survival prolongation compared with conservative treatment or single treatment modality for HCC patients initially presenting with lung metastasis, which may be contribute to its prognosis.

Abstract

AIM: To study the expression of eukaryotic translation initiation factor 4E (eIF4E), which is closely correlated with malignant tumors, and its relationship to prognosis in hepatocellular carcinoma.

METHODS: Western blotting was performed to quantify the eIF4E protein expression in the normal human liver cell line L02 and the hepatoma cell lines Hep3B, HepG2, and Huh7. Forty-six hepatocellular carcinoma samples with complete clinical data were obtained from Changzheng Hospital during the period of December 2008 to July 2009. The expression of eIF4E in the tumor samples and their adjacent tissues were detected by immunohistochemistry. The relationship between the test results and hepatocellular carcinoma (HCC) prognosis was statistically analysed by using a COX proportional hazard model.

RESULTS: Western blotting analysis showed that there were distinct eIF4E protein bands in all three of the hepatoma cell lines. In particular, the HepG2 cell line had the highest level of eIF4E protein expression. The L02 cell group had a low eIF4E expression. Immunohistochemical assay showed that there were 32 cases in which the tumour tissue expression was higher than their adjacent tissues, accounting for 69.57%. There were also 14 cases in which the tumour tissue expression was lower or no significant difference was found, accounting for 30.43%. COX proportional hazards model analysis showed that HCC prognosis was related to the depth of invasion, the overexpression of eIF4E and p53, possibly as independent HCC prognostic predictors.

CONCLUSION: In summary, eIF4E expression is associated with liver cancer, and patients with high eIF4E expression levels have a higher risk of recurrence.

Key words: Hepatocellular carcinoma; Eukaryotic translation initiation factor 4E; Western blotting; Immunohistochemistry; Prognosis

INTRODUCTION

Eukaryotic translation initiation factor 4E (eIF4E) is a member of the eIF family. It can specifically bind to the cap structure located at the 5' end of mRNAs named the "m7GpppN cap", which is necessary for mRNA translation initiation, and affects mRNA metabolism, processing, transportation and translation[1]. It plays an important role

in regulating the initial stage protein synthesis[2,3]. eIF4E is highly expressed in a variety of human malignancies[4-7], which has been confirmed to be relevant to the occurrence, invasion and metastasis of carcinomas such as head and neck squamous cell carcinoma[8], laryngeal cancer, non-small cell lung cancer[9-11], breast cancer[12-18], thyroid cancer, oesophageal cancer, stomach cancer, cholangiocarcinoma, colon cancer[19], non-Hodgkin's lymphoma, acute or chronic myeloid leukaemia[20], and lymphoma[21,22]. Experiments have also confirmed that eIF4E is closely related to the prognosis of many carcinomas. However, eIF4E-related studies in the context of hepatocellular carcinoma (HCC) are still rare.

In this study, we separately compared the eIF4E expression levels in normal liver cells with liver cancer cell lines and liver cancer tissues with precancerous tissues. Additionally, we investigated the influence of eIF4E expression on the prognosis of liver cancer. This research may provide an experimental basis for exploring new ways to treat liver cancer.

MATERIALS AND METHODS

Study objects

We selected 46 patients with pathological evidence of HCC and complete clinical data from Shanghai Changzheng Hospital who had liver surgery from January 2007 to January 2009. In these 46 cases, there were 40 males and 6 females who ranged in age from 31 years to 77 years (median age: 52.26 years). With regards to histological grade, there were 42 cases of moderately differentiated HCC, and 4 cases were poorly differentiated. A total of 33 patients had a cancer embolus in the intrahepatic bile duct or vein or had an infiltrated peplos, and 13 patients had no cancer tissue in cutting edge and gallbladder and no infiltrated peplos. p53 pathological testing was positive in 39 patients and negative in 7 cases. None of the patients received preoperative radiotherapy or chemotherapy. The follow-up time was 24 mo, and no case was lost.

Major materials and reagents

The cell lines used for Western blotting were the human liver cancer cell lines Hep3B, HepG2, Huh7, and the normal human liver cell line L02, which was provided by Shanghai Cell Biology Institution of Academia Sinica.

eIF4E (P-2) is a mouse anti-human monoclonal antibody raised against full-length eIF4E (Santa Cruz Biotechnology, Inc.). It is recommended for the detection of eIF4E by Western blotting (dilution: 1:200; dilution range: 1:100-1:1000) and immunohistochemistry (including paraffin-embedded sections; dilution: 1:50; dilution range: 1:50-1:500). The streptavidin-perosidase (SP) kit was provided by Fuzhou Maixin Biotechnology, Inc.

Detection methods

Western blotting analysis: We tested the *eIF4E* gene expression level in normal liver cells and different liver cancer cell lines. The four of cell lines (*i.e.*, HepG2,

Hep3B, Huh7, and L02) were incubated with high glucose Dulbecco's modified Eagle's medium containing 10% fetal bovine serum at 37.0 °C with 5% CO_2 until the cell concentration reached 5×10^6 cells/mL. Then, we sequentially performed the protein extraction, bicinchoninic acid protein quantification, sodium dodecyl sulfate-polyacrylamide gel electrophoresis electrophoresis, protein transfer, membrane closure, antibody incubation, and Bio-Rad chemiluminescence.

Immunohistochemistry: We detected the eIF4E protein expression levels in HCC and their adjacent tissues (SP, a particular type of immunohistochemistry). The tumour and adjacent tissues from the same patient were fixed, dehydrated, sectioned, and made into paraffin biopsies. We made 46 paraffin sections. The steps of the SP kit included heating on a baking sheet, incubation, washing, sealing, staining, drying, dehydration, and mounting. To analyse the results, we used two scoring methods. The samples were placed in an electron microscope and were scored for staining intensity as follows. 0: No colour; 1: A yellow colour; 2: A claybank colour; and 3: A brown colour. We then graded the samples for the positivity rate as follows. 0: No positive tumour cell staining; 1: ≤ 10% positive cells; 2: 11% to 50% positive cells; 3: 51% to 75% positive cells; and 4: > 75% positive cells. Finally, we added the two scores together, and the sum represented the immunohistochemical score as follows. -: 0; +: 1 to 4; ++: 5 to 8; and + + +: 9 to 12. Each cancer tissue section was compared with its adjacent tissue.

Follow up: We analysed the number of cases that had HCC recurrence and metastasis during the post-operative 24 mo. The liver cancer recurrence risk was measured using COX proportional hazards model for statistical analysis. The patient age, gender, histological grade, depth of invasion, eIF4E, p53 status and other prognostic indicators were used for the COX proportional hazards model analysis.

Statistical analysis

We used the SPSS 17.0 statistical software for the statistical analysis. A COX proportional hazards model testing level of $\alpha = 0.05$ and a $P < 0.05$ was considered statistically significant.

RESULTS

eIF4E protein expression in liver cancer cell lines by western blotting

We tested the eIF4E protein expression level in the liver cell line L02 and the liver cancer cell lines Huh7, HepG2, Hep3B. The eIF4E protein bands are shown in Figure 1. The bands were detected by Bio-Rad chemiluminescence to obtain the data shown in Table 1.

The liver cancer cell lines HepG2, Huh7, Hep3B significantly expressed the eIF4E protein, and in particular, the HepG2 cell line had the highest level of eIF4E protein expression. The normal liver cell L02 also expressed

Figure 1 Eukaryotic translation initiation factor 4E protein and glyceraldehyde-3-phosphate dehydrogenase protein bands in a normal human liver cell line and three hepatoma carcinoma cell lines. A: Eukaryotic translation initiation factor 4E protein bands; B: Glyceraldehyde-3-phosphate dehydrogenase protein bands.

eIF4E	3161.861	5651.885	775.440	4496.191

GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; eIF4E: Eukaryotic translation initiation factor 4E.

eIF4E; however, its expression level was low. Glyceraldehyde-3-phosphate dehydrogenase, which was used as the internal reference had bands in each cell line, and no obvious differences were observed with this protein.

eIF4E protein expression in liver cancer and adjacent tissues by immunohistochemistry

We next detected the eIF4E protein expression level in HCC and adjacent tissues. There were 46 pathological tissue paraffin blocks in which 32 HCC tissue cases had higher eIF4E protein expression than their adjacent tissues, accounting for 69.57%. A total of 14 HCC tissue cases had lower expression or no significant difference compared with their adjacent tissues, accounting for 30.43%. The scores were weighted 154:97 = 1.59:1, meaning that, in general, HCC tissues had a higher eIF4E protein expression level than the adjacent tissues.

Figure 2 show that HCC tissues stained significantly stronger than adjacent tissues, indicating that tumour tissues had a higher eIF4E protein expression level. The lightly stained central area in Figure 2A represents necrotic tissue.

eIF4E may be an independent risk factor for liver cancer prognosis

Follow-up statistics showed recurrence in 33 cases and

Figure 2 Photo of hepatocellular carcinoma tissue and adjacent tissue by electron microscopy. A: Hepatocellular carcinoma tissue and adjacent interstitial tissue; B: Adjacent tissue. (Hematoxylin and eosin stain, ×100).

death in 12 cases. The patient age, gender, histological grade, depth of invasion, eIF4E overexpression, p53 positive status and other prognostic indicators were used for COX proportional hazards model for screening analysis. Ultimately, the depth of invasion, eIF4E, and p53 were included in the model with a Sig < 0.05 as shown in Table 2. The statistical significance suggests that these three factors are independent risk factors for liver cancer prognosis.

DISCUSSION

In eukaryotic cells, translational regulation plays an important role in gene expression. eIF4E is involved in the regulation of the mRNA translation process. It can enhance the translation of some important growth factors and cell growth regulators and affect protein synthesis, the cell cycle, cancer gene activation, and apoptosis; it also plays an important role in malignant transformation and metastasis.

eIF4E regulates the translation of cancer-related mRNAs (i.e., it is involved in the activation of proto-oncogenes, angiogenesis, apoptosis, invasion and metastasis) that are involved in tumour occurrence and development. Normal tissues have a low eIF4E expression level. eIF4E was overexpressed, in a variety of malignant tumours including head and neck squamous cell carcinoma, laryngeal cancer, lung cancer, breast cancer, thyroid cancer and other cancer tissues[4,23]. Its high expression was correlated with tumour invasion and metastasis. However, studies of eIF4E in liver cancer are rare. At present, there are studies

that involve the targeting eIF4E in head and neck squamous cell carcinoma[24,25], breast cancer[13-18], non-small cell lung cancer[26], blood malignancies[27-29] and other studies[6,30-32]. However, few studies have focused on targeting eIF4E in HCC.

In this study, we tested the expression of eIF4E protein in a normal human liver cell line and three different liver cancer cell lines. eIF4E protein expression was high in the three liver cancer cell lines and higher than in the normal liver cell L02. The HepG2 cell line had an especially high level of eIF4E protein expression. By comparing 46 cases of human liver cancer and adjacent tissues, we found that eIF4E protein expression was higher in most of the cancer tissues than in the adjacent tissues. COX proportional hazards model analysis showed that the depth of invasion, eIF4E, and p53 status were independent risk factors of liver cancer prognosis.

Based on these studies, we believe that eIF4E protein expression may be closely associated with the occurrence of human liver cancer development and prognosis. It has been confirmed *in vivo* and *in vitro* that sorafenib treatment can inhibit the RAF/MEK/ERK signal transduction pathway, reduce the eIF4E phosphorylation level, reduce Mcl-l protein, and induce hepatoma cell apoptosis[33,34]. Accordingly, we suggest that lower levels of *eIF4E* gene expression may inhibit liver cancer. Targeting and adjusting the eIF4E level and activity may inhibit cancer cell growth[6,30,31,35], which may become a new paradigm in the field of the biological treatment of liver cancer[36].

COMMENTS

Background

Hepatocellular carcinoma (HCC), which has a poor prognosis and a low five-year survival rate, is the most common malignant tumour in our country. At present, there are no effective therapies including radiotherapy, chemotherapy, and surgery. Eukaryotic translation initiation factor 4E (eIF4E) plays an important role in the translation initiation phase of a eukaryotic cell. It has been confirmed that eIF4E can specifically bind to the 5' mRNA cap (m7GpppN) and modulate its translation and expression. Its expression is closely associated with the generation, infiltration, and metastasis of many tumours such as head and neck, larynx, lung, mammary gland, thyroid gland, oesophagus, stomach, bile duct, colon.

Research frontiers

There are many researchers that are targeting eIF4E in head and neck squamous cell carcinoma, breast cancer, non-small cell lung cancer, blood malignancies and other carcinomas; however, studies that involve the targeting eIF4E in HCC are rare.

Innovations and breakthroughs

Research concerning the effects of eIF4E on HCC is limited. The authors tested the expression of the eIF4E protein in liver cancer cell lines and cancer tissues and used COX proportional hazards model analysis to show that eIF4E was an independent risk factor HCC prognosis.

Applications

The targeted regulation of the level and activity of eIF4E may inhibit cancer cell growth, which may become a new treatment paradigm in the liver cancer field.

Terminology

eIF4E is a member of the eIF family. It can specifically bind to the cap structure located at the 5' end of mRNAs named the "m7GpppN cap", which is necessary for mRNA translation initiation, and affects mRNA metabolism, processing, transportation and translation. It plays an important role in regulating the initial stage protein synthesis. eIF4E is highly expressed in a variety of human malignancies, which has been confirmed to be relevant to the occurrence, invasion and metastasis of carcinomas such as head and neck squamous cell carcinoma, laryngeal cancer, non-small cell lung cancer, breast, thyroid cancer, oesophageal cancer, stomach cancer, cholangiocarcinoma, colon cancer, non-Hodgkin's lymphoma, acute or chronic myeloid leukaemia, and lymphoma. Experiments have also confirmed that eIF4E is closely related to the prognosis of many carcinomas.

Peer review

This paper is interesting and worth being published if authors can satisfactorily address the concerns raised regarding immunohistochemical expression of eIF4E.

Abstract

AIM: To conduct a meta-analysis to estimate the determinants of the association between erosive esophagitis (EE) and body mass index (BMI).

METHODS: We identified the studies using PubMed. Studies were selected for analysis based on certain inclusion and exclusion criteria. Data were extracted from each study on the basis of predefined items. Meta-analyses were performed to verify the risk factors, such as obesity and gender.

RESULTS: Twenty-one studies were included in this systematic review. These studies demonstrated an association between increasing BMI and the presence of EE [95% confidence interval (CI): 1.35-1.88, overweight, odds ratio (OR) = 1.60, P value homogeneity = 0.003, 95% CI: 1.65-2.55, obese, OR = 2.05, $P <$ 0.01]. The heterogeneity disappeared by stratifying for gender. No publication bias was observed in this meta-analysis by the Egger method.

CONCLUSION: This analysis demonstrates a positive association between BMI and the presence of EE, especially in males. The risk seems to progressively increase with increasing weight.

INTRODUCTION

The symptoms of gastroesophageal reflux disease (GERD) are common health problems in industrialized societies. It is a highly prevalent gastrointestinal disorder encountered in clinical practice[1,2]. Erosive esophagitis (EE) is one of the most common forms of GERD. It occurs when excessive reflux of acid and pepsin results in necrosis of surface layers of the esophageal mucosa, thus causing erosions and

ulcers[3]. The etiology of EE may be multifactorial. Esophageal mucosal resistance, gastroesophageal reflux, volume and composition of the gastric contents, contact time for the refluxed material, the degree of incompetence of the intrinsic lower esophageal sphincter, and the presence of a sliding hiatus hernia are likely important determinants[4]. It is a chronic disease that exhausts socioeconomic and medical resources and its symptoms may lower the quality of life of the patients. Additionally, patients with EE are at increasing risk of developing Barrett's esophagus and esophageal adenocarcinoma[5].

During the past several decades, obesity has emerged as a major health concern in the Western world[6]. Several studies have found an increased risk of esophagitis in overweight patients[7-9]. Excess adiposity is a known risk factor for morbidity, including several cancers[10]. Recently, a relationship between obesity and GERD has been reported[11]. One recent population-based case control study reported a strong association between body mass index (BMI) and esophagitis in females, but not in males[12]. Given these associations, it would seem logical that increasing BMI is associated with EE. However, studies on the association between BMI and reflux esophagitis have yielded inconsistent results[13-16], though a few have found a strong relationship between obesity and EE[17,18].

The aim of this study was to investigate the effect of BMI on risk for EE by performing a meta-analysis of all available literature published in PubMed up to April 2011. By performing a meta-analysis of the studies that met our selection criteria, we hoped to better characterize the association between increased BMI and EE.

MATERIALS AND METHODS

Search strategy
Two investigators independently performed a systematic search of all existing English-language literatures published up to April 2011 using PubMed, an electronic search engine for published manuscripts. Search terms included "obesity", "BMI", "overweight" or "BMI", combined with "reflux or EE". A total of 268 articles were identified after the preliminary search was reviewed in further details.

Study selection
Studies were included if they met all the following inclusion criteria: (1) Cross-sectional, case control, or cohort studies that permitted assessment of a causal relationship between BMI and EE; (2) Studies with documented and clearly-defined BMI in kg/m^2 for all participants; (3) Studies that reported a relative risk or odds ratio (OR) with confidence intervals or provided sufficient data to permit their calculation; and (4) Studies with EE diagnosed by upper endoscopy. The inclusion criteria were not otherwise restricted by study size or publication type. The followings were chosen as the exclusion criteria: (1)

Studies not limited to humans or not written in English; (2) Studies that did not report risk estimates or raw data to allow independent calculation of these estimates; and (3) Case reports, case series or studies that lacked a control group.

Data abstraction
The abstracted data included information on the source of the study population, study design (case control, cohort, or cross-sectional), length of the study period, primary aim of the study, exposure definitions (BMI definitions of normal, overweight or obese), exposure measurement method (self-reported *vs* measured BMI), outcome definitions (diagnosis of EE with endoscopy), total number of subjects with EE, case and control criteria, ORs or risk ratios with and without adjustment for potential confounders and potential confounders used for adjustment.

Exposure definition
We defined body mass categories using the following BMI [weight (in kilograms)/height (in meters)^2]: "normal" (BMI between 18.5 and 25 kg/m^2), "overweight" (BMI between 25 and 28 kg/m^2), and "obese" (BMI $\geqslant$ 28 kg/m^2). These groupings represented the divisions or quartiles most frequently reported in the literature even though they differed somewhat from BMI categories in common use (overweight, BMI 25-29.9 kg/m^2; obese, BMI $\geqslant$ 30 kg/m^2)[11]. We also created a category that included both overweight and obese (BMI $\geqslant$ 25 kg/m^2). For each study, we selected the BMI classification that most closely approximated each of these categories. We included more than one estimate from the studies (e.g., if a study reported an OR for persons with a BMI 25-28 kg/m^2 and an OR for persons with a BMI $\geqslant$ 28 kg/m^2, both ORs were included in the summary estimate as BMI $\geqslant$ 25 kg/m^2)[11]. We then compared the risk of EE among the BMI categories.

We used estimates adjusted for potential confounders whenever they were available; if no adjusted estimates were provided, unadjusted estimates were used or calculated from the data[11].

Outcome definition
An outcome was defined as EE diagnosed with endoscopy. The severity of EE was graded from A to D according to the LA classification[19] or modified Savary-Miller classification (grade I, single or multiple non-confluent erosions; grade II, confluent non-circumferential multiple erosion; grade III, circumferential erosions; and grade IV, ulcer and/or stricture)[20].

Statistical analysis
The BMI data were extracted from each study and analyzed with STATA 11.0 (StataCorp, College Station, TX, United States, www.stata.com). Summary OR estimates were calculated using either relative risks (for cohort stud-

Figure 1 Flow diagram. BMI: Body mass index.

ies) or OR (for case control studies). Summary OR estimates were calculated based on the assumption of fixed effects and heterogeneity was tested using the Mantel-Haenszel method[21]. We evaluated heterogeneity by comparing the results between the fixed effects model and a random effects model[21]. Heterogeneity among the studies was analyzed using χ^2 test and considered present if $P \leqslant 0.05$ or if there was more than a 20% difference in the summary estimates between the two models. To enhance the confidence of the results of the statistics when the number of combined studies was deficient, we used the I^2 metric, which describes the proportion of variability across studies that is due to score heterogeneity. If $I^2 = 0$, there is no heterogeneity. $I^2 > 50\%$ is considered to be indicative of heterogeneity. Larger values indicate greater heterogeneity. If these tests indicated heterogeneity, we explored possible causes[21-24]. Then, to exclude the excessive influence of any single study, we assessed whether exclusion of any single study substantially altered the magnitude or heterogeneity of the summary estimate. We also stratified analyses by several factors[25-31]. Funnel plots were produced and Egger's test[32] was conducted to examine publication bias.

RESULTS

We identified 268 published articles or abstracts (Figure 1). After review of titles and abstracts, 31 articles appeared to meet the initial inclusion criteria. The excluded studies were review articles, animal experiments, case series that lacked appropriate control groups and studies that did not report the subject of interest. These 31 studies underwent a complete data abstraction. Ten additional studies were excluded after data abstraction for the following reasons: BMI categories that were inconsistent with the proposed reference ranges[7,33-36], inconsistent outcome definition[37], lack of proper control group[38],

and lack of evaluable risk estimates within the proposed categories[39-41].

The remaining 21 studies[4,8,12,42-59] (i.e., four cross-sectional, three cohort, 14 case control studies) were included in the primary analysis (Tables 1 and 2). Twelve studies were conducted for the primary purpose of evaluating the relationship between BMI and EE[4,44,45,49-52,54,55,57-59], eight studies were conducted to identify the variety of risk factors for EE, including BMI[8,12,42-48,53,56], and one study described the clinical characteristics of EE and non-erosive reflux disease, including BMI[43]. In Table 1, controls and normal groups were composed of general population and healthy volunteers. Eighteen studies were included in Table 3 because of their stratification by gender.

The pooled OR of EE related to BMI of 25 kg/m^2 or higher was 1.64-fold greater than that of EE related to BMI less than 25 kg/m^2 (OR, 1.64, 95% CI: 1.45-1.85, test for homogeneity, $P = 0.000$, $I^2 = 65.7\%$) (Figure 2, Table 3).

Stratification by gender and BMI category showed a homogeneous positive association between increased BMI and EE, and the strength of the association with increased BMI (Table 3). The risk for overweight males (OR, 1.40, 95% CI: 1.11-1.75, $P = 0.285$) increased further for obese males (OR, 1.75, 95% CI: 1.02-2.96, $P = 0.099$) (Figure 3). The pooled OR in females and males for BMI greater than 25 kg/m^2 were 1.45 (95% CI: 1.26-1.66) and 1.52 (95% CI: 1.24-1.87), respectively. Therefore, we considered there was a strong positive association between increasing BMI and EE in males, but not in females.

Evaluation of heterogeneity

The initial summary estimates for EE were heterogeneous, as described above. Stratification by BMI category did not substantially resolve the heterogeneity; however, additional stratification by gender provided more homogeneity. Stratification of the entire population by exposure measurement (e.g., self-report *vs* measured), or study design (case control *vs* cohort) did not substantially influence the initial heterogeneity (Table 3).

Publication bias

The rank correlation test did not suggest the presence of publication bias for the main summary estimates for either the overweight ($P = 0.656$) or the obese and overweight ($P = 0.804$). A review of funnel plots did not demonstrate patterns strongly suggestive of publication bias (Figure 4).

DISCUSSION

Our pooled results of observational studies demonstrated a positive association between increased BMI and the risk of EE. The strength of the association increased with increasing BMI and there was a trend towards a stronger association in males than in females. Unlike other non-modifiable risk factors such as age, race and gender, BMI is potentially modifiable. Thus, identifying a relationship

between obesity and EE might have significant implications for counseling.

A recent meta-analysis of BMI and GERD complications found heterogeneous results and it was not able to identify strata with homogeneous results[60]. It was pos-sibly due to their methods of stratification, the utilization of estimates with markedly different measures of BMI association, the absence of studies included in the cur-rent analysis, and the inclusion of studies that did not set up a non-GERD control group. In contrast, in the cur-

Table 2 Exposure and outcome definitions

Authors	Yr	Exposure (source)	BMI reference (kg/m²)	Exposure (definitions)			Outcome (source)	Outcome (definitions)
				BMI overweight (kg/m²)	BMI obese (kg/m²)	BMI overweight + obese (kg/m²)

BMI: Body mass index; NA: Not available.

Figure 2 Erosive esophagitis and body mass index (overweight and obese) in males and females. The size of the square represents the weight that the corresponding study exerts in the meta-analysis. RR: Relative risk; OR: Odds ratio.

Study ID	RR/OR (95% CI)	Weight (%)
Nilssom *et al*[12], 2002	1.06 (0.56-2.01)	8.74
Moki *et al*[56], 2007	1.80 (1.30-2.50)	23.38
Nocon *et al*[55], 2007	1.36 (1.22-1.52)	48.66
Wang *et al*[46], 2010	2.46 (1.29-4.70)	8.61
Nam *et al*[44], 2010	1.57 (0.89-2.78)	10.61
Overall (I^2 = 36.3%, *P* = 0.179)	1.52 (1.24-1.87)	100.00

NOTE: Weights are from random effects analysis

Figure 3 Erosive esophagitis and body mass index (overweight and obese) in males. The size of the square represents the weight that the corresponding study exerts in the meta-analysis. RR: Relative risk; OR: Odds ratio.

Table 3 Meta-analysis results in association between body mass index and erosive esophagitis

BMI category	OR (95% CI)	$P_{homogeneity}$	I^2 (%)	No. of studies
Overall				
Overweight	1.60 (1.35-1.88)	0.003	59.8	12[4,8,12,44,45,50,51,53,54,57-59]
Obese	2.05 (1.65-2.55)	0.000	74.2	15[4,8,12,44-46,50-54,56-59]
Overweight + obese	1.64 (1.45-1.85)	0.000	65.7	18[4,8,12,43-47,49,50-54,56-59]
Females				
Overweight	1.47 (1.15-1.88)	0.011	7.4	3[12,44,55]
Obese	3.76 (0.92-15.28)	0.340	78.0	3[12,44,55]
Overweight + obese	1.45 (1.26-1.66)	0.579	0.0	4[12,44,55,56]
Males				
Overweight	1.40 (1.11-1.75)	0.285	20.8	4[12,44,46,55]
Obese	1.74 (1.02-2.96)	0.099	52.1	4[12,44,46,55]
Overweight + obese	1.52 (1.24-1.87)	0.179	36.3	5[12,44,46,55,56]

BMI: Body mass index; OR: Odds ratio.

Figure 4 Evaluation of publication bias using a funnel plot. No significant funnel asymmetry was observed which could indicate publication bias. The horizontal line in the funnel plot indicates the random effects summary estimate, while the sloping lines indicate the expected 95% CI for a given standard error, assuming no heterogeneity between studies. Each trial is represented by a circle, the area of which represents the trial's precision. Larger circles represent trials that offer more information.

rent study, after the creation of more categories of BMI among the studies, stratification by gender demonstrated a homogeneous increase in EE with increasing BMI. A study showed a positive correlation between BMI and EE in females, but not in males[12] and a study of reflux patients showed that obese females, but not obese males, had an increased risk of severe esophagitis[55]. The study by Nilsson[12] also found that the association between obesity and EE was further strengthened by the use of oestrogen replacement medication. The prevalence of GERD symptoms as determined in a study investigating a cohort from North America did not differ between males and females[61]. In contrast, in another study, EE was more common in males than in females from Asia[42]. However, in our study, we found a strong positive association between increasing BMI and EE in males, but not in females. This may be because the populations of the included studies were from Asia.

Several hypotheses have been proposed to explain how obesity can cause EE. Abdominal fat may cause reflux through an increase in intrabdominal pressure and subsequent esophageal acid exposure[62,63]. Also, there was a suggestion that hormonal factors related to adiposity are more important than mechanical factors[63]. Obesity is also associated with increased transient lower oesophageal sphincter relaxation[64]. Strengths of this analysis include the use of strict criteria for defining our outcome of interest and the consistency of the BMI-EE association within the males despite different patient populations and different study designs. All the included studies used endoscopy to confirm the diagnosis of EE, which eliminated the possibility of false positive EE cases. Also, we included stratification by study design, location, and source population.

There are potential limitations of this analysis. First, only observational studies were included; study results may be influenced by the presence of measured or unmeasured confounding factors, such as physical activity. Second, bias may also exist in the present study because unpublished data were not included, nor were conference abstracts or articles published in a language other than

English. Third, the exposure definitions (i.e., normal, obese or overweight) differed slightly among the studies. We addressed this, however, by creating more comparable and consistent categories, although few differences still remained. Also, the accuracy of the BMI measurement and its reliability as a measure of adiposity are known to be imperfect.

In summary, based on our extensive review and synthesis of the literature, there appears to be a statistically significant association between elevated BMI and EE. Considering the prevalence of obesity and increasing incidence rates of EE, it is important to pay more attention to further studies that evaluate the influence of gender, ethnicity or age on EE to examine this association. Several studies have found abdominal visceral obesity to be an independent risk factor for EE[44,57]. Nam *et al*[44] demonstrated that association between EE and abdominal visceral adipose tissue volume was consistent among males and females, unlike the association between EE and BMI. However, CT or MRI is needed to test abdominal visceral adipose, which are time consuming and costly. So, measuring BMI may be more feasible. It is also important to determine whether weight loss can decrease the incidence of EE. Further studies are needed to evaluate the relationship between obesity and EE.

COMMENTS

Background
Both obesity and erosive esophagitis (EE) have a high prevalence worldwide. The relationship between them remains controversial.

Research frontiers
Many studies have been performed to evaluate the body mass index (BMI) for gastroesophageal reflux disease risk. It has been found that there was a positive correlation between BMI and EE in females, but not in males.

Innovations and breakthroughs
Findings from this meta-analysis suggested the importance of BMI in EE, especially in males.

Applications
This study provided the potential measurement indicators to identify high-risk groups for EE in obesity population, especially in males.

Terminology
BMI: BMI is a heuristic proxy for human body fat based on an individual's weight and height. It is defined as the individual's body mass divided by the square of his or her height; EE: EE is a term used to indicate any inflammation, swelling, or irritation of the esophagus. The esophagus becomes inflamed (swollen, irritated and red).

Peer review
The meta-analysis presents the data on association between obesity and EE. The topic is interesting and the methodology of the meta-analysis is appropriate.

BRIEF ARTICLE

Serum inter-cellular adhesion molecule 1 is an early marker of diagnosis and prediction of severe acute pancreatitis

Abstract

AIM: To determine if serum inter-cellular adhesion molecule 1 (ICAM-1) is an early marker of the diagnosis and prediction of severe acute pancreatitis (SAP) within 24 h of onset of pain, and to compare the sensitivity, specificity and prognostic value of this test with those of acute physiology and chronic health evaluation (APACHE) II score and interleukin-6 (IL-6).

METHODS: Patients with acute pancreatitis (AP) were divided into two groups according to the Ranson's criteria: mild acute pancreatitis (MAP) group and SAP group. Serum ICAM-1, APACHE II and IL-6 levels were detected in all the patients. The sensitivity, specificity and prognostic value of the ICAM-1, APACHE II score and IL-6 were evaluated.

RESULTS: The ICAM-1 level in 36 patients with SAP within 24 h of onset of pain was increased and was significantly higher than that in the 50 patients with MAP and the 15 healthy volunteers ($P < 0.01$). The ICAM-1 level (25 ng/mL) was chosen as the optimum cutoff to distinguish SAP from MAP, and the sensitivity, specificity, positive predictive value, negative predictive value (NPV), positive likelihood ratio and negative likelihood ratio were 61.11%, 71.42%, 0.6111, 0.7142, 2.1382 and 0.5445, respectively. The area under the curve demonstrated that the prognostic accuracy of ICAM-1 (0.712) was similar to the APACHE-II scoring system (0.770) and superior to IL-6 (0.508) in distinguishing SAP from MAP.

CONCLUSION: ICAM-1 test is a simple, rapid and reliable method in clinical practice. It is an early marker of diagnosis and prediction of SAP within the first 24 h after onset of pain or on admission. As it has a relatively low NPV and does not allow it to be a stand-alone test for the diagnosis of AP, other conventional diagnostic tests are required.

INTRODUCTION

Most cases of acute pancreatitis (AP) are mild and self limiting, and recover spontaneously, but approximately 20% of attacks turn to severe acute pancreatitis (SAP) with a life-threatening morbidity and a mortality rate

of 20%-30%. Hence, early diagnosis and prediction of the severity of AP are of particular significance[1]. Early prediction of the severity of AP is still difficult in clinical practice. Ranson's score can only be evaluated 48 h after admission. The acute physiology and chronic health evaluation II (APACHE II) score can be used within a few hours after admission, but its complex and cumbersome performance limits its clinical use[2]. Several laboratory markers have been developed over the past decade for the early diagnosis and prediction of SAP. Since there is no correlation found between the degree of structural damage to pancreas and clinical manifestation of the disease, no ideal predictive system or biochemical marker has been available. Several reports showed that serum intercellular adhesion molecule-1 (ICAM-1) levels were elevated during the course of AP and correlated with the severity of the disease and patient outcome. ICAM-1 can be detected as an early marker in the diagnosis of lung injury[3,4]. However, the details of the clinical use of this test for early diagnosis and prediction of SAP remain obscure, especially within the first 24 h in the patients after admission. The aim of this prospective study was to evaluate the use of the ICAM-1 in early diagnosis and prediction of SAP.

MATERIALS AND METHODS

Study population
All patients with AP were included in the primary analysis according to the guidelines of diagnosis and treatment of AP established by Branch of Gastroenterology, Chinese Medical Association in 2003[5]. The diagnosis of AP was based on the following features: (1) Prolonged abdominal pain characteristic of AP; (2) Elevated serum amylase and/or lipase levels by at least 3-folds that of normal range; and (3) Characteristic findings of AP on abdominal ultrasonography and/or computed tomography (CT) scan. Patients who were admitted within the first 24 h of the onset of abdominal pain were not included in the study. Patients with an accompanying disease that might influence the outcome data were excluded, such as postoperative, post-traumatic, post-endoscopic retrograde cholangiopancreatographic pancreatitis. Other causes of acute abdominal pain were ruled out. Eighty-six patients with AP included in this pilot study were analyzed in a prospective 1-year investigation performed at a single institution.

Clinical assessment
The study was approved by the Committee of Research Ethics of our hospital, and informed consent was obtained from all the patients and healthy volunteers before enrollment. Demographics (gender, age, occupation, course and characteristics of symptom) and the cause of the pancreatitis (cholelithiasis, alcohol abuse, hyperlipidemia and others) were recorded. Routine clinical observation, laboratory test and treatment were performed. The APACHE-II score was determined within the first

24 h and 48 h of the onset of pain after admission[6]. Ultrasonography was performed every other day in all the patients and/or spiral CT with intravenous contrast was performed in some patients within 48-72 h after admission to assess the extent of inflammation and the degree of pancreas necrosis according to Balthazar's classification. After the examinations, patients' data were reviewed to determine the eligibility for inclusion into the study.

Clinical classification
Ranson's score was recorded in the first 24 h and 48 h after admission. Since Ranson *et al*[7] in 1974 identified 11 prognostic factors, considerable researches have been undertaken to find the ideal predictor(s) that allow rapid and correct assessment of the severity of AP to suit different clinical and regional settings. SAP was categorized based on the clinical and laboratory data using Ranson's score. Cases meeting less than three positive criteria were classified as mild acute pancreatitis (MAP) and those meeting three or more positive criteria were classified as SAP.

Sample collection and enzyme-linked immunosorbent assay for ICAM-1 and interleukin-6
To check the time kinetics of rise in plasma ICAM-1 and interleukin-6 (IL-6) during AP, its levels were quantified in two time-points. The potential of ICAM-1 and IL-6 to predict SAP within the first 24 h and 48 h after the onset of symptoms or on admission was examined. A 5-mL sample of peripheral venous blood was collected twice from the 85 patients with AP. Blood samples obtained from the 15 healthy volunteers served as controls. The plasma was separated by centrifugation at 3000 r/min for 10 min at 4 ℃ and stored at -20 ℃ until assayed. Plasma ICAM-1 and IL-6 were quantified with commercially available enzyme-linked immunosorbent assay (ELISA) kits (Sen-Xiong Technology Limited Company, Shanghai, China). ELISA plates were read at 450 nm and data was collected. Measurement was performed according to the instructions of the manufacturer.

Presentation of data and statistical analysis
After the examinations, data from each patient were reviewed to ascertain the eligibility for inclusion into the study. The data of gender, etiology of SAP and MAP, and the categorical variables were compared using χ^2 test. Analysis of variance was performed in the continuous variables of age, ICAM-1, IL-6 levels and other relative laboratory tests for SAP and MAP using Student's *t* test. The differences were considered statistically significant if $P \leqslant 0.05$. In order to differentiate SAP from MAP within the first 24 h of the onset of symptoms, the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and positive likelihood ratio (PLR) and negative likelihood ratio (NLR) at different serum levels of ICAM-1 compared with APACHE II and IL-6 levels were calculated, respectively. The level of higher

PLR and lower NLR was chosen as the optimum cutoff point. A receiver operating characteristic (ROC) curves were constructed to determine the reference cutoff point for ICAM-1, APACHE Ⅱ and IL-6 levels that could distinguish between SAP and MAP. An index of the goodness of the test of area under the curve (AUC) was used to measure the ability of distinguishing SAP from MAP. A perfect test had an area of 1.0, while a non-discriminating test had an area of 0.5. All statistical analyses were performed using SPSS v8.00 statistical analysis software (SPSS Inc., Cary, NC).

RESULTS

Clinical characteristics of AP
The prospective study population consisted of 86 consecutive patients with AP (48 men, 38 women with a mean age of 50.7 years; range, 17-79 years) and 15 healthy volunteers (10 men, 5 women with a mean age of 48.7 years; range, 28-58 years). Forty-nine (56.9%) patients were diagnosed as having MAP and 36 (41.8%) as having SAP according to the Ranson's criteria. The clinical characteristics of the patients with AP are summarized in Table 1. Gallstones were the most common cause of both SAP and MAP (*n* = 19, 52.7% and *n* = 20, 40.8%, respectively). There was no difference in the sex, race and etiology of the disease between the SAP and MAP patients. The mean serum amylase and glucose levels were significantly higher in SAP than in MAP (*P* < 0.05). There was no significant difference in the serum level of total bilirubin between the two groups at the first 24 h after the onset of pain.

Mean scores of APACHE-Ⅱ, serum ICAM-1 and IL-1 levels in patients with SAP and MAP
The mean scores of APACHE-Ⅱ in the SAP patients within the first 24 h after the onset of pain were also significantly higher than in the MAP patients *(P < 0.001)*. The mean serum level of ICAM-1 in the SAP patients

within the first 24 h after the onset of pain was significantly higher than in the MAP patients *(P < 0.001)* and the healthy controls *(P < 0.001)*. Significantly higher levels of IL-6 were found in the SAP patients as compared with the MAP patients at the 24 h and the healthy controls *(P < 0.001)*. The APACHE-Ⅱ scores within the first 24 h after admission to hospital were significantly higher in SAP than in MAP patients *(P < 0.001)* (Table 2). The mean serum level of ICAM-1 in SAP patients at 48-72 h after admission was obviously higher than in SAP patients within the first 24 h after admission *(P < 0.001)*. The level of IL-6 declined in the AP patients at 48-72 h after admission, but it was still obviously higher in the SAP patients than in the MAP patients *(P < 0.001)*. The mean scores of APACHE-Ⅱ in SAP and MAP at the 48-72 h after the onset of pain were slightly increased, but the scores in SAP were significantly higher than that in MAP in the first 24 h (Table 3).

Sensitivity, specificity, PPV, NPV, PLR and NLR of ICAM-1 in distinguishing SAP from MAP
The sensitivity, specificity, PPV, NPV, PLR and NLR at different serum ICAM-1 levels (10, 15, 25, 30, 35, 40 and 45 ng/mL) were determined respectively. The ICAM-1 level (25 ng/mL) with higher PLR and lower NLR was chosen as the optimum cutoff to distinguish SAP from MAP within first 24 h of the onset of symptoms, and the sensitivity, specificity, PPV, NPV, PLR and NLR were 61.11%, 71.42%, 0.6111, 0.7142, 2.1382

Table 4 Sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratio and negative likelihood ratio of acute physiology and chronic health evaluation Ⅱ, intercellular adhesion molecule-1 and interleukin-6 in distinguishing severe acute pancreatitis from mild acute pancreatitis

	Cutoffs	Sensitivity (%)	Specificity (%)	PPV	NPV	PLR	NLR
APACHE-Ⅱ	> 8	77.77	55.10	0.5600	0.7714	1.7320	0.2223
ICAM-1	25 ng/mL	61.11	71.42	0.6111	0.7142	2.1382	0.5445
IL-6	50 ng/mL	36.11	63.26	0.6190	0.5740	0.8826	1.1680

APACHE-Ⅱ: Acute physiology and chronic health evaluation Ⅱ; ICAM-1: Intercellular adhesion molecule-1; IL-6: Interleukin-6; PPV: Positive predictive value; NPV: Negative predictive value; PLR: Positive likelihood ratio; NLR: Negative likelihood ratio.

and 0.5445, respectively. The APACHE-Ⅱ scores (< 4, 4-8, 9-12, 13-16, 17-20 and > 20) were also calculated. The sensitivity, specificity, PPV, NPV, PLR and NLR at the optimum cutoffs of APACHE-Ⅱ score > 8 were 77.77%, 55.10%, 0.5600, 0.7714, 1.7320 and 0.2223, respectively. The different serum IL-6 levels (20, 30, 40, 50, 60, 70 and 80 ng/mL) were respectively calculated using the same method. The sensitivity, specificity, PPV, NPV, PLR and NLR at the optimum cutoffs of IL-6 50 ng/mL were 36.11%, 63.26%, 0.6169, 0.5740, 1.5869 and 0.9180, respectively (Table 4).

ROC curves and AUC of ICAM-1, APACHE-Ⅱ and IL-6 in distinguishing SAP from MAP

The optimum cutoffs of APACHE-Ⅱ score > 8, serum ICAM-1 (25 ng/mL) and IL-6 (50 ng/mL) which were used to distinguish SAP from MAP within the first 24 h of the onset of symptoms were analyzed by constructing a ROC curve. The AUC of ICAM-1, APACHE-Ⅱ and IL-6 in predicting SAP was 0.712, 0.770 and 0.508, respectively (Figure 1). The AUC demonstrated that the prognostic accuracy of ICAM-1 was similar to the APACHE-Ⅱ scoring system. The AUC of serum ICAM-1 level was obviously superior to that of IL-6. The serum IL-6 level was not capable of distinguishing SAP from MAP within the first 24 h of the onset of symptoms.

DISCUSSION

In China, the exact incidence of AP is still unknown, but it is increasing gradually in recent years. AP is a life-threatening illness with an annual incidence of 30-50 attacks per 100 000 inhabitants[8]. It is an inflammatory process that presents different severity degrees, ranging from a mild self-limiting disease with interstitial edema in the pancreas, to a severe disease with extensive necrosis[9]. It progresses to a severe illness with a prolonged course in about 15%-20% of the patients. These severely ill patients may develop organ failure and/or local complications such as pancreatic necrosis. Approximately, 75% of the cases are mild with a mortality below 1%. Eighty percent of the patients

Figure 1 Cutoffs of acute physiology and chronic health evaluation Ⅱ score > 8, serum intercellular adhesion molecule-1 (25 ng/mL) and interleukin-6 (50 pg/mL) levels that can distinguish severe acute pancreatitis from mild acute pancreatitis within 24 h of the onset of symptoms were analyzed by constructing a receiver operating characteristic curve. The area under the curve for intercellular adhesion molecule-1 (ICAM-1), acute physiology and chronic health evaluation Ⅱ (APACHE-Ⅱ) score > 8 and interleukin-6 (IL-6) in predicting severe acute pancreatitis was 0.712, 0.770 and 0.508, respectively.

could recover completely, while 20% had their disease worsened according to the Atlanta criteria. The mortality increases up to 20% if the disease progresses into a severe necrotizing form[10] and the mortality can be as high as 30%-40%[11]. Current management strategies for patients with SAP include early admission to intensive care units, vigorous intravenous resuscitation, and urgent endoscopic retrograde cholangiopancreatography when cholangitis or biliary obstruction is present, antibiotic prophylaxis in patients with pancreatic necrosis, and close patient monitoring.

Thus, the management of AP is still challenging mainly due to the delay in admission to hospital after the onset of symptoms and the difficulty in discriminating MAP from SAP, especially within the first 24 h. There is an urgent need for an early and accurate prediction of SAP to ensure timely interventions in a specialized care setting[12]. The early recognition and diagnosis are an important goal in the optimal management of SAP. Severity assessment is indispensable to the selection of proper initial treatment in the management of AP.

Several prognostic scoring systems are being used in predicting SAP: Ranson's, Glasgow's, APACHE-Ⅱ, the bedside index for severity of AP (BISAP), and computed tomography severity index (CTSI). Papachristou *et al*[13] reported that the AUC for BISAP, Ranson's, APACHE-Ⅱ and CTSI in predicting SAP are 0.81, 0.94, 0.78 and 0.84, respectively in 185 patients with AP and found that all these scoring systems had a high accuracy in predicting SAP in the first 24 h after admission. The components of the BISAP score are clinically relevant and easy to obtain. Lujano-Nicolás *et al*[14] evaluated the severity of AP according to the Ranson's and APACHE-Ⅱ scores on admission in 28 patients with AP and correlated these scales with the local pancreatic complications according to the Balthazar classification. They found that

these scales have discrepancies when compared with to-mographic Balthazar and these scales were not correlated well with the tomographic Balthazar degrees. The Ranson's prognostic signs and the Glasgow's score can only be applied 48 h after admission. The APACHE-Ⅱ score has the invaluable advantage of being useful within a few hours after admission, and it can be assessed serially. However, it is cumbersome, which limits its use in clinical practice. The current gold standard for staging AP combines the clinical criteria with CT, but because of the high cost, exposure to ionizing radiation, and lack of sensitivity and specificity in the early stage of the disease, it has limited availability.

Numerous efforts have been made in recent years to identify objective markers that can predict the severity of AP on admission. Various biochemical tests, such as C-reactive protein (CRP), tumor necrosis factor, IL-2 and IL 6, have been developed over the past decade for early diagnosis and prediction of severity of AP[15-17]. However, except for CRP, none of them can accurately predict the disease severity within 24 h of onset, and the outcome in triage to the intensive care unit has not been reported[18]. As there is no correlation between the degree of structural damage to pancreas and clinical manifestation of the disease, there has been no ideal predictive system or biochemical marker for this disease. Little is known about clinical predictors of early readmission for AP. The ideal predictors of the severity of AP are described as being simple, quick, highly sensitive, highly specific, safe, reproducible, and cheap. An immediate test with a high specificity, AUC and low NLR is required. Unfortunately, this ideal predictor is still not available[19].

Adhesion molecules are involved in the inflammatory response during AP. ICAM-1, a single-chain transmembrane glycoprotein with a molecular weight of 80-110 kDa, consists of five Ig-like domains, a hydrophobic transmembrane domain and a short cytoplasmic C-terminal domain. Its ligand includes lymphocyte function-associated antigen-1 and macrophage antigen-1. Under physiological conditions, ICAM-1 is expressed at a low level in endothelial cells and epithelial cells or constitutively on the surface of alveolar cells, providing the underlying molecular basis for cell recognition, activation, proliferation, differentiation and motility, thereby helping stabilize the internal environment of the body. ICAM-1 also plays a key role in pathological events, such as inflammatory reactions, including acute renal failure and acute pancreatitis[20].

One of the most common complications of AP is acute lung injury, during which ICAM-1 plays an important role by participating in leukocyte adhesion and activation as well as by inducing the "cascade effect" of inflammatory mediators, pulmonary microcirculation dysfunction and even acute respiratory distress syndrome, multiple organ failure or death. The upregulation of ICAM-1 expression in the lung during acute lung injury is one of main pathogeneses; the early detection of the ICAM-1 expression level may contribute to the prevention and treatment of acute lung injury[3,4]. Sun *et al*[20] in-vestigated the ICAM-1 in mediating the development of AP from a local disease to a systemic illness in rats and found that upregulation of ICAM-1 and subsequent leukocyte infiltration appear to be significant events of pancreatic and pulmonary injuries. Intracapillary leucocyte accumulation represents a novel protective and potentially lifesaving mechanism of hemostasis in acute pancreatitis. This process depends on the expression of lymphocyte function-associated antigen 1 and ICAM-1 and precedes the classical steps of the leucocyte recruitment cascade[21]. Chooklin *et al*[22] measured the serum levels of pro-inflammatory and anti-inflammatory cytokines in 51 AP patients who were diagnosed with pancreatitis-associated lung injury with and without the development of organ dysfunction and found that in the pathogenesis of respiratory complications in AP cytokines, chemokines and adhesion molecules, in particular ICAM-1, play major roles. High ICAM-1 concentration was found in plasma during AP, which was not reduced by Dx treatment. Dexamethasone down-regulates ICAM-1 expression, but it does not completely prevent leukocyte recruitment during sodium taurocholate-induced AP[23]. Pancreatic ICAM-1 expression was increased in single-nucleotide polymorphism as compared with the controls. After calcitonin gene-related peptide application, pancreatic ICAM-1 expression was attenuated[24]. Graft pancreatitis is induced by ischemia/reperfusion injury in which neutrophil infiltration is believed to be a crucial early event. The data suggested that ICAM-1 was already up-regulated during cold ischemia, possibly representing the mechanism of early neutrophil infiltration observed in human pancreatic ischemia/reperfusion injury[25].

Irrespective of the underlying etiology, the immune response is almost identical in severe cases of AP. While the triggering factors of AP are still poorly understood, cytokines are considered as important mediators in the pathophysiology of SAP. Perejaslov *et al*[26] reported that peak levels of sICAM-1 on admission in AP 87 patients had a subsequent decrease and these mediators are correlated with the disease severity, development of multiple organ dysfunction syndrome and necrosis and may be used as prognostic markers. Several reports showed that serum ICAM-1 levels are elevated during the course of AP and correlate with the severity of the disease and patient outcome. ICAM-1 can be detected as an early marker for the diagnosis of lung injury[20]. Although serum ICAM-1 level was increased in AP patients and closely related to the development of SAP in many clinical studies, the details of the use of ICAM-1 for early diagnosis and prediction of SAP remain obscure, especially in the first 24 h after the admission. The aim of our prospective study was to evaluate the use of the ICAM-1 in early diagnosis and prediction of SAP, and to compare the sensitivity, specificity and prognostic value of this test with those of APACHE-Ⅱ score and IL-6.

Among the 86 patients with AP in this study, 49 patients were diagnosed as having MAP and 36 as having SAP according to the Ranson's criteria. The mean serum

level of ICAM-1 in the SAP patients within the first 24 h of the onset of pain was significantly higher than in MAP patients and the healthy controls. The mean serum level of ICAM-1 in the SAP patients at 48-72 h after admission was obviously higher than in the SAP group. The result showed that ICAM-1 is a simple, rapid and reliable method for use within the first 24 h after admission. It has a higher specificity and a sensitivity for early diagnosis and prediction of SAP. The AUC value demonstrated that the prognostic accuracy of ICAM-1 is similar to the APACHE-Ⅱ scoring system and obviously superior to IL-6 in distinguishing SAP from MAP. Previous reports showed the usefulness of serum IL-6 level in determining the severity of acute pancreatitis[18], but our data indicated that the serum IL-6 level could not distinguish SAP from MAP within the first 24 h. The exact reason for the difference is still unknown. Although the APACHE-Ⅱ scoring system has a high prognostic accuracy, it is too complex and cumbersome, which limits its clinical use. However, ICAM-1 has a relatively low NPV and does not allow it to be a stand-alone tool for diagnosis of acute pancreatitis; and the use of other conventional diagnostic tools remains a requirement.

In conclusion, we found that serum ICAM-1 levels rose within the first 24 h after the onset of AP and that early measurement of serum ICAM-1 levels could distinguish SAP from MAP. It has a higher sensitivity, specificity and NPV. It could be used as a test in screening patients with AP and predicting the outcome in patients with SAP. The predictive accuracy of ICAM-1 is similar to APACHE-Ⅱ scoring system and obviously superior to IL-6. But its low NPV does not allow it to be a stand-alone tool for the diagnosis and prediction of AP. To identify a novel predictor of severity and outcome of AP is needed so as to improve the predictive accuracy.

COMMENTS

Background
Most cases of acute pancreatitis (AP) are mild and self limiting, and recover spontaneously, but approximately 20% of attacks turn to severe acute pancreatitis (SAP) with a life-threatening morbidity and a mortality rate of 20%-30%. There is no established biomarker for early diagnosis and prediction of severe pancreatitis. Early diagnosis and prediction of the severity of AP is of particular significance.

Research frontiers
Serum intercellular adhesion molecule-1 (ICAM-1) levels are elevated during the course of AP and correlate with the severity of the disease. ICAM-1 can be detected as an early marker for the diagnosis of lung injury. The details of the clinical use of ICAM-1 for early diagnosis and prediction of severity in AP remain obscure, especially in the first 24 h after the admission. This study evaluated the use of the ICAM-1 in early diagnosis and prediction of SAP, and compared the sensitivity, specificity and prognostic value of this test with those of acute physiology and chronic health evaluation (APACHE) Ⅱ score and interleukin-6 (IL-6).

Innovations and breakthroughs
Serum ICAM-1 is elevated within the first 24 h after the onset of symptoms. Elevated ICAM-1 levels are associated with the severity of AP with a higher sensitivity, specificity and negative predictive value for early diagnosis and prediction of severity in AP. The predictive accuracy of ICAM-1 is similar to the APACHE-Ⅱ scoring system and obviously superior to IL-6.

Applications
Serum ICAM-1 is an early marker for the diagnosis and prediction of SAP, and

the test is simple, rapid and reliable that can be used in clinic practice. The results obtained are important for both early diagnosis and treatment of pancreatitis.

Terminology
ICAM-1 is a single-chain transmembrane glycoprotein. Under physiological conditions, it is expressed at a low level in endothelial cells providing the underlying molecular basis for cell recognition, activation, proliferation, differentiation and motility. ICAM-1 also plays a key role in pathological events, such as inflammatory reactions, including acute renal failure and acute pancreatitis

Peer review
The manuscript reports that ICAM-1 is a useful marker for early diagnosis and a potential predictor of severe acute pancreatitis. These data are important for early treatment for pancreatitis patients.

Abstract

AIM: To investigate the prevalence and physicians' detection rate of depressive and anxiety disorders in gastrointestinal (GI) outpatients across China.

METHODS: A hospital-based cross-sectional survey was conducted in the GI outpatient departments of 13 general hospitals. A total of 1995 GI outpatients were recruited and screened with the Hospital Anxiety and Depression Scale (HADS). The physicians of the GI departments performed routine clinical diagnosis and management without knowing the HADS score results. Subjects with HADS scores $\geq$ 8 were subsequently interviewed by psychiatrists using the Mini International Neuropsychiatric Interview (MINI) to make further diagnoses.

RESULTS: There were 1059 patients with HADS score $\geq$ 8 and 674 (63.64%) of them undertook the MINI interview by psychiatrists. Based on the criteria of Diagnostic and Statistical Manual of Mental Disorders (4th edition), the adjusted current prevalence for depressive disorders, anxiety disorders, and comorbidity of both disorders in the GI outpatients was 14.39%, 9.42% and 4.66%, respectively. Prevalence of depressive disorders with suicidal problems [suicide attempt or suicide-related ideation prior or current; module C (suicide) of MINI score $\geq$ 1] was 5.84% in women and 1.64% in men. The GI physicians' detection rate of depressive and anxiety disorders accounted for 4.14%.

CONCLUSION: While the prevalence of depressive and anxiety disorders is high in Chinese GI outpatients, the detection rate of depressive and anxiety disorders by physicians is low.

INTRODUCTION

Gastrointestinal (GI) disease is a serious illness, which

frequently affects a patient's physical and emotional wellbeing as well as being heavily affected by stress[1-3]. Meanwhile depression and anxiety have been identified as risk factors for some GI diseases[4-6].

Various studies using a variety of assessment methods have demonstrated that high levels of depression and anxiety exist in patients with GI symptoms[7-9]. It has also been shown that patients with comorbid anxiety and depressive disorders tend towards more severe symptoms, longer recovery times, poorer outcomes, and greater use of healthcare resources[10-12]. Despite the likelihood of GI patients to suffer from emotional distress, it has been reported that physicians in the GI department often fail to identify most cases of depression and/or anxiety, leading to under-treatment in 40%-90% of patients[13-16].

Patients with depressive and anxiety disorders often have one or more somatic symptoms (e.g., cardiopulmonary or gastrointestinal), which may be partly induced by emotional disorders[17-19]. On the other hand, many patients with depression or anxiety visit non-psychiatric departments, especially the GI department, for their physical complaints[20-22]. All these facts contribute to the low detection rate of emotional disorders among GI patients.

It is necessary to determine prevalence estimates of emotional disorders in GI patients to facilitate reasonable medical resources allocation. These have been assessed in a number of studies throughout America, Europe, and China, including the Hong Kong and Taiwan regions[15,23-25]. However, the economic status and cultural traditions of mainland China are unique, and likely to make the situation of mainland Chinese GI patients distinctive.

This is the first large-sample, multicenter study based on a mainland Chinese population to estimate the prevalence of depression and anxiety in adult GI outpatients. This cross-sectional study was carried out with GI outpatients from 13 tertiary general hospitals in Beijing, Shanghai, Guangzhou, Changsha and Chengdu. The purpose of this study was to characterize the prevalence of depressive and/or anxiety disorders among GI outpatients and to determine the non-psychiatric physician identification rate of these disorders in GI outpatients.

MATERIALS AND METHODS

Ethics
This survey was approved by the Shanghai Mental Health Center Ethics Committee. All patients provided informed written consent.

Subjects
A multi-center, cross-sectional study was carried out in the outpatient departments of 15 tertiary general hospitals in Beijing, Shanghai, Guangzhou, Changsha, and Chengdu to estimate the prevalence of depressive and anxiety disorders in adult outpatients from gastroenterology, gynecology, cardiovascular and neurology departments. However, only 13 hospitals provided complete data for the GI department (one lacked a GI department, and the other incomplete patient data). Consecutive patients visiting outpatient departments were recruited for the study. Patients were included if they were over 18 years, consented to study participation, and were able to complete the questionnaires. Exclusion criteria included being previously screened, serious physical or mental condition, language or hearing problem, incomplete records, or ongoing psychological treatment. About 140 consecutive GI outpatients were investigated in each hospital during 4-5 consecutive working days randomly selected from the 22 normal workdays in a month by using SAS (v9.0) software.

Research instruments
The somatic symptoms, as well as depression/anxiety, were assessed with the Patient Health Questionnaire 15-Item (PHQ-15)[26], Hospital Anxiety and Depression Scale (HADS)[27,28], and Mini International Neuropsychiatric Interview (MINI)[29]. PHQ-15 is a self-report questionnaire used to screen and assess somatic symptoms. It consists of 15 physical symptoms, scaled 0-2 points for each. The higher the score, the more severe the symptom. The 14-item HADS[27,28] questionnaire evaluates severity of anxiety and depression using 7 items for each affliction, and is widely used in general hospitals. Each item's severity is rated from 0 (none) to 3 (severe). Scores $\geq$ 8 indicate probable anxiety or depression with great reliability and validity[30], and were regarded as positive in the preliminary screening of this study. MINI[29], a structured diagnostic instrument, is used to make diagnoses according to the Diagnostic and Statistical Manual of Mental Health Disorders (4th edition, DSM-IV) and the International Statistical Classification of Disease-10. The MINI Chinese version has good reliability and validity[31-33].

Study design
This multi-center, cross-sectional study was carried out in five cities: Beijing, Shanghai, Guangzhou, Chengdu, and Changsha (representing north, east, south, west and central China, respectively). In the first stage, outpatients were screened with PHQ-15 and HADS scales, and then visited GI physicians for their original complaints. The coordinators calculated scores of both scales, kept physicians blind to results, and recorded physicians' diagnosis and treatment. In the second stage, subjects with HADS scores $\geq$ 8 were assessed and diagnosed by psychiatrists with MINI. The study design is shown in Figure 1.

Statistical analysis
Data analysis and management were performed using the Statistical Package for Social Sciences v17 (SPSS Inc., Chicago, IL, United States). Demographic data were described by frequency and percentage, and the lack of data in one item, such as sex or diagnosis, was treated as a missing value. Subjects who were positive in the preliminary screening stage but did not complete the psy-

Figure 1 Flowchart of the study on prevalence of depressive disorders and/or anxiety disorders among gastrointestinal outpatients from 13 general hospitals in China. PHQ-15: Patient Health Questionnaire 15-Item; HADS: Hospital Anxiety and Depression Scale; MINI: Mini International Neuropsychiatric Interview.

chiatrists' interview were excluded.

According to a previous publication[34], prevalence was described as the percentage of positive subjects among those who completed the trial, and adjusted prevalence was calculated according to the HADS score distribution among all eligible subjects. The 95% CI of adjusted prevalence were computed using the Gaussian approximation to the log-likelihood. Categorical data, such as differences of prevalence in sex and age, or differences between individuals with and without depressive and/or anxiety disorders, were compared using the χ^2 test at the < 0.05 significance level. Consecutive data with normal distribution, such as age, were expressed as mean $\pm$ SD and analyzed using the t test.

"Recognized" or "detected" indicated diagnosis of depressive or anxiety disorders according to a physician's clinical judgment, prescription of antidepressants or antianxiety drugs, or referral to psychiatry or psychology departments.

RESULTS

Demographic characteristics

The study comprised 1995 outpatients, aged 18-89 (45.2 $\pm$ 15.6) years and 54.19% were female. The patients' demographic characteristics are presented in the first two columns of Table 1. One thousand and fifty-nine subjects screened positive (HADS score $\geqslant$ 8), 580 (54.77%) of whom were female. Among these 1059, 674 completed the second stage screening of psychiatrists' interview with MINI. Among the missing subjects ($n = 385$), 173 (44.9%) did not complete the further interview and 212 (55.1%) refused to attend the interview (Figure 1). There were no significant differences between missed and followed-up cases in sex ($\chi^2 = 0.066$, $P = 0.797$) or age (43.72 $\pm$ 15.45 *vs* 42.89 $\pm$ 14.92, $t = -0.860$, $P = 0.390$).

Of the completed subjects, 371 (55.0%) were women

and 323 (47.9%) were diagnosed with one or more types of depressive disorders and/or anxiety disorders. Among the 323 confirmed subjects, 194 (60.1%) were women (other characteristics are described in the third column of Table 1). Subjects with depressive and/or anxiety disorders were more likely to be female and younger than those without such disorders (Table 1).

Prevalence of depressive and anxiety disorders in gastrointestinal outpatients

The adjusted prevalence of depressive and anxiety disorders are shown in Table 2. One hundred and eighty-one subjects had current depression disorders, 117 had current anxiety disorders, and 59 had current comorbidity. This indicates that 32.6% (59/181) of individuals with current depressive disorders had at least one type of anxiety disorder, and 50.4% (59/117) of subjects with current anxiety disorders were affected by depressive disorders as well.

The prevalence of all types of depressive disorders and anxiety disorders, according to DSM-IV criteria, are detailed in Table 2. Among the depressive disorders, depressive episode was the most common with an adjusted current prevalence of 11.23%, while substance-induced mood disorder had the lowest adjusted current prevalence (0.35%). Among 181 outpatients with depressive disorders, 51 (28.2%) had suicidal problems [suicide attempt or suicide-related ideation prior or current; module C (suicide) of MINI, score $\geqslant$ 1], indicating that over a quarter of individuals with depressive disorders were at suicide risk.

Sex differences among current prevalence of depressive disorders and/or anxiety disorders

The current adjusted prevalence of depressive disorders and/or anxiety disorders was significantly different between male and female outpatients (Table 3). The prevalence of depressive disorders, anxiety disorders, and either depressive or anxiety disorders was significantly ($P < 0.05$) higher in female GI outpatients. The adjusted current prevalence of depressive disorders with suicidal problems was statistically significantly higher in women (mean 5.84%; 95% CI: 4.44-7.24) than in men (mean 1.64%; 95% CI: 0.82-2.46) ($\chi^2 = 23.096$, $P = 0.00$), and the mean relative risk was 3.71 (95% CI: 2.10-6.56, $P < 0.01$).

Physicians' detection and treatment of depressive and anxiety disorders in gastrointestinal outpatients

Among 323 digestive outpatients who were diagnosed with depressive disorders and/or anxiety disorders by MINI, complete information of physicians' diagnoses and treatments was available for 290 cases ($n = 13$ missing diagnosis information, and $n = 21$ missing treatment information).

The detection rate by physicians was 4.14% (12/290). Among the 12 detected subjects, five were treated with psychotropic drugs, including amitriptyline or doxepin ($n = 2$). Another seven were referred to the psychiatry de-

Panic disorder	17	1.35 (0.84-1.86)	24	1.95 (1.34-2.56)
Agoraphobia	17	1.35 (0.84-1.86)	21	1.75 (1.17-2.33)
Obsessive-compulsive disorder	16	1.30 (0.80-1.80)	16	1.30 (0.80-1.80)

Depressive episode is the most common depressive disorder, while substance-induced mood disorder has the lowest adjusted current prevalence. The most common anxiety disorder is general anxiety disorder, followed by social anxiety disorder, panic disorder, agoraphobia, and obsessive-compulsive disorders. MINI: Mini International Neuropsychiatric Interview; GI: Gastrointestinal; DSM-Ⅳ: Diagnostic and Statistical Manual of Mental Health Disorders (4th edition).

partment. Meanwhile, three out of 67 (4.48%) subjects with suicide risk were identified and received psychiatric management, including psychiatry department referral (*n* = 1) and doxepin treatment (*n* = 2).

DISCUSSION

The current study evaluated the prevalence of depressive and anxiety disorders among mainland Chinese out- patients visiting GI clinics, regardless of confirmed GI diagnosis. The adjusted current prevalence of depressive disorders, anxiety disorders, and comorbid disorders was 14.39%, 9.42% and 4.66%, respectively.

It is well recognized that depressive and anxiety disorders impair life quality and cause a heavy disease burden[35-38]. Nevertheless, more than half of patients with depression or anxiety visit non-psychiatric depart- ments, especially the GI department, for somatic symp-

Table 3 Current adjusted prevalence of depressive disorders and/or anxiety disorders and comparison between men and women

Diagnosis based on MINI	Frequency, adjusted current prevalence (%) and 95% CI (%) based on results of MINI exam				χ^2	P value

Depressive disorders or anxiety disorders	92	16.01 (13.63-18.39)	147	21.96 (19.49-24.43)	11.285	0.001[b]

There are significant differences between male and female patients in the current prevalence of depressive disorders ([b]$P < 0.01$), anxiety disorders ([a]$P < 0.05$) and either depressive or anxiety disorders ([b]$P < 0.01$), respectively. MINI: Mini International Neuropsychiatric Interview.

toms[20,21,39,40]. However, most general physicians are not appropriately trained in psychiatry and cannot diagnose or treat depressive and anxiety disorders. Thus, GI physicians tend towards a low detection rate[41-43]. It is meaningful to investigate overall prevalence of depressive and/or anxiety disorders in GI outpatients to understand the actual patient population involved and the importance of diagnosing such disorders.

According to our knowledge, this is the largest study investigating the prevalence of depressive and anxiety disorders in GI outpatients from tertiary general hospitals in mainland China. The reliability of the current prevalence figures was assured by the use of experienced psychiatrists administering a structured diagnostic instrument. The tertiary general hospitals enrolled in this study were distributed in north (Beijing), east (Shanghai), south (Guangzhou), west (Chengdu) and central (Changsha) China, and represent the majority of national tertiary general hospitals. In addition, the DSM-IV-based MINI was used by experienced psychiatrists to produce accurate and consistent diagnoses. Finally, the study was carried out in two stages, preliminary screening and diagnostic interview.

Prevalence of depressive disorders and/or anxiety disorders in general hospitals or primary care

The overall prevalence figures of depressive disorders and/or anxiety disorders in general medical care have been reported previously[15,44]. The current adjusted prevalence of depressive disorders in our study was 14.39%. However, this value was 19.5% in a meta-analysis of primary care patients in ten countries[41]. The current adjusted prevalence of anxiety disorders reported in our study was 9.42%, which was lower than the 19.0% prevalence reported among Belgian outpatients in 86 general practices[45] and the 19.5% prevalence reported in 15 United States general medical care centers[15]. These apparent discrepancies may be a result of subjects in the previous studies being from primary care and the Primary Care Evaluation of Mental Disorders being used for diagnosis.

Furthermore, other previous domestic investigations have reported varying prevalence of depressive disorders and anxiety disorders. Qin *et al*[46] reported prevalence of 11.01% for depressive disorders in internal medical outpatients from 23 general hospitals in Shenyang. The prevalence of depression was 12.5% in family practices in Taiwan[25], while the prevalence of anxiety disorders was 11.61% in six tertiary general hospitals in Shenyang[42]. Generally speaking, these different results were due to variances in subjects and investigation instruments. The prevalence of depressive disorders and/or anxiety disorders in our study and other domestic studies are lower than results from abroad, which may relate to differences in ethnicity or culture[47,48].

The 1.25% current prevalence of dysthymia, the third top depressive disorder in our study, was higher than the 0.6% prevalence in Shanghai subjects reported by the WHO[43] in 1990, but was similar to the 2.1% mean prevalence for all international sites that participated in the research and the 2.8% prevalence of dysthymia in the study of Qin *et al*[46]. It was lower than the 12.6% prevalence of dysthymia among outpatients from 86 general practices in Belgium[45].

It is well-known that comorbidity of depressive disorders and anxiety disorders can exacerbate symptoms, and co-occurrence of anxiety is an independent risk factor of suicide among depressive patients[35,49]. In the current study, anxiety disorders were comorbid in 32.6% of depressive individuals. This comorbid proportion in depressive patients was found to be 68.9% in a study conducted in 15 centers of China[50], and 50.6% in the United States[51]. It is a common phenomenon that depressive disorders and anxiety disorders are in comorbidity among outpatients in general medical care.

Detection rate by physicians in general hospitals or primary care

Detection rate in this study was 4.14%, similar to the 4% reported for Shenyang[42,46]. A United States-based study of outpatients with GI symptoms revealed that 52% of anxious patients and 26% of depressive patients were recognized by gastroenterologists[16]. Family practices surveyed in Taiwan[25] indicated that the recognition rate of depression disorders was 12.5%, and that of general anxiety disorder was 8.0%. Prevalence of depression disorders in internal medicine inpatients was 26.9% and only 40% of these patients received antidepressant treatment[52]. Another MINI-based study of internal medicine inpatients revealed that prevalence of depressive disorders was 26%, and 43.8% of them were treated with antidepressants[53]. A meta-analysis conducted by

Mitchell *et al*[41] indicated that correct diagnosis rate of clinicians was 47.3%-50.1%. The remarkable difference in detection rate between other investigations and ours suggests the urgent need to improve the diagnosing rates in mainland China.

Meanwhile, comorbid disorders deserve great attention due to their significant correlation to suicide risk. Current prevalence of depressive disorders with suicidal problems was 3.91% in our study, suggesting that over a quarter of patients with depressive disorders were at suicide risk, while only 4.48% of those patients were recognized. Carson *et al*[54] indicated that morbidity of major depression with suicide ideation was 29.9%, while its recognition rate by physicians was 58%. Moreover, prevalence of depression and/or anxiety disorders in our study was higher in females than in males, which is consistent with results in Qin's study[42,46], and reminds physicians to pay more attention to female outpatients with mood problems.

Discrepancies of prevalence and detection rate between our study and previous studies likely reflect the limitations of methodology, which require significant effort to be overcome in subsequent research.

These findings confirm the high prevalence of depressive and anxiety disorders and disappointing detection and treatment rate in the GI departments, and highlight the particular challenge posed by the contrasts between these two rates. Although all 13 tertiary hospitals represent the top general hospitals in China, low recognition and treatment rates raise significant concerns and indicate the need to improve the physician's abilities to diagnose and identify emotional disorders in GI patients.

Several potential explanations exist for the high prevalence of depressive and anxiety disorders and low detection rate in GI outpatients. Physicians are less specialized than psychiatrists in recognizing mental disorders correctly. Furthermore, culture may limit physicians' abilities in this regard. In the Chinese traditional culture, social and cognitive processes or mental status are closely related, which contributes to interpreting emotional distress and anxiety as social or ethical problems rather than mental disorders. Somatic symptoms can also serve as cultural idioms of depressive emotion[55-57]. Depressed or anxious people are inclined to experience physical symptoms, masking the underlying mental disorder[39]. In addition, there is a distorted cognition of mental disorders. It is common to consider depressive individuals as having no self-control and weak. Jorm *et al*[58] reported that around a quarter of Australian adults consider antidepressants as harmful to suicidal depressive patients, who are more likely to reject relevant treatments, including psychotherapy. Finally, the established stigma of mental disorders causes hiding of emotional problems and rationalization to resist therapy. Dramatic reports in the mainstream media of aggressive behavior by mental disorder sufferers prejudice both patients and physicians against the disorder[59-61].

Previous studies have proven that depressive and anxiety disorders influence prognosis of physical diseases, raise medical risk, and increase economic burden[62,63]. However, appropriate treatment does benefit recovery from physical disease and maintenance of social function[64-66]. Therefore, clinicians should improve their ability to diagnose depression and anxiety, especially in patients with complaints of unexplained GI symptoms.

Limitations
Several limitations exist in the current study. Firstly, excluding outpatients who could not complete the investigation due to severe physical or mental dysfunction may have biased the results since severity of physical symptoms is positively related to depression, anxiety or other mental problems[67,68]. Secondly, the 385 missing cases (due to busy schedules and denial of mental issues) from the diagnostic interview accounted for 19.3% of the total. There were no statistically significant differences between missing and follow-up cases in sex ($\chi^2 = 0.066$, $P = 0.797$) or age ($t = -0.860$, $P = 0.390$). Although statistical adjustment was performed, representation of the sample in the study may have been impacted.

COMMENTS

Background
Depressive disorders and anxiety disorders are common in general hospitals and represent significant risks to patients' quality-of-life. Patients visiting non-psychiatric departments may have at least one somatic symptom which is partly of emotional origin, challenging non-psychiatric physicians to detect emotional disorders.

Research frontiers
Emotional disorders in gastrointestinal (GI) patients have been assessed in a number of studies in America, Europe and China, including non-mainland regions of Hong Kong and Taiwan. However, the economic status and cultural traditions of mainland China are quite distinctive from foreign countries and even the non-mainland regions of China. It is important to understand the mental health situation of mainland Chinese GI patients.

Innovations and breakthroughs
The current study determined the prevalence of depressive and/or anxiety disorders and physicians' detection rates in tertiary care hospitals across mainland China. In particular, this is the first multi-center study from the mainland of China with a large number of patients to report the prevalence of depression and anxiety in adult GI outpatients. Furthermore, the diagnosis of depressive and anxiety disorders was made with the Mini International Neuropsychiatric Interview diagnostic instrument.

Applications
The results of this study suggest that clinicians should improve their abilities to detect emotional disorders. Furthermore, they serve to remind the government or medical institutions of the importance of promoting productive interactions between psychiatry and other departments.

Peer review
This study is well designed including group analysis and statistics. In particular, this is the first multi-center study from the mainland of China with a large number of patients to report the prevalence of depression and anxiety in adult GI outpatients.

Abstract

AIM: To investigate the role of expressions of Ki-67, p53, epidermal growth factor receptor (EGFR) and cyclooxygenase-2 (COX-2) in gastrointestinal stromal tumor (GIST) grading and prognosis.

METHODS: Tumor tissue was collected retrospectively from 96 patients with GIST. Antibodies against Ki-67, p53, EGFR and COX-2 were used for immunohistochemical staining. Tumor grading was designated according to a consensus system and the staining was quantified in 3 categories for each antibody in the statistical analysis.

RESULTS: The Ki-67 expression in GISTs was significantly associated with the size of the tumors, mitotic rate and the risk of malignancy (χ^2 = 15.51, P = 0.02; χ^2 = 22.27, P < 0.001; χ^2 = 20.05; P < 0.001). The p53 expression was also significantly correlated with mitotic rate and the risk of malignancy (χ^2 = 9.92, P = 0.04; χ^2 = 9.97; P = 0.04). Over-expression of Ki-67 was strongly correlated with poor survival (χ^2 = 10.44, P = 0.006), but no correlation was found between the expression of p53, EGFR or COX-2 and survival. Multivariate analysis further demonstrated that Ki-67 expression (relative risk = 15.78, 95% CI: 4.25-59.37) could be used as an independent prognostic value for GIST patients. Adjuvant imatinib therapy could improve clinical outcomes in the patients with high risk and intermediate risk of recurrence after complete tumor resections (median survival time: 52 mo *vs* 37 mo, χ^2 = 7.618, P = 0.006).

CONCLUSION: Our results indicated that the expression of Ki-67 could be used as an independent prognostic factor for GIST patients.

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is one of the most frequent mesenchymal neoplasms of the gastroin-

testinal tract. In the elderly, micro-GIST (the tumor size smaller than 1 cm) is detected in 20%-30% of individuals over 60 years old[1,2]. GIST occurs along the gastrointestinal tract and commonly invades in the stomach and small intestine. The tumors rarely arise from extragastrointestinal sites, such as omentum or mesentery[3]. Most GISTs express c-kit. Monoclonal antibodies against c-kit, DOG1 and protein kinase C theta have been developed as helpful diagnostic adjuncts in pathology[4-6].

GISTs have a wide clinical spectrum, ranging from virtually benign to highly aggressive tumors. Up to 30% of GISTs recur and progress to metastatic disease even after the complete excision of tumors. Despite a remarkable progress in the understanding of GISTs, it is still difficult to make a prognosis due to the variability of disease[7]. According to the National Institutes of Health (NIH) classification system, GISTs are classified into four categories: very low, low, intermediate and high risk[8]. The prognosis of patients is commonly stratified based on tumor size and mitotic counts in the NIH system. Previous studies have demonstrated that nuclear atypia and tumor necrosis all contribute to prognostic outcomes of GIST patients. Further, some studies showed that gastric GISTs had lower risks of recurrence than nongastric tumors with the same size and same mitotic count[9]. The four-point classification only distinguishes GISTs with high-risk from those with low-risk[10]. The system using multiple histopathological parameters for GIST prognosis is subjective and lacks reproducibility[11].

The proliferation marker Ki-67, tumor suppressor gene *p53*, cyclooxygenase-2 (COX-2) and epidermal growth factor receptor (EGFR) have been identified as prognostic biomarkers in tumors of epithelial origin. However, there has been no study analyzing these markers systematically in a large cohort of mesenchymal tumors, especially in GISTs[12,13]. In this study, Ki-67, p53, EGFR and COX-2 expressions were fully investigated in the GIST tumor specimens from 96 patients and the grade of the tumor was established based on the immunohistochemical staining of each protein. The grades were then compared with patients' clinical features and roles of prognostic values for GISTs were evaluated. The study indicated that determination of these tumorigenetic and cell proliferative proteins provides alternative measurements for follow-up and prognosis.

MATERIALS AND METHODS

Patients

From January 2005 through December 2009, 134 patients were initially diagnosed as having mesenchymal gastrointestinal tumors at Jilin University First Hospital. Thirty-three patients were excluded from the study due to recurred tumors or the tumors being partially resected. Thus, 101 patients underwent successful surgical operations for complete resection of tumors. Following the surgery, patients with high-risk and intermediate risk were treated with imatinib (Glivec®, Novartis Pharmaceuticals,

Basel, Switzerland) at a dose of 400 mg/d for 3 years. No imatinib treatment was given before the surgery. Five cases were lost to follow-up. Ninety-six patients were retrospectively evaluated in the study. Informed consents were obtained from all patients and the study was approved by the local human ethical committee of Jilin University First Hospital. Original hematoxylin and eosin-stained sections were reviewed in each case by two pathologists (Jin MS and Wang YP) according to GIST characteristics described by Miettinen[14]. All tumors from 96 patients were confirmed to be GISTs based on a combination of histological evaluations (highly cellular spindles/epithelioids/mixed cell tumors), and c-kit, DOG1, CD34 positive staining. The clinical information regarding the patients is summarized in Table 1.

Immunohistochemical analysis

Histological sections (4 μm) of 10% formalin-fixed, paraffin-embedded material were used for immunohistochemical staining. Prior to a primary antibody staining, the slide was pretreated with citric acid or ethylenediaminetetraacetic acid buffer in a pressure cooker for antigen retrieval. Endogenous peroxidase activity was quenched by 3% H_2O_2 blocking reagent for 10 min. The slide was incubated with a primary antibody at 4 ℃ overnight, and then immunostained with the avidin-biotin peroxidase complex (DAKO, CA). Finally, the slide was stained with diaminobenzidine according to the manufacturer's protocol (DAKO, CA). The slide was

rinsed three times with phosphate buffered saline after each step of staining. The sections were stained with primary antibodies against c-kit (Clone: YR145, dilution: 1/50, Cell Marque Corporation, CA), CD34 (QBEnd/10, dilution: 1/100, Neomarkers, CA), Ki-67 (MIB-1, dilution: 1/100, DAKO, Carpinteria, CA), DOG1 (SP31, dilution: 1/100, Spring Bioscience, Pleasanton), SMA (IA4, dilution: 1/200, Cell Marque Corporation, CA), p27 (1B4, dilution: 1/20, Novocastra), p53 (SP5, dilution: 1/100, Zymed Laboratories, San Francisco), S-100 (6E6, dilution: 1/100, Neomarkers, CA), Desmin (D33, dilution:1/50, Cell Marque Corporation, CA), EGFR (EGFR.113, dilution: 1/200, Novocastra Laboratories Ltd, Newcastle, United Kingdom), and COX-2 (SP21, dilution: 1/50, Neomarkers, CA, United States), respectively. All primary antibodies used in the study were biotinylated monoclonal antibodies. The stained slides were evaluated quantitatively or semi-quantitatively by two independent pathologists who were blinded from clinical data. Percentages of positive cells stained with a special antibody observed by two pathologists were consistent and the mean values were determined.

The nuclear staining for Ki-67 and p53, and cytoplasmic immunostaining for EGFR and COX-2, were considered as positive cells of the reaction. According to previous studies[15,16], the following scoring assessments for Ki-67 and p53 were used. The score 0 was assigned for < 5%, 1 for > 5% and < 10%, 2 for > 10% of Ki-67 staining positive cells. The p53 scoring system was 0 assigned for < 5%, 1 for > 5% and < 25%, 2 for > 25% of p53 staining positive cells. EGFR scoring system was 0 assigned for < 10%, 1 for > 10% and < 60%, 2 for > 60% of EGFR positive cells based on the systems described by Nakagawa *et al*[17] and Gumurdulu *et al*[18]. The COX-2 scoring system was 0 assigned for no positive cells; 1 for < 25% and score 2 for > 25% of COX-2 staining positive cells according to Fux *et al*[19].

Statistical analysis

The Chi-square test and Fisher's exact test were used to analyze relationships between clinicopathological features and expression levels of biomarkers. Kaplan-Meier test was applied with a log-rank test to study associations between categorical variables and the mean values of survival among groups. Cox proportional hazards regression analysis was used to estimate a hazard risk for survival and 95% CI was applied. The SPSS program (version 18.0) was used for statistical analysis. A *P* value of < 0.05 was considered statistically significant.

RESULTS

Clinicopathological findings and follow-up

Clinicopathological features of the patients are summarized in Table 1. The median age of 96 patients was 55 years (range, 26-82 years). Histomorphology showed that the neoplastic cells were predominantly spindle-shaped (83/96, 86.5%). Based on the modified NIH risk

consensus system, 45 (46.9%), 24 (25.0%), 24 (25.0%) and 3 (3.1%) cases were classified as high-risk, intermediate-risk, low risk and very low risk categories, respectively. Fifty-three cases (55.2%) had mild nuclear atypia; 32 cases (33.4%) showed severe nuclear atypia, but 11 patients (11.4%) had no nuclear atypia. Tumor necrosis was found in 39 cases of the patients (40.6%).

At the time of study, the mean or the median duration of the follow-up period was 31 mo or 29 mo, respectively. Medical charts were available for 96 of 101 patients (95%). Sixty-nine patients (54.2%) received the imatinib treatment at a dose of 400 mg/d for 13 mo to 36 mo (median, 26 mo). Thirty-seven patients (82%) from the high risk group and 15 patients (62.5%) from the intermediate group required the imatinib treatment. Disease specific 1, 2, 3 and 4 year survival probabilities were 0.97, 0.89, 0.79, and 0.77 (0.65-0.87), respectively. Of the 96 cases, 19 patients (19.8%) died from GISTs and 6 patients (6.3%) died from unrelated causes.

Immunohistochemical findings

Eighty-eight (91.3%) tumor specimens were stained positive for c-kit. The tumors isolated from 8 patients (8.7%) were negative for c-kit but positive for DOG1 and/or CD34 staining. Reactivity with Desmin was found in 3 (3.1%) cases. Positive SMA and S-100 staining were also noted in 46 (47.9%) and 12 (12.5%) cases, respectively. Based on the Ki-67 index, 53.1% of tumors (*n* = 51) scored 0; 34.4% (*n* = 33) scored 1; and 12.5% (*n* = 12) scored 2. 34.4% of tumor specimens (*n* = 33) were p53 staining positive in the nuclei of over 25% of the cells. EGFR staining was found in most cases. Forty-two (43.8%) cases scored 2, and 27 (28.1%) cases scored 1 for EGFR staining. COX-2 overexpressed in 36 (37.5%) cases (Table 2 and Figure 1).

Clinicopathological features and GIST grades categorized by the staining of Ki-67, p53, EGFR or COX-2 are established in Table 3. The expression of Ki-67 was significantly associated with tumor size (*P* = 0.02), mitotic rate (*P* < 0.001) and the risk of malignancy (*P* < 0.001). The p53 expression was also correlated with mitotic rate (*P* = 0.04), tumor site (*P* = 0.02) and the risk of malignancy (*P* = 0.04). The levels of COX-2 protein were significantly higher in gastric tumors and spindle cell-like tumors (*P* < 0.001 and *P* = 0.05, respectively). In contrast, no correlation was found between the EGFR expression and clinicopathological factors or the risk of malignancy.

Survival analysis

The 3-year survival rates for disease specific survival (DSS) were 100%, 89%, 79% and 67% for groups at very low-risk, low-risk, intermediate-risk and high risk by the modified NIH risk categories, respectively. Associations between DSS and different protein biomarkers were analyzed using a multivariate analysis (Table 3 and Figure 2). The survival rates were strongly associated with tumor size (*P* = 0.004), mitotic count (*P* = 0.001),

tumor location ($P = 0.018$), the NIH modified criteria ($P < 0.001$, Figure 2A), Ki-67 amplification ($P < 0.001$, Figure 2B), and adjuvant imatinib therapy (median survival period 52 mo *vs* 37 mo, $\chi^2 = 7.618$, $P = 0.006$, Figure 2C). No significance was found when comparing survival rates with the EGFR expression, or the COX-2 expression. In the high-risk group, Ki-67 overexpression was significantly associated with poor survival ($\chi^2 = 10.44$, $P = 0.006$), but no statistical significance was found between the p53 expression and survival ($\chi^2 = 4.744$, $P = 0.089$). Using a multivariate analysis, a poor survival was observed in the high risk category [relative risk (RR) = 12.23; 95% CI: 1.61-92.81] graded using the modified NIH risk consensus system or in category 2

scored by the Ki-67 expression (RR = 15.78; 95% CI: 4.25-59.37) (Table 3).

DISCUSSION

In the absence of reliable genetic and immunohistochemical biomarkers in GISTs, the tumor size and mitotic rate are often used to assess risk probabilities in GIST patients. Large retrospective cohort studies have shown that the NIH classification carries substantial prognostic value[20]. Using classical morphological parameters, our results were consistent with previous studies on the prognosis of GIST patients.

EGFR: Epidermal growth factor receptor; COX-2: Cyclooxygenase-2; RR: Relative risk.

The tumor suppressor p53 plays an important role in the regulation of cell cycle, DNA repair and programmed cell death. The functional loss of p53 disrupts these pathways and results in the selection of tumor cells with growth advantage[24]. p53 has been reported as a prognostic marker in a wide variety of carcinomas, as well as in GISTs[25]. A study showed that impaired p53 expression was often found in advanced GISTs and a strong effect of p53 on the progression-free survival was also observed[18]. The accumulation of p53 protein was significantly associated with mitotic rate and the risk of malignancy in the present study.

The activation of EGFR is associated with cell growth and transformation. There are few reports analyzing the EGFR expression in GISTs. A study has suggested that a transforming growth factor alpha (TGF-α)/EGFR autocrine loop is present in GISTs, in which TGF-α promotes the proliferation of GIST tumor cells through an interaction of EGFR with HER-1[26]. Co-expressions of EGFR and several EGFR ligands were observed with the upregulation of ADAM17 in GISTs. The authors suggested that the EGFR activation was through shedding of EGFR ligands by ADAM17 and consequently resulted in GIST progression and growth[17]. To our knowledge, there has been no study assessing prognostic values of EGFR in a large cohort of GISTs. However, no significant association was found between the EGFR expression and prognostic analysis of GISTs in our study.

Increased COX-2 expression has been observed in colorectal adenoma and carcinoma[27]. The induction of COX-2 has been shown to promote cell growth, inhibit apoptosis and enhance cell motility and adhesion[28]. Over-expression of COX-2 has tumorigenic effects in animal models[29]. Expression levels of COX-2 and vascular endothelial growth factor were found to

eration, expresses in all cell cycle phases except for G0. A recent study demonstrated that the automated assessments of Ki-67 staining with computing image analysis can be used for prognostic assessments of patients with breast cancer[21]. However, the prognostic value of Ki-67 as a potential biomarker has not been fully investigated in GISTs[22,23]. The present study shows that the expression of Ki-67 or p53 is significantly associated with many clinicopathological features in GISTs; higher score for Ki-67 staining was directly correlated with poor survival; Ki-67 was superior to other protein markers tested in survival assessments, particularly in the high risk group, suggesting that Ki-67 immunostaining is a reliable and independent marker for the prediction of clinical outcomes in patients with GISTs.

be significantly higher in malignant GISTs than those in benign and intermediate GISTs[30]. A study reported a correlation between the COX-2 expression and tumor cell proliferation in GISTs, but no association was found between COX-2 expression and mortality, metastasis, tumor size, the risk of stages, the dose of tyrosine kinase inhibitors, or the rate of complete resection[31]. Our results demonstrated that levels of COX-2 expression were significantly different between gastric tumors and nongastric tumors ($P < 0.001$), but no significant relationship was found between the COX-2 expression and risk factors, or survival.

Imatinib therapy reduces rates of recurrence in GISTs. Nevertheless, it remains unclear how to screen patients who would be more likely to benefit from the adjuvant therapy. In our study, we found that imatinib treatment could significantly improve 3-year DSS rates in the intermediate and high risk categories of patients after a complete tumor resection.

In conclusion, Ki-67 expression is significantly associated with GIST malignancy and can be used as a putative prognostic marker in GISTs. p53 and COX-2 also provide additional valuable information in the evaluation of malignancy and types of GISTs.

COMMENTS

Background
Gastrointestinal stromal tumors (GISTs) are known to have a wide variability in malignancy and prognosis. Risk grading based on tumor size, location and mitotic counts has been proposed to predict adverse outcomes of GIST in the literature.

Research frontiers
Recent molecular studies have found that the deregulations of Ki-67, cyclin A, B1, D1, E, cdc2 and other cell-cycle regulators were significantly associated with a shorter disease-free survival in GISTs.

Innovations and breakthroughs
In this study, expressions of Ki-67, p53, epidermal growth factor receptor (EGFR) and COX-2 were investigated in a large cohort of GIST patients and their roles as prognostic values for GISTs were also evaluated. To our knowledge, this is the first assessment of the prognostic value of EGFR in patients with GISTs.

Applications
The immunohistochemical staining of these tumorigenetic and cell proliferative proteins provides an alternative approach for follow-up and clinical decisions regarding the treatment for GISTs.

Peer review
This paper describes a retrospective clinicopathological study of GIST.

Abstract

AIM: To investigate the effects and mechanisms of action of glycine on phagocytosis and tumor necrosis factor (TNF)-α secretion by Kupffer cells *in vitro*.

METHODS: Kupffer cells were isolated from normal rats by collagenase digestion and Percoll density gradient differential centrifugation. After culture for 24 h, Kupffer cells were incubated in fresh Dulbecco's Modification of Eagle's Medium containing glycine (G1: 1 mmol/L, G2: 10 mmol/L, G3: 100 mmol/L and G4: 300 mmol/L) for 3 h, then used to measure phagocytosis by a bead test, TNF-α secretion after lipopolysaccharide stimulation by radioactive immunoassay, and microfilament and microtubule expression by staining with phalloidin-fluorescein isothiocyanate (FITC) or a monoclonal anti-α tubulin-FITC antibody, respectively, and evaluated under a ultraviolet fluorescence microscope.

RESULTS: Glycine decreased the phagocytosis of Kupffer cells at both 30 min and 60 min ($P < 0.01$, $P < 0.05$). The numbers of beads phagocytosed by Kupffer cells in 30 min were 16.9 ± 4.0 (control), 9.6 ± 4.1 (G1), 12.1 ± 5.7 (G2), 8.1 ± 3.2 (G3) and 7.5 ± 2.0 (G4), and were 22.5 ± 7.9 (control), 20.1 ± 5.8 (G1), 19.3 ± 4.8 (G2), 13.5 ± 4.7 (G3) and 9.2 ± 3.1 (G4) after 60 min. TNF-α secretion by Kupffer cells in G1 (0.19 ± 0.03), G2 (0.16 ± 0.04), G3 (0.14 ± 0.03) and G4 (0.13 ± 0.05) was significantly less than that in controls (0.26 ± 0.03, $P < 0.01$), and the decrease in secretion was dose-dependent ($P < 0.05$). Microfilaments of Kupffer cells in G2, G3 and G4 groups were arranged in a disorderly manner. The fluorescence densities of microtubules in G1 (53.4 ± 10.5), G2 (54.1 ± 14.6), G3 (64.9 ± 12.1) and G4 (52.1 ± 14.2) were all lower than those in the controls (102.2 ± 23.7, $P < 0.01$), but the decrease in microtubule fluorescence density was not dose-dependant.

CONCLUSION: Glycine can decrease the phagocytosis and secretion by Kupffer cells *in vitro*, which may be related to the changes in the expression of microfilaments and microtubules induced by Kupffer cells.

INTRODUCTION

Glycine has been well characterized in the spinal cord as an inhibitory neurotransmitter which activates expression of the glycine-gated chloride channel (GlyR) in postsyn-

aptic membranes. Kupffer cells contain a GlyR similar to that described previously in the central nervous system[1,2]. Many studies have shown that dietary or intravenous glycine has a protective effect in rat models against endotoxic shock, hemorrhagic shock, liver ischemia-reperfusion, liver transplantation, and alcohol-induced liver injury and is most likely to exert this effect by inactivating the Kupffer cells *via* this newly identified GlyR[3-10]. Our previous studies also indicated that glycine protected rats from thioacetamide-induced liver injury and intestinal endotoxemia[11,12]. The mechanism involved may be related to inhibition of the release of pro-inflammatory cytokines by Kupffer cells induced by glycine. *In vivo* and *in vitro* experiments have found that glycine inhibits the secretion of tumor necrosis factor (TNF)-α and interleukin (IL)-6 in Kupffer cells[13-15]. However, the impact of glycine on phagocytosis by Kupffer cells has not been reported, and the mechanisms underlying the effect of glycine on TNF-α secretion by Kupffer cells have not been fully understood. Our *in vitro* study showed that lipopolysaccharide (LPS) probably enhanced or inhibited the phagocytosis of Kupffer cells by acting through mechanisms involving microfilaments or microtubules[16]. This study aimed to investigate the effects of glycine on phagocytosis and the mechanisms underlying TNF-α secretion by Kupffer cells *in vitro*.

MATERIALS AND METHODS

Animals
Adult male Wistar rats weighing 300-330 g were obtained from the Experimental Animal Center of Shanxi Medical University (China). All animals were fed with standard laboratory chow and water was available *ad libitum*. The experimental protocols were approved by the Shanxi Animal Research Ethics Committee.

Reagents
Polystyrene beads (1.1 μm), monoclonal anti-α tubulin-fluorescein isothiocyanate (FITC) conjugate, LPS (*Escherichia coli* Serotype 0128:B12), collagenase IV, phalloidin-FITC, hydroxyethyl piperazine ethanesulfonic acid (HEPES) Percoll, and Dulbecco's Modification of Eagle's Medium (DMEM) were purchased from Sigma (St. Louis, United States); a radioimmunoassay kit for TNF-α measurement was purchased from the Radio-Immunity Institute of the Chinese Liberation Army Omni-hospital (Beijing, China); glycine, sodium pentobarbital, fetal bovine serum (FBS), penicillin G, streptaquaine, insulin, glutamine, trypan blue, and all other reagents not specifically mentioned elsewhere were prepared by Beijing Chemical Inc. (Beijing, China).

Isolation and culture of Kupffer cells
Kupffer cells from Wistar rats were isolated by collagenase digestion and differential centrifugation, using Percoll density gradients as described previously with slight modifications[17]. Briefly, the liver was perfused *in situ* through the portal vein with Ca^{2+} and Mg^{2+} free Hanks'

balanced salt solution (HBSS) containing 0.5 mmol/L ethylene glycol-bis (β-aminoethyl ether)-N,N,N,N- tetraacetic acid (EGTA) at 37 ℃ for 5 min at a flow rate of 26 mL/min. Subsequently, perfusion was performed with HBSS containing 0.05% collagenase IV at 37 ℃ for 5 min. After the liver was digested, it was excised and cut into small pieces in collagenase buffer. The suspension was filtered through nylon gauze, and the filtrate was centrifuged twice at $50 \times g$ at 4 ℃ for 3 min to remove parenchymal cells. The nonparenchymal cell fraction was washed with buffer and centrifuged on a density cushion of Percoll at $1000 \times g$ at 4 ℃ for 20 min to obtain the Kupffer cell fraction, and the cells obtained were washed with buffer again. The viability of isolated Kupffer cells was determined by trypan blue exclusion and routinely exceeded 90%. Cells were seeded onto 24-well culture plates (Corning, NY) or 25 mm × 25 mm glass coverslips at a density of 1×10^6 or 5×10^5 and cultured in DMEM supplemented with 10% FBS, antibiotics (100 U/mL penicillin G and 100 μg/mL streptomycin sulfate), 0.1 U/100 mL insulin and 15 mmol/L glutamine at 37 ℃ with 5% CO$_2$. Non-adherent cells were removed after 1 h by replacing the culture medium. All adherent cells phagocytosed latex beads and stained positive for catalase, confirming that they were Kupffer cells, and cells were cultured for 24 h before experiment.

Effects of glycine on Kupffer cells
Cells were seeded onto 24-well plates and 12 mm × 12 mm glass coverslips, and incubated with fresh medium containing glycine (G1: 1 mmol/L, G2: 10 mmol/L, G3: 100 mmol/L and G4: 300 mmol/L) at 37 ℃ with 5% CO$_2$ for 3 h. Phagocytosis and expression of microfilaments and microtubules by Kupffer cells were measured by the bead phagocytosis test, fluorescence staining and immunofluorescence staining, as described below.

Measurement of phagocytosis by Kupffer cells
Phagocytosis by Kupffer cells was evaluated by the Kupffer cell's ability to ingest polystyrene beads according to the modified method of Hirose *et al*[18]. Briefly, cells were seeded onto 12 mm × 12 mm glass coverslips or glass plates and incubated with fresh medium containing 0.05% polystyrene beads for 30 min or 60 min at 37 ℃ with 5% CO$_2$. Following vigorous pipetting to remove non-phagocytosed latex beads, the coverslips or glass plates were washed 3 times with PBS and fixed with 2% formaldehyde or methanol for 5 min. After staining by Giemsa's method for 15 min at room temperature and washing 3 times with PBS, the coverslips were inverted onto glass slides and observed under phase contrast microscope. The mean number of latex beads phagocytosed by each Kupffer cell was counted in at least 20 Kupffer cells per field at magnification of 200 times, 5 fields per coverslip in 6 coverslips.

Measurement of Kupffer cell secretion
Kupffer cells were seeded into 24-well plates at a density of 1×10^6/well and incubated with fresh DMEM

Figure 1 Effects of glycine on phagocytosis by Kupffer cells *in vitro*. A: Phagotosis by Kupffer cells in the control group 30 min after the addition of latex beads, 200×; B: Phagotosis by Kupffer cells in group G3 30 min after the addition of latex beads, 200×.

containing 100 ng/mL LPS for 60 min at 37 ℃ with 5% CO_2. At the end of this period, the medium was collected, centrifuged at $1000 \times g$ at 4 ℃ for 10 min, and the supernatant was stored at -80 ℃ until used for TNF-α assay. TNF-α in medium was measured using the radio-immunoassay kit. The levels of TNF-α in the wells represented the secretion of Kupffer cells.

Measurement of microfilament expression by Kupffer cells

Kupffer cells were stained with phalloidin-FITC according to the modified method of Wulf *et al*[19]. Briefly, Kupffer cells were seeded onto 12 mm × 12 mm glass coverslips at a density of 5×10^5 (1×10^4 to 2×10^4 cells/coverslip), fixed with 2% formaldehyde for 20 min and extracted with 0.5% Triton X-100 for 15 min. The fixed cells were then washed 3 times with PBS (10 mmol/L, pH 7.4) and stained with phalloidin-FITC for 45 min at room temperature in the dark. They were then washed for a further 3 times with PBS, the coverslips were inverted onto mounting medium applied to glass slides, and they were observed and photographed under a ultraviolet (UV) fluorescence microscope with a high magnification of 400 times. Mounted preparations could be stored in the dark at 2 ℃-8 ℃.

Measurement of microtubules in Kupffer cells

Microtubules in Kupffer cells were stained with a monoclonal anti-α tubulin-FITC antibody according to the method recommended by the producer. Briefly, Kupffer cells were seeded onto 12 mm × 12 mm glass coverslips at a density of 5×10^5 (1×10^4 to 2×10^4 cells/coverslip). They were then fixed with cold methanol for 10 min at -20 ℃ and rinsed twice with cold acetone (-20 ℃) for 10 s, then the cell layer was rehydrated in PBS (10 mmol/L, pH 7.4) for at least 30 min and stained with monoclonal anti-α tubulin-FITC (1:25 diluted with PBS containing 1% bovine serum albumin) in a dark-room for 60 min at room temperature. The stained cells were washed 3 times with PBS, the coverslips were inverted onto mounting medium applied to glass slides and observed and photographed under a UV fluorescence microscope. Mounted preparations could be stored in

Table 1 Effects of glycine on phagocytosis by Kupffer cells *in vitro* (mean ± SD)

Groups	Beads observed in Kupffer cells ($n = 6$)	
	30 min	60 min
Control	16.9 ± 4.0	22.5 ± 7.9
G1	9.6 ± 4.1[b]	20.1 ± 5.8
G2	12.1 ± 5.7[a]	19.3 ± 4.8
G3	8.1 ± 3.2[b]	13.5 ± 4.7[b,c]
G4	7.5 ± 2.0[b]	9.2 ± 3.1[b,d]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* control; [c]$P < 0.05$, [d]$P < 0.01$ *vs* G1.

the dark at 2-8 ℃. The fluorescence density was measured in 10 cells using the MIAS-300 picture analysis system from at least 5 fields in each picture at a high magnification of 400 times.

Statistical analysis

All results were expressed as mean ± SD. Statistical differences between means were analyzed by one-way analysis of variance or *t* test using the SPSS 12.0 statistical package. Statistical significance level was set at $P < 0.05$.

RESULTS

Effects of glycine on phagocytosis by Kupffer cells

When incubated in 5% CO_2 with fresh medium containing glycine at 37 ℃ for 30 min or 60 min, phagocytosis by Kupffer cells decreased significantly. The number of beads phagocytosed by Kupffer cells in groups G3 and G4 was less than that of group G1 in 60 min. There were no significant differences in the amount of beads phagocytosed by Kupffer cells among the G2, G3 and G4 groups (Table 1 and Figure 1).

Effects of glycine on TNF-α secretion by Kupffer cells

When incubated in 5% CO_2 with fresh medium containing glycine at 37 ℃ for 3 h, TNF-α secretion by Kupffer cells decreased significantly, and the decrease in secretion was dose dependent. TNF-α concentrations detected in the medium of groups G3 and G4 were significantly lower than in the medium of group G1 (Table 2).

Figure 2 Effects of glycine on expression of microfilaments by Kupffer cells *in vitro*. A: The expression of microfilaments by Kupffer cells in the control group, stained with Phalloidin-fluorescein isothiocyanate (FITC), 400×; B: The expression of microfilaments by Kupffer cells in group G3, stained with Phalloidin-FITC, 400×.

Figure 3 Effects of glycine on expression of microtubules by Kupffer cells *in vitro*. A: The expression of microtubules by Kupffer cells in the control group, stained with monoclonal anti-α tubulin-fluorescein isothiocyanate (FITC) conjugate, 400×; B: The expression of microtubules by Kupffer cells in group G3, stained with monoclonal anti-α tubulin-FITC conjugate, 400×.

Table 2 Effects of glycine on tumor necrosis factor-α secretion and microtubule density of Kupffer cells *in vitro* (n = 6) (mean $\pm$ SD)

Groups	TNF-α detected in medium (μg/mL)	Microtubule density of Kupffer cells
Control	0.26 ± 0.03	102.2 ± 23.7
G1	0.19 ± 0.03[d]	53.4 ± 10.5[d]
G2	0.16 ± 0.04[a,d]	54.1 ± 14.6[d]
G3	0.14 ± 0.03[a,d]	64.9 ± 12.1[d]
G4	0.13 ± 0.05[a,d]	52.1 ± 11.4[d]

[a]$P < 0.05$ *vs* G1; [d]$P < 0.01$ *vs* control. TNF: Tumor necrosis factor.

Effects of glycine on microfilaments of Kupffer cells

After 3 h incubation in 5% CO_2 with fresh medium containing glycine at 37 ℃, Kupffer cells stained with FITC-Phalloidin did not demonstrate organized microfilaments in groups G2, G3 or G4. There were no significant differences in the microfilament fluorescence densities among Kupffer cells in control, G1, G2, G3 and G4 groups (Figure 2).

Effects of glycine on microtubules of Kupffer cells

Following 3 h incubation in fresh medium containing glycine at 37 ℃ with 5% CO_2, Kupffer cells were stained with

monoclonal anti-α tubulin-FITC. A significant decrease in the fluorescence density of microtubules was observed in Kupffer cells incubated with glycine as compared with the controls. However, the fluorescence density of the microtubules did not show a dose-dependent decrease among G1, G2, G3 and G4 groups (Table 2 and Figure 3).

DISCUSSION

Kupffer cells are the main component of the host monocyte-macrophage system, and their two main functions are phagocytosis and secretion. There is much evidence indicating that activation of Kupffer cells and their production of pro-inflammatory cytokines contribute to the pathogenesis of different liver injuries, including alcoholic liver disease (ALD), non-alcoholic fatty liver disease (NAFLD) and liver failure among others[20-22]. Tsujimoto *et al*[23] showed that phagocytic activity of Kupffer cells was decreased in a rat model of nonalcoholic steatohepatitis. Glycine is a nonessential amino acid and an inhibitory neurotransmitter in the central nervous system. Many studies have shown that dietary or intravenous glycine can protect against a variety of liver injuries[3-10]. In this study, we found that glycine decreases the phagocytosis and secretion of Kupffer cells *in vitro*.

Effects of glycine on phagocytosis by Kupffer cells

The mechanisms of Kupffer cell phagocytosis are still not completely understood. The ruffling of the cell membrane and formation of pseudopodia may play an important role and these effects are believed to be accomplished by the cytoskeleton. In the cytoskeleton, actin-myosin interaction through the calcium-calmodulin system plays a major role in this activity[24]. In this system, intracellular Ca^{2+} combines with calmodulin to form the active calcium-calmodulin complex, which activates an enzyme, myosin light chain kinase, to phosphorylate the light chain of myosin. Phosphorylated myosin, but not unphosphorylated myosin, can interact with actin to induce activity of the cell membrane and pseudopodia, leading to phagocytosis. This process is reversible, in that a phosphatase can catalyze dephosphorylation of myosin, restoring it to a form that can not be activated by actin.

Previous studies have shown that integrity of the cytoskeletal system is important for phagocytosis of Kupffer cells. Depolymerization of the cytoskeleton decreased phagocytosis by Kupffer cells[25-27]. However, the effects of glycine on phagocytosis by Kupffer cells have not been reported.

The present experiments show that glycine decreases phagocytosis by Kupffer cells *in vitro*, causes disordering of the microfilaments in Kupffer cells, and reduces their expression of microtubules. All these results show that glycine can decrease the phagocytosis of Kupffer cells by acting on the microfilaments and microtubules.

Effects of glycine on secretion by Kupffer cells

Some studies have shown that both CD_{14} and non-CD_{14} mechanisms are involved in the TNF-α secretion of monocytes and Kupffer cells, and that both endocytosis and Ca^{2+} are required for endotoxin-stimulated TNF-α release by Kupffer cells in rats[28-30]. Previous studies have shown that glycine can protect against many injuries and illnesses in rat models, most likely by inactivating Kupffer cells and decreasing TNF-α secretion[3-15]. An *in vitro* study has shown that glycine prevents the increases in $[Ca^{2+}]_i$ caused to LPS by activating chloride influx-reduced synthesis and release of toxic mediators by Kupffer cells[2]. Thus, glycine can activate the chloride influx, prevent the increases in $[Ca^{2+}]_i$ and reduce the TNF-α secretion of Kupffer cells.

Other studies have demonstrated the involvement of a microtubule-dependent mechanism in TNF-α secretion by monocytes. Taxol, a microtubule-stabilizing antineoplastic agent, induced expression of tumor TNF-α in macrophages[31]. Microtubule-disrupting agents such as colchicine had opposite effects on TNF-α production[32-34]. The present experiments showed that glycine significantly decreased TNF-α secretion and microtubule expression. Some of our results are consistent with previous reports[13-15], leading us to believe that glycine can prevent TNF-α secretion by Kupffer cells through disruption of microtubules.

In summary, glycine decreases both phagocytosis and secretion by Kupffer cells *in vitro*, which is probably related to glycine-induced changes in expression of microfilaments and microtubules in Kupffer cells.

COMMENTS

Background

Activated Kupffer cells are most likely involved in the pathogenesis of different liver injuries. Glycine generally is considered as a protective agent for liver injuries. The mechanism may be related to the fact that glycine inhibits the release of pro-inflammatory cytokines by Kupffer cells. So, it is very important to clarify the impact of glycine on the phagocytosis and secretion by Kupffer cells.

Research frontiers

It is believed that cytoskeleton plays a vital physiological role in phagocytosis by Kupffer cells, and depolymerization of cytoskeleton decreases the phagocytosis by Kupffer cells. Glycine protects against liver injuries by preventing the elevation of intracellular Ca^{2+} and reducing pro-inflammatory cytokines production by Kupffer cells. But the impact of glycine on phagocytosis by Kupffer cells is still unclear, and the mechanisms of glycine on tumor necrosis factor-α secretion by Kupffer cells have not been completely understood.

Innovations and breakthroughs

This is the first study to report that glycine decreases the phagocytosis of Kupffer cells by acting on the microfilaments and microtubules *in vitro*.

Applications

This study suggests that glycine may be an effective agent which could provide a future strategy for therapeutic intervention in the treatment of liver injuries induced by activated Kupffer cells.

Peer review

It is an interesting study with appropriate methodology and the results are clear and of great importance.

Abstract

The first-ever case of a 54-year-old woman who overdosed on non-steroidal anti-inflammatory drugs in an attempt at suicide. Before that incident, she had not been treated for coexisting diseases such as rheumatoid arthritis or depression. At the time of admission to the General Surgery Department, the patient reported pains in the epigastric region with accompanying nausea and vomiting with mucous content as well as the inability to ingest food orally. Despite parenteral and enteral feeding, the patient exhibited a drop in body mass. The histopathologic examination of a sample taken from the stomach during gastroscopy showed some non-specific necrotic and inflammatory masses with granulation. Intraoperatively, a very small, infiltrated stomach with an initial section of duodenum was identified. A total stomach resection together with the reconstruction of digestive tract continuity was performed using the Roux-Y method. Histopathologic examination of the stomach revealed a deep, chronic and exacerbated inflammatory condition with an extensive ulceration over the entire length of the stomach, reaching up to the pylorus. Additionally, numerous lymphatic glands with inflammatory reaction changes were observed.

INTRODUCTION

Currently, total stomach resection is typically performed in adults with stomach cancer[1-9]. Other causes of total stomach resection include chemical burns of the digestive tract caused by the consumption of toxic, most often caustic, substances, which occurs accidentally in children and in adults who have attempted suicide[10]. Most recent studies describe burns in the upper part of the digestive tract occurring after the consumption of concentrated acids, pesticides and bases used as detergents, bleachers or rust-removers[11-13]. Drug poisonings usually cause symptoms in the central nervous system and the circulatory and

respiratory systems as well as bleeding because they most often involve the ingestion of soporific, psychotropic and cardiac medicines. Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used in treatments globally. In some countries, e.g., in the United States, NSAIDs are used protractedly and in large doses, particularly in elderly patients. The administration of NSAIDs involves the risk of complications occurring in the digestive tract. It has been shown that these medicines may damage mucous membranes in the stomach and induce complications such as ulcerations, hemorrhages, or perforations[14-17]. The aim of the article is to present a female patient who consumed a very large amount of NSAIDs and Tramal at the same time in a suicide attempt.

CASE REPORT

A 54-year-old female was admitted to the General Surgery Department of the University Hospital in Olsztyn from the Internal Medicine Department to undergo surgical treatment of a pylorus narrowing that was induced by the consumption of drugs in a suicide attempt. Approximately five months before that, the woman took 60 NSAID pills (including Ibuprom, Ketonal, Diklofenak, Aspirin) and also ingested 300 mg of Tramal. After that episode, she was treated at the intensive care unit and then at the department of internal diseases. During that time, the patient was fed parenterally and, later, also enterally. Prior to that incident, the woman had not been treated for coexisting diseases such as rheumatoid arthritis or depression. At the time of admission to the surgery department, the patient reported epigastric pain with nausea and vomiting with mucous content as well as the inability to consume food orally. Despite parenteral and enteral feeding, the patient exhibited a 16-kg drop in body mass. Upon admission to the surgery department, her weight was 59 kg. The patient also suffered from pain in the epigastric and umbilical regions. However, the belly was soft with no pathological resistance, and the liver was not enlarged. Biochemical examinations showed minimal anemia (hemoglobin 10.4 g/dL) and increased fibrinogen values (up to 479 mg%) at international normalized ratio 1.10. During gastroscopy, a very small stomach was noticeably covered by scars and numerous fibrin-covered ulcerations. The stomach lacked a mucous membrane and hemorrhaged when touched with the device. The length of the stomach in the upper region was 2-3 cm. The distal part of the stomach was excessively narrowed and inaccessible. The pylorus channel allowed only for the insertion of the Flokar Ch10/130 cm catheter, which was placed properly behind the ligament of Treitz, with resistance. The histopathologic examination of a sample taken from the stomach revealed the existence of necrotic and inflammatory masses with granulation. The patient was qualified to undergo surgery operational treatment. A very small, infiltrated stomach with an initial section of duodenum was identified intraoperatively. Those organs exhibited excessive inflammatory infiltration. There were also numerous enlarged lymphatic glands, which were removed. After preparation and total resection of the stomach (Figure 1) with the initial part of the

Figure 1 Pathological changes in atrophic gastritis after treatment. A: Tubular resected stomach as a whole, 9 cm long; B1 and B2: Cross-section of stomach with its 2 cm thick wall and its atrophic mucose membrane.

duodenum, a Roux-Y anastomosis was performed using a 25-mm circular stapler. The esophageal resection line was 10 mm and free from pathological changes; the esophagus was observed to have intact epithelium and stroma with dispersed inflammatory infiltration. The initial duodenum resection line was 12-mm long with a preserved margin of mucous membrane and chronic exacerbated inflammation in the mucous and submucosal membranes. Histopathologic examination of the stomach revealed a deep, chronic and exacerbated inflammatory condition with an extensive ulceration over the entire length, reaching up to the pylorus. Microscopic examination revealed numerous lymphatic glands with inflammatory changes (Figures 2 and 3). The post-operative period was complicated on the fifth day due to bile leakage from the part of the duodenum closed with a linear stapler. A relaparotomy revealed numerous adhesions, as well as an orifice, 2 mm in diameter, on the top of the closed, bloated duodenum

Figure 2 Representative photomicrographs of hematoxylin and eosin stained sections from the stomach's necrosis of submucous membrane. stump, approximately 10 mm from the stitch line, out of which bile flowed heavily. Through the orifice, a drain of the same diameter was introduced into the duodenum as a duodenostomy. Four days after the surgery, the patient was treated with a respirator. On the following days, apart from some non-edemic and inflammatory changes in the lower segments of the lungs, the course of treatment was satisfactory. The patient was fed parenterally and enterally through a Flocare-type tube. When performing control examinations, the drain was removed from the duodenum stump (14th day). On the 16th day, the patient was administered an oral diet that was extended gradually. On the 21st day, she was discharged from the hospital, in good general condition, with body mass of 61.5 kg.

DISCUSSION

Benzodiazepines and other psychotropic drugs are the most common causes of suicide-related drug poisoning. Few studies have examined suicide attempts that involve NSAID overdoses. The long-term administration of NSAIDs, even in therapeutic doses, results in digestive tract complications in the form of inflammation, ulceration, mucous membrane bleeding and hemorrhage as well as perforations to the stomach and duodenum[14-17]. The consumption of NSAIDs in larger amounts causes damage to the stomach's mucous membrane, even resulting in total necrosis, as observed in the current case. During the six-month-long feeding treatment of the

patient and her endoscopic observation at the Department of Internal Medicine, preparations were made for surgery. The patient was in poor psychological condition and did not agree to undergo surgery. Within the borders of the stomach and duodenum, inflammatory infiltrate almost completely closed the pylorus with numerous adhesions to the surrounding tissues. The mucous membrane had slipped down completely, and its place was taken by necrotic and inflammatory tissues. It has already been proven that high doses of acetylsalicylic acid increase the risk of hemorrhage during the course of peptic ulcer disease[18]. In the current case, there was no information related to the adverse effects of NSAIDs administered to patients with osteoarthritis. When patients overdose for suicidal reasons, the duration of contact between the mucous membrane and the caustic substance is long, as in the case of our patient. The exposure time, type of drug (e.g., hydrophilic properties), concentration in the stomach, contents of the stomach before drug consumption, degree of pylorus contraction and operations performed on the digestive tract that impair its motor activity are of crucial importance with respect to the level of damage and the extent of changes to the stomach. The morphological changes to the stomach upon consumption of large amounts of NSAIDs may be accompanied by damage to the liver, kidneys and heart[17,19]. Nelson *et al*[20] described a case of liver failure requiring transplantation and simultaneous intestinal necrosis upon consumption of large amounts of acetaminophen and ibuprofen by their schizophrenic patient. The toxic activity of those drugs damages the mucous membrane and stops the production of prostaglandins in the intestines. A massive hemorrhage from a duodenum or stomach ulcer may often be observed among patients who have consumed NSAIDs even in therapeutic doses[21,22]. Morphological changes in the digestive tract are usually described in the literature as liquefactive or coagulative necrosis but refer to poisonings with concentrated bases or acids. Regardless of the type of poison consumed orally, chronic ulcerations of the stomach's mucous membrane, excessive inflammation, clots in the micro-circulation, bacterial colonization and increased fibroblastic activity may develop. The toxic activity of any drug depends not only on the consumed dose but also on other circumstances. Having a meal, drinking alcohol, and the ingestion of other medicines influences the patient's clinical condition. Most often, oral poisonings cause changes to the upper part of the digestive tract and lead to damage to the liver and kidneys. The current literature lacks reports on total resection of the stomach due to poisoning with NSAIDs and Tramal.

Abstract

A 69-year-old man was admitted to our hospital in October 2003, for further examination of two liver tumors. He was diagnosed with hepatocellular carcinoma (HCC) arising from decompensated hepatitis B virus (HBV)-related cirrhosis. Long-term lamivudine administration improved liver function dramatically despite repeated treatment for HCC. His Child-Pugh score was 9 points at start of lamivudine treatment, improving to 5 points after 1 year. His indocyanine green at 15 min after injection test score was 48% before lamivudine treatment, improving to 22% after 2 years and to 5% after 4 years. Radiofrequency ablation controlled the HCC foci and maintained his liver function. In April 2009, abdominal computed tomography revealed a tumor thrombus in the right portal vein. Since his indocyanine green test results had improved to less than 10%, we performed a right hepatectomy, which was successful. To our knowledge, there have been no documented reports of patients undergoing successful right hepatectomy for HCC arising from decompensated cirrhosis. The findings observed in our patient indicate the importance of nucleoside analogs for treating HBV-related HCC.

INTRODUCTION

The hepatitis B virus (HBV) infects more than 400 million people worldwide[1] and is an important risk factor for the development of hepatocellular carcinoma (HCC). In Japan, about 1% of individuals in the general population are HBV carriers, accounting for about 14% of patients with liver cirrhosis[2] and 15%-20% of those with HCC[3,4]. The prognosis of patients with HCC arising from chronic liver disease is dependent not only on tumor factors but on hepatic functional reserve. Depending on patient age, liver transplantation may be a good therapeutic option in patients with poor functional reserve. Lamivudine treatment is beneficial in patients with HBV-related HCC because it contributes to improvement of remnant liver function. We describe here a patient with decompensated HBV-related cirrhosis who developed HCC. Lamivudine therapy improved liver function and enabled a right hepatectomy 5 years later.

Figure 1 Computed tomography in our patient. It shows a cirrhotic pattern of the liver and massive ascites at first admission (A); Dynamic computed tomography revealed two hepatocellular carcinomas, 4.5 cm (B) and 2.5 cm (C) in diameter, in the right lobe; These two lesions were treated by transcatheter arterial chemoembolization and radiofrequency ablation (D, E).

CASE REPORT

A 69-year old man was admitted to our hospital in October 2003 for examination of two liver tumors. He had been diagnosed with hepatitis B in 1994 and treated with glycyrrhizin. His liver function deteriorated gradually, with ascites appearing in May 2001. He was first admitted to our hospital for treatment of intractable ascites (Figure 1A). Laboratory tests showed that his serum albumin (alb) concentration was 2.7 g/dL, his total bilirubin (T-Bil) was 2.8 mg/dL, his aspartate aminotransferase (AST) was 54 IU/L, his alanine aminotransferase (ALT) was 43 IU/L, and his prothrombin time (PT) was 42%. Administration of diuretic drugs was not effective, but treatment with a preparation of albumin resulted in the disappearance of ascites 1 mo later. Afterward, the ascites was kept under control by administration of diuretics. In October 2003, a computed tomographic (CT) scan of the abdomen revealed two HCCs (4.5 and 2.5 cm in diameter) in the right hepatic lobe (Figure 1B, C). Laboratory tests showed alb 2.5 g/dL, T-Bil 2.4 mg/dL, AST 152 IU/L, ALT 98 IU/L, PT 47%, indocyanine green at 15 min after injection (ICGR15) 48%, alpha-fetoprotein 444 ng/mL, and protein induced by vitamine K absence or antagonist II <10 mAU/mL. He was positive for HBe antigen, negative for HBe antibody, and had an HBV-DNA viral load of 6.7 log copies/mL. Beginning in November 2003, he was treated with 100 mg/d lamivudine. The two HCCs were treated by transcatheter arterial chemoembolization (TACE) and radiofrequency ablation (RFA) (Figure 1D, E). Both tumors were treated successfully and the patient's liver function recovered gradually after initiation of lamivudine treatment. In September 2005, an abdominal CT scan revealed a recurrent HCC, located near one of the previously treated tumors; this lesion was treated successfully with TACE and RFA. At this time, laboratory tests showed alb 3.7 g/dL, T-Bil 0.7 mg/dL, AST 23 IU/L, ALT 22 IU/L, PT 84% and ICGR15 22%. All HCC treatments were based on clinical practice guidelines in Japan[5], with the patient providing informed consent.

In May 2006, two HCC recurrences were detected in the right liver lobe and treated with TACE and RFA. Laboratory tests showed good liver function, alb 3.9 g/dL, T-Bil 1.1 mg/dL, AST 22 IU/L, ALT 11 IU/L, PT 95% and ICGR15 25%. In June 2007, a recurrent HCC was treated with TACE and RFA. Liver function was also excellent at this time (alb 4.0 g/dL, T-Bil 0.7 mg/dL and PT 100%). In September 2007, his viral load had again increased, with breakthrough hepatitis, and the YMDD mutation was detected. Treatment with adefovir dipivoxil plus lamivudine resulted in a gradual reduction in viral load. In December 2007, abdominal CT revealed five HCCs in the right lobe; these were treated by TACE and RFA. The patient was then treated with low-dose cisplatin and 5-fluorouracil infused through the hepatic artery. Laboratory tests showed alb 4.1 g/dL, T-Bil 1.0 mg/dL, AST 38 IU/L, ALT 30 IU/L, PT 88% and ICGR15 5%. Due to the development of a pseudoaneurysm in his hepatic artery, infusion of chemotherapy was discontinued. In March 2009, two HCCs were detected in the right lobe and were treated by RFA. Laboratory tests showed alb 3.7 g/dL, T-Bil 0.7 mg/dL, AST 35 IU/L, ALT 31 IU/L, PT 77% and ICGR15 10%. In April 2009, abdominal CT and CT angiography revealed a tumor thrombus in the right portal vein, but no lesion could be detected in the left lobe (Figure 2). Although he was diagnosed with decompensated cirrhosis, of Child-Pugh C, when first hospitalized, lamivudine treatment improved his liver function sufficiently, with an improve-

Figure 2 Computed tomography during hepatic arteriography, showing a portal tumor thrombus (arrow) in the right portal vein. Hepatocellular carcinoma was not detected in the left lobe.

Figure 4 Abdominal computed tomography showing the recurrence of hepatocellular carcinoma (arrow) in the left lobe two months after right hepatectomy.

ment of ICGR15 results to < 10%, to allow the successful performance of a right hepatectomy in April 2009 (Figure 3A). After liver resection, his AST rose to 1220 IU/L, his T-Bil to 1.9 mg/dL, and his PT decreased to 54%, followed by gradual recovery of liver function. He recovered well and left the hospital 1 mo after surgery.

Histologic examination of the extracted specimen showed a moderately differentiated HCC with portal tumor thrombus (Figure 3B) and multiple intrahepatic metastases. Fibrosis of varying extent was observed in the cancer-free area, with some areas showing severe fibrosis with pseudolobules and others showing mild fibrosis (Figure 3C). Abdominal CT in June 2009 suggested the recurrence of HCC in the left lobe (Figure 4), and abdominal angiography revealed multiple HCCs. These tumors were treated by TACE, but this was not effective. The left lobe tumors subsequently enlarged and the patient's liver function deteriorated gradually. The patient died in December 2009 (Clinical course Figure 5).

DISCUSSION

Chronic hepatitis B is a progressive liver disease, leading to cirrhosis and HCC[6]. Before antiviral agents became

Figure 3 Macroscopic and microscopic appearance of the resected liver. A: A tumor thrombus was detected in the right portal vein (arrow); B: A moderately differentiated hepatocellular carcinoma with a trabecular pattern was seen in the right portal vein [hematoxylin and eosin (HE) stain, ×40]; C: Fibrosis of varying extent was observed in the cancer-free area. Some pseudolobules with severe fibrosis were present in the left part of the photograph (HE stain, ×40).

established as effective treatments for hepatitis B, the prognosis of patients with end-stage HBV infection was generally poor. The 5-year survival rates of patients with compensated and decompensated cirrhosis have been reported to be 55%-84%[7,8] and 14%[9], respectively. Lamivudine, an antiviral drug, is an oral nucleoside analog that inhibits DNA synthesis by terminating the nascent proviral DNA chain. It rapidly reduces both serum HBV-DNA and transaminase concentrations[10]. Prolonged viral suppression can result in histological improvement, including the regression of fibrosis[10-13]. Although a subgroup of individuals with extremely advanced disease require urgent transplantation, lamivudine treatment can achieve significant improvement in liver function and reduce the morbidity of many of patients

Figure 5 Clinical course of the patient. After lamivudine administration, his liver function gradually improved despite repeated treatments for hepatocellular carcinoma (HCC), and his indocyanine green at 15 min after injection (ICGR15) test score was 5% 4 years after initiation of lamivudine treatment. He underwent a successful right hepatectomy for HCC 5 years after beginning lamivudine treatment. alb: Albumin; PT: Prothrombin time; TACE: Transcatheter arterial chemoembolization; RFA: Radiofrequency ablation; 5-FU: 5-Fluorouracil; CDDP: Cisplatin.

with decompensated cirrhosis[14-19]. At present entecavir is recommended as the primary oral agent for hepatitis B because of its strong antiviral effects and low resistance rate, as well as being effective in treating decompensated cirrhosis[20]. Long-term lamivudine monotherapy can induce the emergence of resistant viruses with an amino acid substitution in the YMDD motif of the viral DNA polymerase[21]. Particularly in patients with decompensated cirrhosis, breakthrough hepatitis resulting from such a mutation may lead to hepatic failure[22] if other antiviral drugs such as adefovir dipivoxil[23,24] are not administered. Long-term treatment with lamivudine has been reported to reduce the incidence of HCC[25,26]. In addition, lamivudine has been found to improve liver function[27,28] and survival[29] in patients with HBV-related HCC after initial treatment of HCC. We have described a patient with HCC arising from decompensated HBV-related cirrhosis. Long-term lamivudine treatment improved his remnant liver function dramatically, despite repeated TACE and RFA sessions for HCC. Although his Child-Pugh score at the start of lamivudine treatment was 9 points, it improved up to 5 points 1 year later. Moreover, he scored 48% on an ICGR15 test performed before his first treatment for HCC, but this score improved to 22% after 2 years and to 5% after 4 years, with the latter considered safe for the performance of a right hepatectomy[30].

Despite repeated RFA, the liver function of this patient was well maintained. Generally, RFA has been regarded as safe and effective for HCC, and has been found to maintain liver function[31-33]. In our patient, lamivudine and RFA were effective in maintaining liver function. A previous case report described a patient with decompensated HBV-related cirrhosis, who, following lamivudine treatment, underwent a hepatectomy for HCC after liver function had improved[34]. That patient, however, underwent a partial hepatectomy for a small HCC. To our knowledge, no prior report has described

a successful right hepatectomy for HCC arising from decompensated HBV-associated liver cirrhosis. The findings reported in this patient indicate the importance of nucleoside analogs for treating HBV-related HCC.

In conclusion, we found that lamivudine treatment was beneficial for our patient with decompensated HBV-related cirrhosis and HCC, increasing the likelihood of treatment for HCC.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t* test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. [a]$P < 0.05$, [b]$P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, [c]$P < 0.05$ and [d]$P < 0.01$ are used. A third series of P values can be expressed as [e]$P < 0.05$ and [f]$P < 0.01$. Other notes in tables or under illustrations should be expressed as [1]F, [2]F, [3]F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-beled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/1007-9327office/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ABOUT COVER   Editorial Board Member of *World Journal of Gastroenterology*, Hitoshi Asakura, Director, Emeritus Professor, International Medical Information Center, Shinanomachi Renga Bldg.35, Shinanomachi, Shinjukuku, Tokyo 160-0016, Japan

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Biliary tract cancer is a rare malignant tumor. There is limited knowledge about biology and natural history of this disease and considerable uncertainty remains regarding its optimal diagnostic and therapeutic management. The role of adjuvant therapy is object of debate and controversy. Although resection is identified as the most effective and the only potentially curative treatment, there is no consensus on the impact of adjuvant chemotherapy and/or radiotherapy on the high incidence of disease recurrence and on survival. This is mainly due to the rarity of this disease and the consequent difficulty in performing randomized trials. The only two prospectively controlled trials concluded that adjuvant chemotherapy did not improve survival. Most of the retrospective trials, which had limited sample size and included heterogeneous patients population and non-standardized therapies, suggested a marginal benefit of chemoradiotherapy in reducing locoregional recurrence and an uncertain impact on survival. Well-designed multi-institutional randomized trials are necessary to clarify the role of adjuvant therapy. Two ongoing phase Ⅲ trials may provide relevant information.

INTRODUCTION

Biliary tract cancer (BTC) is a rare tumor accounting for approximately 4% of all malignant neoplasms of the gastrointestinal tract. Marked gender, ethnical and geographical variations exist and, in certain regions of the world, like Chile or North India, BTC is one of the most common causes of cancer mortality. The median age at presentation is the seventh decade of life with a male to female ratio of 1.5[1-5].

Surgical resection is the only potentially curative treatment for BTC. However, the resectability rate has been reported to range between 30% and 70%, with large variability based on tumor location (70% for ampullary cancer, 40%-50% for gallbladder, intrahepatic and distal extrahepatic cancer and 30% for hilar BTC)[6,7]. The type of resection and prognosis vary with anatomical location with a 5-year overall survival (OS) rate of 20%-40% for intrahepatic adenocarcinoma, 50%-70% for ampullary cancer, 25%-50% for distal cholangiocarcinoma and for gallbladder cancer and 15%-35% for hilar BTC[8].

Due to the rarity of this disease, in which patients with curatively resected tumors are in the minority, prospective trials have been rarely performed and, sometimes, eligibility criteria allowed the enrolment of both patients with pancreatic cancer and BTC, thus hampering

the interpretation of results. Accordingly, information with a high level of evidence is lacking and wide areas of debate and controversy on optimal adjuvant therapeutic management exist.

PROGNOSTIC FACTORS

The 5-year OS rate with surgery alone is disappointing, ranging from 15% to 70%[6]. Complete surgical resection with histologically negative (R0) surgical margins has been reported to be the most important prognostic factor[9]. Since prognosis varies also with anatomical location, the heterogeneity of patient population of the reported studies may affect the interpretation of the data[8]. Other prognostic factors such as tumor stage, nodal status, vascular and perineural invasion, elevated baseline CA 19-9 level and histologic grade have been identified in many reports[10-13]. Among those, the prognostic relevance of tumor stage, nodal status, histologic grade and resection margin is almost universally accepted and should be taken into account for the stratification of the patients in prospective trials and for the interpretation of the results in non-randomized series; while the prognostic role of elevated baseline CA 19-9 level and vascular and perineural invasion is still controversial[14-45].

THERAPEUTIC MANAGEMENT

Most patients with BTC are not suitable for curative surgery at diagnosis, and the rate of microscopically positive resection margins (R1) has been reported to be up to 74%[14]. In addition, locoregional failure occurs in more than half of the patients, even after R0 resection[9,10]. Isolated locoregional disease was reported in approximately 15% of patients with gallbladder cancer, 20% with periampullary cancer and 60% with hilar cholangiocarcinoma. In contrast, systemic disease, with or without concomitant locoregional recurrence, occurred in 85% of patients with gallbladder cancer, 75% with periampullary cancer and 41% with hilar cholangiocarcinoma[10,11]. Because of poor survival after curative resection due to frequent local relapse and distant metastases[9-11,36], the role of adjuvant therapy has been widely explored[16,32,38,41-56].

Chemoradiation

Previous studies, mainly focusing on adjuvant chemoradiation therapy (CRT) with a variety of regimens, led to conflicting results and the role of this therapeutic strategy remains controversial. No large randomized trial of adjuvant CRT has ever been performed. A small phase III European Organization for Research and Treatment of Cancer trial, including 92 eligible patients with periampullary adenocarcinoma, demonstrated no statistically significant difference in survival between adjuvant CRT following resection *vs* observation[37]. However, since this trial included a limited number of patients and an outdated chemoradiation in terms of imaging, techniques, planning, dose and concomitant radiosensitizing chemo-

Table 1 Survival outcome for adjuvant chemoradiation

Ref.	No. of patients	Site	Therapy		OS (median)

therapy, definitive conclusions on the role of modern chemoradiation are impossible to draw.

Conversely, a retrospective series of 73 patients with gallbladder cancer treated between 1985 and 2004 at Mayo Clinic[38] suggested that adjuvant CRT may obtain a statistically significant improvement in OS only for patients with lymph node involvement. Similarly, two retrospective series of fluoropyrimidine-based post-operative chemoradiation from MD Anderson Cancer Center[39] and from South Korea[40], including 96 patients affected by ampullary adenocarcinoma and 91 patients with extrahepatic bile duct cancer, respectively, suggested an improved OS only in patients with locally advanced tumor (T3/T4)[39] or with R1 resection[40]. A few other smaller retrospective series also reported a modest potential OS benefit with adjuvant CRT (Table 1)[38,39,41-45].

Apart from the controversial impact on OS, CRT may have a role in improving local control, especially in patients at higher risk of local failure, such as those with R1 margins and positive lymph nodes. In fact, 5-year local control rate raised from 40%-50% in patients with ampullary cancer treated with surgery alone to 65%-80% in those who received post-operative CRT[1,39-41,57].

Unfortunately, the retrospective nature of most of these studies, the small sample size, the lack of correction for multiple comparisons, patient selection bias; heterogeneity in terms of patients' characteristics, treatment regimens, tumor site and stage; long-lasting accrual periods, different surgical, radiotherapy and radiological techniques in different historical periods and other confounding factors do not allow to draw any firm conclusion on the role of CRT. In fact, younger and healthier patients were more likely to be offered adjuvant CRT. On the other hand, patients with high risk features were more likely to receive adjuvant therapy than those with favorable features.

Chemotherapy

A few studies evaluated the role of adjuvant chemotherapy in BTC. A retrospective single centre analysis on 42 patients suggested that postoperative gemcitabine-based chemotherapy may be a promising strategy to improve OS after surgical resection for hilar cholangiocarcinoma[55].

Consistently, the addition of fluorouracil-based chemotherapy to adjuvant CRT seemed to improve disease free survival (3-year DFS 45% *vs* 27%) and OS (3-year OS 63% *vs* 31%) compared to CRT alone in another retrospective series of 120 patients with radically resected extrahepatic BTC.

A phase III trial addressed the role of adjuvant chemotherapy with 5-fluorouracil and mitomycin-C in a series of 508 patients with surgically treated pancreaticobiliary malignancies including 335 patients with BTC[58]. OS was significantly increased when compared to observation arm only in the unplanned subset analysis of 61 resected patients with macroscopically positive resection margins (R2) affected by gallbladder cancer. Similarly, a more recent phase III trial exploring the role of single agent adjuvant chemotherapy with either gemcitabine or 5-fluorouracil, in 304 patients with ampullary adenocarcinoma submitted to curative resection did not demonstrate a survival benefit for any of the adjuvant therapy arms when compared to surgery alone[59].

GUIDELINES AND CURRENT CLINICAL PRACTICE

The National Comprehensive Cancer Network (NCCN) guidelines[60] recommend only observation or adjuvant CRT with concomitant fluoropyrimidine for patients with R0 margins or negative lymph-nodes and adjuvant therapy with concurrent 5-fluorouracil-based CRT followed or not by additional fluoropyrimidine- or gemcitabine-based regimens in patients with R1 margins or metastatic lymph nodes. The use of chemotherapy is recommended due to the high incidence of systemic relapse and to the results observed in the therapeutic management of advanced disease[61,62]. The European Clinical Practice guidelines[63] are more vague, only suggesting CRT as a possible therapeutic option after surgery for BTC. More restrictive indications derive from a modified and implemented version of NCCN guidelines proposed by a committee of specialists of the Middle East and North Africa Region, which recommend only observation or enrolment into a clinical trial after an R0 and/or a negative regional nodes resection, because of conflicting data regarding adjuvant CRT[64].

Given the lack of guidelines based on high level of evidence, it is not surprising that patients submitted to curative surgery for biliary tract tumors receive heterogeneous management around the world. A survey of therapeutic strategies recommended in the clinical practice in 2001-2002, reported that adjuvant CRT was widely adopted in the majority of American centers (71%), followed by Asian/Pacific centers (55%), but only by 29% of European institutions[65]. This scenario may have changed in more recent years with a trend towards possibly increasing use of adjuvant treatment due to the numerous positive experiences reported in the literature in the last decade[9-11,38-42,44,45,55,57-59,66,67]. However, eighty-eight percent of the interviewed physicians recognized the unmet need for achieving higher levels of evidence from large prospective trials to support the routine use of adjuvant treatment[65].

FUTURE DIRECTIONS

Altogether, the available data do not allow to answer the question whether patients submitted to curative resection for BTC should receive an adjuvant therapy and which treatment strategy may provide the largest benefit.

In fact, neither adjuvant CRT nor adjuvant chemotherapy with either single agent or a 5-fluorouracil-mitomycin doublet improved OS when compared to observation alone in phase III trials[14,58,59], while only a modest benefit in loco-regional control rather than on OS was suggested with CRT by retrospective series that, in any case, suffer from previously mentioned methodological limitations[1,38,41-45,65-68].

The causes of this disappointing scenario and of the lack of a convincing answer are manifold. First, when compared to trials on advanced disease, trials on adjuvant therapy are more demanding, also due to the involvement of different specialists (surgeon, radiologist, oncologist and radiotherapist); more resource- and time-consuming, due to the longer patient's life expectancy and to the inferior number of patients; and require a more selective choice of centers to be involved. Second, evidence-based information on the most active and effective chemotherapy regimen against unresectable or metastatic disease is limited as well. Accordingly, the selection of promising regimens that may have a relevant impact on disease natural history is challenging. Only recently, cisplatin and gemcitabine regimen became the new standard of treatment in advanced BTC[61] providing a rational for investigating the role of this combination in the adjuvant setting. Additionally, two ongoing phase III trials are currently exploring the role of capecitabine (NCT00363584) and of GEMOX regimen (NCT01313377) in the adjuvant setting and may provide further information in the next future. Third, the rarity of disease limits the interest of pharmaceutical companies while investigator initiated trials are hindered by the restricted availability of agents already registered and authorized for the treatment of the disease. Fourth, the choice of the most promising therapeutic strategy is crucial in this disease that has a very high rate of both local and systemic recurrence. Systemic chemotherapy and CRT, rather than being taken as alternative therapies, should be combined taken into account in the design of post-operative management. However, the role of sequential therapy with CRT followed by systemic chemotherapy or the inverse sequence was rarely addressed in prospective trials[55]. Fifth, the knowledge on tumor biology is limited and, at the moment, does not allow to identify new agents that may contribute to improve the outcome of the disease. Last but not least, the interpretation of trials result is often challenging due to the heterogeneity of enrolled patients population. Stratification based on tumor location, extent of resection, lymph node

status and resection margin status will be crucial to the success of future studies.

CONCLUSION

A multi-institutional worldwide effort to conduct well designed phase III trial and to expand biological knowledge of the disease is necessary to clarify the role of adjuvant therapy in BTC.

Abstract

Motor vehicle accidents (MVAs) are serious social issues worldwide and driver illness is an important cause of MVAs. Minimal hepatic encephalopathy (MHE) is a complex cognitive dysfunction with attention deficit, which frequently occurs in cirrhotic patients independent of severity of liver disease. Although MHE is known as a risk factor for MVAs, the impact of diagnosis and treatment of MHE on MVA-related societal costs is largely unknown. Recently, Bajaj *et al* demonstrated valuable findings that the diagnosis of MHE by rapid screening using the inhibitory control test (ICT), and subsequent treatment with lactulose could substantially reduce the societal costs by preventing MVAs. Besides the ICT and lactulose, there are various diagnostic tools and therapeutic strategies for MHE. In this commentary, we discussed a current issue of diagnostic tools for MHE, including neuropsychological tests. We also discussed the advantages of the other therapeutic strategies for MHE, such as intake of a regular breakfast and coffee, and supplementation with zinc and branched chain amino acids, on the MVA-related societal costs.

INVITED COMMENTARY ON HOT ARTICLES

We have read with great interest the recent article by Bajaj *et al*[1] describing the diagnosis and treatment of minimal hepatic encephalopathy (MHE) to prevent motor vehicle accidents (MVAs), and would strongly recommend it to the readers.

MVAs are serious social issues worldwide[2]. Various factors are intricately involved in the occurrence of MVAs, and driver illness is an important cause[2]. Besides acute myocardial infarction, epileptic seizure, and hypoglycemia related to the use of anti-diabetic agents, liver cirrhosis with MHE has been reported to increase the risk of MVAs[3-6]. Although MHE occurs in up to 80% of patients with chronic liver disease[3] and diagnostic tools and therapeutic strategies for MHE exist[7-11], little information is available about the management of patients with liver cirrhosis with regard to preventing MVAs and subsequently reducing the associated societal costs.

In their study, Bajaj et al[1] performed a cost-effectiveness analysis to identify management strategies for the diagnosis and treatment of MHE in patients with liver cirrhosis to reduce MVA-related societal costs. They found that the diagnosis of MHE by rapid screening using the inhibitory control test (ICT), and subsequent treatment with lactulose could substantially reduce societal costs by preventing MVAs[1]. This is a significant study, and we agree with the authors about the benefits of the use of the diagnostic test and therapeutic management. However, we suggest that the management strategy should be modified to some extent for use in general medical institutions to prevent MVAs on a larger scale.

The ICT is a computerized test of attention and response inhibition that has been used to characterize attention deficit disorders[12]. The ICT consists of the presentation of several letters at 0.5 s intervals, while the subject is instructed to respond or inhibit their response to the specific letter[13]. The ICT is considered reliable and sensitive for the diagnosis of MHE[5,13]. In addition, unlike standard neuropsychological tests, ICT results are significantly associated with the future occurrence of MVAs[3]. However, the test takes approximately 30 min to complete and patients need to be familiar with computer operation. Furthermore, validation and standardization are required for each population, and therefore, so far, the ICT is not universally accessible. Similarly, other diagnostic tools for MHE also require trained personnel and specialized equipment[11]. In fact, an American Association for the Study of Liver Disease (AASLD) survey showed that the majority of AASLD members are not able to test for MHE because of a lack of time, resources, and suitable personnel[14]. Along with Bajaj et al[14], we propose that rapid and simple tools for the diagnosis MHE should be developed urgently, such as biochemical tests or virtual reality driving simulations.

Lactulose has been used to treat hepatic encephalopathy since 1966[15]. Lactulose reduces blood ammonia levels and improves overt hepatic encephalopathy as well as MHE[7]. In their study, Bajaj et al[1] have demonstrated the benefits of lactulose therapy on the occurrence of MVAs and MVA-related societal costs. However, compliance with lactulose treatment is generally poor, primarily because of its side-effects such as abdominal discomfort[16,17]. Recently, other therapeutic strategies for MHE have been reported. First, as prolonged periods of fasting are linked to the development of MHE, having a regular breakfast improves the attention and executive functions of cirrhotic patients with MHE[18]. Second, coffee intake improves cognitive function in elderly people as well as in patients with type 2 diabetes mellitus[19,20]. Although the beneficial effects of coffee on cognitive function have never been investigated in cirrhotic patients, insulin resistance is frequently seen in patients with chronic liver disease[21-23]. In addition, coffee consumption is known to improve hepatic inflammation and fibrosis in patients with chronic liver disease[24]. Third, the blood ammonia level is regulated by the activity of ornithine transcarbamoylase and zinc is a coenzyme required for its up-regulation[25].

Figure 1 A proposed flow chart of drive permission for patients with chronic liver disease. MHE: Minimal hepatic encephalopathy; BCAA: Branched chain amino acids.

Oral zinc supplementation improves hyperammonemia as well as hepatic encephalopathy, as seen in a double-blind randomized controlled trial[26]. Finally, a decrease in serum branched chain amino acids (BCAA) levels is a feature of chronic liver disease[27]. BCAA is a source of glutamate, which detoxifies ammonia by glutamine synthesis in the skeletal muscle and brain[28]. Therefore, BCAA enhances the detoxification of blood ammonia by incorporating ammonia in the process of glutamine production and is currently used for treating patients with hepatic encephalopathy[29]. Thus, a therapeutic approach comprising the intake of a regular breakfast and coffee, and supplementation with zinc and BCAA may improve the cost-effectiveness of MVA-related events in cirrhotic patients with MHE (Figure 1).

Prevention of MVA by the diagnosis and treatment of MHE is an important component in the management of patients with liver cirrhosis. Collaborative researches among medical institutions, automobile companies, and governmental sectors may help further prevent MVAs and subsequently reduce MVA-related societal costs.

Abstract

Inflammatory bowel disease (IBD) affects women of childbearing age and can influence fertility, pregnancy and decisions regarding breastfeeding. Women with IBD need to consider the possible course of disease during pregnancy, the benefits and risks associated with medications required for disease management during pregnancy and breastfeeding and the effects of mode of delivery on their disease. When indicated, aminosalicylates and thiopurines can be safely used during pregnancy. Infliximab and Adalimumab are considered probably safe during the first two trimesters. During the third trimester the placenta can be crossed and caution should be applied. Methotrexate is associated with severe teratogenicity due to its folate antagonism and is strictly contraindicated. Women with IBD tend to deliver earlier than healthy women, but can have a vaginal delivery in most cases. Caesarean sections are generally recommended for women with active perianal disease or after ileo-anal pouch surgery. While the impact of disease activity and medication has been addressed in several studies, there are minimal studies evaluating patients' perspective on these issues. Women's attitudes may influence their decision to have children and can positively or negatively influence the chance of conceiving, and their beliefs regarding therapies may impact on the course of their disease during pregnancy and/or breastfeeding. This review article outlines the impact of IBD and its treatment on pregnancy, and examines the available data on patients' views on this subject.

INTRODUCTION

Inflammatory bowel disease (IBD) predominantly affects the younger-aged population and therefore is prominent in women of child-bearing age. It often requires medication for maintenance of remission[1]. Literature on pregnancy in IBD has mainly utilized tertiary hospital cohorts and focused on pregnancy outcomes. Current guidelines emphasize the importance of inducing and maintaining disease remission prior to conception and during pregnancy[1,2]. Studies of patients' perspective of the influence of IBD on fertility, pregnancy and breastfeeding

are highly relevant and beginning to emerge. This review article summarizes this evidence and examines the currently available data describing the patients' views.

LITERATURE SEARCH

A literature search was conducted using Pubmed from 1980 to 2010 with the search terms "IBD", "Crohn's disease (CD)", "ulcerative colitis (UC)", "pregnancy", "breast feeding" and "nursing". Further relevant articles were identified from the reference lists of identified articles.

Fertility and fecundity

Factors determining fecundity and fertility in IBD include disease systemic effects (e.g., fatigue and anaemia) as well as libido and sexual inactivity, which, in turn, may be influenced by body image issues and dyspareunia[3]. Furthermore, concerns over the influence of disease activity or medications on a successful pregnancy may also influence fecundability. In UC, overall fertility is comparable to that of the healthy population[3-5], but women with ileo-anal pouches (IPAA) have reduced fecundity[6,7]. Fertility in CD in remission is equivalent to that of healthy women[4,8,9] but may be reduced in patients with active disease[9-12]. As in UC, women with CD also have reduced fecundity following extensive surgery involving the pelvis[5-7,13-18].

Disease behaviour during and after pregnancy

Disease activity during pregnancy is similar to that in non-pregnant women as reported by two Danish cohort studies. In 97 women with UC, flare rates were 34% per year during pregnancy and 32% per year outside pregnancy[19], while in 68 women with CD there was also no increased risk of a flare during pregnancy[20]. The vast majority of women have quiescent disease during pregnancy as shown in a population based cohort of 461 women from the Northern California Kaiser Permanente population[21].

Women with IBD might experience a more benign course of disease in the post-partum period. A significantly reduced number of flares in comparison to pre-pregnancy in a small cohort of 18 CD and 19 UC patients was reported by Castiglione *et al*[22]. A larger pan-European study of 93 women with CD and 173 women with UC confirmed this finding[23]. The reason for this phenomenon is unknown, but it has been proposed that disparity between maternal and foetal human leukocyte antigen class Ⅱ antigens leads to a state of immuno-tolerance or suppression that in turn leads to a more benign course of IBD[24].

Effects of IBD and IBD disease activity on pregnancy

Active disease during pregnancy has been linked to adverse pregnancy outcomes of low birth weight, pre-term birth and foetal loss[19,25-27]. Population-based studies have, however, reported conflicting results. In 461 women (300 with UC) of the Kaiser Permanente population in North America, no correlation between adverse pregnancy outcomes and disease activity was found[21], while a study of 157 Danish women with CD revealed that active disease increased the risk of pre-term birth[28]. The higher proportion of patients with active disease in the Danish study (45% *vs* 20% in the Kaiser Permanente population) may explain this difference.

Some studies, including a meta-analysis by Cornish *et al*[29], reported an increase in pre-term births in IBD patients[21]. Other studies, however, that differentiated UC from CD found an increase in pre-term birth rates for patients with CD only[30,31]. CD women also delivered lower birth weight babies than healthy controls and UC women[30,31]. It is important to recognise that all studies examining pregnancy outcomes in IBD used healthy women controls rather than those with other chronic diseases.

Congenital abnormalities in offspring of mothers with IBD

Congenital abnormalities of variable severities occur in 3%-7% of babies of healthy mothers[32]. Studies of congenital malformations in the offspring of mothers with IBD have reported conflicting results. In a population based cohort of 262 women from Washington state, North America, an increased risk of congenital malformations was found in the offspring of UC patients (7.9% *vs* 1.7% in healthy controls; *P* < 0.001) but not in those of CD patients (3.4%; *P* = NS)[30]. The study did not control for medication use[30]. In contrast, the Hungarian Case Control Surveillance of Congenital Anomalies (HCCSCA) (1980-1996) found no increase in the risk for "any" malformation [odd ratio (OR): 1.2, 95% (confidence interval) CI: 0.9-1.8] in the offspring of 79 UC mothers compared to 95 control mothers after adjusting for parity, age and medication use[33]. Specific malformations of the limb (OR: 6.2, 95% CI: 2.9-13.1), urinary tract (OR: 3.3, 95% CI: 1.1-9.5) and multiple malformations (OR: 2.6, 95% CI: 1.3-5.4), however, were significantly increased[33].

An Italian case-control study reported a significantly increased risk of congenital anomalies in the offspring of 90 women with IBD (5.5% *vs* 0% in 240 healthy controls) and that CD and UC had equivalent risks[31]. The reported 0% incidence of congenital abnormality rate in healthy controls, however, was unusually low given this rate can approach 7%[32].

The risk of congenital malformations in the offspring of 461 women with IBD from the Northern California Kaiser Permanente population was not increased in comparison to 493 healthy controls[21]. Cornish *et al*[29] found in a meta-analysis of four studies an increased risk (OR: 2.37, 95% CI: 1.47-3.82) of reporting congenital abnormalities for UC, while for CD the risk increase was not statistically significant (OR: 2.14, 95% CI: 0.97-4.74; *P* = 0.06).

Data on congenital malformations may be contradictory due to differences in study design, the inclusion of cohort *vs* population subjects, and sample sizes. The majority of studies, however, report an increased risk for malformations in UC, but not in CD. Further prospective

Table 1   Food and Drug Administration categories of drug safety during pregnancy

FDA category	Definition
A	Controlled studies in animals and women have shown no risk in the first trimester, and possible foetal harm is remote
B	Either animal studies have not demonstrated a foetal risk but there are no controlled studies in pregnant women, or animal studies have shown an adverse effect that was not confirmed in controlled studies in women in the first trimester
C	No controlled studies in humans have been performed, and animal studies have shown adverse events, or studies in humans and animals not available; give if potential benefit outweighs the risk
D	Positive evidence of foetal risk is available, but the benefits may outweigh the risk if life-threatening or serious disease
X	Studies in animals or humans show foetal abnormalities; drug contraindicated

FDA: Food and Drug Administration.

studies adjusting for disease activity, medication and age of the mother are needed.

Medication during pregnancy

The risks and benefits of medication need to be considered on an individual patient level, since active disease poses a risk to the pregnancy[26-28]. The European Crohn's and Colitis Organisation (ECCO) guidelines state the risk of adverse pregnancy outcomes from active disease to be higher than the risk of using most IBD medications[2]. The United States Food and Drug Administration issued a categorisation of drugs safety in pregnancy (Table 1)[34].

Aminosalicylates: Sulfasalazine, mesalazine and balsalazide are category B medications, while olsalazine is category C. Initial case reports[35-37] suggesting sulphasalazine teratogenicity was refuted by a Danish cohort study demonstrating no adverse outcomes in 17 pregnant CD patients exposed to sulfasalazine[28]. Another study of 181 pregnant patients with IBD exposed to sulfasalazine reported lower rates of adverse outcomes than those expected in the general population[38]. Sulfasalazine impairs folate absorption, which is vital for neural tube development. Therefore folate supplementation is mandated[2].

Several studies have demonstrated the safety of mesalazine[39-41]. Robust data from a Danish population-based cohort and a prospective controlled trial of 165 pregnant women with mesalazine exposure reported no increased risk of congenital abnormalities[42,43]. It is unclear whether an excess of stillbirth and preterm birth in 88 pregnancies of women with CD on mesalazine reported in the population based study[43], occured as a result of IBD itself rather than the medication since this study incorporated 19 418 pregnancies of healthy women without any chronic illnesses and medication exposure as the control group. Thus, sulfasalazine and mesalazine are

considered safe in pregnancy.

Antibiotics: Antibiotics play an important role in the management of perianal CD[2]. Metronidazole is a category B medication. In a population based case-control study using HCCSCA data (1980-1991), metronidazole exposure during the second or third trimester was associated with cleft defects[44]. Other studies including two meta-analyses and a prospective controlled study, however, found no increased risk of congenital abnormalities relating to metronidazole use[45,46]. Quinolones can induce congenital abnormalities in animals due to their accumulation in bone and cartilage[47]. In 2 human studies totalling over 250 patients without IBD, no increased risk of adverse pregnancy outcomes or foetal malformations was found[48,49].

Short-term antibiotic use in pregnancy appears safe in largely non-IBD cohorts. In IBD, however, exposure to antibiotics can be prolonged and the associated risks may therefore be higher[2]. A small series of IBD patients found no adverse pregnancy outcomes in 27 patients exposed to metronidazole and 18 to ciprofloxacin[50].

Tetracyclines (retardation of foetal skeletal development) and sulphonamides (interferes with folic acid metabolism) should both be avoided in pregnancy[2].

Corticosteroids: Prednisone and budesonide have category C ratings. Corticosteroids cross the placenta and some adverse data exist in humans. A meta-analysis of ten cohort and case-control studies totalling 50 845 patients without IBD found no increase in overall risk of major congenital abnormalities, but there was a significant risk of oral clefts[51]. In contrast a prospective study of 262 women found that neither the overall risk for malformations nor the risk for clefts was increased[52]. No human data exist on orally administered budesonide, but studies looking at women exposed to inhaled or intra-nasal budesonide have found it to be safe during pregnancy[53,54]. Due to oral budesonide's high first pass hepatic metabolism, significant foetal exposure is less likely.

Thiopurines: Mercaptopurine and its pro-drug azathioprine are category D due to previous links with spontaneous abortions[55,56]. Animal studies, using doses of 1.5-2.5 mg/kg, have not reported any adverse outcomes apart from low birth weights[57,58]. Transplant and rheumatology cohorts demonstrated the safety of thiopurines[59-61]. Most studies in pregnant IBD patients report no adverse outcomes[62,63], but a Danish study reported a increased pre-term birth, low birth weight and foetal abnormalities in a cohort of only 10 patients[64]. That study compared pregnancy outcomes in thiopurine exposed patients to those of the general population rather than non-exposed IBD patients. It is therefore unclear whether the increased risk detected in the study was due to medication or IBD itself. In contrast, a prospective Austrian abstract of 33 women[65] and a French study on 86 women show no increase in adverse outcomes[66]. Paternal thiopurine exposure within 3 mo prior to conception led to a higher

rate of pregnancy related complications in one study[67], but another study reported no increased risk of adverse outcomes[68].

Thus, studies comparing outcomes of thiopurine exposed and unexposed IBD patients demonstrate no association with adverse outcomes. The single study showing a possibly increased risk is small and compares exposed patients to the general population[64]. Based on the overall evidence and despite the category D classification, the ECCO guidelines therefore consider thiopurines safe and well tolerated in pregnancy[2].

Methotrexate: Methotrexate is rated category X as it is clearly teratogenic and an abortifacient due its biological action as a folate antagonist. It is associated with numerous foetal abnormalities and high risk of foetal mortality and absolutely contraindicated for women attempting pregnancy[69,70].

Other immunosuppressants: Data on cyclosporine and tacrolimus mainly stems from the transplant and rheumatology literature and both are rated category C[2].

Biological agents: Infliximab has been classed as category B. It does not cross the placenta during the first trimester and hence there is no exposure in this critical phase of development[71]. Infliximab crosses the placenta in later stages of pregnancy and may be present in the newborn for several weeks[71]. Safety data for infliximab are provided by three large scale studies. The Crohn's Therapy Resource, Evaluation and Assessment Tool registry-a prospective, North American observational multi-centre study-enrolled infliximab-exposed and unexposed CD patients from 1999 to 2004[72]. No differences in miscarriages and neonatal complications were found between infliximab-exposed (117 pregnancies) and unexposed (49 pregnancies) women[72]. The retrospective Infliximab Safety Database (maintained by Centocor) found no differences in adverse outcomes between 96 pregnancies in women with infliximab exposure compared to the general population[73]. The Leuven group in Belgium treated 29 women treated with infliximab during 35 pregnancies and six women with adalimumab during seven pregnancies. In comparison to IBD patients without infliximab or adalimumab exposure, no increased risk of adverse events was found[74].

Adalimumab is also classed as a category B drug and expected to have the same placental transfer as infliximab. Apart from the Leuven experience[74] there are few reports on IBD patients exposed to adalimumab during pregnancy[75,76]. The organisation for teratology specialists' registry of women with rheumatoid arthritis compared 34 adalimumab-exposed pregnancies to 52 pregnancies of healthy women and found no increased risk of adverse pregnancy outcomes[77]. Certolizumab and natalizumab are category B and C drugs respectively, but there is currently little data on their effects in pregnancy[2].

Infliximab use in pregnancy resulted in the death of a 3 mo old child with disseminated Bacillus Calmette-Guérin (BCG) after receiving the live BCG vaccination[78]. Live vaccinations are contra-indicated for immuno-compromised patients. Newborns to mothers exposed to infliximab and adalimumab mothers should have their vaccination postponed[78].

Mode of delivery

Patients with IBD (especially CD) were more likely to have a caesarean section in Cornish's meta-analysis of six studies (OR: 1.5, 95% CI: 1.26-1.79; $P < 0.001$) compared to the general population[29], but there was no difference in caesarean rates between UC and controls[29]. Concerns regarding the preservation of the anal sphincter function and the development of perianal disease after traumatic injuries occurring during vaginal delivery may partially explain this phenomenon. However, the chance of developing perianal disease in women with CD without prior perianal involvement is low; in a population based cohort study from Mannitoba, Canada only one of 27 women without prior perianal disease developed perianal disease after vaginal delivery and episiotomy[79]. Conversely, in a self-report survey of 179 women without perianal disease, 18% reported perianal involvement after delivery[80], but it is possible that selection bias, that is, more women with than without perianal disease may have responded, and recall bias may have occurred[80].

A population based cohort study from Mannitoba of 11 patients with inactive perianal disease and two single case reports from France and United States, revealed that inactive perianal disease may tolerate a vaginal delivery with episiotomy if needed without risking a flare[79,81,82]. However, women with active perianal disease should be advised to have a caesarean section as a high risk of deterioration is anticipated. Delivery trauma can lead to poor-healing in the perineum. ECCO guidelines advise that elective caesarean section is indicated for all women with perianal involvement[2] even though there is little evidence suggesting harm from a vaginal delivery in cases of inactive disease.

ECCO guidelines recommend mandatory caesarean sections after IPAA[2]. Changes in anal sphincter function are temporary and long-term disturbances seem to be independent of the mode of delivery in patients with IPAA[14,16,83]. The largest study of 232 females with pregnancies after IPAA found no difference in pouch-related complications between women undergoing vaginal delivery or caesarean section[84]. In another survey, functional pouch outcomes of 85 women with vaginal deliveries after IPAA were no different to those of 343 age matched women who did not have children after IPAA[85]. A Finish survey study of 39 women with IPAA found no differences in pouch function after 19 vaginal deliveries in comparison to 21 caesarean sections and the rate of 5 tears after vaginal delivery was similar to a healthy control group[86]. In a cohort of women investigated four years after IPAA at the Cleveland clinic, United States no clinical differences were demonstrated between 20 women

Table 2 Medication recommendation for pregnancy and breast feeding

Class	Drugs	FDA category	Pregnancy advice	Detection in breast milk
Aminosalicylates	Sulfasalazine, balsalazide, mesalazine	B	Safe to use (folate supplementation for sulfasalazine)	Low levels detectable
Aminosalicylates	Olsalazine	C	Safe to use	
Antibiotics	Metronidazole	B	Safe to use	
Antibiotics	Ciprofloxacin		Limited data; probably safe	
Corticosteroids	Prednisolone, budesonide	C	Safe to use	Detectable
Thiopurines	Azathioprine, 6-mercaptopurine	D	Safe to use	Very low levels detectable
Folate antagonist	Methotrexate	X	Absolutely contraindicated	
Biological agent	Infliximab	B	Probably safe (avoid during 3rd trimester)	Not detectable
Biological agent	Adalimumab	B	Probably safe (avoid during 3rd trimester)	Very low levels detectable

FDA: Food and Drug Administration.

with at least one vaginal delivery compared to 62 women who only had caesarean sections[87]. Subclinical differences in anorectal physiology were however demonstrated as women with vaginal deliveries had significantly lower squeeze pressure on anorectal manometry and significantly more anal sphincter defects detected by anorectal sonography than those women with caesarean sections[87].

The ECCO guidelines state that women are at borderline incontinence after IPAA surgery and that any further disruption by a vaginal delivery might compromise this[2]. This theoretical concern is supported by sonographic and manometric evidence of sphincter dysfunction, but this does not translate to clinical differences in pouch function or quality of life. Precautionary caesarean sections are however recommended[2].

Thus, mandatory recommendation for caesarean sections in IBD is only for very specific indications and decisions should be made on a case by case basis.

Breast feeding
Breast milk provides ideal nutrition and has positive effects for the immune system of the newborn[88]. Data on the protective effect of breastfeeding against the development of IBD report are conflicting. Study design, recall bias, definition of breast feeding (especially duration) and the design bias often inherent in retrospective case-control studies may explain some of the differences[89]. A meta-analysis of 17 studies found reduced ORs of 0.67 (95% CI: 0.52-0.86) for CD and 0.77 (95% CI: 0.61-0.96) for UC. The relevance of a French case-control study reporting an increased risk (OR: 2.1, 95% CI: 1.3-3.4) of developing CD[90] remains unclear, in light of previous studies showing no effect or a protective effect[89,91].

Fewer patients with IBD breastfeed compared to the general population, and this may relate to fears about adverse effects of maternal medication[92]. Most maternal medications can be detected in breast milk, but this does not always lead to biological effects in the infant.

Based on two case reports of bloody diarrhoea in newborns breastfed by mothers taking sulfasalazine and 5-aminosalicylates respectively, the American Academy of Pediatrics advises against breastfeeding by mothers taking these medications[93-95]. In contrast, several studies demonstrate the safety of sulfasalazine and 5-aminosalicy-

lates while breastfeeding by detecting low levels of drug in breast milk or the infant's serum[39,96,97]. Based on above evidence mothers on sulfasalazine and 5-aminosalicylates should not be discouraged from breastfeeding unless the infant develops diarrhoea.

Since corticosteroids are found in human breast milk in low concentrations, women are advised to avoid feeding within 4 h of taking an oral dose to reduce exposure[2,98]. Thiopurine and associated metabolite levels are either at undetectable, or extremely low levels, in human breast milk[99-101], while infants' levels were undetectable[102,103]. Infliximab can not be detected in infants of breastfeeding mothers[104], but adalimumab has been found in miniscule concentrations in breast milk in a single case[105]. Methotrexate should be avoided as it is found in breast milk[106]. Sulfasalazine, 5-aminosalicylates, steroids and thiopurines are all considered advisable during breast feeding[2] (Table 2).

Women's beliefs and attitudes
Few studies have evaluated the perspectives of patients with IBD on fertility, pregnancy, breast feeding and pregnancy outcomes. Women with IBD may have fewer children as more stay "voluntarily childless"[107]. A survey of Crohn's and Colitis Foundation of America members reported that 18% of females with CD and 14% of females with UC decided to stay childless compared to 6% of the general population ($P = 0.001$ for CD, $P = 0.08$ for UC). Notably, the decision to stay childless amongst IBD patients contrasts to the much lower "involuntary" childlessness rates (inability to conceive) (5% in CD, 1.7% in UC and 2.5% in the general population, $P =$ NS)[107]. Concerns about the effect of pregnancy on their disease, about passing on IBD to their children and about their ability to look after children were given as the main reasons for voluntarily childlessness[107]. IBD patients have expressed a high interest in genetic testing to determine their future health or that of their family members[108], but there are no data whether women with IBD would base decisions to have children on the results of genetic testing should a reliable test become available.

Data from an Australian IBD cohort were recently described by Mountifield *et al*[109,110] in two studies. The first postal questionnaire study evaluated the experience and views regarding fertility in 255 women with IBD and

found live birth rates of 1.0 for CD, 1.2 for UC, which are considerably lower than those of the general population of 1.8[109]. This coincided with a fear of infertility in 42.7% of patients, which was particularly apparent in women with CD or previous surgery[109]. Unfortunately, the study did not report whether women fearing infertility were indeed experiencing problems conceiving. Conversely, women sought fertility advice only as often as the general population[109]. The study highlights a difference between the medical evidence and patients' perception of infertility as patients overestimate their risk of infertility largely. The second study examined the experiences and views of 219 women after pregnancy[110]. The patients' main concern related to potential harm towards their pregnancy from IBD medication (84%) rather than the need to control active disease[110]. "Free text" responses suggested that women would rather "put up with the disease than harm my baby with medications". The main concerns regarding side effects of IBD medication related to congenital abnormalities rather than more common adverse outcomes of pregnancy such as pre-mature delivery or low birth weight[110]. Of note, some patients considered steroid "rescue" therapy safer than continuation of IBD maintenance medication[110]. The authors suggested their findings reflected a lack of patients' knowledge in the field of IBD and pregnancy[110]. The study provides insight into patients' views: many opinions were contrary to current medical evidence, and women may make decisions based on incorrect perceptions.

Two population based Danish studies have examined adherence to IBD medication prior and during pregnancy in 58 women with CD and 63 women with UC. Adherence, measured by retrospective self-reporting, was relatively high in both CD (72%)[111] and UC (60%)[112] as adherence in the non-pregnant IBD population ranges from 55%-70%[113]. It is, however, difficult to interpret the study findings since there was no direct control group of non-pregnant patients included and selection bias (responders *vs* non-responders) and recall bias (the questionnaires were sent years after the pregnancies) may be likely. Furthermore, adherence was assessed using a simple question rather than a validated tool. Reasons for non-adherence were quiescent disease (59%) and a fear of negative effects on the unborn child (50%), while forgetfulness was uncommon (5%)[112]. These studies highlight that unwanted effects of medication play an important part in women's views and influence decision making.

CONCLUSION

IBD affects women of childbearing age and may have an effect on their offspring. Fertility is reduced in active CD and after surgery. The risk of active disease during pregnancy carries a significant risk to baby and mother. The limited data available on patients' beliefs and attitudes suggest that many women hold views contrary to medical evidence. Women with IBD are therefore at risk of making uninformed choices that could in turn lead to adverse outcomes. There is a need for further studies examining

women's views in more detail and to investigate whether these beliefs are driven by a lack of knowledge. In the meantime, women with IBD should receive advice and counselling by their physician prior and during pregnancy.

Abstract

Gut flora and bacterial translocation (BT) play important roles in the pathogenesis of chronic liver disease, including cirrhosis and its complications. Intestinal bacterial overgrowth and increased bacterial translocation of gut flora from the intestinal lumen predispose patients to bacterial infections, major complications and also play a role in the pathogenesis of chronic liver disorders. Levels of bacterial lipopolysaccharide, a component of gram-negative bacteria, are increased in the portal and/or systemic circulation in several types of chronic liver disease. Impaired gut epithelial integrity due to alterations in tight junction proteins may be the pathological mechanism underlying bacterial translocation. Preclinical and clinical studies over the last decade have suggested a role for BT in the pathogenesis of nonalcoholic steatohepatitis (NASH). Bacterial overgrowth, immune dysfunction, alteration of the luminal factors, and altered intestinal permeability are all involved in the pathogenesis of NASH and its complications. A better understanding of the cell-specific recognition and intracellular signaling events involved in sensing gut-derived microbes will help in the development of means to achieve an optimal balance in the gut-liver axis and ameliorate liver diseases. These may suggest new targets for potential therapeutic interventions for the treatment of NASH. Here, we review some of the mechanisms connecting BT and NASH and potential therapeutic developments.

Key words: Nonalcoholic steatohepatitis; Bacterial translocation; Insulin resistance; Leaky gut; Lipopolysaccharide

INTRODUCTION

Bacterial translocation (BT) and the derangement of gut flora are of substantial clinical relevance to patients with chronic liver disease and cirrhosis[1,2]. Intestinal bacterial overgrowth and increased bacterial translocation of gut flora from the intestinal lumen predispose patients to bacterial infections and major complications[3,4]. Furthermore, levels of bacterial lipopolysaccharide (LPS), a component of gram-negative bacteria, are increased in the portal and/or systemic circulation in several types of chronic liver disease. Bauer *et al*[5-7] have demonstrated this phenomenon in cirrhosis. Impaired gut epithelial integrity due to alterations in tight junction proteins may be the pathological mechanism underlying bacterial trans-

location. Over the last decade, increased gut permeability and increased LPS levels have been described in patients with alcoholic and nonalcoholic steatohepatitis (NASH)[8,9]. Increased serum LPS levels and activation of proinflammatory signaling cascades have been suggested to be important for disease progression in these settings[10]. Some potential mechanisms to explain the association between BT and liver disease associated with lipid accumulation and the development of NASH are reviewed here. These mechanisms may suggest new targets for potential therapeutic interventions for the treatment of NASH.

BACTERIAL TRANSLOCATION, THE INNATE IMMUNE SYSTEM AND TOLL-LIKE RECEPTORS PLAY A ROLE IN THE PATHOGENESIS OF LIVER DAMAGE

Inflammation is involved in the pathogenesis of chronic liver diseases and plays a role in the development of progressive hepatic damage and fibrosis[11]. Liver inflammation and chronic damage are mediated by innate immune responses that are regulated by toll-like receptors (TLRs)[12]. Innate immune cells can both initiate and maintain inflammation in the liver. Bacteria translocated from the gut activate lymphocytes after interacting at the mesenteric lymph nodes (MLNs)[13].

Innate immune cells, particularly dendritic cells, play a pivotal role in sensing pathogens and initiating adaptive immune responses through the activation and regulation of T lymphocyte responses[11]. The immune system is abnormally activated in patients and experimental models with cirrhosis and ascites[14-16]. In an animal model of cirrhosis, systemic activation of the immune system occurs before ascites develop and is driven by the recirculation of cells activated in hepatic lymph nodes (HLNs)[13]. In compensated cirrhosis, bacterial DNA fragments reach the MLNs, where they elicit a local inflammatory response. Bacterial DNA fragments were present in the MLNs of 54% of rats with cirrhosis, indicating their potential role in systemic inflammation[13]. BT initiates a Th1 immune response in MLNs, leading to T-helper 1 (Th1) polarization and the production of tumor necrosis factor (TNF)-α by monocytes. The recirculation of these activated effector immune cells into the blood promotes systemic inflammation[16]. A systemic inflammatory state with increased circulating TNF-α has been linked to increased susceptibility to bacterial infections and hemodynamic dysfunction in patients with cirrhosis[15-18].

The liver provides a tolerogenic immune environment for antigen-specific T cells. The liver is a source for activated immune cells present in the blood. The activation of Kupffer cells, recruited macrophages, and inflammatory cells results in the production of cytokines and chemokines that lead to prolonged inflammation and hepatocyte damage[11]. A direct correlation between activated cells in the blood and HLNs, but not in MLNs, supports this concept, as does the fact that the changes in activated cells in the MLNs, but not in the blood or HLNs, can be reversed by gut decontamination with antibiotics[13]. Th1 cells and monocytes were expanded and activated to produce intracellular interferon (IFN)-γ and TNF-α in the MLNs of cirrhotic rats[18]. Abrogation of bacterial translocation by bowel decontamination reduced the number of activated Th1 cells and monocytes and normalized IFN-γ and TNF-α production by monocytes in the MLNs and blood[16,19].

TLRs and TLR ligands play roles in the pathophysiology of liver fibrosis[20,21] and cirrhosis, viral hepatitis, ALD[22,23], nonalcoholic fatty liver disease (NAFLD) and hepatocellular carcinoma[24]. TLRs recognize pathogen-associated molecular patterns (PAMPs) to detect the presence of pathogens[24]. TLRs are expressed on immune cells, Kupffer cells, endothelial cells, dendritic cells, biliary epithelial cells, HSCs, and hepatocytes. TLR signaling induces potent innate immune responses in these cells[25]. The liver is constantly exposed to PAMPs, such as LPS and bacterial DNA, through bacterial translocation *via* the portal vein system connecting it to the intestine[25].

TLRs also play a role in the regulation of inflammation based on their ability to recognize endogenous TLR ligands, termed damage-associated molecular patterns (DAMPs)[24]. The liver not only represents a major target of bacterial PAMPs in many disease states but also upregulates several DAMPs following injury[11,24]. The activation of inflammatory cells, including Kupffer cells, is a crucial step in the activation of hepatic stellate cells (HSCs)[25]. Intestinal bacterial microflora and functional TLR4, but not TLR2, are required for hepatic fibrogenesis[20]. Crosstalk between TLR4 signaling and transforming growth factor beta (TGF-β) signaling in HSCs has been reported[25]. Quiescent HSCs have been shown to be the target through which TLR4 ligands promote fibrogenesis. TGF-β signaling through the TLR4-MyD88-NFkappaB axis provides a novel link between proinflammatory and profibrogenic signals[20].

The activation of innate immune responses involving TLR4 and complement play important roles in initiating alcoholic steatohepatitis and fibrosis[26]. Activation of the TLR4-mediated myeloid differentiation factor 88 (MyD88)-independent [TRIF/interferon regulatory factor (IRF)-3] signaling pathway in Kupffer cells contributes to alcoholic steatohepatitis, whereas activation of TLR4 signaling in HSCs promotes liver fibrosis[26].

Activation of the innate immune system and increased release of proinflammatory cytokines and other mediators play an important role in the development of alcoholic liver disease (ALD)[27,28]. Alcohol-induced hepatocellular damage may occur as a result of bacterial or endotoxin translocation due to a reduction in reticuloendothelial system function in ALD. The recognition of gut-derived endotoxin by TLR4 contributes to the development of ALD through the activation of TLR-induced intracellular signaling pathways, cytokine production, and ROS[29]. TLR-dependent, ethanol-induced oxidative stress is important for the regulation of NFkappaB activation and

cytokine production by Kupffer cells[28]. Kupffer cells are stimulated by gut-derived endotoxin *via* mechanisms dependent on increased gut permeability and alcohol-induced liver injury[28].

TLR9 and TLR2 mediate *Propionibacterium acnes*-induced sensitization to LPS-triggered acute liver injury in mice[12]. Ligand-specific activation of TLR2 and TLR9 is dependent on the common TLR adaptor MyD88. MyD88 in immune cells, but not in liver parenchymal cells, plays important roles in inflammatory cell recruitment and liver injury[12].

Activation of TLR9 induces type I interferons *via* IRF-7. Type I IFNs were upregulated during TLR9-associated liver injury in WT mice. Type I IFN signaling is therefore required for protection from immune-mediated liver injury[30]. Type I IFNs have anti-inflammatory effects mediated by endogenous interleukin (IL)-1ra, which regulates the extent of TLR9-induced liver damage[30,31]. These data support the notion that bacterial translocation, the innate immune system and TLRs play an important role in the pathogenesis of liver damage.

BACTERIAL TRANSLOCATION IS ASSOCIATED WITH FAT ACCUMULATION IN THE LIVER

Several mechanisms have been proposed to explain the association between fat accumulation in the liver and bacterial translocation. A link between inflammation and hepatic steatosis was shown both in alcoholic and non-ALD[32,33]. The consumption of refined carbohydrates in soft drinks has been postulated to be a key factor in the development of NAFLD.

Results of several studies have shown that an increased consumption of fructose may result in an increased lipid accumulation in the liver which was accompanied by insulin resistance and elevated plasma triglycerides (Ackerman, 2005 No. 260; Jurgens, 2005 No. 261; Faeh, 2005 No. 262; Lewis, 2004 No. 264). Consumption of high levels of fructose lead to liver damage through overfeeding and also may induce a proinflammatory response by increasing intestinal translocation of endotoxin[34]. In a mouse model, hepatic lipid accumulation was higher in mice consuming fructose; these mice also showed high endotoxin levels in portal blood, lipid peroxidation and TNF-α expression[34].

Macrophages facilitate the clearance of cholesterol from the body *via* reverse cholesterol transport[35]. LPS has been shown to suppress PPARgamma1 and its downstream target genes in macrophages, inducing foam cell formation. This was proposed as a mechanism underlying the development of bacterial infection-induced atherosclerosis[35]. LPS induces the expression of adipocyte enhancer-binding protein 1 (AEBP1) during monocyte differentiation. LPS-induced down-regulation of pivotal macrophage cholesterol efflux mediators, leading to foam cell formation, is mediated by AEBP1. AEBP1-independent pathways contribute to the delayed effects of LPS

on macrophage cholesterol efflux and the development of foam cells[35].

The published data support the hypothesis that bacterial translocation may underlie some of the mechanisms associated with fat accumulation in the liver.

BACTERIAL TRANSLOCATION IS ASSOCIATED WITH MITOCHONDRIAL DYSFUNCTION

Mitochondrial dysfunction is a pathogenic feature of NASH[29,36] and there is evidence that mitochondrial damage contributes to apoptotic/necrotic cellular damage in NASH[37]. NASH is associated with an increase in reactive oxygen species (ROS) production in Kupffer cells and hepatocytes[38]. The greater the decrease in cytochrome and oxidase activity seen, the more significant is the increase in ROS production. Mitochondrial dysfunction and overproduction of ROS play key roles in the progression of chronic hepatitis C and ethanol-induced liver injury. Ethanol also causes bacterial translocation in the intestine, and the resulting LPS activates Kupffer cells to produce pro-inflammatory cytokines[38]. It has been suggested that NASH may also result from increased ROS production in Kupffer cells and hepatocytes that may be dependent on bacterial translocation[38]. Therefore, in addition to its effects which are directly or indirectly associated with fat delivery, BT may also be associated with mitochondrial dysfunction that further contributes to fat accumulation in NAFLD.

BACTERIAL TRANSLOCATION IS ASSOCIATED WITH THE DEVELOPMENT OF NONALCOHOLIC STEATOHEPATITIS

Evidence supporting a role for the liver-gut axis in the pathogenesis of NAFLD has been slowly accumulating over the past 7 years[39-41]. Both preclinical and clinical data suggest an association between BT, small intestinal bacterial overgrowth (SIBO) and NASH[42,43]. Recently, the presence of SIBO has been associated with the severity of liver steatosis[44]. Exposure to bacterial products of intestinal origin, most notably endotoxin, including LPS, leads to liver inflammation, hepatocyte injury and hepatic fibrosis[43].

TLR4[45] and its coreceptor, myeloid differentiation factor-2 (MD-2), recognize LPS and activate proinflammatory signaling pathways. TLR4 can specifically recognize LPS as a danger signal and induce activation of inflammation-associated genes[46,47]. A 4-wk high-fat diet increased plasma LPS concentration two to three times[48] and the LPS recognition complex (TLR4 and MD-2) activates NADPH in liver steatosis and induces fibrosis in a NASH model in mice. These data support the role of these receptors in the development of steatosis, inflammation and fibrosis in NASH[49].

Figure 1 Bacterial translocation is associated with the development of nonalcoholic steatohepatitis. NASH: Nonalcoholic steatohepatitis.

The suppression of inflammation and immune tolerance are known to occur in normal livers. Suppressed inflammation has been shown despite bacterial colonization in normal human livers maintaining liver immune homeostasis[50]. In spite of increased bacterial colonization of liver tissues, lower levels of TLR2/4 mRNA and TLR4 and pIKKalpha, a marker for nuclear factor-kappa B (NFkappaB) activation, proteins were found in liver tissues from healthy subjects compared with samples from patients with primary biliary cirrhosis and NASH. Although these data raise the question of whether BT initiates the inflammatory process in the liver or whether it is instead a result of the inflammatory process, these results further support a role for BT in the pathogenesis of the disease.

SIBO also plays a role in NASH *via* interactions with TLR-4 and the induction of IL-8[43]. SIBO has been reported to coexist with NASH[51-56]. Patients with NASH show higher levels of expression of TLR-4/MD-2 on CD14-positive cells[43]. Serum levels of the proinflammatory cytokine IL-8 were higher in samples from NASH patients than in those from control subjects and were correlated positively with TLR-4 expression.

Leptin is a proinflammatory cytokine associated with the progression of NASH. Leptin enhanced TNF-α production and caused a dose-dependent increase in MAPK activity in LPS-stimulated KCs[57]. KCs isolated from the leptin receptor-deficient Zucker rat (fa/fa) showed reduced production of TNF-α upon stimulation with LPS[57]. Furthermore, treatment of normal rats with leptin increased LPS-induced hepatic TNF-α production in vivo, and leptin receptor-deficient Zucker rats showed reduced hepatic TNF-α production upon addition of LPS *in vivo*[57].

Following BT, LPS activates inflammasomes[58-60]. Inflammasomes respond to endogenous and exogenous danger signals by inducing the processing of pre-IL-1ss

into secreted IL-1ss[36]. In the methionine-choline-deficient (MCD) or high fat diet-induced models, saturated fatty palmitic acid activates the inflammasome and sensitizes hepatocytes to LPS-induced IL-1ss release. Hepatocytes exposed to saturated fatty acid release danger signals that trigger inflammasome activation in immune cells[36]. LPS treatment significantly increased hepatic TNF-α production in MCD mice. LPS also induced a significant increase in TUNEL-positive cells[61]. This increase in apoptosis was inhibited by treatment with a neutralizing anti-mouse TNF receptor antibody or pentoxifylline.

In humans, dietary fructose intake has been associated with increased intestinal permeability and translocation of bacterial endotoxin; plasminogen activator inhibitor (PAI-1) may also contribute to the development of NAFLD in humans[62]. Plasma concentrations of endotoxin and PAI-1 and hepatic mRNA expression levels of TLR4 and PAI-1 were higher in NAFLD patients than in control subjects. Serum levels of LPS-binding protein (LBP) were increased in obese patients with NAFLD[63]. Plasma levels of LBP were further increased in patients with steatohepatitis when compared with patients with simple steatosis[63]. TNF-α mRNA expression in liver tissue was significantly higher in patients with NASH than in control subjects and was correlated with the increase in plasma levels of LBP.

BT is also involved in nitric oxide synthase (NOS) upregulation through the activation of both endothelial NOS and inducible NOS[64-66]. The prevention of intestinal gram-negative bacterial translocation by norfloxacin corrects circulatory changes by decreasing nitric oxide (NO) production in cirrhosis. Norfloxacin administration significantly decreased the incidence of gram-negative bacterial translocation and production of proinflammatory TNF-α, IFN-γ and IL-6[66,67].

The published data support the hypothesis that BT is associated with the development and maintenance of continued lipid accumulation, inflammation and fibrosis in patients with NASH (Figure 1).

BACTERIAL TRANSLOCATION IS CLINICALLY RELEVANT IN CHRONIC LIVER DISEASE

BT was shown to affect the development of chronic liver disease and the associated complications. It is also associated with an impaired prognosis[68]. Bacterial DNA is a marker of bacterial translocation and can be detected in uninfected patients with cirrhosis and ascites[69,70]. It is associated with a marked inflammatory response and with the activation of the inducible form of NOS and the release of NO. A similar effect is observed in patients with SBP[68].

The induction of cirrhosis in rats by CCl4 led to prolonged oxidative stress in the intestine, accompanied by increased sugar content in both the intestinal brush border and the surfactant layers[71]. This was accompanied by changes in bacterial flora in the gut, and these bacteria

showed increased hydrophobicity and adherence to the mucosa. These data support the notion that oxidative stress in the intestine during cirrhosis alters mucosal glycosylation and increases the hydrophobicity of the luminal bacteria, enabling increased bacterial adherence to epithelial cells, facilitating BT[71].

In a human trial, the presence of bacterial DNA was associated with aggravation of peripheral vasodilation and with a worsening of intrahepatic endothelial dysfunction[68]. Patients exposed to bacterial DNA had a significantly lower mean arterial pressure and systemic vascular resistance. In response to increased blood flow caused by postprandial hyperemia, these patients had greater increases in hepatic vein pressure gradient and impaired hepatic vasorelaxation[68]. In contrast, a prospective trial of 151 patients with cirrhosis and ascites found no evidence that the detection of bacterial DNA in the ascites of cirrhotics is of clinical or diagnostic relevance to the detection of SBP[72]. This discrepancy in the published data remains to be resolved.

Increased intestinal permeability and abnormal motility were frequently observed in cirrhotics without ascites, even in the absence of evidence of BT. It has been suggested that these factors facilitate BT and thus precede it[73]. Systemic reactivity to microbial components as measured by the development of antibodies was suggested to reflect the compromised mucosal immunity in cirrhotic patients[74]. The presence of bacterial DNA in blood and ascites correlates with BT and is frequent in patients with advanced cirrhosis without overt infection; BT can also precede the occurrence of overt bacterial infection in patients with cirrhosis[73]. Altered permeability of the mucosa and deficiencies in host immune defenses that allow bacterial translocation from the intestine due to intestinal bacterial overgrowth have been implicated in the development of SBP[71]. Altered intestinal permeability was observed in 45% of patients with cirrhosis and was associated with Child-Pugh status, with the presence of ascites, and with a history of SBP[75,76]. SIBO is much more frequent in patients with cirrhosis and was highly correlated with BT, especially in ascitic patients[77].

Higher levels of *Enterobacteriaceae* were identified in cirrhotic rats than in healthy rats, and *Bifidobacteria* treatment resulted in lower levels of *Enterobacteriaceae*[61]. These results suggest the existence of an imbalance in the gut flora in cirrhotic rats, which may further result in BT and altered liver function[61].

BT to MLNs in cirrhosis has been linked to impaired host defense in these patients[78]. BT and endotoxemia are contributing factors in the expansion of specific subsets of lymphocyte populations[79]. In a clinical trial of 40 cirrhotics, the percentage of activated monocytes and T lymphocytes was increased in patients, and the proportions of effector cells and of those expressing CD95+ were higher. LBP modulates the biologic activity of circulating endotoxin, and its levels have been shown to rise in response to LPS[80-82]. Patients with elevated levels of LBP showed higher frequencies of regulatory T cells

(CD4+CD25+FoxP3+) than those with normal levels of LBP[79]. In a rat model, BT was associated with an increase in the phagocytic capacity of polymorphonuclear leukocytes[78]. Both TNF-α and IL-6 were increased in patients with translocation of bacterial DNA from gram-positive microorganisms regardless of endotoxin and LBP levels[83].

These data suggest that BT is of clinical relevance in patients with chronic liver disease and may be a contributing factor in the development of liver disease and the degree of severity of the associated complications.

BACTERIAL TRANSLOCATION: IMPLICATIONS FOR THERAPY

Detoxification of gut-derived toxins and microbial products from gut-derived microbes is one function of the liver. Levels of bacterial LPS are increased in the portal and/or systemic circulation in several types of chronic liver diseases. Increased gut permeability and LPS also play roles in several liver disorders. NASH is associated with increased serum LPS levels and the activation of proinflammatory signaling[8,11], both of which suggest BT as a potential therapeutic target in these disorders.

Probiotics have been suggested as a treatment for different types of chronic liver damage because of their abilities to augment intestinal barrier function and to prevent BT[84,85]. The administration of probiotics reduced BT in a rat model[86]. Both viable and heat-killed yeast cells prevented BT. This effect was suggested to be the result of an immune modulatory effect and the maintenance of gut barrier integrity[87,88]. Oral treatment with viable or heat-killed *Saccharomyces cerevisiae* strain UFMG 905 prevented BT in a murine model of intestinal obstruction. Treatment with either viable or heat-killed yeast reduced intestinal permeability and increased IL-10 levels. Orally administered probiotics, nonpathogenic *Escherichia coli*, and gentamicin decreased BT and attenuated liver damage, decreasing levels of TNF-α, IL-6, IL-10 and IL-12[89]. An enteral diet supplemented with *Chlorella* sp. microalgae had significant protective effects on the intestinal mucosal barrier in a rat model of obstructive jaundice and reduced BT[90].

Oral treatment with resveratrol, curcumin or simvastatin ameliorated small intestinal inflammation by maintaining gut barrier function, preventing BT, and decreasing Th1-type immune responses[91]. Oral administration of these compounds increased regulatory T cell numbers and augmented intestinal epithelial cell regeneration in the ileum. Levels of the anti-inflammatory cytokine IL-10 in the ileum, MLNs and spleen were increased, whereas the proinflammatory cytokines IL-23p19, IFN-γ and TNF-α were decreased[91]. Treated animals displayed fewer proinflammatory enterobacteria and enterococci and higher anti-inflammatory lactobacilli and Bifidobacteria loads.

Glutamine decreased intestinal permeability and BT to physiologic levels in treated animals and preserved intesti-

nal barrier integrity[92]. Arginine supplementation reduced intestinal permeability and BT, leading to mucosal ileum preservation[93]. A specific nutritional combination rich in protein, L-leucine, fish oil and specific oligosaccharides resulted in reduced BT along with reduced production of proinflammatory cytokines[94], and supplementation with honey in the presence of obstructive jaundice ameliorated BT[95].

Treatment with an anti-TNF-α mAb in a model of CCl4-induced cirrhosis decreased the incidence of BT in a TNF-α- and TNF-α receptor-independent manner without increasing the risk of systemic infection[96].

Desferrioxamine attenuated mucosal injury from post-hepatectomy liver dysfunction, and this was associated with decreased BT in the portal circulation, decreased portal endotoxin levels, and decreased systemic endotoxin levels[97]. Low concentrations of histamine inhibited bacteria from entering epithelial cells and inhibited intestinal BT[98]. In histamine-treated rats, the average numbers of bacteria in the liver and lymph nodes were much lower than those in control rats.

The sympathetic nervous system is activated in advanced cirrhosis, particularly in the splanchnic circulation, and exerts potent immunosuppressive actions. Splanchnic sympathectomy reduced bacterial translocation to MLNs in cirrhotic rats[99].

TREATMENT OF BACTERIAL TRANS-LOCATION AS A MEANS OF TREATING NONALCOHOLIC STEATOHEPATITIS

In light of the potential role of BT in the development of steatosis, steatohepatitis and fibrosis, several studies have evaluated the potential effects of treatments aimed at BT.

Probiotics exhibit immunoregulatory and anti-inflammatory activity. Administration of the probiotic VSL#3 modulated liver fibrosis *via* the modulation of collagen expression and impairment of TGF-β signaling in a NASH model[100]; however, this treatment did not prevent inflammation and steatosis.

Oxidative stress contributes to the development of NASH, suggesting that antioxidants, which decrease oxidative stress, may ameliorate the disease. Increasing hepatic α- or γ-tocopherol protected against LPS-induced NASH by decreasing liver damage, lipid peroxidation, and inflammation without affecting body mass or hepatic steatosis[101]. Resveratrol decreased NAFLD severity in rats *via* TNF-α inhibition and antioxidant activity[102]. Specifically, it decreased fat deposition, increased levels of activity of superoxide dismutase, glutathione peroxidase and catalase and decreased NOS in the liver.

LPS-induced liver injury was prevented by 8A8, a synthetic triglyceride containing an arachidonic acid branch, through the inhibition of TNF-α and NO production by hepatic macrophages[103]. Stimulation of peripheral blood mononuclear cells from NASH patients with LPS resulted in a strong increase in TNF-α production. Pentoxifylline caused a dose-dependent suppression of TNF-α secretion, suggesting that it may be able to serve as a potential treatment for NASH[104].

In an open-label trial, subjects with biopsy-proven NASH and insulin resistance were orally treated for 30 days with an IgG-enhanced fraction of enterotoxigenic *Escherichia coli* colostrum[105] (Imm-124©, Immuron, Australia). An alleviation of insulin resistance was detected by a decrease in fasting glucose levels, an elevation in the early peak of insulin secretion following glucose administration, improved OGTT, improved insulin secretion during the OGTT, and improvements in the HOMA score and HBA1C levels. Treated patients showed a decrease in serum levels of triglycerides, total cholesterol, and LDL cholesterol. A decrease in liver enzymes was noted in most treated patients. These effects were associated with increased serum levels of GLP-1 and adiponectin. An increase in CD25+ and CD4+CD25+Foxp3+ regulatory T cells was also noted. An anti-LPS effect along with the promotion of regulatory T cells suggests that a combined mechanism is responsible for these effects.

CONCLUSION

Alterations to intestinal microbiota seem to play important roles in the induction and promotion of liver damage progression and in the development and severity of NASH. Bacterial overgrowth, immune dysfunction, alteration of the luminal factors, and altered intestinal permeability are all involved in the pathogenesis of NASH and its complications, including progression to cirrhosis, infections, hepatic encephalopathy, SBP and renal failure[84]. A better understanding of the cell-specific recognition and intracellular signaling events involved in sensing gut-derived microbes will help in the development of means to achieve an optimal balance in the gut-liver axis and ameliorate liver diseases[36]. The data described here support the notion that BT may serve as a new therapeutic target for NASH.

BT induces an immune imbalance leading to a state of chronic inflammation, fat accumulation in the liver, mitochondrial dysfunction and NASH.

Abstract

AIM: To assess whether juvenile chronic ferric iron ingestion limit colitis and dysbiosis at adulthood in rats and mice.

METHODS: Two sets of experiments were designed. In the first set, recently weaned mice were either orally administered ferrous (Fe^{2+}) iron salt or ferric (Fe^{3+}) microencapsulated iron for 6 wk. The last week of experiments trinitrobenzene sulfonic acid (TNBS) colitis was induced. In the second set, juvenile rats received the microencapsulated ferric iron for 6 wk and were also submitted to TNBS colitis during the last week of experiments. In both sets of experiments, animals were sacrificed 7 d after TNBS instillation. Severity of the inflammation was assessed by scoring macroscopic lesions and quantifying colonic myeloperoxidase (MPO) activity. Alteration of the microflora profile was estimated using quantitative polymerase chain reaction (qPCR) by measuring the evolution of total caecal microflora, Bacteroidetes, Firmicutes and enterobacteria.

RESULTS: Neither ferrous nor ferric iron daily exposures at the juvenile period result in any effect in control animals at adulthood although ferrous iron repeated administration in infancy limited weight gain. Ferrous iron was unable to limit the experimental colitis (1.71 ± 0.27 MPO U/mg protein *vs* 2.47 ± 0.22 MPO U/mg protein in colitic mice). In contrast, ferric iron significantly prevented the increase of MPO activity (1.64 ± 0.14 MPO U/mg protein) in TNBS-induced colitis. Moreover, this positive effect was observed at both the doses of ferric iron used (75 and 150 mg/kg per day po - 6 wk). In the study we also compared, in both rats and mice, the consequences of chronic repeated low level exposure to ferric iron (75 mg/kg per day po - 6 wk) on TNBS-induced colitis and its related dysbiosis. We confirmed that ferric iron limited the TNBS-induced increase of MPO activity in both the rodent species. Furthermore, we assessed the ferric iron incidence on TNBS-induced intestinal microbiota dysbiosis. At first, we needed to optimize the isolation and quantify DNA copy numbers using standard curves to perform by qPCR this interspecies comparison. Using this approach, we determined that total microflora was similar in control rats and mice and was mainly composed of Firmicutes and Bacteroidetes at a ratio of 10/1. Ferric juvenile administration did not modify the microflora profile in control animals. Total microflora numbers remained unchanged whichever experimental conditions studied. Following TNBS-induced colitis, the Firmicutes/Bacteroidetes ratio was altered resulting in a decrease of the Firmicutes numbers and an increase of the Bacteroidetes numbers typical of a gut inflammatory reaction. In parallel, the subdominant population, the enterobacteria was also increased. However, ferric iron supplementation for the juvenile period prevented the increase of Bacteroidetes and of enterobacteria numbers consecutive to the colitis in both the studied species at adulthood.

CONCLUSION: Rats and mice juvenile chronic ferric iron ingestion prevents colitis and dysbiosis at adulthood as assessed by the first interspecies comparison.

INTRODUCTION

In humans neonates never carry iron deficiency at birth and needs remain low during the first trimester of life because of a slowdown of red blood cells production as well as physiological hemolysis[1]. From the fourth month of life, iron requirements increase and appropriate diet supply, generally corresponding to food diversification, becomes necessary. Western countries recommendations leaded to iron fortification of food for infants to prevent any risk of anemia. Classical forms of supplementation are ferrous (Fe^{2+}) salts but are associated with frequent gastrointestinal side effects leading to poor compliance. In addition to this, presence of ferrous iron in the colon could select gut microbiota for humans that are unfavorable to the host because iron is known to be essential for the growth and virulence of many pathogenic enterobacteria[2]. To limit the unfavorable effects linked to ferrous iron absorption, food industry manufacturers have the possibility of using ferric (Fe^{3+}) forms mainly as of pyrophosphate. However, this form displays not only a poor solubility in the food matrix but also a low bioavailability. To bypass these constraints, ferric pyrophosphate may be microencapsulated in lecithin beads (Lipofer®). The incidence of the daily ingestion of this form in juvenile individuals has not yet been investigated.

At the gut level, and particularly during the perinatal period, the crosstalk between bacteria, epithelium and lymphoid tissue is establishing. This crosstalk is involved in modelling the memory mechanisms of systemic immunity response[3], when those systems mature to reach the full functionality of the intestinal barrier. In humans, postnatal dominant colonisation by facultative anaerobic bacteria, among which we find enterobacteria, quickly gives way to dominant anaerobic bacteria development within a couple of weeks, in order to reach an equilibrium during the second year of life[4]. Intestinal microbiota is a large and extremely complex ecosystem, constituted by dynamic and diverse bacterial communities. The adult human tract environment harbours different bacterial phylotypes superior to 400 different species[5,6]. In permanent contact with the mucosal surface through symbiotic interactions, it takes a prominent part on the maintenance of health of the host[7]. A 10/1 Firmicutes/Bacteroidetes ratio is considered to be representative of an health status[8] which reflects a stable equilibrium between bacteria. However, some groups, that are generally subdominant, such as enterobacteria may become potentially pathogenic and can affect host homeostasis[9]. Several studies have described a higher level of Bacteroidetes and enterobacteria associated to a reduction of Firmicutes in inflammatory bowel disease (IBD) patients[9-14]. IBD are a group of chronic disorders of the gastrointestinal tract and include Crohn's disease (CD) and ulcerative colitis. The pathogenesis is not known but involves, at least in part a loss of tolerance towards the commensal colonic microbiota. Therefore, disruption of this crosstalk results in a deregulation of the immune response to the gut microbiota and may lead to development of chronic inflammation such as IBD[9].

Since ferrous oral iron may be at the origin of enterobacteria proliferation[2] and since this development may contribute to intestinal mucosal barrier function deregulation leading to intestinal inflammation, we hypothesized that ferric iron supplementation may modulate microbiota profile settlement when given to juvenile animals and could modify the course of an experimental colitis in young adults. However, as individuals vary in their resistance to pathogenic stimuli and as interspecies comparisons remain difficult to address, particularly when analysing microbiota profile, this study aimed at: (1) comparing the incidence of microencapsulated ferric iron with the ferrous iron on experimental colitis in mice; (2) evaluating the dose-response effect of ferric iron in this model of inflammation in mice; and (3) analyzing the consequences of repeated exposure to ferric iron on a moderate colitis and microbiota dysbiosis on two models of rodents (mice and rats) to allow interspecies comparisons.

MATERIALS AND METHODS

Chemicals

Ferric pyrophosphate microencapsulated in lecithin beads (Lipofer®) used in this study was kindly provided as a stable solution by Lipofoods SA (Barcelona, Spain). Anesthetics were obtained from Centravet (Nancy, France). All other chemical molecules were purchased from Sigma-Aldrich SA (St Quentin-Fallavier, France) except if specified.

Animals

Experiments were conducted using male BalbC mice (15-17 g) and male Wistar rats (100-125 g) obtained from HARLAN Laboratories, Ganat (France). All animals were housed in stainless steel cages under controlled temperature (21 ± 1 ℃) and a 12 h light-dark cycles. They had free access to food (A04, SAFE, Epinay sur Orge, France) and water throughout the study. This study was performed at the Animal House Unit of the Institut Polytechnique LaSalle Beauvais (policy agreement No. A60) and received prior approval from both the animal protocol review committee and of the Picardie Council veterinary office.

Treatments

Two sets of experiments have been designed. In the first series of experiments, 4 groups of 16 male BalbC mice (10-12 g) were used. Three groups received either a solution of ferrous iron (150 mg/kg per day po) or ferric iron (75 or 150 mg/kg per day po - Lipofer®) daily for 6 wk. The 4th group received water. 2,4,6 Trinitrobenzene sulfonic acid (TNBS) colitis was induced the last week of the experiment on half of each group of animals ($n = 8$/subgroup). The other half served as control (sham colitis). In the second series of experiments, 16 male Wistar rats (75-100 g) were used. The animals were separated in two groups receiving either ferric iron (Lipofer®) at the dose of 75 mg/kg per day po or water under the same conditions for 6 wk. Colitis was also induced during the last week of the experiment. Half of each group of animals were submitted to TNBS colitis ($n = 8$), the other half ($n = 8$) served as a control (sham colitis). Body weight was monitored throughout the experiments.

Experimental colitis

Among the chemically induced experimental colitis[15], TNBS in 50% ethanol is one of the classical models because this mix induces a barrier break resulting in severe colitis with penetrating ulcers, a reduced colon length and thickening of the colon wall as observed in IBD patients[16]. Mice were fasted overnight prior to induction of colitis but were allowed free access to water. They were anesthetized with a mixture (50% v/v) of ketamine and xylazine (100 mg/mL) diluted in saline (NaCl 0.9%-w/v) at a dose 1 mL/kg ip. TNBS (Sigma Aldrich, France) diluted in 50% of ethanol (v/v) was injected *via* a polyethylene catheter inserted at 4 cm from the anus at the dose of 100 mg/kg in 25 μL to induce an experimental colitis. Control mice were also anesthetized and received an equal volume of saline. Following instillation mice were maintained in a head-down position for 2 min and received 0.2 mL sc of saline to prevent dehydration. Their awakening was closely monitored. Mice were sacrificed 7 d later. Rats were anesthetized with the same mixture of anesthetics at the dose of 5 mL/kg ip and the solution of TNBS was administered at 7 cm from the anus at the dose of 40 mg/kg in 100 μL. Saline (0.5 mL sc) was administered to prevent dehydration. Rats were sacrificed 7 d later. At sacrifice, macroscopic lesions were evalu-

ated and pieces of proximal colon (1 cm from the caecocolonic junction) and caecal content were collected, snap frozen and stored at -80 ℃ until further evaluation in both rat and mice experiments.

Assessment of the inflammatory reaction

Macroscopic damage scores: After sacrifice, the colon was removed immediately and severity of colonic mucosal alteration was determined according to a modified scale of Wallace *et al*[17]. Briefly, determination of the inflammatory damage was based on the presence of mucosal hyperaemia and bowel wall thickening, presence and extent of ulceration and necrosis, and the event of adhesions and diarrhea. Final quotation was ranging from 0 (normal appearance) to 10 (severe damage).

Myeloperoxidase assay: Myeloperoxidase (MPO) activity, a marker of polynuclear neutrophils, was measured in pieces of colon adjacent to the instillation point as described previously[18]. Briefly, frozen pieces of the proximal colon were homogenised in a phosphate buffer (50 mmol/L, pH = 6) containing hexadecyl trimethyl ammonium bromide (0.5% w/v) with a tissue lyser Ⅱ (Qiagen, France). The homogenates were submitted to 3 cycles of freezing/thawing (Liquid N2, 1 min/37 ℃, 10 min) and then further disrupted with a sonicator (Bioblock scientific, France) and then centrifuged (6000 *g* at 4 ℃ for 15 min). Supernatants were collected for measuring MPO activity and total protein contents. Samples were diluted into a reaction buffer containing O- dianisidine dihydrochloride (1 mg/mL) and hydrogen peroxide (3×10^{-4} % v/v). Human MPO from purified neutrophils was used as a standard. The absorbance was measured after 10 min of incubation at 450 nm. Total protein content was assessed from the supernatants according to Lowry's method (Bio Rad DC Protein Assay, France).

Real time quantitative polymerase chain reaction for microflora quantification

As we planned to assess microflora DNA from caecal content as well as comparing two species to validate the repeatability, we aimed at optimizing the bacterial DNA extraction by improving the extraction procedure of Gram positive bacteria and by determining the appropriate amount of the initial sample to treat.

DNA extraction: Total DNA from caecal samples (25, 50, 100 and 200 mg content) was extracted using the Qiamp DNA stool Mini Kit (Qiagen, France). Before proceeding according to the manufacturer's recommendations, frozen samples were lysed in an ASL lysis buffer and incubated for 3 consecutive cycles of freezing/thawing (Liquid N2, 1 min/37 ℃, 10 min). The lysates were clarified by centrifugation (14 000 *g* at 4 ℃ for 3 min). Polymerase chain reaction (PCR) inhibitors and impurities were absorbed by action of an inhibitex tablet (Qiagen). The supernatants were collected following a second centrifugation and DNA was automatically purified in the Qiacube automat (Qiagen,

France) using Qiamp Minispin columns. Concentrations were determined on a Hellma TrayCel using a Biophotometer (Eppendorf, France). Absorbance ratios at 260/280 and at 260/230 were determined to quantify and assess the purity of DNA samples.

Plasmids for standard curves: Competent DH10b cells were used for the cloning experiments described previously[19]. The recombinant plasmids containing specific *16S rRNA* gene inserts either from Firmicutes, or Bacteroidetes, or enterobacteria or a consensus sequence for total microflora, were purified using a HiSpeed Plasmid Maxi kit (Qiagen, France). DNA concentration was determined following measurement of optical densities both at 260 nm and 280 nm before converting it into *16S rRNA* gene copy numbers as described previously[19]. Standard curves were established from serial dilutions of recombinants plasmids performed using real-time quantitative PCR. Copy numbers of the plasmid were calculated following a previously established equation [Copy numbers = 6.02 × 10²³ (copy/mol) × DNA amount (g)/DNA length (dp) × 660 (g/mol per dp)][20].

Real time polymerase chain reaction: Two pairs of primers (enterobacteria and Firmicutes) corresponding to specific bacterial regions targets within *16S rRNA* gene were designed (Table 1). The two other pairs used (Total Flora and Bacteroidetes) had already been designed[21-23]. qPCR was performed using an ABI Prism 7300 sequence detector system (Applied Biosystems, France) on both plasmids and samples extracted DNA. Reactions were performed in duplicate using the Sybr Green PCR master mix (Qiagen, France) in a final volume of 25 μL with 0.3 μmol/L final concentration of each primer and appropriate dilutions of DNA samples. Amplification was initiated at 95 ℃ for 3 min to activate Taq plus DNA polymerase followed by 40 cycles at 95 ℃ for 3 s and 61 ℃ for 30 s. Two consecutive tenfold series of dilutions were realized to verify the linearity (slope of -3.32). A melting step was added and curves were analysed to look for any unspecific amplification. Standard curves were obtained following amplification under similar conditions of different samples containing different numbers of copies from the respective specific clones of the targeted

gene. PCR efficiency (E) was calculated according to the equation from the standard curve: E = 10⁻(1/ slope) -1 according to Ibekwe and Grieve[24]. qPCR was realised using the cycle number threshold (Ct) and was based on the calculated standard curves. Each qPCR assay systematically included control reactions performed in parallel to the samples.

Statistical analysis

Results were expressed in mean ± SD error to the mean. Macroscopic lesions scores were compared using the Wilcoxon test for non parametric data followed by the Dunn post-test. For all the others parameters, data were submitted to an ANOVA followed by the Tuckey post-test. A value of $P < 0.05$ was considered to be significant.

RESULTS

Optimization of DNA isolation and quantification of microflora for realising interspecies comparison

Because of high inter- and intra-species variations, we aimed at improving the DNA extraction steps by determining the best amount of caecal content to use and by adding the preliminary step to improve the extraction of Gram positive bacteria. The best yield of DNA extraction was obtained when using 100 mg of caecal content and by adding a preliminary thermic lysis step (data not shown). Specificity of the *16S rRNA* gene targeted primers used for qPCR was tested both in silico and using pure DNA extracts from specific target strains (positive controls) and by confronting it to no target species (negative controls). Selected primers (Table 1) were run and the specificities of the amplification products were confirmed by the analysis of the dissociation curve in both caecal samples and DNA controls. We thus determined that a unique target gene was amplified for each species. Analysis of the regression curve for Ct values obtained from serial dilution of DNA samples showed a linear correlation for all target DNA regions; for all the microbiota species studied, the coefficient of correlation (r^2) was higher than 0.97 and amplification efficiencies were between 100 % and 120 % which involves curve slopes ranging from -3.29 to -2.9 (Table 1). All below mentioned analyses have been performed under those conditions.

Figure 1 Effect of a 6 wk juvenile ingestion of ferrous (150 mg/kg per day po) *vs* **ferric (150 mg/kg per day po) iron on the inflammatory response at adulthood to a trinitrobenzene sulfonic acid-induced colitis in mice.** A: Macroscopic damage scores in non-inflamed (sham-colitis) and inflamed (trinitrobenzene sulfonic acid, TNBS) mice; B: Colonic myeloperoxidase (MPO) activity in non-inflamed (sham-colitis) and inflamed (TNBS) mice. Effects of ferric iron on TNBS colitis

Repeated daily ingestion of ferrous iron (150 mg/kg per day po - 6 wk) by juvenile mice did not prevent the induction of a TNBS-induced moderate colitis. In fact, juvenile ferrous iron daily exposure failed to limit macroscopic lesions (Figure 1A) in TNBS treated mice. In contrast, juvenile ferric iron prevented these lesions (Figure 1A) in inflamed mice. Furthermore, while TNBS enema resulted in an increased MPO activity in controls (2.47 ± 0.22 MPO U/mg protein *vs* 0.91 ± 0.09 MPO U/mg protein), we did not observe any significant reduction of MPO activity in mice exposed to a repeated ingestion of ferrous iron (1.71 ± 0.27 MPO U/mg protein *vs* 2.47 ± 0.22 MPO U/mg protein in the TNBS group) (Figure 1B). In contrast, the daily exposure of juvenile mice to the same dose of ferric iron (150 mg/kg per day po - 6 wk) was able to limit the inflammatory response since MPO activity was significantly lower ($P < 0.05$) (1.64 ± 0.14 MPO U/mg protein *vs* 2.47 ± 0.22 MPO U/mg protein in the TNBS group) (Figure 1B). Furthermore, we observed that before inducing TNBS colitis (5 wk of treatment), mice treated with ferrous iron put on significantly ($P < 0.05$) less weight than mice treated with ferric iron and controls (124.6% ± 1.12% and 136.6% ± 1.33

% *vs* 143.7% ± 2.29 % in control, respectively).

Ferric iron juvenile supplementation and dysbiosis

We also aimed at determining the dose-response effect of ferric iron supplementation on the same model of colitis in mice.

In control animals, the repeated administration of both 75 and 150 mg/kg per day po (6 wk) of ferric iron did not result in any alteration of growth, nor did it result in colonic inflammation or an alteration of the microflora profile. In fact, weight gain under iron treatment remained similar whichever species considered (142.7% ± 2.66% for 75 mg/kg per day and 136.6% ± 1.33 % for 150 mg/kg per day *vs* 143.7% ± 2.29 % in controls). Similarly, no macroscopic alterations of the gut mucosa have been observed on mice following either the low or the high chronic ferric supplementation (Figure 2A). Those results were correlated to low levels of MPO activity in the colonic mucosa following exposure to both doses of ferric iron (1.65 ± 0.21 MPO U/mg protein and 1.58 ± 0.11 MPO U/mg protein for respectively 75 and 150 mg/kg per day ferric iron po *vs* 0.91 ± 0.09 MPO U/mg protein in controls) (Figure 2B). Daily consumption of ferric iron by juvenile rodents did not modify the bacte-

Figure 3 **Effect of a juvenile ferric iron administration for 6 wk on the microflora profile of mice and its evolution consecutively to a trinitrobenzene sulfonic acid-induced colitis.** A: Total Flora; B: Firmicutes; C: Bacteroidetes; D: Enterobacteria. Iron75: Ferric iron 75 mg/kg/d po - 6 wk; Iron150: Ferric iron 150 mg/kg per day po - 6 wk. Data are expressed as mean ± SE (n = 8 per group). [a]P < 0.05, [b]P < 0.01 *vs* Sham-colitis; [d]P < 0.01 *vs* TNBS-treated group.

ria profile since the total flora number remained at circa 11.8 log copy number/g of caecal content (Figure 3A). The Firmicutes number was estimated to be around 11.4 log copy number/g of caecal content (Figure 3B); The Bacteroidetes number remained around 10.5 log copy number/g caecal content (Figure 3C); and enterobacteria levels at 8.7 ± 0.1 log copy number/g of caecal content (Figure 3D).

Daily administration of both the doses of ferric iron on juvenile rodents prevented the TNBS-induced colitis at adulthood. In fact, exposure to ferric iron supplementation before inducing an experimental colitis limited the onset of macroscopic lesions (1.42 ± 0.72 AU and 0.2 ± 0.2 AU *vs* 5.75 ± 0.75 AU in TNBS-treated mice) (Figure 2A) and the increase of colonic MPO activity (1.58 ± 0.15 MPO U/mg protein and 1.64 ± 0.14 MPO U/mg protein *vs* 2.47 ± 0.22 MPO U/mg protein in TNBS-treated mice) (Figure 2B). The limitation of the inflammatory lesions was correlated to the maintenance of a healthy microflora profile. This supplementation also prevented the decrease of the Firmicutes (Figure 3B) and increase of the Bacteroidetes and enterobacteria populations (Figure 3C and D). Since efficiency was observed with the dose of 75 mg/kg per day po for 6 wk, we chose to continue with this dose of ferric iron.

Juvenile exposure to ferric iron comparably prevents a moderate TNBS-induced colitis in both rats and mice

Good comparisons need to be performed under the same conditions necessitating the induction of a comparable inflammatory reaction that is representative of pathophysiological conditions observed in humans. Using the optimised technique of extraction and quantification of DNA, total flora in control rats and mice was estimated to be around 11.8 log copy number/g of caecal content in control animals (Figures 3A and 4A). We also noticed that it is mainly composed of Firmicutes (around 11.3 log copy number/g of caecal content in both species) (Figures 3B and 4B) and Bacteroidetes (around 10.5 ± log copy number/g caecal content) (Figures 3C and 4C) followed by an enterobacteria population ranging from 8.6 ± 0.1 log copy number/g of caecal content in mice to 9.4 ± 0.1 log copy number/g of caecal content in rats (Figures 3D and 4D).

Instillation of TNBS resulted in a significant (P < 0.05) increase of macroscopic damage scores in rats (8.33 ± 0.35 AU) and mice (5.75 ± 0.75 AU) (Figures 2A and 5A) as well as a significant (P < 0.05) increase of MPO activity in rats (773.7 ± 36.62 MPO U/mg protein *vs* 496.1 ± 63.94 MPO U/mg protein) and mice (2.47 ± 0.22 MPO U/mg protein *vs* 0.91 ± 0.09 MPO U/mg protein)

Figure 4 Effect of a 6 wk juvenile ferric iron administration (75 mg/kg per day po) on the microflora profile of rats and its evolution consecutively to a trinitrobenzene sulfonic acid colitis. A: Total Flora; B: Firmicutes; C: Bacteroidetes; D: Enterobacteria; Iron75: Ferric iron 75 mg/kg per day po - 6 wk; Iron150: Ferric iron 150 mg/kg per day po - 6wk. Data are expressed as mean ± SE (n = 8 per group). [a]$P < 0.05$, [b]$P < 0.01$ *vs* Sham-colitis.

Figure 5 Effect of a 6 wk juvenile ferric iron supplementation (75 mg/kg per day po) on the inflammatory response at adulthood of rats submitted or not (sham-colitis) to a trinitrobenzene sulfonic acid-induced colitis. A: Macroscopic damage scores (MDS); B: Myeloperoxidase (MPO) activity Data are expressed as mean ± SE (n = 8 per group). [a]$P < 0.05$ *vs* trinitrobenzene sulfonic acid (TNBS)-treated group, [b]$P < 0.01$ *vs* Sham-colitis.

(Figures 2B and 5B). However, we did not observe any significant modification of total microflora neither in rats nor in mice 7 d after TNBS instillation (circa 11.7 log copy number/g of caecal content in both rodent species) (Figures 3A and 4A). However, the balance between the two major phyla of the bacterial population observed

was altered. A significant reduction ($P < 0.05$) of Firmicutes was registered in both colitic rats (-0.4 Δ log copy number) and mice (-0.3 Δ log copy number) (Figures 3B and 4B) as compared to controls. Conversely, significant higher levels of Bacteroidetes ($P < 0.05$) were detected in both the colitic groups; it increased by 0.5 Δ log copy

number in rats and by 0.7 Δ log copy number in mice (Figures 3C and 4C). Enterobacteria numbers were also found to be significantly higher ($P < 0.05$) in colitic rats and mice with increases of respectively 0.4 and 2 Δ log copy number/g of caecal content as compared to controls (Figures 3D and 4D).

Juvenile ferric iron supplementation for 6 wk, before inducing an experimental colitis, significantly limited the onset of macroscopic lesions not only in TNBS-treated mice (1.42 ± 0.72 AU *vs* 5.75 ± 0.75 AU) but also in TNBS-treated rats (7.25 ± 0.49 AU *vs* 8.33 ± 0.35 AU). Juvenile iron administration also significantly ($P < 0.05$) prevented the increase of colonic MPO activity in TNBS-treated mice (1.59 ± 0.5 MPO U/mg protein *vs* 2.47 ± 0.22 MPO U/mg protein) as well as in TNBS-treated rats (572.5 ± 26.39 MPO U/mg protein *vs* 773.7 ± 36.63 MPO U/mg protein) (Figures 2B and 5B). This juvenile ferric administration (75 mg/kg per day po - 6 wk) did not modify total bacteria number even when inducing colitis (Figure 3A and 4A). Juvenile ferric iron repeated administration before inducing the colitis not only prevented the increase of the Bacteroidetes population (Figures 3B and 4B) but also the enterobacteria population (Figures 3D and 4D) in both mice and rats.

DISCUSSION

When using a microencapsulated ferric pyrophosphate form (Lipofer®), we were the first to evidence a beneficial effect of ferric iron oral supplementation in juvenile animals to prevent the induction of colitis at adulthood. Ferric pyrophosphate is a water insoluble compound, marketed as a food additive in Europe to fortify infant cereals and chocolate powder drinks[25]. Because of its chemical composition, it has been microencapsulated to improve both its bioavailability and its incorporation in food to be fortified[26], rendering it a good alternative to the ferrous forms without having any of the side effects.

First, we provided evidence of the benefits of ferric iron supplementation during the juvenile period. Iron oral administration is recommended in young infants to prevent anemia and its consecutive neurologic and developmental deficits. Iron also has benefits, as a trace element, in supporting immune function by strengthening not only epithelial barriers but also cellular and humoral immune responses. However, ferrous iron may be at the origin of deleterious effects such as lipid peroxydation[27] or enterobacteria growth facilitation[2]. Here, with ferric iron, we did not observe any negative effect of a repeated administration for 6 wk. In fact, in non-inflamed mice, juvenile ferric iron ingestion did not result in either an inflammatory reaction or did it modify the microflora profile since both total bacteria and enterobacteria numbers remained unchanged as compared to non supplemented sham-colitic mice. This absence of action on gut microbiota profile is in favour of the ferric form instead of the ferrous form for infant food fortification.

Secondly, we aimed at evaluating the dose response effect of ferric iron supplementation in the juvenile period

the induction of an experimental colitis at adulthood. Environmental factors such as smoking, luminal enteric bacteria and trace elements such as iron are involved in the pathogenesis of IBD in a genetically susceptible host[28]. In fact, anemia is often described during chronic gut inflammatory disorders such as IBD[29]. This anemia is caused by two factors, the first being impaired proliferation and differentiation of erythroid progenitor cells, and the second being consecutive to iron retention within monocytes and macrophages both activated under the inflammatory conditions. Classically, patients receive either oral or systemic iron supplementation generally as ferrous sulfate or fumarate. However, ferrous iron oral administration often aggravates the inflammatory reaction because of its accumulation in the intestinal lumen and its participation in the Haber-Weiss reaction[27]. Compared to non supplemented mice, ferric iron juvenile supplementation proved to be efficient against this experimental colitis, even at the lowest dose used since their MPO activity levels were similar to those of control mice. The lowest dose of iron used corresponded to an overall daily intake of 1.2 mg iron per day, in other words to 15 μg iron/g mouse/day which is two times lower than the dose used by Werner *et al*[30] but it is however efficient in our model too.

The positive effect of iron supplementation in mice was corroborated by the results obtained in rats. In our study, we were able to demonstrate that ferric iron oral administration did not induce any alteration but rather prevented the course of an experimental colitis in both rodent species. In fact, both rats and mice submitted to iron supplementation did not develop any sign of inflammation. In both those rodent species, we also induced an experimental inflammatory reaction of comparative intensity. In fact, in comparison to the literature[31], they developed a moderate but homogenous colitis characterised by tissular lesions, ulcerations of the distal colon and neutrophil infiltration. These results are in agreement with a previous report indicating that the TNBS-induced colitis model is associated to an increase of inflammatory response including granulomas and tissular MPO activity[31-33].

Finally, we aimed at evaluating the reproducibility of colonic microflora evaluation under control conditions and its alteration during a moderate experimental colitis in rats and mice. This study is the first to evidence a comparative alteration of gut microbiota during an experimental colitis in two rodent species. Following the qPCR optimisation process described above, we observed no difference in total microbiota numbers between control rats and mice groups. In this work, we also found that caecal microflora of rodents is composed predominantly of Firmicutes followed by Bacteroidetes which profile correlates to the observations realised on humans. In fact, human Firmicutes population is 10 times higher than their Bacteroidetes population; which is considered to be a good indicator of health status[34,35]. In this study, we observed the same ratio profile not only in mice but also in rats. In non supplemented animals and under

inflammatory conditions, we did not observe any alteration of total bacteria numbers in both the rodent species. This is in agreement with literature which describes no principal differences in the composition of the total mucosal flora in IBD patients compared to controls[36]. Furthermore, while tissular healing might have already started in the animals, in both murine models we observed a net increase of Bacteroidetes and a reduction of the Firmicutes population indicating a clear reversion of this profile. Similar trends were also observed in clinical studies, showing a lower representation of Firmicutes phyla during inflammatory acute phases[34,37]. As already evidenced, the diminution of the Firmicutes phylum promotes the development and the invasion of tissues by opportunistic bacteria species and the gut becomes very susceptible to invading pathogens among which enterobacteria[38,39]. We also noted, under colitic conditions, a higher level of enterobacteria which is concordant with literature reporting a higher incidence of *Escherichia coli* in IBD patient compared to healthy subjects[40,41]. We chose to work in comparing rat and mice microbiota alteration during this moderate experimental colitis to ensure that not only could we obtain comparative results to human dysbiosis but also to make sure that the results obtained were linked to the intensity of the inflammatory response rather that to species sensitivity. Such comparisons are of great interest in testing the reproducibility of the method set up. Overall, our results are correlated to clinical observations realised on IBD patients such as fever, diarrhea, weight loss, rectal bleeding[42], and severe alteration of the microbiota equilibrium, especially with Bacteroidetes and enterobacteria increases in opposition to Firmicutes reduction[9,10]. In both rats and mice receiving ferric iron in the juvenile period for 6 wk the microbiota profile was not altered. In addition, rats and mice submitted to an experimental colitis during the last week of iron treatment did not display any modification of either total number bacteria or enterobacteria numbers as compared to non supplemented animals. This is in favour of a positive role of ferric iron onto gut microbiota equilibrium which will limit the onset of the inflammatory reaction as compared to classical ferrous forms. It reinforces the idea that iron is one of the key markers for limiting the onset of the inflammatory response in genetically susceptible patients[30]. Furthermore, we may suggest that ferric iron in contrast to ferrous iron contributes to the settlement of an appropriate microflora during the post natal period and that this profile is less sensitive to inflammatory stimuli. One cannot ascertain the mechanisms producing such results, but we may suggest that the lower incidence of ferric iron on colitis might be linked to, either a lower susceptibility to stimulate oxidative stress reactions as compared to ferrous iron, or to its interactions with the immune system which is partly driving an appropriate microbiota implantation during the perinatal period. Rather than working with animals whose microflora profile had been modified because they display a modified immune pattern[43,44], we decided to work on two rodent species of the same age, gender and submitted to a similar level of an inflammatory stimulus Since this microbiota/immune system interaction is said to be species, gender and age specific.

In conclusion, this study shows comparative rodent dysbiosis to human IBD dysbiosis following a moderate TNBS colitis. It also shows the benefits of ferric iron oral ingestion during the juvenile period in the prevention of an experimental colitis induced at adulthood in healthy animals. These interesting results would necessitate checking how anemic juvenile animals would react to such a treatment and especially to an induced colitis at adulthood. To further understand this incidence of ferric iron on overall intestinal functionalisation, one point we did not address is the role of the immune system and particularly its fine orientation modulation by iron fortification during the perinatal period in regards to the observed effects. We may hypothesize that iron could participate in reinforcing the immune system orientation, thus contributing to the limitation of the inflammatory response due to TNBS. This question will be addressed in another set of experiments. If these results are confirmed, this form of microencapsulated ferric iron could thus be clinically assessed as an interesting alternative to iron sulfate in young individuals at risk of anemia but also in subjects at risk of chronic gut inflammation such as CD.

ACKNOWLEDGMENTS

COMMENTS

Background

Juvenile iron supplementation is now widely accepted to limit the risk of anemia. However, oral iron ingestion may have side effects especially at this period when the crosstalk between bacteria, epithelium and the immune system is being set up. In fact, an impaired settlement of this crosstalk may predispose to chronic diseases such as inflammatory bowel disease (IBD). No one has so far evaluated the consequences of food matrix composition during the postnatal period on the predisposition to develop chronic diseases at adulthood. This study was thus aimed at evaluating the consequences of juvenile chronic iron exposure on the onset of experimental colitis and its related dysbiosis in both rats and mice at adulthood.

Research frontiers

In these recent years, research on the role of commensal microbiota has evidenced its strong impact on digestive physiology and particularly its modulating role in IBD. Moreover, recent data evidenced that microbiota implantation in the perinatal period conditions, the maturation of the gut mucosa and the immune system renders the host tolerant to commensal bacteria. Since oral ferrous iron may promote potential pathogenic bacteria growth, which may condition the development of chronic gut inflammation, the authors evaluated in this study the modulation by repeated juvenile administration of ferric iron on the onset of an experimental colitis at adulthood in two rodent species.

Innovations and breakthroughs

Literature largely describes the necessity to maintain a good equilibrium of the microbiota to stay healthy. Food matrix also conditions the diversity and stability of the microbiota especially during the postnatal period crucial for these aspects. This study is the first to evidence the preventive effects of oral ferric iron administration at the juvenile period on the inflammatory response and dysbiosis related to an experimental colitis at adulthood in two rodent species.

Applications

This study proposes to evaluate the consequences of oral supplementation at

infancy on risk of developing gut inflammation at adulthood. These results necessitate being completed by the evaluation of the consequences of ferric iron on the immune system maturation and to be clinically proven but they could represent a good opportunity for families at risk of developing IBD.

Terminology

IBD comprises chronic inflammations of the gut and more especially Crohn's Diseases and Ulcerative Colitis. Microbiota designates the pool of microorganisms harboured in our gut under physiological conditions. They divide into dominant and subdominant and control each other's growth to reach dynamic equilibrium. Dysmicrobism is an alteration of the microbiota equilibrium. Iron is a metal. In aqueous solution, it exists in two oxidation states: ferrous (Fe^{2+}) and ferric (Fe^{3+}).

Peer review

The study aimed to study rodent dysbiosis and compare it to human IBD dysbiosis following a moderate trinitrobenzene sulfonic acid colitis. It shows the benefits of ferric iron oral ingestion during the juvenile period in the prevention of an experimental colitis induced at adulthood. The paper is well written and has potential application in food supplemental.

Abstract

AIM: To investigate the effect of high dose glargine on the expression profiles of microRNAs in human pancreatic cancer cells.

METHODS: Real-time polymerase chain reaction array (RT-PCR) was applied to investigate miRNAs differentially expressed in Sw1990 cells treated with or without 100 IU/L glargine. Stem-loop RT-PCR was used to confirm the results of the array assay in Sw1990 and Panc-1 cells. The effects of miR-95 on cell growth, apoptosis, invasion and migration abilities were respectively examined by CCK8 assay, apoptosis assay, Matrigel invasion and migration assay in Sw1990 and Panc-1 cells. Nude mice xenograft models with Sw1990 cells were built to investigate pancreatic cancer growth *in vivo* after transfection by the lentivirus pGLV3-GFP- miR-95.

RESULTS: Ten miRNAs were significantly up-regulated and 2 miRNAs down-regulated in glargine treated Sw1990 cells when compared with non-treated cells (2.48-fold changes on average, $P < 0.01$). miR-95, miR-134 and miR-34c-3p are the top three miRNAs regulated by glargine (3.65-fold, 2.67-fold and 2.60-fold changes respectively, $P < 0.01$) in Sw1990 cells. Stem-loop RT-PCR confirmed that high dose glargine up-regulated the expression of miR-95 and miR-134 in both Sw1990 and Panc-1 cells. The most obvious change is the apparent increase of miR-95. Forced expression of miR-95 significantly increased cell proliferation (Sw1990: 2.510 ± 0.129 *vs* 2.305 ± 0.187, $P < 0.05$; Panc-1: 2.439 ± 0.211 *vs* 2.264 ± 0.117, $P < 0.05$), invasion (Sw1990: 67.90 ± 12.33 *vs* 47.30 ± 5.89, $P < 0.01$; Panc-1: 37.80 ± 8.93 *vs* 30.20 ± 5.14, $P < 0.01$), migration (Sw1990: 101 ± 6.00 *vs* 51.20 ± 8.34, $P < 0.01$; Panc-1: 91.80 ± 9.22 *vs* 81.50 ± 7.47, $P < 0.01$) and inhibited cell apoptosis (Sw1990: 22.05% ± 1.92% *vs* 40.32% ± 1.93%, $P < 0.05$; Panc-1: 20.17% ± 0.85% *vs* 45.60% ± 1.43%, $P < 0.05$) when compared with paired negative controls, whereas knockdown of miR-95 obtained the opposite effect. Nude mice xenograft models confirmed that miR-95 promoted the growth of pancreatic cancer *in vivo* when compared with negative control (tumor volume: 373.82 ± 23.67 mL *vs* 219.69 ± 17.82 mL, $P < 0.05$).

CONCLUSION: These observations suggested that modulation of miRNA expression may be an important mechanism underlying the biological effects of glargine.

INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related deaths in Western countries and has the poorest survival rate (< 5%) among the common malignancies[1,2]. Recently, antidiabetic therapies have been shown to affect the risk of pancreatic cancer. Some observational studies in humans have linked glargine with a putative increased cancer risk, including pancreatic cancer[3,4].

Glargine (A21Gly, B31Arg, B32Arg human insulin) is a widely used insulin analog in which a 24-h action profile is achieved by altering the amino acid sequence of the alpha (α) and beta (β) chains of the C terminus[5]. It has been shown that glargine increases resistance to apoptosis in several tumor cell lines[6]. Given the increased affinity to the insulin-like growth factor- I receptor (IGF-IR) *in vitro*[7], glargine may increase the bioavailability of IGF- I by altering the levels of IGF-binding proteins[8,9]. IGF- I is a more potent growth factor than insulin, promoting proliferation and inhibiting apoptosis, and plays an important role in facilitating malignant cell survival and metastasis[10,11]. This may be the theoretical basis for the potential carcinogenicity of glargine. However, data regarding the effect of glargine on pancreatic cancer are inconsistent. Administration of glargine didn't alter proliferation of Colo-357 pancreatic carcinoma cells and survival of patients with pancreatic carcinoma[12]. Thus, the role of glargine in pancreatic carcinogenesis deserves further investigation.

MicroRNAs (miRNAs) are endogenous, non-coding small RNAs, 19-25 nucleotides in length, which are now recognized as crucial post-transcriptional regulators of gene expression[13-15]. It has been demonstrated that miRNAs play important roles in biological processes that affect tumor progression including migration, invasion, epithelial to mesenchymal transition (EMT) and metastasis[16-18]. miRNAs are promising as early biomarkers, prognostic indicators and therapeutic targets for anticancer treatments[19-21]. Aberrant miRNA expression has also been frequently reported in pancreatic cancer[22]. However, very few compounds, not to mention glargine, which affect cell growth and/or development, have been shown to affect miRNA expression.

In this present study, we elucidated the miRNAs signature in response to glargine treatment in human pancreatic cancer cells. Our results indicated that glargine alters specific miRNA expression in human pancreatic cells, especially miR-95. The effect of miR-95 on apoptosis, proliferation, migration and invasion ability of pancreatic cancer cells were further investigated. Moreover, nude mice xenograft models were built to investigate pancreatic cancer growth *in vivo* after transfection by the lentivirus pGLV3-GFP-miR-95. It therefore appeared that miR-95-related changes were important effects of glargine.

MATERIALS AND METHODS

Cell lines and cultures

Pancreatic ductal cancer cell lines Sw1990 and Panc-1 were conserved in our own laboratory and were cultured in Dulbecco's modified Eagle's medium (DMEM; GIBCO) with 10% fetal bovine serum (FBS; GIBCO) in a humidified incubator at 37 ℃ with an atmosphere of 5% CO_2.

miRNAs real time polymerase chain reaction array

Sw1990 cells (3×10^5 per well) were plated on 6-well plates in DMEM with 10% FBS. After 24 h of incubation at 37 ℃, the cells were treated with or without 100 IU/L glargine. Glargine was replenished every 24 h. The cultures were incubated for 2 d, then the total RNA was isolated from cell samples using Trizol reagent (Invitrogen) following the manufacturer's protocol. Then, cDNA synthesis was performed using Universal cDNA synthesis kit (Exiqon). The expression levels of 372 human mature miRNAs were examined using the miRCURY LNA™ Universal real time microRNA polymerase chain reaction system, Ready-to-use human panel I (Exiqon, kangchen, China).

Briefly, total RNA containing miRNA was polyadenylated, and cDNA was synthesized using a poly (T) primer with a 3'degenerate anchor and a 5'universal tag. Then, cDNA served as a template for microRNA quantitative real-time polymerase chain reaction (qPCR) using miRCURY LNA Universal RT miRNA PCR kit (Exiqon). The miRNA Ready-to-use human panel I is a 384-well PCR plate containing dried down LNA™ primer sets for one real-time PCR reaction per well. Three small RNA (U6snRNA, SNORD38B, SNORD49A) and three miRNA (miR-103, miR-191 and miR-423-5p) reference genes are included on the panel. The amplification profile was denatured at 95 ℃ for 10 min, followed by 40 cycles of 95 ℃ for 10 s and 60 ℃ for 60 s. At the end of the PCR cycles, melting curve analyses were performed. All reactions were conducted three times. Expression levels of mature miRNAs were evaluated using comparative CT method ($2^{-\Delta CT}$).

Stem-loop real-time reverse transcription-PCR

The miRNAs (miR-95, miR-134 and miR-34c-3p) were quantitated by stem-loop real time reverse transcription (RT)-PCR to confirm the reliability of the miRNA array assay. In brief, Sw1990 and Panc-1 cells (3×10^5 per well) were seeded on 6-well plates in DMEM with 10% FBS. After 24 h of incubation, the cells were treated with different concentrations of glargine (0-150 IU/L) for 48 h or treated with 100 IU/L glargine for different periods (24-72 h). Glargine was replenished every 24 h. Then the total RNA was isolated. 0.2-0.5 μg of total RNA was reverse transcribed to cDNA using a target-specific stem-loop primer indicated in Table 1. cDNA in water was added to 5 μL of the 2 × SYBR green master mix (Applied Biosystems Inc, Foster City, United States), 400 nmol/L of gene-specific primer and water used to make the solution up to 10 μL. The reactions were amplified at 95 ℃ for 10 min followed by 40 cycles at 95 ℃ for 15 s and 60 ℃ for 60 s. U6 small nuclear RNA (U6) served as the endogenous control. The relative amount of each miRNA

to U6 was described using the formula $2^{-\Delta Ct}$ where $\Delta Ct = $ (Ct miRNA - CtU6). Each sample was run in triplicate.

Vector constructs and lentivirus production

The miR-95 sequence was constructed as follows: (forward) hsa-miR-95-*Bam*H I : GATCCGTTCAACGGGTATT-TATTGAGCATTCAAGAGATGCTCAATATACCC-GTTGAACTTTTTTG; (reverse) hsa-miR-95-*Eco*R I : AATTCAAAAAAGTTCAACGGGTATATTGAG-CATCTCTTGAATGCTCAATAAATACCCGTT-GAACG. The sequence was amplified and cloned into the pGLV3-GFP vector (GenePhama) to generate pGLV3-GFP- miR-95. The negative control was pGLV3-shRNA-NC. Virus packaging was performed in HEK 293T cells after the co-transfection of 20 mg pGLV3-GFP-miR-95 vector with 15 mg of the packaging plasmid pHelper 1.0 Vector and 10 mg of the envelope plasmid pHelper 2.0 Vector using Lipofectamine 2000 (Invitrogen).Viruses were harvested 48 h after transfection, and viral titers were determined.

Oligonucleotide construction

After glargine treatment, the expression of miR-95 was increased most obviously in Sw1990 cells and Panc-1 cells, so we further investigated the functional roles of miR-95 in pancreatic cancer cells. miR-95 mimics, miR-95 inhibitor and negative control siRNA oligonucleotides were chemosynthesized (Shanghai GenePhama Co. Ltd). The oligonucleotides used in these studies were has-miR-95 mimics: 5'-UUCAACGGGUAU UUAUUGAG-CA-3' and 5'-CUCAAUAAAUACCCGUUGAAUU-3'. Mimics negative control: 5'-UUCUCCGAACGUGU-CACGUTT-3' and 5'-ACGUGACACGUUCGGAGAA TT-3', hsa-miR-95 inhibitor: 5'-UGCUCAAUAAAU-ACCCGUUGAA-3'. MicroRNA inhibitor negative control: 5'-CAGUACUUUUGUGUAGUACA A-3'.

Cell transfection

Cells were cultured to 80% to 90% confluence after be-

ing seeded into 6-well plates and were transfected with Lipofectamine 2000 (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. For transient transfection, Sw1990 or Panc-1 cells in each well of a 6-well plate were transfected with 12.5 μL miRNA inhibitor or 7.5 μL miRNA mimic oligonucleotides. Transfection efficiency was evaluated by FAM in control vector or real-time PCR. For stably transfected cells, cells were transfected with lentivirus at 80%-90% confluency. Sw1990 cells (1×10^5) were infected with recombinant lentivirus in the presence of 5 μg/mL polybrene (GenePhama).

Cell proliferation assay

A total of 10^4 Sw1990 or Panc-1 cells per well were plated in 96-well plates before transfection and cultured for 24 h in normal conditions. They were then transfected with hsa-miR-95 mimics or hsa-miR-95 inhibitor along with paired negative controls. The cells were incubated at 37 ℃ for 48 h. Cell proliferation was assessed using Cell Counting Kit 8 (Dojindo, Tokyo, Japan) according to manufacturer's protocol.

Apoptosis assay

At 72 h after transfection, apoptosis was detected using Annexin V-FITC Apoptosis Detection Kit (Biovision, United States). Results were calculated by the percentage of apoptotic cells in all cells counted.

Matrigel invasion assay

At 48 h after transfection, the invasive ability of the cells was assayed using Transwells (8 mm pore size, Corning Costar Corp). The Transwells were put into the 24-well plates. First, 0.1 mL Matrigel (50 mg/mL, BD Biosciences) was added onto the plate surface and incubated for 2 h, and then the supernatant was removed. Freshly trypsinized and washed Panc-1 or Sw1990 cells were suspended in DMEM containing 1% FBS. Then 0.1 mL of the cell suspension (1×10^5 cells) was added to the upper chamber of each insert that was coated with Matrigel. Next, 0.6 mL of DMEM containing 10% FBS was added into the lower compartment, and the cells were allowed to invade for 24 h at 37 ℃ in a 5% CO_2 humidified incubator. After incubation, the cells were fixed with 95% absolute alcohol and followed by crystal violet stain. The number of migrated cells on the lower surface of the membrane was counted under a microscope in 10 fields with magnification of × 200. Each experiment was performed in triplicate.

Cell migration

At 48 h after transfection, the ability of Panc-1 or Sw1990 cells to migrate was detected using Transwells (8 mm pore size, Corning Costar Corp). The Transwells were put into the 24-well plates. Freshly trypsinized and washed cells were suspended in DMEM containing 1% FBS. 5×10^4 cells/well were placed in the top chamber of each insert (BD Biosciences, NJ), with the non-coated membrane. 0.6 mL of DMEM containing 10% FBS was added into the lower chambers. After incubating for 24 h at 37 ℃ in

a 5% CO_2 humidified incubator, the cells were fixed with 95% absolute alcohol and stained with crystal violet stain. The number of migrated cells on the lower surface of the membrane was counted under a microscope in 10 fields with magnification of $\times$ 200. Each experiment was performed in triplicate.

Mice xenografts

The stable cell line Sw1990 was harvested from tissue culture flasks after transfection with the pGLV3-GFP-miR-95 and control pGLV3-GFP vector using trypsin and washed three times with PBS. About 1×10^7 cells were implanted into the right flanks of female nu/nu mice (five in each group). Tumor volume (V) was measured with an external caliper every 4 d and it was calculated as V = 0.52 (length $\times$ width^2). After four weeks, all the animals were sacrificed and tumors were removed.

Statistical analysis

Data were expressed as the mean $\pm$ SD unless otherwise noted. The differences between groups were analyzed using a two-tailed Student's *t*-test when only two groups were present and the null hypothesis was rejected at the 0.05 level.

RESULTS

Glargine treatment alters miRNAs expression profiles

To study the responses of miRNAs to glargine, miRNA real time PCR array analysis of miRNA expression was conducted with total RNAs extracted from Sw1990 pancreatic cells treated with or without 100 IU/L glargine. Differential expression between glargine-treated and non-treated cells was defined using a cut off value of 2-fold change. We observed that 10 miRNAs were significantly up-regulated and 2 miRNAs were significantly down-regulated (2.48-fold on average, $P < 0.01$) in glargine treated Sw1990 cells when compared with non-treated cells. miR-95, miR-134 and miR-34c-3p are the top three miRNAs regulated by glargine (3.65-fold, 2.67-fold and 2.60-fold changes respectively, $P < 0.01$) in Sw1990 cells (Figure 1A).

Confirmatory studies with differentially expressed miRNAs by stem-loop real-time PCR

After treatment with increasing concentrations of glargine (50, 100, 150 IU/L) for 48 h, miR-95 was up-regulated by 1.18 fold ($P > 0.05$), 3.41 fold ($P < 0.01$) and 2.92 fold ($P < 0.01$) on average respectively in Sw1990 cells and 1.45 fold ($P < 0.01$), 3.41 fold ($P < 0.01$) and 2.92 fold ($P < 0.01$) on average respectively in Panc-1 cells, when compared with non-treated cells (0 IU/L). No obvious dose dependent responses were observed; miR-134 was up-regulated in a dose dependent manner (Sw1990: 1.69, 2.10 and 2.93 fold on average respectively, $P < 0.01$; Panc-1: 1.56, 1.99 and 2.88 fold on average respectively, $P < 0.01$) in both Sw1990 and Panc-1 cells; miR-34c-3p showed no significant changes (Sw1990: 1.03, 1.05 and 1.06 fold on average respectively, $P > 0.05$; Panc-1: 1.25, 1.25 and 1.19

fold on average respectively, $P > 0.05$) in both Sw1990 and Panc-1 cells (Figure 1B-1,2).

After treatment with 100 IU/L glargine for different periods (24, 48 and 72 h), miR-95 was up-regulated by 2.50 fold ($P < 0.01$), 3.10 fold ($P < 0.01$) and 2.99 fold ($P < 0.01$) on average, respectively, in Sw1990 cells and 2.31 fold ($P < 0.01$), 2.46 fold ($P < 0.01$) and 2.16 fold ($P < 0.01$) on average, respectively, in Panc-1 cells, when compared with the cells at 0 h; miR-134 was up-regulated by 2.22 fold ($P < 0.01$), 2.37 fold ($P < 0.01$), 2.17 fold ($P < 0.01$) on average, respectively, in Sw1990 cells and 2.10 fold ($P < 0.01$), 2.31 fold ($P < 0.01$) and 2.37 fold ($P < 0.01$) on average, respectively, in Panc-1 cells; miR-34c-3p showed no significant changes (Sw1990: 1.16, 1.14 and 1.13 fold on average respectively, $P > 0.05$; Panc-1: 1.17,1.24 and 1.13 fold on average, respectively, $P > 0.05$) in both Sw1990 and Panc-1 cells (Figure 1B-3,4).

miR-95 increases cell proliferation and inhibits cell apoptosis

We investigated the potential oncogenic role of miR-95 in Sw1990 and Panc-1 cells. First, we tested miR-95 expression using stem-loop real-time PCR. It increased or decreased after transfected with miR-95 mimics or anti-miR-95 inhibitor. We observed a significant increase in proliferation (Sw1990: 2.51 $\pm$ 0.13 *vs* 2.31 $\pm$ 0.19, $P < 0.05$; Panc-1: 2.44 $\pm$ 0.21 *vs* 2.26 $\pm$ 0.12, $P < 0.05$) after transfection of miR-95 mimics (Figure 2A-1). In contrast, anti-miR-95 inhibitor significantly decreased cell proliferation (Sw1990: 2.11 $\pm$ 0.07 *vs* 2.23 $\pm$ 0.13, $P < 0.05$; Panc-1: 2.09 $\pm$ 0.09 *vs* 2.31 $\pm$ 0.13, $P < 0.05$) (Figure 2A-2). These data indicate that cell proliferation can be significantly promoted by increase of miR-95 expression.

We further investigated the effect of miR-95 on apoptosis and found that apoptosis decreased dramatically (Sw1990: 22.05% $\pm$ 1.92% *vs* 40.32% $\pm$ 1.93%, $P < 0.05$; Panc-1: 20.17% $\pm$ 0.85% *vs* 45.60% $\pm$ 1.43%, $P < 0.05$) in Sw1990 and Panc-1 cells 72 h after transfection with miR-95 mimics (Figure 2B). It suggested that miR-95 may function as a strong apoptotic suppressor in human pancreatic cancer cells.

miR-95 regulates pancreatic cancer cell invasion and migration in vitro

In the cell invasion and migration assay, we observed that depletion of miR-95 significantly impaired the ability of Sw1990 cells to migrate and invade through the matrigel-coated membranes or the non-matrigel-coated membranes towards serum-containing medium (invasion: 49.40 $\pm$ 6.59 *vs* 65.80 $\pm$ 5.09; migration: 52.30 $\pm$ 10.87 *vs* 88.90 $\pm$ 10.46, $P < 0.01$), when compared with a paired negative control (Figure 3B); Increased expression of miR-95 significantly promoted the ability of Sw1990 cells to migrate and invade through matrigel-coated membranes or non-matrigel-coated membranes towards serum-containing medium (invasion: 67.90 $\pm$ 12.33 *vs* 47.30 $\pm$ 5.89; migration: 101.00 $\pm$ 6.00 *vs* 51.20 $\pm$ 8.34, $P < 0.01$), when compared with the paired negative control (Figure 3A). Similar results were found in Panc-1 cells (depletion of miR-95,

Figure 1 Effect of insulin glargine on miRNAs expression in Sw1990 cell line (A), insulin glargine up-regulated the expression of miR-95 and miR-134, miR-34c-3p showed no obvious changes in Sw1990 and Panc-1 cells (B). Ten miRNAs were significantly up-regulated and two miRNAs were down-regulated after 100 IU/L insulin glargine treatment for 48 h compared with non-treated cells. The cut off line for miRNA expression change was 2-fold. Data were presented as mean ± SD. Sw1990 and Panc-1 cells were incubated with increasing concentrations of insulin glargine (50-150 IU/L) for 48 h or treated with 100 IU/L insulin glargine for different periods (24-72 h). Then the expression of the three miRNAs were detected by stem-loop real-time reverse transcription-polymerase chain reaction array. miR-95 was significantly up-regulated, but no dose or time dependent changes were observed; miR-134 was up-regulated in a dose-dependent manner. miR-181a[*]: The miRNA of lower abundance.

invasion: 57.90 ± 10.55 *vs* 73.80 ± 11.95, migration: 66.40 ± 10.1 *vs* 99.50 ± 8.85, $P < 0.01$; forced expression of miR-95, invasion: 37.80 ± 8.93 *vs* 30.20 ± 5.14; migration: 91.80 ± 9.22 *vs* 81.50 ± 7.47, $P < 0.01$) (Figure 4A and B). These results indicated that miR-95 may be important in the progression of pancreatic cancer through increasing cell invasion and migration.

miR-95 promotes the growth of Sw1990 xenografts

Sw1990 cells transfected with pGLV3-GFP-miR-95 or negative control pGLV3-GFP were injected into the right flank of nude mice. Four weeks later, the tumor volumes of xenografts were 373.82 ± 23.67 mm[3] in the miR-95

transfected group and 219.69 ± 17.82 mm[3] in the negative control group. The weight of xenografts was 0.40 ± 0.08 g in the miR-95 transfected group and 0.23 ± 0.05 g in the negative control group. miR-95 significantly increased the growth of the Sw1990 xenografts (Figure 5, $P < 0.05$).

DISCUSSION

In the present study we demonstrated that glargine altered specific miRNA expression in human pancreatic cells at 50-150 IU/L, which is equivalent to 300-900 nmol and is much higher than the physiological concentration of

Figure 2 miR-95 promotes cell proliferation (A) and enhancement of miR-95 inhibit apoptosis (B). A total of 10^4 Sw1990 or Panc-1 cells per well were plated in 96-well plates for 24 h and then were transfected with hsa-miR-95 mimics or hsa-miR-95 inhibitor along with paired negative controls. The cells were incubated at 37 ℃ for 48 h and then cell proliferation was assessed using Cell Counting Kit 8. Data were shown as mean ± SD. $^aP < 0.05$ *vs* pairing negative control.

insulin (0.1-1 nmol). Our miRNA real time PCR array showed that high dose glargine (100 IU/L) up-regulated the expression of 10 miRNAs and down-regulated 2 miRNAs in Sw1990 pancreatic cancer cells. The most obvious change was the apparent increase of miR-95. Stem-loop real-time PCR confirmed the aberrant changes of miR-95 after treatment of high dose glargine in Sw1990 and Panc-1 pancreatic cancer cells. Then miR-95 showed significant anti-apoptotic and growth-promoting effects *in vitro* and *in vivo*. Ectopic expression and siRNA knock-down of miR-95 confirmed its invasion-promoting activity *in vitro*. Therefore, these results highlighted the miR-95-related changes as important effects of glargine.

Recent studies linked the use of glargine with increased risk of cancer. Hemkens *et al*[4] published a registry study that demonstrated a significantly increased risk of cancer diagnosis associated with high dosages of glargine. However, the Scottish study found a non-significant increased risk for specifically breast cancers[23]. The UK study found no link between glargine and cancer[3]. In addition, although glargine has been shown to increase resistance to apoptosis in several tumor cell lines, administration of

glargine didn't alter proliferation of Colo-357 pancreatic carcinoma cells *in vitro*[12]. Therefore, all epidemiological and laboratory evidence remains inconclusive and new indicators are needed to determine the role of glargine in carcinogenesis.

miRNAs have been recognized as promising diagnostic and prognostic markers for cancer diagnosis or treatment. For example , miR-34a family members were found to be directly regulated by TP53 and act as tumor suppressors[24]; miR-217 inhibited pancreatic cancer cell growth through targeting KRAS[25]; miR-10b promoted pancreatic cancer invasiveness and correlates with a poor prognosis[26]; The miRNA-200 family (miR-200a, miR-200b, miR-200c, miR-141 and miR-429) were found to inhibit tumor invasion and metastasis by regulating EMT[27]; miR-126 can inhibit cell adhesion, migration and invasion through the suppression of CRK[28]. Our study confirmed, for the first time, that miR-95 and miR-134 were primary glargine-responsive miRNAs.

miR-95 has been shown to be involved in carcinogenesis. A highly characterized example is colorectal carcinoma, in which miR-95 can promote cell proliferation by

regulating sorting Nexin 1[29]. In pancreatic cancer, miR-95 is significantly upregulated in most tissues and cell lines[30]. In HeLa cells, inhibition of miR-95 caused a decrease in cell growth[31]. *miR-134* gene is located at 14q32, and is involved in several physiological and pathological pro-

cesses. For example, miR-134 plays an important role in translation-dependent guidance of nerve growth cones[32]; miR-134 is regarded as a potential plasma biomarker for the diagnosis of acute pulmonary embolism[33]; plasma miR-134 in bipolar disorder serves as a potential periph-

eral marker that can respond to acute manic episodes and is associated with effective mood stabilizer treatment[34]. Interestingly, recent studies indicated that miR-134 may also be involved in carcinogenesis. p53/p63/p73, the tu-

mor suppressors, were believed to be regulators of the miR-134 processing complex[35]. Our study showed that high dose glargine can significantly upregulate the expression of miR-95 (no time or dose dependent manner) and

miR-134 (dose dependent manner) *in vitro*, and for the first time investigated the role of miR-95 in pancreatic cancer.

In conclusion, our study demonstrated that alterations of specific miRNAs and miRNA-related changes were important effects of glargine, suggesting an important and novel new mechanism by which glargine mediates its potent effects on cell growth and apoptosis.

COMMENTS

Background
Glargine is widely used in the treatment of type 1 and type 2 diabetes mellitus. Recently, this insulin analogue has been suspected to be associated with an increased risk of cancer, including pancreatic cancer, but available evidence remains inconclusive.

Research frontiers
Anti-diabetic therapies have been shown to affect the risk of pancreatic cancer. Metformin use was associated with reduced risk, and insulin or insulin analogue use was suspected to be associated with increased risk of pancreatic cancer in diabetic patients. However, data regarding the effect of glargine, one of the long-acting insulin analogues, on pancreatic cancer are inconsistent. Several researchers

believed glargine to be a motigen, not a carcinogen. New biomarkers are needed to determine the role of glargine in the carcinogenesis of pancreatic cancer.

Innovations and breakthroughs
Recent reports have highlighted that miRNAs play important roles in biological processes that affect tumor progression and are promising biomarkers for cancer diagnosis or treatment. This is the first study to show the effects of high dose glargine on miRNA expression in pancreatic cancer cells. miR-95 was proved to be affected by high dose glargine and to be involoved in the carcinogenesis of pancreatic cancer.

Applications
By understanding the effects of glargine on pancreatic cancer cells, this study may help to clarify the role of glargine in the progress of pancreatic cancer.

Terminology
Glargine is a widely used insulin analog in which a 24 h action profile is achieved. MicroRNAs (miRNAs) are endogenous, non-coding small RNAs, 19-25 nucleotides in length. It has been demonstrated that miRNAs play important roles in biological processes that affect tumor progression including migration, invasion and metastasis.

Peer review
The authors examined the effects of high dose glargine on pancreatic cancer cells *in vitro*; miR-95 is up-regulated significantly by glargine. miR-95 can significantly increase pancreatic cancer cell proliferation, invasion and migration and inhibit cell apoptosis. Moreover, miR-95 is proved to inhibit pancreatic

cancer growth *in vivo*. The results are interesting and may represent the role of glargine in pancreatic carcinogenesis.

Abstract

AIM: To evaluate the effect of nigericin on colorectal cancer and to explore its possible mechanism.

METHODS: The human colorectal cancer (CRC) cell lines HT29 and SW480 were treated with nigericin or oxaliplatin under the conditions specified. Cell viability assay and invasion and metastasis assay were performed to evaluate the effect of nigericin on CRC cells. Sphere-forming assay and soft agar colony-forming assay were implemented to assess the action of nigericin on the cancer stem cell properties of CRC cells undergone epithelial-mesenchymal transition (EMT).

RESULTS: Compared with oxaliplatin, nigericin showed more toxicity for the HT29 cell line (IC50, 12.92 ± 0.25 μmol *vs* 37.68 ± 0.34 μmol). A similar result was also obtained with the SW116 cell line (IC50, 15.86 ± 0.18 μmol *vs* 41.02 ± 0.23 μmol). A Boyden chamber assay indicated that a significant decrease in the number of HT29 cells migrating through polyvinylidene fluoride membrane was observed in the nigericin-treated group, relative to the vehicle-treated group [11 ± 2 cells per high-power field (HPF) *vs* 19.33 ± 1.52 cells per HPF, $P < 0.05$]. Compared to the control group, the numbers of HT29 cells invading through the Matrigel-coated membrane also decreased in the nigericin-treated group (6.66 ± 1.52 cells per HPF *vs* 14.66 ± 1.52 cells per HPF, $P < 0.05$). Nigericin also reduced the proportion of CD133$^+$ cells from 83.57% to 63.93%, relative to the control group ($P < 0.05$). Nigericin decreased the number of spheres relative to the control group (0.14 ± 0.01 *vs* 0.35 ± 0.01, $P < 0.05$), while oxaliplatin increased the number of spheres relative to the control group (0.75 ± 0.02 *vs* 0.35 ± 0.01; $P < 0.05$). Nigericin also showed a decreased ability to form colonies under anchorage-independent conditions in a standard soft agar assay after 14 d in culture, relative to the control group (1.66 ± 0.57 *vs* 7 ± 1.15, $P < 0.05$), whereas the colony numbers were higher in the oxaliplatin group relative to the vehicle-treated controls (14.33 ± 0.57 *vs* 7 ± 1.15, $P < 0.05$). We further detected the expression of E-cadherin and vimentin in cells treated with nigericin and oxaliplatin. The results showed that HT29 cells treated with nigericin induced an increase in E-cadherin expression and a decrease in the vimentin expression relative to vehicle controls. In contrast, oxaliplatin downregulated the expression of E-cadherin and upregulated the expression of vimentin in HT29 cells relative to vehicle controls.

CONCLUSION: This study demonstrated that nigericin could partly reverse the EMT process during cell invasion and metastasis.

INTRODUCTION

Colorectal cancer (CRC) is the third most commonly diagnosed cancer in men and the second most commonly diagnosed cancer in women[1], with a 5-year survival rate < 10% for patients with metastatic disease[2]. Despite the use of active targeted drugs for treatment of metastatic CRC, the cure rate has remained low in the past decade. Activating invasion and metastasis is the hallmark of cancer[3,4], during which malignant cells spread from the primary tumor to distant organs.

The pathogenesis of metastasis involves a series of steps, often termed the invasion and metastasis cascade, which includes the following: local invasion of the host stroma by tumor cells; detachment and embolization of tumor cell aggregates; extravasation of the tumor embolus; survival of tumor cells that are transported through the circulation and stop in the capillary bed; extravasation of the tumor embolus; proliferation of the tumor cells within the organ parenchyma, resulting in a metastatic focus; and reinitiation of these processes for the development of metastases. The first and decisive step of this process is the local invasion through the epithelial basement membrane, because it requires alteration in cell-cell and cell-matrix interactions, reconstruction of the extracellular matrix, remodeling of the cytoskeleton, and enhancement of cell modulation. Great progress has been made on the capacity for invasion and metastasis over the past decade with powerful novel research tools and refined experimental models becoming available. On the other hand, many critical regulatory genes have been identified.

Epithelial-mesenchymal transition (EMT), a transdifferentiation characterized by decreased epithelial markers such as E-cadherin and increased mesenchymal markers such as fibronectin, has become prominently implicated as a means by which transformed epithelial tumor cells acquire the ability to invade, resist apoptosis, and propagate[5-9]. More importantly, EMT has been shown to result in cancer cells with stem-cell-like characteristics that have a propensity to invade surrounding tissue and display resistance to chemotherapeutic interventions[6,10,11]. Nigericin is a potassium ionophore, which has been reported to be toxic to breast stem cells passing through EMT[12].

Lu *et al*[13] have reported that nigericin, like salinomycin, selectively inhibits Wnt1-mediated signaling in HEK293 cells at nanomolar concentrations.

In this study, we aimed to ascertain the specific activities of nigericin on human CRC cell lines. We selected CD133 as the marker of stem cells of CRC.

MATERIALS AND METHODS

Tumor cell preparation and cell culture
Human CRC cell lines, HT29 and SW116 were used. HT29 cells were cultured in McCoy's 5A medium (Gibco, United States) with 10% fetal bovine serum (FBS). SW116 cells were cultured in RPMI 1640 medium with 10% FBS. The cells were cultured at 37 ℃ in a humidified atmosphere containing 5% CO_2.

Drugs and antibodies
Oxaliplatin and nigericin were both purchased from Sigma-Aldrich (St. Louis, MO, United States). Antibodies used for immunofluorescence staining and Western blotting were as follows: mouse anti-E-cadherin (Abcam Inc., Cambridge, MA, United States), mouse anti-vimentin (Abcam), mouse anti-CD133 (Abcam; used for Western blotting and immunocytochemistry), allophycocyanin-conjugated CD133 antibody (Miltenyi Biotec, Auburn, CA, United States) used for fluorescence-activated cell sorting (FACS), mouse anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Abcam).

Analysis of cell viability
For assessment of cell viability in HT29 and SW116 cell lines under different treatments, cells growing at the exponential stage were plated in triplicate, in 96-well plates at a density of 2000 cells/well in a final volume of 100 μL. After incubation for 24 h, oxaliplatin, nigericin and dimethylsulfoxide (DMSO) control were added to each well of the plates. Cell viability was detected after 24 h using Cell Counting Kit 8 (DOJINDO, Japan). Absorbance for each well was read at 570 nm using a microplate reader. Growth inhibition was calculated as a percentage of the untreated controls. Experiments were done three or more times, often in triplicate, for each cell line, and IC_{50} was determined using the four-parameter logistic model.

Cell migration and invasion
Analysis of cell migration was performed using Boyden chambers according to the manufacturer's protocol (Becton Dickinson Labware, Bedford, MA, United States). For cell invasion study, the inserts of the chamber were prepared by coating the upper surfaces with Matrigel (BD Matrigel Matrix, Phenol Red-free). HT29 cells (3×10^3) treated with DMSO control, oxaliplatin and nigericin in McCoy's 5A medium without FBS were plated to the upper chamber. McCoy's 5A with 20% FBS as chemoattractants were plated in the lower chamber of the 24-well pates. After 24 h, nonmigrating or noninvading cells were removed mechanically from the upper chamber using a cotton swab. Cells that migrated or invaded to the lower

surface of the Transwell membrane were fixed in methanol for 30 min at 37 ℃ and stained with 0.05% crystal violet for 1 h. Cells were quantified by counting the number of stained nuclei in five individual fields by fluorescence microscopy, in triplicate.

Immunoblotting
Cell lysates were subjected to sodium dodecylsulfate polyacrylamide gel electrophoresis, and the separated proteins were electrophoretically transferred to hydrophobic polyvinylidene fluoride (PVDF) membrane. After blocking in 5% skimmed milk solution for 2 h, the membranes were incubated with the primary antibodies diluted with anti-CD133, anti-E-cadherin, and anti-vimentin. Primary antibodies were detected with mouse secondary antibodies directed against human IgG and visualized with Odyssey Infrared Imaging System.

Real-time polymerase chain reaction
mRNA expression was determined by real-time polymerase chain reaction. RNA was extracted by using the TRIzol reagent (Invitrogen, Carlsbad, CA, United States) and reverse transcription was performed using Superscript Ⅱ (Invitrogen) according to the manufacturer's instructions. TaqMan reactions were done utilizing an ABI 7500 real-time quantitative polymerase chain reaction (PCR) system. For data analysis, raw counts were normalized to housekeeping gene average for the same time point and condition (ΔCt). The following primers were used in this study: CD133 forward CATCCACAGATGCTCCTAAGGC and reverse GCTTTATGGGGAGTCTTGGTC; E-cadherin forward CGAGAGCTACACGTTCACGG and reverse GTGTCG AGGGAAAAATAGGCTG; vimentin forward CTCCTCCCCCTGTCACATAC and reverse TGATTG-GCATCAGGACCGTTG. GAPDH was used as an internal control. Analysis was performed with the $\Delta\Delta$Ct method.

Flow cytometric analysis
HT29 and SW116 cells, after different treatments, were washed with PBS. Single cell suspensions were incubated with allophycocyanin (APC)-conjugated CD133 antibody (Miltenyi Biotec) for 30 min at 4 ℃. Mouse IgG1-APC was selected as an isotype control body. 7-Aminoactinomycin was used to eliminate the dead cells. The labeled cells were detected by the BD FACSVantage Systems (Becton Dickinson) according to the manufacturer's protocols. Gating was implemented on the basis of negative control staining profiles.

Colonosphere assay
McCoy's 5A with B27 supplement (Invitrogen), 20 μg/mL epidermal growth factor (Invitrogen), 20 μg/mL fibroblast growth factor (Invitrogen), and penicillin-streptomycin served as the stem cell medium (SCM) for this experiment. HT29 cells, after the indicated treatments, were plated at a concentration of 200 cells/100 μL SCM in each of the 20 wells of a 96-well ultralow-attachment plate (Corning Life Sciences, CA, United States). Cells

were supplemented with 100 μL SCM after 7 d of incubation and analyzed on day 14, and MTT solution (40 μL) was added to each well, and a colorimetric assessment was done. The average absorbance measurement for each group was used as an index of sphere number.

Soft agar colony-forming unit assays
We mixed 1.2% agar with 2 × McCoy's 5A medium at a ratio of 1:1 to make a 0.6% agar growth medium solution. We pipetted 2 mL of the 0.6% growth medium mixture into each well of the six-well cell culture cluster (Corning Life Sciences). We avoided bubble formation and spread the mixture evenly by slowly rotating the plate. We allowed the 0.6% agar growth medium layer to harden for 30-40 min at room temperature in a sterile laminar flow hood. We determined the concentration of HT29 cells treated with DMSO control, oxaliplatin and salinomycin, and adjust the suspension to 5×10^3 cells/mL in 0.3% agar diluted with PBS. We transferred 2 mL of the cell suspension to the 0.6% agar growth medium plate and cultured at 37 ℃ in the presence of 5% CO_2 for 14-21 d. We counted the number of colonies using a microscope.

Immunocytochemistry
Cells were directly sorted onto a glass slide, fixed with 4% paraformaldehyde, and stained with anti-E-cadherin, anti-CD133 and anti-vimentin monoclonal antibodies. Nuclei were identified by staining with 4', 6-diamidino-2-phenylindole. Subcellular localizations were determined by using confocal microscopy. The fluorescence intensity of each region was analyzed by different people on three occasions.

Statistical analysis
All values were shown as mean ± SD. Statistical significance was calculated by *t* test unless otherwise stated (SPSS 17.0), considering $P < 0.05$ as statistically significant.

RESULTS
Nigericin inhibits tumor growth and invasion
We examined the *in vitro* effect of nigericin on tumor growth and metastasis. Compared with oxaliplatin, nigericin exhibited more toxicity for the HT29 cell line (IC$_{50}$, 12.92 ± 0.25 μmol *vs* 37.68 ± 0.34 μmol) (Figure 1A). We also obtained similar results with the SW116 cell line (IC$_{50}$, 15.86 ± 0.18 μmol *vs* 41.02 ± 0.23 μmol) (Figure 1B). We then checked whether nigericin had functional influence on the migratory and invasive capacity of CRC cells. After incubation for 24 h, nigericin induced a conspicuous reduction in the number of cells migrating through the PVDF membrane relative to the vehicle-treated controls [11 ± 2 cells per high-power field (HPF) *vs* 19.33 ± 1.52 cells per HPF, $P < 0.05$] (Figure 1C and D). It was surprising that oxaliplatin promoted the migration of CRC cells through PVDF membrane compared with the vehicle-treated controls (38 ± 2 cells per HPF *vs* 19.33 ± 1.52 cells per HPF, $P < 0.05$) (Figure 1C and D). Compared to

Figure 1 Nigericin inhibits tumor growth and metastasis. A: Dose-response curves of HT29 cells treated with nigericin and oxaliplatin. Bars denote SD (n = 5); B: Dose-response curves of SW116 cells treated with nigericin and oxaliplatin. Bars denote SD (n = 5); C: Boyden chamber assays were done to compare the migratory capacities of HT29 cells treated with oxaliplatin and nigericin. the control group, the numbers of HT29 cells invading through the Matrigel-coated membrane also decreased in the nigericin-treated group (6.66 ± 1.52 cells per HPF *vs* 14.66 ± 1.52 cells per HPF, $P < 0.05$) (Figure 1E and F). Correspondingly, oxaliplatin treatment increased the number of HT29 cells invading through the Matrigel-coated membrane (28.66 ± 2.08 cells per HPF *vs* 14.66 ± 1.52 cells per HPF, $P < 0.05$) (Figure 1E and F).

Effects of nigericin and oxaliplatin on expression of cancer stem cell marker

In order to complete subsequent experiments logically, we treated the HT29 cells with nigericin, oxaliplatin, and DMSO vehicle control for 3 d, and then replaced the culture medium containing drugs with normal McCoy's 5A medium with 10% FBS for another 3 d incubation.

The stem cell marker prominin-1 (CD133), a pentas-

pan membrane protein, may not be the only marker, but it remains the most widely reported marker of cancer stem cells (CSCs) of CRC validated by different groups[14-18].

We further assessed the expression of CD133 on HT29 cells after treatment with nigericin and oxaliplatin using flow cytometry. The results demonstrated that nigericin reduced the positive rate of CD133 from 83.57% to 63.93%, relative to the control group ($P < 0.05$) (Figure 2A and B). In contrast, oxaliplatin treatment increased the expression of CD133 from 79.18% to 97.22%. In order to verify this result, we selected the SW116 cell line to repeat the experiment. Similarly, nigericin decreased the proportion of CD133+ cells from 4.55% to 0.31%; on the contrary, the expression rate of CD133 increased from 4.55% to 36.89% (Figure 2C and D). The data from real-time PCR, Western blotting, and immunocytochemistry indicated analogous results (Figure 2E-G).

GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; DMSO: Dimethylsulfoxid.

Effect of nigericin and oxaliplatin on sphere- or colony-forming ability of CRC cells

To evaluate the ability to form colonies or spheres of HT29 cells treated with nigericin and oxaliplatin in the absence of serum and without attachment to culture plates[19]. We performed the sphere-forming assay and soft agar forming assay under serum-free conditions.

Differences between the nigericin and oxaliplatin groups

were quantitated by plating a limited number of cells in each well of a low-attachment 96-well plate and evaluating the ability of HT29 cells to form colonospheres. Nigericin decreased the number of spheres relative to the control group (0.14 ± 0.01 *vs* 0.35 ± 0.01, $P < 0.05$), while oxaliplatin increased the number of spheres relative to the control group (0.75 ± 0.02 *vs* 0.35 ± 0.01, $P < 0.05$) (Figure 3A). Nigericin also showed a decreased ability to

Figure 3 Effects of nigericin and oxaliplatin on sphere- or colony-forming ability of cancer stem cells. A: Mean OD of sphere-forming HT29 cells after different treatments was assayed by methyl thiazolyl tetrazolium assay. Bars denote SD ($n = 5$); B: Numbers of colonies formed by HT29 cells after treatment in independent experiments. Bars denote SD ($n = 5$); C: Phase-contrast images of colonies formed in soft agar assays after treatment. DMSO: Dimethylsulfoxide; HPF: High-power field.

form colonies under anchorage-independent conditions in a standard soft agar assay after 14 d in culture, relative to the control group (1.66 ± 0.57 *vs* 7 ± 1.15, $P < 0.05$), whereas the colony numbers were higher in oxaliplatin group relative to the vehicle-treated controls (14.33 ± 0.57 *vs* 7 ± 1.15, $P < 0.05$) (Figure 3B and C).

Up-regulation of E-cadherin and downregulation of vimentin in CRC cells after nigericin treatment

E-cadherin, encoded by the *CDH1* gene, has dual functions in epithelial cells: as a cell-cell adhesion molecule and as a negative regulator of the canonical WNT signaling cascade; in particular, of its central mediator β-catenin. E-cadherin downregulation in mammalian cell systems is sufficient to trigger EMT[20]. Gupta *et al*[12] have reported that nigericin preferentially kills cells that have undergone EMT. In colorectal carcinomas, the embryonic EMT is activated during tumor invasion in disseminating cancer cells[21]. Characteristic of these cells is a loss of E-cadherin expression.

We detected the expression of epithelial marker (E-cadherin) and mesenchymal marker (vimentin) of cells treated with nigericin and oxaliplatin to ascertain the effects of diverse compounds on EMT.

As shown in Figure 4A and B, nigericin induced an increase in expression of E-cadherin and a decrease in expression of vimentin relative to vehicle controls. In contrast, the expression of E-cadherin in the cells treated with oxaliplatin was downregulated in contrast to vehicle

controls; correspondingly, oxaliplatin treatment upregulated the expression level of vimentin. The data from real-time PCR showed similar results to immunocytochemistry and Western blotting (Figure 4C).

DISCUSSION

Significant progress has been made in understanding the molecular pathogenesis, diagnosis (hereditary and sporadic), and treatment of CRC. Despite the use of active targeted drugs for treatment of metastatic CRC in the past decade, and improvement of overall survival to nearly 2 years for nonresectable disease, the cure rate remains low[22].

5-Fluorouracil and oxaliplatin formed the mainstay of chemotherapeutic regimens for metastatic CRC. Oxaliplatin covalently binds to DNA, forming platinum-DNA adducts that cause prolonged G2 arrest and inhibition of growth, which lead to apoptotic cell death[23].

There is a large body of evidence that tumor cells that are resistant to chemotherapy represent a subpopulation of cells from the primary tumor, which is molecularly and phenotypically distinct. These cells are referred to by several names, including tumor-initiating cells, tumor-promoting cells, or more commonly, CSCs[16]. EMT is a highly conserved cellular process during embryonic development and a pathogenic feature in tumorigenesis[10,24].

During the process of EMT, epithelial cells lose the expression of E-cadherin and other components of

Figure 4 Upregulation of E-cadherin and downregulation of vimentin in cancer stem cells after nigericin treatment. A: Immunofluorescence staining analysis of treated HT29 cells using epithelial E-cadherin and vimentin staining; B: E-cadherin and vimentin expression in HT29 cells after treatment, assayed by Western blotting; C: Real-time polymerase chain reaction analysis of E-cadherin and vimentin mRNA expression in HT29 cells after treatment with dimethylsulfoxide (DMSO) vehicle, oxaliplatin and nigericin.

epithelial cell junctions, adopt a mesenchymal cell phenotype, and acquire motility and invasive ability[25,26]. Furthermore, Mani *et al*[10] have induced EMT in nontumorigenic, immortalized human mammary epithelial cells (HMLEs) by ectopic expression of either the Twist or Snail transcription factors; these cells formed > 30-fold more mammospheres than did HMLEs infected with the corresponding control vector. They have concluded that the cells generated by EMT acquired yet another attribute of mammary stem cells. EMT, which enables cancer cell dissemination, also imparts a self-renewal capability to disseminating cancer cells.

There is no consensus as to the exact criteria that define a CSC, because markers might vary according to the tumor type. In our study, we suggested CD133 as a marker of tumor-initiating cells of CRC[14-18].

We evaluated the effect of nigericin and oxaliplatin on CRC cell lines, including invasion and metastasis, and growth on colon cancer spheres, or colonospheres. From the results of cell viability and flow cytometry assays, we could see that nigericin specifically targets CD133+ cell

subpopulations within CRC cell lines. Moreover, nigericin induced inhibition of invasion and metastasis in HT29 cells. These effects may have been due to the fact that nigericin upregulated the expression of E-cadherin, while E-cadherin played an important role in cancer progression and EMT induction[27,28].

In a variety of human cancers, E-cadherin loss was closely related to poor prognosis, tumor progression, and metastasis[29,30]. Therefore, E-cadherin also could be a sign of drug efficiency of nigericin therapy in the future. Through analysis of the expression level of E-cadherin and vimentin, we may conclude that nigericin partly reverses EMT to affect the ability of CRC cells to invade and metastasize.

We further evaluated the effects of nigericin treatment on the characteristics of CSC phenotype. The nigericin treatment group had a decreased number of spheres or colonies relative to the vehicle control group. Our data led us to hypothesize further that nigericin treatment suppresses EMT-generating cells with the properties of stem cells. This hypothesis needs further studies using animal

experiments and preclinical and clinical trials. Nigericin may prove to be the therapeutic strategy that is effective in patients with metastatic disease.

However, the molecular mechanisms involved in the effect of nigericin are poorly understood. Lu *et al*[13] have reported that nigericin, as a potassium ionophore, selectively inhibits Wnt1-mediated signaling in HEK293 cells.

The polyether ionophores like nigericin interfere with transmembrane potassium potential and promote mitochondrial and cell potassium efflux. We hypothesize that nigericin treatment antagonizes the Wnt signaling cascade, while Wnt signaling plays a crucial role in embryonic development and cancer[31-35]. Besides, certain other CSC markers and signaling pathways, including EZH2 and Hedgehog pathways may also play some important roles in the mechanism of nigericin treatment, and thus need further studies[36]. Further studies will focus on the relation between nigericin-induced EMT and Wnt signaling.

We showed for the first time that nigericin not only partly reversed the EMT process during cell invasion and metastasis, but also suppressed some of the CSC phenotypes generated by EMT. EMT plays a pivotal role in tumor invasion and metastasis; therefore, nigericin treatment may be of benefit in the future.

COMMENTS

Background
Despite therapeutic innovations, metastatic colorectal cancer (CRC) often has a poor prognosis and high mortality.

Research frontiers
Epithelial-mesenchymal transition (EMT) provides a new basis for understanding the progression of carcinoma towards dedifferentiated and more malignant states. The EMT program, which involves dissolution of adherens and tight junctions and a loss of cell polarity, dissociates the cells with epithelial cell sheets into individual cells that exhibit multiple mesenchymal attributes, including heightened invasiveness. EMT also generates cells with properties of stem cells. Nigericin has been reported recently to act as a selective breast cancer stem cell inhibitor. However, the effect of nigericin on CRC is unknown. In this study, the authors evaluated the anticancer effect of nigericin and its possible mechanisms.

Innovations and breakthroughs
Recent reports have highlighted the important role of EMT during the invasion-metastasis cascade. In particular, EMT can be seen at the edges of colon carcinomas that are invading adjacent tissues. This is the first study to report that nigericin could suppress CRC metastasis. Furthermore, our studies indicated the possible mechanisms of action of nigericin.

Applications
Through understanding the effect of nigericin on CRC cells, this study may indicate a future promising therapeutic strategy in the treatment of patients with metastatic colorectal carcinoma.

Terminology
E-cadherin is a hallmark of epithelial cell protein expression; vimentin is an intermediate filament component of the mesenchymal cell cytoskeleton. CD133 protein, a pentaspan cell surface receptor, is a putative CRC stem cell marker.

Peer review
The study investigated the antitumor activity of nigericin on CRC stem cells. The authors found that nigericin selectively targeted cancer stem cells, and inhibited EMT. It is well designed and well presented.

Abstract

AIM: To investigate the association between autoimmune pancreatitis (AIP) and systemic autoimmune diseases (SAIDs) by measurement of serum immunoglobulin G4 (IgG4).

METHODS: The serum level of IgG4 was measured in 61 patients with SAIDs of different types who had not yet participated in glucocorticosteroid treatment. Patients with an elevated IgG4 level were examined by abdominal ultrasonography (US) and, in some cases, by computer tomography (CT).

RESULTS: Elevated serum IgG4 levels (919 ± 996 mg/L) were detected in 17 (28%) of the 61 SAID patients. 10 patients had Sjögren's syndrome (SS) (IgG4: 590 ± 232 mg/L), 2 of them in association with Hashimoto's thyroiditis, and 7 patients (IgG4: 1388 ± 985.5 mg/L) had systemic lupus erythematosus (SLE). The IgG4 level in the SLE patients and that in patients with SS were not significantly different from that in AIP patients (783 ± 522 mg/L). Abdominal US and CT did not reveal any characteristic features of AIP among the SAID patients with an elevated IgG4 level.

CONCLUSION: The serum IgG4 level may be elevated in SAIDs without the presence of AIP. The determination of serum IgG4 does not seem to be suitable for the differentiation between IgG4-related diseases and SAIDs.

INTRODUCTION

Autoimmune pancreatitis (AIP) is an increasingly recognized type of chronic pancreatitis that is clearly distinct from other types of chronic pancreatitis. It is characterized by its morphology, immunologic features, pathology and glucocorticosteroid responsiveness[1-4].

Immunological examinations in AIP patients have demonstrated high incidences of hypergammaglobulinemia (43%), increased serum levels of immunoglobulin G (IgG) (62%-80%) and IgG4 (68%-92%), and the presence of antinuclear antibodies (40%-64%) and rheumatoid factor (25%). Among all the serological diagnostic features, an elevated serum level of IgG4 has the highest individual diagnostic value; however, it is not disease specific. Furthermore, an elevated serum IgG4 level correlates with the activity of AIP[5,6]. Kamisawa *et al*[7] reported an association between serum IgG4 level and extrapancreatic lesions in patients with AIP. AIP patients with a serum IgG4 level ≥ 2200 mg/L frequently exhibit extrapancreatic lesions.

The immunologic and histologic features of AIP and the glucocorticosteroid responsiveness suggest an autoimmune mechanism for the development of the disease[8]. AIP is accompanied by other autoimmune diseases (sclerosing cholangitis, sclerosing sialadenitis, retroperitoneal fibrosis, enlarged celiac and hilar lymph nodes, chronic thyroiditis and interstitial nephritis, *etc*.) in 50%-63% of cases, suggesting that AIP may be a systemic disorder[1-4]. The occurrence of autoimmune diseases in association with AIP is well documented[9,10], but the incidence of such associations has not been reported.

The aim of the present study was to assess the presence of AIP in different systemic autoimmune diseases (SAIDs) through measurement of the serum IgG4 level and examination of the morphology of the pancreas.

MATERIALS AND METHODS

Patients and diagnosis of diseases
Serum samples were obtained from 61 patients with different SAIDs who had been admitted to our Department of Rheumatology and had not participated in glucocorticosteroid treatment during the past 2 years. One male and 60 females (mean age 54.5 years, range 29-82 years) were recruited.

Autoimmune diseases were diagnosed according to standard diagnostic criteria[11-14]. The diagnosis of AIP was based on the HISORt criteria[15]. The most frequent diagnosis was Sjögren's syndrome (SS), but systemic lupus erythematosus (SLE), Hashimoto thyroiditis, Raynaud's syndrome, polymyositis and systemic sclerosis also occurred (Table 1).

Serum samples were additionally obtained from 7 age- and sex-matched healthy subjects, and 6 patients with AIP. In one AIP patient, the AIP was accompanied by rheumatoid arthritis and ankylosing spondylitis.

All participants provided their written informed consent. The study protocol was approved by the ethics committee at the University of Szeged and was carried out in full accordance with the most recent revisions of the Helsinki Declaration.

IgG4 assay
After collection, serum samples were stored at -70 ℃ until analyzed. The IgG4 subclass was determined by the ra-

Table 1　Distribution of gender and age in groups of patients

	No. of patients	Male/ female	Age mean (range)
Sjögren's syndrome	35	1/34	56.7 (29-82)
Systemic lupus erythematosus	22	0/22	50.2 (31-68)
Systemic sclerosis	4	0/4	59.5 (45-80)
Normal subjects	7	4/3	68 (56-80)
Autoimmune pancreatitis	6	3/3	53.7 (27-75)

Figure 1　Serum immunoglobulin G4 levels in different systemic autoimmune diseases and autoimmune pancreatitis. Dotted line: Cutoff value (400 mg/L).

dial immunodiffusion (RID) method (The Binding Site Limited, Birmingham, United Kingdom). The diameters of precipitation rings were measured after 72 h. The results were read using the RID reference table. The lowest detection limit was 22.4 mg/L. The intra- and inter-assay coefficients of variation were 3.26 and 0.89 CV%, respectively, as stated by the manufacturer. A cutoff value of 400 mg/L was employed.

Patients with a serum IgG4 level of > 400 mg/L were examined by a gastroenterologist. The clinical and laboratory data were reviewed and abdominal ultrasonography (US) and computed tomography (CT) were performed.

Anti-SS-A/SS-B autoantibody determination
The presence of anti-SS-A/SS-B autoantibodies was determined by means of commercial enzyme-linked immunosorbent assays, conducted according to the protocols provided by the manufacturers.

Experimental data were evaluated statistically with the independent-samples *t* test. *P*-values < 0.05 were accepted as being statistically significant. Statistical data is expressed as mean ± SD.

RESULTS
An elevated serum IgG4 level (mean value 919 ± 996 mg/L) was detected in 17 (28%) of the 61 SAID patients (Figure 1). Ten of the 17 patients had SS (mean serum IgG4 590 ± 232 mg/L) (2 cases were associated with Hashimoto's thyroiditis), 7 (mean serum IgG4 1388 ± 985.5 mg/L) were diagnosed with SLE. Two SLE patients showed markedly elevated IgG4 levels (> 3000 mg/L). In

one case, SLE was associated with Raynaud's syndrome, while the other patient suffered from xerophtalmia and bronchial asthma. The serum IgG4 level was elevated (mean serum IgG4 783 ± 522 mg/L) in 5 (83%) of the 6 AIP patients. The patient with a normal level of IgG4 had typical pancreatic histology and his condition improved with steroid therapy. The IgG4 levels in these SLE and SS patients were not significantly different from that in the AIP patients.

US examination revealed a normal pancreas in 11 of the 17 SAID patients with elevated serum IgG4 levels, but raised the suspicion of AIP by demonstrating a gracile pancreas in 2 cases (both suffered from SS), and widening of the body or the tail of pancreas, each in a further one patient (both suffered from SLE). However, in none of these 4 cases was AIP confirmed by an abdominal CT scan. The US examinations indicated pancreatic steatosis in 2 additional cases. None of the SAID patients had pancreatic duct dilatation.

The presence of anti-SS-A/SS-B autoantibodies and the potential relation of this to an elevated IgG4 level were examined in the patients with SS. Both anti-SS-A-positivity and anti-SS-B-positivity was detected in 22 patients; 7 of them exhibited an elevated IgG4 level. The anti-SS-A was positive and the anti-SS-B was negative in 9 cases; 2 of these patients had a high IgG4 level. In 4 patients with SS, neither anti-SS-A-positivity, nor anti-SS-B-positivity was found; an elevated IgG4 level was detected in only one of these cases.

DISCUSSION

The present study has demonstrated that the serum IgG4 level may be elevated in SAIDs, without the presence of AIP.

AIP can be complicated by a variety of extrapancreatic lesions, which appear synchronously or metachronously with the pancreatic lesion, share the same pathological conditions, and show a favorable response to glucocorticosteroid therapy, characteristics indicative of a common pathophysiological background. Among the variety of extrapancreatic diseases, lachrymal and salivary gland lesions are some of the most frequent, found in 23%-39% of patients with AIP[16,17]. Extrapancreatic lesions may mimic or be misdiagnosed as primary lesions of the corresponding organs, e.g., lachrymal and salivary gland lesions for SS. It is therefore necessary to differentiate between IgG4-related diseases and inherent diseases of the corresponding organ. When the pancreatic lesion is obscured, it may be difficult to detect these presumably IgG4-related extrapancreatic lesions[4].

IgG4 is the rarest of the 4 IgG subclasses in humans, with an incidence of about 4%. IgG antibodies are predominantly involved in the secondary immune response; complement activation is possibly their most important biological function. The main role of IgG4 is presumably to protect against the biological effects of the complement-fixing IgG subclasses and to act in parasitic infestation or various forms of atopy[18-20]. Serum IgG4 levels

are frequently and significantly elevated in AIP patients[6] and an elevated level of serum IgG4 has been included among the laboratory criteria for the diagnosis of AIP[4,15]. AIP patients with 3 extrapancreatic lesions have been reported to have significantly higher IgG4 levels than those lacking such lesions[16]. The optimal cutoff value for discriminating AIP patients with extrapancreatic lesions from those without was demonstrated on the basis of receiver operator characteristic curves to be 2200 mg/L[7].

The serum IgG4 level was measured in 61 SAID patients in our study, 28% of whom proved to have an elevated serum level of IgG4. However, none of them could be diagnosed with AIP according to the HISORt criteria. What could be the reason for this?

One explanation is the composition of our patient cohort. In Japan AIP predominantly affects men, with a male:female ratio of 2.85:1[16]. Moreover, there was a male preponderance in the United Kingdom, European and US studies (100%, 66% and 65% male, respectively), similar to in reports from Japan[21-24]. In contrast, there was only one male in our patient population.

Lachrymal and salivary lesions associated with AIP were previously considered to be complications of SS. However, in contrast to those accompanying SS, the lachrymal and salivary gland lesions associated with AIP yield negative results for anti-SS-A/SS-B autoantibodies and show numerous IgG4-positive plasma cell infiltrations in the affected tissues. These lesions are currently thought to correspond to Mikulicz's disease[25]. The explanation for our negative results may be that there was only one patient with negative SS-A/SS-B autoantibodies in our study group.

Another point is that autoantibodies against FcεRIα are detected in the sera of patients with different autoimmune diseases (such as SLE, dermatomyositis, pemphigus and pemphigoid); these antibodies are from subclasses IgG2 and IgG4, but they are functionally inactive[26]. In our study, elevated IgG4 levels were found in 7 patients treated for SLE.

Moreover, our 17 SAID patients with elevated IgG4 levels included 6 who suffered from different concomitant diseases which could cause the increase in the serum level of IgG4. In one patient, nodular sclerosis Hodgkin lymphoma (HL) was diagnosed histologically. HL cells frequently express interleukin 13 (IL-13) and its receptor. Besides exerting several effects on B cells (e.g., promoting their survival and proliferation), IL-13 switches the Ig class to IgG4 and IgE[27]. In another patient, bullous pemphigoid was identified, which is among the most common blistering autoimmune skin lesions. One of the features of the disease is the presence of autoantibodies against hemidesmosomal antigens (i.e., bullous pemphigoid antigen 1 and 2) in the serum and in affected areas of the skin. The major types of these autoantibodies are IgG4 and IgE[28]. In a third patient, cutaneous lymphocytic vasculitis was diagnosed, which could also explain the serum IgG4 elevation[29]. In 2 patients, the underlying disease was accompanied by Hashimoto's thyroiditis, which can elevate the IgG4 level since thyroglobulin autoantibodies

are from subclasses IgG2 and IgG4[30]. There was also one patient with bronchial asthma, in which disease elevated titers of IgG4 can be found[31].

Finally, SS was diagnosed in the remaining 4 patients, one of whom was seronegative, while the others were seropositive. The elevated serum IgG4 level in patients with seronegative SS may possibly be explained by the presence of Mikulicz's disease[32]. Furthermore, an elevated serum IgG4 level has also been reported in SS[33].

However, not all AIP patients display elevated serum IgG and IgG4 levels. IgG4-negative AIP patients seem to occur more frequently in Europe[34]. Furthermore, some AIP cases improve spontaneously[4]. Hence, it cannot be ruled out that our SAID cohort included AIP patients who were not diagnosed by the measurement of serum IgG4 or in whom the morphology of the pancreas had already normalized by the time of our examination.

Overall, it can be concluded that the serum IgG4 level may be elevated in SAIDs, but as a consequence of the concomitant SAID rather than of AIP. The determination of serum IgG4 does not seem to be suitable for the differentiation between IgG4-related diseases and SAIDs.

COMMENTS

Background
Autoimmune pancreatitis (AIP) is frequently associated with some other autoimmune disease, suggesting that it may be a systemic disorder. The determination of serum immunoglobulin G4 (IgG4) is a sensitive marker to diagnose AIP and IgG4-related diseases.

Research frontiers
IgG4 is a sensitive marker in the diagnosis of AIP. The association of AIP and systemic autoimmune diseases (SAIDs), and the usefulness of the determination of serum IgG4 in the diagnosis of AIP in patients with SAIDs are not defined.

Innovations and breakthroughs
The authors revealed that the serum IgG4 level may be elevated in SAIDs without the presence of AIP. The determination of serum IgG4 does not seem to be suitable for the differentiation between IgG4-related diseases and SAIDs.

Applications
This study provides important data about the serum level of IgG4 in SAIDs. The determination of serum IgG4 does not seem to be suitable for the differentiation between IgG4-related diseases and SAIDs. The diagnosis of AIP in SAIDs should be made on the results of morphological and histological examination.

Terminology
AIP is an increasingly recognized distinct type of chronic pancreatitis with a presumed autoimmune etiology. Immunoglobulin G (IgG) has four subclasses (IgG1 through IgG4) and the IgG4 subclass accounts for 3%-6% of total serum IgG.

Peer review
This paper discusses the relationship between autoimmune pancreatitis and an elevated serum IgG4 level in autoimmune diseases, and presents interesting and potentially important information. The patients used in this study are few and biased (1 male and 60 female cases), but it is highly significant as a clinical pilot study. This study is well-designed and written, but there are some points to be clarified.

Abstract

AIM: To evaluate the outcome of sub-centimeter-sized nodules (SCSNs) detected during surveillance for hepatocellular carcinoma (HCC) in patients at risk.

METHODS: We retrospectively analyzed a total of 142 patients with liver cirrhosis or chronic hepatitis B or C without a prior history of HCC in whom a SCSN was detected during HCC surveillance. We calculated the rate of HCC development from SCSNs in the study population and analyzed the differences in the baseline clinical characteristics and imaging features between the patients with SCSNs that eventually developed into HCC and patients with SCSNs that did not develop into HCC.

RESULTS: During 667 person-years of follow-up, HCC developed in 33 patients. The calculated HCC development rate was 4.9% per year. The cumulative one-, two-, three- and five-year HCC development rates were 5.6%, 10.6%, 14.1% and 20.4%, respectively. Upon baseline comparison, the HCC group was older (54.4 ± 8.3 years *vs* 48.9 ± 9.4 years; *P* = 0.003) and had lower albumin levels (3.56 ± 0.58 g/dL *vs* 3.84 ± 0.55 g/dL; *P* = 0.012) and higher baseline alpha-fetoprotein (AFP) levels (8.5 ng/mL *vs* 5.4 ng/mL; *P* = 0.035) compared to the non-HCC group. Nodule pattern and initial radiologic diagnosis also differed between the two groups. Multivariate analysis revealed that age [*P* = 0.012, odds ratio (OR) =1.075, 95% confidence interval (CI) =1.016-1.137], sex (*P* = 0.009, OR = 3.969, 95% CI: 1.403-11.226), and baseline AFP level (*P* = 0.024, OR = 1.039, 95% CI: 1.005-1.073) were independent risk factors for developing HCC.

CONCLUSION: The overall risk of HCC development in patients with SCSNs is similar to that in liver cirrhosis patients. Patients with these risk factors need to be closely monitored during follow-up.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death in the world, and the ninth leading cause of cancer deaths in the United States[1-7]. The number of deaths per year from HCC is virtually identical to the incidence throughout the world, underscoring the high fatality rate of this aggressive disease[8]. The sole approach to achieve long-term survival is to detect the tumor at an early stage, when effective therapy can be applied[9]. Accordingly, the European Association for the Study of the Liver and the American Association for the Study of Liver Diseases recommend performing screening for HCC in patients at risk who would be treated if diagnosed with this condition[10-12]. Under these guidelines, imaging criteria for the diagnosis of HCC are established for lesions 1 cm or larger in patients at risk, but owing to a high false-positive rate, a wait-and-see policy is recommended for nodules smaller than 1 cm in diameter[11,12]. However, the possibility remains high that minute hepatic nodules detected during surveillance may become malignant over time[13,14]. In addition, a delay in the start of treatment of early-stage HCC may be associated with a poorer patient survival[15]. Nevertheless, clinicians have limited data on the clinical course of sub-centimeter-sized nodules (SCSNs) detected during surveillance.

A variety of important risk factors for the development of HCC have been identified. These include chronic hepatitis B and C virus infection and cirrhosis due to almost any cause[16-22]. Almost 80% of cases are due to underlying chronic hepatitis B and C virus infection[17]. Since patients with chronic hepatitis B who may not have fully developed cirrhosis or have regressed cirrhosis as well as patients with cirrhosis are at increased risk of developing HCC, an updated the American Association for the Study of Liver Diseases guidelines recommended surveillance in patients with chronic hepatitis B[12].

The purpose of our study was to evaluate the outcome of SCSNs detected during HCC surveillance in patients at risk and to determine the risk factors for development of those nodules into HCC.

MATERIALS AND METHODS

Patients

This retrospective study was conducted according to the principles of the Declaration of Helsinki. The study involved patients with liver cirrhosis of any etiology or chronic liver disease including chronic hepatitis B and C virus infection, without a prior history of HCC in whom a SCSN was detected during HCC surveillance with ultrasonography (US) or computed tomography (CT) of the liver at Samsung Medical Center, Seoul, South Korea between January 1, 2005 and April 30, 2005 (*n* = 198). At our institution, patients at risk for HCC were followed with alpha-fetoprotein (AFP) and US every 6 mo. In case of a difficult US, such as in obese individuals, CT and US were performed alternately for HCC surveillance.

Even when an SCSN was detected, patients were usually followed with AFP and US every three or six mo as appropriate. However, if any SCSN enlarged or its appearance was typical of HCC, 3 mo surveillance was used for a certain period or other image modalities such as CT or magnetic resonance imaging (MRI) were performed additionally. The medical records of all patients were reviewed thoroughly. Patients who met any of the following criteria were excluded: (1) less than 12 mo of follow-up, except subjects who were diagnosed with HCC within 12 mo of follow-up; (2) subjects who were lost to follow-up and diagnosed with HCC at an outside hospital; and (3) any history of cancer. Thus, a total of 56 patients were excluded from the study. Forty patients had less than 12 mo of follow-up, seven patients were excluded because HCC was diagnosed at the time of inclusion in the study, and three patients were lost to follow-up. Additionally, three patients had hepatic nodules 1 cm or larger in size at inclusion, two patients had other types of cancer, and the etiology of liver disease in one patient was unclear.

Data collection

The following clinical and laboratory information was collected from each patient: age, sex, etiology of liver disease, presence of liver cirrhosis, the Child-Pugh classification, aspartate aminotransferase (AST), alanine aminotransferase (ALT), prothrombin time (PT), serum total bilirubin, platelet count, serum albumin, and baseline and follow-up AFP levels.

Image interpretation

The initial radiologic diagnosis of SCSNs was based on the results of US or CT during surveillance. In addition, all radiologic images were reviewed by one radiologist who had 11 years of experience in liver imaging interpretation. He did not participate in the initial patient selection and was blinded to the final diagnoses and clinical information such as AFP levels. Each detected lesion was evaluated for the number, location, and echogenicity/attenuation of nodules. Lesions were categorized as follows: (1) hypoechoic/low-attenuation; (2) hyperechoic/high-attenuation; and (3) mixed echoic/attenuation (Figure 1). All lesions were included in one of these three categories.

The diagnosis of HCC was based either on biopsy or the clinical criteria of the Korean Liver Cancer Study Group and the National Cancer Center, South Korea[3]. Briefly, the diagnosis of HCC was made when the AFP level was ≥ 400 ng/mL and at least one of the dynamic enhancement CT or MRI showed a vascular pattern typical of HCC in patients at risk including patients with HBV or HCV infection, or liver cirrhosis. If the AFP level was < 400 ng/mL, at least two of the dynamic enhancement CT, MRI or transarterial angiography must show vascular patterns typical of HCC in order to make a diagnosis of HCC.

Statistical analysis

Statistical analyses were conducted using PASW Statistics

Figure 1 Representative cases according to ultrasonography and computed tomography findings. A: Ultrasonography shows scattered sub-centimeter-sized low echoic nodules; B: Arterial phase computed tomography (CT) scan shows a 5 mm sized low attenuated nodule in left lobe of liver; C: Ultrasonography shows a 7 mm sized hyperechoic nodule in right lobe of liver; D: Arterial phase CT scan shows a 5 mm sized high attenuated nodule in right lobe of liver.

18 for Windows (SPSS, Inc, Chicago, IL, United States). The statistical results are presented as the mean ± SD, median (range), or number (%) of patients. The differences in the baseline clinical characteristics and imaging features between the lesions that eventually developed into HCC and those that did not (non-HCC) were statistically analyzed to identify significant risk factors for the development of HCC from SCSNs detected during surveillance.

Continuous variables were compared parametrically using Student's *t*-test or non-parametrically using the Mann-Whitney *U*-test. Categorical variables were compared using the χ^2-test or Fisher's exact test as appropriate. Multiple logistic regression analysis was performed on variables that were different between the non-HCC and HCC groups in the univariate analysis ($P < 0.100$), in order to identify variables independently associated with the development of HCC. HCC development rates were calculated using the Kaplan-Meier method. A two-sided *P* value < 0.05 was considered statistically significant.

RESULTS

A total of 142 patients were included in this study. Their characteristics are summarized in Table 1. Eighty-four patients (59.2%) were male and the mean age was 50.2 ± 9.4 (SD) years. The etiology of liver disease was hepatitis B virus infection in 126 patients (88.7%), hepatitis C virus infection in 9 (6.3%), and alcoholic liver disease in 7 (5.0%). One hundred and eleven patients (78.2%) had cirrhotic liver. Ninety-eight patients (88.3%) were Child-Pugh class A, 10 (9.0%) were class B, and 3 (2.7%) were class C. A total of 33 patients had at least one SCSN: 23 patients were detected by US and 10 were detected by CT. There was one SCNS in 26 patients (18.3%), two SCSNs in 7 (5.0%), three in 3 (2.1%), four in 1 (0.7%), and more than four in 105 (73.9%). The SCSNs were hypoechoic/low-attenuation in 77 patients (54.3%), hyperechoic/high-attenuation in 31 (21.8%), and mixed echoic/attenuation in 34 (23.9%). Initial radiologic diagnosis of the hepatic nodules was regenerative nodule (RN)/dysplastic nodule (DN) in 119 patients (83.8%), hemangioma in 17 (12.0%),

indeterminate nodule in 5 (3.5%), and arterioportal shunt in 1 (0.7%).

During 667 person-years of follow-up (mean, 28.5 ± 20.0 mo), HCC developed in 33 patients (23.2%). The mean durations of follow-up were 32.6 ± 19.5 and 64.3 ± 17.6 in the HCC and non-HCC groups, respectively. The mean time to diagnosis of HCC after detection of SCSNs was 33.1 ± 18.9 mo. Except for one biopsy-proven case, most of the HCC cases were diagnosed according to the clinical criteria of the Korean Liver Cancer Study Group and the National Cancer Center, South Korea[3], which were not same as the international guidelines[10,11] at that time. However, when retrospectively reevaluated, all diagnoses of HCC were satisfied with the updated American Association for the Study of Liver Diseases guidelines[12]. Following diagnosis, twelve patients (36.4%) underwent radiofrequency ablation, 13 (39.4%) underwent transarterial chemoembolization, 5 (15.2%) underwent surgical resection, 1 (3.0%) underwent liver transplantation, and 2 (6.0%) did not receive any treatment.

The calculated HCC development rate was 4.9% per year. The cumulative one-, two-, three- and five-year HCC development rates were 5.6%, 10.6%, 14.1% and 20.4%, respectively.

Clinical features and initial radiologic results of patients in the HCC and non-HCC groups

Patients diagnosed with HCC were older (54.4 ± 8.3 years *vs* 48.9 ± 9.4 years; $P = 0.003$) and had lower albumin levels (3.56 ± 0.58 g/dL *vs* 3.84 ± 0.55 g/dL; $P = 0.012$) and elevated baseline AFP levels [8.5 (range: 3.2-211.6) ng/mL *vs* 5.4 (range: 1.0-55.9) ng/mL; $P = 0.035$] compared to patients with non-HCC nodules. In terms of nodule pattern, patients diagnosed with HCC had more hypoechoic/low-attenuation nodules and less hyperechoic/high-attenuation nodules than patients with non-HCC nodules [23 (69.7%) *vs* 54 (49.5%) and 1 (3.0%) *vs* 30 (27.5%), respectively, $P = 0.011$]. In the initial radiologic diagnosis of hepatic nodules, RN/DN accounted for 31 (93.9%) in patients diagnosed with HCC, while RN/DN and hemangioma accounted for 88 (80.7%) and 17 (15.6%), respectively, in patients with non-HCC nodules ($P = 0.036$). There were no significant differences in

sex, etiology of liver disease, presence of liver cirrhosis, Child-Pugh class, AST, ALT, PT, bilirubin, platelet count, or number of nodules between patients diagnosed with HCC and patients with non-HCC nodules (Table 2).

Multivariate analysis revealed that old age [*P* = 0.012, odds ratio (OR) = 1.075, 95% confidence interval (CI) = 1.016-1.137], male sex (*P* = 0.009, OR = 3.969, 95% CI: 1.403-11.226), and high baseline AFP level (*P* = 0.024, OR = 1.039, 95% CI: 1.005-1.073) were associated with an increased risk of developing HCC from SCSNs detected during surveillance (Table 3).

DISCUSSION

The purpose of our study was to evaluate the outcome of SCSNs detected during surveillance in patients at risk and to determine risk factors for developing HCC from those nodules. The current practice guidelines recommend follow-up of SCSNs every few months in order to detect growth suggestive of malignant transformation[10-12]. However, early diagnosis of HCC has a significant impact on survival because it enables the timely implementation of

Table 3 Multivariate analysis of risk factors for the development of hepatocellular carcinoma from sub-centimeter-sized hepatic nodules

effective treatment strategies, including hepatic resection, loco-regional ablative therapy, and liver transplantation[23,24]. In addition, even in cases of HCC that are

detected early and can be treated with radiofrequency ablation, a delay (more than five weeks) in treatment may be associated with poorer patient survival[15]. Therefore, in the present study, we focused on the SCSNs, which have not been investigated so far, even though occasionally encountered in practice, and identified clinical risk factors for the development of HCC from SCSNs.

Several studies have reported an HCC yearly incidence in HBV or HCV infection, which is between 2%-8% per year depending on the study population[12,18,21,25-33]. In the present study, the annual HCC incidence from SCSNs was 4.9% per year, which is similar to above-mentioned HCC incidences of 2%-8%/year in chronic HBV or HCV infection. Thus, although the detection of SCSNs during surveillance is not infrequent and their management could be a major clinical challenge, it seems that the HCC incidence does not increase significantly in patients with SCSNs compared to patients without SCSNs.

There have been a few studies of sub-centimeter-sized HCC[34,35]. Park *et al*[34] reported that small (5-10 mm) arterially enhancing nodules at the hepatic arterial phase of CT in surveillance for HCC have a 29.5% probability of developing into HCC over a mean 35.7 mo of follow-up on a per-person basis. They also identified the presence of HCC treatment history, a larger size of small (5-10 mm) arterially enhancing nodules, presence of coexistent HCC, and absence of coexistent typical arterioportal shunts as independent risk factors for future development of HCC. In our study, SCSNs had a 23.2% probability of developing into HCC over a mean of 28.5 mo of follow-up. The unique feature of the present study that differentiates it from that of Park *et al*[34] is that our study population had no prior HCC history and included 77 (54.3%) patients who had hypoechoic/low-attenuation SCSNs. In addition, patients diagnosed with HCC had more hypoechoic/low-attenuation SCSNs than patients with non-HCC nodules (69.7% *vs* 49.5%; *P* = 0.011; Table 2), although the difference was not significant in the multivariate analysis (*P* = 0.081). This could be due to hemangiomas, which are mainly hyperechoic/high-attenuation and benign, because 17 patients with a hemangioma were included only in the non-HCC group (Table 2). Therefore, we selected patients who had RN/DN and performed a subgroup analysis. The proportion of patients with hypoechoic/low-attenuation SCSNs did not differ between the two groups (70.0% *vs* 56.5%, *P* = 0.134). According to our results, non-enhancing minute hepatic nodules also might have considerable malignant potential and should receive as much attention as enhancing nodules.

A study by Forner *et al*[36] evaluated the accuracy of contrast-enhanced US and dynamic MRI for the diagnosis of nodules 20 mm or smaller detected during US surveillance. The study included 89 patients with cirrhosis, of whom 13 patients (14.6%) had a SCSN. Among those with SCSNs, 2 (15.4%) were ultimately diagnosed with HCC. Significant differences were found in age, no-

dule size, and the presence of a halo between patients diagnosed with HCC and patients with non-HCC nodule in all subjects, although multivariate analysis was not performed. In our study, old age, male sex, and high baseline AFP levels were associated with an increased risk of developing HCC from SCSNs detected during surveillance. Among these variables, male sex was the strongest risk factor (*P* = 0.009, OR = 3.969, 95% CI: 1.403-11.226). Elevated baseline AFP levels may be affected by undiscovered HCC. Therefore, we excluded subjects who were diagnosed with HCC at the time of inclusion in the study. Additionally, we investigated the change in AFP levels and calculated the AFP ratio as the last AFP level divided by the baseline AFP level. The AFP ratios were also significantly elevated in the HCC group compared to the non-HCC group [1.0 (range: 0.2-74.3) *vs* 0.7 (range: 0.0-4.7); *P* = 0.040], even though baseline AFP levels were elevated. Thus, elevated AFP level at baseline could be considered a risk factor for developing HCC, and an increased AFP ratio during follow-up should be considered a critical warning sign for HCC development.

The present study had some limitations. First, the retrospective design likely introduced selection bias. Second, there was a lack of histological confirmation for the benign lesions, which were defined on the basis of radiologic images. However, it is unlikely that HCCs were incorrectly categorized as benign because our follow-up period was sufficiently long. Furthermore, pathological confirmation of these lesions would not be practical in clinical settings. Last, our assessments regarding the number, location, nodule pattern, and size of SCSNs had an element of subjectivity due to the small nodule sizes and sometimes ill-defined margins. To overcome this limitation, all radiologic images were reviewed by an experienced radiologist who was blinded to the final diagnoses.

In conclusion, the overall risk of HCC development in patients with SCSNs is similar to that in liver cirrhosis patients. However, since old age, male sex, and high baseline AFP level are associated with an increased risk of developing HCC from SCSNs, patients with these risk factors need to be closely monitored during follow-up.

COMMENTS

Background
During hepatocellular carcinoma (HCC) surveillance, the detection of sub-centimeter-sized nodules (SCSNs) is not infrequent and their management is a major clinical challenge. Owing to a high false-positive rate, a wait-and-see policy is recommended for those nodules. However, the possibility remains high that small nodules detected during surveillance may become malignant over time and a delay in the start of treatment of even early-stage HCC may be associated with a poorer patient survival.

Research frontiers
Clinicians have limited data on the clinical course of SCSNs. In this study, the authors investigated outcomes of SCSNs detected during HCC surveillance in patients at risk.

Innovations and breakthroughs
This is the first report to evaluate the outcome of SCSNs detected during surveillance in patients with cirrhosis or chronic liver disease and to determine

risk factors for developing HCC from those nodules. Therefore, the study could provide valuable information to clinicians managing patients with chronic liver disease.

Applications

The study results suggest that patients with risk factors such as old age, male sex and high baseline alpha-fetoprotein need to be closely monitored during follow-up.

Peer review

This study is very informative for clinicians because the detection of SCSNs during surveillance is frequently encountered in practice setting. In addition, their results have scientific relevance for understanding the epidemiology of the disease.

Abstract

AIM: To evaluate the relationship between a positive family history of primary liver cancer and hepatocellular carcinoma (HCC) development in Korean HCC patients.

METHODS: We studied a total of 2242 patients diagnosed with HCC between January 1990 and July 2008, whose family history of primary liver cancer was clearly described in the medical records.

RESULTS: Of the 2242 patients, 165 (7.4%) had a positive family history of HCC and 2077 (92.6%) did not. The male to female ratio was 3.6:1, and the major causes of HCC were chronic hepatitis B virus (HBV) infection in 75.1%, chronic hepatitis C virus infection in 13.2% and alcohol in 3.1%. The median ages at diagnosis in the positive- and negative-history groups were 52 years (range: 29-79 years) and 57 years (range: 18-89 years), respectively ($P < 0.0001$). Furthermore, among 1713 HCC patients with HBV infection, the number of patients under 45 years of age out of 136 patients with positive family history was 26 (19.1%), whereas those out of 1577 patients with negative family history was 197 (12.5%), suggesting that a positive family history may be associated with earlier development of HCC in the Korean population ($P = 0.0028$).

CONCLUSION: More intensive surveillance maybe recommended to those with a positive family history of HCC for earlier diagnosis and proper management especially when HBV infection is present.

Key words: Liver cancer; Hepatocellular carcinoma; Family history; Epidemiology

INTRODUCTION

Hepatocellular carcinoma (HCC) accounts for up to 90% of primary liver cancers. It is the fifth most common can-

cer and the third most common cause of cancer-related death worldwide[1-3]. The major risk factors for the development of HCC include liver cirrhosis of any etiology, chronic hepatitis B virus (HBV) infection, chronic hepatitis C virus (HCV) infection, heavy alcohol consumption and non-alcoholic steatohepatitis[2,4].

Familial clustering has been reported in many types of cancer including pancreas, colon, stomach, lung and breast cancers based on either meta-analyses or registry-based studies throughout the world[5-9]. However, no data on familial clustering for HCC is available in Korea to date although a few studies are reported in some other countries[10-15]. The development of HCC in Caucasian populations are reported to be less related to chronic HBV infection, but the clustering of HBV infection among family members was reported to be the major cause associated with family histories of HCC in Asia[3,12,14,16]. Still, the impact of family history of HCC in the development of HCC remains to be determined along with the possible confounding effects of important risk factors for HCC. Here, we report a large retrospective cohort study evaluating the effect of family history of HCC on its development among Korean patients with various risk factors.

MATERIALS AND METHODS

Study population
This study was a single-hospital-based study; cases were retrospectively evaluated. The data were recruited retrospectively from the medical records of 2242 patients who had first been diagnosed with and treated for HCC between January 1990 and July 2008. Before the analysis, the diagnosis of HCC was reconfirmed based on the American Association for the Study of Liver Diseases Practice Guidelines for Management of HCC[17], with either positive histopathology on liver biopsy and/or non-invasive criteria of hepatic imaging demonstrating one or more space-occupying lesions showing arterial hypervascularization on triphasic computed tomography and/or magnetic resonance imaging with or without an elevated alpha-fetoprotein (AFP) level.

All patients were screened for hepatitis virus infection when diagnosed with HCC, and if a patient had no evidence of chronic viral hepatitis, he or she underwent studies for autoimmune hepatitis and metabolic and/or genetic disorders such as Wilson's disease, hemochromatosis, primary biliary cirrhosis. HBV infection was diagnosed by testing for hepatitis B surface antigen, hepatitis core IgG, and HBV DNA, and HCV infection was diagnosed by testing for anti-HCV antibodies and HCV RNA; testing was performed at the central lab of Seoul St. Mary's Hospital. Alcohol-related cirrhosis was clinically diagnosed based on a compatible history of sustained alcohol consumption over 75 g/d in the absence of any other cause for liver disease.

A family history of HCC was determined based on medical records written during personal interviews on admission.

Tumor staging
Tumor staging for HCC was based on a classification system modified from the Union for International Cancer Control staging classification[18-20].

Statistical analysis
The results are presented as frequency (*n*) and percentage for categorical data and median (minimum to maximum) for continuous data.

To compare the general characteristics according to HCC family history, categorical variables were analyzed using either the χ^2 test or Fisher's exact test, as appropriate. Continuous variables were compared using the Mann-Whitney *U*-test. To identify differences in HCC family history according to HBV and HCV infections, statistical analyses were performed by the χ^2 test, Fisher's exact test, or the Mann-Whitney *U*-test, as appropriate.

All statistical analyses were performed using SAS software, Version 9.1 (SAS Institute Inc., Cary, NC). A 2-tailed *P*-value of < 0.05 was considered statistically significant.

RESULTS

Patient characteristics
The demographic features of the HCC patients are summarized in Table 1. A total of 2242 cases with HCC were recruited by a retrospective chart review. The number of male patients (*n* = 1765) was approximately 3.6 times that of female patients (78.7% *vs* 21.3%, respectively). The median age at the time of diagnosis was 57 years (18-89 years), and the median age at the peak incidence of HCC was in the sixth decade (*n* = 722, 32.2%) followed by the seventh (*n* = 640, 28.6%) for all cases. When classified by gender, male patients were most commonly diagnosed with HCC in their fifties, whereas female patients were most commonly diagnosed in their sixties.

The most common single cause of HCC was HBV (*n* = 1683, 75.1%); the second was HCV, and the fourth was alcohol. The group classified as "unknown" was the third largest group and included the patients with non-B, non-C, and non-alcoholic liver cirrhosis and those for whom the cause of HCC could not be identified even after thorough evaluation (Table 1). In patients with chronic hepatitis B, the peak incidence of HCC was observed in the sixth decade of life; however, it was observed 10 years later in patients for whom HCC was caused by chronic hepatitis C or alcohol (data not shown). In 32 (1.4%) of 2242 patients, more than one etiology was identified. HBV co-infection with HCV was the most common combination and affected 17 patients; HBV with alcohol was the second most common and affected 13 patients; the remaining two cases were caused by HCV with alcohol. When the patients were classified based on whether a patient had HBV infection, the HBV-positive group consisted of 1713 patients (76.4%), whereas the HBV-negative group included only 529 (23.6%) patients. The patients were then reclassified into HCV-positive and

AFP: Alpha-fetoprotein; Alb: Serum albumin; ALT: Alanine transaminase; HBV: Hepatitis B virus; HCV: Hepatitis C virus; FHx: Family history; PIVKA-II: Protein induced by vitamin K deficiency-II; TB: Serum total bilirubin.

-negative groups; the HCV-positive group included only 14.1% (*n* = 315) of all patients.

By the modified International Union Against Cancer (UICC) staging classification, only 185 patients (8.3%) were diagnosed at stage I, followed by 655 (29.2%) patients at stage II, 648 (28.9%) patients at stage III, and 753 (33.6%) patients at stage IV. Thus, over half of the patients (62.5%) were diagnosed at advanced stages of HCC, including stages III and IV.

Laboratory data at diagnosis did not indicate severe hepatic dysfunction. The medians of serum alanine transaminase, serum total bilirubin, serum albumin, and platelet count were 47 U/L (3.0-3505.0), 1.1 mg/mL (0.1-58), 3.5 g/dL (1.2-4.98), and 121 500/μL (8000-1 084 000), respectively. With regard to tumor markers, the median serum AFP level was 69.1 ng/mL (0.0-529 470.0), and the median level of serum protein induced by vitamin K deficiency (PIVKA-II) was 88.0 Mau/mL (1.0-16 636.8). No statistical difference between the positive- and negative-family-history groups was found.

Family history of HCC

As shown in Table 1, 165 (7.4%) of 2242 patients had a positive family history of HCC in one or more family members, whereas 2077 (92.6%) patients had no family

history of any HCC. Because the main concern was the influence of a positive family history in the development of HCC, positive histories in the offspring of the patients were not considered. Among those 165 patients with positive family histories, 159 had a positive family history in one or more first-degree relatives, including parents and siblings. Of the remaining six patients (all of these patients as well as their mothers had HBV infection), five had a positive family history of HCC in a brother or sister of the patient's mother, and one had a positive family history in the grandmother and in an uncle on the mother's side. We considered these patients to have positive family histories because vertical transmission of HBV and its oncogenic effects on the affected individual and on his or her family members cannot be omitted in a population with a high prevalence of HBV infection. The number of patients with a positive family history in a single family member was 143. A father, a mother, or a sibling was a single family member with a history of HCC in 25, 29 and 89 patients, respectively. The number of patients with a positive family history in two or more family members were as follows: both mother and father in two, a father and a sibling in two, a mother and a sibling in 10, a mother and two siblings in one, two siblings in one, a grandmother and an uncle in one, a sibling and

an uncle in two, and a mother, grandmother, and an aunt in one. Considering 159 the patients positive family history only in the first degree relative, when grouped into HBV-positive and -negative, the median age at diagnosis of HCC was 51.5 and 57.0, respectively ($P = 0.049$).

Age at diagnosis: Regardless of the family history of HCC, both groups had a peak incidence of HCC diagnosis in their fifties. However, the median age at diagnosis was 52 years (range: 29-79 years) for those with positive family histories, which was significantly younger ($P < 0.0001$) than that for those with negative family histories (57; range: 18-89 years). In the positive-family-history group, 61 (37.0%) patients were diagnosed in their fifties, and 48 (29.1%) in their forties. In the negative-family-history group, 661 (31.8%) patients were diagnosed in their fifties, and 606 (29.2%) in their sixties ($P < 0.001$) (Table 1).

Among the patients in the positive-family-history group, the median age at diagnosis in the HBV-positive patients (*n* = 136) *vs* the HBV-negative patients (*n* = 29) was 52 *vs* 57, respectively; this difference was not sig-

nificant ($P = 0.065$). HBV-positive patients were most frequently diagnosed with HCC in their fifties (*n* = 56, 41.2%), followed by their forties (*n* = 39, 28.7%). The median age at diagnosis in the HCV-positive patients (*n* = 18) *vs* the HCV-negative patients (*n* = 147) was 54 *vs* 52 years, respectively; this difference also failed to reach statistical significance ($P = 0.629$) (Table 2).

Risk factors: HBV and HCV were two important causes of HCC development with or without a family history of HCC. Among patients with a positive family history, 135 cases were caused by HBV infection only, and 16 cases were caused by HCV only; one patient had both HBV and HCV infections (Table 1). In the negative-family-history group, 1548 (74.5%) cases were caused by HBV infection, followed by 280 (13.5%) cases of HCV infection, and these percentages were not significantly different from those found in the positive-family-history group ($P = 0.236$) (Table 1).

Among those with a positive family history of HCC, the median age at diagnosis of 136 patients with HBV infection was 52 years (range: 30-78 years), whereas that of 29 patients without HBV infection was 57 years (range: 29-79 years) ($P = 0.132$). With regard to HCV infection among those with a positive family history, the median age at diagnosis was 54 years (range: 29-75 years) in the HCV-infected group and 52 years (range: 30-79 years) in the HCV-noninfected group ($P = 0.562$) (Table 2).

Staging at diagnosis: HCC staging was based on a modified UICC staging system, with UICC stages IVa and IVb defined here as stage IV. Stages Ⅰ, Ⅱ, Ⅲ and IV included 18 (10.9%), 54 (32.7%), 38 (23.0%) and 55 (33.4%) patients, respectively, in the positive-family-history group, and 167 (8.0%), 602 (29.0%), 610 (29.4%) and 698 (33.6%) patients, respectively, in the negative-family-history group ($P = 0.221$). When the stages were reclassified into earlier (stages Ⅰ and Ⅱ) *vs* advanced stages (stages Ⅲ and IV), the early and advanced stages included 72 (43.6%) and 93 (56.4%) patients in the positive-family-history group and 768 (37.0%) and 1308 (63.0%) patients in the negative family history group ($P = 0.090$), respectively.

HBV infection and family history of HCC

As shown in Table 3, 1711 patients had HBV infections, and 134 (7.8%) of these had a positive family history of HCC. The median age of these 134 patients was 52 years (30-78 years), and among those without a family history (*n* = 1577, 92.1%), the median age was 57 years (range: 18.0-89.0 years), showing a significant statistical difference between the two groups ($P < 0.0001$). Among 529 patients without HBV infection, 29 (5.5%) had a positive family history of HCC, and their median age was 57 years (range: 29-79 years), whereas the remaining 500 patients without a family history had a median age of 61 years (range: 22-88 years) ($P = 0.164$). The patients were then divided into two groups based on age: a younger group (ages under 45 years) and an older group (ages 45 years or more). Among the HBV-positive patients, the numbers

HBV: Hepatitis B virus; HCV: Hepatitis C virus; FHx: Family history.

of patients in the younger group with positive and negative family histories were 26 and 197, respectively, *vs* 110 and 1380, respectively, in the older group (*P* = 0.028). In the HBV-negative group with 529 patients, no significant difference was observed between the younger and older groups either in positive- (5 *vs* 24) or negative-family-history group (57 *vs* 443).

Considering the tumor staging at diagnosis, the numbers of patients with HBV infection and a positive family history were 17 (12.5%), 46 (33.8%), 26 (19.1%) and 47 (34.6%) in stages Ⅰ, Ⅱ, Ⅲ and Ⅳ, respectively. These frequencies were significantly different (*P* = 0.018) from those among patients with HBV infection and a negative family history, for whom the corresponding numbers were 122 (7.7%), 443 (28.1%), 473 (30.0%) and 539 (34.2%). The patients without HBV infection and with a positive family history at each stage numbered 1 (3.2%), 8 (25.8%), 12 (38.7%) and 8 (32.3%), and those without HBV infection and with a negative family history numbered 45 (9.0%), 159 (31.8%), 137 (27.4%) and 159 (31.8%) in stages Ⅰ, Ⅱ, Ⅲ and Ⅳ, respectively (*P* = 0.425).

DISCUSSION

This is the first extensive investigation of the relationship between a family history of HCC and the risk of HCC development in Korea, with further considerations regarding major risk factors for HCC development. We observed that 7.4% (*n* = 165) of 2242 patients with HCC reported having a positive family history of HCC.

The most significant finding in this study was that the median age at diagnosis was 5 years younger among patients with a positive family history than among those with a negative family history (*P* < 0.0001). Also, the age distribution was significantly different between the groups (Table 1, *P* < 0.001). The age at diagnosis of HCC had been analyzed in a previous study evaluating the association of family history of liver cancer with HCC development in the United States, but in that study, the mean age at diagnosis in patients with a positive family history (mean age: 64.1 years, *n* = 21) and in patients without a

family history (mean age: 59.9 years, *n* = 156) did not differ significantly (*P* = 0.1)[12,21]. It was said that the lack of significant association between HCC and affected parents or offspring in the study can be related to the small numbers[12]. On the other hand, the age difference of 5 years was significant in our study, and was younger in patients with a positive family history, we conclude that the significance was partly influenced by the large number of cases recruited in our study. Considering only the HBV-positive patients, we observed that the age at diagnosis was also significantly younger by 5 years in patients with a positive family history of liver cancer compared with those with a negative family history (*P* < 0.0001). This may be a natural corollary, as several reports have reported an association between the development of HCCs in infants and children and vertical transmission of HBV[22,23]. From these observations, we also concluded that the age of diagnosis with HCC may be influenced by the family history of HCC regardless of whether it is related to HBV infection and that infection with HBV earlier in life is not the only factor affecting the earlier development of HCC in HBV endemic regions[24-26]. This may also imply that a person with a history of HCC in any family member should pay special attention to screening for the development of HCC. Still, the effects of genetic backgrounds in these patients remain to be evaluated in the future.

The age recommendation for HCC surveillance in Asian males with HBV is over 40 years, and the recommendation for Asian females is over 50 years[3,4,16,27]. In our study, when the HBV-positive patients were grouped into younger (ages under 45 years) *vs* older (ages 45 years or more) age groups, the patients with positive family histories were diagnosed with HCC at earlier ages compared with those with negative family histories (*P* = 0.042). These results are not surprising and support the common assumption that prolonged exposure to HBV seems to be a possible explanation for a relatively earlier occurrence of HCC[21,25,26,28-32].

Another important finding in this study was the significant association between tumor staging at diagnosis and positive family history among HBV-infected patients

($P = 0.018$). Because HBV is the most common risk factor for HCC, and the vertical transmission of HBV is a medical concern in Korea (although well controlled), these findings may suggest that earlier surveillance for HCC, perhaps earlier than typically recommended, in HBV-positive patients with a positive family history of HCC may allow these patients to be diagnosed at earlier stages; this would facilitate better control of HCC and better treatment outcomes in Korean HCC patients[33-35].

Despite the current increased efforts in HBV vaccination and in prevention of vertical transmission in Korea, HBV was the most prevalent hepatitis virus in our study population, as is expected in many Asian countries. This may reflect the effect on HCC development of vertical transmission several decades ago, before vaccination and prevention were available in Korea, and future study results may differ from ours.

This single-hospital-based study has limitations. The first is the limitation on HCC patients studied, as a single hospital cannot represent the whole country; fortunately, the general characteristics of our study subjects were not much skewed compared with other reports on HCC epidemiology in Korean patients[30]. Second, the medical records describing family histories of primary liver cancer were solely dependent on each patient's memory. Also, the data collection was not performed prospectively, but by reviewing the medical records retrospectively, which may have led to some misclassification. Because this was, in part, a cohort study, we restricted the cases to those with clearly detailed medical records to minimize any misleading information. Third, it is possible that the findings may have been influenced by the surveillance program for HBV infection in Korea, which may have assisted in diagnosis at early ages and at early stages of HCC among patients with HBV infection and positive family histories. It is possible that chronic HBV carriers were diagnosed with HCC earlier than are patients without HBV infection because many of them had regular follow-ups at a liver clinic. However, at this point, because a patient would not be able to be diagnosed with HCC if he or she did not visit a doctor, this bias may be unavoidable unless the whole population was examined. Finally, the genetic characteristics of those who develop HCC must be evaluated in the future because not all patients with HBV infection are prone to developing HCC.

In conclusion, a positive family history of liver cancer may influence the age at diagnosis of HCC, and this difference was also in patients with HBV infection. Furthermore, we cautiously recommend more intensive checkups earlier in life and at shorter intervals for patients who have positive family histories of liver cancer, as this may foster detection of HCC at more treatable stages.

ACKNOWLEDGMENTS

COMMENTS

Background
Hepatocellular carcinoma (HCC), which is the fifth most common cancer and the third most common cause of cancer-related death worldwide, has some well known risk factors for its development. The three well-known causes for this devastating disease are hepatitis B virus (HBV), hepatitis C virus (HCV), and alcoholic liver disease. Recent reports showed familial clustering of this disease based on the perinanatal transmission of the HBV.

Research frontiers
Although the clustering of HBV infection among family members, which is related to vertical transmission, was reported to be the major cause associated with family histories of liver cancer and HCC, the family history of liver cancer affecting HCC development and its familial aggregation along with the possible confounding effects of important risk factors remains to be determined.

Innovations and breakthroughs
This extensive investigation revealed a significant finding that the median age at diagnosis of HCC was 5 years younger among patients with a positive family history than among those without a family history of HCC. Another important finding in this study was the significant association between tumor staging at diagnosis and positive family history in HBV-infected patients.

Applications
The study suggests that a positive family history of liver cancer may influence the age at diagnosis of HCC, and cautiously proposed that earlier surveillance for HCC, perhaps earlier than typically recommended, especially in HBV-positive patients with a positive family history of liver cancer may allow these patients to be diagnosed at earlier stages, as this may foster detection of HCC at more treatable stages.

Terminology
Familial clustering of cancers: Whether based on genetic background, environmental factors, or vertical transmission of a particular infection, familial clustering of cancers has been reported in many types of cancer, including pancreas, colon, stomach, lung and breast cancers.

Peer review
In this retrospective study, the authors have evaluated the impact of a positive family history on the development of hepatocellular carcinoma in a group of Korean patients. 7.4% of 2242 patients had a positive family history of HCC. The median age at diagnosis was significantly lower in those that had a positive family history. This result was maintained even after analyzing separately the population with non-HBV etiology. The authors conclude that a positive family history may be associated with earlier appearance of HCC, warranting a stricter surveillance.

Abstract

AIM: To investigate the allele and genotype frequencies and associated risk of interleukin (*IL*)-8 -251T>A polymorphism on colorectal cancer (CRC) susceptibility risk.

METHODS: Peripheral blood samples of 255 normal controls and 255 clinically and histopathologically confirmed CRC patients were genotyped for *IL-8* -251T>A polymorphism employing allele-specific polymerase chain reaction. The relative association of variant allele and genotypes with CRC susceptibility risk was determined by calculating the odds ratios (ORs). Corresponding χ^2 tests on the CRC patients and controls were carried out and 95% confidence intervals (CIs) were determined using Fisher's exact test. The allele frequencies and its risk association were calculated using FAMHAP, haplotype association analysis software.

RESULTS: On comparing the frequencies of genotypes of patients and controls, the homozygous variant AA was significantly higher in CRC patients ($P = 0.002$) compared to controls. Investigation on the association of the polymorphic genotypes with CRC susceptibility risk, showed that the homozygous variant *IL-8* -251AA had a significantly increased risk with OR 3.600 (95% CI: 1.550-8.481, $P = 0.001$). In the case of allele frequencies, variant allele A of *IL-8* -251 showed a significantly increased risk of CRC predisposition with OR 1.32 (95% CI: 1.03-1.69, $P = 0.003$).

CONCLUSION: Variant allele and genotype of *IL-8* (-251 T>A) was significantly associated with CRC susceptibility risk and could be considered as a high-risk variant for CRC predisposition.

INTRODUCTION

Colorectal cancer (CRC), the incidence of which has been increasing worldwide for the past few years, represents a significant cause of morbidity and mortality. CRC develops as a result of progressive accumulation of genetic and epigenetic alterations that lead to a series of histo-

pathological changes, initiated by transition from normal mucosa to adenoma to carcinoma. Excluding inherited types of CRC, the susceptibility of a certain individual to development of sporadic CRC remains largely undetermined. Sporadic CRC is a multifactorial disease, therefore, environmental factors, host genotype and immunological factors all could significantly contribute to initiation and even progression of this malignancy.

Recently, chronic inflammation has been linked to increased risk of various types of cancer[1,2]. Epidemiological observations, animal models and clinical studies have established an association between continuous inflammatory conditions and CRC[1,3,4]. Patients with inflammatory bowel disease (IBD), including Crohn's disease and ulcerative colitis, are at increased risk of developing CRC[5]. The associations between inflammatory response genes and IBD make them attractive candidate susceptibility genes for CRC because approximately 1:6 individuals with IBD are estimated to develop colorectal malignancy[6]. Despite this evidence strongly implicating chronic inflammation as a culprit in colorectal carcinogenesis, surprisingly little research has directly addressed the genetic predisposing factors that mediate inflammatory response and favor CRC development.

Genetic polymorphisms have emerged in recent years as important determinants of disease susceptibility and severity. Polymorphic variants of several genes are thought to play a key role in determining how individuals respond at the cellular level to various environment conditions including inflammation. If inflammation constitutes one of the molecular networks underlying susceptibility to CRC, genes that mediate inflammatory responses might be a group of candidate genes for CRC predisposition. Few genes are known to be important for inflammation of the colorectum, and their allelic variants have been shown to have biological effects[7,8]. Interleukin (*IL*)-8 is a chemokine and one of the major mediators of inflammatory responses, and is believed to play a role in the pathogenesis of cancer. Several polymorphisms have been detected in the *IL-8* gene, and a common polymorphism at the -251 position (251T>A) of the promoter region has been associated with transcriptional activity of the gene. A case-control study was designed to investigate the *IL-8* -251T>A polymorphic allele and genotype frequencies in healthy controls and sporadic CRC patients in the Malaysian population, and to determine the influence of the polymorphic genotype of *IL-8* -251T>A on sporadic CRC susceptibility risk.

MATERIALS AND METHODS

Recruitment of subjects

The study was approved by the Research Review Board and Ethics Committee of Universiti Sains Malaysia and Ministry of Health (MOH) Malaysia. In this case-control study, cases comprised 255 CRC patients (139 male and 116 female), recruited from Hospital Universiti Sains Malaysia, and from a few hospitals under the MOH, Malay-

Table 1 Distribution of sex and age in cases and controls

	Patients	Controls
Sex, *n* (%)		
Female	116 (45.5)	140 (54.9)
Male	139 (54.5)	115 (45.1)
Age (mean ± SD)	57.26 ± 7.074	48.91 ± 12.020

sia like Hospital Sultanah Bahiyah, Alor Setar, Kedah and Hospital Raja Perempuan Zainab Ⅱ, Kota Bharu, Kelantan, Malaysia. An equal number of sex- and age-matched (± 5-10 years) normal healthy individuals (115 male and 140 female) were also recruited as controls. The ages of the patients ranged from 27 to 77 years with a mean age of 57.26 years. For the controls, the age ranged from 33 to 78 years with a mean age of 48.91 years. The sex and age distribution of the study subjects are shown in Table 1.

DNA extraction

Peripheral blood samples of 255 normal controls and 255 clinically diagnosed and histopathologically confirmed CRC patients were collected in EDTA tubes, after obtaining written informed consent. The collected samples were stored at -20 ℃ till use. Genomic DNA was extracted using commercial DNA extraction kit (QIAGEN, Hilden, Germany) and the gene of interest was amplified using appropriate primers. Single nucleotide polymorphism -251 T>A in the *IL-8* gene was determined using allele-specific polymerase chain reaction (PCR).

Genotyping

For genotyping, the allele-specific primers used were 5' -CCACAATTTGGTGAATTATCAAT-3' and (251A) or 5'-TGCCCCTTCACTCTGTTAAC-3' (251T). The consensus primer used was 5'-TGCCCCTTCACTCTGT-TAAC-3' (giving a PCR product of 366 bp). The *IL-8* -251T>A polymorphic sequence was amplified using PCR with composition master mix using 100 ng DNA template, primer (0.2 μmol/L), 2.0 mmol/L MgCl2, 10 × buffer, 10 mmol dNTP (0.2 μL) and 5 U *Taq* DNA polymerase (Applied Biosystems, Foster City, CA, United States) with a total volume of 25 μL PCR mixture. The annealing temperature was 56.7 ℃, and 35 PCR cycles were carried out. The PCR products were isolated on 2% agarose gels and visualized with SYBR Green. The *IL-8* -251T>A polymorphic genotypes were categorized into homozygous wild, heterozygous and homozygous variant.

Statistical analysis

The difference in various genotype frequencies of *IL-8* among the cases and controls was calculated. The relative associations of various genotypes with CRC susceptibility risk was determined by calculating the odds ratios (ORs). Corresponding χ^2 tests on the CRC patients and controls were carried out and 95% confidence intervals (CIs) were determined using Fisher's exact test. Statistical analysis was carried out using SPSS version 18. The allele frequen-

Figure 1 Various interleukin-8 -251T>A genotype patterns in sporadic colorectal cancer patients observed after genotyping using allele-specific polymerase chain reaction. The genotype was considered as homozygous wild type [interleukin (*IL*)-8 -251TT] when only one band appeared at the T allele. When two bands appeared, each at the A allele and T allele, it was considered as heterozygous variant (*IL-8* -251TA). The homozygous variant genotype was characterized by the appearance of only one band at the A allele. M: DNA ladder; 1: Homozygous wild type (*IL-8* -251TT); 2: Heterozygous (*IL-8* -251TA); 3 and 4: Homozygous variant (*IL-8* -251AA).

cies and risk associations were calculated using FAMHAP, haplotype association analysis software to derive ORs.

RESULTS

Visualization of PCR product of IL-8 -251T>A

Various *IL-8* -251T>A genotype patterns in CRC patients in the Malaysian population are showed in Figure 1. A sample was considered as homozygous wild type (*IL-8* -251TT) when only one band appeared at the T allele. When two bands appeared at both the T allele and A allele, it was considered as heterozygous variant (*IL-8* -251TA). For the homozygous variant genotype (*IL-8* -251AA), only one band appeared at the A allele.

Frequencies of IL-8 -251T>A genotypes in CRC cases and controls

The frequencies of *IL-8* -251T>A genotypes in cases and controls are shown in Table 2. Among the 255 controls, the homozygous wild TT genotype was observed in 54 (21.18%), the heterozygous TA genotype was observed in 189 (74.12%) and the homozygous variant genotype AA was detected in 12 (4.7%) individuals. In the case of 255 CRC patients, 40 (15.69%) showed homozygous wild-type TT genotype (15.69% *vs* 21.18%, *P* = 0.11), 183 (71.76%) showed heterozygous variant TA genotype (71.76% *vs* 74.12%, *P* = 0.55), and 32 (12.55%) showed homozygous variant AA genotype. On comparing the frequencies of the polymorphic genotypes among the cases and controls, the homozygous variant genotype frequency was significantly higher among CRC cases (12.55% *vs* 4.7%, *P* = 0.002).

Association risk of IL-8 -251T>A genotypes with CRC susceptibility

Table 2 shows the associated risk of *IL-8* -251T>A genotypes with CRC susceptibility in this population. When the association of the polymorphic genotypes with CRC susceptibility risk was investigated, the *IL-8* homozygous variant genotype (AA) showed significantly increased risk with OR 3.600 (95% CI: 1.550-8.481, *P* = 0.001).

	Patients	Controls	OR (95% CI)	*P* value
IL-8 genotype				
Wild type -251TT	40 (15.69)	54 (21.18)	[1] (Ref.)	-
Hetero -251TA	183 (71.76)	189 (74.12)	1.307 (0.808-2.117)	0.250
Variant -251AA	32 (12.55)	12 (4.7)	3.600 (1.550-8.481)	0.001
Allele				
Wild type	263 (51.6)	297 (58.2)	0.76 (0.59-0.97)	-
Variant	247 (48.4)	213 (41.8)	1.32 (1.03-1.69)	0.003

Table 2 Association risk and frequencies of T and A alleles of interleukin-8 -251T>A genotypes with colorectal cancer susceptibility

IL-8: Interleukin-8; OR: Odd ratio; CI: Confidence intervals.

Allele frequencies and risk association of inflammation response genes with CRC susceptibility

The allele frequencies and risk association of T and A alleles in cases and controls in the Malaysian population are showed in Table 2. The frequency of wild-type allele T was 51.6% and the frequency of variant allele A was 48.4% among the CRC cases. In the case of controls, the frequency of the wild-type allele T was 58.2% and 41.8% showed variant allele A. When the risk association of variant allele was examined, variant allele A of *IL-8* showed a significantly higher risk with OR 1.32 (95% CI: 1.03-1.69, *P* = 0.003).

The patient group included patients from different parts of Malaysia and so the clinicopathological features of many of these patients could not be collected. Therefore, these details could not be specified. For the same reason, the association of genotype frequencies with patient prognostic subgroups could not be evaluated.

DISCUSSION

Inflammation, which is part of the immune response, may also induce or exaggerate some diseases through production of proinflammatory cytokines. Inflammatory cytokines are major inducers of chemokines that play a central role in leukocyte recruitment to sites of inflammation. Chemokines have pleiotropic biological effects that can play several roles in cancer progression, including angiogenesis, inflammation, cell recruitment and migration. *IL-8* or chemokine CXC ligand 8 is the prototype member of the CXC chemokine family. Evidence has shown that the individual level of cytokine production is affected by single nucleotide polymorphisms in cytokine genes, and the observed differences in cytokine production among individuals can be at least partially explained by gene polymorphisms. Genetic polymorphisms might directly influence inter-individually in the magnitude of inflammatory response, and this might contribute to an individual's ultimate clinical outcome. Genetic polymorphisms of cytokine genes have been identified to play a role in susceptibility to various diseases including cancer[9]. A common polymorphism in the -251 position (251T>A) of the promoter region of *IL-8* has been identified.

We investigated the frequencies and potential risk mo-

dification of *IL-8* -251T>A polymorphic genotype and allele on CRC susceptibility in the Malaysian population. Compared to controls, the prevalence of homozygous variant AA genotype was significantly higher in CRC patients (4.70% *vs* 12.55%, *P* = 0.002), whereas for the homozygous wild-type genotypes (TT) and heterozygous variant genotypes (TA), there was no significant difference in frequencies between the two groups. In a study by Yang *et al*[10], on the association of *IL-8* -251T>A polymorphism with prostate cancer, there was no significant difference in the distribution of *IL-8* polymorphic genotypes between prostate cancer cases and controls.

It has been suggested that *IL-8* and its receptors are crucial to the development and progression of many malignancies[11]. Genetic polymorphisms of the *IL-8* gene have been implicated in the susceptibility to a range of cancers including oral cancer[12], breast carcinoma[13] and gastric cancer[14]. Our interest was to investigate whether the genetic variants are related to the CRC risk in the Malaysian population. Our results showed that the polymorphism in the *IL-8* gene was significantly associated with the risk of CRC. The -251AA genotype was associated with a significantly increased risk of CRC as compared with the -251TT genotype (OR: 3.600, 95% CI: 1.550-8.481, *P* = 0.001). Similarly, for allele frequencies, such an association was observed. When compared with wild-type allele T of SNP *IL-8* -251, the variant allele A *IL-8* -251 showed significantly increased risk for CRC predisposition with OR 1.32 (95% CI: 1.03-1.69, *P* = 0.003). The strong association that we observed in CRC patients prompts us to suggest that *IL-8* gene -251AA polymorphism could contribute significantly to CRC susceptibility.

A few other molecular genetic epidemiological studies in diverse ethnic populations have found consistent as well as inconsistent results with ours. The *IL-8* -251T>A polymorphism has been associated with the risk of gastric cancer and gastric ulcer in Japanese patients with *Helicobacter pylori* infection[15]. Taguchi *et al*[14] also have reported that *IL-8* -251T>A polymorphism is associated with higher expression of *IL-8* protein, more severe neutrophil infiltration, and increased risk of atrophic gastritis and gastric cancer in the Japanese population. In the study of Gunter *et al*[16], homozygous variant genotype of the *IL-8* -251T>A had a 2.7-fold increased risk of colorectal adenoma compared to the homozygous wild type in the American population. In the French population, Küry *et al*[17] have reported that the heterozygous and homozygous variants of *IL-8* c -352 T>A are associated with an elevated risk of CRC compared to the homozygous major genotype. Li *et al*[18] have found that the risk of gastric cancer in the Chinese population is significantly elevated in patients with the *IL-8* -251AA genotype with OR 2.02 (95% CI: 1.27-3.21). In contrast with our study, Landi *et al*[19] have reported that the *IL-8* -251T>A genotypes have a protective role against CRC predisposition in the Spanish population, and Theoropoulus has reported that this SNP has no effect on CRC

susceptibility risk in the Greek population[8]. A few other studies have suggested that the *IL-8* -251AA genotype is associated with an increased risk of prostate cancer in the Caucasian population[20] and Kaposi's sarcoma in the Dutch population[21], but a decreased risk of CRC[4].

The 251T>A polymorphism at the promoter region of *IL-8* gene is associated with the transcriptional activity of the gene[22], and to influence production and expression of *IL-8*[14,15]. Disrupted gene expression or altered protein formation of the *IL-8* gene may contribute positively or negatively to the establishment or progression of CRC. According to Wei *et al*[22], higher promoter activity of *IL-8* -251AA polymorphism might increase production and expression of *IL-8*, inducing a Th1-predominant immune response and leading to more susceptibility to CRC.

Free radicals generated as a result of oxidative stress produced by inflamed tissues may cause alteration in many metabolic reactions such as regulation of DNA, RNA and lipids, and thus can lead to cancer development[23,24]. Meira *et al*[25] have demonstrated that in inflamed colon cancer tissues, reactive oxygen species (ROS) and reactive nitrogen species are produced from activated inflammatory cells, and that these two species enhance DNA damage and this can cause mutation in areas of inflammation. Moreover, in CRC-associated colitis, chronic inflammation has been reported to cause oxidative damage to DNA, influence mutations in the *p53* gene in the inflamed tissues, and drive the cells to malignant transformation[26]. Oxidative stress produced by inflammatory cells in inflamed tissues in the intestinal tract has been reported to influence the development of CRC in patients with IBD[27]. These studies have clearly highlighted the importance of *IL-8* in modulating inflammation of the colorectum. According to Okada *et al*[28], ROS produced by inflammatory cells cause not only direct DNA damage but also indirect effects such as dysregulation of cell proliferation and apoptosis, stimulation of angiogenesis, and modification of gene/protein expression and protein activities that will cause cancer. Therefore, the relevance of *IL-8* -251T>A polymorphism in CRC susceptibility could be explained by the enhanced transcriptional activity of the gene, resulting in functional alteration of the gene product.

To the best of our knowledge, this is the first study on the association of the *IL-8* gene -251 T>A polymorphism and CRC risk in the Malaysian population. Our results show that the genetic variation of *IL-8* gene influences susceptibility to CRC in the Malaysian population, and suggest inflammation-mediated pathways in the process of colorectal carcinogenesis.

COMMENTS

Background

Colorectal cancer (CRC), the incidence of which has been increasing worldwide for the past few years, represents a significant cause of morbidity and mortality. Genetics has a key role in predisposition to CRC and in its initiation and progression. Identifying predisposing genetic variations is important for our understanding of the carcinogenic process. Recently, chronic inflammation has been linked to increased risk to various types of cancer including CRC. Despite evidence strongly implicating chronic inflammation as a culprit in colorectal carcinogenesis, surprisingly little research has directly addressed the genetic predisposing factors that mediate inflammatory response and favor CRC development. Thus, it was of interest to explore the contribution of single nucleotide polymorphisms (SNPs) in inflammation genes as predisposing factors for CRC susceptibility.

Research frontiers

If inflammation constitutes one of the molecular networks underlying susceptibility to CRC, genes that mediate inflammatory response might be a group of candidate genes for CRC predisposition. Interleukin (IL)-8 is a chemokine and one of the major mediators of inflammatory responses, and is believed to play a role in the pathogenesis of cancer. IL-8 is a proangiogenic cytokine that is overexpressed in many human cancers and its expression promotes tumor growth, angiogenesis and metastasis. A polymorphism at -251 position (251T>A) of the promoter region of IL-8 has been associated with transcriptional activity of the gene. This study was designed to determine the frequencies and influence of the *IL-8* -251T>A polymorphic genotype and alleles on sporadic CRC susceptibility risk in the Malaysian population.

Innovations and breakthroughs

There are not many data available on the contribution of SNPs in inflammation response genes in mediating CRC predisposition risk, especially from the Asian population, and none from the Malaysian population. This is believed to be the first report of an association of genetic variation of *IL-8* with CRC susceptibility risk in the Malaysian population. We observed that the genetic diversity of the *IL-8* gene influences patient susceptibility to CRC and implies the importance of inflammation-mediated pathways in the process of colorectal carcinogenesis. From our results, it is reasonable to pronounce that *IL-8* gene may be an important candidate in the modulation of colorectal inflammation and the *IL-8* 251AA (homozygous variant genotype) could be considered as an important high-risk variant for CRC predisposition in the Malaysian population.

Applications

Early diagnosis is important for successful management of CRC patients and is facilitated by both invasive and noninvasive means of surveillance. Identification of genetic predisposition factors of CRC will help with better understanding of the colorectal carcinogenic process and in the design of diagnostic, therapeutic and preventive strategies. Understanding the genes and pathways that control the earliest steps of the disease and individual susceptibility can contribute to clinical management in the near future. In the future, study can be extended to a population level and individuals with high-risk predisposition genotypes can be identified. Once identified, they can be enrolled in cancer surveillance programs that will help in CRC prevention strategies.

Peer review

In this case-control study to determine the influence of the polymorphic genotype on sporadic CRC susceptibility risk in the Malaysian population, the *IL-8* -251T>A polymorphic allele and genotype frequencies were evaluated in 255 patients with sporadic CRC and 255 normal healthy controls. The frequency of the homozygous variant AA was significantly higher in CRC patients compared to controls. Furthermore, the homozygous variant *IL-8* -251AA was significantly associated with increased risk of CRC predisposition. This study is of interest because previous studies on the relationships between *IL-8* -251T>A polymorphism and CRC have yielded contradictory results.

Abstract

AIM: To determine whether *Helicobacter pylori* (*H. pylori*)-infected children have reduced body weight (BW) and height (BH) growth, and if *H. pylori* eradication may restore growth while improving serum acylated ghrelin.

METHODS: This longitudinal cohort study with one-year follow-up enrolled 1222 children aged 4 to 12 years old into an observation cohort (18 with and 318 without *H. pylori*) and intervention cohort (75 with and 811 without). The 7-d triple therapy was used for eradication in the intervention cohort. The net increases of BW and BH as well serum acylated ghrelin after one-year follow-up were compared between successful eradicated *H. pylori*-infected children and controls.

RESULTS: In the observation cohort, the *H. pylori*-infected children had lower z score of BW (-1.11 ± 0.47 *vs* 0.35 ± 0.69, *P* = 0.01) and body mass index (BMI) (0.06 ± 0.45 *vs* 0.44 ± 0.73, *P* = 0.02) at enrollment and lower net BW gain after one-year follow-up (3.3 ± 2.1 kg *vs* 4.5 ± 2.4 kg, *P* = 0.04) than the non-infected controls. In the intervention cohort, the *H. pylori*-infected children had lower z score of BMI (0.25 ± 1.09 *vs* 0.68 ± 0.87, *P* = 0.009) and serum acylated ghrelin levels (41.8 ± 35.6 pg/mL *vs* 83.6 ± 24.2 pg/mL, *P* < 0.001) than the non-infected controls. In addition to restoring decreased serum ghrelin levels (87.7 ± 38.0 pg/mL *vs* 44.2 ± 39.0 pg/mL, *P* < 0.001), the *H. pylori*-infected children with successful eradication had higher net gains (*P* < 0.05) and increase of z scores (*P* < 0.05) of both BW and BH as compared with non-infected controls after one-year follow-up.

CONCLUSION: *H. pylori*-infected children are associated with low serum acylated ghrelin and growth retardation. Successful eradication of *H. pylori* restores ghrelin levels and increases growth in children.

Yang YJ, Sheu BS, Yang HB, Lu CC, Chuang CC. Eradication of *Helicobacter pylori* increases childhood growth and serum acylat-

INTRODUCTION

Primary infection with *Helicobacter pylori* (*H. pylori*) usually occurs during childhood[1]. This organism has been proven to cause chronic gastritis, peptic ulcer diseases, and had a high correlation with gastric cancer in humans[2,3]. In children, the *H. pylori* prevalence rate was relatively lower than adults[4,5]. Besides the link with gastric diseases, the association between *H. pylori* infection and growth retardation in children has raised clinical attention to this issue and caused some debate recently. Some cross-sectional analyses have indicated that *H. pylori*-infected children had subnormal growth retardation as compared with non-infected children[6-8], but some others did not support such findings[9,10]. Long-term observational studies have reported that children with persistent *H. pylori* infection have reduced body weight (BW) and height (BH) growth than the non-infected peers[11-13]. Therefore, to further support the causal relationship between *H. pylori* infection and growth retardation in children, interventional trials involving *H. pylori* eradication may provide new insights using a rigorous study design.

Ghrelin, a growth-hormone-releasing peptide biosynthesized mainly in the fundic mucosa, regulates appetite and body composition and is affected by inflammatory and atrophic events associated with *H. pylori* infection[14,15]. Previous studies showed conflicting results regarding the correlation between plasma ghrelin levels and *H. pylori* infection after eradication of bacteria[16-18]. This controversy may be caused by the measurement of total plasma ghrelin, which contains both acylated and desacylated forms. Acylated ghrelin is a more potent agonist on the growth-hormone-stimulating receptor than the desacylated form and undergoes a compensatory elevation in patients with chronic atrophic gastritis[19-21]. This study seeks to examine active ghrelin levels and its relationship with growth in patients before and after *H. pylori* eradication.

Although eradication of *H. pylori* can restore body mass index (BMI) and serum albumin in adult patients with infection[22,23], such improvement has not yet been documented in *H. pylori*-infected children. Moreover, it is unclear whether the improving growth parameters after *H. pylori* eradication are subsequently linked to increase serum acylated ghrelin levels. Therefore, this study sought to examine whether *H. pylori* eradication improves BW and BH growth in children in parallel with increases in serum acylated ghrelin levels.

MATERIALS AND METHODS

Subject enrollments in the two cohorts

This study enrolled 1292 students, aged 4 to 12 years old from three elementary schools and their associated pre-

school kindergartens in Tainan City, Taiwan. The participants were consecutively enrolled into two study cohorts. Each participant provided informed consent documentation that was signed by her/his parents.

The first cohort (observation cohort) enrolled 400 children in 2005 to screen for the *H. pylori* infection, and they were then scheduled to return for follow-up growth status by a half-year interval of up to one year. The second group was an interventional cohort which enrolled 892 children in 2006 to screen for the *H. pylori* infection. Moreover, the *H. pylori*-infected subjects were invited to receive one-week of triple therapy for *H. pylori* eradication. As well, the children in the 2nd cohort were scheduled to return for follow-up growth status by a half-year interval of up to one year.

In each cohort, both the enrolled children and their parents were reviewed with a questionnaire to record data on underling medical diseases, *H. pylori* infection status, and a range of demographic variables, including socio-economic status, such as number of family members[8], and annual household income (low income indicated less than $15 000 US/year). The same nursing assistant provided the introduction of questionnaire to the enrolled subjects. Children with pre-established and severe medical/organic conditions predisposing to the failure of thrive, such as genetic/metabolic disorders and cyanotic congenital heart diseases, were not included. The study also excluded children with a known past history to receive anti-*H. pylori* therapy and children underwent eradication therapy or acid suppressors, during the follow-up period in the observation group. In both groups, the control cases were randomly selected (1:4 in the observation and 1:3 in the interventional cohorts) and were matched by age and gender to children with ^{13}C-labeled urea breath test (^{13}C-UBT)-confirmed *H. pylori* infection. Moreover, for the *H. pylori*-infected (confirmed by a positive ^{13}C-UBT) children at entry, the *H. pylori* status was assessed with a ^{13}C-UBT after 6 mo (intervention cohort) and one year follow-up (both cohort).

BMI and z scores of weight, height and BMI

For each participant, the overnight fasting BW and BH were serially measured at enrollment and at the follow-up period on the 6th mo and the 12th mo, respectively. The BMI was defined as BW in kilograms/squared of body length in meter (kg/m^2). The z scores (SD scores) of BW, BH and BMI were calculated using the reference population of 2003 Taiwanese boys and girls based on health-related physical fitness and based on 2006 World Health Organization standards[24]. The net changes of BW, BH and BMI were calculated by the value of each parameter at follow-up minus the corresponding value at enrollment. We also defined the increase of z score means that z scores of BW, BH and BMI were upgrade at the one-year follow-up than at the enrollment (the net change > 0).

Serological screening of H. pylori infection and confirmation by urea breath test

In each enrolled child, the serum was tested for anti-*H. pylori*

Figure 1 The study flow diagram and the case numbers were listed for the different study follow-up periods. *H. pylori*: *Helicobacter pylori*; [13C]-UBT: [13C]-labeled urea breath test.

IgG antibodies (HEL-p TEST™ Ⅱ, AMRAD Bio-tech, Australia) by enzyme-linked immunosorbent assay (ELISA) methods. The serologic kit has been validated with a favorable sensitivity and specificity (> 90%) in detecting *H. pylori* infection in our previous studies[25]. The seropositive children further confirmed by [13C]-UBT to diagnose ongoing *H. pylori* infection[8]. The cut-off value of positive [13C]-UBT was defined as excess $^{13}CO_2/^{12}CO_2$ ratio more than 3.5‰[8,26].

Eradication therapy for H. pylori-infected children
For the *H. pylori*-infected children in the intervention cohort, lansoprazole (1 mg/kg per day, max. 30 mg bid), amoxicillin (50 mg/kg per day, max. 1 g bid), and clar-ithromycin (15 mg/kg per day, max. 500 mg bid) were prescribed for one week[26]. We have educated the partici-pants and their parents for the compliance and report of complications. Successful eradication therapy was defined by a negative result of [13C]-UBT on both the 6th and the 12th mo follow-up, respectively[27].

Serial serum acylated ghrelin levels before and after H. pylori eradications
The serum acylated ghrelin levels of the interventional cohorts at enrollment were compared between children with and without *H. pylori* infection. In addition, the serial serum acylated ghrelin levels of the children with *H. pylori* eradication collected at enrollment, the 6th mo, and the 12th mo follow-up were compared. Each blood sample of child was collected in the morning before breakfast and was incubated in the ice-bath container immediately. The sera were separated by centrifugation within 2-3 h and were stored in a -80 ℃ refrigerator until use. These samples' serum acylated ghrelin levels were analyzed in duplicate by a commercial kit (LINCO Research, St. Charles, Missouri, United States), using ELISA methods.

Statistical analysis
The χ^2 test with the odds ratio (OR) and 95% conference interval (CI) and logistic regression test were applied as an estimate of the possibly related factors between *H. pylori*-infected and non-infected children. The Student's *t* test and one-way analysis of variance with least significant dif-ference test correction were used as appropriate to com-pare the differences of ghrelin, BW, BH, BMI and their net changes during one-year follow-up periods among different study groups. The paired *t* test was used to ana-lyze the difference of the serial serum acylated ghrelin levels before and after eradication therapy within the same study group. A *P* value less than 0.05 was consid-ered statistically significant.

RESULTS
Participants and H. pylori infection
There were 84% (336/400) children in the observation and 99% (886/892) children in the intervention cohorts who completed the questionnaires and provided their sera for the anti-*H. pylori* IgG antibodies tested, respec-tively. In Figure 1, the case numbers of each cohort were serially summarized during the one-year follow-up. One hundred and twenty-one (27 in the observation cohort, 94 in the intervention cohort) were defined with sero-positivity of *H. pylori* infection. Among them, 113 chil-dren received [13C]-UBT, of which only 93 (82%) children were positive (18 in the observation cohort and 75 in the intervention cohort). Accordingly, the overall *H. pylori* prevalence was 7.6% in these two cohorts.

For the 18 *H. pylori*-positive children in the observation cohort, the infection was persisted with a positive [13C]-UBT until the end of follow-up on the 1st year. Among the 75 *H. pylori*-infected children in the intervention co-hort, 57 children were enrolled to receive the 7-d eradica-

Low income: Indicated < $15000 US/year. Increase of z score means that z scores of body weight, height and body mass index (BMI) were upgrade at the one-year follow-up than at the enrollment (the net change > 0). The difference of the body weight, height, BMI and ghrelin level among the three groups were analyzed by oneway analysis of variance model with least significant difference correction. The difference of the up-shift of the z scores of body weight, height and BMI were analyzed by χ^2 test. [a]*P* < 0.05 between *H. pylori*-positive subjects with eradication failure and controls, [c]*P* < 0.05 between *H. pylori*-positive subjects with eradication success and controls.

tion therapy. A total of 6 subjects withdrew or were lost to follow-up. All of the finally eligible subjects had good drugs compliance (taking drugs at least 6 d) and none had major adverse complications. The intention-to-treat and per-protocol eradication rate of *H. pylori*-infected children were 60% (34/57) and 67% (34/51), respectively.

A lower BW, HW and BMI in the H. pylori infected subject
In the observation cohort, there were 72 age- and gender-matched subjects selected to serve as *H. pylori*-negative controls. In Table 1, the *H. pylori*-infected children had lower BW (29.9 ± 7.0 kg *vs* 35 ± 10.1 kg, *P* = 0.02), z score of BW (-1.11 ± 0.47 *vs* 0.35 ± 0.69, *P* = 0.01), BMI (16.8 ± 1.6 kg/m^2 *vs* 18.4 ± 2.8 kg/m^2, *P* = 0.03) and z score of BMI (0.06 ± 0.45 *vs* 0.44 ± 0.73, *P* = 0.02) than those non-infected controls. Moreover, after one-year follow-up, the *H. pylori*-infected children had a significantly lower BW (33.2 ± 7.5 kg *vs* 39.5 ± 11.3 kg, *P* = 0.007), z score of BW (-0.17 ± 0.45 *vs* 0.38 ± 0.67, *P* = 0.002), BMI (17.2 ± 1.7 kg/m^2 *vs* 19 ± 3.0 kg/m^2, *P* = 0.01), and z score of BMI (0 ± 0.38 *vs* 0.45 ± 0.75, *P* = 0.01) than the non-infected ones. Also in Table 1, there was a significantly lower net BW gain in the *H. pylori*-infected children than that in the non-infected controls (3.3 ± 2.1 kg *vs* 4.5 ± 2.4 kg, *P* = 0.04) after one-year follow-up. However, the net changes of BH, and BMI were not different between the children with and without *H. pylori* infections (*P* > 0.05).

In the intervention cohort (57 *H. pylori*-infected and 153 controls), children with *H. pylori* infection had significantly lower BMI (17.7 ± 3.8 kg/m^2 *vs* 19.0 ± 3.7 kg/m^2, *P* = 0.02) and z score of BMI (0.25 ± 1.09 *vs* 0.68 ± 0.87, *P* = 0.009) than controls at the enrollment. In Table 2, there was no difference with regards to patients' demographic background among the eradication failure, eradication success, and control groups at enrollment. In comparison to the observation cohort, the z score of BMI at enrollment was significantly lower in successful eradication group (0.21 ± 1.14 *vs* 0.68 ± 0.87, *P* = 0.007) than in the non-infected controls. The baseline BW and BH were still lower in the *H. pylori*-infected children (either with eradication success or failure) than in controls, although it is not statistically significant.

Successful H. pylori eradication improves body growth of children within one year
There were 34 children with successful *H. pylori* eradica-

A

B

Figure 2 Comparison of the serum acylated ghrelin levels (mean) at enrollment, at 6th mo and at 12th mo follow-ups between the two groups of *Helicobacter pylori*-infected children with success (A) and with failure (B) of eradication therapy. The significance was analyzed by paired *t* test.

tion and 17 children with failure of who completed the one-year follow-up study. Moreover, we completed the one-year follow-up to the 153 age- and sex-matched non-infected controls. One-year after eradication therapy, the *H. pylori*-infected children with successful eradication had significantly higher net increases of BW (5.84 ± 3.37 kg *vs* 4.84 ± 2.85 kg, *P* = 0.04) and BH (8.00 ± 2.78 cm *vs* 5.85 ± 1.81 cm, *P* < 0.001) than the *H. pylori*-negative controls. Moreover, the rates of increase of z scores of BW (38.2% *vs* 17.6%, *P* = 0.02) and BH (35.3% *vs* 15.7%, *P* = 0.02) were significantly higher in children with successful eradication than controls. We further analyzed the enrolled age as a confounder for the increase of z scores of BW and BH by multiple logistic regression analysis. The results confirmed the successful eradication of *H. pylori* was an independent factor to predict the increase of BW (*P* = 0.01) and BH (*P* = 0.01) in the intervention cohort. Although triple therapy failed to achieve successful eradication, these *H. pylori*-infected children still had a higher net increase of BH (7.20 ± 2.85 cm *vs* 5.85 ± 1.81 cm, *P* = 0.01) than the non-infected controls. However, these *H. pylori*-infected children and non-infected controls had no difference in the net increase of BW (5.03 ± 2.77 kg *vs*

4.84 ± 2.35 kg, *P* = 0.78) and increase of z scores of BW (23.5% *vs* 17.6%, *P* = 0.79) during one-year follow-up.

Lower serum acylated ghrelin correlated to *H. pylori* infection and lower BW

In the intervention cohort, the *H. pylori*-infected children had a significantly lower serum acylated ghrelin level (41.8 ± 35.6 pg/mL *vs* 83.6 ± 24.2 pg/mL, *P* < 0.001) than the controls. In Table 2, at enrollment, both the *H. pylori*-infected children with and without eradication success during follow-up had lower serum acylated ghrelin levels than the non-infected controls (both *P* < 0.001). As the *H. pylori*-infected children exhibited lower BW and lower serum acylated ghrelin, the study further tested whether the children with lower BW, within the age ranges, could have a lower serum acylated ghrelin. We compared the serum acylated ghrelin levels of the children between those with BW and z score of BW above and below the selected cut-off point in the different age ranges (Table 3). Only in the *H. pylori*-infected children with age ranges as 8-12 years, the serum acylated ghrelin level was lower in the children with BW below the cut-off point than that with BW above (23.8 ± 22.1 pg/mL *vs* 51.8 ± 40.9 pg/mL, *P* = 0.02).

Improvement of the serum acylated ghrelin level after eradication therapy

In addition to the baseline serum acylated ghrelin levels, the study subjects of the intervention cohort underwent testing for serial serum acylated ghrelin levels after triple therapy. In Figure 2A, for the children with successful *H. pylori* eradication, the serum acylated ghrelin levels were significantly increased after eradication therapy as early as the 6th mo (88.2 ± 17.3 pg/mL *vs* 44.2 ± 38.1 pg/mL, *P* < 0.001), until the 12th mo (87.7 ± 38.0 pg/mL *vs* 44.2 ± 38.1 pg/mL, *P* < 0.001). In Figure 2B, for the children with failure of *H. pylori* eradication, the serum acylated ghrelin levels could be also significantly increased by eradication therapy at the 6th mo (93.2 ± 31.6 pg/mL *vs* 37.2 ± 30.9 pg/mL, *P* < 0.001) and at the 12th mo (80.6 ± 28.8 pg/mL *vs* 37.2 ± 30.9 pg/mL, *P* = 0.003).

DISCUSSION

Extra-gastric diseases related to *H. pylori* infection are emerging in importance, such as iron deficiency anemia and growth retardation in children[28]. Other studies have argued that lower socioeconomic status is conjunction with the presence of *H. pylori* accounts for poor growth in children[29]. For overcoming the influencing bias of poor socioeconomic status, indicated by low income, to child growth, multiple logistic regression confirmed that *H. pylori* infection was closely related to both z scores of BW and BMI independent to socioeconomic status. Accordingly, the current study should have not encountered significant bias of social backgrounds on growth limitation in children.

Based on the data of the observation cohort, the *H. pylori*-

[1]*P* value	0.68	0.09	0.91	0.15

[1]The *P* value indicated the difference of serum acylated ghrelin levels between the children with body weight (BW) and z score of BW above or equal to the cut-off point and those with below the cut-off point within the same age ranges, analyzed by the Student's *t* test. The BW (z score of BW) cut-off point was determined by the mean (median) of non-*Helicobacter pylori* (*H. pylori*) infected children within the same age ranges.

infected children had significantly lower BW and BMI than gender- and age-matched controls at enrollment. In addition, the BH of *H. pylori*-infected children was 4.5 cm less than that of the non-infected children. After one-year follow-up, the *H. pylori*-infected children had profoundly lower BW, BMI, and net BW gain than the non-infected children. These findings comparing infected and matched disease-free subjects suggest that *H. pylori* infection exerted a negative effect on childhood growth. One possibility is that the presence of *H. pylori* leads to chronic gastric inflammation and thereby decreases food intake[30]. Alternatively, *H. pylori* infection may modify hormones related with the appetite, such as ghrelin[19-21,31,32].

Besides having a lower BW, the *H. pylori*-infected children had a significantly lower baseline serum acylated ghrelin level than that of the gender- and age-matched controls. These data not only suggest a relationship between *H. pylori* infection and lower BW, but that infection is linked to reduced ghrelin levels. Accordingly, it is important to determine whether children with a lower BW had lower serum acylated ghrelin. Supported by the findings in Table 3, only in the *H. pylori*-infected children with age ranging from 8-12 years, the serum acylated ghrelin levels were lower in children with BW below the cut-off point than that with BW above. This finding indicates a lower serum acylated ghrelin, which is induced by the *H. pylori* infection, could be related to induce a lower BW in children aged 8-12 years old.

Eradication of *H. pylori* in symptomatic adult patients has been reported to increase BMI[22,23], and to restore decreased ghrelin levels induced by *H. pylori* infection[16,17]. However, there is still limited evidence to prove such effects in children. Recently, a trial demonstrated *H. pylori* eradication may result in a significant increase in BMI, but with a decrease in the circulating ghrelin levels in a small group of children[33]. Consistent with these findings, our study supported *H. pylori* eradication to address positive impact on the improvement of childhood growth concomitant with an increase of serum acylated ghrelin

level during the one-year long-term follow-up. Therefore, this study is the first to support that *H. pylori* eradication can restore decreased serum acylated ghrelin in children with lower BW. In the future, a longer follow-up study may help to determine whether ongoing elevations in BMI will ultimately lower serum ghrelin via a feedback loop. Our study was nonetheless sufficient to show that within one-year of *H. pylori* eradication, the children could achieve normal growth stature with concomitant restoration of the decreased serum acylated ghrelin induced by the *H. pylori* infection.

Even though some *H. pylori*-infected children had a failure of triple therapy, there was still existed an increase of BW, BH, and serum acylated ghrelin levels at the 6th and the 12th mo. Triple therapy can decrease bacterial loads or gastric inflammation[15,33]. We have analyzed the 51 pairs of ^{13}C-UBT and ghrelin levels (at enrollment, the 6th and 12th mo follow-up) in 17 children with a failure of triple therapy. The result shows the bacterial loads, indicated by the values of ^{13}C-UBT are not correlated well to the ghrelin levels ($r^2 = 0.03$, $P = 0.25$). Therefore, it is possibly due to transient improvement of gastric inflammation to restore serum acylated ghrelin levels. Lack of endoscopic evidence in children with failure of therapy is the limitation in this study. A longer follow-up period is thus needed to clarify this transient improving effect in children with failure of therapy.

In summary, *H. pylori* infection can be associated with decreased serum acylated ghrelin levels, BW and BH in children. Successful *H. pylori* eradication can restore ghrelin levels and the growth of BW and BH in the infected children with growth retardation.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) infection in children causes not only gastric inflammation and peptic ulcer diseases but also extragastric disorder. Longitudinal observational have found that children with persistent *H. pylori* infection have reduced body weight (BW) and height (BH) growth than the non-infected

ones. In addition, previous studies showed conflicting results regarding the correlation between plasma ghrelin levels and *H. pylori* infection after eradication of bacteria. Therefore, long-term follow up the childhood growth as well ghrelin levels in *H. pylori*-infected children after eradication therapy can illustrate the causal relationship between *H. pylori* infection and growth retardation in children.

Research frontiers
Growth retardation in *H. pylori*-infected children without any organic diseases remains controversial for eradication therapy. The authors aimed to establish a new indication for treating *H. pylori* infection in children with growth retardation and to explore the serum acylated ghrelin levels correlated to eradication therapy.

Innovations and breakthroughs
This study demonstrated that *H. pylori* infection can be associated with decreased serum acylated ghrelin levels, BW and BH in children. In the interventional study, successful *H. pylori* eradication can restore serum acylated ghrelin levels and the growth of BW and BH in the infected children with growth retardation at the 1-year follow-up.

Applications
This study confirmed the causal relationship of *H. pylori* infection and childhood growth retardation. Therefore, we supposed that eradication therapy should be considered as a treatment strategy in *H. pylori*-infected children with growth retardation, which was not related to other organic diseases.

Terminology
Growth retardation is indicated by poor BW and BH growth as compared to the age- and gender-matched normal population. Eradication therapy means that a treatment strategy to eradicate *H. pylori* from stomach. The first-line regiment consists of one proton pump inhibitor and two antibiotics.

Peer review
This is an interesting study aimed at determining whether *H. pylori*-infected children have reduced growth rates and lower levels of ghrelin compared to uninfected and if *H. pylori* eradication may reverse those changes. The study is well written and well designed.

Abstract

AIM: To evaluate the sensitivity and specificity of transfesrrin dipstick test (Tf) in colorectal cancer (CRC) screening and precancerous lesions screening.

METHODS: Eight hundreds and sixty-one individuals at high-risk for CRC were recruited. Six hundreds and eleven subsequently received the three fecal occult blood tests and colonoscopy with biopsy performed as needed. Fecal samples were obtained on the day before colonoscopy. Tf, immuno fecal occult blood test (IFOBT) and guaiac fecal occult blood test (g-FOBT) were performed simultaneously on the same stool. To minimize false-negative cases, all subjects with negative samples were asked to provide an additional stool specimen for a second test even a third test. If the results were all negative after testing three repeated samples, the subject was considered a true negative. The performance characteristics of Tf for detecting CRC and precancerous lesions were examined and compared to those of IFOBT and the combination of Tf, IFOBT and g-FOBT.

RESULTS: A total of six hundreds and eleven subjects met the study criteria including 25 with CRC and 60 with precancerous lesions. Sensitivity for detecting CRC was 92% for Tf and 96% for IFOBT, specificities of Tf and IFOBT were both 72.0% (95% CI: 68.2%-75.5%; χ^2 = 0.4, P > 0.05); positive likelihood ratios of those were 3.3 (95% CI: 2.8-3.9) and 3.4 (95% CI: 2.9-4.0), respectively. In precancerous lesions, sensitivities for Tf and IFOBT were 50% and 58%, respectively (χ^2 = 0.8, P > 0.05); specificities of Tf and IFOBT were 71.5% (95% CI: 67.6%-75.1%) and 72.2% (95% CI: 68.4%-75.8%); positive likelihood ratios of those were 1.8 (95% CI: 1.3-2.3) and 2.1 (95% CI: 1.6-2.7), respectively; compared to IFOBT, g-FOBT+ Tf+ IFOBT had a significantly higher positive rate for precancerous lesions (83% *vs* 58%, respectively; χ^2 = 9.1, P < 0.05). In patients with CRC and precancerous lesions, the sensitivities of Tf and IFOBT were 62% and 69% (χ^2 = 0.9, P > 0.05); specificities of those were 74.5% (95% CI: 70.6%-78.1%) and 75.5% (95% CI: 71.6%-79.0%); positive likelihood ratios of those were 2.5 (95% CI: 2.0-3.1) and 2.8 (95% CI: 2.3-3.5). Compared to IFOBT alone, combining g-FOBT, IFOBT and Tf led to significantly increased sensitivity for detecting CRC and cancerous lesions (69% *vs* 88%, respectively; χ^2 = 9.0, P < 0.05).

CONCLUSION: Tf dipstick test might be used as an additional tool for CRC and precancerous lesions screening in a high-risk cohort.

Key words: Transferrin; Immuno fecal occult blood test; Colorectal cancer; Precancerous lesions; Transferrin dipstick test

INTRODUCTION

Colorectal cancer (CRC) is one of the major diseases threatening human health. In the United States, CRC is the third most frequently diagnosed cancer among men and women, and the third leading cause of cancer death[1]. In China, the prevalence of CRC has risen in recent years, possibly attributable to changes in the population's lifestyle and dietary habits[2,3]. In most cases, CRC is believed to arise within precancerous lesions that develop slowly over many years[4,5].

Currently, many tools are be used for CRC screening. CRC screening tests recommended by the American Cancer Society (ACS) can be grouped into 2 categories: (1) tests that primarily detect CRC, which include tests that look for blood, such as guaiac fecal occult blood test and fecal immunochemical test, or exfoliated DNA [single-strand DNA (sDNA)] in stools; and (2) tests that can detect cancer and advanced lesions, which include endoscopic and radiological exams, i.e., colonoscopy, double-contrast barium enema (DCBE), and computed tomography colonography (CTC) (or virtual colonoscopy)[6]. However, these tests all have certain limitations.

Several published randomized trials have showed that the most widely accepted test method, fecal occult blood test (FOBT), can reduce CRC incidence[7] and mortality rate[8]. However, guaiac fecal occult blood test (g-FOBT) has been criticized for its high false positive because it detects non-human haem in food[9,10]. Compared with that of g-FOBT, the sensitivity of immuno fecal occult blood test (IFOBT) is significantly higher[11-13]. IFOBT specifically detects human hemoglobin (Hb) in stool by antibody-antigen reaction, which has no restrictions on diet or drug intake. However, Hb is unstable in feces because it can be degraded by bacteria. Furthermore, Hb can not be used to detect lesions that are not accompanied by bleeding[14-17]. Fecal DNA test was developed based on the molecular genetics of CRC. It is suggested that the occurrence of most CRCs has close relationship with chromosomal instability, with mutations progressively accumulating in the *adenomatous polyposis coli* gene, the p53 tumor-suppressor gene, and the K-ras oncogene[18]. Despite relatively high specificity[19], Fecal DNA test has many problems[20], including the lack of adequate fecal DNA makers, complex extraction steps, and so on. Furthermore, population-based studies showing the capability of the method to decrease mortality of CRC have been lacking[21]. Other non-invasive methods include testing for faecal calprotectin, which has high sensitivity but low specificity[22].

DCBE is a preferred method for screening in children, old people and those who can not undergo colonoscopy. However, its false positive and false negative ratios are both higher than those of colonoscopy[15,23]. Colonoscopy can detect CRC in the entire colonic lumen and is the most sensitive and specific test. A report showed that the incidence and mortality of CRC rate were reduced to 67% and 65%, respectively, after colonoscopy screening in an average-risk cohort[24]. However, colonoscopy is invasive and has risks to certain extent[25]. High costs and painful procedure has prevented colonoscopy from being used as a method for large-scale screening of CRC. Practically it is only used for final diagnostic test of positive patients. In 2008, two additional tests have been added to CRC screening guidelines of the ACS[26]: sDNA and CTC. CTC is a minimally invasive method for examination of the whole colon. It is safe and the entire colon can be examined thoroughly. A recently study shows that for ≥ 10 mm colorectal lesions, the sensitivity of CTC is similar to that of colonoscopy. However, for < 10 mm and flat neoplasms, the sensitivity of CTC is lower than colonoscopy[27]. Additionally, CTC can not perform biopsy and is an expensive procedure. For these reasons, our study sought to develop a method to improve the sensitivities and specificities of CRC and precancerous lesions screening.

Transferrin (Tf), which is present in plasma by the release of neutrophil-specific granules, is undetectable in normal human gastrointestinal tract. Detection of Tf in feces or contents in the stomach indicates bleeding in gastrointestinal tract. Unlike hemoglobin, Tf is resistant to degradation by digestive enzymes and bacteria. Thus, compared to hemoglobin, Tf is more stable in feces[28]. It has been reported that fecal Tf is elevated in patients with colorectal tumor, compared to healthy individuals[29]. Recently, a number of proteomic studies showed that Tf could be used as a marker expressing in a number of cancers[30,31]. Saitoh *et al*[32] and Hirata *et al*[33] compared fecal Tf with IFOBT in clinical studies and found that Tf was as useful as IFOBT in diagnosing colorectal diseases. However, these two studies did not analyze patients with precancerous lesions. Sheng *et al*[34] compared fecal Tf with IFOBT for their sensitivities in detecting CRC and precancerous lesions in CRC patients. However, the subjects of this study were CRC patients, and specificity was not analyzed.

So far, Tf has not been recommended as a method for CRC screening by the ACS. Based on the above studies, we assumed that the sensitivity and specificity of Tf in detecting CRC and precancerous lesions were equal or superior to IFOBT. Using a combination of the three measurements (g-FOBT, Tf and IFOBT) appears to increase the sensitivity of diagnosis in high-risk population. In order to investigate whether Tf can be applied in the screening of CRC and precancerous lesions, we conducted this study to compare the effectiveness of Tf and IFOBT in the detection of colorectal cancer and precancerous lesions.

MATERIALS AND METHODS

Study materials

The stool specimen collection, colonoscopy and pathologic examination were performed in the Eighth Hospital of Wuhan City which is a hospital specializing in anorectal diseases. G-FOBT, IFOBT and Tf kits were purchased from Baso Diagnostics Inc and WHPM Inc.

Study group

From January 2010 to September 2010, 861 subjects at high-risk (a personal history of curative-intent resection of CRC or intestinal polyps; family history of colorectal cancer; having the following two or more: chronic diarrhea, chronic constipation, abdominal pain, dark stool, blood or mucus on stool) were recruited. The inclusion criteria were as following: age over 14 years, male or female. Subjects with age < 14 years were excluded. All participants provided written informed consent and were instructed on diet and drug restrictions three days before and during the period of stool collection.

Fecal samples collection and IFOBT and Tf analysis

All fecal samples were collected the day before colonoscopy and processed in accordance with manufacturer's instructions. We applied the fecal sample on the strip and the result was read out within 5 min (the result was invalid after 5 min). A red bar in control area (C) only was considered as negative. A red bar in both the testing area (T) and the control area (C), was considered as positive. If there was no red bar in the control area(C), the test was considered invalid. Tf, IFOBT and g-FOBT were performed simultaneously on the same stool. To minimize false-negative cases, all subjects with negative samples were asked to provide an additional stool specimen for a second test; if the second test still gave negative result, a third test would be conducted. As long as one of the three tests showed positive results, the subject was considered to have a positive sample. If the results were all negative after testing three repeated samples, the subject was considered a true negative. Approximately 10% of the samples were repeated and the concordance was 100%.

Statistical analysis

The positive rate of Tf alone, IFOBT alone, Tf combined with IFOBT (Tf + IFOBT), Tf and IFOBT combined with g-FOBT (Tf + IFOBT + g-FOBT), as well as their respective specificity, likelihood ratio, odd ratio and 95% confidence interval were calculated to compared the sensitivity of Tf, IFOBT, Tf+ IFOBT and Tf + IFOBT + g-FOBT in detecting CRC and precancerous lesions. χ^2 and McNemar's test were conducted to determine the significance of difference. $P < 0.05$ in a two-tailed test was considered statistically significant. Analyses were performed using SPSS version 17.0.

RESULTS

Subject enrollment flow is described in Figure 1. Of the

Figure 1 Flow diagram of the study. [1]Includes polyps that were less than 3 mm in diameter, broadbased, sessile and fat.

861 participants in this study, 250 subjects who have taken neither FOBTs nor colonoscopy, or have taken only one of the tests were excluded in this survey. Six hundred and eleven subsequently received both FOBTs and colonoscopy with biopsy performed as needed. Among them, 286 were found to have abnormalities by colonoscopy, while 447 were classified as low risk population including no abnormalities (325 cases) and benign lesions (122 cases). Benign lesions included chronic enteritis, chronic schistosomiasis bowel disease, intestinal diverticula, colorectal erosive inflammation (a total of 112 cases) and inflammatory intestinal mucosa by biopsy (10 cases). One hundred and seventy-four subjects were found to have polyps or neoplasm. Pathological examination showed CRC (25 cases), precancerous lesions (60 cases), inflammatory intestinal mucosa (10 cases); Polyps (79 cases) that were less than 3 mm in diameter, broad-based, sessile and flat were not subjected to biopsy. Precancerous lesions included tubular adenoma, villous adenoma, tubular villous adenoma and hyperplastic polyp with moderate-severe dysplasia (with histological confirmation).

The overall demographic information of 611 subjects (Table 1). There were 310 men and 301 women among the participants, with a median age of 50 years (range 14-85 years). Among them, 10 men and 15 women had CRC, with a median age of 62 years; 35 men and 25 women had precancerous lesions, with a median age of 56 years.

The positive rate of g-FOBT, Tf, Tf+ IFOBT, and g-FOBT+ Tf+ IFOBT in fecal samples from five groups of participants is shown in Table 2. In CRC, the positive rates of Tf and IFOBT were 92% and 96%, respectively ($\chi^2 = 0.4$, $P > 0.05$). In precancerous lesions, the positive

Table 1 Patient demographics

Charac-teristic	No. of participants	Colorectal cancer	Precancerous lesions	Polyp	Abnor-mality	Low risk
Total	611	25	60	79	286	447
Sex						
Male	310	10	35	49	152	216
Female	301	15	25	30	134	231
Age, yr						
Median	50	62	56	53	53	48
Range	14-85	39-85	24-84	25-84	17-85	14-81

rates for Tf and IFOBT were 50% and 58%, respectively ($\chi^2 = 0.8$, $P > 0.05$); compared to IFOBT, g-FOBT+ Tf+ IFOBT had a significantly higher positive rate for precancerous lesions (83% *vs* 58%, respectively; $\chi^2 = 9.1$, $P < 0.05$). In CRC and precancerous lesions, the positive rates for Tf and IFOBT were 62% and 69% ($\chi^2 = 0.9$, $P > 0.05$), whereas g-FOBT+ Tf+ IFOBT also provided significantly higher positive rate compared to IFOBT alone (88% *vs* 69%, respectively; $\chi^2 = 9.0$, $P < 0.05$). For Tf alone, a difference in positive rate was observed for detecting CRC and precancerous lesions (92% *vs* 50%, respectively; $\chi^2 = 13.3$, $P < 0.05$).

The performance characteristics of various tests examined by our study (Table 3). For detecting CRC, The specificities of Tf and IFOBT were both 72.0% (95% CI: 68.2%-75.5%); positive likelihood ratios of those were 3.3 (95% CI: 2.8 - 3.9) and 3.4 (95% CI: 2.9-4.0), respectively. For detecting precancerous lesions, specificities of Tf and IFOBT were 71.5% (95% CI: 67.6%-75.1%) and 72.2% (95% CI: 68.4%- 75.8%); positive likelihood ratios of those were 1.8 (95% CI: 1.3-2.3) and 2.1 (95% CI: 1.6-2.7), respectively. For detecting both CRC and precancerous lesions, specificities of Tf and IFOBT were 74.5% (95% CI: 70.6%-78.1%) and 75.5% (95% CI: 71.6%-79.0%); positive likelihood ratios of those were 2.5 (95% CI: 2.0-3.1) and 2.8 (95% CI: 2.3-3.5), respectively. In these tests, the specificity of Tf and IFOBT for detecting CRC was the same. Likelihood ratio can accurately reflect how likely it is that patients with CRC will test positive. The likelihood ratio showed that Tf and IFOBT detected CRC (3.3 and 3.4, respectively) more effectively than they detected precancerous lesions (1.8 and 2.1, respectively).

DISCUSSION

The data from our study demonstrated that the sensitivities and specificities of Tf and IFOBT were similar in the detection of colorectal cancer and precancerous lesions in high-risk cohort. These results suggest that when using Tf alone, the sensitivity and specificity have no visible difference compared to using IFOBT alone; when combining these three methods, the sensitivity can be enhanced.

There had been several comparative studies of Tf and IFOBT previously. Saitoh *et al*[32] found that the sensitivities of Tf and IFOBT for detecting CRC were similar

(53.8% and 61.5%, respectively). The study used enzyme-linked immunosorbent assay (ELISA) kit for fecal Tf and Latex agglutination for IFOBT. Hirata *et al*[33] found that the sensitivities of Tf and IFOBT were both 50%, whereas combining both methods gave a slightly higher sensitivity of 61.1%. The study measured the Tf and Hb quantitatively by sandwich ELISA. Both studies analyzed the sensitivity for detecting colorectal diseases (colon cancer, colorectal polyps, ulcerative colitis, Crohn's disease, *etc.*) but not precancerous lesions. In addition, in both previous studies, each patient was tested only once with one stool specimen. In contrast, our study strove to minimize false negative results by testing up to three stool specimens from a single patient, hence achieving a more accurate estimation of sensitivity. Sheng *et al*[34] found that the positive ratio of Tf and IFOBT for detecting colorectal cancer were 80% and 75%, respectively. For detecting precancerous lesions, the positive ratios were 72% (Tf) and 44% (IFOBT). The difference is statistically significant. Combining the two methods gave a positive ratio of 78% in detecting precancerous lesions. Three possible reasons might explain the differences between Sheng *et al*[34] and our study. First, the tested subjects were different. The previous study tested CRC patients. Our study tested those who are at high-risk. Second, the sample size was different. Our study had 611 samples, compared to 110 in the previous study. Third, the design of the studies was different. The previous study took only one stool specimen from an individual patient and retested the sample if the result was negative. We took at least one specimen from every participant and up to three specimens from those showing negative results. None of the three previous studies analyzed the specificities of colorectal cancer and precancerous lesions detection. The difference in specificity may be caused by variation in other factors, such as degradation of hemoglobin, samples, experiment and the quality of reagents, *etc.*

The study shows that Tf and IFOBT both have false positive and false negative results in colorectal cancer and precancerous lesions screening. IFOBT specifically detects the Hb in stool by antibody-antigen reaction. Anti-Hb antibody do not react with animal blood, fruits and vegetables in the testing material, and do not confer per-oxidase activity, which obviously reduce the false positive rate. However, the test has several problems, including (1) some participants' hemoglobin may not be recognized by the anti-Hb antibody used in the test; (2) hemoglobin can be degraded by bacteria, resulting in the loss of antigen; (3) the symptom of bleeding in early colorectal lesions is intermittent; and (4) the massive bleeding causes an excessive amount of antigen to be present in the reaction system and hence the "pre-band phenomenon". These are all possible causes of false negative results in the detection using IFOTB. Tf, a type of β1 globulin with a molecular weight of 77 KD, transports extracellular iron into cells through membrane receptor-mediated endocytosis[35]. Tf can resist degradation caused by digestive enzymes and bacteria, and is more stable than hemoglobin in stool. But Tf can only be detected at a concentration

Tf: Transferrin; IFOBT: Immuno fecal occult blood test; g-FOBT: Guaiac-fecal occult blood test; CRC: Colorectal cancer; CI: Confidence interval.

greater than 10 ng/mL. The ratio of hemoglobin and Tf is 5.4:1 in specimens containing blood. Thus, if the subject has low level of Tf, or the bleeding is very trivial, the testing threshold can not be reached and false negative results will be the outcome. Our study tested the stool specimen repeatedly, therefore reduced the error rate. All subjects underwent standard colonoscopic examination with biopsy performed as needed. In this way, an accurate test was performed to examine the sensitivities and the specificities of the three methods.

The results of this study have a significant implication for CRC screening. A number of studies showed that early detection based on fecal occult blood test helped decrease CRC mortality by 15%-25%[4,7,36]. Mandel *et al*[7,37] found that screening once every year or once every two years with g-FOBT or IFOTB can decrease the mortality of CRC and CRC related diseases, compared to no screening. In our test, for 65 subjects, IFOBT showed negative result while Tf were positive. Hence, Tf is appropriate for the screening of CRC and precancerous lesions. Positive likelihood ratio, which involves both sensitivity and specificity of screening, can fully evaluate the

diagnosing value of screening. It is very stable and not subject to morbidity. Results of our study demonstrated that the positive likelihood ratio of Tf detecting CRC was similar with that of IFOBT in various populations, which indicates that Tf has a similar value with IFOBT and is fit for the CRC screening in an average- risk population. Further, the findings of the analysis suggest that a combination of Tf, IFOBT and g-FOBT enables compensation of the inadequacy of single tests, which will reduce false negative rate and improve the positive ratio. So, in order to enhance the sensitivities of detecting CRC and precancerous lesions, all three methods should be used simultaneously.

Our study does have some limitations, and the first is its study subject. The sensitivity and specificity of Tf had been calculated in this study, those of that in an average-risk group are yet to be further determined. Prospective studies in an average-risk group are needed to validate these results. Nevertheless, hardly everyone at average-risk group can undergo colonoscopy, leading that the specificities of fecal occult blood tests can not be evaluated. We prepare to apply computed tomographic virtual

colonoscopy to screen patients who are at average-risk for CRC. The second is the range of age in this study is very wide. The third major limitation of our study is that the three stool occult blood tests were all qualitative and certain amount of deviation was existed compared to quantitative test.

In conclusion, Tf dipstick test can be applied to screen for CRC and precancerous lesions and the efficacy is approximately the same as that of IFOBT in high risk cohort. By combining g-FOBT, Tf and IFOBT, the sensitivity can be improved significantly while the specificity is sacrificed. Large-scale and prospective clinical studies will be needed to determine whether Tf dipstick test can be used as a screening method for CRC and precancerous lesions in different screening population.

COMMENTS

Background

Fecal occult blood test (FOBT) is a simple and convenient tool for colorectal cancer (CRC) screening. Immuno fecal occult blood test (IFOBT) has limited sensitivities and specificities for detecting CRC and precancerous lesions.

Research frontiers

FOBT, a non-invasive method, can reduce CRC incidence and mortality rate. However, hemoglobin (Hb) is unstable in feces because it can be degraded by bacteria. Furthermore, Hb can not be used to detect lesions that are not accompanied by bleeding. Transferrin (Tf), which is present in plasma by the release of neutrophil-specific granules, is undetectable in normal human gastrointestinal tract. Tf can resist degradation caused by digestive enzymes and bacteria, and is more stable than hemoglobin in stool.

Innovations and breakthroughs

Tf dipstick test was found to be as sensitive and specific as IFOBT in the detection of CRC and precancerous lesions in high-risk cohort. Combining guaiac fecal occult blood test, IFOBT and Tf enhanced the sensitivity.

Applications

Tf dipstick test can be applied to screen for CRC and precancerous lesions and the efficacy is approximately the same as that of IFOBT in high risk cohort.

Terminology

Transferin (Tf), a type of β1 globulin with a molecular weight of 77 KD, transports extracellular iron into cells through membrane receptor-mediated endocytosis. Detection of Tf in feces or contents in the stomach indicates bleeding in gastrointestinal tract.

Peer review

The study seeks to evaluate biomarkers for colorectal cancer screening. To develop non-invasive method such as fecal test for cancer screening is clinically relevant. The study has tested a reasonable size of cohorts and found combined test of several markers let to significantly increased sensitivity of detecting cancerous lesions compared to the commonly used method. The results suggest that the transferrin dipstick test might be used as an additional tool for colorectal cancer and precancerous lesions screening in a high-risk cohort.

Abstract

AIM: To investigate and evaluate the change in health-related quality of life (HRQoL) by tumor node metastasis (TNM) staging system in patients with hepatocellular carcinoma (HCC).

METHODS: A total of 140 patients diagnosed with HCC between June 2008 and April 2009 in our department were enrolled to this study. One hundred and thirty-five (96.5%) patients had liver cirrhosis secondary to hepatitis B virus (HBV) infection, 73 (54.07%) of them being HBV DNA positive; the other etiologies of liver cirrhosis were alcoholic liver disease (1.4%), hepatitis C (1.4%) or cryptogenic (0.7%). All subjects were fully aware of their diagnosis and provided informed consent. HRQoL was assessed before treatment using the functional assessment of cancer therapy-hepatobiliary (FACT-Hep) questionnaire. Descriptive statistics were used to evaluate demographics and disease-specific characteristics of the patients. One-way analysis of variance and independent samples t tests were used to compare the overall FACT-Hep scores and clinically distinct TNM stages. Scores for all FACT-Hep items were analyzed by frequency analyses. The mean scores obtained from the FACT-Hep in different Child-Pugh classes were also evaluated.

RESULTS: The mean FACT-Hep scores were reduced significantly from TNM Stage Ⅰ to Stage Ⅱ, Stage ⅢA, Stage ⅢB group (687 ± 39.69 *vs* 547 ± 42.57 *vs* 387 ± 51.24 *vs* 177 ± 71.44, *P* = 0.001). Regarding the physical and emotional well-being subscales, scores decreased gradually from Stage Ⅰ to Stage ⅢB (*P* = 0.002 *vs* Stage Ⅰ; *P* = 0.032 *vs* Stage Ⅱ; *P* = 0.033 *vs* Stage ⅢA). Mean FACT-Hep scores varied by Child-Pugh class, especially in the subscales of physical well-being, functional well-being and the hepatobiliary cancer (*P* = 0.001 *vs* Stage I; *P* = 0.036 *vs* Stage Ⅱ; *P* = 0.032 *vs* Stage ⅢA). For the social and family well-being subscale, only Stage ⅢB scores were significantly lower as compared with Stage Ⅰ scores (*P* = 0.035). For the subscales of functional well-being and hepatobiliary cancer, there were significant differences for Stages ⅡⅠ, ⅢA and ⅢB (*P* = 0.002 *vs* Stage Ⅰ).

CONCLUSION: HRQoL of patients with HCC worsens gradually with progression of TNM stages. The most impaired subscales of HRQoL, as measured by FACT-Hep, were physical and emotional well-being.

INTRODUCTION

In recent years, there has been increased interest in quality of life as it pertains to patients' health status. Many different questionnaires, such as the functional assessment of cancer therapy-hepatobiliary (FACT-Hep), the Health-Related Quality of Life (HRQoL), and the Short Form (36) Health Survey are becoming key instruments in the evaluation of patients' health status. HRQoL results may be more relevant than length of life, as patients are frequently more concerned about life quality than longevity.

The incidence of hepatocellular carcinoma (HCC) in China is increasing. HCC is now the second leading cause of death of cancers[1]; about 15%-40% of the hepatitis B virus carriers may develop cirrhosis and HCC[2]. Approximately 80% of the patients diagnosed with HCC are unable to undergo surgical resection or transplantation[3]. Non-surgical treatment, such as transcatheter chemo-embolization or chemotherapy may improve the patients' prognosis to varying degrees[4-8]. Symptoms can be extremely variable in advanced HCC; the compensated patients may be symptomatic for months or decades. The impact is significant on patients' functioning and well-being. Patients may experience anxiety because of emotional concerns associated with the disease and treatment. Complications and extra-hepatic manifestations of advanced disease may reduce the quality of life, as therapeutic interventions may restrain outdoor activities. These challenges may negatively affect the quality of life, including physical, emotional, and functional well-beings[9].

Assessment of HRQoL with cancer has become an important outcome indicator during the last two decades[10]. The FACT-Hep is the most widely used evaluation tool focusing on hepatobiliary cancer such as HCC, pancreatic cancer and cancers of the gallbladder[11]. In clinical studies, the FACT-Hep performs well in assessing the quality of life of patients with HCC, and is considered to be of utmost importance for improving survival rates and quality of life[11].

The FACT-Hep[12] is a new and important index for evaluation of prognosis of the patients and the results of clinical trials, complementing the traditional end-points assessment, such as tumor response rate and survival time[13-15].

As HCC worsens, quality of life generally decreases, but two unanswered questions remain. First, FACT-Hep has not been used to assess prognosis with a large series of HCC patients at different tumor node metastasis (TNM) stages. Second, quality of life is a broad concept, and no data are available to examine the impact of disease on patients' self-perception and the factors which are associated with poor HRQoL on the FACT-Hep.

The aim of this study was to determine the HRQoL of patients at different TNM tumor stages of HCC by FACT-Hep, and to determine the factors associated with impaired HRQoL. The TNM Classification of Malignant Tumors was based on physical exam findings, imaging studies (ultrasound, computed tomography or magnetic resonance imaging) and other tests[16]. For solid tumors, such as HCC, TNM is the most commonly used staging system.

MATERIALS AND METHODS

Patients

Most patients admitted to our department had primary liver cancers. On admission, patients' quality of life was evaluated using the Chinese version of the FACT-Hep. During an 11-mo period from June 2008 to April 2009, we studied 140 patients with HCC (133 males, 7 females; aged 28-75 years). Patients completed the study questionnaire following the diagnosis of HCC, and prior to therapeutic intervention. All subjects were fully aware of their diagnosis and provided informed consent to participate. The ethical committees of the participating centers approved the study. The TNM staging system[17] (edition 6 published in 2002; and instituted in 2003) was used in this study. Patients were selected based on the demographic characteristics or clinical status.

Inclusion criteria

(1) Patients aged $\geq$ 18 years; (2) diagnosis of HCC was established by imaging examinations (ultrasound or computed tomography) and confirmed by α1-variable fetoprotein levels exceeding 10 times the normal values, or liver biopsy; (3) patients who had no prior history of malignancy with encephalopathy and no cognitive impairment (as judged by the attending clinician); (4) patients who should speak, read, understand and write Chinese; (5) Karnofsky $\geq$ 60. The expected survival was at least six months; (6) patients who voluntarily agreed and were able to make the decision to participate in the study; and (7) patients who provided written informed consent.

Exclusion criteria

(1) Illiteracy; (2) current psychosis or homicidal ideation; (3) serious visual or auditory disease; (4) evidence of cognitive impairment or psychiatric disturbance that would prevent informed consent; (5) physical condition too poor to complete the required the 20-25 min of questionnaires; and (6) patient's family requests that the patient's condition should be kept a secret from the patients.

FACT-Hep

The FACT-Hep is a 45-item, self-report instrument designed to measure HRQoL in patients with HCC. The FACT-Hep consists of 27-item FACT-General (FACT-G), which assesses generic HRQoL concerns using five subscales, and the newly validated 18-item hepatobiliary subscale, which assesses specific symptoms of hepatobiliary

that the patient complete the FACT-Hep again.

Statistical analysis

SPSS 13.0 software was used to process and analyze the data. Descriptive statistics were used to evaluate demographic and disease-specific characteristics. One-way analysis of variance and independent samples *t* tests ($P < 0.05$) were used to compare FACT-Hep scores between clinically distinct groups.

RESULTS

Sample size

FACT-Hep questionnaires were issued to 145 patients. Two patients dropped out of the study due to disease exacerbation and three questionnaires were omitted from analysis because of missing data (> 5 questions). In total, 140 questionnaires were completed (with a completion rate of 98.19%). The average time for finishing a FACT-Hep was 13.50 ± 2 min.

Patient characteristics

Of the 140 patients, 133 were male (95.0%) and the mean age at diagnosis was 52.34 ± 9.73 years (range: 28-75). The TNM tumor stages were as follows: Stage I : 49 cases; Stage II: 35 cases; Stage IIIA: 29 cases; and Stage IIIB: 27 cases. All patients had cirrhosis. One hundred and thirty-five (96.5%) subjects had liver cirrhosis secondary to hepatitis B virus (HBV) infection, with 73 (54.07%) of them being HBV DNA positive; the other etiologies of liver cirrhosis included alcoholic liver disease (2), hepatitis C (2) or cryptogenic (1). Demographic and clinical characteristics are shown in Table 1.

FACT-Hep scores and TNM stage

Median FACT-Hep scores decreased as TNM stage advanced, and FACT-Hep scores were strongly associated with TNM stage (Figure 1).

Differences in FACT-Hep items

Mean FACT-Hep subscale scores were: PWB 16.47 ± 4.272; SFWB 14.52 ± 3.351; EWB 12.74 ± 3.394; FWB 17.90 ± 4.06; and HepCS 41.46 ± 9.52. The overall mean differences are presented in Table 2.

cancer and side effects of treatment. The five FACT-Hep subscales are: (1) physical well-being (PWB, 7 questions); (2) social and family well-being (SFWB, 7 questions); (3) emotional well-being (EWB, 6 questions); and (4) functional well-being (FWB, 7 questions); and (5) hepatobiliary cancer subscale (HepCS, 20 questions).

The FACT-Hep shows a high internal consistency at initial assessment (Cronbach's alpha range: 0.72-0.94) and retesting (Cronbach's alpha range: 0.81-0.94)[11]. Measurement stability is also high for all aggregated scales (test-retest correlation range: 0.84-0.91; interclass correlation coefficient range: 0.82-0.90)[11]. The FACT-Hep can be used independently as a brief measure of disease-related symptoms and functioning in assessing HRQoL of patients with HCC[11]. In this study, the FACT-Hep was translated into Chinese and adjusted appropriately based on the local cultural background. Early research using the Chinese version of the FACT-Hep showed a better reliability and validity (a reliability > 0.5 and a validity > 0.73)[11]. The present study aimed to assess the relationship between the HRQoL in HCC patients as measured by the Chinese version of the FACT-Hep and TNM tumor stage.

All FACT items were rated on 5-point scales ranging from 1 to 5. Converse items should be unified before analysis. The PWB, FWB, SFWB and EWB were summed to get the FACT-G total score. The FACT-G and HepCS scores were summed to obtain the FACT-Hep total score. Higher scores on all subscales of the FACT-Hep reflect higher functioning and fewer symptoms.

Patients completed the FACT-Hep after receiving uniform written instructions from a medical doctor (Li MD) or nurse (Dong HJ). Following FACT-Hep, another doctor (Lang QB) reviewed the forms for missing items. If there were more than three missing items, we requested

Child-Pugh classification and FACT-Hep

Scores for each FACT-Hep item worsened with increasing severity of hepatic cirrhosis, based on the Child-Pugh classification (Table 3). Further analyses of factors impacting specific HRQoL were performed using percent analysis.

Physical well-being: Lack of physical strength was reported by 86% of patients; nausea by 51%; illness affecting the role at home by 83%; pain by 66%; recent uncomfortable feelings by 92%; and frequent bed rest by 55%. Patients had variable decreases in daily exercise capacity.

Social and family well-being: Patients kept close contact with friends (92%); received emotional support at home (59%); had support from friends (69%); had family who understood the patient's condition (49%); communicated about their condition with family (69%); and had close ties with a lover (43%). Only five patients answered questions regarding their sex lives (3.5%).

Emotional well-being: Sorrow and sad emotions were reported by 83% of patients; fear of death by 79%; and concern about disease progression by 74%. Only 53% of patients completed the item regarding current treatment and losing confidence in overcoming the current disease.

Functional well-being: Working ability was reported by 41%; sense of satisfaction with work by 51%; enjoyment of life by 55%; acceptance of the disease by 59%; insomnia by 95%; enjoyment from hobbies by 63%; and quality of life satisfaction by 52%.

Hepatobiliary cancer subscale: Patients reported stomach distension (65%); weight loss (57%); abnormal intestinal function (87%); digestive dysfunction (87%); diarrhea (64%); good appetite (36%); concern regarding appearance (61%); shoulder and back pain (71%); constipation (54%); fatigue (84%); ability to independently accomplish daily affairs (47%); jaundice 60 cases (43%); fever (36%); itching (27%); food taste changes (48%); cold sensitivity (61%); dry mouth (76%); stomach pain (63%); and swollen ankles (20%). No patients had bile drainage tubes.

DISCUSSION

Our study showed that patients with HCC had a perceived health status which varies by TNM stage for most FACT-Hep items. This conclusion was based on questionnaires widely used in Chinese clinical studies which indicate that the quality of life is an important prognostic factor and predicts survival time in patients with HCC[18].

HCC, an end-stage complication of liver disease, is expected to affect quality of life, but limited results have been reported previously[19]. Both disease-related and treatment-related symptomatic relief has been the primary goal in advanced HCC management because of the low survival rate of the patients. Alleviating clinical symptoms and improving quality of life have become targets for HCC treatment[20]. Quality of life and related factors in patients with liver cancer have been reported in some studies as indicators of treatment efficacy[21-23]. The FACT-Hep has been widely used in clinical studies to assess HRQoL[11]. Although traditional clinical diagnostic indicators (survival time and tumor response rates) and patients' subjective feelings are the primary components of quality of life for patients with HCC, the FACT-Hep can provide more comprehensive clinical evaluations[24,25].

There are several staging systems for HCC, such as the Japan Integrated Staging score, the new barcelona

clinic liver cancer (BCLC) staging classification, and the Tokyo score. These proposed staging systems consider both tumor size and liver function for HCC evaluation[26].

We classified patients' disease status using the BCLC and found that advancing BCLC stage was associated with a decreasing trend for FACT-Hep scores, because BCLC staging is related to liver function. Patients with cirrhosis had lower FACT-Hep scores (lower scores represent lower quality of life, Table 3). Previous studies have assessed the relationship between liver function and HRQoL deterioration and fatigue in patients with quantified inflammatory activity and degree of fibrosis[27]. Additionally, quality of life in patients with cirrhosis secondary to primary biliary cirrhosis or chronic hepatitis C has been reported previously[28-30].

The FACT-HepG mean scores showed that HRQoL in HCC patients significantly declined from TNM Stage I to Stage II to Stage IIIA to Stage IIIB. Thus, FACT-Hep scores could reflect varying levels of HCC disease severity.

Our results demonstrate that HCC has a significant and potentially adverse impact on physical health and psychological well-being, causing disruptions to patients' normal lives. Because the SFWB status of patients with HCC was impaired, family and friends' emotional support becomes particularly important. Although these symptoms may appear minor in the clinical setting, these factors may significantly predict the poor quality of life. Unfortunately, relevant information about sex life on the FACT-Hep questionnaire was limited and controversial; only five patients completed these questions. This limited response may be due to Chinese cultural norms regarding discussion of sexual activity. Throughout the five FACT-Hep items, we found that EWB was variably impaired. Thus, it appears that patients who have an established diagnosis of HCC experience a wide range of negative emotional symptoms such as sorrow and fear of death. Patients reported various levels of FWB based on the disease stage. On the HepCS, patients most commonly reported abnormal intestinal function, digestive dysfunction and fatigue.

Some limitations must be considered in evaluating these results. To avoid the variability of different therapeutic effects, we chose a simple analysis of untreated patients on admission. However, we believe that this approach may more accurately reflect the relationship between FACT-Hep results and TNM stage. Additionally, it may be more significant, in both clinical work and clinical perspective studies, to use the FACT-Hep as a tool to evaluate the patients' quality of life prior to treatment. Careful consideration of digestive dysfunction and emotional support is needed, as symptoms greatly impact HRQoL. Only 3.5% of patients responded to questions regarding sexual activity on the FACT-Hep scale. Cultural influences may preclude the use of these questions and it may be more instructive to focus on HCC patients' psychological states in tumor remission and long-term quality of life, which are other important elements of FACT-Hep. Regarding sleep, the sleep disorders in patients with advanced HCC may be due to the increased burden of physical and psychological factors.

Frequency percents of depression, anxiety and other psychiatric symptoms were significantly higher than other factors. This may be related to the disease itself, which is often associated with a range of negative emotional responses at the time of diagnosis. Furthermore, the poor prognosis, short survival time, need for repeated treatment, and high treatment cost may directly affect patients' mental health status, as demonstrated by the FACT-Hep results for stress, anxiety, fear of death and disease progression.

In conclusion, this study demonstrated that advancing TNM tumor stages were associated with the declining patient quality of life. These results may be useful for physicians to adjust HCC management according to patients' physical condition, extent of disease, and quality of life. Results of this study could be used to provide improved health services to meet the needs of HCC patients at different TNM tumor stages prior to initiating the treatment. In addition, more attention should be paid to the sad emotions, digestive dysfunction, fatigue and insomnia. Despite these findings, more definite evidence of the benefits of FACT-Hep questionnaire is required to justify its use. We plan to perform a long-term follow-up of these HCC patients to closely monitor the quality of life changes and to explore and predict their trends.

COMMENTS

Background
The incidence of hepatocellular carcinoma (HCC) in China is increasing, and HCC is now the second leading cause of death of cancers. Although many therapies have improved survival rates, symptoms become extremely variable in advanced HCC disease; compensated patients may be symptomatic for months or decades. In recent years, there has been increased interest in quality of life as it pertains to patients' health status. Many different questionnaires, such as the functional assessment of cancer therapy-hepatobiliary (FACT-Hep), the health-related quality of life (HRQoL), and the short form (36) health survey are becoming key components in the evaluation of patients' health status. HRQoL results may be more relevant than length of life, as patients are frequently more concerned about life quality than longevity.

Research frontiers
The Chinese version of the FACT-Hep is a new and important tool for the evaluation of prognosis and clinical trials, complementing the traditional end-point methods such as tumor response rate and survival time. This study demonstrated that advancing tumor node metastasis (TNM) stages were associated with the declining patient quality of life. These results may be useful for physicians to adjust HCC management according to patients' physical condition, extent of disease, and quality of life.

Innovations and breakthroughs
As HCC disease worsens, quality of life generally decreases, but two unanswered questions remain. First, FACT-Hep has not been used to assess prognosis with a large series of HCC patients at different TNM tumor stages. Second, quality of life is a broad concept, and no data are available to examine the impact of disease on patients' self-perception and the factors associated with poor HRQoL on the FACT-Hep.

Applications
This study demonstrated that advancing TNM tumor stages were associated with the declining patient quality of life. These results may be useful for physicians to adjust HCC management according to patients' physical condition, extent of disease, and quality of life. Results of this study could be used to provide improved health services to meet the needs of HCC patients at different TNM tumor stages prior to initiating the treatment

Terminology

The FACT-Hep is a 45-item, self-report instrument designed to measure HRQoL in patients with HCC. The FACT-Hep consists of 27-item FACT-G, which assesses generic HRQoL concerns using five subscales, and the newly validated 18-item hepatobiliary subscale, which assesses specific symptoms of hepatobiliary cancer and side effects of treatment. The five FACT-Hep subscales are: (1) physical well-being (7 questions); (2) social and family well-being (7 questions); (3) emotional well-being (6 questions); and (4) functional well-being (7 questions); and (5) hepatobiliary cancer subscale (20 questions).

Peer review

The paper quantifies the quality of life of 140 consecutive and unselected patients with HCC. They have used the FACT-Hep questionnaire and classified their patients according to TNM staging system.

Abstract

AIM: To investigate the effect of intensive *vs* conventional insulin therapy on perioperative nutritional substrates metabolism in patients undergoing radical distal gastrectomy.

METHODS: Within 24 h of intensive care unit management, patients with gastric cancer were enrolled after written informed consent and randomized to the intensive insulin therapy (IIT) group to keep glucose levels from 4.4 to 6.1 mmol/L or the conventional insulin therapy (CIT) group to keep levels less than 10 mmol/L. Resting energy expenditure (REE), respiratory quotient (RQ), resting energy expenditure per kilogram (REE/kg), and the lipid oxidation rate were monitored by the indirect calorimeter of calcium citrate malate nutrition metabolism investigation system. The changes in body composition were analyzed by multi-frequency bioimpedance analysis. Blood fasting glucose and insulin concentration were measured for assessment of Homeostasis model assessment of insulin resistance.

RESULTS: Sixty patients were enrolled. Compared with preoperative baseline, postoperative REE increased by over 22.15% and 11.07%; REE/kg rose up to 27.22 ± 1.33 kcal/kg and 24.72 ± 1.43 kcal/kg; RQ decreased to 0.759 ± 0.034 and 0.791 ± 0.037; the lipid oxidation ratio was up to 78.25% ± 17.74% and 67.13% ± 12.76% supported by parenteral nutrition solutions from 37.56% ± 11.64% at the baseline; the level of Ln-HOMA-IR went up dramatically ($P < 0.05$, respectively) on postoperative days 1 and 3 in the IIT group. Meanwhile the concentration of total protein, albumin and triglyceride declined significantly on postoperative days 1 and 3 compared with pre-operative levels ($P < 0.05$, respectively). Compared with the CIT group, IIT reduced the REE/kg level (27.22 ± 1.33 kcal/kg *vs* 29.97 ± 1.47 kcal/kg, $P = 0.008$; 24.72 ± 1.43 kcal/kg *vs* 25.66 ± 1.63 kcal/kg, $P = 0.013$); and decreased the Ln-HOMA-IR score ($P = 0.019, 0.028$) on postoperative days 1 and 3; IIT decreased the level of CRP on postoperative days 1 and 3 ($P = 0.017, 0.006$); the total protein and albumin concentrations in the IIT group were greater than those in the CIT group ($P = 0.023, 0.009$). Postoperative values of internal cell fluid (ICF), fat mass, protein mass (PM), muscle mass, free fat mass and body weight decreased obviously on postoperative 7th day compared with the preoperative baseline in the CIT group ($P < 0.05$, respectively). IIT reduced markedly consumption of fat mass, PM and ICF compared with CIT ($P = 0.009$ to 0.026).

CONCLUSION: There were some benefits of IIT in decreasing the perioperative insulin resistance state, reducing energy expenditure and consumption of proteins and lipids tissue in patients undergoing gastrectomy.

Abstract

AIM: To investigate the function of gamma-aminobutyric acid (GABA) and gamma-aminobutyric acid A receptor θ subunit (GABRQ) in hepatocellular carcinoma (HCC).

METHODS: Semiquantitative polymerase chain reaction was used for detecting the expression of GABRQ receptor among HCC cell line HepG2, normal liver cell line L-02, non-malignant Chang's liver cells, 8 samples of HCC tissues and paired non-cancerous tissues. HepG2 cells were treated with GABA at serial concentrations (0, 1, 10, 20, 40 and 60 μmol/L), and their proliferating abilities were analyzed with the methyl thiazolyl tetrazolium assay, cell cycle analysis and tumor implanted in nude mice. Small interfering RNA was used for knocking down the endogenous GABRQ in HepG2. Proliferating abilities of these cells treated with or without GABA were analyzed.

RESULTS: We identified the overexpression of GABRQ in HCC cell lines and half of the tested HCC tissues. Knockdown of endogenous GABRQ expression in HepG2 attenuated HCC cell growth, suggesting its role in HCC cell viability. We studied the effect of GABA in the proliferation of GABRQ-positive cell lines *in vitro* and *in vivo*, and found that GABA increased HCC growth in a dose-dependent manner. Notably, the addition of GABA into the cell culture medium promoted the proliferation of GABRQ-expressing HepG2 cells, but not GABRQ-knockdown HepG2 cells, which means that GABA stimulates HepG2 cell growth through GABRQ.

CONCLUSION: GABRQ play important roles in HCC development and progression and could be a promising molecular target for the development of new diagnostic and therapeutic strategies of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common

primary liver cancer and one of the most common malignancies in the world, accounting for approximately one million deaths per year[1,2]. Although liver resection and local ablation are regarded as potentially curative treatment[3], its prognosis is poor. Most of the patients are diagnosed with advanced disease at presentation for which palliative therapy forms the mainstay of treatment[4].

To improve this situation, the development of novel molecular therapies against effective targets is an urgent issue. Toward this direction, we previously used a method combining an in silico screen and experimental verification to identify genes that are differentially expressed in cancers compared with their corresponding normal tissues[5]. Among genes that are overexpressed in HCC cells, we focused on the gamma-aminobutyric acid (*GABA*) gene. Gamma-aminobutyric acid A receptor θ subunit (GABRQ) is a subunit of gamma-aminobutyric acid A (GABAA) receptors that may associate with other GABAA receptor subunits to form a functional chloride channel which mediates inhibitory synaptic transmission in the mature central nervous system (CNS). GABA primarily functions as an inhibitory neurotransmitter in the mature CNS by activating the GABA receptor, but it can also modulate the proliferation, migration and differentiation of neuronal cells during CNS development[6-9] and the proliferation of peripheral non-neuronal cells[10,11]. GABA and GABAA receptors are also present in peripheral tissues, including cancerous cells, but their precise functions are poorly defined.

This study demonstrates that GABRQ is overexpressed in HCC and that GABA promotes the proliferation of cancer cells through GABRQ.

MATERIALS AND METHODS

Cell lines
HCC cell line HepG2 and normal liver cell lines Chang's liver and L-02 were maintained by our lab and cultured in Dulbecco-modified Eagle medium (DMEM, Gibco) supplemented with 10% fetal bovine serum (FBS, Gibco). Cells were maintained at 37 ℃ atmosphere of humidified air with 5% CO_2.

Collection of tissues
All samples of HCC tissues and paired non-cancerous tissues (5 cm away from tumor) were obtained during surgical resection from the Xiangya Hospital of Central South University. Written consent was obtained from the patients, who agreed to the collection of tissue samples. The resected tissue samples were immediately cut into small pieces and snapfrozen in liquid nitrogen until use. All tumor tissue and paired non-cancerous tissue samples were pathologically confirmed.

Semiquantitative polymerase chain reaction
RNA isolated from cells was reverse-transcribed and amplified using the One-Step reverse transcription polymerase chain reaction (RT-PCR) System (Fermentas, Vilnius, Lithu-

ania). The sets of primers for GABRQ receptor subunit are Sense 5'-TCGAGTTCTCCTCTGCTGTG-3', Antisense 5'-TATGCAGATCCAGGGACAA-3' (465 bp); Sense 5'-AATCCCATCACCATCTTCCA-3' and antisense 5'-CCTGCTTCACCACCTTCTTG-3' for glyceraldehyde-3-phosphate dehydrogenase (GAPDH, 580 bp). After heating at 95 ℃ for 1 min, samples were exposed to 30 cycles (GAPDH, 25 cycles) of 95 ℃ for 30 s, 60 ℃ for 30 s and 68 ℃ for 1 min 30 s with a final extension at 68 ℃ for 10 min. Reaction products were separated on 1.5% agarose gels containing ethidium bromide and the level of amplification was analyzed using a Phosphor Imager.

RNA interference
To knockdown GABRQ expression, we used pGCsi-U6/Neo/GFP vector encoding a small hairpin RNA directed against the target gene in HepG2.The target sequences for GABRQ were: 5'-taGCAAGGAGGTGTATTTCTA-3' (Si-1), 5'-caGCTATGGTGTTCGCTTTAA-3'(Si-2), 5'-caGGCTGATGACAGTA TTATT-3'(Si-3), 5'-aaGGAT-GCTTTCGTGCATGAT-3'(Si-3). As a negative control, we used shRNA vector without hairpin oligonucleotides (Si-Mock).

Cell transfection
Human HCC cell line HepG2 was plated onto 6-well plates, and transfected with these small interfering RNA (siRNA) expression vectors using FuGENE6 (Roche) according to the instructions of the manufacturer, followed by 800 μg/mL of neomycin selection. The cells were harvested 10 d later to analyze the knockdown effect on GABRQ by RT-PCR using the primers shown above and by flow cytometry using rabbit anti-human polyclonal antibody against GABRQ (Chemicon).

Impact of GABRQ-siRNA on the growth of hepatocellular carcinoma cells
HepG2/Si-1, HepG2/Si-Mock cells were seeded with serum-free medium at a density of 10^3 cells/well in 96-well plates (*n* = 6), grown overnight, washed in phosphate-buffered saline (PBS), and incubated with 10% FBS with or without 40 μmol/L GABA DMEM at 37 ℃, 5% CO_2, for varying periods and exposed to fresh media every other day. During the last 4 h of each day's culture, the cells were treated with methyl thiazolyl tetrazolium (MTT, 50 μg per well, Sigma, United States). The generated formazan was dissolved in dimethyl sulfoxide (DMSO) and the ODs at 490 nm were measured for detecting the cell viability.

The effect of GABRQ silencing on the colony formation of HepG2 cells was analyzed by colony formation assay. HepG2/Si-1, HepG2/Si-Mock cells at 100 cells per well in 6-cm plates were incubated with serum-fee medium for 24 h, and then cultured in 10% FBS with or without 40 μmol/L GABA DMEM at 37 ℃, 5% CO_2, for 3 wk. The cell colonies were washed twice with PBS, fixed by 4% paraformaldehyde for 15 min and stained with Giemsa for 30 min. Individual clones with more than 50

[a]$P < 0.05$ *vs* Si-1.

cells were counted. Clone forming efficiency for individual type of cells was calculated, according to the number of colonies/number of inoculated cells × 100%.

To evaluate the impact of GABRQ silencing on the HepG2 cells and the effect of GABA stimulation on the HepG2 cells, cell cycle was examined by flow cytometry analysis. HepG2/Si-1, HepG2/Si-Mock cells were incubated with serum-fee medium for 24 h, and then cultured in DMEM with 10% FBS with or without 40 μmol/L GABA, then harvested at 70%-80% confluence and resuspended in fixation fluid at a density of 10^6/mL; 1500 μL propidium iodide (PI) solution was added, and the cell cycle was detected by FACS Caliber (Becton-Dickinson).

Effect of gamma-aminobutyric acid on the growth of hepatocellular carcinoma cells

To study the effect of GABA on the proliferation of GABRQ-expressing HCC cells, cell proliferation was tested *in vitro*. In the MTT assay, HepG2 cells were seeded with serum-free medium at a density of 10^3 cells/well in 96-well plates (n = 6), grown overnight, washed in PBS, and incubated with GABA (Sigma-Aldrich) at serial concentrations (0, 1, 10, 20, 40 and 60 μmol/L) in appropriate medium supplemented with 1% FBS. The samples were tested every 24 h for 6 d. MTT was added (50 μg/well) for 4 h. Formazan products were solubilized with DMSO, and the optical density was measured at 490 nm.

In the flow cytometry assay, HepG2 cells were incubated with serum-fee medium for 24 h, and then cultured in DMEM with 10% FBS and serial concentrations (0, 1, 10, 20, 40 and 60 μmol/L) GABA for 48 h. Cells were harvested and resuspended in fixation fluid at a density of 10^6/mL, 1500 μL PI solution was added, and the cell cycle was detected by FACS Caliber (Becton Dickinson).

Tumor formation in nude mice

The influence of GABRQ silencing and GABA stimulation on the tumor development of HCC *in vivo* was examined. Briefly, HepG2, HepG2/Si-Mock and HepG2/Si-1 cells were treated with or without GABA (40 μmol/L) for 24 h first, and then the cells (3 × 10^6) were suspended in 0.2 mL of extracellular matrix gel and injected subcutaneously in the left back flank of the animals. The 8-wk-old BALB/c nude (nu/nu) mice (Slac Laboratory Animal Center, Shanghai, China) were divided into six groups: (1) the mice were injected with HepG2 and treated with 0.9% NaCl injection (150 μL) into the implanted tumor (HepG2, n = 4); (2) the mice were injected with HepG2 and treated with GABA injections (40 μmol/L in 150 μL of 0.9%

NaCl) into the implanted tumor (HepG2 + GABA, n = 4); (3) the mice were injected with HepG2/ Si-Mock and treated with 0.9% NaCl injection (150 μL) into the implanted tumor (HepG2/Si-Mock, n = 4); (4) the mice were injected with HepG2/Si-Mock and treated with GABA injections (40 μmol/L in 150 μL of 0.9% NaCl) into the implanted tumor (HepG2/Si-Mock + GABA, n = 4); (5) the mice were injected with HepG2/Si-1 and treated with 0.9% NaCl injection (150 μL) into the implanted tumor (HepG2/Si-1, n = 4); and (6) the mice were injected with HepG2/Si-1 and treated with GABA injections (40 μmol/L in 150 μL of 0.9% NaCl) into the implanted tumor (HepG2/Si-1 + GABA, n = 4). The same operator carried out the injections every other day starting from "day 0" when the tumors were implanted. Tumor variables were measured every 3 d by an electronic caliper, and tumor volume was calculated using a standard formula[12,13]: tumor volume = width^2 × length × 0.5. At the end of the experiment, all mice were sacrificed and individual tumor weights were measured.

Statistical analysis

All data were expressed as mean ± SD. Differences among groups were determined by analysis of variance analysis and comparison between two groups was analyzed by the Student's t test using the GraphPad Prism soft-ware version 4.0 (GraphPad Software, Inc, San Diego, CA). A value of $P < 0.05$ was used to indicate statistical significance.

RESULTS

Expression of GABRQ receptors

We documented GABRQ mRNA expression in HepG2, Chang's liver and L-02 cell lines as well as in 8 pairs of HCC and adjacent non-tumor tissues. The results of semi-quantitative RT-PCR show GABRQ receptor subunit was detected in HepG2 and in Chang's liver cells, but not in normal cell line L-02 (Figure 1A). GABRQ receptor subunit was also detected in HCC tissues (6/8), but not in adjacent non-tumor tissues (Figure 1B).

Impact of GABRQ-siRNA on the growth of hepatocellular carcinoma cells

To investigate the biological significance of GABRQ overexpression in HCC cells, we constructed four siRNA expression vectors (Si-1, Si-2, Si-3 and Si-4) specific to GABRQ transcripts and transfected them into HepG2 cells that endogenously expressed high levels of GABRQ, as shown in Figure 1. A knockdown effect was observed by RT-PCR when we transfected Si-1, but not Si-2, Si-3, Si-4 or a negative control Si-Mock (Figure 2A). MTT assay (Figure 2B) revealed a drastic reduction in the number of cells transfected with Si-1 compared with Si-Mock for which no knockdown effect was observed. Cell proliferation was detected by flow cytometry; results showed HepG2 cells with GABRQ siRNA blocked the cell cycle in G1 phase, which may inhibit the growth of HepG2 cells (Table 1). This result was consistent with the MTT analysis.

A RT-PCR verified the knockdown effect on GABRQ expression by Si-1, but not by Si-2, Si-3, Si-4 and a negative control Si-Mock in HepG2 cells. GPDH was used to quantify RNAs; Figure 2B illustrates MTT assay of HepG2 cells transfected with Si-1 vectors to GABRQ and a negative control vector (Si-Mock). Y-axis: Average value of absorbance at 490 nm, measured with a microplate reader ($n = 6$, $P < 0.05$).

Effect of gamma-aminobutyric acid on the growth of hepatocellular carcinoma cells

Results displayed in Figure 3A show the addition of GABA in the culture media enhanced the proliferation of HepG2 cells in a dose-dependent manner. The promoting effect on HCC cell proliferation was more evident with the GABA concentration ranging from 1 μmol/L to 40 μmol/L. When the GABA concentration was increased to 60 μmol/L, the promoting effect became insignificant.

The promoting effect on HCC cell proliferation was also detected by flow cytometry analysis. After treating with GABA at serial concentrations, the G0/G1-phase fraction of HepG2 cells significantly decreased; on the contrary, S-phase cells significantly increased, especially at the concentration of 20 μmol/L and 40 μmol/L (Figure 3B, Table 2); this result was consistent with the results above.

In the nude mice implanted with tumors (injected with HepG2 cells), the development of solid HCC tumors was monitored for 40 d. As a result, a significant difference in tumor weight was found in GABA-treated (at the concentration of 40 μmol/L) mice compared with mice injected with 0.9% NaCl only (Figure 3C and D).

Effect of GABA on the growth of hepatocellular carcinoma cells after down-regulated expression of GABRQ

To examine the function of GABRQ as a GABA receptor on the growth of GABRQ-expressing HCC cells, we treat-

Figure 3 The effect of gamma-aminobutyric acid on the growth of hepatocellular carcinoma cells. A: The effects of serial concentration gamma-aminobutyric acid (GABA) on proliferation of HepG-2 cells; B: Cell cycle measured by flow cytometry; C: Forty days after tumor cell injection, mice were sacrificed and tumor weight was recorded ($n = 4$, $P < 0.01$); D: Comparison of tumor weight (the left was tumor of mice injected with 0.9% NaCl only, the right was the tumor of mice treated with 40 μmoL/L GABA).

	Si-Mock	**Si-Mock + GABA**	**Si-1**	**Si-1 + GABA**
G0/G1 (%)	49.95 ± 3.16	46.21 ± 2.98	53.95 ± 2.62	48.68 ± 2.49
G2/M (%)	21.61 ± 3.43	20.82 ± 2.43	22.38 ± 2.19	21.45 ± 2.26
S (%)	28.74 ± 3.35	33.64 ± 3.76[a]	24.29 ± 2.72[b]	27.43 ± 1.95

[a]$P < 0.05$, [b]$P < 0.01$ *vs* Si-Mock.

ed HepG2/Si-1 and HepG2/Si-Mock cells with or without GABA (40 μmol/L). The results are shown in Figure 4A: GABA enhanced the growth of HepG2/Si-Mock compared with the HepG2/Si-Mock without GABA. On the other hand, the proliferating ability of HepG2/Si-1, which did not express GABRQ, was not enhanced by GABA. In the nude mice injected with HepG2/Si-Mock, the tumor weight of the mice treated with GABA was much larger than that of the mice treated without GABA, while the mice injected with HepG2/Si-1 did not present such differences (Figure 4C and D).

To further explore GABA stimulation of HepG2 cell growth through GABRQ, we examined the effects of Si-1 and Si-Mock on cell cycle. After treatment with 40 μmol/L GABA, the G0/G1-phase fraction of HepG2/Si-Mock cells significantly decreased; in contrast, S-phase

cells significantly increased, but this event did not occur in HepG2/Si-1 cells (Table 3, Figure 4B).

The other illustration of growth effect of reduced GABRQ expression in HepG2 cells was achieved in a colony formation assay (Figure 4E and F). As a result, the average colony number of Si-1 cells was decreased compared with Si-Mock cells. After treatment with 40 μmol/L GABA, the numbers of cell colonies of HepG2/Si-Mock cells significantly increased, but this did not occur in HepG2/Si-1 cells. These data indicate that GABA stimulates HepG2 cell growth through GABRQ.

DISCUSSION

In this study, we validated the overexpression of GABRQ in more than half of the tested HCC tissues compared with the adjacent non-tumor liver tissues; GABRQ was expressed in malignant liver cell lines HepG2 and moderately expressed in normal cell line Chang's liver, but not in normal cell line L-02, implicating that GABRQ may be a good molecular target for the diagnosis of HCC. Functional analysis using siRNA of GABRQ strongly supported its involvement in the development and progression of HCC. In our study, the proliferation rate of HepG2 cells after GABRQ knockdown was significantly reduced, whereas proliferation of Si-Mock cells was not inhibited. This result indicated that GABRQ may increase the pro-

Figure 4 The effect of gamma-aminobutyric acid on the growth of hepatocellular carcinoma cells after down-regulated expression of gamma-aminobutyric acid A receptor θ subunit. liferation ability of hepatocytes. Primarily, GABA and GABA receptors function as an inhibitory neurotransmitter in the mature CNS, but their precise functions in non-neuronal cells or tumor cells are unknown. Joseph *et al*[14]

reported that GABA could inhibit colon cancer migration associated with the norepinephrine-induced pathway. On the other hand, another report showed that GABA and GABAB receptor pathways could be involved in

prostate cancer metastasis or invasion through the regulation of metalloproteinase production[15]. Therefore, it is controversial whether GABA-associated pathways could act positively or negatively in the regulation of cancer cell behavior. However, our findings in this study can clearly indicate evidence supporting the theory that GABA and GABAA receptor with GABRQ promote HCC cell proliferation.

By comparing the proliferative activity of the GABRQ-knockdown HepG2 cells treated with GABA, we found that GABA stimulated HepG2 cell growth through GABRQ. The proliferating ability of the cells treated with GABA was not enhanced compared with the cells without GABA treatment. Previous studies suggest that GABA stimulates collagen synthesis and proliferation of human fibroblasts[16]. Biju *et al*[17] reported that, in N-nitrosodiethylamine-induced neoplasia in the rat liver, GABAB receptors were increased and that the GABAB receptor agonist baclofen increased epidermal growth factor-mediated DNA synthesis in hepatocytes. Thus, GABA-associated pathways also could act positively in the regulation of cancer cell behavior. Our findings in this study also support the theory that GABA and GABRQ promote HepG2 cell proliferation *in vivo* and *in vitro*. Interestingly, GABAA receptor antagonist bicuculline methiodide could also promote the proliferation of HepG2 cells (data not shown), indicating that it might activate some other signal pathways[18].

Although GABA usually induces hyperpolarization in adult neurons, GABA has been shown to exert depolarizing responses in the immature CNS structures and CNS tumors[19,20]. In particular, GABA increased the proliferation of immature cerebellar granule cells through the activation of GABAA receptors and voltage-dependent calcium channels[21,22]. Takehara *et al*[23] reported that GABA stimulated pancreatic cancer growth through GABRP by increasing intracellular Ca^{2+} levels and activating the mitogen-activated protein kinase/extracellular signal-regulated kinase cascade. Also, Minuk *et al*[24] reported that human HCC tissues were depolarized compared with adjacent non-tumor tissues. From the results above, we deduce that GABA may promote the HepG2 cell proliferation through GABRQ by voltage-dependent calcium channels. Interestingly, GABA inhibited the growth of the GABRQ-knockdown HepG2 cells. This indicates that GABA activates some other receptors to inhibit the proliferation without GABRQ, which is identical to some previous reports[25-27].

In conclusion, compared with adjacent non-tumor tissues, HCC tissues have increased GABRQ receptor expression. Knockdown of GABRQ expression in receptor-expressing malignant hepatocytes results in attenuated *in vitro* and *in vivo* tumor growth. Moreover, GABA promotes hepatocyte proliferation through GABRQ. These findings highlight the importance of elucidating the role of GABAergic activity in the pathogenesis of HCC. They also raise the potential for new therapeutic and diagnostic approaches to human HCC.

COMMENTS

Background
Gamma-aminobutyric acid A receptor θ subunit (GABRQ) is a subunit of the gamma-aminobutyric acid A (GABAA) receptors that may associate with other GABAA receptor subunits to form a functional chloride channel which mediates inhibitory synaptic transmission in the mature central nervous system (CNS). gamma-aminobutyric acid (GABA) functions as an inhibitory neurotransmitter for activating GABA receptors.

Research frontiers
Recently, abnormal levels of gene and protein expression of some GABA receptor subunits have been detected in many malignant tumors. This research indicates that GABAergic system may play an important role in the pathogenesis and development of malignant tumors.

Innovations and breakthroughs
This study demonstrated the overexpression of GABRQ in hepatocellular carcinoma (HCC), which has not been previously described, and illustrated that GABA stimulates HCC cell proliferation through GABRQ.

Applications
Further characterization of GABRQ will provide new insights into the role of GABRQ in the molecular pathogenesis and therapy of HCC.

Terminology
GABA stands for gamma-aminobutyric acid, which is an inhibitory neurotransmitter. GABRQ stands for gamma-aminobutyric acid A receptor θ subunit.

Peer review
The authors have analyzed the expression and the role of GABRQ in hepatocellular carcinoma. The manuscript is well-written and the study is conducted appropriately in order to understand the molecular mechanisms that control hepatocarcinogenesis, and also raise the potential for new therapeutic and diagnostic approaches to human HCC.

Abstract

AIM: To investigate the correlation between expression of phosphatase and tensin homolog (PTEN) and cetuximab effects in colorectal cancer.

METHODS: We searched PubMed, EMBASE and ASCO to identify eligible studies. Finally, 8 randomized control studies were included in the meta-analysis. STATA 10.0 Software was used to investigate heterogeneity among individual studies and to summarize all the studies. Risk ratios (RRs) and hazard ratios (HRs) with 95% confidence intervals (CIs) were used to assess the strength of the association.

RESULTS: Compared with 20 of 266 patients with loss of PTEN, 206 of 496 patients with intact PTEN protein expression had a better objective response rate to cetuximab-based therapy (RR, 4.75; 95% CI, 2.59-8.72; $P < 0.001$). PTEN positivity was associated with better progression-free survival (PFS) (HR, 0.675; 95% CI, 0.473-0.964; $P = 0.031$) but not with better overall survival (OS) (HR, 0.608; 95% CI, 0.411-0.899; $P = 0.013$). In patients with KRAS wild-type status, PTEN positivity did not predict a longer PFS or OS (PFS: HR, 0.707; 95% CI, 0.440-1.138; $P = 0.154$; OS: HR, 0.943; 95% CI, 0.646-1.377; $P = 0.761$).

CONCLUSION: Expression of PTEN is related to the effect of cetuximab in colorectal cancer patients and should be considered in treatment with cetuximab.

INTRODUCTION

Colorectal cancer (CRC) is the fourth common malignancy and the second leading cause of cancer death in Western countries[1]. More than half of CRC patients will develop metastatic lesions (mCRC), which are often found in the liver[2]. Although novel pharmaceutical and surgical interventions have been introduced to treat mCRC, the 5-year survival rate for mCRC remains below 10%[3,4]. Recently cetuximab, a monoclnonal antibody that targets the epidermal growth factor receptor (EGFR) has

been proven to be efficacious in mCRC patients[3]. Cetuximab binds to EGFR *via* its ligand-binding domain to inhibit the activation of EGRF signaling. In clinical trials, cetuximab has been reported to achieve a response rate of 10% as a single agent and of 23%-25% in combination with chemotherapy[5,6]. The addition of cetuximab to chemotherapies enhances their antitumor activity[7]. The proposed mechanisms include: reducing tumor cell proliferation, angiogenesis, and DNA repair capacity; increasing apoptosis; and inducing cell cycle arrest at treatment-sensitive points[5]. These effects may enhance and restore tumor sensitivity to cytotoxic agents[8].

In CRC patients, EGFR is overexpressed in 75% of the tumors and its overexpression is associated with worse outcome[3,9]. EGFR was accordingly an obvious candidate for targeted therapy in this malignancy[5]. The tumor suppressor phosphatase and tensin homolog (PTEN) is an important negative regulator of cell-survival signaling[1]. To date, there is evidence to suggest that loss of expression of PTEN has negative association with the prognosis of CRC, especially mCRC. Loss of PTEN expression results in increased phosphatidylinositol phosphate-3 concentration, which induces subsequent protein kinase B hyperphosphorylation, thus protecting cancer cells from apoptotic stimuli[10-12]. In Addition, underexpression of PTEN confers resistance to cetuximab-induced apoptosis[10].

It is important to reveal the relation between the expression of PTEN and the prognosis of mCRC patients treated with cetuximab, as this will be helpful for adopting appropriate targeted therapy for patients[13]. At present, there are many studies which have reported the clinical outcomes of cetuximab in mCRC patients with loss of expression of PTEN. Hence, we carried out a meta-analysis to analyze the relation between the expression of PTEN and prognosis of CRC patients treated with cetuximab.

MATERIALS AND METHODS

Eligibility criteria
The purpose of this research was to systematically review the published articles of cetuximab-based chemotherapy in CRC (both primary and metastatic). Studies which reported the patients' PTEN status and compared the prognosis, were included in the analysis. The primary outcomes of interest were overall survival (OS) and progression-free survival (PFS). Care was taken to include only primary data or data that superseded earlier work.

Identification of studies
The search for studies was performed using the electronic database PubMed with the keywords "colorectal cancer", "cetuximab" and "PTEN". We also referred to the electronic database ASCO and EMBASE. All studies matching the eligibility criteria were retrieved and their bibliographies were checked for other relevant publications. Review articles and bibliographies of other relevant stud-

ies were identified through hand-searching to identify the additional studies. Data from review articles, case reports, abstracts, and letters were not included. Pharmaceutical industries and authors were not contacted. Characteristics of the studies were extracted from published articles and summarized in a consistent manner to aid comparison[14].

Statistical analysis
The meta-analysis was conducted by using Stata software (version 10.0; StataCorp Lakeway, College Station, TX, United States). Before performing the analyses, data of each published study were carefully checked and verified for coherence with the original publications. The strength of the association between status of PTEN and response of cetuximab-based therapy was measured by the risk ratio (RR) with 95% confidence intervals (CIs). Individual trial level time-to-event data was summarized by the hazard ratio (HR) with 95% CIs. Pooled estimations of RR and HR were obtained by calculating a weighted average of RR and HR from each study.

Statistical heterogeneity between studies was evaluated with the χ^2 test with significance set at a P value of 0.05. The percentage of total variation across the studies, with higher values indicating a greater degree of heterogeneity, was measured by the I^2 statistic. If the P value was $\leqslant 0.05$, the assumption of homogeneity was deemed invalid, and the DerSimonian-Laird method[15] (random-effects model) was used after exploring the causes of the heterogeneity; otherwise, the Mantel-Haenszel method[16] (fixed-effects model) was used. In the absence of heterogeneity, the fixed-effects and random-effects models provided similar results. I^2 lay between 0% and 100%, and a value of 0% indicated no observed heterogeneity, while larger values indicated increasing heterogeneity[17].

Findings of the meta-analysis are depicted in classical Forest plots, with point estimates and 95% CIs for each trial and overall size of the squares proportional to the effect size[18]. It was statistically significant when the two-tailed P value < 0.05. Publication bias was adjusted using the trim-and-fill method, and assessed by visual inspection of funnel plots (Figure 1)[19].

RESULTS

Description of studies
After exclusion of duplicate and irrelevant studies (Figure 2), our search yielded 8 eligible published studies that were retrieved for more detailed evaluation and meta-analysis[3,5,9,10,20-23]. The main characteristics of these selected studies are summarized in Table 1, and the description of PTEN status listed in Table 2. Most of the patients received a cetuximab-based therapy as second-line or later therapy after chemotherapy failure. All 8 studies including a total of 698 patients, of whom 513 were allocated to cetuximab plus irinotecan and others to cetuximab only or with various regimens as shown in detail in Table 1. The outcome measures of the above studies were evaluated based on the Response Evaluation Criteria in Solid Tu-

mor criteria, PFS and OS. Patients with stable disease or progression of disease were defined as non-responders. Results are presented for the comparisons with the available data.

Analysis of status of the PTEN homolog and objective response

Five articles documented the response rate of cetuximab-based therapy (Figure 3A). There were 266 patients with loss of PTEN and 496 patients with normal expression of PTEN. In total, compared with 20 of 266 patients with

loss of PTEN, 206 of 496 patients with intact protein expression had an objective response rate to cetuximab-based therapy (RR, 4.75; 95% CI, 2.59-8.72; $P < 0.001$). There was no heterogeneity between trials ($P = 0.637$, $I^2 = 0.0\%$). We also analyzed the response to cetuximab-based therapy in metastatic and primary colorectal tumors. Cetuximab-based therapy achieved significantly higher RR among patients with PTEN expression for metastatic tumors (RR, 6.46; 95% CI, 2.94-14.19; $P < 0.001$). In contrast, among 128 assessable primary tumors, 32 of 87 PTEN-positive and 5 of 41 PTEN-negative patients were

responders, and there was no significant difference observed (RR, 2.226; 95% CI, 0.893-5.548; P = 0.086). There was no evidence for heterogeneity between the studies (P = 0.697, I^2 = 0.0%; P = 0.765, I^2 = 0.0%; respectively).

Analysis of status of the phosphatase and tensin homolog and survival

Only two trials involving 170 patients were included in this comparison, because none of the other eligibility criteria had sufficient follow-up data listed (Figure 3B). The HR summarizes survival for PTEN-positive compared with PTEN-negative patients after cetuximab-based therapy, with an HR of less than 1 indicating a survival advantage for expression of PTEN in colorectal tumors. As for PFS, PTEN positivity was associated with better survival (HR, 0.675; 95% CI, 0.473-0.964; P = 0.031). The analysis for OS confirmed that loss of PTEN was significantly associated with poor clinical outcome (HR, 0.608; 95% CI, 0.411-0.899; P = 0.013). There was no significant intertrial heterogeneity for the end points of PFS (P = 0.259, I^2 = 21.6%) or OS (P = 0.414, I^2 = 0.0%).

Combined analysis of the PTEN homolog and KRAS status and survival

The studies selected for this analysis are listed in Figure 3C. The HR summarizes survival for PTEN-positive/wt-KRAS *vs* PTEN-negative/wtKRAS, with an HR of less than 1 indicating a survival advantage for PTEN-positive/wtKRAS. Overall, among patients with KRAS wild-type status, PTEN positivity did not predict a longer PFS or OS (PFS: HR, 0.707; 95% CI, 0.440-1.138; P = 0.154; OS: HR, 0.943; 95% CI, 0.646-1.377; P = 0.761). Heterogeneity was not found among trials for the analysis of PFS (P = 0.308, I^2 = 3.9%). However, there was marked intergroup heterogeneity for the combined analysis of OS making it difficult to obtain a clear conclusion (P = 0.002, I^2 = 84.5%). To adjust for this bias, the trim-and-fill method was implemented. The adjusted estimates for OS were obtained by using the random-effects model (HR, 0.759; 95% CI, 0.268-2.153; P = 0.604). In the results from the data, there was no difference between the fixed-effects and the random-effects model, indicating the reliability of this meta-analysis, so we can reach a real conclusion.

DISCUSSION

Nowadays, there is a trend towards individualized treatment in tumor therapy. The optimized application of cetuximab has paved a way for individualized treatment of CRC[24]. In recent years, cetuximab has been widely used in the patients with mCRC, and most of the patients have better prognosis than those treated with combined chemotherapy alone. However, personalized cancer medication is based on the genetics of individual colorectal tumors[24]. Hence, the effects of molecular alterations, especially the activating mutations in the KRAS protein, and the corresponding therapeutic effect of cetuximab have been widely discussed[25-27]. KRAS mutation testing is used

in the setting of EGFR-targeted therapy for metastatic disease worldwide[28]. Nevertheless, an intact KRAS is necessary but not sufficient to obtain benefit from EGFR inhibition[29-32]. Alterations in other downstream effectors of EGFR, such as BRAF and PIK3CA/PTEN have been found to give rise to cetuximab resistance[1,33]. Therefore, there is a deep need to reveal possible interactions between targeted agents, so that we can better select patients likely to respond to cetuximab-based treatment[28,29,34].

In this study, we focused on the association between the alteration of PTEN protein expression and the therapeutic effects of cetuximab in CRC patients. In addition, patients treated with panitumumab were also listed in the study search, because the two EGFR inhibitors, cetuximab (the chimeric IgG1 monoclonal antibody) and panitumumab (the humanized IgG2 monoclonal antibody), are currently approved in medication for CRC[34,35]. Both of the molecules bind to the EGFR, leading to inhibition of its downstream signaling and providing some clinical benefit.

PTEN is a tumor suppressor protein, which works as a negative regulator of PI3K/PTEN/Akt, which is a cell-survival signaling pathway[36]. Loss of PTEN expression was associated with the aggressive capacity of CRC, and that understanding the biologic mechanisms responsible for regulation of PTEN expression may allow better translational treatment of CRC patients. Furthermore, CRC patients with loss of PTEN expression show resistance to cetuximab[1].

In our selected studies, patients with normal PTEN expression had higher RR in all CRC with cetuximab-based therapy (especially in mCRC). Also we revealed that patients with PTEN normal expression with cetuximab treatment have better prognosis than those without cetuximab treatment and statistical analysis (OS and PFS) also presents significant differences (P < 0.05). In these studies we concluded that PTEN be proposed as an independent predictive factor[1] of cetuximab efficacy. We suggested that PTEN could help to predict prognosis and efficacy of cetuximab. Diagnostic evaluation of PTEN expression might provide additional guidelines for the treatment strategies for CRC patients and valuable prognostic information.

On the other hand, we did a combined analysis of PTEN and KRAS status on OS and PFS. Unfortunately, among patients with wild-type KRAS, PTEN positivity did not predict longer PFS and OS. Only one report showed the interaction between KRAS mutations with or without expression of PTEN in CRC. Thus, we could not perform a meta-analysis. The conclusion obtained in the report was that the PFS and OS of PTEN-positive patients with KRAS mutations were not significantly longer than in all other patients who presented with KRAS mutations and were PTEN-negative[10]. Survival analyses by Loupakis *et al*[10] demonstrated that BRAF mutations (HR, 3.75; P = 0.015) but not PIK3CA mutations (HR, 1.20; P = 0.672), were significantly associated with decreased OS, whereas neither of these alterations was significantly

associated with PFS. Further clinical data are necessary to identify a certain genes-alteration signature to predict the therapeutic effects of cetuximab-based therapy.

There are some limitations in this meta-analysis. First, the numbers of published studies were not adequate for a comprehensive analysis. Second, only 3 trials reported data of PFS and OS, and a lack of the original data in some studies limited our evaluation of survival, which may cause serious confounding bias. Third, although significant heterogeneity in some end-point variables were at least partly overcome by random-effects analysis, there was still heterogeneity between the relevant studies for inclusion, which may have affected the final results.

In conclusion, our meta-analysis showed an important role of PTEN status in determining the application of cetuximab-based targeted therapy. More clinical trials are warranted in this field to obtain more accurate results. Further improvement in the tailoring of EGFR targeted therapies needs more studies on molecular dissection of the EGFR-initiated oncogenic signaling cascade.

COMMENTS

Background
Cetuximab as a monoclnonal antibody (mAb) that has been used in colorectal cancer (CRC) patients. However, the responses vary in different individuals. Phosphatase and tensin homolog (PTEN) is an important negative regulator and its downregulation has been found in many CRC patients. The relationship between PTEN expression and the effects of cetuximab in CRC patients is still uncertain. The aim of this meta-analysis was to obtain a correlation.

Research frontiers
Cetuximab is a mAb that targets the epidermal growth factor receptor (EGFR). It binds to EGFR *via* its ligand-binding domain to inhibit the activation of EGRF signaling. Cetuximab has been reported to achieve a response rate of 10% as a single agent and of 23%-25% in combination chemotherapy. PTEN is an important negative regulator of cell-survival signaling and underexpression of PTEN confers resistance to cetuximab-induced apoptosis.

Innovations and breakthroughs
Many studies have reported the clinical outcomes of cetuximab in CRC patients with loss expression of PTEN. An exact conclusion has not been achieved mainly because of the limitation of sample size. This is the first study to report the relation between the expression of PTEN and prognosis of CRC patients treated with cetuximab.

Applications
This study may be helpful for adopting appropriate target therapy of cetuximab in patients with CRC.

Terminology
PTEN is the tumor suppressor phosphatase and tensin homolog that plays as an important negative regulator of cell-survival signaling.

Peer review
This is an interesting manuscript presenting a systematic analysis of the impact of PTEN expression on CRC response to cetuximab. It has clear limitations due to the quality of published papers. However, its findings are interesting.

Abstract

AIM: To investigated whether *sall3* transcription was regulated by promoter CpG island hypermethylation in hepatocellular carcinoma (HCC).

METHODS: The cell lines Huh7, HepG2, SK-HEP1, SM-MC7721, Bel7402, QGY7703 and a cohort of 38 HCC tissue specimens and corresponding nontumorous tissues were subjected to analysis for *sall3* promoter CpG island methylation and mRNA transcription. *sall3* promoter CpG island methylation levels were determined using the MassARRAY platform and mRNA transcription levels of the gene were detected by quantitative real-time polymerase chain reaction.

RESULTS: The levels of *sall3* mRNA were decreased by more than twofold in 33 of 38 tumor tissues compared to adjacent noncancerous tissues. Among these 33 tumor tissues with lower levels of *sall3* mRNA, 24 showed higher levels of methylation. Based on these results, we hypothesized that the decrease in *sall3* mRNA transcription level was likely due to promoter CpG island hypermethylation. Changes in *sall3* mRNA transcription and promoter CpG island methylation were determined in the above six cell lines after treatment with 0, 0.1, 0.5 and 2.5 μmol 5-aza-2-deoxycytidine, a demethylating agent. Promoter CpG island methylation levels decreased in a dose-dependent manner in all six cell lines, while the mRNA transcription level increased dose-dependently in Huh7, HepG2, SK-HEP1 and SMMC7721 cells and irregularly in Bel7402 and QGY7703 cells.

CONCLUSION: These results indicated that promoter CpG island hypermethylation contributes to the downregulation of *sall3* mRNA transcription in HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors, representing a major public health issue, especially in Asia[1]. The pathogenesis of HCC involves chronic hepatitis virus infection and activation of oncogenes and/or inactivation of tumor suppressor genes by mutations and epigenetic modification[2]. Epigenetic inactivation of tumor suppressor genes by DNA hypermethylation plays an important role in carcinogenesis[3]. Many groups have reported that promoter hypermethylation of CpG islands is associated with development, stage, recurrence, progression and survival in HCC[4,5]. In many cases, aberrant methylation of promoter regions within genes is correlated with a loss of gene expression[6]. Furthermore, in contrast to mutations, epigenetic changes may be reversible, raising the possibility of developing therapeutics based on restoring a normal epigenetic state in cancer-associated genes[7,8].

sal was originally identified as a region-specific homeotic gene in *Drosophila*[9]. *sall3* is one of four mammalian members of the sal-like (sall) gene family (*sall1*, *sall2*, *sall3* and *sall4*), which are involved in embryonic development[10]. *sall3* is one of several genes deleted in 18q deletion syndrome, characterized by hearing loss, mental retardation, midfacial hypoplasia, delayed growth, and limb abnormalities[11]. Loss of the *sall3* gene leads to palate deficiency, abnormalities in cranial nerves, and perinatal lethality[12]. Recently, it was reported that sall3 can interact with DNMT3A and shows the ability to inhibit CpG island methylation in HCC[13]. However, when scanning the nucleotide sequences of *sall3*, we found a CpG island in the promoter. It has been reported that *sall3* gene methylation levels are significantly increased in bladder cancer compared to nontumorous controls, and may be a new biomarker for the sensitive and specific detection of bladder cancer[14]. Furthermore, it has been reported that the *sall3* gene CpG island has a higher frequency of hypermethylation in HCC tumors compared with adjacent noncancerous tissues as determined by a qualitative methylation method[15]. However, the decreased *sall3* mRNA transcription levels in human HCC tissues and whether this is caused by promoter CpG island hypermethylation have not been fully examined.

Here, we show that sall3 mRNA transcription was downregulated in most (33/38) tumor tissues examined compared with adjacent noncancerous tissues. Most (24/33) downregulation of mRNA transcription was strongly associated with hypermethylation of the promoter CpG island. This association was further confirmed by subsequent cell line experiments; treatment of the cell lines with the DNA methyltransferase inhibitor 5-aza-2-deoxycytidine reversed promoter CpG island hypermethylation and restored *sall3* mRNA transcription. These results indicated that promoter CpG island hypermethylation is the main reason for the downregulation of *sall3* mRNA transcription in HCC.

MATERIALS AND METHODS

Tissue specimens and cell lines

Thirty-eight paired clinical samples of HCC, including tumor tissues and adjacent noncancerous tissues, were collected from surgical specimens at the Department of Hepatobiliary Surgery, Nanfang Hospital (16 cases), and the Cancer Institute of Sun Yat-sen University (22 cases), both in Guangzhou, China. All specimens were obtained immediately after surgical resection and were stored at -70 ℃ until DNA/RNA extraction.

Written informed consent was obtained from all patients prior to inclusion in the study. The study protocol was approved by the Nanfang Hospital Ethics Committee at Southern Medical University and the Sun Yat-sen Cancer Center Ethics Committee at Sun Yat-sen University.

Cell culture and 5-aza-CdR treatment

Six HCC cell lines (Huh7, HepG2, SMMC-7721, Bel-7402, SK-HEP1, QGY7703) were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco-BRL, Gaithersburg, MD), supplemented with 10% fetal bovine serum, 100 units/mL penicillin, 100 μg/mL streptomycin and incubated in a 5% CO_2 atmosphere at 37 ℃. The demethylating agent, 5-aza-2-deoxycytidine (5-aza-CdR; Sigma, St. Louis, MO), was freshly prepared in ddH_2O. HepG2 cells (3×10^5 cells/well) and other hepatoma cells (1×10^5 cells/well) in exponential growth phase were seeded in 6-well plates. After 24 h of culture, cells were treated with 5-aza-CdR at 0, 0.1, 0.5 and 2.5 mol for 3 d. The culture medium was replaced every 24 h with fresh media containing 5-aza-CdR. Total RNA and genomic DNA were extracted for real-time quantitative reverse transcription-polymerase chain reaction (qRT-PCR) and DNA methylation level analysis.

Detection of sall3 CpG Island DNA hypermethylation

Genomic DNA was extracted from cells and HCC samples using a QIAamp DNA Minikit (Qiagen, Valencia, CA). Genomic DNA (1 μg) was modified with sodium bisulfite using the EZ DNA methylation kit (Zymo Research, Orange, CA). DNA methylation levels of clinical samples and cell lines were determined using the MassARRAY platform (Sequenom, San Diego, CA) as described previously[16]. Briefly, two fragments covering 38 CpG sites from *sall3* were amplified from bisulfite-modified DNA. A 10-mer tag sequence was added to the forward primer, and a T7-promoter tag was added to the reverse primer to balance the PCR primer length. The primers used were 5'-AGGAAGAGAGGGATTGTTTGGATTTGATTT-TAATTT-3' (sense) and 5'-CAGTAATACGACTCAC-TATAGGGAGAAGGCTCACAAATAACCTCCTA-AAACTTCCC-3' (antisense); 5'-AGGAAGAGAGTTT-TAAGGTTGGTTTTTATTTTGTTT-3' (sense) and 5'-CAGTAATACGACTCACTATAGGGAGAAGGCTT-CTCAAAAATAATCTCAAACCCCTA-3' (antisense). Methylation data for individual units (1-3 CpG sites per unit) were analyzed using the EpiTyper software (Sequenom).

Figure 1 Average methylation levels were calculated from 38 tumors (T) and adjacent non-cancerous tissues (N) on 24 CpG units from *sall3* CpG island respectively. The data was analyzed by Wilcox rank sum test ([a]$P < 0.05$ *vs* non-cancerous tissues). Error bar, 95% confidence interval.

RNA extraction and quantitative real-time PCR analysis

Total RNA was extracted from cell lines and tissue samples using the Trizol reagent (Invitrogen), according to the manufacturer's protocol. First-strand cDNA was generated using a SYBR PrimeScript RT-PCR Kit (TaKaRa, Kyoto, Japan). *sall3* mRNA expression was detected by qRT-PCR using a SYBR Premix Ex *Taq* Kit (TaKaRa) on an ABI 7500 Real-Time PCR System (Applied Biosystems). β-actin was used as an internal control. The primers used were as follows: *sall3* forward primer: 5'-GCT-GCCTTCTCAGTTATTTGACC-3', reverse primer: 5'-TGACCGTTCACTTCCATTTTGA-3'; β-actin forward primer: 5'-TTGTTACAGGAAGTCGCTTGCC-3', reverse primer: 5'-ATGCTATCACCTCCCCTGTGTGT-3'. Relative levels of *sall3* mRNA were calculated and expressed as $2^{-\Delta\Delta Ct}$[17].

Statistical analysis

qRT-PCR results in different groups were analyzed by Student's *t* test. The methylation levels of Oct-6 in HCC tumors and adjacent noncancerous tissues were compared using the Wilcox rank sum test. All tests were two-sided. In all analyses, $P < 0.05$ was taken to indicate statistical significance.

RESULTS

sall3 promoter CpG island aberrant methylation and sall3 mRNA transcription in human HCC tissues

To determine whether *sall3* promoter CpG island hypermethylation changes leads to decreased *sall3* mRNA transcription in human HCC tissues, the methylation levels of the *sall3* promoter CpG island in 38 HCC tumors and adjacent noncancerous tissues were examined using the MassARRAY platform (Sequenom). Of the 38 tumors, 27 (71%) showed higher methylation levels at the *sall3* CpG island compared with adjacent noncancerous tissue, while methylation levels were similar at the *sall3* CpG

island in tumor tissue and adjacent noncancerous tissue in 11 cases (29%). None of the tumors showed lower methylation levels at the *sall3* CpG island compared with adjacent noncancerous tissues. Average methylation levels for each CpG unit in the 38 tumor tissues and adjacent noncancerous tissues are listed in Figure 1. Among the total of 24 CpG units (1-3 CpG sites per unit), the average methylation levels of 20 CpG units in 38 tumors were significantly higher than those in adjacent noncancerous tissues.

To determine whether aberrant CpG island DNA methylation in HCC tissues may be correlated with the decreased *sall3* mRNA transcription, *sall3* mRNA levels in 38 paired samples were determined by qRT-PCR (Figure 2). The relative ratio between methylation and mRNA expression levels of *sall3* are negatively correlated in 26 of 38 tumor tissues *vs* corresponding adjacent noncancerous tissues (Figure 3). Of the 38 tumor tissues, 33 (86.8%) showed a decreased *sall3* mRNA level compared to adjacent noncancerous tissues (Figure 2). Among these 33 tumor tissues with lower mRNA levels, 24 showed higher methylation levels and a negative association was found between CpG island methylation and mRNA expression (Figure 3); nine tumor tissues showed methylation levels that were not significantly different from adjacent noncancerous tissues. Of the 38 tumor tissues examined, three (7.9%) showed higher *sall3* mRNA expression than adjacent noncancerous tissues (Figure 2). Methylation level was similar to the adjacent noncancerous tissue in one of these three tumor tissues, while the methylation levels in the remaining two tumor tissues were higher than those in the adjacent noncancerous tissue. Of the 38 tumor tissues, two (5.3%) showed similar *sall3* mRNA expression to adjacent noncancerous tissues (Figure 2). Of these two tumor tissues, one showed no significant difference in methylation level compared with adjacent noncancerous tissues, while the methylation level in the other was higher than that the in the adjacent noncancer-

Figure 2 *sall3* mRNA is analyzed in 38 tumor tissues (T) and adjacent non-cancerous tissues (N). Error bars, SD from triplicates.

Figure 3 Correlation between methylation levels and mRNA expression of *sall3* in 24 tumor tissues and corresponding adjacent noncancerous tissues.

ous tissue. Together, these results indicated a negative correlation between *sall3* promoter CpG island hypermethylation and *sall3* mRNA transcription in 24 tumor tissues and their adjacent noncancerous tissues (Figure 3). *sall3* mRNA transcription in other tissues showed no association with *sall3* promoter CpG island hypermethyl-

ation, suggesting regulatory mechanisms other than those involved in HCC.

sall3 promoter CpG island hypermethylation correlates its mRNA transcription in human HCC cell lines
To determine whether decreased *sall3* mRNA transcrip-

Figure 5 Relative sall3 expression in six hepatocellular carcinoma cells after 5-AZA-CdR treatment. Error bars, SD from triplicates.

tion levels in human HCC tissues are due to promoter CpG island hypermethylation, six human HCC cell lines (Huh7, HepG2, SK-HEP1, SMMC7721, Bel7402 and QGY7703) were exposed to 0, 0.1, 0.5 or 2.5 μmol 5-aza-CdR, an inhibitor of DNMTs, for 72 h. As expected, after treatment with 0.1, 0.5 or 2.5 μmol 5-aza-CdR, promoter CpG island methylation levels showed dose-dependent downregulation in all six cell lines (Figure 4). *sall3* mRNA levels also showed dose-dependent upregulation

in Huh7, HepG2, SK-HEP1 and SMMC7721 cells, while it was irregularly upregulated in Bel7402 and QGY7703 cells (Figure 5). These data indicated that *sall3* promoter CpG island hypermethylation is likely responsible for the decrease in *sall3* mRNA transcription level.

DISCUSSION

HCC is one of the most common gastrointestinal ma-

lignancies, ranking fifth in the occurrence of common cancers, and third in common causes of cancer-related death[18]. Early-stage HCC is potentially curable with surgical resection or hepatic transplantation[19,20]. However, most patients present with advanced disease and are not amenable to surgical resection or transplantation. Therefore, they have a poor prognosis[21], and improved methods for early diagnosis are urgently required. DNA methylation is a gene expression regulatory mechanism and plays a fundamental role in carcinogenic processes[22,23]. Aberrant CpG island methylation of tumor-related genes is an early and frequent event in the process of carcinogenesis, and DNA methylation status of tumor-related genes is a potential diagnostic marker[24-26]. As it is possible to restore the function of methylated tumor suppressor genes, combinations of epigenetic modifiers and other therapeutic agents may also become a promising alternative to conventional treatments[27-29].

Although an increasing number of genes undergoing aberrant CpG island methylation have been reported in HCC[4,5,30,31], the methylated genes have not yet been fully characterized. Yu *et al*[14] reported that *sall3* was a novel target of aberrant methylation in bladder cancer. Xia *et al*[15] reported that the hypermethylation frequency in tumor tissues was significantly higher than those in adjacent noncancerous tissues, but whether the decreased transcription of *sall3* was caused by hypermethylation of the promoter CpG island in HCC remained unknown.

In the present study, we found that the levels of *sall3* mRNA were decreased in 33 of 38 tumor tissues compared with those in adjacent noncancerous tissues. Twenty-four of these 33 tumor tissues with reduced *sall3* mRNA levels showed elevated methylation levels, suggesting that the decreased *sall3* mRNA transcription levels were likely caused by promoter CpG island hypermethylation. We also confirmed that six HCC cell lines (Huh7, HepG2, SK-HEP1, SMMC7721, Bel7402 and QGY7703) were hypermethylated at the *sall3* promoter. Using the demethylating agent 5-aza-CdR, the transcription of *sall3* could be restored in these cells when the *sall3* promoter region was partially demethylated. Taken together with the results in HCC tissue samples, it is clear that promoter hypermethylation in *sall3* was strongly associated with the reduced transcription of *sall3* mRNA. However, in more than 25% of the HCC cases (9/33), decreased mRNA transcription was observed with similar CpG island methylation levels. In addition, there were three tumor tissues with promoter hypermethylation without decreased mRNA transcription compared with corresponding nontumorous tissues; the levels of mRNA transcription were increased in two of these cases and similar in the remaining one case. These results suggested that other regulatory mechanisms unrelated to promoter hypermethylation may also be involved. Further studies are needed to clarify this issue. However, the overall strong association between promoter hypermethylation and decreased mRNA transcription suggests a causative role of aberrant *sall3* promoter methylation and decreased mRNA transcription in most cases of HCC.

In conclusion, we showed that *sall3* mRNA transcrip-tion was downregulated in most (33/38) tumor tissues compared with adjacent noncancerous tissues in HCC. Most cases (24/33) with downregulated mRNA transcription were strongly associated with promoter CpG island hypermethylation. This association was further confirmed by subsequent experiments in cell lines; treatment of the cell lines Huh7, HepG2, SK-HEP1, SMMC7721, Bel7402 and QGY7703 with the DNA methyltransferase inhibitor 5-aza-2-deoxycytidine reversed promoter CpG island hypermethylation and restored *sall3* mRNA transcription. These results indicated that promoter CpG island hypermethylation is the main reason for downregulation of *sall3* mRNA transcription in HCC. These finding regarding *sall3* mRNA transcription and DNA methylation associated with human HCC provide new insights into the pathogenesis of HCC and may serve as a powerful molecular marker for detecting HCC in biopsy tissues of HCC patients.

COMMENTS

Background
Inactivation of tumor suppressor genes by promoter CpG island hypermethylation plays a key role in cancer pathogenesis.

Research frontiers
Aberrant CpG island methylation of tumor-related genes is a early and frequent event in carcinogenetic process and DNA methylation status of tumor-related genes is a potential diagnostic marker. Using demethylating agents to restore the function of methylated tumor suppressor genes also becomes a promising alternative to conventional treatments.

Innovations and breakthroughs
sall3 mRNA transcription was downregulated in most tumor tissues compared with adjacent noncancerous tissues. Downregulation of mRNA transcription was strongly associated with hypermethylation of the promoter CpG island. This association was further confirmed by subsequent cell line experiments; treatment of the cell lines with the DNA methyltransferase inhibitor 5-aza-2-deoxycytidine reversed promoter CpG island hypermethylation and restored sall3 mRNA transcription.

Applications
The finding of sall3 mRNA transcription and DNA methylation associated with human hepatocellular carcinoma (HCC) provide new insights into pathogenesis of HCC and may serve as a powerful molecular marker for detecting HCC in biopsies tissues of HCC patients.

Terminology
To concisely and accurately describe, define or explain the specific, unique terms that are not familiar to majority of the readers, but are essential for the readers to understand the article. DNA methylation typically occurs at CpG sites (cytosine-phosphate-guanine sites, that is, where a cytosine is directly followed by a guanine in the DNA sequence). This methylation results in the conversion of the cytosine to 5-methylcytosine. Hypermethylation typically occurs at CpG islands in the promoter region and is associated with gene inactivation. Demethylation is the chemical process resulting in the removal a of methyl group (CH_3) from a molecule.

Peer review
This is a nice human study conducted by a group of competent researchers. The study is nicely done. Also, the paper is well written.

Abstract

Pediatric Menetrier's disease (MD) is an uncommon, acute, self-limited hypertrophic gastropathy characterized by enlarged gastric folds associated with epithelial hyperplasia and usually accompanied by protein losing gastropathy. Gastric cytomegalovirus infection is found in one third of MD children and its treatment is often associated with remission. Diagnosis often requires full-thickness biopsy due to inability to detect typical histological findings with conventional endoscopic biopsy. We report an uncommon case of non self-limited pediatric MD needing endoscopic mucosal resection for diagnosis which was then successfully treated with octreotide long-acting release (LAR). To the best of our knowledge, this is the first pediatric MD case successfully treated with octreotide LAR. Our experience suggests octreotide LAR as treatment for refractory MD before gastrectomy.

INTRODUCTION

Menetrier's disease (MD) is a rare hypertrophic gastropathy characterized by enlarged gastric rugal folds and epithelial hyperplasia, accompanied by protein losing gastropathy[1]. Primarily seen in adults, MD can have a long clinical course and is associated with considerable morbidity and even mortality, which are related to surgical resection and potential risk for malignant transformation[2-4]. Pediatric MD often presents as oedema and hypoalbuminemia due to protein loss through the abnormal gastric mucosa and usually has a benign self-limited course with symptoms resolving within 5 wk[4,5]. Diagnosis often requires full-thickness biopsy in conjunction with endoscopic view of enlarged gastric folds[6] while histology includes foveolar hyperplasia with cystic

dilation of pits, accompanied by glandular atrophy of the gastric body[1,2]. Gastric cytomegalovirus (CMV) infection is found in one third of MD children and its treatment is often associated with remission[7,8]. We describe the first case of non self-limited and non protein losing MD, diagnosed with endoscopic mucosal resection (EMR) and successfully treated with octreotide long-acting release (LAR).

CASE REPORT

A 4-year-old boy was referred to our Unit for severe iron deficiency anemia (haemoglobin level: 4.7 g/dL and iron studies consistent with iron-deficiency anemia) already treated with blood transfusion in a territorial hospital. The child had a normal physical development with regular growth curve. Liver and spleen diseases were excluded on a clinical and biochemical basis. A grandfather underwent total gastrectomy due to MD. At upper gastrointestinal endoscopy there were marked thickened gastric folds with overlying erosions and exudate involving the corpus and fundus, whereas the antrum and pylorus were normal (Figure 1). Mucosal biopsies showed mild foveolar hyperplasia, dilation of some glands and were negative for *Helicobacter pylori* and CMV. The latter was also negative in the gastric juice, serum and urine. There was no clinical and laboratory evidence of protein-losing enteropathy and serum gastrin level was normal.

After 2 mo of unsuccessful treatment with omeprazole at 2 mg/kg per day, an EMR was done in the area of greatest gastric folds thickening to obtain a wider sample for a histological diagnosis. Thus, a diagnosis of MD was made. based on the presence of marked epithelial hyperplasia with tortuous and cystically dilated foveolar glands, discontinuous atrophy of stomach glands and significant reduction of parietal cells; a strong small vessel congestion with a diffuse edema was also observed within the lamina propria (Figure 2).

Following a lack of response to conventional therapies and due to preliminary reports on successful use of octreotide in adult MD[9-13], the patient was given ten doses of octreotide (50 μg subcutaneously two times a day), which was well tolerated. He then began octreotide LAR (5 mg intramuscularly every 28 d). Two months later haemoglobin and iron levels were normal. Six months later therapy was stopped and a rapid reduction of the haemoglobin level ensued. Thus, we continued octreotide with long-term normalization of the haemoglobin levels. Fifteen months later gastric folds were less prominent and no erosions at endoscopic follow-up were seen; however the histology was unchanged.

DISCUSSION

MD is characterized by hypertrophic folds in the body of the stomach, foveolar hyperplasia and hypoproteinemia[1]. While spontaneous remission is rare in adults and gastrectomy is not uncommonly required in refractory disease[2,3], pediatric MD is commonly an acute, self-limited,

Figure 1 Endoscopic view of markedly thickened gastric folds, with overlying erosions and exudates involving fundus (A) and corpus (B).

Figure 2 Histopathology from endoscopic mucosal resection (HE staining; A: 40×, B: 20×) shows elongated, tortuous and cystically dilated foveolar glands, discontinuous atrophy of gastric glands and significant reduction of parietal cells.

protein-losing gastropathy[5]. However, a hyperplastic hypersecretory variant of MD with normal or increased acid secretion and no protein loss is reported: it often

requires full-thickness biopsy due to an inability to detect typical histological findings with conventional endoscopic biopsy[6].

Therapy in children is supportive and includes adequate hydration, antisecretory agents (histamine 2 receptor antagonists and proton pump inhibitors) and albumin replacement[3-5]. Treatment of CMV, when detected, is usually associated with remission[7,8].

Interestingly, transforming growth factor α, one of the ligands for the epidermal growth factor receptor (EGF-R), has been implicated in the mechanisms underlying MD[14]: it causes dose-dependent *in vitro* proliferation of gastric epithelial cells and reduction of acid secretion, which are hallmarks of the disease[15,16].

Treatment with an experimental monoclonal antibody against EGF-R has been successful in 3 severe MD cases[17,18]. There is also evidence that somatostatin decreases the number of EGF binding sites at the cell surface[19]; thus, octreotide may modulate EGF-R signalling at several levels[20,21]. These mechanisms and preliminary reports on successful use of octreotide in adults with MD[9-13] prompted us to use this agent in our patient.

In conclusion, we describe an uncommon case of pediatric MD with atypical presentation (only anemia) and chronic unremitting course. MD should be considered in all children with thickened gastric folds at endoscopy, even in the absence of typical clinical and laboratory manifestations. EMR is a good alternative to full thickness biopsy for diagnosing disorders associated with gastric wall thickening such as MD.

To the best of our knowledge, this is the first pediatric MD case successfully treated with octreotide LAR. Our experience suggests octreotide LAR as treatment for refractory MD before gastrectomy.

Abstract

To report the result of rapid ulcer healing by infliximab in Crohn's patients with severe enterocolic bleeding. During 2005 and 2010, inflammatory bowel disease database of King Chulalongkorn Memorial and Samitivej hospitals were reviewed. There were seven Crohn's disease (CD) patients (4 women and 3 men; mean age 52 ± 10.4 years; range: 11-86 years). Two of the seven patients developed severe gastrointestinal bleeding (GIB) as a flare up of CD whereas the other five patients presented with GIB as their first symptom for CD. Their mean hemoglobin level dropped from 12 ± 1.3 g/dL to 8.7 ± 1.3 g/dL in a 3-d period. Median packed red blood cells units needed for resuscitation was 4 units. Because of uncontrolled bleeding, surgical resection was considered. However, due to the poor surgical candidacy of these patients (*n* = 3) and /or possible development of short bowel syndrome (*n* = 6), surgery was not pursued. Likewise angiographic embolization was not considered in any due to the risk of large infarction. All severe GIBs successfully stopped by one or two doses of intravenous infliximab. Our data suggests that infliximab is an alternative therapy for CD with severe GIB when surgery has limitation or patient is a high risk.

Aniwan S, Eakpongpaisit S, Imraporn B, Amornsawadwatana S, Rerknimitr R. Infliximab stopped severe gastrointestinal bleeding in Crohn's disease. *World J Gastroenterol* 2012; 18(21): 2730-2734 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i21/2730.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i21.2730

INTRODUCTION

Although severe gastrointestinal bleeding (GIB) is an uncommon complication of inflammatory bowel disease (IBD), severe GIB occurs in 0.1% of ulcerative colitis[1] and 1.2%-1.3% of Crohn's disease (CD)[1,2]. This in turn sometimes progresses to a potential life-threatening condition. Approximately one third of CD patients developed GIB as a flare up and another one fourth of CD patients presented with GIB as an initial symptom[3]. Bleeding sources were mostly found in the colon (50%-85%) and the small bowel (15%-50%). Unfortunately, one third of CD related GIBs were severe and surgery was required because of refractory bleeding especially after failed conventional medical and endoscopic treatment[1,3]. Therefore treatment for severe hemorrhage in IBD remains a challenge. Recently, there has been only a handful of case reports of severe CD related GIB controlled with tumor

necrosis factor (TNF)-α antibody (infliximab). We report the largest number (n = 7) of CD patients presenting with severe GIB who were successfully treated with infliximab without the need for surgery.

CASE REPORT

There were seven CD patients (4 women and 3 men; mean age 52 ± 10.4 years; range: 11-86 years). Two of the seven patients developed severe GIB as a flare up of CD whereas the other five patients presented with GIB as their first symptom for CD (Tables 1 and 2).

In a group with flared CD (n = 2), one patient was diagnosed as colonic CD for 2 mo. She was steroid dependent who required oral prednisolone 35 mg/d and azathioprine 1.5 mg/kg per day. She was admitted because of severe bleeding per rectum and developed orthostatic hypotension. She required 4 units of pack red cell for resuscitation during those 3 d of hospitalization. Another patient was diagnosed as ileocolonic CD for 7 mo. She had been taking budesonide 9 mg/d and mesalamine 2 g/d to control her CD before admission. She developed acute abdominal pain, fever and severe hematochezia. Her hemoglobin (Hb) dropped from 12 to 10 g/dL within 2 d. A unit of pack red cell was required to maintain hemoglobin level.

In patients who presented with hematochezia as their first CD symptom (n = 5), three of the five patients had had abdominal pain and watery diarrhea for 10-14 d prior to the present of hematochezia. The other two presented initially with hematochezia without prior warning gastrointestinal (GI) symptoms. All of those denied the use of non-steroidal anti-inflammatory drugs (NSAIDs) prior to the presentation. Skin signs and symptoms that suggestive of Behçet's disease were not recognized in any.

The average baseline Hb was 12 ± 1.3 g/dL in all patients. Coagulogram and platelets count were normal. The average C-reactive protein level was high (mean 14 ± 18 mg/L; normal 0-6). Endoscopy and ileo-colonoscopy were performed as the initial investigations. One patient with suspected proximal ileal bleeding underwent a double balloon enteroscopy. Endoscopic findings showed multiple discrete deep ulcers with either active oozing or visible vessel in all seven patients. Of these, two patients with visible vessel found on the ulcer underwent endoscopic hemostasis with hemoclipping. However, recurrent hematochezia developed in both and repeat endoscopy failed to indentify other source of bleeding despite the inactive status of previously clipped vessels. Bleeding sources located in the small bowel and mainly in the ileum without colonic source in five patients, while the other had pure colonic lesion. One patient had ulcers in both ileum and colon. Biopsies from Ileum and colon were done in all patients and they revealed acute and chronic inflammation. No granuloma was identified. All specimens were negative for inclusion body and *Mycobacterium tuberculosis* (by polymerase chain reaction).

Despite, an intravenous dexamethasone 5 mg was given at every 6 h for 3-5 d, all patients still had persistent hematochezia. Their mean Hb level dropped from 12 ± 1.3 g/dL to 8.7 ± 1.3 g/dL in a 3-d period. Median packed red blood cells units needed for resuscitation was 4 units. Because of uncontrolled bleeding, surgical resection was considered. Due to the poor surgical candidacy of these patients (n = 3) and/or possible development of short bowel syndrome (n = 6), surgery was not pursued. Likewise angiographic embolization was not considered in any due to the risk of large infarction from multiple areas of embolization. Then infliximab (5 mg/kg) was infused instead. Infliximab rapidly stopped bleeding definitely within 24 h in 6 patients. Another patient developed recurrent bleeding after 3 d of the first dose of infliximab. Subsequently, bleeding ceased promptly after the second dose of infliximab that administered at day tenth. Median doses of infliximab were two. All underwent a follow-up ileo-colonoscopy that revealed a significant improvement of ileal and colonic ulceration (Figures 1 and 2). At the 30-d follow up, no patients reported recurrent bleeding.

DISCUSSION

In our case series, we identified CD patients with severe GIB presented as either the first manifestation or a flare up of disease. None of our patients had histories or findings suggestive of NSAIDs induced ulcers or Behçet's disease. The common location of ulcers in our series involved ileum, ileocolic region, colon and a combination of all areas. The most common endoscopic findings were extensive multiple deep ulcers with or without active oozing. Infliximab was used as a last resort for controlling bleeding after failure of standard treatments. In fact, surgical treatment was considered in all cases, but it was not opted as mentioned earlier. Almost all patients responded promptly within 24 h after a single dose of infliximab. Only one patient with ileocolonic CD needed the second dose to achieve definite hemostasis after the recurrent bleeding.

Management of severe GIB in CD is problematic since there are multiple lesions with the possibility of bleeding from multiple sites. Endoscopy should be attempted in all patients, but only a quarter of patients that the bleeding sites could be precisely identified[3]. Medical therapies such as steroids, azathioprine and mesalamine also have been reported to control bleeding, but the prompt response is uncertain. Surgical resection is also a crucial therapy[4-6]. Recurrent bleeding was significantly lower in surgically treated patients (5.7%) compared with medically treated patients (38.5%). However, there is a significant rate of post operative and perioperative mortality at 6.9%[7]. In addition, the risk of developing short bowel syndrome after resection should be considered because these patients may have an extensive small bowel involvement[8-10]. Radiological intervention, one of the alternative treatments for small bowel bleeding[11], can accidentally contribute to small bowel infarction after multiple area of embolization. From those five series reported on GIB related to CD (n = 101), an angiographic embolization

was attempted only in one patient[1-3,12,13]. Unfortunately, that such patient subsequently necessitated surgery due to small bowel infarction after an ileocecal artery embolization[3]. Angiography with intra-arterial vasopressin infusion in case where embolization is not possible has previously been proven to be successful in two CDs related GIB[14,15]. However, many side effects and complications could develop from this technique including hypertension, coronary vasoconstriction, cardiac arrhythmia, and bowel infarction. To decrease the risk for bowel infarction, it is advisable to use superselective angiographic embolization[16]. Although the risk of bowel infarction may be decreased, this serious complication cannot be ignored. In experienced centers, bowel infarction still developed in 5%-24% of lower GIB patients who treated with superselective mesenteric arterial embolization[17,18].

The pathogenesis of hemorrhagic type CD remains unclear. One possible hypothesis is transmural inflammations leading to mucosal ulcers erode to blood vessels. On endoscopic examinations, all of our patients had diffuse deep ulcers and majority of them (86%) had active oozing. Since severe hemorrhage usually develops from ulcers eroding into blood vessels, any treatment that can rapidly heal the mucosa is an ideal therapeutic tool to control and prevent recurrent hemorrhage. Anti-TNF-α (infliximab) has been shown to induce rapid mucosal healing[19,20]. Therefore, infliximab has a possible role in treating severe hemorrhagic CD. Moreover, the identification for precise bleeding site is not required since infliximab can systematically heal multiple small bowel ulcers.

To date, eleven CDs related GIB treated with infliximab from the seven series has been reported (Table

3)[7,21-26]. Severe hematochezia was presented in eight flare-up CD patients and the other three presented with hematochezia as their initial CD manifestation. Four patients previously had undergone for surgical treatment including ileocolectomy and total colectomy[7,23,25,26]. Colon and ileocolon were the most common locations of GIB. Ileocolonoscopy showed multiple discrete deep ulcers in all. Majority of patients had more than one potential site of bleeding[7,21-26]. The high risk bleeding stigmata was found in only one patient that presented with diffuse spontaneous mucosal bleeding[21]. One patient underwent a total colectomy and small bowel resection, but the bleeding recurred[23]. No patient underwent angiographic therapy. Infliximab was administered as a last resource for uncontrolled bleeding. Most of patients responded to the first dose of infliximab. Only one patient required the second dose of infliximab on day fourteenth to control recurrent bleeding[26]. Six patients received three doses of infliximab and another five received only a single dose of infliximab. Maintenance with infliximab was considered only in one patient[23]. Surgery was not pursued in any[4,15-20].

To our knowledge, we report the largest cases series of severe GIB in CD in which infliximab had been used. Infliximab was able to control hemostasis as a result of rapid ulcer healing. Definite hemostasis was achieved after the first or second dose of infliximab. Nevertheless, more further prospective studies are required to confirm the utilization of infliximab for severe GIB in CD.

In conclusion, infliximab may be a good alternative treatment to control severe bleeding related to small bowel and colonic ulcers in active CD especially in patients with high risk for surgery and/or high risk to develop a short bowel syndrome.

Abstract

We evaluated the efficacy and tolerability of a dual therapy with rabeprazole and amoxicillin (AMX) as an empiric third-line rescue therapy. In patients with failure of first-line treatment with a proton pump inhibitor (PPI)-AMX-clarithromycin regimen and second-line treatment with the PPI-AMX-metronidazole regimen, a third-line eradication regimen with rabeprazole (10 mg q.i.d.) and AMX (500 mg q.i.d.) was prescribed for 2 wk. Eradication was confirmed by the results of the ^{13}C-urea breath test (UBT) at 12 wk after the therapy. A total of 46 patients were included; however, two were lost to follow-up. The eradication rates as determined by per-protocol and intention-to-treat analyses were 65.9% and 63.0%,

respectively. The pretreatment UBT results in the subjects showing eradication failure; those patients showing successful eradication comprised 32.9 ± 28.8 permil and 14.8 ± 12.8 permil, respectively. The pretreatment UBT results in the subjects with eradication failure were significantly higher than those in the patients with successful eradication (P = 0.019). A low pretreatment UBT result ($\leqslant$ 28.5 permil) predicted the success of the eradication therapy with a positive predictive value of 81.3% and a sensitivity of 89.7%. Adverse effects were reported in 18.2% of the patients, mainly diarrhea and stomatitis. Dual therapy with rabeprazole and AMX appears to serve as a potential empirical third-line strategy for patients with low values on pretreatment UBT.

TO THE EDITOR

Eradication of *Helicobacter pylori* (*H. pylori*) has been reported as an effective strategy in the treatment of peptic ulcers and gastric mucosa-associated lymphoid tissue lymphomas and also prevents the recurrence of gastric cancer after endoscopic resection[1-7]. The first-line regimen for the treatment of *H. pylori* infection in Japan is triple therapy with a proton pump inhibitor (PPI), amoxicillin (AMX) and clarithromycin (CLR) administered for 7 d. Failure of this first-line therapy against *H. pylori* infection has been reported in approximately 20% of infected patients[8,9]. With the increase in the frequency of CLR-resistant *H. pylori*, there is rising concern about the potential decline in the eradication rate of this infection[10]. Although therapy with PPI-AMX-metronidazole (MNZ) administered for 1 wk has been found to be effective as a second-line regimen in patients failing the

first-line regimen, approximately 10% of patients fail to respond to even second-line treatment, necessitating the establishment of an alternative third-line strategy for the effective eradication of *H. pylori*[3,11].

Although *H. pylori* bacteria easily develop resistance to CLR and MNZ, *H. pylori* has been considered to seldom become resistant to AMX. AMX is the preferred antibiotic because it is bactericidal and resistance is rare; therefore, it can be used again after treatment failure[8]. A number of studies have suggested that good success rates for *H. pylori* eradication could be obtained with AMX and PPI dual therapy if the effective PPI dose and frequency of administration were increased[12]. The majority of patients who experience two eradication failures have the rapid metabolizer genotype of CYP2C19. Because omeprazole and lansoprazole are extensively metabolized by CYP2C19 in this genotype, their plasma concentrations will not attain levels sufficient to inhibit acid secretion, and therefore, antibiotics such as AMX will be less stable in the stomach, resulting in a lower eradication rate[13]. The PPI rabeprazole is a substitute of benzimidazole. CYP2C19 is less involved in the metabolism of rabeprazole than in that of omeprazole and lansoprazole[14]. Moreover, rabeprazole has a greater and more rapid acid-inhibitory effect than does omeprazole. Several reports on the pharmacokinetics and pharmacodynamic characteristics of PPIs have indicated that a sufficient plasma concentration of PPIs can be achieved in patients with the rapid metabolizer genotype of CYP2C19 by frequent PPI dosing[12,15]. Furuta *et al*[16] recently reported an excellent eradication rate of 87.8% following dual therapy with rabeprazole 4 times/day and AMX as a third-line rescue. However, their study was completed at only one or two centers. Our study was designed as a prospective, multicenter trial with the participation of 16 Japanese hospitals affiliated with the National Hospital Organization to investigate the efficacy of dual therapy with 4 times daily dosing of rabeprazole and AMX as empiric third-line rescue therapy.

A total of 46 patients (26 males, 20 females; age 60.7 ± 12.9 years, mean ± SD) referred to us between January 2009 and January 2012 were enrolled. Endoscopic examinations were conducted before treatment in all patients, and *H. pylori* positivity was confirmed by histology, stool antigen test, *H. pylori*-specific IgG antibodies or the ^{13}C-urea breath test. All patients had a history of two treatment failures (first-line treatment used: triple therapy with PPI-AMX-CLR for 7 d; second-line treatment used; triple therapy with PPI-AMX-MNZ for 7 d). The exclusion criteria in this study were (1) age < 18 years; (2) presence of clinically significant underlying disease (hepatic or renal disease, diabetes mellitus); (3) history of gastric surgery; and (4) allergy to any of the drugs used in the study. *H. pylori* eradication failure was defined as a positive ^{13}C-urea breath test (UBT) at the end of 12 wk after completion of treatment. The ^{13}C-urea used was 100 mg ^{13}C-labelled urea, produced by Otsuka pharmaceutical Co., LTD, Japan. The procedure was modified from the European standard protocol for the detection of *H. pylori*[17]. We

Table 1 Demographic characteristics of the patients and the results of eradication therapy

Characteristics	Total ($n = 46$)	Eradication success ($n = 29$)	Eradication failure ($n = 15$)	P value

chose 2.5 permil for cut-off level of the rise in the delta value of $^{13}CO_2$ at 15 min after the ingestion of ^{13}C-urea.

The treatment regimen was rabeprazole 10 mg q.i.d. and AMX 500 mg q.i.d. administered for 2 wk. Participants were requested to return at the conclusion of the therapy for an interview regarding any adverse events. Successful *H. pylori* eradication was defined as a negative UBT at the end of 12 wk after completion of treatment. Statistical analyses were performed using the chi-square, Fisher's exact and Student's *t* tests, as appropriate. *P* values of less than 0.05 were accepted as representing statistical significance. The study was conducted with the approval of the Ethics Committee of the National Hospital Organization Tokyo Medical Center, and informed consent was obtained from all patients prior to the examinations. The clinical trial registration number of the University Hospital Medical Information Network was R000003204.

Of the 46 patients enrolled, 2 dropped out of the study, leaving 44 patients in the per protocol (PP) set. *H. pylori* eradication was confirmed in 29 patients, representing an eradication rate of 63.0% [95% confidence intervals (CI): 47.6%-76.8%] by intention-to-treat (ITT) analysis and 65.9% (95% CI: 50.1%-79.5%) by PP analysis (Table 1). Patient compliance with the prescribed treatment was excellent. Adverse events were recorded in 8 patients (18.2%; 95% CI: 8.2%-32.7%). Six patients had mild diarrhea or soft stools but went on to complete the study. Two patients developed stomatitis.

Because the numerical results of the UBT are a function of the total urease activity within the stomach, they represent a quantitative index of the density of gastric *H. pylori* colonization[18]. As a low pretreatment UBT value could be one of the predictive factors for eradication success, the pretreatment UBT value was analyzed. The pretreatment UBT results in the subjects with eradication failure and in those with successful eradication were 32.9 ± 28.8 and 14.8 ± 12.8 (permil, mean ± SD), respectively. The results of the statistical analysis showed that the pretreatment UBT results in the subjects with eradication failure were significantly higher than those in the patients with successful eradication ($P = 0.019$, effect size 0.81). We plotted original receiver operator characteristic (ROC)

curves for the pretreatment UBT results to establish the appropriate cutoff value. According to the ROC curves, the optimal cutoff value in our population was 28.5. When patients were assigned to two groups (UBT results $\leq$ 28.5 permil and > 28.5 permil), the eradication rates were 81.3% (26/32) and 25.0% (3/12), respectively ($P = 0.001$). A low pre-treatment UBT value ($\leq$ 28.5 permil) predicted the success of the eradication therapy with a sensitivity of 89.7%, specificity of 60.0%, positive predictive value of 81.3%, negative predictive value of 75.0% and accuracy of 79.5%.

Currently, a standard third-line therapy still remains to be established. *H. pylori* isolates after two eradication failures are often resistant to both MNZ and CLR. The alternative candidates for third-line therapy are fluoro-quinolones-AMX-PPI, rifabutin-AMX-PPI, and high-dose PPI/AMX therapy[2,19-21]. Gisbert *et al*[22] conducted a prospective multicenter study to evaluate the outcomes of treatment with a third-line levofloxacin-based regimen. The patients were treated for 10 d with a regimen consisting of omeprazole, levofloxacin and AMX. The eradication rates as determined by PP and ITT analyses were 66% and 60%, respectively. However, resistance to fluoroquinolones has been shown to be easily acquired, and in countries with a high rate of use of these drugs, the resistance rates are relatively high. González Carro *et al*[23] evaluated the efficacy of a third-line rifabutin-based triple therapy. The patients were treated with PPI, rifabutin and AMX for 10 d. The eradication rates as determined by PP and ITT analyses were 62.2% and 60.8%, respectively. However, it has been suggested that the use of rifabutin be reserved for the treatment of multidrug-resistant *Mycobacterium tuberculosis* strains[24].

Our results for the dual therapy with 4 times daily dosing of rabeprazole and AMX for 14 d, which yielded eradication rates in the PP and ITT analyses of 65.9% and 63.0%, were as successful as other empiric third-line therapy regimens. In particular, a low pretreatment UBT result ($\leq$ 28.5 permil) predicted the success of the eradication therapy with a positive predictive value of 81.3%, sensitivity of 89.7% and specificity of 60.0%, so the dual therapy appeared to serve as a promising option for empiric third-line rescue therapy in patients with a low pretreatment UBT value.

We recently reported the resistant rates of *H. pylori* to AMX. The resistance rates to AMX (MIC $\geq$ 0.06 μg/mL) in the groups with no history of eradication treatment, a history of one treatment failure, and a history of two treatment failures were 13.6%, 26.5% and 49.5%, respectively. The MIC_{90} of AMX increased by 2-fold after each eradication failure[25]. Resistance to AMX in *H. pylori* was gradually induced after unsuccessful eradication. Because the AMX resistance rate after two treatment failures was relatively high, the eradication rate of the present study was lower than that of previous report by Furuta *et al*[16]. Therefore, antimicrobial susceptibility testing of *H. pylori* is desirable before the selection of a suitable third-line therapy, although the culture-based antibiotic susceptibil-

ity testing for *H. pylori* is expensive, time-consuming, and not always available on a routine basis[26]. There are several limitations to our study. First, our eradication study was single armed using the dual therapy, and different doses or superiority over quinolone-based therapy was not evaluated. Second, we did not examine the *in vitro* susceptibility in patients treated with the dual therapy. Thus, *in vitro* resistance to AMX was not elucidated. These issues should be re-evaluated in future studies.

Finally, although we did not achieve excellent eradication success, the dual therapy appeared to serve as a promising option for empiric third-line rescue therapy in patients with low pretreatment UBT values. The antimicrobial susceptibility testing of *H. pylori* is desirable before the selection of a suitable third-line therapy in patients with high pretreatment UBT values.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean $\pm$ SD or mean $\pm$ SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 $\pm$ 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

Book reviews: http://www.wjgnet.com/1007-9327/g_info_20100312231947.htm

Guidelines: http://www.wjgnet.com/1007-9327/g_info_20100312232134.htm

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (http://www.wjgnet.com/1007-9327office/). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://

www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Upper gastrointestinal haemorrhage (UGIH) remains a common medical emergency worldwide. It is increasingly recognised that early risk assessment is an important part of management, which helps direct appropriate patient care and the timing of endoscopy. Several risk scores have been developed, most of which include endoscopic findings, although a minority do not. These scores were developed to identify various end-points including mortality, rebleeding or clinical intervention in the form of transfusion, endoscopic therapy or surgery. Recent studies have reported accurate identification of a very low risk group on presentation, using scores which require simple clinical or laboratory parameters only. This group may not require admission, but could be managed with early out-patient endoscopy. This article aims to describe the existing pre- and post-endoscopy risk scores for UGIH and assess the published data comparing them in the prediction of outcome. Recent data assessing their use in clinical practice, in particular the early identification of low-risk patients, are also discussed.

Key words: Upper gastrointestinal haemorrhage; Bleeding; Endoscopy; Risk assessment; Scoring systems; Blatchford; Rockall

INTRODUCTION

Upper gastrointestinal haemorrhage (UGIH) continues to be a major cause of hospital admission and mortality throughout the world. A recent United Kingdom national prospective audit of 6750 patients with UGIH reported a median five day length of stay and 10% mortality[1]. In that audit, peptic ulcer disease and variceal bleeding accounted for 36% and 11% patients respectively.

Management of UGIH consists of appropriate resuscitation and assessment, with timely endoscopy to diagnose and if necessary treat the underlying lesion. Similar to other common medical conditions, risk scores have been developed to try and identify those at lower or higher risk of poor outcome. Two recent international consensus documents have emphasised the importance of risk assessment in patients with UGIH[2,3].

An ideal risk score is one that is easy to calculate, accurate for relevant outcomes and can be measured early after presentation with UGIH. Most risk scores require endoscopy although others do not. If a low risk group can be identified soon after presentation, it may allow non-admission of this group with arrangements made for out-patient endoscopy. Higher risk groups require in-patient endoscopy for full evaluation and therapy. This

review describes the existing risk scores for UGIH (clinical and endoscopy based) and gives an update on data regarding their use in clinical practice.

METHODOLOGY

A Medline and PubMed search was undertaken using the keywords: upper gastrointestinal haemorrhage, bleeding, endoscopy, risk assessment and scoring systems. The period covered was 2000-2011 although earlier major publications were used for this review, including those referenced by articles and guidelines within the search period.

It is well recognised that patients with variceal bleeding constitute a specific and high risk group, with outcome largely dependent on the severity of underlying liver disease as assessed by the Childs-Pugh score or model for end stage liver disease (MELD)[4]. This review was not designed to describe scores specifically designed for patients with variceal bleeding and will not describe assessment of this subgroup in detail.

The review is split into assessment and comparisons of risk scores for UGIH which require endoscopy, and those which do not (pre-endoscopy scores) which can be calculated early after presentation. Where studies have directly compared scores for specific end-points, the area under the receiver operator curves (AUROC) are given if available. Finally there is a section describing the optimum clinical use of scores, focusing on the important issue of early identification of low-risk patients who may be suitable for discharge or even non-admission.

RISK SCORES REQUIRING ENDOSCOPY

The most commonly used risk scoring system in UGIH is the Rockall score, which was described in 1996 following analysis of data from a large English audit[5] (Table 1). The score was developed to assess the risk of death following presentation with UGIH and incorporates patient age, haemodynamics, comorbidities and endoscopic findings. Due to the importance of underlying liver disease or failure in prognosis, most generic scoring systems for UGIH including the Rockall score incorporate this as a score component.

The American Baylor score was developed in 1993 to predict rebleeding after endoscopic therapy for non-variceal UGIH[6]. It includes five clinical and endoscopic variables. The Cedar Sinai predictive index is another American score which was derived after a structured literature review to predict outcome and length of hospital stay after UGIH[7]. It includes endoscopic findings, haemodynamics, comorbidities and time from symptoms.

The Spanish Almela score was developed to identify a low risk non-variceal group suitable for out-patient management and includes components from the history, haemodynamics and endoscopic findings[8]. An Italian 10 point score was recently developed to predict mortality after non-variceal bleeding[9]. Several other endoscopy based guidelines and clinical prediction models

Table 1 Rockall score				
Component score	0	1	2	3
Age (yr)	< 60	60-79	≥ 80	-
Haemodynamics:				
Pulse (bpm)	< 100	≥ 100	-	-
Systolic BP (mmHg)	≥ 100	≥ 100	< 100	-
Comorbidities	None	-	IHD, cardiac failure, other major comorbidity	Renal or liver failure, disseminated malignancy
Diagnosis	MW or no lesion and no stigmata	All other diagnosis	Malignant lesions of UGIT	-
Stigmata of haemorrhage	No stigmata or dark spot on ulcer	-	Blood in UGIT, adherent clot, visible/ spurting vessel	-

A score of ≤ 2 identifies a low-risk patient suitable for early discharge. UGIT: Upper gastrointestinal tract; IHD: Ischaemic heart disease; MW: M-Weiss tear; GI: Gastrointestinal; BP: Blood pressure.

for UGIH have been reported from America[10,11], Hong Kong[12] and Italy[13].

COMPARISONS OF ENDOSCOPY BASED RISK SCORES

The Rockall score has been externally validated in several countries[14-17]. It has been also been shown to be superior to the Baylor and Cedar-Sinai scores in identifying low risk patients among a cohort with non-variceal bleeding[14]. In this study, all three scores were better at predicting mortality than rebleeding. The AUROC figures for mortality for the Rockall, Cedar-Sinai and Baylor scores were 0.85, 0.81 and 0.78 respectively, with the corresponding figures for rebleeding 0.68, 0.67 and 0.59. The Italian 10-point score was recently reported to be superior to the Rockall score for predicting 30-d mortality (AUROC 0.81 vs 0.66), but this requires external validation[9].

At present, the Rockall score is the most widely used and studied post-endoscopy score to predict outcome. No other endoscopy based score has yet been validated to be of proven superiority in clinical use.

PRE-ENDOSCOPIC RISK SCORES

An abbreviated pre-endoscopic or "admission-Rockall" score is often used, omitting the last two (endoscopic) components of the full Rockall score. However there has been debate about its accuracy and general clinical applicability. The Glasgow Blatchford Score (GBS) was developed in 2000 to predict the need for hospital based intervention (transfusion, endoscopic therapy, or surgery) or death following UGIH[18] (Table 2). Romagnuolo et al[19] described a modified GBS (due to unavail-

Table 2 Glasgow blatchford score

ability of serum urea or history of syncope) from Canadian data which predicted high risk endoscopic stigmata, rebleeding and mortality.

The Cambridge score[20] and artificial neural networks (ANNs)[21,22] are other reported pre-endoscopic scoring systems. The former requires 14 clinical and laboratory variables and has not been externally validated. The latter require analysis of even more variables using computer software and are only applicable to non-variceal UGIH. Partly for these reasons the scores are not widely used.

COMPARISONS OF PRE-ENDOSCOPIC RISK SCORES

Six recent studies from United Kingdom and Taiwan have shown the GBS to be superior to the admission Rockall score in predicting need for clinical intervention or death[18,23-28]. Interestingly, a large United Kingdom multicentre study indicated the GBS was also superior to the full (post-endoscopy) Rockall score for predicting these combined outcomes, with AUROC figures for the GBS, full Rockall and admission Rockall scores 0.90, 0.81 and 0.71 respectively[23]. Another recent United Kingdom study comparing the GBS and admission Rockall scores for the same end-points has reported similar AUROC figures at 0.92 and 0.75, respectively[28].

In a larger (*n* = 1555 patients) follow-up publication from the United Kingdom multi-centre study group, AUROC figures for mortality were similar using the GBS, full Rockall and admission Rockall scores at 0.74, 0.79

and 0.76 and respectively[26]. An even higher mortality AUROC figure of 0.81 was recently reported using the GBS in a large study from Singapore and Malaysia[29].

The United Kingdom multicentre follow-up study reported similar figures for the GBS and full Rockall scores in predicting need for endoscopic therapy or surgery, with both superior to the admission Rockall score. AUROC figures for this end-point were 0.79, 0.76 and 0.63 respectively. In a recent large study from Hong Kong, the GBS was again shown to be a better predictor of need for endoscopic therapy than the admission Rockall score, with an AUROC of 0.72[30]. In this study, the admission Rockall score was unable to predict need for endoscopic therapy.

Superiority of a modified GBS over the admission Rockall score in predicting high risk endoscopic stigmata or rebleeding has been reported from North America[19]. The GBS has also been shown to be superior to both the full and admission Rockall scores in predicting need for transfusion (AUROC figures 0.92, 0.75 and 0.69 respectively), presumably because the GBS includes admission haemoglobin as a component variable[26].

Two recent studies assessing relatively complex ANNs have reported them to be superior to the admission Rockall and equivalent to the full Rockall score in predicting endoscopic therapy and superior to the full Rockall score in predicting mortality in non-variceal UGIH[21,22]. The larger of these studies revealed AUROC figures of 0.95 and 0.67 in predicting mortality using the ANN and the Rockall score respectively[22]. This is an impressive figure, but the complexity of ANNs is a significant limitation.

Whilst these studies suggest that some pre-endoscopic scores are equivalent or better at predicting outcome compared with the full Rockall score, all higher risk patients require in-patient endoscopy to diagnose and possibly treat underlying pathology. However pre-endoscopic scores may allow early identification of a low risk group who may not require in-patient endoscopy. As indicated above, studies from several countries have suggested that the relatively simple GBS is superior to the admission Rockall score in predicting clinically relevant end points. Interestingly the GBS also appears to perform well in comparison to the (post endoscopy) full Rockall score. Other pre-endoscopy scores have either not been externally validated or appear too complex for routine clinical use.

OPTIMUM CLINICAL USE OF SCORES FOR UPPER GASTROINTESTINAL HAEMORRHAGE

The major existing risk scores for UGIH are summarised in Table 3. It is usually recommended that all patients with UGIH, except a very low-risk group, are admitted and have endoscopy within 24 h[2,3]. There is no clear evidence of benefit if endoscopy is undertaken earlier than 24 h, although a small group of patients with massive bleeding and haemodynamic compromise will

Table 3 Summary of major published risk scores for upper gastrointestinal haemorrhage

Score[Ref.]	Endoscopy required?	Number of variables	Suitable for unselected upper GI bleeding patients?
Full Rockall[5]	Yes	6[1]	Yes
Baylor[6]	Yes	5	No
Cedars Sinai[7]	Yes	6	Yes
Admission Rockall[5]	No	4[1]	Yes
Glasgow Blatchford[18]	No	5[2]	Yes
ANN[21]	No	20	No

[1]Comorbidities variable describes 5 specific conditions; [2]History and co-morbidities variable describes 4 specific situations. GI: Gastrointestinal; ANN: Artificial neural network.

require emergency endoscopy. The decision on urgent endoscopy in this emergency group is usually based on clinical judgement rather than a specific score, however the recent study from Singapore and Malaysia suggested survival benefit for patients with a GBS of ≥ 12 who were endoscoped within 12 h[29]. This approach requires further study.

The most helpful use of a score in clinical practice is possibly identification of a low risk group who are suitable for early discharge or even non-admission. Interestingly, most scores seem to perform better in patients at low rather than higher risk[14].

Early identification of low-risk patients using endoscopy based scores

Patients with a Rockall score of ≤ 2 are generally accepted as being at low-risk of poor outcome, but calculation requires endoscopy[5,31]. Of the initial cohort used to develop the score, 26% patients met these criteria[5]. Long-streth reported safe early discharge using endoscopic and clinical guidelines to identify low risk patients[32]. Interestingly 32% of patients defined as low risk in this study had a Rockall score > 2. Two relatively small randomised studies suggested that early discharge of selected patients deemed "low risk" using endoscopic and clinical parameters did not affect outcome and offers cost savings[13,33].

Local evaluation of the Cedars-Sinai predictive index reported that 70% patients achieved low risk status after endoscopy, and hospital stay was significantly reduced[7]. The Almela score identified over one third of non-variceal UGIH patients as suitable for early discharge following endoscopy[8]. There were five deaths in this early discharge group, although none were related to UGIH.

Although endoscopic resources vary internationally, it is interesting that the recent United Kingdom national audit revealed that only 52% hospitals had 24 h emergency endoscopy cover and only 50% patients admitted with UGIH had their endoscopy within 24 h[34]. At weekends, American and United Kingdom data show that endoscopy is significantly delayed[35,36]. Therefore the ability to identify low risk patients prior to endoscopy who may be suitable for out-patient management is very attractive.

Early identification of low-risk patients using pre-endoscopy scores

A GBS of zero has been reported to have > 99% sensitivity in identification of those who do not require intervention, rebleed or die in studies from Hong Kong (China)[30], United States[37], Japan[38], Taiwan (China)[27] and United Kingdom[18,23,25,28]. The proportion of patients with a GBS of zero in the above studies ranged from 5%-22%, probably due to differences in local populations and healthcare organisation. Several studies have assessed extending the definition of low risk patients suitable for out-patient management to those with GBS ≤ 1 or ≤ 2, but safety of this approach requires further study[24,28,38,39].

An admission Rockall score of zero is often cited as identifying low risk patients, and identified 15% patients in the initial report[4]. However, studies have shown that up to 18% in this "low risk" group have clinically relevant end-points including endoscopic therapy, rebleeding and death[23,25,28,36]. Whilst no score will be perfect in clinical use for identifying low risk patients, most clinicians would prefer to err on the safe side and use a score with high sensitivity, to avoid discharging patients who may require intervention or die.

CONCLUSION

Risk scores are of critical importance in UGIH, allowing early discharge of low risk patients and appropriate therapy for higher risk patients. The Rockall score is the most widely used and studied post-endoscopy score. The GBS is more accurate than the admission Rockall score for early (pre-endoscopic) prediction of clinically relevant outcomes, and is highly sensitive in identifying low risk patients suitable for out-patient management. Whilst other UGIH risk scores have been described, they require external validation and further comparative studies with the established GBS and Rockall scores.

Abstract

There is an increasing understanding of the roles that microsatellite instability (MSI) plays in Lynch syndrome (by mutations) and sporadic (by mainly epigenetic changes) gastrointestinal (GI) and other cancers. Deficient DNA mismatch repair (MMR) results in the strong mutator phenotype known as MSI, which is the hallmark of cancers arising within Lynch syndrome. MSI is characterized by length alterations within simple repeated sequences called microsatellites. Lynch syndrome occurs primarily because of germline mutations in one of the MMR genes, mainly *MLH1* or *MSH2*, less frequently *MSH6*, and rarely *PMS2*. MSI is also observed in about 15% of sporadic colorectal, gastric, and endometrial cancers and in lower frequencies in a minority of other cancers where it is often associated with the hypermethylation of the *MLH1* gene. miRNAs are small noncoding RNAs that regulate gene expression at the posttranscriptional level and are critical in many biological processes and cellular pathways. There is accumulating evidence to support the notion that the interrelationship between MSI and miRNA plays a key role in the pathogenesis of GI cancer. As a possible new mechanism underlying MSI, overexpression of *miR-155* has been shown to downregulate expression of MLH1, MSH2, and MSH6. Thus, a subset of MSI-positive (MSI+) cancers without known MMR defects may result from *miR-155* overexpression. Target genes of frameshift mutation for MSI are involved in various cellular functions, such as DNA repair, cell signaling, and apoptosis. A novel class of target genes that included not only epigenetic modifier genes, such as *HDAC2*, but also miRNA processing machinery genes, including *TARBP2* and *XPO5*, were found to be mutated in MSI+ GI cancers. Thus, a subset of MSI+ colorectal cancers (CRCs) has been proposed to exhibit a mutated miRNA machinery phenotype. Genetic, epigenetic, and transcriptomic differences exist between MSI+ and MSI– cancers. Molecular signatures of miRNA expression apparently have the potential to distinguish between MSI+ and MSI– CRCs. In this review, we summarize recent advances in the MSI pathogenesis of GI cancer, with the focus on its relationship with miRNA as well as on the potential to use MSI and related alterations as biomarkers and novel therapeutic targets.

INTRODUCTION

A type of genetic instability characterized by length alterations within simple repeated microsatellite sequences, termed microsatellite instability (MSI), occurs in a majority of patients with Lynch syndrome (also known as hereditary nonpolyposis colorectal cancer) by mutations and in a subset of sporadic gastrointestinal (GI) and other cancers by mainly epigenetic changes[1-10]. Genetic and epigenetic inactivation of DNA mismatch repair (*MMR*) genes results in the mutator phenotype, mutations in cancer-related genes, and cancer development (Figure 1). MSI underlies a distinctive carcinogenic pathway because MSI-positive (MSI+) cancers exhibit many differences in clinical, pathological, and molecular characteristics relative to MSI-negative (MSI-) cancers irrespective of their hereditary or sporadic origins. The differences in genotype can be explained because deficient MMR leads to a strong mutator phenotype with a very specific mutation spectrum. MSI accumulates frameshift mutations in repeated sequences located in coding regions of target tumor suppressor genes. The peculiar genotype of MSI+ cancers also includes specific patterns of gene regulation. MSI+ GI cancers often show an aberrant epigenetic pattern such as hypermethylation of various genes, including the key *MMR* gene, *MLH1*. The differences in genotype and phenotype between MSI+ and MSI- GI cancers are likely to be causally linked to their differences in biological and clinical features. Diagnostic characterization of the MSI status thus has implications in basic and clinical oncology. MiRNAs are small RNA molecules that regulate gene expression at the posttranscriptional level and are critical for many cellular functions[11-20]. There is accumulating evidence to support the notion that the interrelationship between MSI and miRNA plays a key role in the pathogenesis of GI cancer.

MSI BY THE OVEREXPRESSION OF MIR-155 OR MIR-21

Various pathogenic events, including germline and somatic mutations, promoter methylation, and reduced histone acetylation[21], lead to inactivation of core MMR proteins. A vast majority of MSI+ cancers can be explained by mutation and/or epigenetic inactivation of the core MMR proteins[22]. The etiologies of the remaining MSI+ cancers remain poorly understood. In an unselected se-

ries of 1066 colorectal cancer (CRC) patients, 135 (13%) were MSI+[22]. Of these, 23 (6%) had germline mutations in one of the *MMR* gene, and 106 (79%) showed methylation of the *MLH1* promoter. Approximately 5% of these MSI+ cancers displayed loss of expression of at least one of the core MMR proteins without a well-defined genetic or epigenetic cause[22].

Vareli *et al*[23] have shown that overexpression of *miR-155* significantly downregulates the core MMR proteins; namely, MLH1, MSH2, and, MSH6 in CRC cell lines, thus inducing an MSI. The downregulation of MLH1 and MSH2 proteins by *miR-155* lead to destabilization of the respective heterodimeric complex proteins and a mutator phenotype[24]. An inverse correlation between *miR-155* overexpression and the expression of MLH1 and MSH2 was further demonstrated in human CRC tissues. Most MSI+ cancers without a known cause of MMR inactivation show *miR-155* overexpression. However, not all CRCs with increased miR-155 expression were MSI+. It is also possible that miR-155 affects other related DNA repair proteins, thus enhancing the phenotypic effect of MMR defects. Although further confirmation is required, the results suggest that *miR-155* overexpression is an additional mechanism underlying the development of MSI in cancer (Figure 2)[23].

The reduced expression of a single allele of the adenomatous polyposis coli and transforming growth factor (*TGF*)-β receptor I gene has been linked to CRC[25,26]. Thus, incomplete repression of MMR proteins by *miR-155* is not unique to tumor suppressor genes in cancer. Recently, miR-NAs have been suggested to act as transactivating elements involved in allele and gene expression regulation[27,28]. These results support the notion that miRNAs play a role in the non-Mendelian regulation of *MMR* genes.

miR-21 is overexpressed in various types of human cancers, including CRC[29]. Valeri *et al*[30] reported that *miR-21* directly targets the 3' untranslated region (UTR) of *MSH2* and *MSH6* mRNA, resulting in downregulation of protein expression. The inverse correlation between *miR-21* overexpression and MSH2 expression was shown in CRC tissues. Cells that overexpress *miR-21* showed significantly reduced 5-fluorouracil (5-FU)-induced G2/M damage arrest and apoptosis that is characteristic of defective MMR. Because *miR-21* expression could increase in cell lines continuously exposed to 5-FU[31], cancer cells may develop a secondary resistance to 5-FU through *miR-21* overexpression. Thus, *miR-21*-dependent downregulation of *MSH2-MSH6* may be responsible for both primary and secondary resistance to 5-FU.

TARGET CANCER-RELATED GENES OF MSI

The instability in cancer-related genes at coding microsatellites causes frameshift mutations and functional inactivation of affected proteins, thereby providing a selective growth advantage to deficient MMR cells[32]. For instance, *TGF-β receptor II* and the pro-apoptotic gene *BAX* are

Figure 3 Representative target genes in microsatellite instability+ gastrointestinal cancers. A number of cancer-related genes mutated in microsatellite instability+ gastrointestinal cancers have been reported. The relevance of each mutation is not necessarily proven.

frequently inactivated by slippage-induced frameshift mutations in mononucleotide tracts present in their gene coding regions[33,34]. These findings have provided proof for the causative link between MSI and mutations in cancer-related genes, and they were also convincing examples of the differences between the mutator and suppressor pathways for cancer. These genes have also been mutated in cancers in the suppressor pathway, but at decreased frequencies and not by slippage-linked frameshifts[35,36].

A number of cancer-related genes mutated in MSI+ cancers have been reported (Figure 3). Mutations that promote cancer cell growth are assumed to be the driving force during MSI+ carcinogenesis and are designated as real common target genes (Figure 2)[37]. Mutations of microsatellite-harboring genes that do not contribute to carcinogenesis are designated as bystander genes. However, it is not always clear which mutations are "driver mutations" and which are "passenger mutations"[9,38]. The Selective Targets database (SelTarbase) (http://www.seltarbase.org) of human mononucleotide-microsatellite mutations and their potential impact to carcinogenesis and immunology has been developed[39]. The database includes a comprehensive database of all human coding, untranslated, noncoding RNA and intronic mononucleotide repeat tracts and is useful for basic and clinical oncology.

Because MSI+ cancers accumulate many mutations, disruption of cell growth and survival regulation can be accomplished in different cancers by mutations in different genes of the same signaling pathways[40]. Therefore, genes with infrequent and/or monoallelic mutations should not be regarded as irrelevant. Thus, the relevance of microsatellite-specific mutations in MSI+ cancers can be proven only when there is supporting evidence for functionality irrespective of mutation incidence[2].

Target cancer-related genes of MSI+ cancers can be functionally categorized as tumor suppressors and genes involved in DNA repair, cell cycle, cell proliferation, apoptosis and others (Figure 3). Interestingly, every human *MMR* gene except *MLH1* contains a mononucleotide repeat of at least A7[41]. Thus, frameshift mutations of *MSH3* and *MSH6* led to the concept of "the mutator that mutates the other mutator" (Figure 2)[42].

The spectrum of mutations of target genes could affect cancer biology, therapeutic response, and prognosis of patients. Most putative MSI target genes have been proposed mainly on the basis of high mutation frequency detected within their coding regions. However, genes containing microsatellites that are located within noncoding regulatory regions, such as introns, promoters, and 5' and 3' UTRs, could be also mutated in MSI+ cancers. Alterations within untranslated mononucleotide repeat tracts can alter transcription level or transcript stability. It has been suggested that some intronic repeat mutations in genes, such as *ATM*, *MYB*[43], and *MRE11*[44], play a

Figure 4 MiRNA biogenesis and genes mutated in microsatellite instability+ gastrointestinal cancers. A consequence of perfect complementarity between miRNA and mRNA is mRNA cleavage and degradation. Imperfect alignment represses gene translation. ORF: Open reading frame; RISC: RNA-induced silencing complexes.

role in MSI carcinogenesis[45]. Decreased matrix metallo-proteinase (MMP)-3 expression due to insertions and/or deletions in the *MMP-3* promoter region led to a decrease in the levels of the active MMP-9 form, which may explain the less invasive potential of MSI+ cancer cells[46] and the propensity for a good prognosis in the case of MSI+ CRCs[47].

Genomic copy number changes are frequently observed in cancers. It is well known that MSI+ cancers show less genomic copy number changes and are mostly diploid[48]. However, genes responsible for chromosomal instability (CIN) could be mutated in MSI+ cancers, and these defects may be selected during the course of cancer progression (Figures 2 and 3)[49]. Furthermore, mutations of *RAD50* and *MRE11* are reportedly associated with defects in nonhomologous end-joining, leading to chromosomal alterations during cancer progression[45].

Altered histone modifications that affect chromatin structures are also involved in carcinogenesis[49]. Epigenetic modifier genes could also be MSI target genes. Ropero *et al*[50] detected frameshift mutations in the histone deacetylase (*HDAC*) 2 gene in MSI+ GI cancers. This *HDAC2* mutation made mutation-positive cancer cells more resistant to the antiproliferative and proapoptotic

effects of certain HDAC inhibitors such as trichostatin A, but not to others such as butyric acid and valproic acid. Since HDAC inhibitors may serve as therapeutic agents for cancer, these findings support the use of *HDAC2* mutation status in future pharmacogenetic treatment[50].

MIRNA PROCESSING MACHINERY GENES AS MSI TARGET GENES

MiRNAs are small noncoding RNAs that regulate gene expression at the posttranscriptional level and are critical in many biological processes and cellular pathways (Figure 4)[11-20]. MiRNA expression profiles of human cancers have been characterized by an overall mature miRNA downregulation[51-53]. The causes of the aberrant miRNA expression patterns in cancer involve DNA copy number amplification or deletion[54], inappropriate transactivation, transcriptional repression by oncogenic and/or other factors[55], failure of miRNA post-transcriptional regulation[56], and genetic mutation[57] or transcriptional silencing associated with hypermethylation of CpG island promoters[58-62].

The control of the miRNA biosynthesis pathway is important in the spatiotemporal pattern of miRNA expression in cells. Thus, impaired miRNA processing pathways

may themselves be targets of genetic and/or epigenetic disruption in cancer[63,64]. Recently, it has been reported that mitogenic signaling can be translated into changes in cell viability and proliferation through the miRNA biogenesis pathway. A *TAR RNA-binding protein 2* (*TARBP2*) gene encodes TRBP, an essential functional partner of DICER1 (Figure 4)[65,66]. TARBP2 is phosphorylated under normal growth conditions, which increases the stability of TARBP2 and DICER[67]. Upon growth factor stimulation, MAPK/ERK pathway increases TARBP2 phosphorylation, leading to a coordinated increase in levels of growth-promoting miRNA and a decrease in the expression of *let-7* tumor suppressor miRNA. In contrast, pharmacological inhibition of MAPK/ERK resulted in an anti-growth miRNA profile[67]. These results further suggest the important role of miRNA processing mediated by TARBP2 in preservation of a normal, untransformed cell state[17].

Melo *et al*[68] have found truncating heterozygous mutations in *TARBP2* in MSI+ cancer cell lines and in primary sporadic and hereditary MSI+ GI cancers (Figure 4). *TARBP2* mutations diminished TRBP protein expression, resulting in impaired miRNA processing and enhanced cellular transformation. The TRBP impairment was associated with a secondary defect in DICER1 activity by destabilization of the DICER1 protein. Thus, *TARBP2* mutations may explain overall miRNA downregulation in a subset of MSI+ cancers. Because the restoration of efficient miRNA production by the reintroduction of TRBP can suppress cancer cell growth, these findings are important for the development of new therapeutic strategies for the treatment of cancer[68].

MUTATIONS OF THE *EXPORTIN 5* GENE

Because of the nuclear retention of certain precursor miRNAs (pre-miRNAs), mature miRNA expression levels are not consistent with pre-miRNA expression levels in various human cancer cell lines[17]. Thus, defects in the nuclear export of pre-miRNAs may be one of the mechanisms underlying the global impairment of mature miRNAs in human cancer. The *exportin 5* (*XPO5*) mediates nuclear export of pre-miRNA (Figure 4). Melo *et al*[69,70] have identified inactivating heterozygous mutations of *XPO5* in MSI+ cancer cell lines and in primary sporadic and hereditary MSI+ GI cancers. The mutant form of XPO5 does not comprise a C-terminal region that is important for the formation of the pre-miRNA/XPO5/Ran-GTP ternary complex. Thus, the XPO5 defect trapped certain pre-miRNAs in the nucleus, reduced miRNA processing, and impaired miRNA-target inhibition. It is important to note that the restoration of XPO5 functions rescued the disturbed export of critical tumor-suppressive pre-miRNAs, which results in tumor suppression[69].

Interestingly, although the heterozygous *XPO5* mutation decreased accumulation of a fraction of detectable miRNAs, many others were not affected. It seems that XPO5 does not bind to pre-miRNAs universally but has

certain substrate preferences, which are possibly mediated by sequence or structure[38]. Strategies directed toward stimulating the activity of miRNA processing factors and restoring the production of mature growth inhibitory miRNAs may have therapeutic value[69].

MUTATED MIRNA MACHINERY PHENOTYPE AS A NEW CANCER PHENOTYPE

Recent works have suggested that the other component of the miRNA biogenesis pathway, DICER1, is a haploinsufficient tumor suppressor[71,72]. Therefore, it appears that at least three components of the miRNA biogenesis pathway are haploinsufficient tumor suppressors, with TARBP2 and XPO5, but not DICER, mutations prevalent in MSI+ cancers[38]. In addition, the miRISC components *AGO2*, *TNRC6A*, and *TNRC6C* can also be mutated in MSI+ cancers (Figure 4)[73], although the functional significances remain to be determined[38,70].

From these observations, a new cancer phenotype known as mutated miRNA machinery phenotype (MMMP) has been proposed for MSI+ CRCs having mutations in the miRNA machinery genes and the deregulated miRNAome. Although larger studies are required to fully characterize and validate this feature as a criterion for classification, a broader miRNAome-modifying approach may be effective for cancer patients with MMMP[15].

TRANSCRIPTOMIC DIFFERENCES BETWEEN MSI+ AND MSI- CRCS

As molecular markers, gene expression profiles are being developed for many cancers. Array technology has identified a number of genes that are expressed differentially between MSI+ and MSI- CRCs[74-76]. By using supervised analysis of cDNA microarray data, Giacomini *et al*[77] identified a robust expression signature distinguishing MSI+ and MSI- CRC cell lines. By using high-density oligonucleotide microarrays, Kruhoffer *et al*[78] constructed a gene signature that distinguished MSI+ and MSI- CRCs. The authors further constructed a signature that distinguished sporadic and hereditary cases of MSI+ CRCs. Identification of a signature for MMR deficiency would be relevant, both biologically and clinically[78].

As for miRNAs, Lanza *et al*[79] analyzed 16 MSI+ and 23 MSI- CRCs for genome-wide expression of miRNA and mRNA. On the basis of combined miRNA and mRNA expression, a molecular signature comprising 27 differentially expressed genes, including 8 miRNAs, could correctly distinguish MSI+ and MSI- CRCs. Among the differentially expressed miRNAs, various members of the oncogenic *miR-17-92* family were significantly upregulated in MSI- cancers. Among these, *miR-17-5p*, *miR-20*, *miR-25*, *miR-92-1*, *miR-92-2*, *miR-93-1*, and *miR-106a* were significantly upregulated in MSI- when compared with

Figure 5 Targeted therapies based on molecular alterations in microsatellite instability+ colorectal cancers. Microsatellite instability+ cancers may be managed more effectively with novel targeted therapies based on molecular alterations. MSI: Microsatellite instability; HDAC: Histone deacetylase; PI3K/mTOR: Phosphoinositide 3-kinase/mammalian target of rapamycin; XPO5: Exportin 5.

MSI+ CRCs. Because members of the *miR-17-92* family act as oncogenes, these results may explain, at least in part, the less aggressive behavior of MSI+ CRCs when compared with their MSI- counterparts.

Earle *et al*[80] analyzed 22 MSI-H, including 6 Lynch syndrome, 8 MSI-L, and 25 MSS CRCs for a selected panel of 24 miRNAs. Relative expression of *miR-26b*, *miR-31*, *miR-92*, *miR-155*, *miR-196a*, and *miR-223* were significantly different among MSI subgroups, and *miR-31* and *miR-223* were overexpressed in CRCs of patients with Lynch syndrome. These findings indicate that miRNA expression in CRC is associated with MSI status, including Lynch syndrome and MSI-L, and that miRNAs may play significant roles in these MSI subgroups in addition to having possible effects on cancer characteristics.

Slattery *et al*[81] analyzed 70 CRCs for 866 miRNAs using microarrays. At the 1.5-fold level, 143 miRNAs were differentially expressed in MSI+ CRCs. *MiR-139-3p*, *miR-223*, and *miR-370* were upregulated and *miR-24-2*, *miR-424*, *miR-552*, and *let-7g* were downregulated at a level of 1.5-fold or greater in MSI+ CRCs when compared with MSI- CRCs.

Thus, differentially expressed miRNAs are likely to be relevant, both biologically and clinically, although their functional significances remain to be determined. High levels of *miR-21* in the stroma of CRCs reportedly predict short disease-free survival in stage Ⅱ CRC patients; however, the levels are not associated with the MSI status[82].

DEFECTIVE MMR AS A NOVEL THERAPEUTIC TARGET

MSI+ cancers may be managed more effectively with novel targeted therapies based on molecular alterations (Figure 5). A combination of treatments that target both primary alterations of DNA *MMR* gene and secondary alterations, such as frameshift mutations of target genes, may be also effective. A synthetic lethal relationship, where the simultaneous inhibition of two different regulatory pathways leads to cell death, is a recent therapeutic strategy[83]. Therefore, identification of synthetic lethal interactions with MMR deficiency could potentially lead to the identification of specific therapeutic targets[84]. The inhibition of poly (adenosine diphosphate-ribose) polymerase (PARP) is a potential synthetic lethal therapeutic strategy for the treatment of cancers with specific DNA repair defects, such as a BRCA1 or BRCA2 mutation[85].

A subset of MSI+ CRCs may also be suitable for this strategy. A novel PARP inhibitor, ABT-888, showed preferential activity on MSI+ CRC cell lines harboring mutations in both *MRE11* and *RAD50* genes when compared with MSI- cell lines that were wild type for both genes[86]. Recently, Vilar *et al*[87] reported that MSI+ CRCs deficient in double strand break (DSB) repair due to *MRE11* mutations show a higher sensitivity to PARP-1 inhibition. A phase Ⅱ study assessing the efficacy of a PARP-1 inhibitor, olaparib, in CRCs stratified by MSI status is ongoing. Further clinical studies regarding combinations of a PARP-1 inhibitor with other DSB-inducing therapies, such as radiation or irinotecan, are warranted in MSI+ CRCs with *MRE11* mutations. Although these results need to be confirmed in other settings, they suggest that specific mutations such as *MRE11* can be used to exploit the concept of synthetic lethality in MSI+ cancers, which has been successful in BRCA1-mutant breast cancers[88].

Methotrexate reportedly induces oxidative DNA damage and is selectively lethal to cancer cells with MSH2 defects[84,89]. Thus, a synthetic lethal relationship between deficient MSH2 and treatment with methotrexate led to a phase Ⅱ trial, incorporating measurement of 8-oxoG

DNA lesions as a biomarker, in metastatic CRC patients with germline mutation or loss of MSH2.

Because MSI+ CRCs often harbor a near diploid stable karyotype, these cancers may be sensitive to mitotic inhibitors, such as taxanes and kinesin-5 inhibitors[90]. To determine the effect of CIN and MSI on the efficacy of the microtubule-stabilizing agent patupilone/EPO960, a phase Ⅱ study called CIN and Anti-Tubulin Response Assessment in CRC is ongoing. It is assumed that MSI+ CRC patients will benefit more than MSI- CRC patients.

Gene expression signatures can also be used for new MSI+ cancer therapies. Fourteen of the 164 compounds were shown to target MSI+ cancer cell lines using combined gene expression data sets and a connectivity map[91]. Rapamycin, LY-294002, 17-(allylamino)-17-demethoxygeldanamycin, and trichostatin A were the most convincing candidate compounds. MSI+ cell lines with *MLH1* hypermethylation were preferentially targeted by rapamycin and LY-294002 when compared with MSI- cells. These results underscore the relevant role of the PI3K/AKT/mTOR pathway and its therapeutic application in MSI+ cancer, although its clinical significance needs confirmation.

MiRNA-based cancer therapy is limited mainly to targeting a single miRNA[92,93]. However, if most cancers are characterized by a defect in miRNA production and global mature miRNA downregulation[51-53], restoration of the global miRNAome may be an attractive approach in cancer therapy. Melo *et al*[94] have found that the small molecule enoxacin, a fluoroquinolone used as an antibacterial compound, enhances the miRNA-processing machinery by binding to TRBP. Enoxacin was shown to inhibit the growth of a variety of cancer cells. The enhanced miRNA-processing activity by enoxacin did not depend on general fluoroquinolone activity but on the unique chemical structure of enoxacin. These results highlight the key role of disturbed miRNA expression in carcinogenesis, and suggest the potential of novel miRNA-based cancer therapy to restore the disrupted miRNAome of cancer cells.

Finally, it remains to be determined whether *XPO5* mutations can be exploited therapeutically. Since it is difficult to directly restore XPO5 activity, restoring miRNA accumulation by alternative methods may be a more realistic strategy. Given that only a few deregulated tumor suppressor miRNAs appear to be critical for the tumor-promoting effect of *XPO5* mutations, it may be possible to supply those miRNAs exogenously as miRNA duplexes that would not need to undergo nuclear export. It may also be possible to find a subset of important target genes of deregulated tumor suppressor miRNAs, which may be responsive to inactivation by conventional pharmacological methodologies or novel biologics.

CONCLUSION

The biological and clinical implications of MSI in GI cancers continue to develop. Recent findings, such as overexpression of *miR-21* and *miR-155* and mutations of *TARBP2* and *XPO5* in MSI+ GI cancers, further suggest the important interrelationship between MSI and miRNA in MSI carcinogenesis. The clinicopathological, genetic, epigenetic, prognostic, and therapeutic characteristics of MSI+ cancers are becoming clear, but remain to be fully determined. Analysis of MSI status in cancer patients is warranted as a screening for Lynch syndrome; it could be a potential predictive marker of response to chemotherapy. Since molecular targeting therapeutics are being used in clinical settings and trials, it seems important to clarify if molecular target genes are differentially regulated between MSI+ and MSI- cancers and if the MSI status has the prognostic or predictive significance in metastatic CRC. Further analysis is required to gain insight into MSI carcinogenesis, for a better understanding of disease pathogenesis, and for the development of new diagnostic and/or therapeutic approaches targeting essential pathogenetic alterations.

Toxic hepatitis in occupational exposure to solvents. *World J Gastroenterol* 2012; 18(22): 2756-2766 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i22/2756.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i22.2756

Abstract

The liver is the main organ responsible for the metabolism of drugs and toxic chemicals, and so is the primary target organ for many organic solvents. Work activities with hepatotoxins exposures are numerous and, moreover, organic solvents are used in various industrial processes. Organic solvents used in different industrial processes may be associated with hepatotoxicity. Several factors contribute to liver toxicity; among these are: species differences, nutritional condition, genetic factors, interaction with medications in use, alcohol abuse and interaction, and age. This review addresses the mechanisms of hepatotoxicity. The main pathogenic mechanisms responsible for functional and organic damage caused by solvents are: inflammation, dysfunction of cytochrome P450, mitochondrial dysfunction and oxidative stress. The health impact of exposure to solvents in the workplace remains an interesting and worrying question for professional health work.

INTRODUCTION

Some studies have suggested that exposure to organic solvents may induce liver toxicity[1,2] because most chemicals are metabolized in the liver and toxic metabolites generated through the metabolism are the main cause of liver damage.

Work activities with hepatotoxin exposure are numerous and include chemists, dry cleaners, farm workers, painters, health care workers, nurses, and printers. Organic solvents are used in various industrial processes such as spray painting, paint manufacturing, degreasing, metal processing, aeronautical and auto manufacturing maintenance and manufacturing, as well as various chemical storage facilities. Exposure to hepatotoxins can occur through intentional or accidental ingestion in food or absorption of toxic contaminants through the skin. Contamination includes the ingestion of water, skin absorption *via* water baths, and volatilization of solvents, and heated bathrooms with a shower of water.

Although a number of industrial chemicals are known

to be hepatotoxins, liver disease from occupational exposure is rarely suspected or diagnosed[3].

Three conditions must be fulfilled for the diagnosis of professional toxic hepatitis: (1) Liver damage should take place after occupational exposure to a substance; patient occupational history and the workplace in question is necessary; (2) Liver enzymes must increase to at least double the upper limit of normal levels; and (3) Tertiary conditions, such as other causes of liver disease, must be excluded[4,5].

The most important factors contributing to toxicity liver are protein binding, species differences, points of binding inside the liver intracellular, nutritional condition, genetic factors, interaction with medications in use, alcohol abuse and interaction, and age. For the age factor, it has been shown that age susceptibility clearly plays a role. For instance, neonatal rats are less susceptible to carbon tetrachloride and bromobenzene toxicity as compared to adult animals[6].

The hepatotoxic effects of some of the solvents were recognized as early as 1887. Very little is known about the frequency of occupational liver injury by solvents. It is still difficult to assess the damage from exposure due to difficult controls in the workplace[7-9]. Clinical presentation of occupational liver disease may be acute/subacute or chronic, but is often insidious.

Occupational toxic hepatitis can be divided into three types: hepatocellular, cholestatic and mixed (Table 1).

Liver damage is likely to be more severe in the hepatocellular type than in the cholestatic or mixed type; a patient with elevated bilirubin levels in hepatocellular liver injury indicates serious liver disease.

Patients with the cholestatic or mixed type are likely to develop chronic disease more frequently than those with the hepatocellular type.

The solvents suspected to be responsible for liver occupational disease are: dimethylformamide (DMF), dimethylacetamide (DMA), trichloroethylene (TCE), tetrachloroethylene, carbon tetrachloride, xylene, toluene, and chloroform, whose organoleptic properties and main uses are schematically presented in Table 2.

The solvents that follow are the most extensively used in the chemical industry.

DIMETHYLFORMAMIDE

DMF is an organic compound with the formula $(CH_3)_2$-NC(O)H that takes the form of a colorless, water-soluble liquid. Pure dimethylformamide is odorless, whereas technical grade or degraded dimethylformamide often has a fishy smell due to the impurity of dimethylamine. Its name is derived from the fact that it is a derivative of formamide, the amide of formic acid.

Dimethylformamide has been termed the universal solvent and is used commercially as a solvent for vinyl resins, adhesives and epoxy formulations (the latter for use in laminated printed circuit boards); for purification and/or separation of acetylene, acid gases and aliphatic hydro-

carbons; and in the production of polyacrylic or cellulose triacetate fibres and pharmaceuticals. It is also used as a catalyst in carboxylation reactions; in organic synthesis; as an industrial paint; as a carrier for gases, and in inks and dyes in printing and fibre-dyeing applications[10-12].

It is widely used for resins and polar polymers and in applications such as protective coatings, films, printing inks and adhesives. It is also used in the pharmaceutical industry in the formulation of pesticides, and in the manufacture of synthetic leathers[13,14].

Occupational exposure to dimethylformamide may occur in the production of organic chemicals, resins, fibers, paints, inks and adhesives. Exposure can also occur during the use of ink coatings, adhesives, in the synthetic leather industry, and in the repair of aircraft.

In 100 workers occupationally exposed to this solvent for at least one year (mean exposure of 5 years; range = 1-15 years), a statistically significant incidence of hepatic impairment was found, as indicated by elevated gamma-glutamyl transpeptidase levels and digestive disturbances[15].

Symptoms of irritation occurring during work with DMF include watery eyes, dry throat, and coughing. The exposed workers also reported a reduced sense of smell and dry coughs. Workers exposed to DMF also reported facial flushing and palpitations after ingesting alcohol. This condition is related to alcohol intolerance, characterized by a disulfiram-type reaction.

DIMETHYLACETAMIDE

DMA is an organic compound with the formula CH_3C-(O)N(CH_3)_2$ that is widely used in the synthetic fiber and resin industries[16].

It is colorless, water miscible, has a high boiling point, and is commonly used as a polar solvent in organic chemistry, as a solvent for vinyl resins, cellulose derivatives, polyacrylonitrile, linear polyesters and styrene. It is also used as in catalyst and solvent elimination, cyclization, alkylation reactions and halogenations.

DMA is a widely used solvent in acrylic and elasthane fiber spinning, and is also used as: a solvent in the production of X-ray contrast media; a solvent in the production process of antibiotics like cephalosporins (such as cefadroxil, cefalexin and cefradine); and a solvent and

Table 1	Clinical-diagnostic types of occupational toxic hepatitis				
Type of disease	ALT	ALP	γ-GT	Bilirubin	Bile acids
Hepatocellular	> 2 ULN	N	> 2	Elevated levels	Elevated levels
Cholestatic	N	> 2 ULN	> 4	Normal or moderate level	Elevated levels
Mixed	> 2 ULN	≥ ULN	> 2	Normal or moderate level	Elevated Levels

ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; GT: Glutamyl transferase; ULN: Upper limit of normal; N: Normal value. Normal value, ALT 9-63 U/L; ALP 38-126 U/L; γ-GT 7-50 U/L; Bilirubin 0.20-1.5 mg/dL; Bile acids < 10 μmol/L.

Table 2 Main features of the solvents described

Solvents	Organoleptic properties	Main uses	Main mode of absorption
Dimethylformamide	Water-soluble liquid	Production of organic chemicals, resins, fibers, paints, inks and adhesives	Inhalation
	Colorless	Vinyl resins, adhesives and epoxy formulations	Skin
	Odorless	Purification and/or separation of acetylene	
	Polar polymer	Production of polyacrylic or cellulose triacetate fibres and pharmaceuticals	
		Industrial paint	
		Protective coatings, films, printing inks and adhesives	
		Pharmaceutical industry	
		Formulation of pesticides

reaction medium in the manufacture of polyimide resins, polysulfones and cellophane.

The hepatic toxicity of DMA is well known in animals, with reports of an increase in liver weight, steatosis, hepatic focal cystic degeneration, transaminasemia, biliary hyperplasia and centrilobular single cell necrosis[17].

It was discovered that a worker in a polyurethane plastic producing plant who was accidentally exposed to DMA mixed with ethylenediamine developed chemical induced hepatitis with several toxic features[18].

There was another report of a male worker in a factory of synthetic stretch fabric who was exposed to mixed solvents, including DMA, in a confined space continuously for 4-6 h/d for three days developing hepatic injury with other clinical manifestations of acute DMA intoxication. Toxic hepatitis following excessive skin exposure to DMA was reported among workers from a new production line of acrylic fiber[19,20].

TRICHLOROETHYLENE

TCE is a volatile organic compound with the chemical formula C_2HCl_3. A chlorinated hydrocarbon, it is used as an industrial solvent, and takes the form of a clear non-flammable liquid with a sweetish smell resembling chloroform.

Until 1975, it was used as a volatile anesthetic (however, it produced depression of the central nervous system) and inhaled obstetrical analgesic in millions of patients, as well as an extractant in food-processing. It is now used for vapor degreasing and as a solvent[21].

TCE is a solvent for a wide variety of organic materials, but is also used in the food industry for the decaffeination of coffee and the preparation of flavoring extracts from hops and spices.

Higher concentrations can cause tachypnea, and many types of cardiac arrhythmias which are exacerbated by epinephrine (adrenaline).

TCE has also been used as an inhaled patient controlled analgesic agent, mainly for the treatment of trigeminal neuralgia.

It was found that 10% of workers exposed to TCE became jaundiced with massive hepatic necrosis[22].

The data in humans, although limited, clearly suggests a toxic effect on human livers. Case reports describe TCE as inducing hepatitis and liver necrosis[23].

TETRACHLOROETHYLENE

Also, known under the name tetrachloroethene, tetrachloroethene is a chlorocarbon with the formula $Cl_2C=CCl_2$. It is a colorless liquid that is volatile, highly stable, and nonflammable, and mainly used as a solvent in dry cleaning and metal cleaning. It is also used for veterinary anthelmintic, processing and finishing in the textile industry, as an extraction solvent, grain fumigant, heat-exchange fluid, and in the manufacture of fluorocarbons.

Tetrachloroethylene is an excellent solvent for organic materials. It is also used to degrease metal parts in the automotive and other metalworking industries and appears in certain consumer products including spot removers, paint strippers, silicone lubricants, and food[24,25]. Its toxicity presents itself as different effects in the central nervous system, kidneys and liver. Symptoms of toxicity from exposure include fatigue, dizziness, headache, vomiting and nausea, signs of hepatic or renal failure, and pulmonary edema[26].

Tetrachloroethylene causes irritation of the eyes and nose mucosal. Severe exposure can lead to behavior alteration, coma and death[24,26].

CARBON TETRACHLORIDE

Carbon tetrachloride, also known by numerous other names, is an organic compound with the formula CCl_4 that takes the form of a clear liquid that very easily evaporates. Most carbon tetrachloride that finds its way into the environment is therefore found as a gas.

Carbon tetrachloride does not burn easily. It normally has a sweet smell, but this can change to a more unpleasant odor when the concentration of carbon tetrachloride reaches 10 parts per million parts of air (ppm).

In the 20th century, carbon tetrachloride was commonly used as a dry cleaning solvent, as a refrigerant, and in lava lamps[27]. One specialty use of carbon tetrachloride was by stamp collectors to reveal watermarks on the backs of postage stamps without damaging the stamp. However, once it became apparent that carbon tetrachloride exposure had severe adverse health effects, safer alternatives such as tetrachloroethylene were found for these applications, and its use in these roles declined from about 1940 onward.

Carbon tetrachloride was used as a pesticide to kill insects in stored grain but, in 1970, it was banned in consumer products in the United States. Before the Montreal Protocol, large amounts of carbon tetrachloride were used to produce the Freon refrigerants R-11 (trichlorofluoromethane) and R-12 (dichlorodifluoromethane). However, these refrigerants were identified as playing an important role in ozone depletion, and therefore their use was banned. Carbon tetrachloride is still used to manufacture less destructive refrigerants however.

Carbon tetrachloride is one of the most powerful solvents toxic to the liver, and is widely used in scientific research to assess liver damage and hepatoprotective agents[28].

Indeed, carbon tetrachloride has been known for many years to be toxic to the liver. It has been shown to produce hepatic damage including necrosis and fatty degeneration in various experimental animal species[29,30]. Several experiments have also shown that single doses can cause areas of necrosis in the liver within minutes[31,32], as well as liver enzyme abnormalities known to indicate liver damage[33,34].

XYLENE

Xylene is a clear, light-colored or colorless, flammable liquid which evaporates rapidly and is also called "xylol," "dimethylbenzene," or "mixed xylenes". Its odor is strong and sweetish like other aromatic solvents.

Xylene may be found in: solvents for gums, resins, rubber cleaners, degreaser paints, lacquers, varnishes, adhesives, cements, epoxy resins, inks, dyes, and gasoline.

The xylene in commercial use is composed of a mixture of the three isomers ortho-xylene, meta-xylene, and para-xylene; the meta-isomer predominates in these mixtures. O-Xylene and m-xylene are clear, colorless, flammable liquids that have characteristically sweet, balsamlike odors. At low temperatures, the para-isomer occurs in the form of clear, colorless plates[35].

TOLUENE

Toluene occurs as a colorless, flammable, refractive liquid that is slightly soluble in water, has a sweet and pungent odor, and has the chemical formula $C_6H_5CH_3$[36].

It is used to produce benzene and as a solvent in paints, coatings, synthetic fragrances, adhesives, inks, and cleaning agents. Toluene is also used in the production of polymers used to make nylon, plastic soda bottles, polyurethanes, and for pharmaceuticals, dyes, cosmetic nail products, and the synthesis of organic chemicals[36]. Exposed to toluene may occur from breathing ambient or indoor air, from the use of common household products (paints, paint thinners, adhesives, synthetic fragrances and nail polish), and cigarette smoke. The deliberate inhalation of paint or glue may result in high levels of exposure to toluene, as well as other chemicals, in solvent abusers[36].

Toluene exposure may also occur in the workplace, especially in occupations such as printing or painting, where toluene is frequently used as a solvent. Automobile emissions are the principal source of toluene in the ambient air. Toluene may be released to the ambient air

during the production, use, and disposal of industrial and consumer products that contain toluene. Levels of toluene measured in rural, urban, and indoor air averaged 1.3, 10.8, and 31.5 micrograms per cubic meter (μg/m^3), respectively[36].

Toluene is metabolized by the liver; however, the liver does not appear to be a primary target for toluene toxicity. Indeed, the central nervous system (CNS) is the primary target for toluene toxicity in both humans and animals for acute and chronic exposures. CNS dysfunction (which is often reversible) and narcosis have been frequently observed in humans acutely exposed to low or moderate levels of toluene by inhalation; symptoms include fatigue, sleepiness, headaches, and nausea. CNS depression and death have occurred at higher levels of exposure.

A study of printing factory workers who were exposed to toluene at a concentration of less than 200 ppm showed minimal changes to liver enzymes[37]. A study by Svensson *et al*[38] looked at 47 rotogravure workers occupationally exposed to toluene and showed elevation of liver enzymes and chemical hepatitis.

Hepatotoxicity has been observed in the literature in individuals exposed to xylene and toluene[39].

CHLOROFORM

Chloroform is a volatile organic compound that takes the form of a colorless liquid with a non-irritating odor and a slightly sweet taste. It will burn only when it reaches very high temperatures. In the past, chloroform was used as an inhaled anesthetic during surgery, but it is not used for that purpose today. Today, chloroform is used to make other chemicals and can also be formed in small amounts when chlorine is added to water. Other names for chloroform are "trichloromethane" and "methyl trichloride".

It is produced as a byproduct of water chlorination and the bleaching of paper. Chloroform may also be elicited as a vehicle exhaust. In 1923, Meyer and Pessoa showed the toxicity of chloroform to the human liver[40].

MECHANISMS OF HEPATOTOXICITY

The pathophysiologic mechanisms of hepatotoxicity are still being explored, but are characterized by organic and functional damage of the liver. The principal alterations are: (1) Disruption of the hepatocyte; with a decrease in ATP levels. Disassembly of actin fibrils at the surface of the hepatocyte with blistering and rupture of the membrane; (2) Disruption of the transport proteins; toxins may affect transport proteins at the canalicular membrane and can interrupt bile flow. It also detects interruption of transport pumps; (3) Cytolytic T-cell activation: the covalent binding of a toxin to the P-450 enzyme acts as an immunogen, activating T cells and cytokines and stimulating a multifaceted immune response; (4) Apoptosis of hepatocytes; activation of the apoptotic pathways by the tumor necrosis factor-alpha receptor of Fas may trig-

ger the cascade of intercellular caspases, which results in programmed cell death; and (5) Bile duct injury; toxic metabolites excreted in bile may cause injury to the bile duct epithelium[41]. In cultured rat hepatocytes, the hydrophobic bile acid glycochenodeoxycholate at pathophysiologically relevant concentrations (20-100 mmol/L) induces apoptosis, as documented by cell shrinkage, nuclear condensation and lobulation, caspase activation, DNA fragmentation, and phosphatidylserine externalization. Thus, bile acids provide a valuable model to dissect the mechanisms of liver cell apoptosis and the role of apoptosis in liver injury from endogenous toxicants. Apoptosis occurs by one of two pathways: (1) a death receptor pathway; and (2) the mitochondrial pathway.

The main pathogenic mechanisms responsible for functional and organic damage caused by solvents are: inflammation, dysfunction of cytochrome P450, mitochondrial dysfunction and oxidative stress.

INFLAMMATION

Inflammation plays an important role in classical chemical toxicities[42,43]. Hepatic non-parenchymal cells, the Kupffer, sinusoidal endothelial, and fat-storing or Ito (stellate) cells, and recruited leukocytes, i.e., monocytes and neutrophils, contribute to the pathogenesis of hepatic toxicity.

Proinflammatory cytokines, chemokines, reactive oxygen and nitrogen species, that promote oxidative stress in the damage induced by toxic substances, are produced by Kupffer cells and neutrophils.

In response to a direct action of the chemical, the Kupffer cells are activated resulting in the production of proinflammatory cytokines such as interleukin (IL)-1, IL-6 and tumor necrosis factor (TNF) α, and chemokine receptor chemokines.

Each of these factors can upregulate expression of β-2 integrin [cluster of differentiation (CD)11b/CD18] and prime neutrophils for reactive oxygen species (ROS) formation. C5a also stimulates Kupffer cells to release ROS.

The aforementioned cytokines can regulate genes for the production of factors that induce and/or promote apoptosis, or that stimulate the proliferation of hepatocytes.

These cytokines can mediate many pathological effects, including inflammatory cell infiltrates, lipogenesis, fibrogenesis and cholestasis[44].

For example, TNF α/IL-6 induction occurs within minutes following CCl$_4$ exposure and is responsible for the activation of nuclear transcription factors including AP-1, NFκB, and STAT 3[45,46], which regulate genes involved in cell growth. Liver toxicity induced by solvents is presented schematically in Figure 1.

In addition, cytokines activate the expression of adhesion molecules on endothelial cells and hepatocytes. If primed neutrophils receive a chemotactic signal from the parenchyma, they will transmigrate and adhere to hepatocytes. This leads to the final activation of neutrophil with degranulation (protease release) and adherence-dependent

Figure 1 Hypothetical role of inflammation in chemical-induced hepatotoxicity. TNF: Tumor necrosis factor; IL: Interleukin; PMN: Prime neutrophils.

Figure 2 Effects of solvents on cytochrome P450.

oxidant stress, which causes cell necrosis. Mediators generated during cell injury, such as lipid peroxidation products (LPO) and chemokines, become chemotactic signals for further neutrophil activation and transmigration[47].

Therefore, both neutrophils and Kupffer cells, directly or through activation of a complement, are activated by solvents and drugs toxicity, tissue trauma, ischemia-reperfusion, sepsis, and other pathophysiological events. In particular, Kupffer cells release cytotoxic mediators, such as proinflammatory mediators, and reactive oxygen species, such as cytokines and chemokines. Functionally, complement factors (e.g., C5a) and cytokines prime and activate neutrophils to promote their recruitment into the hepatic vasculature. Chemotactically-stimulated neutrophils extravasate and adhere to parenchymal cells. Through the release of reactive oxygen and proteases, they induce necrotic cell death adhesion molecules on neutrophils (β-2 integrins, especially CD11b/CD18) and ICAM-1 on endothelial cells and hepatocytes, which are are essential for neutrophil margination, extravasation, and oxidant production.

Cytokines can induce hepatic adhesion molecule and chemokine formation, which in turn is modulated by oxidant stress[48].

CYTOCHROME P450

Cytochrome P450 (P450 or CYP) plays an important role in the biotransformation of many endogenous compounds and xenobiotics. The most common enzyme system for oxidation of xenobiotics is cytochrome P450,

also known as CYP450 monooxygenase, hydroxylase or oxidase[49,50].

The liver is the major source of P450, although it is expressed in various extrahepatic tissues like the kidney[51].

P450 isoform CYP2E1 is the most abundant isoform in the human liver and therefore is responsible for the metabolism of a wide variety of exogenous and endogenous substrates[52,53]. CYP2E1 dependent ethanol metabolism produces oxidative stress through generation of ROS, a possible mechanism by which solvents are hepatotoxic[54,55].

The cyt p450 is a membrane protein for the disposal of xenobiotics. It is mainly associated with the smooth membranes of the ER of liver cells, while the enzymes for changes to endogenous substances (prostaglandins, cholesterol, *etc.*) are mainly associated with mitochondria.

For example, toxic substances that are known to be substrates of cytochrome P450 enzymes include acetaminophen, cyclophosphamide, doxorubicin and diclofenac.

The detoxification process *via* enzymatic systems, principally the glutathione and cytochrome P450, is different genetically and therefore plays a significant role in the way some individuals detoxify solvents differently from others. It has been shown that all conditions resulting in reduced activity of cytochrome P450, reduced the ability to detoxify solvents and, alternatively, increase the percentage of fat in the liver (e.g., malnutrition). In the study of toxic hepatitis there is a need to evaluate the potential inhibition and inductions of some of the substances involved, and assess the potential interaction with the myriad of drugs that are substrates of CYP[56,57] (Figure 2).

The metabolite responsible for the liver damaging effect of carbon tetrachloride is a C Chloride Ⅲ which is formed from carbon tetrachloride[31-58].

The studies by Brady *et al*[59] and Lindros *et al*[60] have shown that the enzymes involved in the bioactivation of carbon tetrachloride are cytochrome P-450, localized in the liver endoplasmic reticulum.

MITOCHONDRIAL DYSFUNCTION

Various endogenous and exogenous substances impair mitochondrial β-oxidation to cause micro-vesicular

steatosis through oxidative stress and damage to mitochondrial proteins, lipids, and DNA. In humans, these oxidative lesions cause mitochondrial DNA (mtDNA) deletions[61].

In normal mitochondria, enzymes involved in the import and β-oxidation of fatty acids or the tricarboxylic acid cycle are encoded by nuclear DNA[62]. Import polypeptides and enzymes involved in the β-oxidation of long-chain fatty acids are in the inner membrane, while those involved in the β-oxidation of medium- and short-chain chain fatty acids or the tricarboxylic acid cycle are in the matrix, together with mtDNA[62].

mtDNA is a circular, double-stranded molecule. Each cell contains many copies of this DNA, as there are several mtDNA copies in a single mitochondrion and many mitochondria per cell[62,63]. MtDNA is extremely sensitive to oxidative damage owing to its proximity to the inner membrane (the main cellular source of ROS), the absence of protective histones, and incomplete repair mechanisms in mitochondria[62-64].

Many solvents (cationic and amphiphilic) are able to concentrate in mitochondria as a result of the mitochondrial membrane potential[65]. Accumulation of these solvents within liver mitochondria inhibits fatty acid β-oxidation (causing steatosis) and electron transfer along the respiratory chain[65]. Overly reduced respiratory chain intermediates react with oxygen to form the superoxide anion. ROS oxidize fat deposits[65]. Similarly, in alcohol abuse, increased ROS formation causes extensive peroxidation of fat deposits and frequent steatohepatitis[66].

OXIDATIVE STRESS

The oxidative damage caused by free radicals is thought to be a basic mechanism underlying many pathological conditions, including hepatotoxicity by solvents.

Oxidative stress develops when there is an imbalance between the pro-oxidant and antioxidant ratio, leading to the generation of ROS. Environmental contaminants such as solvents, herbicides, and insecticides are known to modulate antioxidant defensive systems and cause oxidative damage in organisms by ROS production[67,68].

Oxidative damage accumulates more in mitochondria than in the rest of the cells because electrons continually leak from the respiratory chain to form damaging ROS (Smith, R., 1999).

ROS, such as hydrogen peroxide (H_2O_2), superoxide anion O_2-, and hydroxyl radical (OH•) at supranormal levels, can react with biological macromolecules potentially leading to enzyme inactivation, LPO, DNA damage and cell death, but at low concentrations their effects are less pronounced[69].

These free radicals are capable of damaging many cellular components such as DNA, proteins and lipids[70].

CLINIC OF TOXIC HEPATITIS

Toxic effects on the liver have been studied as early as

1887 and it was determined that there must be a change in the rate of the metabolism of these compound in order to create toxic products, otherwise toxicity will not occur. This chain of events is obligatory from a pharmacokinetic point of view for the majority of solvents[7-9].

There are a few clinical features associated with occupational liver disease including fatigue, appetite loss, arthralgia, hypertransaminasemia, hypergamma glutamyl transferase (GT), and splenomegaly. As there are many causes of liver injury, it is essential to exclude other aetiologies. Other aetiologies include viral hepatitis, biliary diseases, alcohol abuse, and non-alcoholic fatty liver disease.

Clinical presentation of occupational liver disease may be acute/subacute or chronic but is often insidious. Since some of the solvents may cause chronic health effects, it may take decades to study and document such events. Some hepatotoxins are capable of causing malignancy. The most famous example is vinyl chloride which was once thought to be safe and was used for many years until it was found to cause liver tumors.

Signs and symptoms of toxic hepatitis occurring may include: jaundice, itching, and abdominal pain in the upper right portion of the abdomen, fatigue, loss of appetite, nausea and vomiting, rash, weight loss, and dark or tea-color urine.

In acute toxic hepatitis the patient's condition is similar to viral hepatitis and rapidly deteriorates, resulting in marked liver dysfunction, encephalopathy and coagulopathy. The features of toxic hepatitis are: apoptosis of hepatocytes, ischemic liver injury, sepsis, and cholestasis. Hepatocyte apoptosis and necrosis, when massive, result in fulminant hepatic failure[71].

Acute exposure and toxicity has been associated with liver necrosis, and liver steatosis, and chronic exposure has been associated with liver cirrhosis. The mechanism of injury is most likely the result of metabolic changes by the liver.

Liver damage in the form of hepatomegaly, jaundice, and elevation in levels of several hepatic transaminases and bilirubin has also been reported.

Orthotropic liver transplantation (OLT) has improved the survival of these patients (49% undergo OLT), yet 37% die while awaiting OLT.

Steatosis (fat accumulation in the liver) is important in order to look at the effect of solvents, which are known to be toxic to the liver. Steatosis is the result of anomalous transport of lipids and, as a consequence, accumulation of lipids in the liver. For that reason, exposure to hepatotoxic solvents is clinically associated with liver steatosis, among others, and is a good clinical marker of solvent hepatotoxicity (having ruled out other factors).

After steatosis, necrosis is the second most common effect of liver damage as a result of hepatotoxic solvents. It is the result of destruction of the cell architecture, as well as damage of the biochemical pathways.

Chronic effects on the liver in long-term occupational exposure to low levels of organic solvents remain undetermined.

Indeed, epidemiological studies in this field were difficult for several reasons.

These include: (1) the cause of chronic liver injury can be attributed to a number of factors and not only isolated in occupational exposure; and (2) failure to control chronic liver damage among workers because of vague symptoms and signs, and lack of specificity and sensitivity of conventional liver enzyme tests[72].

Many cases of liver cirrhosis with no known aetiology raise the suspicion that some may be of occupational origin.

DIAGNOSIS OF TOXIC HEPATITIS

Laboratory

Liver damage can be of two types: hepatocellular damage (death of liver cells), in which alanine aminotransferase and aspartate aminotransferase are altered; and cholestatic damage (bile stasis) with an increase of parameters such as alkaline phosphatase and γ-GT. Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities are routinely used as clinical endpoints indicative of hepatotoxicity. Toxic hepatic damage includes necrosis and fatty degeneration.

The liver is one of the target organs for toxins, thus biological effects monitoring is required medical surveillance of workers exposed to hepatotoxin. It is also important to evaluate platelet count abnormalities and serum bilirubin in patients.

The evaluation of plasma enzyme showed the advantage of being in the past been well tested in clinical practice, but the main disadvantage is that the enzymes are not organ specific and this can cause occasional diagnostic problems in clinical practice[73,74].

Alanine aminotransferase is considered to be liver-specific in the rat[75]. Aspartate aminotransferase activity is high in the rat liver, along with the kidney, pancreas and erythrocytes[76], which means that elevated serum AST is indicative of tissue and cellular damage, but is not specific for hepatotoxicity.

As a general rule, clinically significant liver injury is often defined as ALT > 3 times the upper limit of normal (ULN)[77].

A factor that may portend a worse prognosis than the elevation of transaminases litter alone is associated with the increase with aminotransferase[78,79].

Serum levels of γ-GT have been recognized as a marker of hepatobiliary disease. Conditions that could cause increases in γ-GT levels are different; hepatotoxic agents and other non-hepatic factors such as renal, pulmonary, and myogenic (including cardiac) disorders. Indeed γ-GT is not merely a sensitive marker for liver and bile disorders, but it may also serve as a risk marker for a multiplicity of other chronic diseases; the metabolic syndrome (namely, obesity, hypertension, lipid metabolism, and in particular type 2 diabetes) for example[80,81].

The measurement of total bile acids in serum may be a more sensitive indicator of hepatic function and has the advantage of being organ specific. Measurement of bile

acids has not been standard clinical practice, however, and interpretation of high results might present difficulties.

Bile acids are synthesized from cholesterol in the liver, and secreted to the duodenum *via* the bile duct[82].

Secreted bile acids are reabsorbed almost completely into the intestine and returned to the liver (Hofman, 2007). Thanks to efficient enterohepatic circulation of bile acids, less than 10% of intestinal bile acids are eliminated in the feces. The secretion of bile acids into the systemic circulation is small. The blood concentration of bile acids is less than 10 μmol/L under normal conditions, but is increased in the case of a disorder of the liver or biliary tract[82]. Hepatotoxicity implicated from occupational and drug exposure has also been associated with elevations in total bile acid concentrations. Retention of bile constituents within the hepatocyte during cholestasis is associated with hepatocyte apoptosis.

In cholestatic disease, endogenously generated bile acids produce hepatocellular apoptosis by stimulating Fas translocation from the cytoplasm to the plasma membrane, where self-aggregation occurs, to trigger apoptosis. In cholestasis, secretion is impaired, resulting in elevated concentrations[83] of toxic bile acids (TBA) within hepatocytes. At pathophysiologic concentrations, TBA trigger translocation of intracellular Fas bearing vesicles to the plasma membrane where they self-aggregate in the absence of ligand. Activated Fas receptor complexes on the plasma membrane then cause caspase 8 activation and an apoptotic cascade.

Evaluation of the concentration of bile acids is not widely used as a routine screening test. Recently, a simpler and more rapid method is the direct enzymatic assay of urine sulfated bile acids (USBA)[84].

Mild forms of toxic hepatitis may not cause any symptoms and may be detected only by blood tests. Histological samples obtained from workers exposed to solvents that had only mild biochemical abnormalities have shown prominent fatty change, or steatosis, with degrees of inflammation and fibrosis, which suggest that parenchymal changes may be an early feature of solvent induced liver injury.

Diagnostic imaging

The diagnosis of toxic hepatitis improves with the use of imaging techniques (ultrasound, contrast enhanced ultrasonography, computed tomography, magnetic resonance imaging). In most cases the findings are not characteristic, but history and laboratory investigations allow us to make a diagnostic hypothesis. Indeed, they are essential in determining the clinical-pathological example for the evaluation of steatosis[85].

Routine evaluation includes ultrasound (US) and contrast enhanced ultrasound (CEUS), as reliable methods of first instance. Assessment may include, where necessary, computed tomography (CT) scans, magnetic resonance imaging (MRI) and liver biopsy.

Presently, the most widely used method for assessment of fatty liver is abdominal ultrasound, as it has sev-

eral advantages. It is not invasive, is readily available, and provides reliable information.

CT and MRI techniques are sensitive for the evaluation of steatosis, but are more expensive and less readily available[86].

However, it is necessary to clarify that recent studies have shown that abdominal ultrasound is not accurate in cases of chronic liver disease with fibrosis. In the latter case, it is important to confirm the steatosis and hepatic fibrosis assessment CT[87].

Toxic hepatitis is characterized by different degrees of steatosis and fibrosis, which can lead to cirrhosis.

Various degrees of steatosis can be defined as: (1) "light steatosis", presence of slight "bright liver" and no deep attenuation; (2) "moderate steatosis", presence of mild "bright liver" and with deep attenuation; and (3) "severe steatosis", presence of diffusely severe "bright liver" and deep attenuation without visibility of the diaphragm.

Chronic toxic hepatitis can progress to cirrhosis and liver failure. Early diagnosis of cirrhosis is important to prevent the development of severe liver failure. The diagnosis of cirrhosis of the liver requires a histological demonstration for the evaluation of abnormal nodules of regeneration and fibrosis. Therefore, liver biopsy is still considered the gold standard instrument. However, liver biopsy is limited by a number of disadvantages, such as availability of expert practitioners, cost, invasiveness of the procedure, and risk of complications (bleeding, pneumothorax, pain perforation and bile peritonitis)[88,89].

CONCLUSION

Many occupational activities can cause abnormalities in liver function tests without any symptoms suggestive of liver disease.

In patients with abnormalities in liver function tests without an obvious cause, a careful history including not only drugs, but also herbal remedies, should first be obtained.

History taking should also include occupational activity, exposition time, alcohol consumption and underlying chronic liver disease.

Abstract

AIM: To investigate the reliability of massive hepatectomy models by using clip techniques.

METHODS: We analyzed anatomical findings in 100 mice following massive hepatectomy induced by liver reduction > 70%. The impact of various factors in the different models was also analyzed, including learning curves, operative time, survival curves, and histopathological findings.

RESULTS: According to anatomical results, models with 75%, 80%, and 90% hepatectomy produced massive hepatectomy. Learning curves and operative times were most optimal with the clip technique. Each hepatectomy performed using the clip technique produced a reasonable survival curve, and there were no differences in histopathological findings between the suture and clip techniques.

CONCLUSION: Massive hepatectomy by the clip technique is simple and can provide reliable and relevant data.

Simple and reproducible hepatectomy in the mouse using the clip technique. *World J Gastroenterol* 2012; 18(22): 2767-2774 Available from: URL: http://www.wjgnet.com/1007-9327/full/v18/i22/2767.htm DOI: http://dx.doi.org/10.3748/wjg.v18.i22.2767

INTRODUCTION

New insights into mechanisms in the hepatology field have been established from experimental animal models. The rodent hepatectomy model is mainly employed to examine liver regeneration, liver failure, and tumor metastasis, and the 70% hepatectomy by *en bloc* ligation of the lobes is well established in the rat[1,2]. However, mouse

models allow for the use of gene-altered or knockout strains and for laboratory assays, due to the development of specific agents and antibodies[3]. At present, there are a number of murine hepatectomy models[4-10], of which the 70% hepatectomy (termed 2/3 partial hepatectomy) is most common. The introduction of microsurgical techniques has also enabled high rates of successful surgery, especially in individualized dissection and ligation of vessels[6,11,12]. However, murine hepatectomy remains challenging because of the delicate nature of the liver, the lack of intravenous access, and the risk of hemorrhage[9], resulting in high rates of mortality and morbidity[5,13]. In a previous paper, the rate of complications was reported as approximately 30%[6,14,15]. Currently, innovative methods for the hepatectomy model have been documented, such as the ligation method[7,9,14,15] and clip technique[5].

Despite the widespread use of the 70% hepatectomy[4-7], alternative hepatectomy models with resected volumes > 70% (so-called, "massive hepatectomy") are required to provide more clinically relevant experiments on liver regeneration and hepatic failure. Nikfarjam *et al*[5] reported benefits of the hemostatic clip in hepatectomy models with 37% and 70% of resected volumes in the mouse. Herein, we describe detailed surgical procedures of our institutional hepatectomy models with > 70% resection using suture hemostatic clip in the mouse and compare various factors between suture and clip techniques. Then, we discuss the usefulness of this simple and reproducible technique in hepatectomy models of > 70% resection.

MATERIALS AND METHODS

Animals
Inbred C57BL/6 mice (male, 10-20 wk of age, approximately 25 g body weight) were used (C57BL/6NHsd; Harlan Laboratories, Indianapolis, IN, United States). All mice were maintained under specific pathogen-free conditions. All experimental protocols were approved by IACUC at Mayo Clinic (Protocol No. 33307 and 24907).

Hepatectomy by suture technique
General anesthesia was provided with an anesthesia system (VetEquip Inc., Pleasanton, CA, United States). Inhalational anesthesia was induced and maintained by isoflurane (Isoflurane USP, 250 mL; Webster Veterinary, Sterling, MA, United States). Isoflurane with oxygen flow at 5 L/min was used in the induction phase, and was reduced to 0.5-2.0 L/min in the maintenance phase. Body weight was measured after anesthesia. The abdominal wall was shaved and prepped with povidone-iodine. A transverse incision was performed and hemostasis was obtained using an electrocautery scalpel of bipolar type (Bipolar forceps, Martin ME 102 Electrosurgical unit and Bipolar Accessory Set for ME 102; Harvard Apparatus, Holliston, MA, United States) and that of monopolar type (Bovie, low temperature cautery kit; Aaron Medi-

cal, Clearwater, FL, United States). Mice that received only laparotomy served as a control group in the study. The gastrointestinal tract was moistened with warm saline, covered with gauze, and positioned to the outside of the left abdominal cavity. The liver was handled delicately with cotton-tipped applicators (Hardwood Products Company, Guilford, ME, United States). A surgical microscope at 5-10 × magnification (Surgical Scope M680, Type 10445496; Leica Microsystems Inc., Bannockburn, IL, United States) was used. Even though high magnification (12.5-20 × magnification) is not required, a sufficient light source was indispensable. We used fine-tipped and delicate scalpels which are suitable for ultra-microsurgery, i.e. structures including nerve or vessels < 0.5 mm in diameter[16]. The murine liver was divided into three lobes (right, left, and caudate lobes) and arranged into six segments[4-6,14,17]: right anterior segment (RAS), right middle segment (RMS), right posterior segment (RPS), left anterior segment (LAS), left posterior segment (LPS), and omental segment (OS) (Figure 1A and B). The falciform and triangular ligaments were sharply cut. The infra-hepatic vena cava runs into the RMS and RPS. The infra-hepatic inferior vena cava was skeletonized. The LPS was freed from the diaphragm and OS. The LAS and LPS were mobilized off the hepatic hilum and gastroduodenal tract.

We did not use Pringle's maneuver during the operation. Hepatectomy by suture technique requires a proximal hepatic margin for suture bait. An atraumatic clamp (Micro Vascular Clip, RS-6470 or RS-6472; Roboz Surgical Instrument Co., Gaithersburg, MD, United States) was placed on the hepatic segment, and the optimal proximal hepatic margin was 2-3 mm from the division of each segment. The clamped segment was sharply cut with a 1 mm distal hepatic margin (Figure 1C). Monofilament polypropylene sutures (7-0 Prolene, BV-1, 8304H-X, or 8-0 Prolene, BV130-5, 8732H; Ethicon, Inc., Somerville, NJ, United States) were bilaterally placed without involvement of a clamp. These bilateral sutures were ligated, and each suture was grasped with a curved bulldog clamp (Cooley Bulldog clamps, curved, serrated, MB586R or MB587R; V.Mueller, Aesculap Inc., Center Valley, PA, United States). The liver was sutured by a loose continuous suture that initially involved the clamp, and the last suture reached the right side. The clamp was removed and the suture was tightened and ligated with the stay suture (Figure 1D). The presence of bleeding points was carefully checked using a cotton swab. An additional suture was made with a monofilament nylon suture (10-0 Ethilon, BV130-3, 2820G; Ethicon, Inc.) for well-focused hemostasis if required. Microfibrillar collagen (Avitene; C.R. Bard, Inc., Murray Hill, NJ, United States) was used in hemostasis.

The intraperitoneal cavity and organs were washed with warm saline. The peritoneum and fascia were closed with a continuous suture using absorbable thread (5-0 Coated Vicryl Plus; Ethicon, Inc.). The skin layer was closed separately using the same method.

Figure 1 Hepatic segments and hepatectomy by suture or clip techniques. A: The murine liver is divided into six segments (RAS, RMS, RPS, LAS, LPS, and OS); B: The gallbladder is detected between the RAS and LAS; C: Atraumatic clamp was placed on hepatic segment, with optimal proximal hepatic margin of 2-3 mm from division of each segment. Clamped segment was sharply cut with 1 mm distal hepatic margin (red line). Sutures not involving the clamp were placed bilaterally. Bilateral sutures were ligated, and each suture was grasped with a curved bulldog clamp. By using suture of left-side ligation, cut surface of liver was sutured from left side to right side with loose continuous suture that involved a clamp, and the last suture reached the right side; D: Clamp was removed (dotted red arrow) and hepatic margin was immediately treated by tightening the continuous suture. The thread of tightened continuous suture was ligated with stay suture of right side without over-tightening. Continuous suture was made from right side to left side. The last suture was ligated with stay suture of left side without over-tightening; E: The relevant segment was cut with a 3-5 mm distal hepatic margin (red line); F: Ischemic change of distal hepatic margin at 24 h after 80% hepatectomy was shown. Although liver remnants after massive hepatectomy showed color change due to vacuolization, distal hepatic margins clearly showed necrotic changes. Color change between liver remnant and distal hepatic margin was more enhanced at autopsy; G: Percentages of total volume of each segment were 21.2% ± 3.3% for RAS, 11.5% ± 2.1% for RMS, 14.8% ± 4.0% for RPS, 11.9% ± 1.7% for LAS, 31.6% ± 3.6% for LPS, and 9.0% ± 1.6% for OS; H: Traditional 2/3 hepatectomy of RMS + RPS + OS (35.4% ± 4.0%) is shown. Additional resection of OS (blue line) will make a 75% hepatectomy (RMS + RPS, 26.4% ± 3.8 %); I: Hepatic remnant in 80% hepatectomy was RMS + OS (20.6% ± 2.6%). Additional resection of OS (blue line) will make an RMS-remnant 90% hepatectomy (RMS, 14.8% ± 4.0%); J: OS-remnant 90% hepatectomy is shown (OS, 9.0% ± 1.6%). Dilation of portal vein due to portal hypertension is confirmed in reverse proportion to volume of hepatic remnant (yellow arrows). LAS: Left anterior segment; LPS: Left posterior segment; OS: Omental segment; RAS: Right anterior segment; RMS: Right middle segment; RPS: Right posterior segment.

Hepatectomy by hemostatic clip technique

The preparation and mobilization of each liver segment was similarly performed as described above. M-sized hemostatic clips were used (Horizon Ligation System; Teleflex Medical, Durham, NC, United States). The hepatic segment was retracted using tissue forceps when the clip was applied. A hemostatic clip was applied near the point of division of each segment (Figure 1E), and the proximal hepatic margin was approximately 1 mm from a segmental division. The segment was then cut with a distal hepatic margin of 3-5 mm. An additional suture for complete hemostasis was not typically required. Even during surgery, color change of the clipped segment due to ischemia was confirmed, and the color change between remnant liver and distal hepatic margin was observed at autopsy (Figure 1F).

Post-operative care

A warmer (RightTemp, RTHS-SM; Kent Scientific Co., Torrington, CT, United States) was used to maintain body temperature immediately after surgery, and a heating pad (E12107; Sunbeam, Gainesville, FL, United States) was used to warm the cage until mice completely recovered from anesthesia and surgery. Each mouse was kept separately. Postoperative observation was performed every 2 h for the first 12 h after surgery, and thereafter every 4 h. An analgesic agent (0.1 μg/g body weight, i.m.; buprenorphine 100 μg/mL; Cerilliant, Round Rock, TX, United States) was routinely given intramuscularly every 12 h for 5 d after surgery. Antibiotics (30 μg/g body weight, i.p.; Cephalexin Hydrate; MP Biomedicals, Cleveland, OH, United States) was administered every 12 h for 24 h after surgery. For each mouse, 1 mL of lactate Ringer's solution (Lactated Ringer's Injection USP; B. Braun Medical Inc., Irvine, CA, United States) was routinely administered every 6 h for 24 h.

Assessments and data analysis

We weighed each segment in a total of 100 mice, and segmental percentages were calculated as segmental weight (g)/whole liver weight (g) for each mouse. The extent of the hepatectomy is based on the segmental volumes. Of note, the gallbladder can be easily detected in the mouse between the RAS and the LAS (Figure 1B), while the rat does not have a gallbladder.

The learning curve for surgery is important for reliability of the hepatectomy model. To compare hepatectomy models using the suture technique *vs* the clip technique, we examined learning curves and operative time.

Rare complications of outflow block or biliary obstruction due to surgical clips were previously reported[18,19]. To confirm that the surgical issues were due to the clip itself, it was proposed that the clip may secondarily obstruct outflow or biliary ducts near the proximal hepatic margin or hepatic remnant. At first, we checked histopathological findings of the hepatic remnant near the proximal hepatic margin and the distal hepatic margin in the hepatectomy model by suture and clip techniques.

Focal and/or patchy necrosis is an important histopathological finding after hepatectomy[4,20]. To calculate the rate of the appearance of focal and/or patchy necrosis in hepatectomy models by the suture and clip techniques, we examined ten cases for each technique on the same day. Histopathological analyses and calculations were performed at 6 h after hepatectomy. These examinations were repeated three times.

In this study, data are presented as mean ± SD. Student's *t* test was used for the comparisons of unpaired variables between the two groups. A survival curve was made by the Kaplan-Meier method, and the log-rank test was used for the comparisons of survival rates between two groups. Statistical calculations were performed using StatView Version 5.0 (SAS, Cary, NC, United States). A *P* value < 0.05 was considered statistically significant.

RESULTS

Measurement of the weight of each segment

The percentages of total volume for each of the segments were 21.2% ± 3.3% for RAS, 11.5% ± 2.1% for RMS, 14.8% ± 4.0% for RPS, 11.9% ± 1.7% for LAS, 31.6% ± 3.6% for LPS, and 9.0% ± 1.6% for OS (Figure 1G).

Hepatectomy models with > 70% resection in the mouse

Based on our results in the measurement of segmental weights, we calculated the liver volume of resection and the hepatic remnant. The hepatic remnant in the 75% hepatectomy was RMS + RPS (26.4% ± 3.8%); while for traditional 2/3 hepatectomy the remnant was RMS + RPS + OS (35.4% ± 4.0%) (Figure 1H). Hepatic remnant in the 80% hepatectomy was RMS + OS (20.6% ± 2.6%) (Figure 1I). We had two surgical options for 90% hepatectomy by sparing either OS (9.0% ± 1.6%) or RMS (11.5% ± 2.1%) (Figure 1J). Portal venous dilatation inversely proportional to the volume of the hepatic remnant was observed.

Learning curves

For each technique, ten cases were performed on the same day as one unit for training. The required units that showed no statistical differences in survival curves after hepatectomy with those at the next unit were analyzed. The survival curves of hepatectomy after the training period were compared between the two techniques.

Survival curves of each batch of 10 cases at early term in training in the 80% hepatectomy by the suture technique, and statistical results, are shown in Figure 2A. The *P* values between the first 10 cases and the second 10 cases, between the second 10 cases and the third 10 cases, between the third 10 cases and the fourth 10 cases, and between the fourth 10 cases and the fifth 10 cases were 0.0445, 0.0471, 0.4790, and 0.8941, respectively. The first and second units showed statistical differences in comparison with the next unit. Survival curves of each batch of 10 cases at early term in training in the 80% hepatectomy

Figure 2 **Survival outcomes in 80% hepatectomy after initial training.** A: In 80% hepatectomy by suture technique, survival curves of each 10 cases at early term in training are shown; B: In 80% hepatectomy by the clip technique, survival curves of each 10 cases at early term in training are shown; C: In each technique, operative time was investigated in 20 cases of 80% hepatectomy. These data were corrected by experienced surgeons. Operative times of 80% hepatectomy by suture and clip techniques were significantly different ($P <$ 0.0001). NS: Not significant.

Figure 3 **Actual survival curves after each hepatectomy with > 70% resection.** A: Actual survival curves of each hepatectomy by suture technique; B: Actual survival curves of each hepatectomy by clip technique. NS: Not significant.

comparison with the second unit.

In the 80% hepatectomy, the fifth batch of 10 cases (i.e., 10 cases after the experience of 40 cases) in the suture technique and the fourth batch of 10 cases (i.e., 10 cases after the experience of 30 cases) in the clip technique showed similar survival curves (P = 0.8516), even though 30 cases in the suture technique and 20 cases in the clip techniques seemed to be enough statistically. Our institution has similar results in the 90% hepatectomy model.

Operative time

Operative time data were also collected from experienced surgeons in 20 cases of 80% hepatectomy for each technique. Even with experienced surgeons, operative times for hepatectomy using the suture technique and the clip technique were significantly different ($P <$ 0.0001) (Figure 2C). Operative times were clearly shortened in the clip techniques.

Survival curves after hepatectomy with > 70% resection

Actual survival curves of each hepatectomy are shown in Figure 3A and B. Twenty cases were followed for each hepatectomy by suture (Figure 3A) or clip technique (Figure 3B).

In the 90% hepatectomy, either the OS or RMS was

by the clip technique, and statistical results, are shown in Figure 2B. The P values between the first 10 cases and the second 10 cases, between the second 10 cases and the third 10 cases, between the third 10 cases and the fourth 10 cases, and between the fourth 10 cases and the fifth 10 cases were 0.0363, 0.6854, 0.9127, and 0.9007, respectively. Only the first unit showed statistical differences in

Figure 4 Histopathological findings of hepatic remnant near proximal hepatic margin and distal hepatic margins. Findings at 6 h after 80% hepatectomy are shown by hematoxylin and eosin staining at 100 × magnification. A: No findings suggested obstructions in hepatic remnant near proximal hepatic margin of hepatectomy by suture technique; B: In distal hepatic margin of hepatectomy by suture technique, severe ischemia and massive necrosis are confirmed; C: No findings suggested obstructions by hemostatic clip itself in clip-touched hepatic remnant near proximal hepatic margin of hepatectomy by clip technique; D: In distal hepatic margin of hepatectomy by clip technique, severe ischemia and massive necrosis are confirmed.

left as the remnant. Although not shown, we observed no significant differences in survival curves between the OS-remnant and the RMS-remnant following the 90% hepatectomy using suture and clip techniques ($P = 0.3784$ and 0.3588, respectively).

In the 90% hepatectomy, although not shown, there were no significant differences in survival curves after hepatectomy by suture technique between the OS-remnant ($n = 10$) and the RMS-remnant ($n = 10$) ($P = 0.3784$). Similarly, there were no significant differences in survival curves after hepatectomy by clip technique between the OS-remnant ($n = 10$) and the RMS-remnant ($n = 10$) ($P = 0.3588$).

Histopathological findings of hepatic remnant and distal hepatic margin

Histopathological findings of the hepatic remnant near the proximal hepatic margin at 6 h after 80% hepatectomy by suture technique are shown in Figure 4A. No findings suggested obstructions by the suture, except for the changes consistent with hepatectomy. Histopathological findings of the distal hepatic margin showed severe ischemic and massive necroses at 6 h after 80% hepatectomy by the suture technique (Figure 4B).

Histopathological findings of the clip-touched hepatic remnant near the proximal hepatic margin at 6 h after 80% hepatectomy by the clip technique are shown in Figure 4C. Again, no findings suggested obstructions

by the hemostatic clip. Histopathological findings of the distal hepatic margin at 6 h after 80% hepatectomy by clip technique are shown in Figure 4D, showing severe ischemic and massive necroses as expected.

Focal and/or patchy necrosis after hepatectomy

Focal and patchy necrosis is usually observed as early as one hour after hepatectomy, as reported by others[20,21]. In our studies, we observed similar occurrence of focal necrosis following all types of massive hepatectomy. At 6 h after 70%, 80%, and 90% hepatectomies, there was no difference in the rate of appearance of focal and/or patchy necrosis between the suture technique and the clip technique ($P = 0.6202$; data not shown).

DISCUSSION

A number of different survival curves have been previously reported following hepatectomy with > 70% resection in the mouse. Differences in study design and institutional methodology, as well as various complications, may explain these discrepancies[4]. As such, we recommend that survival curves should be checked beforehand according to institutional methodology and study design in each laboratory. In our institution we have two types of 90% hepatectomy models available, while other models of approximately 90% hepatectomy exist[1,7]. Anatomical analysis of each institution's animal strain is crucial for de-

velopment of reliable models. All mice that receive 90% hepatectomy eventually die after surgery, although 90% hepatectomy has some advantages, especially in studies of liver failure and hepatic surgery. Inderbitzin *et al*[8] reported that the OS exhibits different behaviors according to the degree of liver-volume, and will not work in small-volume hepatectomy. Currently, our massive hepatectomy models employed the OS in only the 80% hepatectomy model, because we have a surgical option in the 90% hepatectomy model. In our experience, the OS of some mice exhibit few branches from veins, except for the portal vein, because swelling due to portal hypertension was often mild even after 90% hepatectomy, and color change was often not enhanced after ligation of the portal venous trunk. Overall, we consider that RMS-remnant 90% hepatectomy will provide more relevant data from the viewpoint of strict effects (*i.e.*, liver damage) due to portal hypertension.

The outcomes of murine hepatectomy can vary greatly if surgical procedures are not performed properly. It is difficult to strictly estimate the stability of surgery, because the learning term may be still not enough, even if statistical analysis showed no differences. Based on our experience, we speculate that approximately 40 cases are required in hepatectomy by the suture technique for initial achievement of reliable survival curves, and that approximately 50 or more cases are required to start the study. By contrast, approximately 30 or 40 cases seem to be enough in hepatectomy by the clip technique for reliable samples. Our results of operative time for hepatectomy clearly indicated that the procedures in the suture technique were more complicated than those in the clip method. Overall, we suggest that the clip technique is advantageous even in hepatectomy models with > 70% resection because of its simplicity.

The hepatocyte is the first cell to start the proliferation reaction after hepatectomy[4]. Although histopathological injury can be confirmed from several hours after hepatectomy, some important signals for liver regeneration start in the later phase. As such, a suitable hepatectomy model must be selected according to experimental purpose. Jin *et al*[22] reported no focal and/or patchy necrosis even after hepatectomy models with 70% and approximately 90% resections, although this necrosis is an important finding after hepatectomy[4,20]. These histopathological findings are confirmed several hours after hepatectomy[4,20]. However, in our study a few mice that received 80% or 75% hepatectomy did not demonstrate necrosis, while all mice that received 90% hepatectomy showed necrosis in the early postoperative period. These discrepancies may be consistent with survival curves because a few mice that received 80% or 75% hepatectomy survived long term. These survivors can be used to provide liver samples with long-term observation after hepatectomy with > 70% resection and are useful for many studies that require long recovery times after hepatectomy with > 70% resection. Based on our results of survival curves and histopathological findings in comparison with suture technique, clip method seems to provide reliable

and relevant data, even in murine hepatectomy models with > 70% resection.

Focal and patchy necroses are also observed as secondary findings after biliary stasis and/or congestion by outflow obstruction. Some surgical problems, including inflow and outflow obstructions, massive bleeding, and bile stasis, will invalidate results. All mice move well after complete recovery, and it is possible that the clip may slide following aggressive movements after recovery from anesthesia and surgery, although our results showed similar phenomena between the clip and suture techniques. During surgery, the hepatic margin may be changed according to clip size. Large-sized clips require more proximal hepatic margin for flow safety and more distal hepatic margin for complete hemostasis. Although we often treat the RAS and LAS in an *en bloc* manner using an ML-sized clip, only one of the smallest feasible clips to one segment should be used to prevent unexpected surgical issues. Surgeons should also note any unexpected findings after hepatectomy procedures. A dilated infrahepatic inferior vena cava is a sign of disturbed flow of the inferior vena cava, because clipping of the RAS, LAS and LPS may cause a twist of the supra-hepatic inferior vena cava, while clipping of the RMS and RPS may cause stenosis of the hepatic vena cava. Segmental congestion and partial color change in the liver also suggest outflow and/or inflow obstruction. During autopsy, unexpected color changes of the liver, massive coagula, and bile leakage are informative for unstable postoperative course. To produce reliable samples, mice that indicate unexpected signs during surgery or autopsy should not be used to take samples.

In conclusion, our clip technique for murine hepatectomy models with > 70% resection (*i.e.*, 75%, 80%, and 90% hepatectomy models) is simple and requires only basic surgical skills. Moreover, this technique provides reproducible results in comparison with the suture technique.

ACKNOWLEDGMENTS

COMMENTS

Background
New insights into mechanisms in the hepatology field have been established from experimental animal models. Reliable models for massive hepatectomy in the mouse are required for experimental liver research.

Research frontiers
Despite the widespread use of the 70% hepatectomy, alternative hepatectomy models with resected volumes > 70% (so-called, "massive hepatectomy") are required to provide more clinically relevant experiments on liver regeneration and hepatic failure.

Innovations and breakthroughs
In 2004, Nikfarjam *et al* reported benefits of the hemostatic clip in hepatectomy models with 37% and 70% of resected volumes in the mouse. Herein, the

authors describe detailed surgical procedures of our institutional hepatectomy models with > 70% resection using suture hemostatic clips in the mouse and compare various factors between suture and clip techniques. The clip technique for murine hepatectomy models with > 70% resection is simple and requires only basic surgical skills.

Applications

The clip technique provides reproducible results in comparison with suture technique, even for massive hepatectomy in the mouse. This technique has an advantage in the simplicity of surgical procedures.

Peer review

The authors presented mouse experimental models for hepatectomy exceeding 70%. They evaluated two techniques of hepatectomy, which is suture technique and clip technique. They concluded that clip technique was superior to suture technique. The manuscript was well organized and well written.

Abstract

AIM: To define the rational extent of regional lymphadenectomy for gallbladder cancer and to clarify its effect on long-term survival.

METHODS: A total of 152 patients with gallbladder cancer who underwent a minimum of "extended" portal lymph node dissection (defined as *en bloc* removal of the first- and second-echelon nodes) from 1982 to 2010 were retrospectively analyzed. Based on previous studies, regional lymph nodes of the gallbladder were divided into first-echelon nodes (cystic duct or pericholedochal nodes), second-echelon nodes (node groups posterosuperior to the head of the pancreas or around the hepatic vessels), and more distant nodes.

RESULTS: Among the 152 patients (total of 3352 lymph nodes retrieved, median of 19 per patient), 79 patients (52%) had 356 positive nodes. Among node-positive patients, the prevalence of nodal metastasis was highest in the pericholedochal (54%) and cystic duct (38%) nodes, followed by the second-echelon node groups (29% to 19%), while more distant node groups were only rarely (5% or less) involved. Disease-specific survival after R0 resection differed according to the nodal status (*P* < 0.001): most node-negative patients achieved long-term survival (median, not reached; 5-year survival, 80%), whereas among node-positive patients, 22 survived for more than 5 years (median, 37 mo; 5-year survival, 43%).

CONCLUSION: The rational extent of lymphadenectomy for gallbladder cancer should include the first- and second-echelon nodes. A considerable proportion of node-positive patients benefit from such aggressive lymphadenectomy.

INTRODUCTION

Oncological resection for gastrointestinal cancers con-

ventionally involves *en bloc* resection of the primary tumor and the regional lymphatic basin. However, in cases of gallbladder cancer, most surgeons have developed a negative attitude toward regional lymphadenectomy because of reported poor outcomes after radical resection for node-positive disease[1-5]. In contrast, some surgeons including us advocate aggressive lymphadenectomy[6-10]. Thus, the role of regional lymphadenectomy in treating gallbladder cancer remains controversial.

The National Comprehensive Cancer Network (NCCN) guidelines[11] recommend portal lymph node dissection for pathologic T1b (pT1b) or more advanced gallbladder cancer, where the extent of lymphadenectomy is described as "porta hepatis, gastrohepatic ligament, retroduodenal." The guidelines also state, "Patients with nodal disease outside this area are unable to undergo resection"[11]. In contrast, some Japanese and Western groups advocate more extensive lymphadenectomy including some peripancreatic (head only) node groups[6,12-14]. Thus, the extent of regional lymphadenectomy for gallbladder cancer remains nonstandardized worldwide.

Previously we explored the routes and directions of gallbladder lymphatic drainage in a dye injection study[6]; lymph flow originating from the gallbladder descends around the bile duct, and *via* the first-echelon nodes (cystic duct or pericholedochal nodes) into the second-echelon nodes located posterosuperior to the head of the pancreas or around the portal vein/hepatic arteries, before finally flowing into the paraaortic nodes[6]. Thereafter, we adopted *en bloc* removal of the first- and second-echelon nodes (designated as "extended" portal lymph node dissection) as a standard procedure for pT2 or more advanced gallbladder cancer[6,10,15].

This retrospective study sought to define a rational extent of regional lymphadenectomy for gallbladder cancer and to clarify outcomes after such a procedure in 152 patients subjected to radical resection. The study goal was to establish the role of regional lymphadenectomy in treating gallbladder cancer.

MATERIALS AND METHODS

Patient population

From May 1982 through December 2010, a total of 173 consecutive Japanese patients with gallbladder cancer underwent a radical resection at the Niigata University Medical and Dental Hospital. A radical resection was defined as removing both the primary tumor and the regional lymph nodes of the gallbladder. Cancer arising in the cystic duct was included as gallbladder cancer[16]. We excluded 13 patients due to an invasive primary malignancy in other organs and 8 patients who did not undergo removal of the second-echelon nodes, leaving 152 patients in this study. They included 96 women and 56 men ranging in age from 37 years to 86 years (median, 68 years).

Radical resection procedures

A variety of radical resection procedures were performed

Table 1 Radical resection procedures for 152 patients with gallbladder cancer

Procedure	No. of patients
Extended cholecystectomy (*n* = 93)	
C + WR + BD + N[1]	54
C + WR + N	21
C[2] + BD + N	12
C[2] + N	6
More extensive resection (*n* = 59)

C[2] + PD + N	2

[1]Designated as "extended" radical cholecystectomy (modified Glenn operation) at our department since 1982; [2]Cholecystectomy with full-thickness dissection: cholecystectomy combined with removal of the cystic plate; [3]Resection of Couinaud segments IV, V, and VIII; [4]Left hemihepatectomy extended to an inferior portion of the right anterior section. C: Cholecystectomy; WR: Wedge resection of the gallbladder fossa; BD: Bile duct resection; N: Regional lymphadenectomy; ERH: Extended right hepatectomy (right hemihepatectomy extended to an inferior portion of Couinaud segment 4); PD: Whipple pancreaticoduodenectomy; PPPD: Pylorus-preserving pancreaticoduodenectomy.

for gallbladder cancer in the patients analyzed; the choice of procedure for each patient depended on the extent of tumor spread (Table 1). An "extended" radical cholecystectomy, which was instituted at our department in 1982[6,10,15], was the most common operation used among our study cohort; it involved a cholecystectomy, wedge resection of the gallbladder fossa with a rim of non-neoplastic liver tissue (about 2 cm in thickness or more), resection of a suprapancreatic segment of the extrahepatic bile duct (bile duct resection), and "extended" portal lymph node dissection in an *en bloc* fashion. This "extended" radical cholecystectomy is a modification of the "radical cholecystectomy" (Glenn operation) as proposed by Glenn *et al*[17,18] in 1954; we now also call it the "modified Glenn operation"[15].

Some patients with early-stage disease, comorbid disease(s), or advanced age had a less aggressive resection, by omitting the bile duct resection and/or wedge hepatectomy (Table 1). Although pT1 tumors do not warrant radical resection[19], 14 patients with pT1 tumors underwent a radical resection because pT2 or more advanced tumor was not ruled out preoperatively. In contrast, patients with late-stage disease often required more extensive resections such as major hepatectomy (removal of two sections or more extended hepatectomy), pancreaticoduodenectomy (Whipple procedure or pylorus-preserving procedure), or combined major hepatectomy and pancreaticoduodenectomy (Table 1)[12,20].

Despite an aggressive attitude toward lymphadenectomy, we maintain a rather modest attitude toward hepatectomy for gallbladder cancer, and consequently, the most common hepatectomy procedure in our series was

Table 2 Topographical distribution of 3352 lymph nodes evaluated in 152 patients with gallbladder cancer

Node group	No. of patients with node group evaluated	No. of lymph nodes evaluated		No. of patients with positive nodes	No. of positive nodes	
		Range per patient (median)	Total		Range per patient (median)	Total
First-echelon node groups						
Pericholedochal[1]	152	0-9 (2)	410	43	1-9 (1)	75
Cystic duct	152	0-2 (1)	109	30	1-2 (1)	33
Second-echelon node groups						
Retroportal	152	0-9 (3)	458	23	1-5 (2)	47
Posterior superior pancreaticoduodenal[2]	150	0-9 (2)	341	20	1-7 (1)	37
Hepatic artery	148	0-12 (3)	536	20	1-10 (1)	50
Right celiac[3]	128	0-8 (2)	320	15	1-4 (1)	28
Hilar (porta hepatis)	121	0-5 (0)	37	0	NA	0
More distant node groups						
Superior mesenteric	50	0-14 (2)	171	4	1-5 (2)	10
Posterior inferior pancreaticoduodenal	38	0-7 (1)	56	3	1-5 (2)	8
Anterior superior pancreaticoduodenal	29	0-5 (0)	19	1	1-1 (1)	1
Anterior inferior pancreaticoduodenal	27	0-4 (0)	15	2	1-3 (2)	4
Perigastric	52	0-23 (2)	205	4	1-1 (1)	4
Paraaortic node groups	93[4]	1-28 (6)	675	15	1-16 (2)	59

[1]Also referred to as retroduodenal nodes in the NCCN guidelines[11]; [2]Also referred to as posterosuperior pancreaticoduodenal nodes in our previous study[6] or superior retropancreaticoduodenal nodes by Uesaka *et al*[22]; [3]Also referred to as posterior common hepatic nodes by Uesaka *et al*[22]; [4]Includes 55 who underwent a paraaortic lymph node dissection and 38 who underwent a sampling of paraaortic nodes for staging of the disease.

Figure 1 Topographical distribution of the regional lymph nodes of the gallbladder, shown after a full Kocher maneuver. Solid ellipses represent individual lymph nodes: first-echelon nodes (red), second-echelon nodes (blue), and more distant nodes (black). The yellow painted area represents the head of the pancreas, and the dashed line indicates the border of the uncinate process of the pancreas. Arabic numerals indicate each of the first- and second-echelon node groups: (1) pericholedochal, nodes along the common bile duct; (2) cystic duct, node(s) along the cystic duct; (3) retroportal, nodes posterior to the portal vein and cephalad to the uncinate process; (4) posterior superior pancreaticoduodenal, nodes on the posterosuperior aspect of the head of the pancreas; (5) hepatic artery, nodes along the common or proper hepatic artery; (6) right celiac, nodes located right of the celiac axis and posterior to the common hepatic artery; and (7) hilar, nodes within the porta hepatis. The pale green area indicates the extent of a typical "extended" portal lymph node dissection (*en bloc* removal of the first- and second-echelon node groups) in the study department. GB: Gallbladder; IVC: Inferior vena cava; Ao: Aorta; IMA: Inferior mesenteric artery.

(nonanatomic) wedge resection of the gallbladder fossa. However, cases of deep hepatic invasion through the gallbladder fossa and/or invasion of the right portal pedicle (i.e., extension into the triangle of Calot) required a right hemihepatectomy extended to an inferior part of Couin-aud segment 4 (designated as extended right hepatectomy in this study) for tumor clearance. Five patients underwent other hepatectomy procedures (Table 1).

There were also 25 patients in this study who underwent a combined resection of contiguous tissues comprising the transverse colon (*n* = 12), portal vein (*n* = 9), duodenum (*n* = 5), stomach (*n* = 2), and inferior vena cava (*n* = 2). Of the 152 patients, 127 underwent an initial radical resection and 25 underwent a radical second resection after a prior simple cholecystectomy for presumed benign disease.

Regional lymph nodes of the gallbladder

According to earlier studies[6,8,15,21,22], we classified the regional lymph nodes of the gallbladder into three categories as detailed in Table 2: first-echelon nodes, second-echelon nodes, and more distant nodes. The topographical distribution of the first- and second-echelon node groups is illustrated in Figure 1. Briefly, the first-echelon nodes are located along the cystic duct or the common bile duct, and the second-echelon nodes are located posterosuperior to the head of the pancreas or around the portal vein/hepatic arteries. Although the hilar (porta hepatis) nodes were not regarded as significant regional nodes[6,21,22], we categorized them as second-echelon nodes for convenience (Table 2) because these nodes are located within the hepatoduodenal ligament, and thus are usually harvested during regional lymphadenectomy[11]. Perigastric nodes are not regarded as regional, but they were analyzed in this study since they were included in the Whipple procedure collection. Paraaortic lymph nodes were considered the terminal station for the regional lymphatic system of the gallbladder[6,21,22].

Figure 2 Computed tomography revealing enlarged peripancreatic nodes with heterogeneous contrast enhancement (N). Note that the posterior superior pancreaticoduodenal node (N, left) and the retroportal node (N, right) are adhered to the head of the pancreas (P). The latter node shifts the portal vein (arrowhead) in a right-upper direction. Histological examination confirmed metastases in 10 regional nodes, some of which had invaded the pancreatic parenchyma. This patient remains well with no evidence of disease at 15 years after a pancreaticoduodenectomy combined with wedge resection of the gall-bladder fossa. The arrow indicates common bile duct; V: Inferior vena cava; A: Aorta.

Figure 3 Photographs taken during an "extended" portal lymph node dissection. A: The posterior superior pancreaticoduodenal artery (PSPDA; arrowheads) is shown following dissection of the posterior superior pancreaticoduodenal nodes. The common hepatic artery is secured with the red loop; B: The superior border of the uncinate process (arrowheads) is exposed, ensuring that dissection of the retroportal nodes is complete. The common bile duct was already transected at the level of PSPDA. The blue loops secure the portal vein, whereas the red loops secure the hepatic arteries. A forceps is picking up the node-bearing adipose tissues dissected *en bloc*. L: Liver; HDL: Hepatoduodenal ligament; GDA: Gastroduodenal artery; IVC: Inferior vena cava; Panc: Head of the pancreas; Du: Duodenum; St: Stomach.

Regional lymphadenectomy procedures for gallbladder cancer

In the current study, regional lymphadenectomy for gall-bladder cancer was divided into two categories according to the extent of nodal dissection: "extended" portal lymph node dissection and "peripancreatic (head only) lymph node dissection with pancreaticoduodenectomy"[15]. The former was defined as *en bloc* removal of the first- and second-echelon node groups (without pancreaticoduodenectomy), while the latter was defined as *en bloc* removal of more distant node groups with pancreaticoduodenectomy in addition to the first- and second-echelon node groups. The extent of an "extended" portal lymphadenectomy is illustrated in Figure 1.

Of all the study patients, 125 underwent an extended portal lymph node dissection (without pancreaticoduodenectomy), while the remaining 27 patients underwent a peripancreatic (head only) lymph node dissection with pancreaticoduodenectomy (Table 1). In addition, 55 of the total number of patients who showed suspected (or confirmed) regional nodal disease also underwent a para-aortic (mainly interaortocaval) lymph node dissection, provided that they were fit enough.

It should be noted that despite our consistent policy of aggressive lymphadenectomy, the degree of regional lymphadenectomy varied somewhat in individual patients at the discretion of the individual surgeons, primarily due to the current study spanning a long period of time. For example, elderly patients or those with comorbid diseases tended to undergo a less aggressive lymphadenectomy.

Details of "extended" portal lymph node dissection

The following describes the technical details of our "extended" portal lymph node dissection (combined with both wedge hepatectomy of the gallbladder fossa and bile duct resection) for gallbladder cancer. After laparotomy, scrutinizing distant metastases by meticulous inspection and palpation is mandatory. Any suspicious nodules in the liver or on the peritoneal surface should be excised and submitted to frozen section examination, while any plan of radical resection should be abandoned if distant metastases are confirmed histologically. If no distant metastases are found, a full Kocher maneuver should be conducted (Figure 1) to enable the peripancreatic nodal status to be appropriately assessed. We favor extended portal lymphadenectomy in the absence of clinically evident peripancreatic (head only) nodal disease, while pancreaticoduodenectomy is often required for peripancreatic (head only) nodal disease adherent to or invading the pancreatic parenchyma (Figure 2)[15].

"Extended" portal lymph node dissection usually starts by dissecting the posterior superior pancreaticoduodenal nodes, where a layer of node-bearing adipose tissue is carefully peeled from the posterosuperior surface of the head of the pancreas. Several superior duodenal vessels are then divided to expose the superior aspect of the head of the pancreas. After the lesser omentum is incised, the common hepatic artery is secured with tape and skeletonized with dissecting nodes around the artery; the hepatic-gastroduodenal artery junction is also exposed. The posterior superior pancreaticoduodenal artery (PS-PDA), usually the first branch of the gastroduodenal artery, which traverses the common bile duct, can now be identified (Figure 3A). This ensures that dissection of the posterior superior pancreaticoduodenal nodes is complete. We often sacrifice PSPDA, because its tiny branches often cause unexpected bleeding due to injury during the nodal dissection. Transection of the common bile duct, just above or at the level of PSPDA, ensues.

The peritoneum covering the hepatoduodenal ligament is incised longitudinally along the proper hepatic artery, which is then skeletonized. The right hepatic artery is also skeletonized by dividing its ductal branch. The portal vein is then secured with tape and skeletonized by dissecting the retroportal nodes, which are then dissected from the superior border of the uncinate process. Next, the right celiac nodes are dissected from the right of the celiac artery. At this stage, the whole node-bearing tissues dissected *en bloc* are freed from the hepatic vessels and the head of the pancreas (Figure 3B); exposure of the superior border of the uncinate process ensures that dissection of the retroportal nodes has been completed (Figure 3B). A wedge hepatectomy of the gallbladder fossa ensues. Following parenchymal division, the cystic plate is exposed as a dense fibrous plate connecting with the portal pedicle of the right hemiliver, and then is divided at its base. The adipose tissue within the triangle of Calot, underneath the cystic plate, contains a cystic node(s), and is dissected downward by dividing the cystic artery at its origin. The extended portal lymph node dissection is now complete. Finally, the common hepatic duct is transected just below the confluence of the right and left hepatic ducts, and the surgical specimen including the gallbladder, gallbladder fossa, bile duct, and node-bearing tissues is harvested *en bloc*.

Retrieval of lymph nodes from fresh surgical specimens

Immediately after resection, the surgeon(s) retrieved lymph nodes from the node-bearing adipose tissues of the fresh surgical specimen, which were then divided by the surgeon(s) into individual node groups according to their locations.

Pathological examination

Pathological findings were documented using the American Joint Committee on Cancer (AJCC) cancer staging manual (7th edition)[16]. The primary tumor was pT1 in 14 patients, pT2 in 60, pT3 in 54, and pT4 in 24. Resection margin status was judged as no residual tumor (R0) or microscopic/macroscopic residual tumor (R1-2). The lymph nodes retrieved were examined histologically for metastases using a representative 3-μm thick section cut from each node.

The number of positive lymph nodes as well as the total lymph node count (TLNC) was recorded for each patient. Here, TLNC represented the sum of regional and paraaortic (if any) nodes evaluated in the patient; the number of positive lymph nodes represented the sum of positive regional and paraaortic (if any) nodes in the patient.

Patient follow-up after resection

Of 152 patients, 6 died during their hospital stay for the definitive resection, giving an in-hospital mortality rate of 4%. Patients discharged to home were followed regularly in outpatient clinics every 1-6 mo for at least five years, with a median follow-up time of 142 mo (range, 0.5 mo to 351 mo). Adjuvant chemotherapy was administered to 53 patients at the discretion of the individual surgeons.

Statistical analysis

Medical records and survival data were obtained for all 152 patients. Continuous variables were compared with the Mann-Whitney *U* test. Only deaths from tumor recurrence were treated as failure cases in the analysis of disease-specific survival (DSS), whereas those from other causes were recorded as censored cases. The survival time in each patient was defined as the interval between the date of definitive resection and the date of last follow-up or death. Survival curves were constructed using the Kaplan-Meier method, and differences in survival were evaluated with the log rank test. The IBM SPSS Statistics 19 software (IBM Japan, Inc., Tokyo, Japan) was used for all statistical evaluations. All tests were two-tailed and $P < 0.05$ was used to indicate statistical significance.

RESULTS

Topographical distribution of lymph nodes harvested by regional lymphadenectomy

A total of 3352 lymph nodes taken from the 152 study patients were evaluated. TLNC ranged from 3 to 78 (median, 19) per patient and varied according to the type of regional lymphadenectomy: 27 patients who underwent a peripancreatic (head only) lymph node dissection with pancreaticoduodenectomy had a greater TLNC (median, 36; range, 7 to 78) compared with 125 patients who underwent an extended portal lymph node dissection (median, 17; range, 3 to 53) ($P < 0.001$).

The topographical distribution of the analyzed lymph nodes included 519 first-echelon nodes and 1692 second-echelon nodes (Table 2). There were significantly more second-echelon nodes per patient (median, 10; range, 2 to 29) than first-echelon nodes (median, 3; range, 0 to 10) ($P < 0.001$).

Topographical distribution of positive lymph nodes

Of the 152 study patients, 79 (52%) had a total of 356 positive lymph nodes. The number of positive nodes per patient ranged from 1 to 41 (median, 2). None of the 14 patients with pT1 tumor had nodal disease, whereas 79 (57%) of 138 patients with pT2 or more advanced tumor had nodal disease.

The topographical distribution of all positive lymph nodes is shown in Table 2. Among the 79 node-positive patients, the prevalence of nodal disease was highest in the pericholedochal (43 of 79; 54%) or cystic duct (30 of 79; 38%) node group, followed by the retroportal (29%), posterior superior pancreaticoduodenal (25%), hepatic artery (25%), and right celiac (19%) node groups. The hilar nodes were not involved in any of our patients. The prevalence of nodal disease was 5% or less in more distant node groups. Of note, paraaortic nodal involvement was found in 15 (19%) patients.

Of 27 patients with a single positive node, 20 (74%)

Table 3 Site of nodal involvement in 27 patients with a single positive node

Node group involved	No. of patients
Cystic duct	11
Pericholedochal	9
Posterior superior pancreaticoduodenal	3
Retroportal	2
Hepatic artery	1
Paraaortic	1

LND: Lymph node dissection; PD: Pancreaticoduodenectomy (Whipple procedure or pylorus-preserving procedure).

had nodal disease in either the pericholedochal or cystic duct node group, suggesting that initial nodal involvement occurred primarily in these node groups (Table 3).

Route of lymphatic spread

Analysis of the topographical distribution of positive lymph nodes (Tables 2 and 3) can be used to derive the route of lymphatic spread from gallbladder cancer. In our study patients, gallbladder cancer primarily spread to the first-echelon nodes, then to the second-echelon nodes (other than the hilar nodes), and finally to the paraaortic nodes, while other distant node groups were only rarely involved.

Long-term outcome after regional lymphadenectomy

For all 152 patients, DSS was significantly worse in 22 patients undergoing an R1-2 resection than in 130 patients undergoing an R0 resection ($P < 0.001$; Figure 4); all of the patients undergoing an R1-2 resection died of recurrence within 5 years of resection. This indicates that an R0 resection is a prerequisite for long-term survival after radical resection.

We then focused on a subgroup of 130 patients who had undergone an R0 resection for survival analysis; they comprised 68 node-negative and 62 node-positive patients. DSS after R0 resection differed according to the nodal status ($P < 0.001$; Figure 5), with most node-negative patients achieving long-term survival (median survival time, not reached; 5-year survival rate, 80%). Of the 62 node-positive patients, 22 survived for more than 5 years after an R0 resection, 37 expired within 5 years, and the remaining 3 had survived within 5 years at the time of last follow-up (median survival time, 37 mo; 5-year survival rate, 43%) (Figure 5). These findings suggested that regional lymphadenectomy could achieve

No. of patients at risk

R0 resection	130	100	87	81	76	69	59	46	41	39	34
R1-2 resection	22	10	5	4	2	0	0	0	0	0	0

Figure 4 Kaplan-Meier disease-specific survival estimates stratified for residual tumor (R) status in all 152 patients. The median survival was not reached with a 5-year survival rate of 63% in patients undergoing an R0 resection, whereas it was 13 mo with a 5-year survival rate of 0% in patients undergoing an R1-2 resection.

No. of patients at risk

A	68	60	56	54	52	47	41	32	27	26	23
B	62	40	31	27	24	22	18	14	14	13	11

an acceptable rate of long-term survival even in patients with nodal metastasis, provided that an R0 resection is feasible.

Five-year survival with node-positive disease

The 22 patients with node-positive disease who survived for more than 5 years (Figure 5) comprised 13 with a single positive node, 5 with 2-3 positive nodes, and 4 with ≥ 4 positive nodes (Table 4). Of the 5-year survivors with ≥ 4 positive nodes, three underwent a peripancreatic (head only) lymph node dissection with pancreaticoduodenectomy for marked peripancreatic

nodal disease (Figure 2), suggesting that the addition of pancreaticoduodenectomy is effective for selected patients with peripancreatic nodal disease.

DISCUSSION

The high propensity for lymphatic spread in gallbladder cancer[6,8,10,15,23] renders adequate lymphadenectomy indispensable for improving patient outcomes after resection. However, what constitutes adequate lymph node dissection for these patients remains unresolved and prompted the current study. Since the 1980s, we have routinely harvested at least the first- and second-echelon nodes (Figure 1) during curative-intent resection for pT2 or more advanced gallbladder cancer. As a result, and to the best of our knowledge, we report herein the largest single-institutional series of 5-year survivors (22 patients) with nodal disease ever analyzed. The study findings also indicated that a considerable proportion of node-positive patients could benefit from regional lymphadenectomy, providing that an R0 resection is feasible, and would seem to justify continuing our policy of aggressive lymphadenectomy for gallbladder cancer.

In this study cohort, initial nodal involvement occurred primarily in the cystic duct or pericholedochal nodes (Table 3). Although these node groups are widely accepted as first-echelon nodes of the gallbladder, further possible routes of lymphatic spread have been poorly defined[6,21-23]. In 1991, an autopsy study by Ito and colleagues[21] implicated the cholecystoretropancreatic pathway, which descends along the common bile duct into the retroportal nodes, as the main lymphatic pathway of the gallbladder. Soon after, we identified the same pathway in a dye injection study and showed the second-echelon nodes located posterosuperior to the head of the pancreas or around the hepatic vessels; the dye solution finally drained into the interaortocaval nodes near the left renal vein[6]. In 1996, Uesaka *et al*[22] reported similar findings using vital staining. These studies therefore uniformly confirmed that lymph from the gallbladder first flows in a hepatofugal direction around the common bile duct and into the first-echelon nodes, before reaching the second-echelon nodes (other than the hilar nodes), and finally the paraaortic nodes[6,21,22]. In addition, the prevalence of nodal disease in our series was high in both the first-echelon and second-echelon node groups (other than the hilar nodes), while the other node groups were only rarely involved (Table 2). Thus, the rational extent of regional lymphadenectomy for gallbladder cancer should include at least the first- and second-echelon node groups as defined in the current study (Figure 1).

Despite a number of 5-year survivors with nodal disease reported in the Japanese literature[8,10,12,13], such survivors are exceptionally rare in the Western literature[1,2,5,24]. Since the first proposal by Glenn *et al*[17] in 1954, portal lymph node dissection has been regarded as the standard lymphadenectomy procedure for localized gallbladder cancer throughout the world[15]. However, the scope of portal lymph node dissection differs considerably among institutions. In 2005, Dixon *et al*[24] from the University of Toronto described "a complete portal lymph node dissection, with thorough skeletonization of the portal structures, down to and including the suprapyloric lymph node overlying the hepatic-gastroduodenal artery junction," while Ito and colleagues from the Memorial Sloan-Kettering Cancer Center (MSKCC) in 2011[5] reported a portal lymphadenectomy including "the lymph nodes in the hepatoduodenal ligament and those along with the common hepatic artery." The NCCN guidelines[11] described the extent of portal lymphadenectomy as "porta hepatis, gastrohepatic ligament, retroduodenal." From the above descriptions, we thus assume that the portal lymphadenectomy performed in North America may leave behind some of the second-echelon nodes, particularly the retroportal, posterior superior pancreaticoduodenal, and right celiac node groups, which were frequently involved in the current series (Table 2). This may explain, in part, why portal lymph node dissection only rarely achieves 5-year survival in cases of node-positive gallbladder cancer[1,2,5,24].

Although the AJCC staging manual (6th edition)[25] recommended "analysis of a minimum of three lymph nodes" for accurate staging of gallbladder cancer, a recent population-based study by Coburn *et al*[26] disclosed that among patients in the United States with resectable T1-T3 disease, only 5.3% had retrieval of three or more lymph nodes. In addition, a recent report from MSKCC of 122 patients who underwent a portal lymph node dissection cited a median TLNC of only 3[5]. In contrast, TLNC was much greater (median, 19) in the current series. Insufficient lymph node retrieval with portal lymphadenectomy may also explain, in part, the poor survival of node-positive patients in the Western literature[5,26].

Thorough dissection of the second-echelon nodes is challenging even in the hands of expert hepatobiliary surgeons. In particular, complete removal of the posterior superior pancreaticoduodenal, retroportal, and right celiac node groups mandates a meticulous technique. As described in the Materials and Methods section, there are some measures that can be taken to facilitate adequate dissection of the second-echelon nodes: first, a full Kocher maneuver (Figure 1) is essential for assessing the peripancreatic nodal status; second, identification of PSPDA (Figure 3A) ensures that dissection of the posterior superior pancreaticoduodenal nodes has been completed; and third, exposure of the superior border of the uncinate process (Figure 3B) ensures complete dissection of the retroportal nodes.

In our institution, we prefer to perform bile duct resection in fit patients with pT2 or more advanced gallbladder cancer; indeed, 66 (71%) of the 93 patients who underwent an extended cholecystectomy had a bile duct resection (Table 1). Although the presence of ductal involvement is an absolute indication for such an approach, controversy exists regarding bile duct resection for tumors without clinically evident ductal involvement[27]. Our rationale for bile duct resection for tumors with no evident ductal in-

volvement is to facilitate regional lymphadenectomy, to remove the pericholedochal lymphatic vessels and nodes simultaneously, and to remove the possible presence of microscopic ductal (periductal) involvement as suggested by Shimizu *et al*[28]. Another justification is to avoid the occurrence of ischemic biliary stricture after aggressive periductal nodal dissection[29]. The suprapancreatic segment of the extrahepatic bile duct gets its arterial blood supply mainly from ductal branches of both PSPDA ("retroduodenal artery" by Northover *et al*[30]) and the right hepatic artery[30]. As described in the Materials and Methods section, during our extended portal lymph node dissection, the PSPDA (Figure 3A) was often sacrificed with division of the ductal branch of the right hepatic artery. In addition, skeletonization of the bile duct may inadvertently injure the periductal arterial plexus with "the 3 o'clock and 9 o'clock arteries"[30]. Thus, we believe that simultaneous bile duct resection is a safer option if such aggressive periductal nodal dissection is required[29].

Indications for pancreaticoduodenectomy for gallbladder cancer include direct invasion of the pancreaticoduodenal region and evident peripancreatic (head only) nodal disease (Figure 2)[10,12,15]. While the former indication is widely accepted, it seems that most Western surgeons hesitate to undertake this procedure for the purpose of lymph node dissection because they believe that peripancreatic nodal disease is beyond the scope of resection[1,11,16,27]. Shirai *et al*[12] in 1997 and Sasaki *et al*[13] in 2006 independently reported the effectiveness of pancreaticoduodenectomy for selected cases of peripancreatic nodal disease. This was also suggested by the current study. In 2002, Doty *et al*[14] also suggested that the addition of pancreaticoduodenectomy could result in an R0 resection by removing extensive peripancreatic nodal disease in a select group of patients. Western surgeons should therefore be more open than ever to performing pancreaticoduodenectomy for gallbladder cancer.

The main limitations of the current study revolved around the retrospective nature of the analysis and considerable variability in the degree of nodal dissection among individual patients. However, the unique nature of this study has more clearly defined the role of regional lymphadenectomy for gallbladder cancer than earlier studies, although the survival of node-positive patients remains unsatisfactory (Figure 5). Since 2009, we have therefore routinely administered adjuvant chemotherapy (using gemcitabine and/or S-1 for 6-12 mo) to patients with nodal disease (especially those with multiple positive nodes) to improve survival. In addition, we now use "extended" portal lymphadenectomy for both gallbladder and bile duct cancers, with the latter also showing some success (unpublished data). Thus, it seems that "extended" portal lymph node dissection is applicable to a wide range of biliary tract malignancies.

In conclusion, gallbladder cancer first spreads to the first-echelon nodes (cystic duct or pericholedochal nodes), then to the second-echelon nodes located posterosuperior to the head of the pancreas or around the portal vein/hepatic arteries, and finally to the paraaortic nodes. The rational extent of regional lymphadenectomy for pT2 or more advanced tumors should include the first- and second-echelon node groups. Such aggressive lymphadenectomy can achieve an acceptable rate of long-term survival even in patients with nodal metastasis, provided that a potentially curative (R0) resection is feasible. The addition of pancreaticoduodenectomy may also be beneficial in selected patients with peripancreatic (head only) nodal disease. This study confirmed that regional lymphadenectomy plays a key role in radical surgery for gallbladder cancer.

COMMENTS

Background
The extent of regional lymphadenectomy for gallbladder cancer has not been standardized worldwide. Since 1982, the authors have consistently adopted an aggressive lymphadenectomy strategy. What constitutes adequate lymph node dissection for gallbladder cancer remains unresolved and prompted the current study.

Research frontiers
The study aims to define the rational extent of regional lymphadenectomy for gallbladder cancer and to clarify its effect on long-term survival.

Innovations and breakthroughs
The authors clearly define the rational extent of regional lymphadenectomy for pT2 or more advanced gallbladder cancer as at least the first- and second-echelon node groups. They also demonstrate that such aggressive lymphadenectomy can achieve an acceptable rate of long-term survival even in node-positive patients.

Applications
The authors imply that "extended" portal lymph node dissection is applicable to a wide range of biliary tract malignancies (both gallbladder and bile duct cancers).

Terminology
First-echelon nodes mean lymph nodes located along the cystic duct or the common bile duct; second-echelon nodes mean lymph nodes located posterosuperior to the head of the pancreas or around the portal vein/hepatic arteries; "extended" portal lymph node dissection mean *en bloc* removal of the first- and second-echelon node groups.

Peer review
This paper provides detailed description of their surgical technique for gallbladder cancer, "extended" portal lymph node dissection, of which this group has been conducting over the years. Documentation of detailed surgical technique is important not only as a material and method of a study, but even more as a tool to compare studies, and as guidance to the next generation of surgeons. They boast the largest single-institutional number of 5-year survivors with nodal disease (22 cases), suggesting the effectiveness of such aggressive lymphadenectomy.

Abstract

AIM: To establish a simple model consisting of the routine laboratory variables to predict both minimal fibrosis and cirrhosis in chronic hepatitis B virus (HBV)-infected patients.

METHODS: We retrospectively investigated 114 chronic HBV-infected patients who underwent liver biopsy in two different hospitals. Thirteen parameters were analyzed by step-wise regression analysis and correlation analysis. A new fibrosis index [globulin/platelet (GP) model] was developed, including globulin (GLOB) and platelet count (PLT). GP model = GLOB (g/mL) × 100/PLT (× 10^9/L). We evaluated the receiver operating characteristics analysis used to predict minimal fibrosis and compared six other available models.

RESULTS: Thirteen clinical biochemical and hematological variables [sex, age, PLT, alanine aminotransferase, aspartate aminotransferase (AST), albumin, GLOB, total bilirubin (T.bil), direct bilirubin (D.bil), glutamyl-transferase, alkaline phosphatase, HBV DNA and pro-thrombin time (PT)] were analyzed according to three stages of liver fibrosis (F0-F1, F2-F3 and F4). Bivariate Spearman's rank correlation analysis showed that six variables, including age, PLT, T.bil, D.bil, GLOB and PT, were correlated with the three fibrosis stages (FS). Correlation coefficients were 0.23, -0.412, 0.208, 0.220, 0.314 and 0.212; and *P* value was 0.014, < 0.001, 0.026, 0.018, 0.001 and 0.024, respectively. Univariate analysis revealed that only PLT and GLOB were significantly different in the three FS (PLT: *F* = 11.772, *P* < 0.001; GLOB: *F* = 6.612, *P* = 0.002). Step-wise multiple regression analysis showed that PLT and GLOB were also independently correlated with FS (R^2 = 0.237). By Spearman's rank correlation analysis, GP model was significantly correlated with the three FS (*r* = 0.466, *P* < 0.001). The median values in F0-F1, F2-F3 and F4 were 1.461, 1.720 and 2.634. Compared with the six available models (fibrosis index, AST-platelet ratio, FIB-4, fibrosis-cirrhosis index and age-AST model and age-PLT ratio), GP model showed a highest correlation coefficient. The sensitivity and positive predictive value at a cutoff value < 1.68 for predicting minimal fibrosis F0-F1 were 72.4% and 71.2%, respectively. The specificity and negative predictive value at a cutoff value < 2.53 for the prediction of cirrhosis were 84.5% and 96.7%. The area under the curve (AUC) of GP model for predicting minimal fibrosis and cirrhosis was 0.762 [95% confidence interval (CI): 0.676-0.848] and 0.781 (95% CI: 0.638-0.924). Although the differences were not statistically significant between GP model and the other models (*P* all > 0.05), the AUC of GP model was the largest among the seven models.

CONCLUSION: By establishing a simple model using available laboratory variables, chronic HBV-infected patients with minimal fibrosis and cirrhosis can be diagnosed accurately, and the clinical application of this model may reduce the need for liver biopsy in HBV-infected patients.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a global public health problem and it is estimated that approximately 350 000 000 people are infected with this virus in the world. More often, it may progress into liver cirrhosis and hepatocellular carcinoma (HCC). Although anti-virus therapy has reduced greatly the risk of cirrhosis and HCC, some positive hepatitis B surface antigen (HBsAg) carriers with less HBV-DNA may eventually develop cirrhosis and HCC[1,2]. Liver biopsy is not common. Patients with more than a 2-fold increase in aminotransferase levels were regarded as having severe liver necroinflammation. However, liver fibrosis was difficult to evaluate by noninvasive methods.

Liver fibrosis is known as the major problem causing morbidity and mortality in chronic HBV-infected patients. Once diagnosed, fibrosis should be treated as early as possible by appropriate methods. Although liver biopsy is being used as the gold standard in diagnosing the degree of fibrosis, not many patients are willing to undergo a liver biopsy because of its invasiveness and there might be inter- and intra-observer variability in the evaluation of specimens obtained[3], and a risk of complications (even if it is low) causing discomfort[4,5].

Some noninvasive methods are expected and used in patients with hepatitis C or B virus infection. The best results were obtained with liver stiffness measurement by means of transient elastography (TE) (FibroScan), or with FibroTest-ActiTest (Biopredictive, Labcorp)[4] and Fibrospect Ⅱ (Prometheus)[5]. However, all these noninvasive methods are expensive and/or require equipments not widely used. Therefore, it is necessary to screen for simpler and cheaper methods for the examination of hepatic fibrosis. Poynard *et al*[6-10] investigated the correlations between the serum aminotransferases level, age, hyaluronic acid level, collagen level, platelet count and different fibrosis stages (FS), but did not draw clear con-clusions. Several scoring systems like age-platelet count (PLT) ratio (AP index), aspartate aminotransferase (AST)-platelet ratio (APRI), age-AST model, fibrosis index (FI), FIB-4 and fibrosis-cirrhosis index (FCI), using different thresholds, have been proposed to detect presence or absence of fibrosis or cirrhosis in patients infected with hepatitis C virus (HCV) or HBV[11-18]. HBV-infected patients are prone to fibrosis; however, there have been few studies on the relationship between noninvasive fibrosis biomarker and liver biopsy. For this purpose, in this study we developed a new noninvasive serum model by assessing several clinicopathological features. We also compared and evaluated the diagnostic accuracy of this noninvasive model consisting of the variables of FI, APRI, FIB-4, FCI, age-AST model and AP index.

MATERIALS AND METHODS

Patients

This is a retrospective cross-sectional study and was carried out from March 2008 to March 2011. Screening of patients was conducted at the Department of Liver Disease (Ruikang Hospital of Guangxi Traditional Chinese Medical University, Nanning, China) and Department of Infectious Disease (The First Affiliated Hospital of Guangxi Medical University, Nanning, China). A total of 114 patients were enrolled to the study (male/female 91/23; mean age 38.32 ± 11.36 years, range 15-67 years. Diagnosis of chronic HBV-infected patients was established based on the presence of positive results of surface antigen (> 0.5 ng/mL) and/or e antigen (> 0.05 NCU/mL) lasting more than six months. Clinical, biochemical and hematologic data were recorded from each patient at the time of liver biopsy. Patients with the following conditions were excluded: presence of other causes of liver disease such as hepatitis A/C/E virus infection, HCC, prior nucleoside medication, prior interferon therapy, fatty liver disease, alcohol intake > 30 g/wk (female) and 60 g/wk (male), insufficient liver tissue for staging of fibrosis, clinical or ultrasonographic evidence of cirrhosis.

Histological staging

Ultrasonographic-guided liver biopsy was performed according to a standardized protocol. The liver biopsy procedure, its advantages and possible adverse effects were explained to the patients. Informed consent was obtained from the patients about the possible transmission of HBV infection. Specimens of 15-20 mm liver tissues were fixed, paraffin-embedded, stained with hematoxylin-eosin and Masson's trichrome. A minimum of six portal tracts was required for diagnosis. Liver biopsy was evaluated with or without knowing the history of the patients. Five fibrosis degrees of histological staging were defined according to "The program of prevention and cure for viral hepatitis", generally used in hospitals of China[19], as F0 (no fibrosis), F1 (mild fibrosis without septa), F2 (moderate fibrosis with few septa), F3 (severe fibrosis

Table 1 Characteristics of the study population

Features	mean ± SD	Minimum	Maximum
Gender (male/female)	91/23		
HBV DNA (copies/mL)			
(< 1000/ ≥ 1000)	44/70		
(< 10^3/10^3-10^5/ ≥ 10^5)	44/32/38

ALP (IU/L)	80.10 ± 27.38	24	154
GGT (IU/L)	59.46 ± 66.92	5	430
PT (s)	12.01 ± 1.58	9.3	18.1

HBV: Hepatitis B virus; GLOB: Globulin; PLT: Platelet count; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; T.bil: Total bilirubin; D.bil: Direct bilirubin; ALB: Albumin; GGT: Glutamyltransferase; ALP: Alkaline phosphatase; PT: Prothrombin time.

with numerous septa without cirrhosis) and F4 (cirrhosis). In our study, we simplified the FS as F0-F1 (minimal fibrosis), F2-F3 (advanced fibrosis) and F4 (cirrhosis).

Blood tests

All tests were performed in the patients after a fasting period of 12 h. The routine liver function tests included alanine aminotransferase (ALT), AST, total bilirubin (T.bil), direct bilirubin (D.bil), albumin, globulin (GLOB), glutamyltransferase (GGT), alkaline phosphatase (ALP), PLT, HBV-DNA and prothrombin time (PT). Serum tests were performed using an automatic biochemistry analyzer. The viral load was measured by real-time polymerase chain reaction, with a detection limit of 1000 copies/mL. All biochemical tests and their scores were evaluated without knowledge of liver biopsy results. Thirteen clinical, biochemical and hematological variables were used for the analysis: sex, age, PLT, ALT, AST, albumin, GLOB, T.bil, D.bil, GGT, ALP, HBV DNA and PT.

Statistical analysis

The data was analyzed using statistical package SPSS version 13.5 for Windows. A P value of 0.05 was considered statistically significant. All data was presented as mean values or number of patients. Spearman's rank correlation was used to assess the significant correlation between variables and liver FS. The Student t test or variance analysis was used to compare arithmetic means and parameters, while χ^2 test was used to compare categorical data.

A predictive model, named Globulin/platelet (GP) model, was constructed by modeling the values of the independent variables and their coefficient of regression. The diagnostic value of the model was assessed by calculating the areas under the receiver operating characteristic (ROC) curves. An area under the curve (AUC) of 1.0 rep-

resentes an ideal test, whereas 0.5 indicates a test of no diagnostic value. The diagnostic accuracy was calculated by sensitivity, specificity, positive predictive values (PPV) and negative predictive values (NPV).

The best cutoff points were selected according to the Youden index from the ROC curve to identify the presence and absence of minimal fibrosis or cirrhosis. For this purpose, we selected cutoff points with a 95% certainty, thus assuming a 5% false negative result which is acceptable clinically.

Comparison of available noninvasive biomarkers to evaluate patient's liver biopsy data

Serum samples and data of the characteristics of the patients and liver specimens were collected from each patient for further biochemical analysis. All patients were evaluated for FI, APRI, FIB-4, FCI, age-AST model and AP index. Superiority of GP model was compared with the other selected fibrosis models, and ROC curves and correlation analysis were employed to predict minimal fibrosis or cirrhosis, and deduce the diagnostic accuracy.

RESULTS

Patient data

The demographic and clinical outcomes of the 114 patients with HBV infection are shown in Table 1. The evaluation of inflammatory grade yielded mild chronic hepatitis in 44 patients, moderate chronic hepatitis in 64 patients and severe chronic hepatitis in 6 patients. And 22 patients had liver fibrosis at stage F0, 34 at F1, 28 at F2, 18 at F3, and 12 at F4. Among the patients with HBV DNA < 1000 copies/mL, there were 20 cases of mild chronic hepatitis, 24 moderate chronic hepatitis, and none had severe chronic hepatitis, while among those with HBV DNA > 1000 copies/mL, there were 24 cases of mild chronic hepatitis, 40 moderate chronic hepatitis, and six severe chronic hepatitis. The latter showed a higher inflammatory grade than the former ($\chi^2 = 37.487$, $P < 0.001$). Among the E antigen positive (e+) patients, 12 at stage F0, 15 at F1, 11 at F2, 7 at F3, and 7 at F4. Among E antigen negative (e-) patients, 10 at stage F0, 19 at F1, 17 at F2, 11 at F3 and 5 at F4. There was no significant difference between e+ and e- patients in FS ($\chi^2 = 2.301$, $P = 0.681$).

Correlation between clinical findings and three FS

Three levels of liver fibrosis (F0-F1, F2-F3 and F4) were analyzed. Thirteen demographical, hematological, and biochemical variables were studied. HBV DNA was divided into two groups (≥ 1000 copies/mL and < 1000 copies/mL) or three groups (< 1000 copies/mL, ≥ 1000 copies/mL and < 10^5 copies/mL, ≥ 10^5 copies/mL) and gender was described as categorical data. Of the 13 variables studied by Bivariate Spearman's rank correlation analysis, 6 variables (age, PLT, T.bil, D.bil, GLOB and PT) were correlated significantly with the three FS (cor-

Figure 1 Scores of platelet count (A) and globulin (B) in three fibrosis stages (F0-F1, F2-F3 and F4). The top and bottom of each box are the 25% and the 75% centiles. The line through the box is the median, and the error bars are the 5th and 95th centiles. GLOB: Globulin; PLT: Platelet count.

relation coefficients were 0.23, -0.412, 0.208, 0.220, 0.314 and 0.212; *P* value 0.014, < 0.001, 0.026, 0.018, 0.001 and 0.024).

Selection of variables and construction of a model for predicting FS

Univariate analysis revealed that only PLT and GLOB of the 13 variables were independent predictive factors and significantly different in FS (PLT: $F = 11.772$, $P < 0.001$, GLOB: $F = 6.612$, $P = 0.002$). There was no difference among the other variables (P all > 0.05). These biochemical markers can also be helpful in staging the liver fibrosis. Figure 1 shows the box plots of the two markers with liver histological stages. It is clear from Figure 1 that as the fibrosis progressed, GLOB level increased, while PLT gradually decreased with fibrosis progression. However, it was interesting to note that GLOB and PLT both were in the normal limits, making the diagnosis of fibrosis difficult by using single biochemical markers.

To amplify the opposite relationship between the stage of fibrosis and the two markers, GLOB and PLT, based on their significance not only by the rank correlation analysis but also by univariate analysis, we developed a new fibrosis model named GP model in HBV infection for predicting cirrhosis and minimal fibrosis. It can be represented as GP model = GLOB (g/dL) $\times$ 100/PLT ($\times 10^9$/L).

The GP model distribution for the patients in the respective FS is represented in Figure 2. The median values for GP model in F0-F1, F2-F3 and F4 patients were 1.461, 1.720 and 2.634, respectively. GP model was correlated significantly with the liver FS ($r = 0.466$, $P < 0.001$). The diagnostic values of GP model to predict F0-F1 and F4 patients were evaluated by the AUC (Figure 3).

Step-wise multiple regression analysis, which was used to formulate a suitable multivariable model for the correlation between 11 count variables and the three FS, F0-F1, F2-F3 and F4, revealed that PLT and GLOB were also independently correlated with histological FS, $R^2 = 0.237$. The contribution of PLT and GLOB to R^2 was 0.197 and 0.04, respectively (data not shown). The final multiple regression model incorporating both PLT and GLOB was: FS = 1.683 - 0.008 $\times$ PLT ($\times 10^9$/L) + 0.485 $\times$ GLOB (g/dL). We simplified it as: FS = 1.7 - 0.01 $\times$ PLT ($\times 10^9$/L + 0.5 $\times$ GLOB (g/dL).

The median values for FS model in F0-F1, F2-F3 and F4 patients were 1.218, 1.480 and 2.085, respectively. FS model significantly correlated with the liver FS (Spearman's rank correlation coefficient, $r = 0.47$, $P < 0.001$, data not shown). The diagnostic values of FS to differentiate F0-F1 and F4 patients were assessed using the ROC. Interestingly, AUC was very close between FS model and GP model in F0-F1 (0.760 *vs* 0.762) and F4 (0.781 *vs* 0.783), and in complete coincident sensitivity and specificity for the detection of minimal fibrosis and cirrhosis (data not shown). GP model was simpler than FS model in term of calculation. Therefore, we used GP model to express our findings.

Comparison of GP model with FI, APRI, FIB-4, FCI, age-AST model and AP index

The scores of six indexes (FI, APRI, FIB-4, FCI, age-AST model and AP index) were calculated by the formula shown in Table 2. The relationship between the histological severity of fibrosis (F0-F1, F2-F3 and F4) and six models is shown in Figure 2 and Table 3. There was a significant correlation between F0-F1, F2-F3 and F4 and serum indexes of FIB-4, AP index and GP model ($P < 0.05$), but not in FI, APRI, FCI, age-PLT model ($P > 0.05$). A gradual increase at the level of AP index, FIB-4, GP model was observed in different FS. GP model showed the strongest correlation with the three FS ($r = 0.441$, $P < 0.001$).

The predictive value of the seven noninvasive models for predicting minimal fibrosis (F0-F1) is summarized in Table 4. APRI, FIB-4 and FCI had a high PPV, specificity, but the sensitivity and NPV were low. AP index had a high sensitivity and NPV, but specificity and PPV were low. GP model had not only high PPV and specificity, but also high NPV and sensitivity. AUC of age-AST model was close to 0.5, showing little value for prediction of minimal fibrosis. We compared the AUC of GP model with the other five noninvasive models using the 95% confidence interval (CI) and the standard error (SE) of the mean, and found that although the differences were not statistically

Figure 2 Box plot of fibrosis index, aspartate aminotransferase-platelet ratio, FIB-4, fibrosis-cirrhosis index, age-aspartate aminotransferase model, age-platelet count ratio and globulin/platelet model in relation to F0-F1, F2-F3 and F4 fibrosis stage. The box represents the interquartile range. The whiskers indicate the highest and lowest values, and the asterisks represent outliers. The line across the box indicates the median value. FI: Fibrosis index; GP: Globulin/platelet; FCI: Fibrosis-cirrhosis index; AST: Aspartate aminotransferase; APRI: AST-platelet ratio; AP index: Age-platelet count ratio.

Figure 3 Receiver operating characteristic curves generated by globulin/platelet model for prediction of F0-F1 (A) and F4 (B). The area under the curve of GP model for the discrimination between minimal fibrosis (F0-F1) and significant fibrosis (F2, F3, F4), and between non-cirrhosis (F0, F1, F2, F3) and cirrhosis (F4) was 0.732 [confidence interval (CI): 0.642-0.823] and 0.738 (CI: 0.612-0.864). Using a cutoff value of < 1.68, GP model had a sensitivity of 72.4%, a positive predictive value (PPV) of 71.2%, a specificity of 69.6%, and a negative predictive value (NPV) of 70.8% for the prediction of F0-F1. For the prediction of cirrhosis (F4) at a cutoff value of > 2.53, GP model had a sensitivity of 72.7%, a PPV of 33.4%, a specificity of 84.5%, and a NPV of 96.7%.

significant, the GP model seemed to have a best predictive value (largest AUC) (*P* all > 0.05) (Table 4).

The predictive value of GP model for cirrhosis (F4) is shown in Table 5. All of the models had very good NPV (> 96%), also high sensitivity (> 70%). The AUC of age-AST model was less than 0.5, which cannot be used to predict cirrhosis. We compared the AUC of GP model with the other five noninvasive models as well using the 95% CI and the SE, and found that AUC of GP model was not significantly high (*P* all > 0.05) (Table 5).

DISCUSSION

Although only a small number of patients with chronic inactive HBV infection develop advanced liver disease[20-22], the risk of HCC is higher for HBV infected patients than for those without HBV infection[23]. The cirrhosis in HBsAg carriers often progress insidiously. Chu *et al*[24] concluded that the so-called inactive carrier state cannot be considered generally as an innocuous, persistent condition with good prognosis, suggesting that regular follow-

up is necessary. Active HBV infection more often caused significant fibrosis and cirrhosis than inactive HBV infection. We attempted to find a simple and common index to evaluate their fibrosis in active and inactive HBV infections. We retrospectively studied the pathological changes about fibrosis in patients with HBV infection from two liver disease centers. We found that the HBV DNA with a higher inflammation grade, was not significantly different among different FS. We also found no significant difference between e+ and e- populations in FS. A study[25] recruited patients with HBV DNA < 10^4 copies/mL, and found the mean liver stiffness in inactive HBsAg carriers was 5.6 ± 2.1 kPa, significantly higher than in normal subjects. In 16.4% (23) of inactive carriers, liver stiffness exceeded 7 kPa (the cutoff for fibrosis F2-F4); and in patients with undetectable viral loads (with a detection limit of 51 copies/mL for HBV DNA), the mean liver stiffness was significantly lower than in those with detectable DNA (< 10^4 copies/mL). Assessing the noninvasive liver stiffness in inactive HBsAg carriers by transient elastography, Fattovich *et al*[26] reported that HBeAg-negative chronic hepatitis patients had a higher risk for progression to cirrhosis (8-10 per 100 person years) than HBeAg-positive chronic hepatitis patients. This may reflect the duration of infection, and a late phase in the natural history of the disease, as opposed to *de novo* infec-

tion with a variant not producing HBeAg. Another study found in chronic HBV carriers with clinical normal liver function tests, inflammation grade and FS had no correlation with the level of HBV DNA or the state of HBeAg positivity[27]. Our study with a detection limit of 1000 copies HBV DNA/mL, enrolled all of HBV-infected patients, including some patients with active inflammation. This may be the reason for the inconsistency with other studies[28].

Many studies on prediction of significant fibrosis (F2-F4) and cirrhosis (F4) in patients with HBV infection have been published in the past few years, such as Fibroscan and FibroTest-ActiTest, galactose and methacetin breath tests, TE, fibrotest, cirrhosis discriminant score, AST/ALT ratio, APRI, FIB-4 and AP index[11,29-33]. However, some of the tests need expensive instruments and some are somewhat difficult to use in clinical practice, since these assay utilizes less common biochemical markers such as α2-macroglobulin, haptoglobin, and apolipoprotein A1, and also requires use of a special computer program to perform calculations.

In our study, we attempted to develop a single model using routinely available laboratory test results to predict minimal fibrosis and cirrhosis in treatment-naive patients with HBV infection. We found by Step-wise multiple regression analysis and correlation analysis, that PLT and GLOB were significantly correlated with different FS. Other variables such as T.bil, D.bil, PT, or GGT may play a role in the discrimination function and have been found useful in patients with minimal fibrosis or cirrhosis. However, compared with PLT and GLOB, other variables were correlated with the histological FS at a much smaller coefficient of determination. Wai *et al*[16] also suggested that two variables can be practically used as a prediction index, and in our model we used PLT and GLOB because of their convenience of application in general practice. Nevertheless, the value of these two parameters was proposed to evaluate minimal fibrosis and cirrhosis. The concept in prediction of minimal fibrosis by a ratio of two important variables is not new. These findings echoed results from many previous studies. The value of PLT as a marker of liver fibrosis has already been reported[6,16,34-37]. Some studies showed that GLOB was correlated with FS and was a predictor of either significant fibrosis or cirrhosis[28,38].

GP model was simple to use and accurate in predicting both minimal fibrosis and cirrhosis in HBV-infected patients (Figure 3 and Tables 3-5). To evaluate its predictive value, we compared GP model with the other available models, because the variables used in these models were also involved in our collected data. GP model showed the highest correlation coefficient with FS. Comparison of GP model with the other six models in AUC, GP model showed the highest value than other models, although there was no significant difference. Using values below the lower cut-off level (1.68), a presence of minimal fibrosis could be predicted in 71% of patients. Similarly, using values below the higher cut-off level (2.53),

a prediction of non-cirrhosis could be made in 96% of patients.

There exist some limitations in our study. Our study is based on the data from liver biopsy, which is considered as the gold standard for assessing hepatic fibrosis, but sampling error as well as intra- and inter-observer variability can complicate the correlations between histology and noninvasive markers of hepatic fibrosis. Arase *et al*[39] found that some patients with a nodular liver surface at laparoscopy were not diagnosed as having liver cirrhosis when only histological samples were used; HBV-positive patients with a nodular liver surface have a tendency of sampling error compared with the HCV-positive patients. On the other hand, there was overlap among patients with different stages of fibrosis. Thus, the value of GP model for the prediction of fibrosis in individual patients with HBV infection must be confirmed in prospective studies. However, we are not yet able to get enough patient data for verification of GP model in a new cohort. The data of patients were derived from two different hospitals, and the sample size is still small. Whether the model can reflect the change of FS in treatment process awaits further studies.

In conclusion, We established a simple model using available laboratory variables. Minimal fibrosis and cirrhosis can be diagnosed accurately using this model, thus reducing the need for liver biopsy in chronic HBV-infected patients.

COMMENTS

Background
Liver fibrosis is known as the major condition causing morbidity and mortality in chronic hepatitis B virus (HBV)-infection patients. Liver biopsy (LB) as an invasive method is used as the gold standard in diagnosing the degree of fibrosis, but because there is a risk of complications causing discomfort, not many patients are willing to undergo a LB. HBV-infected patients are prone to fibrosis, but there have been few studies about the relationship between noninvasive fibrosis biomarker and liver LB among these patients.

Research frontiers
Some noninvasive methods were expected and used in patients with hepatitis C or B virus infection. Simpler and cheaper methods for the prediction of hepatic fibrosis are being studied. Several scoring systems have been proposed, such as age-platelet count (PLT) ratio (AP index), aspartate aminotransferase (AST)-platelet ratio, age-AST model, fibrosis index, FIB-4, and fibrosis-cirrhosis index, using different thresholds to predict presence or absence of fibrosis or cirrhosis in patients infected with hepatitis C virus or HBV.

Innovations and breakthroughs
This study developed a new noninvasive serum model named Globulin/platelet (GP) model, including globulin and PLT, by assessing several clinicopathological features. Comparing with six available models, GP model showed highest correlation coefficient. The sensitivity and positive predictive value at a cutoff value < 1.68 for predicting minimal fibrosis F0-F1 were 72.4% and 71.2%. The specialty and negative predictive value at a cutoff value < 2.53 for the prediction of cirrhosis were 84.5% and 96.7%. The area under the curve of GP model for predicting minimal fibrosis and cirrhosis were 0.762 and 0.781, respectively, which is the largest among the seven models.

Applications
The simple model developed in this study using readily available laboratory results can identify chronic HBV-infected patients with minimal fibrosis and cirrhosis with a high degree of accuracy, and it seems more efficient than frequently used models. This model may decrease the need for liver biopsy in

HBV-infected patients.

Peer review

This study might be interesting and useful for the readers regarding the daily management of patients with viral hepatitis. Application of this model may decrease the need for liver biopsy in HBV infection cases.

Abstract

AIM: To determine if the observed paracellular sucrose leak in Barrett's esophagus patients is due to their proton pump inhibitor (PPI) use.

METHODS: The *in vivo* sucrose permeability test was administered to healthy controls, to Barrett's patients and to non-Barrett's patients on continuous PPI therapy. Degree of leak was tested for correlation with presence of Barrett's, use of PPIs, and length of Barrett's segment and duration of PPI use.

RESULTS: Barrett's patients manifested a near 3-fold greater, upper gastrointestinal sucrose leak than healthy controls. A decrease of sucrose leak was observed in Barrett's patients who ceased PPI use for 7 d. Although initial introduction of PPI use (in a PPI-naïve population) results in dramatic increase in sucrose leak, long-term, continuous PPI use manifested a slow spontaneous decline in leak. The sucrose leak observed in Barrett's patients showed no correlation to the amount of Barrett's tissue present in the esophagus.

CONCLUSION: Although future research is needed to determine the degree of paracellular leak in actual Barrett's mucosa, the relatively high degree of leak observed with *in vivo* sucrose permeability measurement of Barrett's patients reflects their PPI use and not their Barrett's tissue *per se*.

INTRODUCTION

The sucrose permeability test is designed to measure paracellular (non-transcellular) leak of sucrose from the lumen

of the upper gastrointestinal (GI) tract into the vasculature because sucrose is markedly hydrophilic and lacks any significant affinity for any carbohydrate transport proteins on the cell surface[1]. Moreover sucrose is destroyed enzymatically in the duodenum, and ceases to exist as a disaccharide after the early-mid portion of the small bowel. Sucrose leak would therefore be detected only while the probe (sucrose) still exists chemically in the upper GI lumen. This limits potential sites of leak to the esophageal, gastric and early intestinal mucosa. However, considerations of surface area and contact time (after oral consumption of the sucrose) argue that the sucrose permeability test results reflect primarily the gastroduodenal mucosa and less so the esophageal mucosa which has the smallest surface area (no villi or folds-except in Barrett's) and the shortest contact time.

Still, Barrett's patients are believed not to have a histological mucosal defect other than in the esophagus. Therefore when in previous work our group published that patients with a known diagnosis of Barrett's esophagus (BE) manifested a greater magnitude of transepithelial sucrose leak across the upper gastrointestinal tract than that seen in healthy control subjects, the strong difference was ascribed to the presence of Barrett's metaplasia in these patients[2]. In other words, a transepithelial leak was presumed to exist in the Barrett's metaplasia.

In this current work we revisited that conclusion by asking whether considerations other than the simple presence of Barrett's metaplasia were the reason for the increased leak observed in BE patients. Aside from the presence of Barrett's tissue, the foremost distinction about BE patients is their chronic, long-term use of acid suppression medications, most notably proton pump inhibitors (PPIs). We therefore posed the question of whether the leak we observed in BE patients was traceable to their regular use of PPI medications or to the presence of Barrett's metaplasia. Results indicated that the observed leak is due to PPI use by these patients.

MATERIALS AND METHODS

Study population

Patients with a prior known history of Barrett's esophagus or healthy controls with no current or history of upper GI disease were recruited by a gastroenterologist in a tertiary care teaching hospital bordering the suburbs of Philadelphia, PA. Diagnosis of BE was made by endoscopic exam and only after biopsies were documented to possess goblet cell metaplasia. All enrolled subjects gave informed consent and the study was approved by the Main Line Hospitals Institutional Review Board committee.

Test subjects were recruited without regard to gender or ethnicity. Exclusion criteria were: diabetes mellitus, steroid use, prior gastric or esophageal surgery, age < 18 years, current GI bleeding, weight loss, intractable nausea and vomiting or renal insufficiency. PPI use comprised omeprazole, esomeprazole, lansoprazole, pantoprazole and rabeprazole.

Sucrose permeability testing

All test subjects consumed in their homes a chilled solution of 100 g of sucrose in 200 cc of water containing 5 g of a citric acid-based flavoring agent at bedtime. An 8 h (overnight) urine sample was collected in a container with 5 mL of 10% thymol in isopropanol and mixed. For patients undergoing upper endoscopic examination, the sucrose permeability test was performed either before the procedure or at least two weeks later to avoid potential effects of endoscope trauma on epithelial barrier tissue. The total urine volume was measured and recorded. The concentration of sucrose in the urine sample was then measured by an enzymatic/spectrophotometric assay after prior desalting of the urine sample by anion and cation exchange resins[3]. The total amount of sucrose in the urine in mg was determined by multiplying the urine volume in mL by the sucrose concentration in mg/mL. This equates to the amount of sucrose which leaked out of the upper GI lumen.

Test subjects were instructed to refrain from solid food for at least 2 h prior to the sucrose permeability test and 8 h after testing. Specific foods were however not prohibited. Test subjects were also instructed to refrain from alcohol or non-steroidal anti-inflammatory medications for 24 h prior to testing and for 8 h after testing. Brushing teeth or flossing was proscribed before testing and until at least 20 min after testing.

Statistical analysis

Data are reported throughout as the mean $\pm$ SE. Experimental and control groups are compared throughout by unpaired Student's *t* tests, with statistical significance being ascribed when $P < 0.05$.

RESULTS

Sucrose permeability testing was conducted on 19 patients, 9 carrying a diagnosis of BE and 10 being healthy controls. The 9 BE patients were on PPI therapy at the time of their testing while the healthy controls were receiving no acid-suppressive medication. As was shown in previous studies from our group[2], a significantly greater sucrose leak was observed in the BE patients (345.9 $\pm$ 59.6 mg) compared to the healthy controls (124.7 $\pm$ 26.9 mg) (Figure 1). This difference was statistically significant with a $P < 0.003$. Following this confirmation of an increased transepithelial sucrose leak in BE patients, the etiology of the leak (as a result of BE itself or of PPI use) was pursued.

First, a second group of BE patients was studied to evaluate the effect of cessation of their PPI therapy on their observed sucrose leak. Thirty-eight BE patients underwent sucrose permeability testing while on a continuous PPI regimen. They then performed a second sucrose permeability test after having stopped their PPIs for 7 d, in order to look for any change in observed leak. Patients were allowed to consume antacid medications during this period but not PPIs or H-2 receptor antagonists. Any patients reporting very difficult reflux symptoms

Figure 1 Results of sucrose permeability studies showing a significant difference in sucrose leak in patients with Barrett's esophagus (and taking proton pump inhibitors) compared to healthy controls. Data represents the mean ± SE. $P < 0.003$ (Student's *t* test). SE: Standard error.

Figure 2 Sucrose leak among Barrett's esophagus patients after discontinuation of proton pump inhibitors for 7 d. Data represents the mean ± SE. $P = 0.28$ ($n = 38$). SE: Standard error; PPI: Proton pump inhibitor.

were allowed to leave the study. The mean sucrose leak decreased by approximately 30% from 155.4 ± 40.8 mg to 109.5 ± 15.3 mg after PPI medications were temporarily stopped for this 7 d period (Figure 2). These findings were however not statistically significant, with a $P = 0.283$ (paired Student's *t*-test). As before, a high SE was found for patients on PPI therapy, indicating a considerable amount of variability. The sucrose leak observed in the BE patients after their PPIs were discontinued for 7 d decreased to nearly the same level observed in Figure 1 for healthy controls not taking PPIs.

Since BE exists in a wide range of segment lengths, and a (passive diffusion) transepithelial leak due specifically to Barrett's metaplasia should correlate with the surface area of the Barrett's metaplasia, we investigated whether sucrose leak in the Barrett's patients correlated with length of segment of the Barrett's tissue. Endoscopically, characteristic findings of reddish/velvety Barrett's mucosa are defined as short segment BE if < 3 cm and long segment BE if ≥ 3 cm in length. Data from 49 BE patients were examined. Greater leak was not observed in patients with long-segment Barrett's. Mean leak was actually greater in short-segment Barrett's (209 *vs* 148.9). Analysis of sucrose leak between the two segment groups showed similar medians of 130.5 ± 40.4 mg (short) and 121.0 ± 21.4 mg (long) ($P = 0.36$) with no statistically significant difference between them.

Due to the magnitude of sucrose leak variability that we observed among patients (especially among patients on PPIs), other potential confounding sources of variability were explored. First, the issue of potential effect of duration of PPI use on observed transepithelial sucrose leak was investigated. In a non-BE population taking PPIs on a regular, long-term basis (gastroesophageal reflux disease patients not known to have Barrett's), the sucrose leak was found to vary as a function of the duration of PPI use. Specifically, the magnitude of leak correlated inversely with the length of time on PPI medi-

cations (Figure 3A). A statistically significant difference in leak was observed in patients on PPIs for < 3 mo (336.9 ± 53.8 mg) in comparison to those on PPIs for 3 mo to 25 years (135.4 ± 22.8 mg) ($P < 0.0003$; Figure 3B). The PPI-induced leak thus appeared to exhibit tachyphylaxis, and this would lead to wider observed variation in leak data if one did not correct for duration of PPI therapy.

Discontinuation of long-term PPI use followed by resumption of PPIs did not result in re-induction of leak. In a separate group of 14 patients on long-term PPI therapy, PPI use was discontinued for 7 d, and was then reinstituted. Sucrose permeability testing was again utilized to assess upper gastrointestinal leak 7 d after resumption of PPI use. A significant leak did not re-occur in these patients who had previously been on long-term PPI treatment (Table 1). This is in sharp contrast to patients taking PPIs for the first time, where induced sucrose leak is substantial[3].

DISCUSSION

When our clinical studies with Barrett's patients were begun in 2005, we did not anticipate increased barrier leak being induced by PPIs. In fact, the opposite was expected due to PPIs' documented ability to allow for mucosal (both gastric and esophageal) healing from inflammation and micro-ulceration by means of suppression of acid secretion and subsequent elevation of the pH of gastric luminal contents. Therefore when we first noted a transmucosal leak in BE patients we ascribed the observed leak to the presence of Barrett's metaplasia, as BE patients typically do not have other upper GI pathology[2]. When we later observed that Barrett's patients' transmucosal sucrose leak did not correlate with the length of the Barrett's segment and the surface area of the Barrett's metaplasia, we began to question if the source of the leak was in fact the metaplasia. We realized that PPI medications were the other common characteristic-in addition to the metaplasia itself-of all the Barrett's patients studied.

Figure 3 Proton pump inhibitor-induced transepithelial leak as a function of time. A: Scatter plot illustrating a decrease in sucrose leak in reflux disease patients on proton pump inhibitors (PPIs) over time with each data point representing the sucrose leak of one patient (*n* = 41); B: Statistically significant decrease in sucrose leak between patients on PPIs for < 3 mo *vs* 3 mo to 25 years. Data represents the mean ± SE. *P* = 0.003. SE: Standard error.

Table 1 Sucrose leak in Barrett's patients as a function of proton pump inhibitor use

	On PPIs	7 d off PPIs	7 d after PPI resumption
Median	87.8	101.9	63.0
mean ± SE	116.6 ± 16.5	142.7 ± 34.2	101.5 ± 21.0

Sucrose leak in Barrett's esophagus patients (*n* = 14) on proton pump inhibitors (PPIs), following 7 d off PPIs, and after the reintroduction of PPIs for 7 d. The acute leak phenomenon observed in previous studies in PPI naïve patients is not seen with resumption of PPIs after 7 d. A statistical significance in sucrose leak is not demonstrated among the different groups (on PPIs *vs* off PPIs *P* = 0.497, off PPIs *vs* back on PPIs *P* = 0.323, on PPIs *vs* back on PPIs *P* = 0.574). SE: Standard error.

We then began a series of clinical studies to ask whether PPIs in fact could induce upper GI leak in healthy controls free of upper GI disease, and found that PPIs indeed have this effect[3]. We further explored that phenomenon in an animal model (Sprague Dawley rat), observing that exposure of rat gastric corpus to omeprazole can lead to an immediate increase in transmucosal permeability which is bidirectional, concentration-dependent and size-specific[4-6]. This work confirmed the earlier findings by Hopkins *et al*[7] that omeprazole induced leak to ^{14}C-mannitol in rat gastric corpus. These previous findings together with our current observation (that the sucrose leak seen in Barrett's patients decreases when their PPI medications are discontinued) suggests that PPI use, not the presence of BE *per se*, is the cause of the upper GI leak seen in BE patients.

Note however that this still does not address whether Barrett's epithelium is or is not paracellularly leaky. It simply means that the clinical, *in vivo*, sucrose permeability test which is employed here is reflecting the effects of PPIs on upper GI barrier function. To determine whether Barrett's metaplasia is leaky will likely require Ussing chamber-type permeability studies with actual Barrett's

tissue. This could be difficult to perform since the major source of Barrett's tissue that is large enough in surface area for typical Ussing studies is esophagectomy surgery for adenocarcinoma. Here, adjacent Barrett's tissue may be available but it can be considerably modified/eliminated by radiation and chemotherapy prior to surgery, which is now a current, common practice in esophageal adenocarcinoma management. This is therefore clearly a situation where Ussing studies using Barrett's biopsy tissue (readily available through upper endoscopic screening) would be highly useful[8-10].

An unanswered question from our earlier study on sucrose leak in Barrett's patients is that not only was sucrose leak in Barrett's patients significantly greater than sucrose leak in healthy controls, but it was also greater than the leak measured in patients with chronic gastroesophageal reflux disease (GERD)[1]. As both GERD and Barrett's patient groups would be receiving PPI therapy, it is unclear why leak in the Barrett's group would be quantitatively and significantly different if PPIs were the cause of leak in both patient groups. One possible explanation is that our patient population happened to be too small in the earlier study to get a fully accurate representation, and that sucrose permeability testing can carry intrinsically high variability, being affected by certain dietary constituents as well as certain over-the-counter drugs such as aspirin[11-13].

The sucrose leak that we observed in the Barrett's cohort, or any of our patient groups taking PPIs, was not only high in absolute value but was associated with a large variance and high standard error of the mean. This led us to examine whether the PPI-induced leak was stable over time, since the length of the duration on PPI therapy was a frequent variable in our studies. As shown in Figure 3, the effect of PPIs on leak is indeed not stable over time, but in fact decreases over long-term PPI use. In contrast, a similar tachyphylactic aspect to PPI activity has not been observed for PPI-inhibition of acid secretion[14]. The inability of PPIs to induce a major transmucosal, molecular leak (> 200 mg of sucrose in the described test) after long-term PPI use has been interrupted for 7 full days, suggests that long-term PPI use has caused modification of intracellular signaling pathways and/or cell/tissue structural aspects that mitigate against reintroduction of leak.

In summary, sucrose leak observed in Barrett's esophagus patients appears to be due to the use of PPIs by these patients, not due to their Barrett's metaplasia. This PPI-induced upper GI leak appears to diminish during long-term PPI therapy. After long-term use of PPIs, leak is difficult to re-induce even after short interruption of PPI therapy. Finally, variability associated with sucrose permeability testing in a clinical population may necessitate use of relatively large patient groups to support one's conclusions.

ACKNOWLEDGMENTS

COMMENTS

Background

In earlier work, the research group has shown that Barrett's esophagus (BE) patients manifest a barrier leak to the paracellular probe, sucrose, in their upper gastrointestinal tract. This phenomenon could be due to a molecular-level leak in the Barrett's metaplasia, or to some other aspect of the Barrett's patient cohort. This study was an attempt to determine if the common medication of all BE patients, proton pump inhibitors (PPIs), is responsible for the phenomenon.

Innovations and breakthroughs

The phenomenon of PPI-induced gastric barrier leak is certainly an unexpected side-effect of PPI therapy. The mechanism for the phenomenon remains unknown. More importantly, the clinical implications of the phenomenon are as yet poorly understood.

Applications

If one adopts a stance that a PPI-induced gastric barrier leak is clinically benign, it is possible that the phenomenon could be useful in drug delivery. However a greater understanding of the characteristics of the leak are needed (what can actually permeate through the leak), as well as a full realization of the clinical implications (if any). These could range from localized inflammation to altered kinetics of uptake of other (oral) medications into the bloodstream.

Terminology

Barrier function refers here to the ability of the gastric mucosa to separate the stomach luminal compartment from interstitial fluid and bloodstream. Barrier leak can result from either injured/dying/detaching epithelia or altered (and leaky) epithelial tight junctions.

Peer review

This study found that BE manifested a greater magnitude of transepithelial sucrose leak across the upper gastrointestinal tract than that seen in healthy control subjects, previously. In the present study, they determined if the observed paracellular sucrose leak in BE patients is due to their proton pump inhibitors use. This subject is a new topic in the research area and may contribute to the literature.

Abstract

AIM: To investigate plasma microRNA (miRNA) profiles indicative of hepatotoxicity in the setting of lethal acetaminophen (APAP) toxicity in mice.

METHODS: Using plasma from APAP poisoned mice, either lethally (500 mg/kg) or sublethally (150 mg/kg) dosed, we screened commercially available murine microRNA libraries (SABiosciences, Qiagen Sciences, MD) to evaluate for unique miRNA profiles between these two dosing parameters.

RESULTS: We distinguished numerous, unique plasma miRNAs both up- and downregulated in lethally compared to sublethally dosed mice. Of note, many of the greatest up- and downregulated miRNAs, namely 574-5p, 466g, 466f-3p, 375, 29c, and 148a, have been shown to be associated with asthma in prior studies. Interestingly, a relationship between APAP and asthma has been previously well described in the literature, with an as yet unknown mechanism of pathology. There was a statistically significant increase in alanine aminotransferase levels in the lethal compared to sublethal APAP dosing groups at the 12 h time point ($P < 0.001$). There was 90% mortality in the lethally compared to sublethally dosed mice at the 48 h time point ($P = 0.011$).

CONCLUSION: We identified unique plasma miRNAs both up- and downregulated in APAP poisoning which are correlated to asthma development.

INTRODUCTION

Acetaminophen (APAP) continues to be an important cause of acute liver failure in the developed world, second only to infectious etiologies worldwide[1]. It is also the most common cause of death due to analgesic ingestion in the United States[2]. Numerous emergency department

patients in the setting of acetaminophen overdose are admitted to hospital for N-acetylcysteine (NAC) treatment. This necessary treatment modality places these patients at risk for health-care associated disease. It also places likely unnecessary additional financial strain on an already burdened healthcare system. In addition, the estimated United States cost of treating intentional acetaminophen overdose is $86.9 million per year[3]. However, in over 30 years of research it is still unclear how the exact mechanism of acetaminophen toxicity occurs[4].

Current literature implicates N-acetyl-para-benzoquinone-imine, or N-acetyl-p-benzoquinoneimine (NAPQI), as the primary metabolite responsible for hepatotoxicity. An estimated 90% of APAP is metabolized in the liver *via* either glucuronidation or sulfation. Another approximate 5% is urinated unaltered. However, approximately 5% of APAP is metabolized by the cytochrome P450 2E1 pathway into NAPQI. In the scenario of APAP overdose, the normal route of metabolism becomes overburdened, so an overabundance of NAPQI is produced, causing hepatotoxicity. Glutathione can rescue this process, and is the reason NAC is used as a treatment modality. However, it is presumed only a portion of hepatotoxicity occurs *via* this mechanism. Lipid peroxidation *via* free radical formation, and mitochondrial dysfunction *via* increased permeability of the mitochondrial permeability transition, are also postulated as causes of APAP-associated hepatotoxicity[5,6].

Clearly, a better understanding of how APAP specifically causes hepatic toxicity from a pathophysiologic perspective still needs to be determined. In addition, standard clinical laboratory testing may not reveal evidence of hepatic injury for up to 24 h following APAP ingestion. A considerable proportion of APAP-exposed individuals therefore receive unnecessary empiric treatment with an antidote before hepatic injury can be ruled out. To overcome this clinical problem, early diagnostic indicators of hepatic injury have been sought.

MicroRNA fragments (miRNAs), are short, chemically stable biomolecules, noncoding posttranslational regulators that bind to untranslated mRNA sequences to produce gene silencing[7-10]. Moreover, each miRNA targets several different mRNAs; the same target gene may be regulated by several different miRNAs in different biological situations, a process that allows enormous complexity and flexibility in their regulatory potential. miRNAs have been characterized as regulators of protein expression in diverse disease processes, including acute hepatic injury[9,10]. Importantly, miRNAs have already been successfully utilized as early biomarkers for esophageal squamous cell carcinoma detection in serum[7], identifying Parkinson's disease onset and disease progression[8], and diagnosis of hepatocarcinoma[9,10], demonstrating miRNAs as an ideal area of research to determine other early biomarkers for disease states, notably APAP-associated hepatotoxicity[11]. In addition, miRNA fragments do not require the post-translational modifications necessary in protein production; with fewer human miRNAs to evaluate (an estimated 1000 human miRNAs compared to approximately 20 000 proteins), there is an improved likelihood of identifying unique APAP-associated miRNA profiles[11].

Recent work has also shown the medical utility of miRNA[12,13]. Interestingly, literature also supports its association specifically in the setting of acetaminophen toxicity. For instance, Wang *et al*[11] (2009) showed increased levels of miR-122 and miR-192 in the plasma of acetaminophen overdosed mice, yet decreased levels of these miRNAs in the liver tissue. In addition, these determined markers changed with time and dosing corresponding to histologic liver damage. Of note, these profiles were not evaluated at the lethal APAP dosing of 500 mg/kg, a parameter requiring further investigation to specifically compare lethal and sublethal miRNA profiles. Furthermore, additional literature has described miRNA involvement in acetaminophen toxicity, as well as the utility of miRNAs as biomarkers useful in the setting of other hepatotoxic disorders, such as hepatitis B and C, alcoholic liver disease, non-alcoholic fatty liver disease, and primary biliary cirrhosis[14].

However, these miRNAs could be a potential marker for liver toxicity in the human patient as well, specifically in the setting of acetaminophen overdose. The identification of early plasma markers of acetaminophen toxicity is necessary and paramount. Early identification of acetaminophen toxicity would identify those requiring more expeditious treatment, potentially improving morbidity and mortality of these individuals. It would also possibly abrogate the need for patient admission, mitigating the resultant financial system burden and iatrogenic risk of hospital-acquired infections.

MATERIALS AND METHODS

Acetaminophen toxicity

C57Bl/6 wild-type mice were purchased from Jackson Laboratory (Bar Harbor, ME) and received proper care in agreement with animal protocols approved by the Institutional Animal Use and Care Committee of the University of Massachusetts Medical School.

For all experiments, 6-wk-old female C57/BL6 mice, with food deprivation 12 h prior to experimentation, were used for intraperitoneal (ip) injections. For lethal dosing APAP experiments, 20 C57/BL6 mice were each injected with acetaminophen 500 mg/kg (0.9% normal saline suspension) ip at time zero. For the sublethal dosing APAP experiments, 20 C57/BL6 mice were injected with acetaminophen 150 mg/kg acetaminophen (0.9% normal saline suspension) ip at time zero. At times 0.5 h, 2 h, 12 h, 24 h, and 48 h, 5 mice per group (both lethal and sublethal) were sacrificed *via* cervical dislocation. Just prior to sacrifice, 400 mL of cheek blood was obtained from each mouse. The whole blood was then centrifuged at 14 000 *g* for 10 min at room temperature. The plasma was removed, aliquoted, and stored at -80 ℃. After sacri-

Figure 1 Plasma microRNA both up- and downregulated in lethally (500 mg/kg) compared to sublethally (150 mg/kg) dosed acetaminophen mice at the 12 h time point. A total of 528 microRNAs were screened using the reverse transcriptase[2] miRNA polymerase chain reaction (PCR) array of mouse whole genome, per the manufacturer's protocol (SABioscience, Qiagen Sciences, MD). Quantitative PCR data were analyzed using manufacturer software (http://pcrdataanalysis.sabiosciences.com/pcr/arrayanalysis.php).

fice, livers were snap frozen in liquid nitrogen for protein, stored in RNA stabilization reagent (RNAlater, Qiagen, Hilden, Germany) for RNA extraction, or fixed in 10% neutral-buffered formalin for histopathologic analysis. Five mice were injected with saline only ip and sacrificed at time 48 h as controls.

Hepatotoxicity verification
Alanine aminotransferase (ALT) was quantified by biochemical assay (D-Tek Analytical Laboratories Inc, San Diego, CA).

Survival studies
Ten mice were injected with APAP 500 mg/mL ip and an additional 10 mice were injected with APAP 150 mg/mL, all at time zero. Mice were monitored for 48 h and the mortality for each recorded and plotted using Kaplan-Meier survival statistics (GraphPad Prism Software, LaJolla, CA). All mice were housed, watered and fed under the same conditions throughout the experimental protocol.

Histopathologic analysis
Sections of formalin-fixed, paraffin-embedded livers after sublethal and lethal APAP dosing were stained with hematoxylin and eosin and assessed for inflammatory infiltrate calculated with Microsuite (Olympus Soft Imaging Solution GmbH, Munster, Germany) image analysis software in 20 X objective.

MicroRNA library screen
MicroRNA was purified from plasma using the MiRNeasy Mini kit (Qiagen Sciences, MD). The cDNA was prepared using (reverse transcriptase[2]) RT[2] First Strand cDNA kit (SABiosciences, Qiagen Sciences, MD). The libraries were screened using pooled plasma samples from the 12 h time point for each APAP dosing parameter using saline injected mice as controls (5 mice/group). The

Figure 2 Increased hepatotoxicity (measured in elevated alanine aminotransferase levels) in lethally dosed acetaminophen mice over time. [a]$P < 0.05$ *vs* 0.5 h time point for the 150 mg/kg and 500 mg/kg treatment groups, respectively. ALT: Alanine aminotransaminase.

screening libraries utilized were the RT[2] miRNA PCR arrays for mouse whole genome, per the manufacturer's protocol (SABiosciences, Qiagen Sciences, MD). Real-time quantitative polymerase chain reaction (QPCR) was performed using RT[2] QPCR SYBR green MasterMix (SABiosciences, Qiagen Sciences, MD) and the iCycler iQ Cycler (Bio-Rad Laboratories, Inc, Hercules, CA).

QPCR data were analyzed using manufacturer software (http://pcrdataanalysis.sabiosciences. com/pcr/arrayanalysis.php).

RESULTS

APAP toxicity confirmation: ALT levels and survival
Numerous plasma miRNAs were both upregulated and downregulated, respectively, for the lethally compared to sublethally dosed APAP mice (Figure 1). Increase in serum levels of ALT is a well characterized marker of liver injury in the clinical setting as well as in animal models. Hepatotoxicity induced by APAP administration in our experiments was confirmed utilizing an ALT assay. An ALT average for the sublethal APAP dosing (150 mg/kg) peaked at 883 IU/L and for the lethal APAP dosing (500 mg/kg) peaked at 7396 IU/L, both at 24 h (Figure 2). There was a statistically significant increase in ALT levels in the lethal dosing compared to the sublethal dosing groups (642 IU/L compared to 6796 IU/L, respectively) starting at the 12 h time point ($P < 0.001$). There remained statistically significant increased ALT levels for both the sublethal and lethal dosed groups at the 48 h time point compared to the 0.5 h and 2 h time points (Figure 2).

With administration of a high dose APAP (500 mg/kg), we found that there was 90% lethality compared to no lethality with the sublethal dosing (150 mg/kg) at the 48 h time point as demonstrated by the nonparametric maximum likelihood estimate of a Kaplan-Meier survival curve (Figure 3). This difference was statistically significant at $P = 0.011$, with ten mice utilized per dosing pa-

Figure 3 Survival of lethally compared to sublethally dosed acetaminophen mice. Kaplan-Meier survival curve over time (h) after sublethal (150 mg/kg) and lethal (500 mg/kg) acetaminophen poisoning ($P = 0.011$).

Figure 4 Histopathologic analysis of liver after lethal compared to sublethal acetaminophen dosing. Hematoxylin and eosin liver tissue staining at 12 h of (A) sublethally (150 mg/kg) acetaminophen poisoned mice, with no signs of centrilobular inflammation or necrosis; and (B) lethally (500 mg/kg) acetaminophen poisoned mice with extensive centrilobular necrosis, enlarged hepatocytes, and highly vacuolated cytoplasm.

rameter analyzed (Graphpad Prism Software; LaJolla, CA).

APAP toxicity confirmation: Histology

For the sublethally dosed mice, the portal and periportal regions appear normal, with no signed of centrilobular necrosis or inflammation (Figure 4A). However, for the lethally dosed mice, obvious extensive centrilobular necrosis and inflammation were present, with distinctively en-

larged hepatocytes and highly vacuolated cytoplasm. The lethal dosed liver also demonstrated pyknotic nuclei with extensive ballooning vacuolar degeneration (Figure 4B).

MicroRNA profile of APAP toxicity

In an attempt to evaluate plasma miRNAs as potential indicators of APAP-induced liver damage, we screened plasma of mice after administration of a lethal or sublethal dose of APAP. Out of the 528 murine miRNAs analyzed, there were more than 40 potential miRNAs that were both greater than 2-fold up- and downregulated in the lethal (500 mg/kg) compared to sublethal (150 mg/kg) dosing (Table 1). The miRNAs listed were effectively detected suggesting the actual fold-change value is as large as the calculated and reported fold-change result (SABiosciences, Qiagen Sciences, MD). The small nucleolar RNA, C/D Box 68 (Snord68), was used as the internal control for each library evaluated.

Finally, we performed an extensive literature search to gather information on the known and putative targets of 12 miRNAs that were uniquely changed in the plasma after administration of the lethal dose of APAP (Table 2). Interestingly, we found 6 out of the top 12 miRNAs with the greatest fold change (both up- and downregulated) in the lethally compared to sublethally dosed APAP mice were associated with asthma. The other miRNAs found both highly up- and downregulated were found to be associated with hypoxia-inducible factor (HIF)-1[15], follicle stimulating hormone[16], type 1 diabetes[17], procollagen type Ⅲ[18], colon cancer[19], gastric carcinoma[20], and elongation factor 2 tumor suppression[21] (Table 2).

DISCUSSION

Our study reveals numerous miRNAs, notably 574-5p, 135a*, 466g, 1196, 466f-3p, and 877, are upregulated

Table 2 Lethal acetaminophen associated plasma microRNAs and potential correlative function

in the setting of lethal compared to sublethal APAP-associated hepatotoxicity, whereas miRNAs 342-3p, 195, 375, 29c, 148a and 652 are markedly downregulated. We demonstrate elevated ALT levels as well as histologic evidence supporting worsened hepatotoxicity in the setting of lethally dosed mice compared to non-lethally dosed mice (Figures 2 and 4). With 90% lethality in the lethally dosed mice in relation to no lethality in sublethally dosed mice ($P = 0.0011$), this supports the premise that unique plasma miRNA profiles may correlate with non- *vs* life-threatening APAP dosing (Figure 3). The fold-change of a variety of miRNAs in the setting of lethally dosed mice compared to sublethal doses is of interest. Of note, more than 40 were both up- and downregulated, with the greatest fold miRNA changes reported (Table 1).

A literature search to investigate possible functions of the miRNAs both up- and downregulated was undertaken. Intriguingly, many of those most up- and downregulated in the lethally compared to sublethally dosed mice, namely 574-5p, 466g, 466f-3p, 375, 29c, and 148a, have also been implicated in the development of asthma[22,23]. For instance, 574-5p may be involved with asthma pathogenesis, with decreased miRNA 574-5p in chronic compared to acute asthma in a mouse model sensitized with ovalbumin[23]. In another study, a potential relationship between histocompatibility antigen-G, chronic asthma, and miRNA 29c was determined[22]. This consequently suggests a pathophysiologic relationship between APAP toxicity and asthma[22,23].

Interestingly, prior research has shown an association between APAP use and asthma although the exact association is still unclear[24,25]. For instance, an adult case control study described a relationship between acetaminophen use and asthma[26]. Additional literature revealed an increased risk of wheeze in children whose mothers

used prenatal APAP[27]. The etiology still remains unclear. However, one theory is that decreased glutathione (due to depletion secondary to APAP toxicity) provides the opportunity for unchecked reactive oxygen species to promote asthma development[24]. Additional theories include increased prostaglandin E2 production secondary to elevated cyclooxygenase-2 activity in the presence of APAP promoting a T2 allergic response[25]. A third cause could be direct lung damage from NAPQI, a byproduct of APAP metabolism[28]. Clearly, more information is needed to further elucidate the relationship between APAP and risk of asthma.

The previous literature describing the function of the other miRNAs up- and downregulated in our study is more varied. For example, some literature reveals a miRNA 135a association with HIF 1-α[15]. Interestingly, previous literature has demonstrated HIF 1-α induction prior to APAP toxicity in the setting of lethal APAP dosing, with toxicity prevented by the presence of cyclosporine A, a HIF 1-α inhibitor which prevents mitochondrial permeability transition and oxidative stress[29]. Additional studies have also shown elevation of HIF 1-α in the setting of APAP toxicity, with increased HIF 1-α causing increased glucose transporter-1 expression[30]. Of note, miRNAs 195 and 342-3p have been shown as involved with hepato cytopathology in the setting of tumor suppression in hepatocellular carcinoma models[21] and hepatitis B virus hepatocarcinoma diagnosis[10], respectively.

However, how these miRNAs in total affect hepatotoxicity in the setting of APAP poisoning still needs to be elucidated. Prior studies reveal upregulation of plasma miR-122 in the setting of APAP-associated liver toxicity, while our data suggest downregulation of plasma miR-122 at the 12 h time point. This discrepancy could be potentially explained by examination of upregulation of miR-122 at 1 h, 3 h and 24 h time points, not at a 12 h time point in previous literature. In addition, different APAP dosing levels were used in each study (300 mg/kg compared to 500 mg/kg), again demonstrating the dynamic nature of miRNA regulation across both time and clinical setting[11]. Of note, we found upregulation of plasma miR-298 and miR-370, whereas other researchers found downregulation of these miRNAs in the setting of APAP-associated hepatotoxicity[31]. Again, this may be due to evaluation at different time points (6 h compared to 12 h) and differing APAP dosing parameters (1000 mg/kg compared to 500 mg/kg)[31]. Together, these results demonstrate the need for further identification of additional plasma microRNA profiles at various time points and dosing levels.

Our ultimate goal would be to eventually have a miRNA APAP nomogram to be used for human patient care, similar to the previous effective Rumack-Matthew nomogram[32,33]. The problem with this current nomogram, however, is that it relies on knowing when a patient initially ingested APAP. This is often difficult, if patients are poor historians or have ingested mind-altering substances

such as alcohol at the time of evaluation. In addition, patients may have been taking APAP chronically, not acutely, making use of the Rumack-Matthew nomogram pointless. The importance of our work is to establish a novel miRNA nomogram that would be used for patients who have taken APAP at an unknown time or with chronic ingestions. In turn, this would avoid investigation of patients who have taken it chronically, thus preventing unnecessary treatment and iatrogenic ingestions. Additional studies in this field, with additional time points and dosing levels, however, are clearly still necessary.

The specificity of this profile also requires further improvement. For instance, in a recent report miRNA-122 was shown to be increased in the setting of APAP toxicity, although this increase was under the detection cut-off of our study[11]. Of note, miRNA-122 is also upregulated in hepatitis C settings which, by itself, is evidently not specific enough to uniquely identify APAP toxicity[14]. However, with additional future studies and data analysis, this may possible. This approach may also be used as a model to develop profiles for additional disease processes, namely non-alcoholic fatty liver disease and hepatocellular carcinoma, since microRNA profiles are already being used as early biomarkers for numerous pathologic states[9,10]. Together, this may improve the diagnostic accuracy of hepatopathology, namely early APAP-induced hepatotoxicity. In turn, this may allow clinicians to better and more rapidly distinguish which patients who have ingested APAP will actually mandate therapy. Subsequently, this may result in decreasing the number of patients who receive unnecessary, expensive empiric treatment.

In conclusion, lethal dosing of APAP in a murine model is consistent with hepatotoxicity and up- and downregulation of a unique pattern of circulating plasma miRNAs, which is different from the plasma miRNA profile associated with sublethal APAP dosing. These differences may be useful in the future to distinguish lethal and sublethal APAP toxicity in humans.

COMMENTS

Background
Acetaminophen (APAP) continues to be an important cause of acute liver failure in the developed world, being the most common cause of death due to analgesic ingestion in the United States. The authors report unique microRNA (miRNA) profiles associated with lethal acetaminophen poisoning. Determining which specific miRNAs are associated with lethal acetaminophen toxicity may prove helpful in the future for prognosticating which patients will require N-acetylcysteine treatment.

Innovations and breakthroughs
The importance of our work is to establish a novel miRNA nomogram that would be used for patients who have taken APAP at an unknown time or with chronic ingestions. This would be the first miRNA profile that could prognosticate patients who will require treatment for hepatotoxicity due to acetaminophen poisoning.

Applications
The ultimate goal is to eventually have a miRNA APAP nomogram to be used for human patient care. The limitation of the current Rumack-Matthew nomogram for APAP toxicity is that it relies on knowing the time of APAP ingestion. This is often difficult if patients are poor historians or have ingested mind-altering substances at the time of evaluation, or have been chronically ingesting APAP.

Terminology
Recent work has also shown the medical utility of miRNA. miRNAs, are short, chemically stable biomolecules that produce gene silencing. Furthermore, additional literature has described miRNA involvement in acetaminophen toxicity, as well as the utility of miRNAs as biomarkers.

Peer review
The manuscript provides some interesting information on the potential use of miRNAs for the early diagnosis of APAP associated liver toxicity. The scientific goal of the study has significant clinical application but the interpretation of the data needs to be revised.
